To decrease the occurrence of rubella, recommended public health policies include vaccinating all children aged 12 to 15 months or older and all adolescents and adults not known to be immune, unless they are pregnant or have other contraindications to vaccination. Also, all obstetric patients should be screened as early as possible in their pregnancy.³¹⁸ Contraindications to vaccination include febrile illness, immunosuppression, and pregnancy. Precautions also are necessary in the rare individual with neomycin allergy.

Rubeola

EPIDEMIOLOGY

The measles (rubeola) virus is a single-stranded RNA paramyxovirus that closely is related to the canine distemper virus. The wild virus is pathogenic only for primates, and humans are the only natural host.

The virus is spread by respiratory droplets and is highly contagious. Between 75% and 90% of susceptible contacts become infected after exposure. Before a measles vaccine was available, essentially all children experienced natural measles infection. Since licensure of the first measles vaccine in 1963, the incidence of infection has decreased by almost 99%. As expected, children younger than 10 years of age have shown the greatest decline in incidence. During the mid-1980s, almost 60% of reported cases affected children older than 10 years of age, compared with only 10% of cases occurring during between 1960 and 1964.³²⁵

In recent years, two major types of measles outbreaks have occurred in the United States. One type has developed among unvaccinated preschoolers, including children younger than 15 months of age. Another type has occurred among previously vaccinated school-age children and college students. In the latter type of outbreak, approximately one third of the cases have occurred in individuals who were previously vaccinated. Presumably, these cases resulted from either *primary failure* to respond to the first vaccine or *secondary failure*, a situation in which an adequate serologic response develops initially but immunity wanes over time.^{325,326}

The clinical manifestations of measles usually appear within 10 to 14 days after exposure. The most common signs and symptoms are fever, malaise, coryza, sneezing, conjunctivitis, cough, photophobia, and Koplik spots (blue-gray specks on a red base that develop on the buccal mucosa opposite the second molars). Patients typically develop a generalized nonpruritic maculopapular rash that begins on the face and neck and then spreads to the trunk and extremities. It usually lasts for about 5 days and subsequently recedes in the same sequence in which it appeared. The duration of illness is approximately 7 to 10 days (hence, the name, "10-day measles"). Patients are contagious from 1 to 4 days before the onset of coryza until several days after appearance of the rash. Immunity to measles should be lifelong after wild virus infection and is mediated by both humoral and cell-mediated mechanisms.

Although measles is typically a minor illness, some patients develop serious sequelae. Otitis media occurs in 7% to 9% of infected patients; bronchiolitis and pneumonia affect 1% to 6%. A severe form of hepatitis also may occur. In a report by Atmar and associates,³²⁷ 7 (54%) of 13 pregnant women with measles developed hepatitis.

Encephalitis occurs in approximately 1 in every 1000 cases of measles. It results from both viral infection of the CNS and a hypersensitivity reaction to the systemic viral infection. Measles encephalitis may lead to permanent neurologic impairment, including mental retardation; the mortality rate from this complication is approximately 15% to 33%. Another unusual, but extremely serious, complication of measles is subacute sclerosing panencephalitis. This complication occurs in 0.5 to 2 cases per 1000. It usually develops about 7 years after the acute measles infection and is more common in children who had measles before the age of 2 years. The disorder is characterized by progressive neurologic debilitation and has an almost uniformly fatal outcome.^{325,327}

A final complication is *atypical measles*. This disorder is a severe form of measles reinfection that affects young adults previously vaccinated with the formalin-inactivated killed measles vaccine that was distributed in the United States from 1963 to 1967. Affected patients have extremely high antibody titers to measles, and they experience high fever, pneumonitis, pleural effusion, and a coarse maculopapular, hemorrhagic, or urticarial rash. Although the disease usually is self-limited, atypical measles can lead to hepatic, cardiac, and renal failure. Interestingly, affected patients are not contagious to others.^{325,328}

Five clinical criteria should be present to establish the diagnosis of measles: fever of 38.3°C or higher, characteristic rash lasting longer than 3 days, cough, coryza, and conjunctivitis. Although the virus can be cultured, the mainstay of diagnostic tests is detection of antibody to measles. The hemagglutination inhibition assay and the enzyme-linked immunosorbent assay (ELISA) are the most useful serologic tests for determination of

a patient's susceptibility to measles and for confirmation of infection. The serologic confirmation of acute measles virus infection is based on detection of IgM-specific antibody or a fourfold change in the IgG titer in acute and convalescent sera. The acute titer for IgG antibody should be obtained within 3 days after the onset of the rash, and the convalescent titer should be obtained 10 to 20 days later.

OBSTETRIC CONSIDERATIONS

Several reports have documented an increase in maternal mortality associated with measles infection during pregnancy; most deaths have been caused by pulmonary complications. In one of the earliest investigations, Christensen and colleagues³²⁹ described an epidemic of measles in Greenland in 1951. Four (4.8%) of 83 pregnant women who developed measles died. An unspecified number of these women also had active tuberculosis. In the report by Atmar and associates,³²⁷ 1 (8%) of 13 pregnant women with measles died as a result of severe respiratory infection. Eberhart-Phillips and coworkers³³⁰ evaluated 58 pregnant women with measles. Thirty-five (60%) required hospitalization, 15 (26%) developed pneumonia, and 2 (3%) died.

Reports also have described a slight increase in the frequency of preterm delivery and spontaneous abortion among women who developed measles during pregnancy. In the study by Eberhart-Phillips and colleagues,³³⁰ 13 (26%) of 50 women with continuing pregnancies delivered preterm. The frequency of congenital anomalies is not increased significantly in women who contract measles during pregnancy, an observation quite different from that for rubella infection in pregnancy.

Although congenital anomalies are rare, infants of mothers who are acutely infected at the time of delivery are at risk for *neonatal measles*. This infection typically develops within the first 10 days of life and results from transplacental transmission of the virus. The mortality rates in preterm and term infants with neonatal measles have been reported to be as high as 60% and 20%, respectively.³³¹

PREVENTIVE MEASURES

Ideally, all women of reproductive age should have evidence of immunity to measles before attempting pregnancy. Originally, public health officials thought that a single injection of live measles vaccine when a child was approximately 15 months of age provided lifelong immunity. As noted previously, however, several outbreaks of measles have occurred as a result of secondary vaccine failures. Accordingly, the Advisory Committee on Immunization Practices (ACIP) recommends that all individuals who have not been infected with the live virus receive a second dose of the vaccine at 4 to 6 years of age. If this second dose is not administered in childhood, it should be administered before a woman plans her first pregnancy. There are only three contraindications to use of the live measles vaccine: pregnancy, severe febrile illness, and history of anaphylactic reaction to egg protein or neomycin.³³²

If a susceptible pregnant woman is exposed to measles, she should immediately receive passive immunoprophylaxis with immune globulin, 0.25 mL/kg intramuscularly, up to a maximum dose of 15 mL. If she develops measles despite immunoprophylaxis, she should be observed for evidence of serious complications such as otitis media, hepatitis, encephalitis, and pneumonia. Secondary bacterial infections should be

treated promptly with antibiotics. Administration of aerosolized ribavirin may be of benefit to patients with severe viral pneumonitis.³³³

The affected patient should be counseled that the risk of injury to her fetus is very low. The most effective method of evaluating the fetus for in utero infection is an ultrasound examination. Findings suggestive of in utero infection include microcephaly, growth restriction, and oligohydramnios. If the mother developed measles within 7 to 10 days of delivery, the neonate should receive intramuscular immunoglobulin in a dose of 0.25 mL/kg. These infants subsequently should receive the live measles vaccine when they are 15 months of age.³³³

Syphilis

Syphilis is a chronic systemic infection resulting from the spirochete *Treponema pallidum*. It has been recognized for several centuries that primary, secondary, and early latent syphilis in pregnant women cause infection of the fetus with resultant stillbirths, congenital abnormalities, and active disease at birth. Because of this significant morbidity, great emphasis has been placed on routine screening of all pregnant women for syphilis. Acquisition is usually through sexual contact.

EPIDEMIOLOGY

Since the startling prediction in 1937 by United States Surgeon General Thomas Parran that 10% of Americans would be infected with syphilis during their lives, the rates of primary and secondary syphilis have dramatically decreased, finally reaching a nadir in 2000 (Fig. 51-8).³³⁴ This striking decline was associated with the institution of public health control measures and the availability of penicillin. The generally downward trend in the syphilis rate was temporarily interrupted in the late 1970s and early 1980s when the rates of primary and secondary syphilis began increasing, in large part due to increases among men having sex with men. After the advent of the HIV/AIDS epidemic and public health efforts promoting safer sex, the rates of syphilis resumed their downward trend.

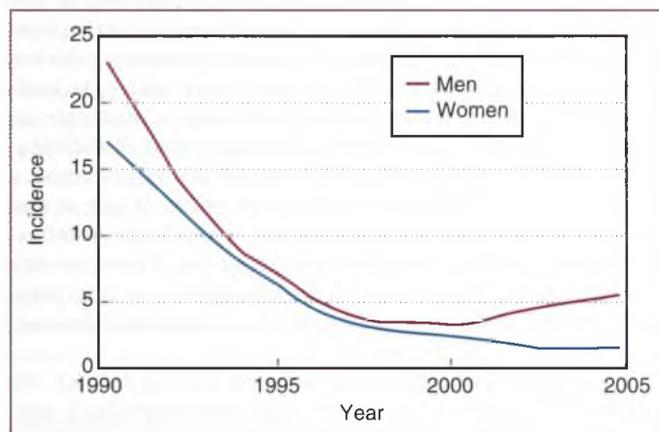

Figure 51-8 Incidence of primary and secondary syphilis per 100,000 population, by sex—United States, 1990-2005. During 2004-2005, the incidence of primary and secondary syphilis in the United States increased slightly, from 2.7 to 3.0 cases per 100,000 (from 0.8 to 0.9 per 100,000 in women, and from 4.7 to 5.1 per 100,000 in men).

However, in the late 1980s, another transient epidemic of primary and secondary syphilis occurred in the United States.⁴ Coincident with this rise was a dramatic increase in reported cases of congenital syphilis.³³⁵ After a low of 108 cases of congenital syphilis in 1978, 350 cases were reported in 1986, and 3850 cases in 1992, with an incidence rate of 100 per 100,000 live births (Fig. 51-9). Almost 90% of congenital syphilis cases occurred among blacks or Hispanics, and 50% occurred among mothers receiving no prenatal care. Reasons for this dramatic upsurge included exchange of drugs such as “crack” cocaine for sex; decreased funding for syphilis control; treatment of penicillinase-producing *N. gonorrhoeae* with spectinomycin, which does not treat incubating syphilis; and the use of revised reporting guidelines for congenital syphilis, which were introduced in 1989.

This latest epidemic peaked in 1990, with more than 112,000 reported cases of primary and secondary syphilis (18.4 cases per 100,000 population). A nadir was reached in 2000 with fewer than 6000 reported cases (2.1 per 100,000 population), the lowest rate since syphilis reporting began in 1941. Concomitant with the plummeting rates of primary and secondary syphilis, the rates of congenital syphilis also dramatically fell, declining from 3850 cases in 1992 to 451 cases in 2002.³³⁶

As a result of this impressive decline in syphilis rates, the CDC launched the National Syphilis Elimination Plan in 1999. However, this plan for elimination of syphilis in the United States has proved overly optimistic.³³⁷⁻³³⁹

PATHOGENESIS

T. pallidum is efficiently transmitted during sexual contact, and syphilis is acquired in 50% to 60% of partners after a single sexual exposure to an infected individual with early syphilis. Spirochetes may gain access through any break in the skin or via microscopic tears in genital tract mucosal surfaces, which occur almost universally during sexual intercourse. The mean incubation time is 21 days, with a range of 10 to 90 days.⁴

The primary stage of syphilis is characterized by the chancre, which appears at the site of entry for *T. pallidum*. The chancre

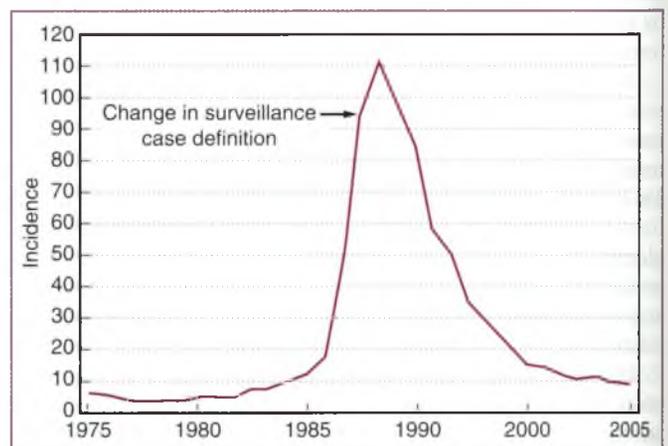

Figure 51-9 Incidence of congenital syphilis (per 100,000 live births) among infants aged 0 to 12 months—United States, 1975-2005. The incidence of congenital syphilis has declined since 1991. In 2005, the rate was 8.0 cases per 100,000 live births.

is a painless, nontender, ulcerated lesion with a raised border and an indurated base. The most common site for the chancre is the genital area. In men, the lesion is easily apparent, and syphilis is often diagnosed in its primary stage. In women, the lesion most commonly is on the cervix or in the vagina and is not recognized. Therefore, the chancre often escapes detection in women, and it is unusual to diagnose the primary stage of syphilis in females. Usually only a single chancre is present, but multiple chancres occur in up to 30% of cases. Painless inguinal lymphadenopathy is frequently present. The primary chancre, even without treatment, heals spontaneously in 3 to 6 weeks.

After resolution of the primary stage, the patient enters the secondary or spirochetemia (bacteremia) stage of syphilis. Syphilis always disseminates during the secondary stage. Any organ can potentially be infected, especially the CNS. Although the secondary stage of syphilis is characterized by involvement of all major organ systems by *T. palladium*, it manifests most commonly with skin and mucous membrane lesions. These clinical manifestations of secondary syphilis include a generalized maculopapular rash that begins on the trunk and proximal extremities and spreads to the entire body, especially involving the palms and soles; mucous patches; condyloma latum; and generalized lymphadenopathy. These mucocutaneous lesions are highly contagious.

Even without treatment, the manifestations of secondary syphilis spontaneously clear within 2 to 6 weeks, and the latent stage of syphilis is entered, in which there is no apparent clinical disease. In the era before the availability of penicillin, about 25% of such patients had a recrudescence of secondary syphilis. Because these relapses usually occurred within 1 year, the term "early latent period" was applied to this time period. In the late latent stage (>1 year), patients are not contagious by sexual transmission, but the spirochete may still be transplacentally transmitted to a fetus.^{340,341}

Without treatment, one third of patients progress to tertiary syphilis.³⁴⁰ One half of patients with tertiary syphilis have late benign syphilis, which is characterized by gummas affecting multiple organ systems. One fourth develop cardiovascular disease, and one fourth have neurologic disease. The cardiovascular manifestations of tertiary syphilis include aortic aneurysm and aortic insufficiency. In the CNS, tertiary disease produces general paresis, tabes dorsalis, optic atrophy, and meningovascular syphilis. The Argyll-Robertson pupil (i.e., pupil does not react to light but accommodates) is virtually pathognomonic of tertiary syphilis. The pathogenesis of tertiary syphilis is based on the tropism of *T. pallidum* for arterioles, which results in obliterative endarteritis with subsequent tissue destruction.

CONGENITAL SYPHILIS

The clinical spectrum in congenital syphilis includes stillbirth, neonatal death, nonimmune hydrops, clinically apparent syphilis during the early months of life (early congenital syphilis), and the classic stigmata of late congenital syphilis (Box 51-8).⁴ The most severe adverse pregnancy outcomes occur with primary or secondary syphilis. Pregnant women diagnosed with syphilis are usually in the latent stage and have had the disease for longer than 1 year. Consequently, about two thirds of infants with early congenital syphilis are asymptomatic at birth and do not develop evidence of active disease for 3 to 8 weeks. Chancres do not occur unless the disease is acquired at the time of passage

BOX 51-8 CONGENITAL SYPHILIS CASE DEFINITION

CONFIRMED CASE

Infant in whom *Treponema palladium* is identified by dark-field microscopy, fluorescent antibody, or other specific stains in specimens from lesions, placenta, umbilical cord, or autopsy material

PRESUMPTIVE CASE

1. Any infant whose mother had untreated* or inadequately treated syphilis at delivery, regardless of signs or symptoms[†] or
2. Any infant or child who has a reactive treponemal test for syphilis and any one of the following:
 - a. Evidence of congenital syphilis on physical examination
 - b. Evidence of congenital syphilis on long-bone radiography
 - c. Reactive CSF VDRL test
 - d. Elevated CSF white blood cell count (>5/mm³) or protein concentration (>5 mg/dL)
 - e. Reactive test for FTA-ABS-19S-IgM antibody

*Including mothers receiving penicillin therapy at the time of delivery or within 30 days before delivery.

[†]Clinical signs in an infant include hepatosplenomegaly, characteristic skin rash, condyloma lata, snuffles, jaundice, pseudoparalysis, anemia, thrombocytopenia, and edema. Stigmata in children older than 2 years of age include interstitial keratitis, nerve deafness, anterior bowing of shins, frontal bossing, mulberry molars, Hutchinsonian teeth, saddle nose, rhagades, and Clutton joints.

CSF, cerebrospinal fluid; FTA-ABS, fluorescent treponemal antibody absorption; IgM, immunoglobulin M; VDRL, Venereal Disease Research Laboratory.

From Centers for Disease Control and Prevention: Congenital syphilis case definition, Atlanta, GA, 1998, U.S. Department of Health and Human Services.

through the birth canal. The characteristic manifestations of early congenital syphilis (onset at <2 years of age) include a maculopapular rash that may progress to desquamation or formation of vesicles and bullae, snuffles (a flulike syndrome associated with a nasal discharge), mucous patches in the oral pharyngeal cavity, hepatosplenomegaly, jaundice, lymphadenopathy, pseudoparalysis of Parrot due to osteochondritis, chorioretinitis, and iritis.³⁴¹

Untreated or incompletely treated early congenital syphilis will progress to the classic manifestations of late congenital syphilis. These include Hutchinsonian teeth, mulberry molars, interstitial keratitis, eighth-nerve deafness, saddle nose, rhagades, saber shins, and neurologic manifestations (mental retardation, hydrocephalus, general paresis, optic nerve atrophy, and Clutton joints). These stigmata associated with late congenital syphilis are the result of scarring induced by early lesions or reactions to persistent inflammation.³⁴¹

T. pallidum can cross the placenta and infect the fetus as early as the sixth gestational week.³⁴² Anatomic abnormalities in the fetus are not apparent until after 16 weeks of gestation, when fetal immunocompetence develops. Therefore, the risk to the fetus is present throughout pregnancy, and the degree of risk is related to the quantity of spirochetes in the maternal bloodstream. Transmission may also occur intrapartum via contact with active genital lesions in the mother. Women with primary or secondary syphilis are more likely to transmit infection to their offspring than are women with latent disease. Maternal primary syphilis and secondary syphilis are associated with a

50% probability of congenital syphilis and a 50% rate of perinatal death; early latent syphilis in the mother is associated with a 40% risk of congenital syphilis and a 20% mortality rate; and late latent maternal syphilis is associated with a 10% risk of congenital syphilis.^{343,344} Similar high rates of morbidity and mortality among the infants of mothers with untreated syphilis of less than 4 years' duration were reported in 1959 by Inrahan,³⁴⁵ who reported a perinatal death rate of 43% (29% stillborn, and 14% neonatal); among liveborn infants, 41% had congenital syphilis.

Experience during the syphilis epidemic in the late 1980s and early 1990s confirmed that untreated syphilis is associated with significant and frequent adverse effects on pregnancy. Ricci and associates³⁴⁶ reported that, among 56 cases of congenital syphilis, 19 (35%) were stillbirths, and the perinatal mortality rate was 464 per 1000 live births. Preterm labor and delivery were significantly more common, infants with congenital syphilis had significantly lower birth weights, and 21% had intrauterine growth restriction. McFarlin and coworkers³³⁵ reviewed 253 cases of maternal syphilis. They reported a preterm delivery rate of 28%; 10 (13.9%) of 72 infants with congenital syphilis were stillborn.

The manifestations of congenital syphilis are usually less severe in association with long-standing maternal disease than with early syphilis (<1 year's duration). Coles and colleagues,³⁴⁷ in a review of 322 cases of congenital syphilis in upstate New York from 1989 to 1992, reported 31 (10%) stillbirths and 59 (19%) newborns with clinical evidence of congenital syphilis. Factors believed to contribute to the development of congenital syphilis included infection late in pregnancy, treatment less than 30 days before delivery, misdiagnosis or inappropriate treatment of the mother, and no serologic testing during pregnancy.

DIAGNOSIS

The most definitive methods for diagnosing early syphilis are dark-field microscope examination or direct fluorescent antibody tests of lesion exudates or tissue.¹² A presumptive diagnosis can be made using serologic testing. The serologic tests are classified into two types: nonspecific tests for reagin-type antibodies and specific antitreponemal antibody tests.

Nonspecific antibody tests include the Venereal Disease Research Laboratory (VDRL) test and the rapid plasma reagin (RPR) test. These assays are used for screening. All pregnant women should be tested at their initial prenatal visit. High-risk patients should be rescreened at 28 weeks of gestation. In areas with high rates of congenital syphilis, rescreening at admission in labor is also recommended. In populations in which prenatal care is less than optimal, RPR-card test screening is recommended at the time pregnancy is diagnosed, with treatment of patients who have a reactive test. The CDC recommends that any woman who delivers a stillborn infant after 20 weeks' gestation should be screened for syphilis. In addition, the CDC advises that no infant should leave the hospital without the maternal serostatus for syphilis having been assessed at some time in the pregnancy.¹²

Treponema-specific tests are used to confirm the diagnosis of syphilis in patients who have reactive VDRL or RPR results. These tests include the fluorescent treponemal antibody absorption (FTA-ABS) test and the *T. pallidum* particle agglutination (TP-PA) test.

Usually the nonspecific test result becomes nonreactive after treatment. In some patients, a low titer persists for a long time, in some cases for life. Once reactive, specific treponemal tests usually remain positive for life. In pregnancy, it is best to consider all seropositive women as infected unless an adequate treatment history is documented and sequential serologic antibody titers have declined.

It is critical to recognize that when the syphilitic chancre first appears, both the nonspecific test results and the treponemal-specific test results may be nonreactive. Therefore, lesions suspicious for syphilis should be sampled for detection of spirochetes and submitted to the laboratory for dark-field examination and fluorescent-antibody staining.

Although the CNS is involved in almost half of the patients with early syphilis, fewer than 10% of patients with untreated syphilis progress to symptomatic late neurosyphilis. If patients are treated appropriately for early syphilis, neurosyphilis is extremely rare. The CDC has stated that, unless clinical signs or symptoms of neurologic involvement are present, lumbar puncture is not recommended for routine evaluation in primary or secondary syphilis. In patients with latent syphilis, prompt CSF examination should be performed if any of the following conditions is present¹²:

1. Clinical evidence of neurologic involvement (e.g., cognitive dysfunction, motor or sensory deficits, ophthalmic or auditory symptoms, cranial nerve palsies, symptoms or signs of meningitis)
2. Evidence of active tertiary syphilis (e.g., aortitis, gummas, iritis)
3. Treatment failure
4. HIV infection with latent syphilis or syphilis of unknown duration

Recently, it has been suggested that only HIV-infected patients with neurologic manifestations or a serum RPR result of 1/32 or greater require a lumbar puncture.³⁴⁸ Marra and colleagues³⁴⁹ studied 326 patients with syphilis in an attempt to define clinical and laboratory features that identify patients with neurosyphilis. Sixty-five patients (20.1%) had neurosyphilis. In multivariate analysis, an RPR titer of 1/32 or greater increased the odds of neurosyphilis almost 11-fold in HIV-uninfected individuals and almost sixfold among HIV-infected patients. In HIV-infected subjects, a CD4⁺ count of 350 cells/mL or less conferred 3.10-fold increased odds of neurosyphilis.

No single test is adequate to diagnose neurosyphilis in all patients. The diagnosis is based on various combinations of tests, including reactive serologic tests, abnormal CSF cell count, elevated protein, and/or a reactive CSF VDRL, with or without clinical manifestations. CSF studies demonstrating pleocytosis, elevated protein levels, and a reactive CSF VDRL are diagnostic of neurosyphilis. On occasion, however, results may be nonreactive when neurosyphilis is present. It has been suggested that increased levels of tau protein may be useful in discriminating neurosyphilis from syphilis without nervous system involvement.³⁵⁰

The diagnosis of reinfection or persistence of active syphilis can be made in patients previously known to have syphilis by monitoring the titer of the quantitative VDRL. With successful therapy, the VDRL titer should decrease and become negative or very low within 6 to 12 months in early syphilis and within 12 to 24 months in late syphilis (>1 year's duration). A rising titer indicates the need for further diagnostic measures, such as a lumbar puncture, and appropriate treatment.

The diagnosis of congenital syphilis is easily confirmed in the clinically apparent case in which a jaundiced, hydropic baby with florid disease and a large, edematous placenta are delivered and laboratory studies confirm the presence of the disease. However, most infected newborns are asymptomatic at birth. Although the cord blood may give a positive nonspecific test result for syphilis, the diagnosis of congenital syphilis is complicated by the transplacental transfer of maternal nontreponemal and treponemal IgG antibodies to the fetus.¹²

As a result, the interpretation of reactive serologic tests for syphilis in infants is difficult. Treatment decisions must be frequently made on the basis of (1) identification of syphilis in the mother; (2) adequacy of maternal treatment; (3) presence of clinical, laboratory, or radiologic evidence of syphilis in the infant; and (4) comparison of maternal and infant nontreponemal serologic titers at the time of delivery using the same test and same laboratory.¹² Any infant with a positive VDRL result but no clinical evidence of syphilis should have serial monthly quantitative VDRL tests for at least 9 months. A rising titer indicates active disease and the need for therapy. Infected infants may be asymptomatic and the serum VDRL may be normal if maternal infection occurred late in pregnancy.

In 1998, the CDC implemented a new case definition for congenital syphilis surveillance (see Box 51-8). A diagnosis of congenital syphilis can be confirmed by identifying spirochetes in suspicious lesions, body fluids, or tissues with dark-field microscopy, silver staining, immunofluorescence, or PCR for *T. pallidum* DNA.³⁵¹ Several new laboratory tests have been introduced to facilitate the diagnosis of congenital syphilis. These include PCR and the rabbit infectivity test (RIT).

TREATMENT

All pregnant women who have a history of sexual contact with a person with documented syphilis, dark-field microscope confirmation of the presence of spirochetes, or serologic evidence of syphilis documented by a specific treponemal test should be treated. In addition, patients in whom the diagnosis cannot be ruled out with certainty and those who have been previously treated but now show evidence of reinfection, such as dark-field microscope confirmation or a fourfold rise in titer on a quantitative nontreponemal test, should receive appropriate treatment.

Treatment schedules for syphilis recommended by the CDC in 2010 are shown in Table 51-10. Penicillin administered parenterally is the preferred treatment for all stages of syphilis.¹²

The preparation of penicillin used and the length of treatment are determined by the stage and clinical manifestations of the disease. Although several alternatives to penicillin might be effective in nonpregnant penicillin-allergic patients, parenteral penicillin G is the only therapy with documented efficacy for syphilis during pregnancy. In pregnancy, parenteral penicillin G is effective for treating maternal infection, preventing transmission to the fetus, and treating established fetal infection. Therefore, the CDC recommends that pregnant patients with syphilis in any stage who are allergic to penicillin should be desensitized and treated with penicillin.¹²

Desensitization is a relatively safe and straightforward procedure that can be accomplished orally or intravenously. Oral desensitization is believed to be safer and easier to perform. Patients should be desensitized in a hospital setting, because serious IgE-mediated allergic reactions can occur.

TABLE 51-10 CDC-Recommended Treatment of Syphilis during Pregnancy, 2010

Diagnosis	Treatment
1. Primary, secondary, and early latent syphilis (<1 yr)	Benzathine penicillin G, 2.4 million units IM in a single dose
2. Late latent syphilis (>1 yr), latent syphilis of unknown duration, and tertiary syphilis	Benzathine penicillin G, 7.2 million units total, administered as 3 doses of 2.4 million units IM each at 1-wk intervals
3. Neurosyphilis	Aqueous crystalline penicillin G, 18-24 million units per day administered as 3-4 million units IV every 4 hr or by continuous infusion for 10-14 days OR Procaine penicillin, 2.4 million units IM daily, plus probenecid 500 mg PO qid, both for 10-14 days
4. Penicillin-allergic	Pregnant women with a history of penicillin allergy should have allergy confirmed and then be desensitized

Modified from Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines, 2010, MMWR Recomm Rep 59(RR-12):1-111, 2010.

TABLE 51-11 Oral Desensitization Protocol for Patients with a Positive Skin Test for Penicillin Allergy*

Penicillin V Suspension Dose†	Amount (units/mL)‡	Cumulative Dose (units)		
		mL	Units	(units)
1	1,000	0.1	100	100
2	1,000	0.2	200	300
3	1,000	0.4	400	700

13	80,000	4.0	320,000	656,700
14	80,000	8.0	640,000	1,296,700

*Observation period: 30 minutes before parenteral administration of penicillin.

†Interval between doses, 15 minutes; elapsed time, 3 hours and 45 minutes; cumulative dose, 1.3 million units.

‡The specific amount of drug is diluted in approximately 30 mL of water and then administered orally.

From Wendel GO Jr, Stark BJ, Jamison RB, et al: Penicillin allergy and desensitization in serious infections during pregnancy, *N Engl J Med* 312:1229-1232, 1985. Reprinted with permission from the New England Journal of Medicine.

Desensitization can be accomplished in approximately 4 hours (Table 51-11), after which the first dose of penicillin is administered. After desensitization, patients must be maintained on penicillin continuously for the duration of their therapeutic course.

Although erythromycin was at one time considered an alternative to penicillin for the treatment of syphilis during

pregnancy, its efficacy for treatment of syphilis in the fetus and for prevention of transmission is inadequate. Although doxycycline and tetracycline are alternatives for nonpregnant patients, they usually are not used in pregnancy because of concern about discoloration of the infant's teeth.

Concern has been raised as to whether the recommended regimens of penicillin are optimal in pregnancy. Several reports demonstrated worrisome instances of treatment failures despite adherence to recommended guidelines.^{335,352} A high maternal VDRL titer at the time of diagnosis, unknown duration of infection, treatment within 4 weeks of delivery, and signs of fetal syphilis (e.g., hepatomegaly, fetal hydrops, placentomegaly) on ultrasonography are associated with failure to prevent congenital syphilis.³⁵³ Because of these reports demonstrating a high failure rate for treatment of syphilis in pregnancy, some experts recommend additional therapy.¹² A second dose of benzathine penicillin G (2.4 million units intramuscularly) may be given 1 week after the initial dose for pregnant women with primary, secondary, or early latent syphilis.

Syphilis can involve the CNS during any stage of disease. Therefore, any patient with syphilis who demonstrates clinical evidence of neurologic involvement should have a lumbar puncture to assess the CSF for evidence of neurosyphilis. Patients with neurosyphilis should be treated with high doses of aqueous penicillin G, as noted in Box 51-8.

Obstetric caregivers should be aware that women treated for syphilis during the second half of pregnancy are at risk for preterm labor or fetal distress if the Jarisch-Herxheimer reaction occurs. The Jarisch-Herxheimer reaction occurs commonly during the treatment of early syphilis; among 33 pregnant women, the reaction complicated therapy in 100% and 60% of patients treated for primary or secondary syphilis, respectively.³⁵⁴ The Jarisch-Herxheimer reaction characteristically includes fever, chills, myalgia, headache, hypotension, and transient worsening of cutaneous lesions. It commences within several hours after treatment and resolves by 24 to 36 hours. Among pregnant women, the most frequent findings are fever (73%), uterine contractions (67%), and decreased fetal movement (67%). Transient late decelerations were observed in 30% of monitored fetuses.

Because of these findings, sonographic assessment of the fetus before initiation of therapy for early syphilis in the last half of pregnancy has been recommended.³⁵⁵ If the results are normal, ambulatory treatment may be initiated. If abnormal findings suggesting fetal infection are identified, hospitalization for treatment and fetal monitoring is recommended. Sanchez and Wendel³⁵² demonstrated that, in the presence of severe fetal compromise before treatment, early delivery with treatment of the mother and neonate after delivery may yield an improved outcome.

For primary and secondary syphilis, patients should be re-examined clinically and serologically at 6 months and 12 months after treatment. A response is defined as a two-dilution (fourfold) decline in the nontreponemal titer at 1 year after treatment.³⁵⁶ Patients with signs or symptoms that persist or recur and those with a sustained fourfold increase in the nontreponemal test titer have probably failed treatment or become reinfected. They should be re-treated and assessed for HIV infection and CNS infection. For re-treatment, weekly injections of benzathine penicillin G 2.4 million units IM for 3 weeks is recommended.¹²

In cases of latent syphilis, quantitative nontreponemal titers should be repeated at 6, 12, and 24 months. Patients with a

normal CSF examination should be re-treated for latent syphilis if (1) titers increase fourfold, (2) an initially high titer ($\geq 1:32$) fails to decline at least fourfold (i.e., two dilutions) within 12 to 24 months after therapy, or (3) signs or symptoms of syphilis develop.¹²

In pregnant women treated for syphilis, the CDC recommends repeating serologic titers at 28 to 32 weeks' gestation, and again at delivery, and following the recommendations described earlier for the stage of disease. Alternatively, serologic titers can be checked monthly in women who are at high risk for reinfection or who live in a geographic area where the prevalence of syphilis is high.¹²

Congenital syphilis is unusual if the mother received adequate treatment with penicillin during pregnancy. Infants should be treated for presumed congenital syphilis if they were born to mothers in the following categories:

1. Mothers who have untreated syphilis at delivery
2. Mothers who have serologic evidence of relapse or reinfection after treatment (i.e., a rise in titer by at least fourfold)
3. Mothers who were treated for syphilis during pregnancy with nonpenicillin regimens
4. Mothers who were treated for syphilis less than 1 month before delivery
5. Mothers who do not have a well-documented history of treatment of syphilis
6. Mothers who do not demonstrate an adequate response (fourfold decrease) of nontreponemal antibody titers despite appropriate penicillin treatment
7. Mothers who were treated for syphilis appropriately before pregnancy but had insufficient serologic follow-up to ensure response to treatment.

Any child with symptomatic congenital syphilis should undergo a lumbar puncture, complete blood count, and long-bone radiography before treatment. If these results are normal, a single intramuscular dose of benzathine penicillin G (50,000 units/kg) should be given. With abnormal results or if compliance is not ensured, the infant should be given a 10-day course of either aqueous crystalline penicillin G (50,000 units/kg IV every 12 hours for the first 7 days of life, and then every 8 hours for the next 3 days) or procaine penicillin (50,000 units/kg/day IM).¹²

PREVENTION

Serologic screening of all pregnant women during the early stages of pregnancy is recommended. In geographic areas with a high prevalence of syphilis and in patients at high risk, serologic testing should be repeated at 28 to 32 weeks' gestation and at delivery.¹²

Toxoplasmosis

EPIDEMIOLOGY AND PATHOGENESIS

Toxoplasma gondii is a protozoan that has three distinct life forms: trophozoite, cyst, and oocyst. The life cycle of this organism is dependent on wild and domestic cats, which are the only known host for the oocyst. The oocyst is formed in the intestine of the cat and subsequently is excreted in feces. Mammals, such as cows, ingest the oocyst, which is disrupted in the animal's intestine, releasing the invasive trophozoite. The trophozoite

then is disseminated throughout the body, ultimately forming cysts in brain and muscle.³⁵⁷

Human infection occurs when infected meat is ingested or oocysts are ingested via contamination by cat feces. Infection rates are highest in areas of poor sanitation and crowded living conditions. Stray cats and domestic cats that eat raw meat are most likely to carry the parasite. The cyst is completely destroyed by heating.

Approximately half of all adults in the United States have antibody to this organism. Immunity is usually long-lasting except in immunosuppressed patients. The prevalence of antibody is highest in lower socioeconomic classes. The frequency of seroconversion during pregnancy is approximately 5%, and about 3 in 1000 infants show evidence of congenital infection. Clinically significant infection occurs in only 1 in 8000 pregnancies. Clinical manifestations of infection are the result of direct organ damage and the subsequent immunologic response to parasitemia and cell death. Immunity to this infection is mediated primarily through T lymphocytes.³⁵⁷

DIAGNOSIS

Most infections in humans are asymptomatic. However, even in the absence of symptoms, patients may have evidence of multiorgan involvement, and clinically apparent disease can develop after a long period of asymptomatic infection. Symptomatic toxoplasmosis usually manifests as an illness similar to mononucleosis.

In contrast to infection in the immunocompetent host, toxoplasmosis can be a devastating infection in the immunosuppressed patient. In these individuals, dysfunction of the CNS is the most common manifestation of infection. Findings typically include encephalitis, meningoencephalitis, and intracerebral abscess. Pneumonitis, myocarditis, and generalized lymphadenopathy also occur commonly.

Routine screening for toxoplasmosis in pregnancy is not indicated. However, immunosuppressed patients, women who have contact with outdoor cats, and patients with suspicious symptoms should be tested. The diagnosis of toxoplasmosis in the mother is best confirmed by detection of organisms in maternal serum by PCR and by detection of antibody to the parasite. Serologic tests suggestive of an acute infection include identification of IgM-specific antibody, demonstration of an extremely high IgG antibody titer, and documentation of IgG seroconversion from negative to positive. Serologic assays for toxoplasmosis are not well standardized. Therefore, if initial laboratory tests suggest an acute maternal infection, additional evaluation, as detailed in the following paragraphs, is indicated before concluding that the fetus is at risk for serious injury.^{357,358}

Approximately 40% of neonates born to mothers with acute toxoplasmosis have evidence of infection. Congenital infection is most likely to occur when maternal infection develops during the third trimester. The risk of injury to the fetus is greatest, however, when maternal infection occurs in the first trimester.

The usual clinical manifestations of congenital toxoplasmosis include a disseminated purpuric rash, enlargement of the spleen and liver, ascites, chorioretinitis, uveitis, periventricular calcifications, ventriculomegaly, seizures, and mental retardation. Chronic or latent infection in the mother is unlikely to be associated with serious fetal injury.

The most valuable test for confirmation of congenital toxoplasmosis is detection of toxoplasmic DNA in amniotic fluid

using the PCR methodology. In an important initial investigation, Hohlfeld and associates³⁵⁹ identified 34 infants with confirmed congenital toxoplasmosis. Amniotic fluid specimens from all affected pregnancies were positive by PCR, and test results were available within 1 day after specimen collection. In a subsequent investigation, Romand and colleagues³⁶⁰ reported that the PCR test for toxoplasmic DNA had an overall sensitivity of 64% (CI, 53% to 75%). No false-positive results were noted, and the positive predictive value was 100%. Once amniocentesis has confirmed toxoplasmic infection, targeted ultrasound examination is indicated to look for specific findings suggestive of severe fetal injury.

TREATMENT

In the immunocompetent adult, toxoplasmosis usually is an asymptomatic or self-limited illness that does not require treatment. Immunocompromised patients should be treated with a combination of oral sulfadiazine (4-g loading dose followed by 1 g four times daily) plus pyrimethamine (50 to 100 mg initially, then 25 mg daily). Extended courses of treatment may be necessary to cure the infection.

When acute toxoplasmosis occurs during pregnancy, treatment is indicated, because maternal therapy reduces the risk of congenital infection and decreases the late sequelae of infection. Pyrimethamine is not recommended during the first trimester of pregnancy because of possible teratogenicity. Sulfonamides may be used alone, but single-agent therapy appears to be less effective than combination therapy. Spiramycin has been used extensively in European countries with excellent success. It is available in the United States through special permission from the CDC.³⁵⁸

Aggressive early treatment of infants with congenital toxoplasmosis is indicated and consists of combination therapy with pyrimethamine, sulfadiazine, and leucovorin for 1 year. Early treatment reduces, but does not eliminate, the late sequelae of toxoplasmosis (e.g., chorioretinitis). Early treatment of the neonate appears to be comparable in effectiveness to in utero therapy.³⁶¹

In pregnant women, prevention of toxoplasmosis is of paramount importance. Pregnant women should be advised to avoid contact with cat litter if at all possible. If they must change the litter, they should wear gloves and wash their hands afterward. They should always wash their hands after preparing meat for cooking, and they should never eat raw or rare beef, fowl, or pork. Meat should be cooked thoroughly until the juices are clear. Fruits and vegetables also should be washed carefully to remove possible contamination by oocysts.

Varicella-Zoster Virus Infection

EPIDEMIOLOGY AND PATHOGENESIS

The varicella-zoster virus (VZV) is a DNA organism that is a member of the herpesvirus family. The organism causes varicella (chickenpox) and herpes zoster infection (shingles). Varicella is of great importance in pregnancy because it poses risks to the mother, fetus, and neonate.³⁶² Herpes zoster infection can be a painful and somewhat debilitating condition, especially in an immunosuppressed patient. However, because it occurs in a patient who already has antibody against VZV, herpes zoster poses essentially no risk to the fetus or neonate and is not discussed further in this chapter.

Varicella occurs in approximately 1 to 5 cases per 10,000 pregnancies. The infection is transmitted by respiratory droplets and by direct contact with vesicular lesions. The incubation period of the organism is 10 to 14 days. Varicella is among the most highly contagious of any viral infection.³⁶³

DIAGNOSIS

The typical clinical manifestation of varicella is a disseminated, pruritic, vesicular rash. The lesions typically occur in crops and evolve in sequential fashion from papule to vesicle to pustule, eventually crusting over to form a dry scab. Varicella is almost always a mild, self-limited infection in children. However, approximately 20% of infected adults develop pneumonia, and approximately 1% develop encephalitis. Both of these complications can cause serious morbidity and even mortality. The diagnosis of varicella is usually obvious on clinical examination but can be confirmed by identification of anti-VZV IgM antibody.³⁶³

TREATMENT

All pregnant women should be questioned about prior varicella at the time of their first prenatal appointment. If they have a well-defined history of infection, they should be reassured that second infections are extremely unlikely and that, should a second infection occur, the risk to the fetus is negligible. Women who are not certain of prior exposure should have an anti-VZV IgG assay. Approximately 75% of individuals who are uncertain about their prior history actually have definitive serologic evidence of immunity. Women who do not have antibody against varicella should be cautioned about the need to avoid exposure to people who have vesicular viral eruptions.^{364,365}

If a susceptible pregnant patient is exposed to someone with varicella, she should be treated within 72 to 96 hours with one of two agents to prevent active infection. The most extensively tested regimen is intramuscular varicella-zoster immune globulin (VZIG), 1 vial per 10 kg of weight up to a maximum of 5 vials.³⁶⁶ However, the U.S. company that manufactured this agent has discontinued its production, and securing the product through international manufacturers is problematic. An alternative method of prophylaxis is to administer oral acyclovir (800 mg, five times daily for 7 days) or oral valacyclovir (1000 mg, three times daily for 7 days).³⁶⁷

Pregnant women who develop varicella despite immunoprophylaxis should be treated with oral acyclovir or valacyclovir in the same dose as outlined for prophylaxis. Patients who have evidence of pneumonia, encephalitis, or disseminated infection and those who are immunosuppressed should be hospitalized and treated with intravenous acyclovir (10 mg/kg infused over 1 hour every 8 hours for 10 days).^{363,366,368}

Acute varicella infection during pregnancy has been associated with spontaneous abortion, intrauterine fetal death, and congenital anomalies. However, these complications are rare. Investigations have shown that the frequency of fetal anomalies is less than 1% when maternal infection occurs in weeks 1 through 12 of pregnancy and 2% or less when infection occurs in weeks 13 through 20.^{369,370}

The most valuable test to identify fetal injury due to congenital varicella is ultrasound examination. Possible findings include intrauterine growth restriction, microcephaly, ventriculomegaly, echogenic foci in the fetal liver, and limb anomalies.³⁶³

Neonatal varicella, as opposed to congenital varicella infection, occurs when the mother develops acute varicella during the period from 5 days before to 2 days after delivery. If infection occurs at this time, there is no opportunity for protective antibody to cross the placenta. The manifestations of neonatal varicella include disseminated mucocutaneous lesions, visceral infection, pneumonia, and encephalitis. In the absence of timely antiviral chemotherapy, up to 30% of infected infants die of complications of neonatal varicella. Infants born during this window of time must avoid contact with vesicular lesions on the mother's skin. These infants, and any infants with suspected exposure in the nursery or postpartum ward, also should receive immunoprophylaxis with VZIG or treatment with antiviral agents such as acyclovir or valacyclovir.³⁶³

PREVENTION

In an effort to prevent the serious conditions described here, all women of reproductive age should be vaccinated for varicella if they have not already acquired natural immunity. The varicella vaccine (Varivax, Merck) is a live-virus vaccine that is highly immunogenic. Individuals aged 1 to 12 years should receive one dose of the vaccine subcutaneously. Individuals older than 12 years of age require two subcutaneous doses, administered 4 to 6 weeks apart. Contraindications to the vaccine include pregnancy, an immunodeficiency disorder, high-dose corticosteroid therapy, untreated tuberculosis, severe systemic illness, and an allergy to neomycin, which is one component of the vaccine.^{365,371,372} The CDC guidelines³⁶⁶ indicate that the vaccine may be considered in breastfeeding mothers, although there is little information about whether the vaccine virus is excreted in breast milk. Vaccine recipients pose minimal risk of transmitting infection to susceptible contacts if no rash develops after the vaccination. If a rash does develop, there is a very small risk of transmission to susceptible contacts.³⁶⁵

Viral Influenza

EPIDEMIOLOGY

Influenza is caused by an RNA virus of the myxovirus family. Traditionally, three antigenically different influenza viruses have been identified. Type A influenza is responsible for most epidemics and is associated with a severe clinical presentation. Type B influenza is less frequently implicated in epidemics and tends to cause milder clinical disease. Type C is the least frequent type and, as a result, is not accounted for in the annual influenza vaccine. Recently, however, a novel strain of the virus, H1N1, has assumed increasing importance as a cause of disease in humans, posing a special threat to pregnant women.³⁷³

Influenza is of major clinical importance, both in the United States and worldwide. In the United States, the disease causes 30,000 to 40,000 excess deaths and approximately 200,000 hospitalizations annually.^{374,375} Pregnant women have suffered disproportionate morbidity and mortality during influenza pandemics, including the H1N1 epidemic.³⁷⁶

Influenza is a persistent problem because of low-level alterations of the surface proteins of influenza A (hemagglutinin A and neuraminidase). This antigenic drift allows the virus to change enough to evade the host's immune system response and cause the yearly epidemics. At approximately 20- to 40-year

intervals, a more profound change of the surface proteins occurs, possibly as a result of genetic recombination, and leads to a substantially different surface protein configuration. It is this antigenic shift that imparts the novel properties for a virulent strain of influenza virus associated with pandemics. The aggressive nature of pandemic influenza also results, in part, from the lack of relevant immunity in the population to this novel surface protein configuration.³⁷⁶

Three influenza pandemics occurred in the last century: 1918, 1957, and 1968. The pandemic of 1918 was responsible for between 30 and 50 million deaths worldwide and 500,000 deaths in the United States. The Asian influenza pandemic of 1957-1958 and the recent H1N1 epidemic also caused substantial morbidity and mortality, in both the general population and the obstetric population.^{377,378}

Annually, in the United States, influenza is responsible for 82 million infections and health care costs estimated at billions of dollars.³⁸⁰ Epidemics in the United States usually occur during the winter months (November through March), but the H1N1 epidemic actually began in the late spring. The rates of infection are highest in children, who are a major reservoir for spread of infection to adults, including pregnant women. As a general rule, the rates of serious illness and death have been highest among persons 65 years of age and older, children younger than 2 years of age, and people of any age who have medical conditions that place them at increased risk for complications of influenza. However, the H1N1 epidemic was unique in that younger patients, including pregnant women, seemed to be at greater risk for mortality than the elderly.^{382,383}

PATHOGENESIS

The influenza virus is transmitted primarily by respiratory droplets and, to a limited extent, by direct contact. The incubation period is relatively short, 1 to 5 days. Epidemics recur with regularity because the virus mutates in important ways from year to year. Immunity to the strains that caused infection in one year does not necessarily provide protection against strains that circulate in subsequent years.

Influenza can range in severity from a mild respiratory infection to a life-threatening pneumonia. The illness typically begins abruptly with prodromal symptoms of malaise, myalgia, and headache in association with fever. Subsequently, the patient develops a dry, nonproductive cough, coryza, mild dyspnea, and sore throat. On physical examination, the temperature is found to be elevated and the pharynx is inflamed; auscultation of the chest discloses rales and rhonchi. In some patients, a secondary bacterial pneumonia develops, and their cough then becomes productive of purulent sputum.³⁸²

Influenza virus infects the ciliated columnar epithelial cells of the respiratory tract, with resultant cellular necrosis and sloughing. Consequently, either the upper or the lower respiratory tract may be a site of infection.

In pregnancy, the major concern is the increased risk for development of life-threatening pneumonia.^{373,376} Influenza virus has not been associated with an increased risk of spontaneous abortion, stillbirth, or congenital anomalies. However, an infant delivered to an acutely infected patient may develop neonatal influenza as a result of close personal contact with the mother after delivery. In addition, mothers with severe respiratory infections may have an increased risk of preterm labor. In all reports of influenza pandemics, pregnant women experi-

enced increased morbidity and mortality compared with nonpregnant patients.^{373,378,383-385}

Neuzil and coauthors³⁸⁶ assessed the impact of influenza on pregnant women during nonpandemic "flu" seasons. They reported that the relative risk for hospitalization with cardiorespiratory complications in pregnant women, compared with nonpregnant women, was 1.4 at 14 to 20 weeks' gestation and rose to 4.7 in weeks 37 through 42. Moreover, women in the third trimester had a hospitalization rate similar to that of nonpregnant women with high-risk medical conditions.

DIAGNOSIS

The presence of the clinical manifestations described earlier is highly suggestive of influenza. The diagnosis can be confirmed by culture of the virus from respiratory secretions and by documentation of characteristic rises in serum antibody to influenza A and B. Chest radiography also may be of great value in assessing the severity of the pulmonary infection.

TREATMENT

The management of influenza in pregnant women is similar to that in nonpregnant persons, consisting of symptomatic relief, with bed rest, analgesics, liberal fluid intake, and fever control with acetaminophen (650 mg PO every 6 hours, maximum 3 g/24 hours). Patients should be reevaluated immediately if signs of worsening pneumonia or preterm labor develop. In addition, if they have severe symptoms, they should be offered treatment with either zanamivir (10 mg by inhalation twice daily for 5 days) or oseltamivir (75 to 150 mg PO twice daily for 5 days).³⁸⁷ Treatment is most effective when it is initiated within 48 hours after the onset of symptoms. Although amantadine is effective in nonpregnant patients, it has been associated with teratogenic effects in animals and is not recommended for use in pregnancy.³⁷³ If pneumonia occurs in a pregnant woman with influenza, she should be hospitalized promptly and treated with broad-spectrum antibiotics that cover bacteria likely to cause superinfection (e.g., *S. aureus*, *Streptococcus pneumoniae*, *Haemophilus influenzae*). Respiratory support is indicated in the presence of inadequate oxygenation, retention of carbon dioxide, or excessively labored breathing.

PREVENTION

The key to the prevention of influenza is vaccination. Immunization is 70% to 90% effective in either preventing influenza or diminishing the severity of illness. The ACIP^{381,388} now recommends annual vaccination for everyone older than 6 months of age. Children should receive the attenuated intranasal vaccine. This vaccine also may be given to individuals who are younger than 49 years of age. Those older than 49 years should receive the inactivated vaccine. As a general rule, adults have greater protection from the inactivated vaccine.³⁸¹

Unvaccinated adults, including pregnant women, should receive prophylactic antiviral therapy after an acute exposure to a person with influenza. The appropriate dose of oseltamivir for prophylaxis is 75 mg orally once daily for 10 days after household exposure and 7 days after other exposure. For zanamivir, the appropriate prophylactic dose is two inhalations (10 mg) once daily for 10 days for household exposure or 7 days after other exposure.³⁸⁷

Viral Hepatitis

HEPATITIS A

Hepatitis A is the second most common form of viral hepatitis in the United States. The infection is caused by an RNA virus that is transmitted by fecal-oral contact. The incubation period ranges from 15 to 50 days. Infections in children are usually asymptomatic; infections in adults are usually symptomatic. The disease is most prevalent in areas of poor sanitation and close living.³⁹⁰

The typical clinical manifestations of hepatitis include low-grade fever, malaise, poor appetite, right upper quadrant pain and tenderness, jaundice, and acholic stools. The diagnosis is best confirmed by detection of IgM antibody specific for the hepatitis A virus.

Hepatitis A does not cause a chronic carrier state. Perinatal transmission rarely occurs, and, therefore, the infection does not pose a major risk to either the mother or the baby. The exception is the development of fulminant hepatitis and liver failure in the mother, but such a situation is extremely rare.³⁹⁰

Hepatitis A can be prevented by administration of an inactivated vaccine. The vaccine is highly effective for both pre-exposure and post-exposure prophylaxis. Two formulations of the vaccine are available: Vaqta (Merck) and Havrix (Glaxo-SmithKline). Both vaccines require an initial intramuscular injection, followed by a second dose 6 to 12 months later. The vaccine should be offered to individuals in the following categories^{391,392}:

- International travelers
- Children in endemic areas
- Intravenous drug users
- Individuals who have occupational exposure (e.g., workers in a primate laboratory)
- Residents and staff of chronic care institutions
- Individuals with liver disease
- Homosexual men
- Individuals with clotting factor disorders

Standard immune globulin provides reasonably effective passive immunization for hepatitis A if it is given within 2 weeks after exposure. The standard intramuscular dose of immune globulin is 0.02 mg/kg.³⁹¹

HEPATITIS E

Hepatitis E is caused by an RNA virus. The epidemiology of hepatitis E is similar to that of hepatitis A. The incubation period averages 45 days. The disease is rare in the United States but is endemic in developing countries of the world. In these countries, maternal infection with hepatitis E often has an alarmingly high mortality rate, in the range of 10% to 20%. This high mortality is probably less the result of virulence of the microorganism and more related to poor nutrition, poor general health, and lack of access to modern medical care.³⁹⁰

The clinical presentation of acute hepatitis E is similar to that of hepatitis A. The diagnosis can be established with the use of electron microscopy to identify viral particles in the stool of infected patients. The most useful diagnostic test, however, is serology.

Hepatitis E does not cause a chronic carrier state. Perinatal transmission can occur but is extremely rare.³⁹³

HEPATITIS B

Hepatitis B is caused by a DNA virus that is transmitted parentally and via sexual contact. The infection also can be transmitted perinatally from an infected mother to her infant.

Acute hepatitis B occurs in 1 or 2 of every 1000 pregnancies in the United States. The chronic carrier state is more frequent, occurring in 6 to 10 of 1000 pregnancies. Worldwide, more than 400 million individuals are chronically infected with hepatitis B virus (HBV). In the United States alone, approximately 1.25 million people are chronically infected.³⁹⁰

Approximately 90% of patients who acquire hepatitis B mount an effective immunologic response to the virus and completely clear their infection. Fewer than 1% of infected patients develop fulminant hepatitis and die. Approximately 10% of patients develop a chronic carrier state. Some individuals with chronic hepatitis B infection ultimately develop severe chronic liver disease such as chronic active hepatitis, chronic persistent hepatitis, cirrhosis, or hepatocellular carcinoma. This sequela is particularly likely in patients who are coinfecting with hepatitis D or C.³⁹⁰

The diagnosis of hepatitis B is best confirmed by serologic tests. Patients with acute hepatitis B are positive for the hepatitis B surface antigen and positive for IgM antibody to the core antigen. Patients with chronic hepatitis B are positive for the surface antigen and positive for IgG antibody to the core antigen. Acutely or chronically infected patients may or may not be positive for the hepatitis B e antigen. If this latter antigen is present, it denotes active viral replication and a high level of infectivity.³⁹⁴

In the absence of intervention, approximately 20% of mothers who are seropositive for hepatitis B surface antigen will transmit infection to their neonates. Approximately 90% of mothers who are positive for both the surface antigen and the e antigen will transmit the infection. Fortunately, excellent immunoprophylaxis for prevention of perinatal transmission of hepatitis B infection is now available. Infants delivered to seropositive mothers should receive hepatitis B immune globulin (HBIG) within 12 hours after birth. Before their discharge from the hospital, these infants also should begin the hepatitis B vaccination series. The CDC now recommends universal vaccination of all infants for hepatitis B. In addition, the vaccine should be offered to all women of reproductive age.³⁹⁴

Immunoprophylaxis for the neonate is highly effective but does not offer perfect protection against infection, particularly in women with a high HBV DNA load. Presumably, most of the treatment failures result from antenatal transmission of the virus across the placenta. Recently, Shi and colleagues³⁹⁵ showed that antenatal administration of lamivudine to the mother (usually 100 mg daily from 28 weeks' gestation until 1 month after delivery) significantly reduced the risk of perinatal transmission, below that achieved with neonatal immunoprophylaxis alone, in patients who had a high viral DNA load (defined as $>10^3$ colonies/mL). In this meta-analysis, HBIG (100 to 200 international units IM at 28, 32, and 36 weeks' gestation) was also highly effective in reducing antenatal transmission of HBV infection.

HEPATITIS D (DELTA VIRUS INFECTION)

Hepatitis D is caused by an RNA virus that is dependent on coinfection with HBV for replication. Therefore, the

TABLE 51-12 Hepatitis in Pregnancy: Summary of Key Features

Infection	Mechanism of Transmission	Best Diagnostic Test	Carrier State	Perinatal Transmission	Vaccine	Remarks
Hepatitis A	Fecal-oral	Antibody detection	No	No	Yes	Passive immunization with immune globulin
Hepatitis E	Fecal-oral	Antibody detection	No	Rare	No	High maternal mortality in developing countries
Hepatitis B	Parenteral, sexual contact	Antigen detection	Yes	Yes	Yes	Passive immunization with hepatitis B immune globulin
Hepatitis D	Parenteral, sexual contact	Antibody detection	Yes	Yes	Prevented by hepatitis B vaccine	Virus cannot replicate in absence of hepatitis B infection
Hepatitis C	Parenteral, sexual contact	Antibody detection	Yes	Yes	No	Cesarean delivery for women with detectable serum hepatitis C virus RNA
Hepatitis G	Parenteral, sexual contact	Antibody detection	Yes	Yes	No	No clinical significance of infection

epidemiology of hepatitis D is essentially identical to that of hepatitis B. Patients with hepatitis D may have two types of infection. Some have acute hepatitis D and hepatitis B (coinfection). These individuals typically clear their infection and have a good long-term prognosis. Others have chronic hepatitis D superimposed on chronic hepatitis B (superinfection). These patients are particularly likely to develop chronic liver disease.³⁹⁰

The diagnosis of hepatitis D can be established by identifying the delta antigen in liver tissue or serum. However, the most useful diagnostic tests are detection of IgM and/or IgG antibody in serum.³⁹⁰

Hepatitis D can cause a chronic carrier state in conjunction with HBV infection. Perinatal transmission of hepatitis D occurs but is uncommon. Moreover, the immunoprophylaxis outlined for hepatitis B is highly effective in preventing transmission of hepatitis D.^{390,394}

HEPATITIS C

Hepatitis C is caused by an RNA virus. The hepatitis C virus (HCV) may be transmitted parenterally, via sexual contact, and perinatally. In many patient populations, hepatitis C is as common or more common than hepatitis B. Chronic hepatitis C now is the number one indication for liver transplantation in the United States.^{390,396-398}

Hepatitis C is usually asymptomatic, at least in its initial stages. The diagnosis is best confirmed by detection of viral RNA in the serum by PCR and by conventional serologic testing. The initial screening test should be an EIA. The confirmatory test is a recombinant immunoblot assay (RIBA). Seroconversion may not occur for up to 16 weeks after infection. In addition, although these immunologic tests have been available for many years, they still do not consistently and precisely distinguish between IgM and IgG antibody.³⁹⁰

In patients who have undetectable viral RNA in the serum and who do not have coexisting HIV infection, the risk of perinatal transmission of hepatitis C is less than 5%. If the patient's serum PCR is positive or she is coinfecting with HIV, or both, the perinatal transmission rate may approach 25%.^{399,400} Several small, nonrandomized, uncontrolled cohort studies (level II evidence) have supported a role for elective cesarean delivery before the onset of labor and rupture of membranes in selected women who have detectable HCV RNA. For women who have undetectable serum concentrations of RNA, vaginal delivery appears to be a reasonable plan of management.^{401,402} There is no contraindication to breastfeeding in women who have hepatitis C.

HEPATITIS G

Hepatitis G is caused by an RNA virus that is related to HCV. Hepatitis G is more prevalent, but less virulent, than hepatitis C. Many patients who have hepatitis G are coinfecting with hepatitis A, B, C, and/or HIV. Coinfection with hepatitis G does not adversely affect the prognosis of these other infections.⁴⁰³⁻⁴⁰⁶

Most patients with hepatitis G are asymptomatic. The diagnosis is best established by detection of the virus on PCR and identification of antibody on ELISA testing.

Hepatitis G can cause a chronic carrier state, and perinatal transmission has been documented. However, the clinical effects of infection in both mother and baby appear to be minimal. Accordingly, patients should not routinely be screened for this infection, and no special treatment is indicated even if infection is confirmed.³⁹⁰

Table 51-12 summarizes the key features of each form of hepatitis.

The complete reference list is available online at www.expertconsult.com.

Cardiac Diseases

DANIEL G. BLANCHARD, MD | LORI B. DANIELS, MD, MAS

Diagnosis of Heart Disease in Pregnancy

Pregnant women with heart disease are at higher risk for cardiovascular complications during pregnancy and also have a higher incidence of neonatal complications.¹ However, the significant hemodynamic changes that accompany pregnancy make the diagnosis of certain forms of cardiovascular disease difficult. During normal pregnancies, women frequently experience dyspnea, orthopnea, easy fatigability, dizzy spells, and, occasionally, even syncope. On physical examination, dependent edema, rales in the lower lung fields, visible neck veins, and cardiomegaly are commonly found. Systolic murmurs occur in more than 95% of pregnant women, and internal mammary flow murmurs and venous hums are common. A third heart sound (S₃ gallop) is often present.² Nevertheless, certain findings indicate heart disease in pregnancy and should suggest the presence of a significant cardiovascular abnormality. These symptoms include severe dyspnea, syncope with exertion, hemoptysis, paroxysmal nocturnal dyspnea, and chest pain related to exertion. Physical signs of organic heart disease include a fourth heart sound (S₄ gallop), cyanosis, clubbing, diastolic murmurs, sustained cardiac arrhythmias, and loud, harsh systolic murmurs.³

If there is a strong suspicion of heart disease during pregnancy, confirmatory diagnostic tests should be initiated. The changes of normal pregnancy must be recognized so that the findings are not misinterpreted. For example, nonspecific ST-segment and T-wave abnormalities and shifts in the electrical axis can occur.⁴ Pregnancy also produces changes in the echocardiogram, including alterations in cardiac dimensions and performance. The internal dimensions of all the cardiac chambers are increased, and slight regurgitation through the four valves is frequently observed. The ejection fraction (EF) and stroke volume are concomitantly larger, and the cardiac output is increased.⁵ A small pericardial effusion can be a normal finding in pregnant women.⁶ Both radiographic and radionuclide diagnostic procedures should be avoided during pregnancy unless the procedure is deemed essential for the health and safety of the mother.

Pre-Conception Counseling

If a woman plans to become pregnant but knows that she has heart disease, she and her physicians must be fully aware of several fundamental principles. The cardiovascular system undergoes specific adaptations to meet the increased demands of the mother and fetus during pregnancy. The most important of these are increases in blood volume, cardiac output, and heart rate. These adaptations exacerbate the symptoms and

clinical signs of heart disease and may necessitate significant escalation in treatment.

Cardiac risk varies among the specific forms of heart disease and also with severity. During pre-pregnancy counseling, the physician should describe the nature of the heart disease in terms comprehensible to the prospective parents. The risk to the woman, which can vary from negligible to prohibitive, should be spelled out as clearly as possible.⁷ On this basis, the patient may be advised either that the contemplated pregnancy is safe, will be uncomfortable and will necessitate treatment, carries a significantly increased risk, or would be extremely dangerous and should not be undertaken.

In the case of certain cardiac conditions, the patient should be strongly advised to undergo the necessary treatment before pregnancy and to allow several months to elapse before becoming pregnant. Examples in this category include the following:

- Large intracardiac shunt (atrial or ventricular septal defect) with mild to moderate pulmonary hypertension
- Patent ductus arteriosus (PDA) with mild to moderate pulmonary hypertension
- Severe coarctation of the aorta
- Severe mitral stenosis or regurgitation
- Severe aortic stenosis or regurgitation
- Tetralogy of Fallot
- Various congenital malformations and acquired heart diseases

Again, it is imperative that the palliative procedure be carried out before pregnancy is undertaken and that a year or so elapse before pregnancy occurs. Flexibility in clinical judgment is necessary, however. A woman with moderately severe valvular disease may require a prosthetic valve in the future. In such a case, the patient should be advised to have her family before valve replacement—with its associated anticoagulant risk—is required⁸ (see Pregnancy in Patients with Artificial Heart Valves, later). The valvular heart lesions associated with high and low maternal and fetal risk during pregnancy are listed in Boxes 52-1 and 52-2.

As previously noted, some cardiac disorders are so serious that the physiologic changes of a superimposed pregnancy pose prohibitive risks to the mother; they carry such a high maternal mortality risk that pregnancy is contraindicated. In such circumstances, patients must be strongly cautioned against becoming pregnant. If such a patient is seen for the first time when she is already pregnant, termination of the pregnancy is recommended. The most serious of the cardiac disorders are those involving pulmonary hypertension, particularly those associated with a right-to-left shunt in cardiac blood flow (Eisenmenger syndrome). Low cardiac output states and entities in which there is an increased risk of aortic dissection (Marfan

BOX 52-1 VALVULAR HEART LESIONS ASSOCIATED WITH HIGH MATERNAL OR FETAL RISK DURING PREGNANCY

Severe AS with or without symptoms
 AR with NYHA functional class III-IV symptoms
 MS with NYHA functional class II-IV symptoms
 MR with NYHA functional class III-IV symptoms
 Aortic and/or mitral valve disease resulting in severe pulmonary hypertension (pulmonary pressure greater than 75% of systemic pressures)
 Aortic and/or mitral valve disease with significant LV dysfunction (EF < 40%)
 Mechanical prosthetic valve requiring anticoagulation
 Marfan syndrome with or without AR

BOX 52-2 VALVULAR HEART LESIONS ASSOCIATED WITH LOW MATERNAL AND FETAL RISK DURING PREGNANCY

Asymptomatic AS with low mean gradient (<25 mm Hg, and aortic valve area >1.5 cm²) in the presence of normal LV systolic function (EF >50%)
 NYHA functional class I or II AR with normal LV systolic function
 NYHA functional class I or II MR with normal LV systolic function
 MVP with no MR or mild to moderate MR with normal LV systolic function
 Mild MS (mitral valve area >1.5 cm², gradient <5 mm Hg) without severe pulmonary hypertension
 Mild to moderate pulmonary valve stenosis

AR, aortic regurgitation; AS, aortic stenosis; EF, ejection fraction; LV, left ventricular; MR, mitral regurgitation; MS, mitral stenosis; MVP, mitral valve prolapse; NYHA, New York Heart Association.

Reproduced with permission from Bonow RO, Carabello B, Chatterjee K, et al: 2008 Focused update incorporated into the ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 1998 Guidelines for the Management of Patients with Valvular Heart Disease)—endorsed by the Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons, *Circulation* 118:e523–e661, 2008.

syndrome) also represent an extraordinarily high risk of maternal mortality. High-risk maternal cardiovascular disorders are listed in Table 52-1.

In some women with specific dangerous cardiovascular diseases, pregnancy is contraindicated because of the substantial risk of maternal death.⁹ Examples include the following:

- Dilated cardiomyopathy or left ventricular dysfunction (EF <40%) of any cause
- Severe pulmonary hypertension of any cause
- Marfan syndrome, especially with aortic root dilation (diameter >4 cm)

TABLE 52-1 High-Risk Maternal Cardiovascular Disorders

Disorder	Estimated Maternal Mortality Rate (%)
Aortic valve stenosis	10-20
Coarctation of the aorta	5
Marfan syndrome	10-20
Peripartum cardiomyopathy	15-60
Severe pulmonary hypertension	50
Tetralogy of Fallot	10

If a patient with one of these disorders presents when she is already pregnant, she should be strongly urged to consider early termination. A carefully planned suction curettage before 13 weeks' gestation would place such a patient at minimal risk. Termination of pregnancy beyond 13 weeks increases the risk to the mother, because many of the cardiovascular alterations that occur in pregnancy have taken place.

Infective endocarditis often causes rapid and serious deterioration of the cardiac status, posing a major threat to the life and health of the mother and, therefore, of the fetus as well. Scrupulous attention to prophylaxis against endocarditis is critical during pregnancy. Pregnant women must pay meticulous attention to their dental health; if they have cardiac lesions susceptible to infective endocarditis, neglect of antibacterial prophylaxis could have dire consequences.^{10,11}

The prospective parents will want to know not only about the risk to the health and life of the future mother but also about the fetal risks. One of the most important questions is whether the mother's heart disease is hereditary and, if so, what is the risk that the infant will be born with the same defect. A detailed family cardiac history must be obtained before pregnancy, especially if the prospective mother has heart disease.

Some of the cardiomyopathies, especially hypertrophic forms, may be inherited in a mendelian manner.¹² Familial dilated cardiomyopathy has also been described. Approximately 20% of idiopathic dilated cardiomyopathy is inherited.¹³ There is a strong familial tendency in certain congenital malformations, such as PDA and atrial septal defect (ASD). Additionally, mothers with congenital heart disease may have children with unrelated congenital malformations: this risk appears to be approximately 5%.^{3,14} Also, pregnant women with advanced heart disease, especially those with low cardiac output or severe hypoxia, experience a greatly increased incidence of spontaneous abortion, stillbirths, and small or deformed children.⁹ For most pregnant women with heart disease, vaginal delivery (with a low threshold for forceps or vacuum assistance) is recommended. Elective cesarean section is recommended in cases of Marfan syndrome or aortic aneurysm of any cause.³

Today's prospective mother wants to know about the risks to her fetus of drugs, other therapies, and diagnostic tests that are used to treat heart disease. Echocardiography poses no threat to the fetus, but radiation incurred with radionuclide angiography, cardiac catheterization with contrast angiography, or computed tomography pose a potential hazard to the fetus. If these studies are required, they should be performed before pregnancy occurs; they should be repeated thereafter only if mandated for the safety of the mother, and pelvic shielding should be used.

Every pregnant woman who is known or thought to have heart disease should, at a minimum, be evaluated once by a cardiologist who understands the cardiovascular adaptations to pregnancy. The cardiologist will prescribe necessary diagnostic studies and treatments and, of equal importance, will not allow unnecessary ones. The effects of heart disease can often be ameliorated by correcting coexisting medical problems, such as anemia, chronic infection, anxiety, thyroid dysfunction, hypertension, and arrhythmia.

Cardiovascular Adaptations to Pregnancy

INCREASED BLOOD VOLUME

The cardiovascular alterations observed in pregnancy are discussed in detail in Chapter 7 but are reviewed here briefly. It is worthwhile to reconsider and emphasize some of the most important cardiovascular changes that occur during pregnancy, because they may significantly alter the course of cardiac disease or may themselves be influenced by a specific disorder.

Blood volume and cardiac output increase during pregnancy.¹⁵ The uterus hypertrophies, endometrial vascularization is greatly increased, and the placenta becomes a highly vascular structure that functions to some extent as an arteriovenous shunt. In addition, generalized arteriolar dilation develops, mediated most probably by estrogen. These mechanisms combine to lower systemic vascular resistance and increase the pulse pressure. The total blood volume rises steadily during the first trimester and is increased by almost 50% by the 30th week, remaining more or less constant thereafter.¹⁶ Several mechanisms are responsible for increasing blood volume in pregnancy, including steroid hormones of pregnancy, elevated plasma renin activity, and elevated plasma aldosterone levels. Human placental lactogen, atrial natriuretic factor, and other peptides may also play significant roles in governing changes of blood volume in pregnancy. Hypervolemia also occurs with trophoblastic disease, indicating that a fetus is not essential for its development. Heart rate increases by 10 to 20 beats/min. In a normal pregnancy, blood pressure does not increase, because the increased intravascular volume is balanced by decreased peripheral vascular resistance mediated by the placenta. Plasma volume tends to increase more than the red blood cell mass, accounting for a “physiologic anemia” that is common in pregnancy. Treatment with iron corrects the anemia which, if left untreated, may become significant (a hematocrit as low as 33% and a hemoglobin level of 11 g/dL).

CARDIAC OUTPUT

Cardiac output rises during the first few weeks of pregnancy and is 30% to 45% above the nonpregnant level by the 20th week, remaining there until term.¹⁵ The increase in cardiac output in the first trimester begins rapidly and peaks between the 20th and 26th weeks. Early in pregnancy, the dominant factor is elevated stroke volume; later, increased heart rate predominates.¹⁷ In late pregnancy, the enlarged uterus partially impedes venous return by compressing the inferior vena cava, accounting for lower cardiac output. This is one reason why some obstetricians prefer to manage labor with the patient in the left decubitus position.

CARDIAC PERFORMANCE

Echocardiographic studies have shown increases in the left ventricular fiber shortening velocity and in EF. These changes do not necessarily indicate increased myocardial contractility but may simply be the result of decreased peripheral vascular resistance and increased preload. In any case, stroke volume is increased, and cardiac output is further augmented by the 10% to 15% increase in heart rate that characterizes normal pregnancy.¹⁸

Demands on the cardiovascular system increase significantly during labor and delivery. Pain increases sympathetic tone, and uterine contractions induce wide swings in the systemic venous return. With placental separation, autotransfusion of at least 500 mL takes place, placing an acute load on the diseased heart, unless it is offset by blood loss. These large shifts in blood volume can precipitate, on the one hand, shock, and on the other, pulmonary edema in women with severe heart disease.

If a chest radiograph is obtained in a pregnant woman, the cardiac silhouette often appears slightly enlarged as a result of the combined effects of volume overload and elevation of the diaphragm. Routine echocardiographic studies have demonstrated that a small, silent pericardial effusion is quite common.⁶

ELECTROCARDIOGRAPHIC CHANGES

The mean QRS axis may shift to the left¹⁹ as a result of the elevated diaphragm. In later pregnancy, the axis may shift to the right when the fetus descends into the pelvis. Minor ST-segment and T-wave changes may be observed, usually in lead III but sometimes aVF as well. Less often, T-wave inversions may appear transiently in the left precordial leads. Occasionally, small Q waves may accompany T-wave inversion in leads III and aVF. These changes are seldom of sufficient magnitude to raise the question of ischemic heart disease, which in any case is relatively uncommon in pregnancy, especially if the mother is young and free from symptoms. Extrasystoles and supraventricular tachycardia are more common during pregnancy. Symptoms of palpitations are common during pregnancy but only rarely signify the presence of organic heart disease.

General Guidelines for Management

During treatment of all pregnant patients with heart disease, priority must be given to maternal health, but all possible therapeutic measures should also be taken to protect the developing fetus. The aspects of management are outlined in Box 52-3.

BOX 52-3 CARDIAC DISEASE IN PREGNANCY: ASPECTS OF MANAGEMENT

- Activity restriction
- Diet modification
- Team approach for medical care
- Infection control
- Immunizations
- Prophylaxis against bacterial endocarditis in high-risk individuals
- Interruption of pregnancy
- Counseling
- Contraception or sterilization
- Cardiovascular surgery
- Cardiovascular drugs

Because pregnancy increases the demands on the heart, physical exertion frequently must be restricted, especially if it causes symptoms. Some women with certain forms of cardiac disease, such as significant mitral stenosis and cardiomyopathy, tolerate pregnancy poorly and cannot endure physical exertion. They may require strict bed rest for the duration of the pregnancy, particularly during the last trimester. Women with heart disease have a limited ability to increase cardiac output to meet increased metabolic demands and should minimize the demands placed on the heart from physical activity.

CARDIOVASCULAR DRUGS

Some of the drugs commonly used in the management of cardiovascular disease have potentially harmful effects on the developing embryo and fetus. For example, there is no question that oral anticoagulants are potential teratogens when administered in the first trimester (see Chapter 31 and later discussion in this chapter). Warfarin embryopathy, consisting of nasal hypoplasia, optic atrophy, digital abnormalities, and mental impairment, occurs in a minority of cases. The actual risk of warfarin embryopathy is difficult to estimate: it has ranged from 4% to 67% in various reports.^{20,21} A risk of 4% to 10% seems more reasonable.²² There is some evidence that embryopathy is less likely if the warfarin dosage is 5 mg/day or less.²³ The risks to the fetus continue beyond the first trimester, because warfarin increases the possibility of both fetal and intrauterine bleeding.

Anticoagulation presents a significant practical problem in the management of atrial fibrillation, systemic or pulmonary embolism, thrombophlebitis, and pulmonary hypertension in pregnancy. The most vexing problem arises in the setting of prosthetic heart valves^{10,11} (discussed later). In the case of mechanical valve prostheses, warfarin appears to be superior to heparin in preventing valvular thrombosis. Although heparin is safer for the fetus, there is probably an increased risk for the mother.^{20,24} This is a complex medical issue, and no randomized

trial to determine the optimal anticoagulant therapy for pregnant women with a prosthetic valve has been conducted. Therefore, recommendations are based on smaller studies and on clinical judgment.^{10,11} No single regimen is likely to be applicable to all such cases, because the issue is complicated by the type and generation of the prosthetic valve, the cardiac rhythm, and the size and contractility of the cardiac chambers.

β -Adrenergic blocking agents, used for the treatment of hypertension and tachyarrhythmia, have been associated with neonatal respiratory depression, sustained bradycardia, and hypoglycemia when administered late in pregnancy or just before delivery. However, if they are used judiciously in selected cases (e.g., in women with cardiomyopathy and heart failure), β -blockers are usually well tolerated.

The thiazide diuretics are another class of drugs that can produce harmful effects on the fetus—especially if they are used in the third trimester or for extended periods—and may impair normal expansion of plasma volume. Rarely, severe neonatal electrolyte imbalance, jaundice, thrombocytopenia, liver damage, and even death have been reported.

There have been numerous reports of fetal and neonatal renal complications after the use of angiotensin-converting enzyme (ACE) inhibitors during pregnancy.^{25,26} These complications suggest a profound and deleterious effect on fetal renal function, leading to decreased renal function and oligohydramnios, as well as neonatal renal failure. ACE inhibitors are absolutely contraindicated during pregnancy. Another class of antihypertensive drugs, the angiotensin receptor blockers, also may affect fetal renal function and are likewise absolutely contraindicated in pregnancy. Hydralazine, another vasodilator and oral antihypertensive agent, can be substituted for ACE inhibitors during pregnancy. Amlodipine is another alternative to ACE inhibitors, and it can be used with hydralazine if needed.

The indications and possible adverse effects of commonly prescribed cardioactive drugs during pregnancy are summarized in Table 52-2.

TABLE 52-2 Indications for and Possible Adverse Effects of Commonly Prescribed Cardioactive Drugs on Mother and Fetus

Drug	Use in Pregnancy	Potential Side Effects	Breastfeeding	Risk Category*
Adenosine	Maternal and fetal arrhythmias	No side effects reported; data on use during first trimester are limited	Data NA	C
Amiodarone	Maternal arrhythmias	IUGR, prematurity, congenital goiter, hypothyroidism and hyperthyroidism, transient bradycardia, prolonged QT in the newborn	Not recommended	C
Amlodipine	Hypertension	Limited human data	Data NA	C
ACEIs and angiotensin receptor blockers	Hypertension	Oligohydramnios, IUGR, prematurity, neonatal hypotension, renal failure, anemia, death, skull ossification defect, limb contractures, patent ductus arteriosus	Compatible	X
β -Blockers	Hypertension, maternal arrhythmias, myocardial ischemia, mitral stenosis, hypertrophic cardiomyopathy, hyperthyroidism, Marfan syndrome	Fetal bradycardia, low placental weight, possible IUGR, hypoglycemia; no information on carvedilol	Compatible; monitoring of infant's heart rate recommended	Acebutolol: B Labetalol: C Metoprolol: C Propranolol: C Atenolol: D
Digoxin	Maternal and fetal arrhythmias, heart failure	No evidence for unfavorable side effects on the fetus	Compatible	C
Diltiazem	Myocardial ischemia, tocolysis	Limited data; increased incidence of major birth defects	Compatible	C

TABLE 52-2 Indications for and Possible Adverse Effects of Commonly Prescribed Cardioactive Drugs on Mother and Fetus—cont'd

Drug	Use in Pregnancy	Potential Side Effects	Breastfeeding	Risk Category*
Disopyramide	Maternal arrhythmias	Limited data; may induce uterine contraction and premature delivery	Compatible	C
Diuretics	Hypertension, congestive heart failure	Hypovolemia leads to reduced uteroplacental perfusion, fetal hypoglycemia, thrombocytopenia, hyponatremia, hypokalemia; thiazide diuretics can inhibit labor and suppress lactation	Compatible	C
Flecainide	Maternal and fetal arrhythmias	Limited data; two cases of fetal death after successful treatment of fetal SVT reported, but relationship to flecainide uncertain	Compatible	C
Heparin	Anticoagulation	None reported	Compatible	C
Hydralazine	Hypertension	None reported	Compatible	C
Lidocaine	Local anesthesia, maternal arrhythmias	No evidence for unfavorable fetal effects; high serum levels may cause CNS depression at birth	Compatible	C
Nifedipine	Hypertension, tocolysis	Fetal distress related to maternal hypotension reported	Compatible	C
Nitrates	Myocardial infarction and ischemia, hypertension, pulmonary edema, tocolysis	Limited data; use is generally safe; few cases of fetal heart rate deceleration and bradycardia have been reported	Data NA	C
Procainamide	Maternal and fetal arrhythmias	Limited data; no fetal side effects reported	Compatible	C
Propafenone	Fetal arrhythmias	Limited data; fetal death reported after direct intrauterine administration in fetuses with fetal hydrops	Data NA	C
Quinidine	Maternal and fetal arrhythmias	Minimal oxytocic effect, high dosages may cause premature labor or abortion; transient neonatal thrombocytopenia and damage to eighth nerve reported	Compatible	C
Sodium nitroprusside	Hypertension, aortic dissection	Limited data; potential thiocyanate fetal toxicity, fetal mortality reported in animals	Data NA	C
Sotalol	Maternal arrhythmias, hypertension, fetal tachycardia	Limited data; two cases of fetal death and two cases of significant neurologic morbidity in newborns reported, as well as bradycardia in newborns	Compatible; monitoring of infant's heart rate recommended	B
Verapamil	Maternal and fetal arrhythmias, hypertension, tocolysis	Limited data; other than one case of fetal death of uncertain cause, no adverse fetal or newborn effects reported	Compatible	C
Warfarin	Anticoagulation	Crosses placental barrier; fetal hemorrhage in utero, embryopathy, CNS abnormalities	Compatible	X

*U.S. Food and Drug Administration classification of drug risk. B: Either animal reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women, or animal reproduction studies have shown an adverse effect that was not confirmed in controlled studies in women. C: Either studies in animals have revealed adverse effects on the fetus and there are no controlled studies in women, or studies in women and animals are not available. Drug should be given only if the potential benefits justify the potential risks to the fetus. D: There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk. X: Studies in animals or human beings have demonstrated fetal abnormalities. The risk of the use of the drug in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant.

ACEI, angiotensin-converting enzyme inhibitor; CNS, central nervous system; IUGR, intrauterine growth restriction; NA, not available; SVT, supraventricular tachycardia.

TEAM APPROACH TO MEDICAL CARE

Medical care for pregnant women with heart disease is best provided through the cooperative efforts of a cardiologist who is familiar with the hemodynamic changes of pregnancy and an obstetrician. Frequent visits to both specialists, along with open

consultations, can provide the patient with consistent advice and reassurance and can circumvent the worry and anxiety created by confusing and conflicting information. In addition, the anesthesiologist needs to be consulted during the antepartum period to outline the anticipated approach to intrapartum management, a time of maximal risk for most of these women.

The role of the anesthesiologist and the approach to women with pregnancies complicated by cardiac disease are summarized in Chapter 70.

▣ Congenital Heart Disease

A number of simple congenital malformations are compatible with a normal or nearly normal pregnancy. Congenital malformations previously associated with high maternal morbidity and mortality and fetal wastage now frequently end satisfactorily because of palliative or corrective surgery. Despite recent advances, however, women with congenital heart disease who become pregnant still have a significant risk of miscarriage, cardiac complications, and premature delivery.²⁷

The care of adults with congenital heart malformation is an important and growing branch of cardiology^{7,28,29} that requires the cooperative efforts of adult and pediatric cardiologists, cardiac surgeons, and, in the case of pregnancy, obstetricians and anesthesiologists.^{30,31}

LEFT-TO-RIGHT SHUNT

Atrial Septal Defect

ASD may be undiscovered before pregnancy because symptoms are often absent and the physical findings are not blatant. Other causes of left-to-right shunt, such as PDA and ventricular septal defect (VSD), are more likely to be discovered and treated in infancy or childhood. Physicians should be alert to the higher possibility of uncorrected defects in women who have emigrated from an undeveloped country.

Closure of uncomplicated large ostium secundum ASD is straightforward and safe and is usually curative. Therefore, the procedure should be done before pregnancy. Many ASDs can now be closed percutaneously, using a “clamshell” or “umbrella” device inserted via a transvenous catheter.³² If the patient is unwilling to undergo ASD closure, she can be advised that the lesion is unlikely to complicate pregnancy and labor, provided that pulmonary hypertension is not present.³

Metcalfe and colleagues³³ reported one maternal death among 219 pregnancies in 113 women with ASD. Peripheral vasodilation, if anything, reduces the left-to-right shunt.¹⁷ Because ASD in young women is not associated with heart failure, diuretics and extreme limitation of intravenous infusion are not warranted. A small percentage of patients with ASD have atrial flutter or fibrillation, which usually is paroxysmal. This arrhythmia can be managed along conventional lines, often with digoxin if necessary. The prospective mother should be informed that closure of the defect does not prevent atrial fibrillation once the arrhythmia has occurred.

ASD can be difficult to diagnose during pregnancy. The murmur associated with ASD may be inconspicuous, being a pulmonary ejection systolic murmur and therefore not unlike the physiologic murmur of pregnancy. However, the second heart sound is widely split and may be fixed throughout the respiratory cycle, a distinctly abnormal finding. The electrocardiogram (ECG) shows incomplete right bundle branch block and, in the case of the much more common ostium secundum defect, right axis deviation. In the less common ostium primum defect, marked left axis deviation accompanies incomplete right bundle branch block. The chest radiograph shows right atrial and right ventricular enlargement, prominent pulmonary arteries, and plethoric lung fields. Echocardiography establishes or

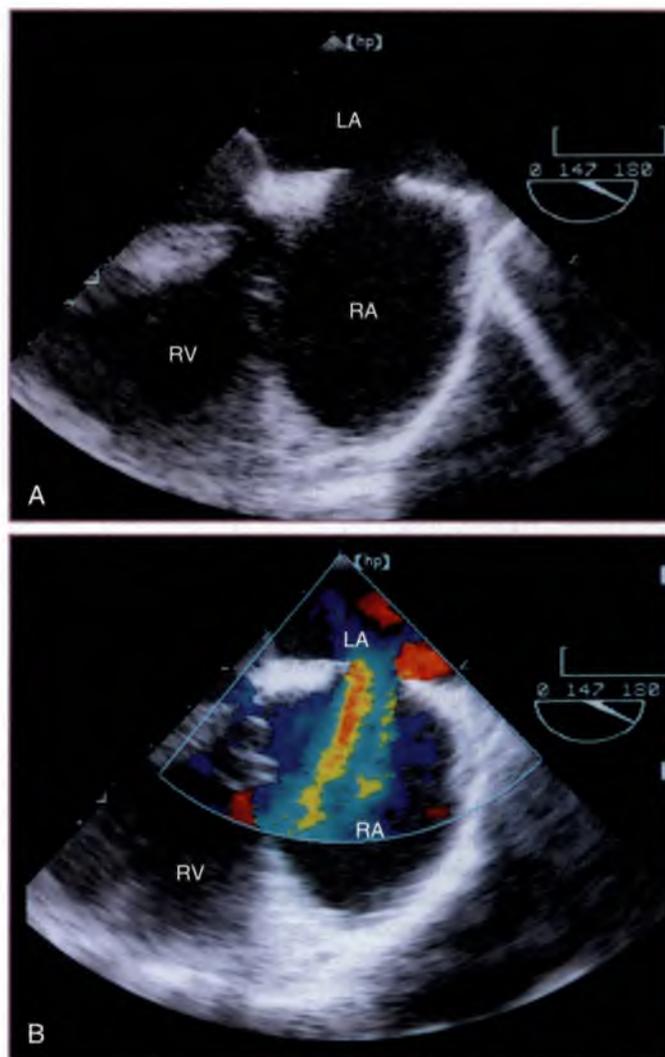

Figure 52-1 Transesophageal echocardiographic image of atrial septal defect (ostium secundum). A, A large defect in the interatrial septum is present. B, The blue and yellow colors represent blood flow from the left atrium (LA) into the right atrium (RA). RV, right ventricle.

confirms the diagnosis (Fig. 52-1; Video 52-1), obviating the need for cardiac catheterization in many cases.

Complicated Atrial Septal Defect

If atrial arrhythmias recur frequently—and especially if the heart rate is difficult to control—catheter ablation may be successful in restoring normal sinus rhythm without the need for antiarrhythmic drugs. In most cases, this procedure should not be done until after delivery because of the extensive radiation exposure that is needed. In rare instances, pregnancy and labor may be associated with a paradoxical systemic embolus resulting from a thrombus migrating from the inferior vena cava across the ASD into the left atrium.

In the uncommon event that the patient is more than 35 years old and has an uncorrected large ASD, the likelihood of chronic atrial fibrillation, right ventricular dysfunction, and pulmonary hypertension rises significantly. Pregnancy is not advised if any one of these sequelae is present. If the patient insists on going through with the pregnancy, prolonged bed rest

will be required, and vigorous treatment of heart failure may be needed. The maternal risk is increased, and there is significant risk of fetal loss. Although warfarin is generally recommended for chronic atrial fibrillation, its use is best avoided (especially in the first trimester); aspirin would be a reasonable compromise. Severe pulmonary hypertension, an uncommon feature of an ostium secundum ASD, is a contraindication to pregnancy. The ostium primum ASD, which is associated with Down syndrome and poses a risk of endocarditis, is more often associated with severe pulmonary hypertension. Infective endocarditis rarely, if ever, complicates a simple ostium secundum ASD; therefore, prophylaxis during labor is not warranted.

Ventricular Septal Defect

The clinical spectrum and risk of VSD may range from so mild that it has little or no effect on pregnancy, to so high that maternal or fetal death can occur. Small defects in the muscular ventricular septum frequently close spontaneously during childhood. However, these defects occasionally persist, allowing a small left-to-right shunt, manifested by a loud pansystolic murmur along the left sternal border accompanied by a coarse thrill. The chest radiograph is often normal, as is the ECG. The echocardiogram is usually diagnostic (Fig. 52-2; see Video 52-2 demonstrating communication between the ventricles in a VSD). These findings constitute the *maladie de Roger*. Prophylaxis against infective endocarditis is no longer indicated unless recent repair with prosthetic material has been performed. Otherwise, this lesion has no effect on pregnancy or labor. (See Use of Prophylactic Antibiotics, later.)

When the defect is in the membranous septum, spontaneous closure is rare. In the absence of significant pulmonary vascular disease, the same pansystolic murmur and thrill are found. If the shunt is large, however, the lung fields are plethoric on chest radiography, and the heart and pulmonary arteries are enlarged. The classic ECG shows a pattern of biventricular hypertrophy. In such cases, flow through the pulmonary vascular bed is usually at least twice the systemic cardiac output. Patients with a relatively large, uncomplicated left-to-right shunt through a VSD tolerate pregnancy well and, in this respect, are comparable to patients with ASD. However, prophylaxis against endocarditis is no longer recommended in cases of VSD (unless endocarditis has occurred previously or recent surgical repair with prosthetic material has been performed).

Here it is appropriate to detour from clinical description to pathophysiology. Pulmonary vascular resistance is calculated as the pressure drop across the pulmonary vascular bed divided by the flow through it:

$$R = (MPAP - MPCWP) / Q_{\text{pulm}}$$

where R is pulmonary vascular resistance in Wood units; MPAP and MPCWP (in mm Hg) are the mean pulmonary arterial and capillary wedge pressures, respectively; and Q_{pulm} is total flow through the right heart and pulmonary circulation (i.e., cardiac output plus left-to-right shunt) in liters per minute.

Resistance can be described in Wood units or in $\text{dyne} \cdot \text{s} / \text{cm}^5$. The Wood unit has the merit of simplicity and is derived from clinical units of pressure and flow. The more fundamental but less friendly $\text{dyne} \cdot \text{s} / \text{cm}^5$ can be obtained by multiplying Wood units by 80. Normal pulmonary vascular resistance is 0.5 to 1.5 Wood units. When a clinician is faced with a pregnant woman with pulmonary hypertension, the key to her risk during

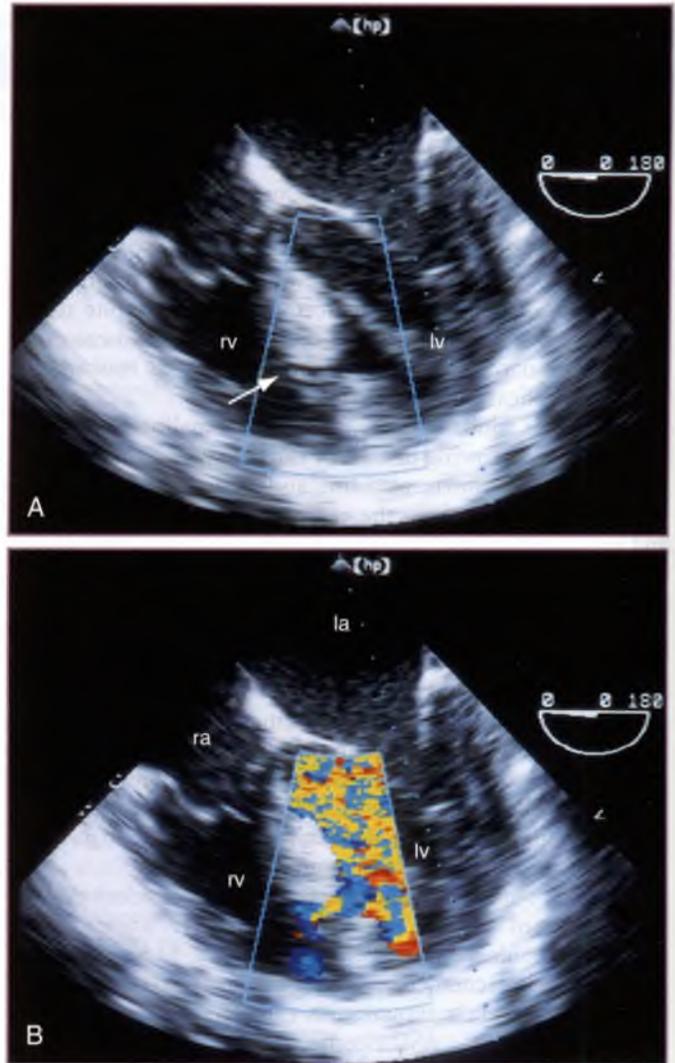

Figure 52-2 Transesophageal echocardiographic image of a small muscular ventricular septal defect. A, A small communication is seen (arrow) between the right ventricle (rv) and the left ventricle (lv). B, Color imaging confirms blood flow between the two chambers. la, left atrium; ra, right atrium.

pregnancy lies in the pulmonary vascular resistance. High flow, by itself, can be the mechanism for pulmonary hypertension without dangerous elevation in the resistance. This mechanism can be appreciated by rewriting the resistance equation to read as follows:

$$P = Q \cdot R$$

where P is the pressure drop and Q is the flow across the pulmonary vascular bed.

A patient at one extreme may have a large shunt with pulmonary flow of 20 L/min and an R of 3 units, yielding an MPAP of 55 mm Hg (assuming a normal MPCWP of 5 mm Hg). At the other extreme, a patient with pulmonary vascular disease may have a pulmonary blood flow of 7 L/min and an R of 7 units, yielding an MPAP of 44 mm Hg. The higher the pulmonary vascular resistance (R), the greater the maternal risk. The risk is prohibitive when R reaches the systemic level

(approximately 15 Wood units). In borderline cases (e.g., patients with R between 5 and 8 units), a pulmonary arteriolar vasodilating agent is sometimes administered to determine whether the increased resistance is partially reversible or completely irreversible. An increase in pulmonary vascular resistance of 3 to 4 units is considered mild, 5 to 7 units is moderate, and more than 8 units is severe.

VSD may be associated with considerable increase in pulmonary vascular resistance, reflecting occlusive disease of the small pulmonary arteries and arterioles. This development, if it is to occur, usually does so in childhood; unless corrected, it leads to the Eisenmenger syndrome (discussed later). However, a small number of adults may survive with a VSD and with pulmonary vascular resistance that is significantly elevated but falls short of the Eisenmenger syndrome. Such patients are at high risk for death during pregnancy or labor, and there is a high risk of fetal impairment or loss. The patient should be told that early therapeutic abortion would be the safest option, and that later pregnancy would be hazardous and would require intensive care, with physical exercise strictly curtailed and prolonged bed rest enforced. The combination of decreased physical activity, pulmonary hypertension, and pulmonary vascular disease would constitute a sound rationale for instituting anticoagulation, which is another reason why pregnancy is better avoided or terminated.

Some authorities strongly advise that delivery be effected prematurely by means of cesarean section and urge sterilization at the same operation. The dangers must be thoroughly understood by women in this category who insist on continuing pregnancy.

Patent Ductus Arteriosus

The loud, continuous or machinery-like murmur of a typical PDA with a large left-to-right shunt and no pulmonary vascular disease is so striking that the lesion is almost invariably detected and corrected in infancy or childhood. Occasionally, however, women of childbearing age or pregnant women from underdeveloped countries may present with a PDA. If the left-to-right shunt is large, the circulation is hyperdynamic, with a wide arterial pulse pressure, low arterial diastolic pressure, and hyperactive precordium. The heart may be somewhat enlarged on clinical and radiologic examination, and the ECG may show left ventricular hypertrophy. The echocardiogram is useful for demonstrating a shunt between the two great vessels (Fig. 52-3). The signs of hyperdynamic circulation resulting from the PDA are exaggerated by pregnancy.

Because the murmur of a PDA is systolic-diastolic, it is commonly referred to as a continuous murmur, although it usually peaks late in systole. Because of its characteristics, the murmur is also referred to as a machinery-like murmur. It is maximal in the left infraclavicular region. It must be distinguished from a venous hum, which is loudest in the neck rather than the infraclavicular area. Venous hum is common in pregnant women, and it changes dramatically with changes in the position of the head.

Division or occlusion of the PDA should be accomplished before pregnancy is begun. Currently, most PDAs can be closed by the insertion of an occluder device delivered via a percutaneous intravascular catheter.³⁴ If a patient does become pregnant before PDA occlusion, an uncomplicated left-to-right shunt can be managed safely. Endocarditis is a risk in patients with a PDA, and physicians should remain alert to this possibility at all

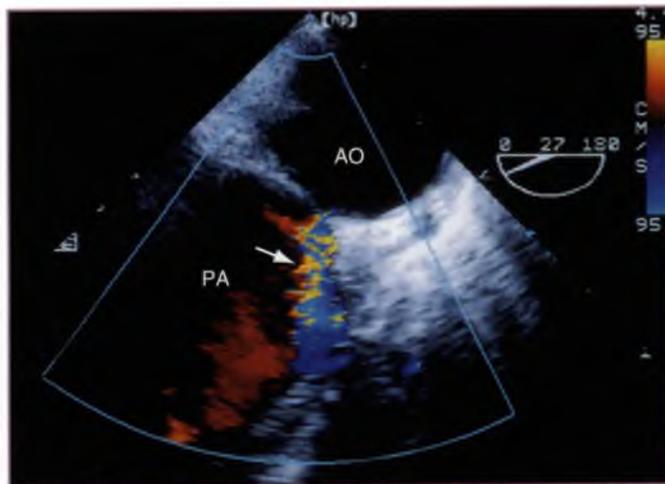

Figure 52-3 Transesophageal echocardiographic image of a patent ductus arteriosus. A communication is present between the proximal portion of the descending aorta (AO) and the pulmonary artery (PA). Color imaging (arrow) confirms blood flow from the AO into the PA.

times. Embolic complications of infective endocarditis and endarteritis secondary to PDA may take the form of infected pulmonary emboli. The patient becomes febrile with respiratory symptoms, and the chest radiograph shows multiple opacities and infiltrates.

The leading cause of Eisenmenger syndrome is a large VSD, followed in prevalence by a large PDA. As with a VSD, individuals with a PDA may sustain severe increases in pulmonary vascular resistance with the corresponding pulmonary hypertension and right ventricular hypertrophy yet fall short of Eisenmenger physiology. The maternal risk during pregnancy is high in this situation, similar to that encountered in VSD with equivalent pathology. Treatment is the same as for a VSD with Eisenmenger syndrome. When the pulmonary pressure rises, the aortopulmonary shunt decreases, and the murmur becomes progressively quieter and shorter until it finally disappears.

In general, the woman with uncomplicated PDA tolerates pregnancy well. If pulmonary hypertension supervenes, the risk to the mother becomes significant. Therefore, if pulmonary hypertension is suspected and documented, termination of pregnancy is strongly recommended.

EISENMENGER SYNDROME

Eisenmenger syndrome is characterized by a congenital communication between the systemic and pulmonary circulations and increased pulmonary vascular resistance, either to systemic level (so that there is no shunt across the defect) or exceeding systemic level (allowing right-to-left shunting). As mentioned, the most common underlying defect is a large VSD, followed in prevalence by a large PDA. Eisenmenger pathophysiology is less common in ASD. Occasionally, this type of pathophysiology develops in other, less common defects. By the time the syndrome is fully developed, it is often difficult to diagnose the underlying defect clinically. For this discussion, the VSD serves as a good model (Fig. 52-4).

Eisenmenger pathophysiology develops only if the defect is large and is not restrictive, resulting in equal systolic pressure

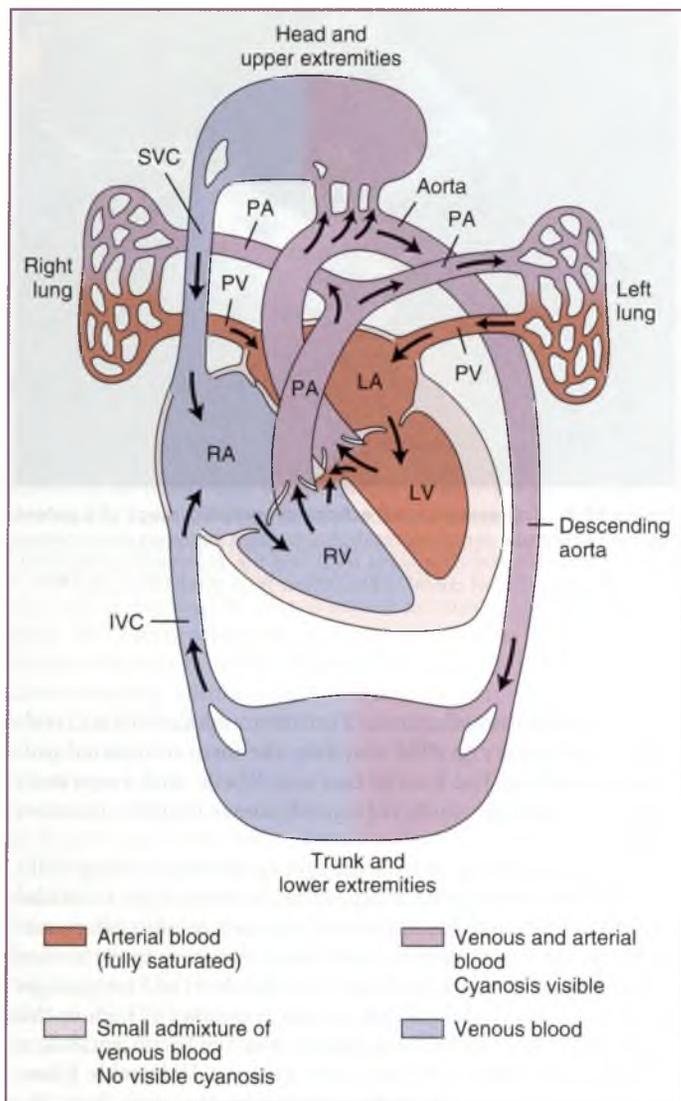

Figure 52-4 Eisenmenger complex. Here, the cause of a right-to-left shunt across the ventricular septal defect is increased pulmonary vascular resistance arising in the small pulmonary arteries (PA) and arterioles. IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava. (Reprinted by permission of the publisher. From Taussig HB: *Congenital malformations of the heart*, Cambridge, MA, 1960, Harvard University Press. Copyright © 1960 by the Commonwealth Fund by the President and Fellows of Harvard College.)

in the two ventricles. It is more common in girls and develops at a young age. Therefore, when increased pulmonary vascular resistance is detected in a child with a large VSD, operative closure must be done as soon as possible to prevent the development of Eisenmenger pathophysiology. Once this has appeared, pulmonary hypertension is irreversible, and the VSD is consequently inoperable (unless lung transplantation is performed as well).

The major clues that pulmonary vascular resistance is increasing are (1) diminution of evidence of a left-to-right shunt and (2) the appearance of progressively severe pulmonary hypertension. The pansystolic murmur of VSD or the continuous murmur of PDA is replaced by a short ejection systolic

murmur. The lungs are no longer plethoric but show large central pulmonary arteries and small peripheral arteries characteristic of severe pulmonary hypertension. Because the shunt has disappeared, the radiographic cardiothoracic ratio returns to normal but the main pulmonary segment is prominent. There is usually a striking right ventricular heave, a loud and palpable pulmonary valve closure sound, and an ejection sound in early systole. When concentric ventricular hypertrophy gives way to dilation and right-sided heart failure, evidence of tricuspid regurgitation appears. Until then, the mean venous pressure is normal but the amplitude of the *a* wave may be increased, reflecting decreased right ventricular diastolic compliance.

If pulmonary vascular resistance is significantly higher than systemic levels, right-to-left shunting of blood occurs and causes cyanosis and clubbing of the fingers and toes. This shunting of deoxygenated blood into the systemic circulation leads to hypoxemia and triggers a reactive erythrocytosis as the system attempts to increase peripheral oxygen delivery. This increases blood viscosity and can cause sludging and decreased flow of blood, especially in small vessels. A high hematocrit value, however, is not an automatic indication for serial phlebotomy, because this approach can lead to iron deficiency and microcytosis. Tissue hypoxia may then actually worsen, a particularly undesirable result in pregnancy. Phlebotomy is reserved for patients without evidence of iron deficiency on laboratory testing who have symptoms of hyperviscosity, including headache, dizziness, visual disturbance, myalgia, and bleeding diathesis. Quantitative volume replacement is necessary during phlebotomy.

Attempted surgical correction of a congenital cardiac shunt after Eisenmenger syndrome is present usually results in the death of the patient.³⁵ Many patients ultimately die of right-sided heart failure, pulmonary hypertension, or pulmonary hemorrhage.³⁶

The woman with Eisenmenger syndrome must be informed that pregnancy carries a mortality risk of about 50%.³⁷ Even if the mother survives, the outcome for the fetus is likely to be poor, because the fetal mortality rate exceeds 50% in cyanotic women with Eisenmenger syndrome.³⁶ Sudden death may occur at any time, but labor, delivery, and particularly the early puerperium seem to be the most dangerous periods.³⁸ Any significant fall in venous return, regardless of cause, impairs the ability of the right heart to pump blood through the high, fixed pulmonary vascular resistance. Hypotension and shock can occur quickly and are often unresponsive to medical therapy.

The major physiologic difficulty in pulmonary hypertension is maintenance of adequate pulmonary blood flow. Any event or condition that decreases venous return, such as vasodilation on the systemic side of the circulation from epidural anesthesia, or pooling of blood in the lower extremities from vena caval compression, decreases preload to the right ventricle and pulmonary blood flow. Therefore, management during pregnancy centers on the maintenance of pulmonary blood flow. If the patient insists on continuing her pregnancy, limitation of physical activity is essential, as is the use of pressure-graded elastic support hose, low-flow home oxygen therapy, and monthly monitoring of blood and platelet counts. Because of the precarious physiologic balance, a planned delivery should be performed with intensive care monitoring, including a Swan-Ganz catheter and provisions for skilled obstetric anesthesia care. Anesthetic considerations for this entity are discussed in Chapter 70.

On a more optimistic note, a report published in 1995 described 13 pregnancies in 12 women with Eisenmenger syndrome who elected not to accept advice to terminate pregnancy.³⁹ Mean systolic pulmonary arterial pressure was 113 mm Hg. Three spontaneous abortions, one premature labor, and two maternal deaths occurred. The seven patients who reached the end of the second trimester were hospitalized until term, treated with oxygen and heparin, and delivered by cesarean section. One patient died a month after delivery. Most of the infants were small, and one died. Despite this better-than-average outcome, pregnancy should not be encouraged in women with Eisenmenger syndrome or in those with a systemic level of pulmonary hypertension of any cause.

PRIMARY PULMONARY HYPERTENSION

Severe idiopathic (“primary”) pulmonary hypertension, like the Eisenmenger syndrome, carries a high risk in pregnancy, and the same principles apply to its management. Pregnancy is not advised in women with this condition, because the mortality rate approaches 50%.⁴⁰

Severe pulmonary hypertension can result from taking appetite-suppressing drugs. The fenfluramine-phenentermine regimen (“fen-phen”) was a notorious culprit⁴¹ and was withdrawn from the market. Treatment strategies include vasodilators, sometimes by chronic intravenous infusion, and nitric oxide inhalation. In some 25% of cases, pulmonary arterial pressure is lowered by prostacyclin infusion.⁴² This response predicts a favorable response to chronic oral nifedipine administration and a good prognosis. Balloon atrial septostomy,^{43,44} through the foramen ovale or via transseptal puncture, can be used, in extreme cases of pulmonary hypertension, to relieve right heart pressure, usually as a bridge to transplantation.

Congenital Obstructive Lesions

Some congenital cardiac malformations are characterized by obstruction to left or right ventricular outflow. The more common examples include pulmonic stenosis, aortic stenosis, and coarctation of the aorta. The hypoplastic left heart syndrome seldom allows survival to childbearing age, and those who do survive usually have undergone a major palliative procedure, such as construction of a ventriculoaortic conduit with a prosthetic valve, that would constitute a strong contraindication to pregnancy.

MITRAL STENOSIS

Congenital mitral stenosis is a rare malformation. When it is associated with an ASD, it constitutes the Lutembacher syndrome. Survival to childbearing age is usual. Both lesions tend to promote atrial fibrillation. Ideally, the mitral valve and the atrial defect should be repaired before pregnancy.

AORTIC STENOSIS

(See also Aortic Stenosis under Aortic Valve Disease, later.)

Bicuspid aortic valve is one of the more common congenital malformations that may lead to aortic stenosis, regurgitation, or both (Fig. 52-5; Video 52-3). Often, aortic stenosis is not present during early life but progresses over time because of valve calcification and gradual restriction in leaflet motion. The

Figure 52-5 Transesophageal echocardiographic image of a bicuspid aortic valve. During systole, only two aortic valve (AV) leaflets are seen. LA, left atrium; RVOT, right ventricular outflow tract.

bicuspid valve may occur as an isolated defect or in combination with other congenital anomalies, most commonly aortic coarctation. Congenital aortic stenosis, on the other hand, can be severe at birth and may cause severe left ventricular hypertrophy that limits the ability of the heart to respond to demands for increased cardiac output.

In the syndrome of severe congenital aortic stenosis, the pulses have a slow upstroke and diminished amplitude. Unlike adults with acquired aortic stenosis, children and young adults with congenital aortic stenosis have an abnormally loud aortic valve closure sound. Left ventricular ejection is prolonged, so that the aortic valve closure sound may occur after the pulmonary valve closure sound. Therefore, splitting of the second heart sound is paradoxical and is heard in expiration instead of inspiration. Often a loud ejection sound is heard in early systole. The duration of the ejection murmur and the time to its peak intensity increase with worsening severity of aortic stenosis.

The ECG shows severe left ventricular hypertrophy. The chest radiograph is characterized by poststenotic dilation of the aorta. Although some patients complain of dyspnea, chest pain, and syncope, others remain asymptomatic. The lesion can be recognized and its severity assessed by Doppler echocardiography.

Critical calcific aortic stenosis is usually treated by aortic valve replacement in older patients, but aortic valve repair is often possible in younger women of childbearing age with congenital aortic stenosis. If aortic stenosis is severe—and especially if it is symptomatic—the woman should be advised against becoming pregnant. She should be advised that, if the aortic valve had to be replaced, pregnancy and labor would be difficult and dangerous because of the need for anticoagulant treatment after a mechanical prosthesis is implanted. Maternal mortality rates as high as 17% have been reported,⁴⁵ although more recent data have suggested a somewhat lower risk. However, these studies also emphasize the adverse effects of severe maternal aortic stenosis on fetal outcomes, including increased rates of preterm delivery and intrauterine growth restriction.⁴⁶ If aortic stenosis is moderate in severity, the patient should be advised to complete her pregnancies before the aortic valve is replaced. Labor can be managed in such cases without

a high maternal or fetal risk, but assisted shortening of the second stage of labor is recommended.⁴⁷

Strict limits on physical exertion and prolonged periods of bed rest may be required. Left ventricular failure may appear and may necessitate the use of diuretic agents and digitalis. Rarely, even in the presence of severe aortic stenosis, heart failure may have another cause (e.g., peripartum cardiomyopathy).⁴⁸ Prophylaxis against bacterial endocarditis at delivery is no longer recommended.

Vasodilators, helpful in patients with heart failure of other etiology, are dangerous in patients with aortic stenosis, because the impeded left ventricle may not be able to fill the dilated peripheral vascular bed. It should be remembered that the lowered systemic vascular resistance of pregnancy adversely affects aortic stenosis. The obstructed left ventricle is limited in its ability to fill the dilated peripheral bed, a situation that can lead to syncope or more serious manifestations of limited, relatively fixed cardiac output.

PULMONIC STENOSIS

The murmur of pulmonic stenosis is loud and often accompanied by a thrill. The lesion is usually detected in early childhood and is likely to have been corrected before the childbearing age. Expectant mothers who have not had adequate health supervision in childhood may have unrecognized pulmonic stenosis.

The diagnosis is suggested by a long, harsh systolic murmur over the upper left sternal border that is usually preceded by an ejection sound. The venous pressure is normal, but there are striking *a* waves in the jugular venous pulse. The pulmonic valve closure sound is usually too soft to hear when pulmonary stenosis is severe. Severe pulmonary stenosis causes massive concentric right ventricular hypertrophy; this is manifested by a left parasternal heave and by tall R waves and deeply inverted T waves in the right precordial leads of the ECG. Tall, pointed P waves are also present, denoting right atrial enlargement.

Right ventricular enlargement and poststenotic dilation of the main and left pulmonary arteries are seen on the chest radiograph, which also may show slightly diminished peripheral pulmonary vasculature. Echocardiography demonstrates limited opening of the pulmonic valve leaflets (Fig. 52-6), right ventricular hypertrophy, and abnormally high velocity of blood flow in the pulmonary artery. Doppler echocardiography also allows calculation of the right ventricular pressure and the systolic pressure gradient across the valve. These pressures can also be measured directly in the hemodynamics laboratory (Fig. 52-7).

Pulmonic stenosis is generally well tolerated, and neither pregnancy nor labor poses a significant threat.⁴⁹ Prophylaxis against infective endocarditis is no longer considered necessary. More severe pulmonary stenosis requires treatment. Unlike aortic stenosis, however, critical pulmonary stenosis does not require valve replacement or open repair. Most cases are treated successfully with transvenous balloon valvuloplasty.⁵⁰ Ideally, this should be carried out before pregnancy is begun; if a woman does become pregnant and develops intractable right-sided heart failure, the procedure can still be safely performed (but at some risk to the fetus). Extreme pulmonary stenosis (right ventricular systolic pressure > systemic systolic pressure) is a contraindication to pregnancy until the lesion is adequately treated.

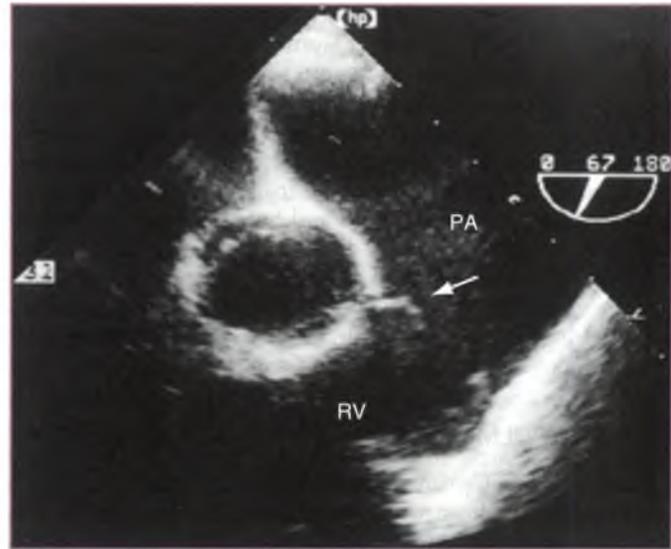

Figure 52-6 Transesophageal echocardiographic image of pulmonic stenosis. The pulmonic valve leaflets exhibit characteristic doming (arrow). PA, pulmonary artery; RV, right ventricle.

RIGHT-TO-LEFT SHUNT WITHOUT PULMONARY HYPERTENSION (TETRALOGY OF FALLOT)

The congenital cyanotic heart diseases discussed so far have been associated with a communication between the pulmonary and systemic circulations, and with a pulmonary vascular resistance sufficiently high to cause a right-to-left shunt. However, cyanosis occurs in other congenital malformations in which there is not only a defect between the right and left sides of the heart but also right ventricular outflow obstruction (Figs. 52-8 and 52-9). Examples include the tetralogy of Fallot and tricuspid atresia.

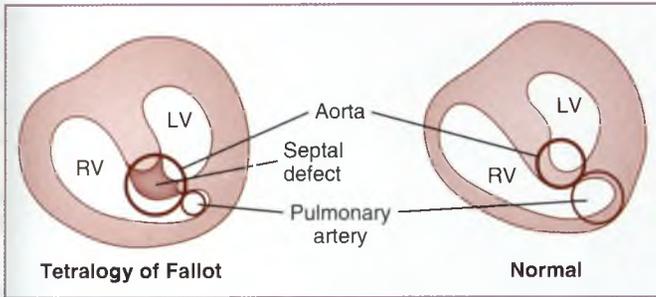

Figure 52-8 Tetralogy of Fallot. The anatomic pathology (left) compared with normal (right). Note the ventricular septal defect, the aorta (which overrides the defect), the pulmonary stenosis, and the right ventricular hypertrophy. LV, left ventricle; RV, right ventricle. (Reprinted by permission of the publisher. From Taussig HB: Congenital malformations of the heart, Cambridge, MA, 1960, Harvard University Press. Copyright © 1960 by the Commonwealth Fund of the President and Fellows of Harvard College.)

Figure 52-9 Transthoracic echocardiographic image of tetralogy of Fallot. A large ventricular septal defect is present, and the aorta (AO) overrides the interventricular septum. LV, left ventricle; MV, mitral valve; RV, right ventricle.

Tetralogy of Fallot is used to illustrate this class of congenital malformation of the heart because it is by far the most common form of cyanotic congenital heart disease encountered in pregnancy. Moreover, the offspring of a mother with tetralogy of Fallot has a 2% to 13% chance of inheriting the condition.⁵¹ The syndrome includes (1) a large defect high in the ventricular septum; (2) pulmonary stenosis, which may be at the valve itself but more commonly is in the infundibulum of the right ventricle; (3) dextroposition of the aorta so that the aortic orifice sits astride the VSD and overrides, at least in part, the right ventricle; and (4) right ventricular hypertrophy (Fig. 52-10; see Video 52-4 demonstrating displacement of the aortic root).

A wide spectrum of clinical presentations may be present, depending on the relative size of the VSD and the degree of right ventricular outflow obstruction that diverts blood flow through the VSD. In the typical case, right and left ventricular systolic pressures are equal but the pulmonary artery pressure is exceedingly low. A loud, long systolic murmur is audible along the left sternal border. The murmur is caused by an abnormal flow pattern through the obstructed right ventricular

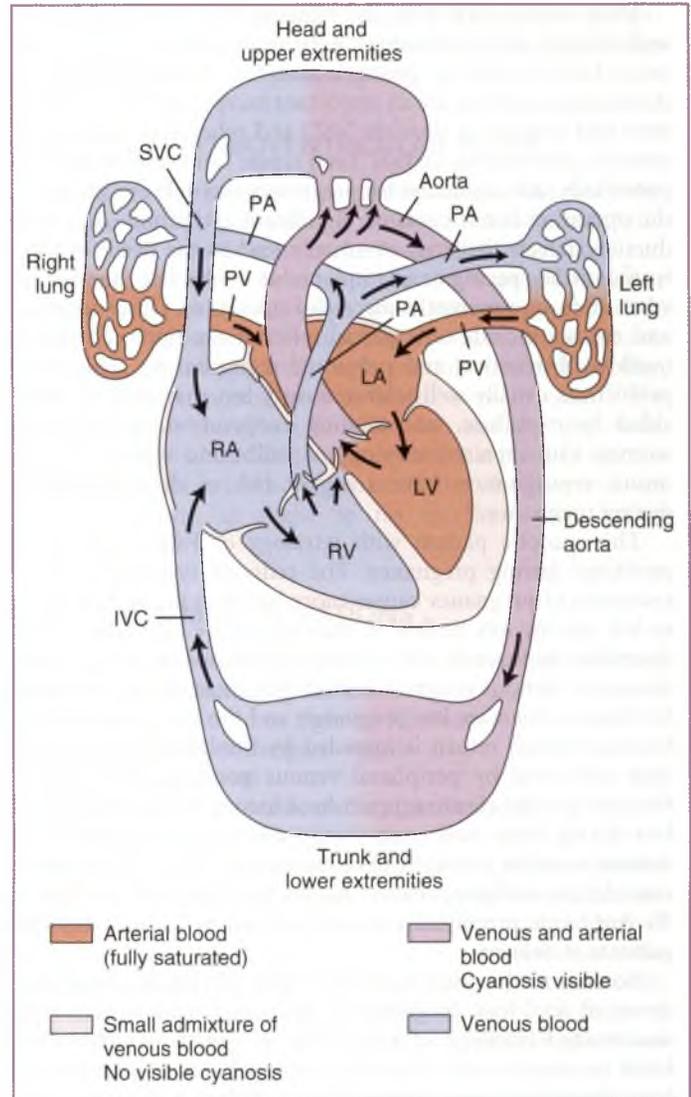

Figure 52-10 Tetralogy of Fallot. Blood shunts from left to right through the ventricular septal defect because its flow to the lungs is impeded by pulmonary stenosis; this results in cyanosis. IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava. (Reprinted by permission of the publisher. From Taussig HB: Congenital malformations of the heart, Cambridge, MA, 1960, Harvard University Press. Copyright © 1960 by the Commonwealth Fund by the President and Fellows of Harvard College.)

outflow tract. The pulmonary valve closure sound is usually inaudible. Patients are usually cyanotic and often have significant clubbing of the fingers and toes. The hematocrit value is greatly elevated because of the severe erythrocytosis. Phlebotomy is not indicated to treat the hematocrit level per se but is indicated if symptoms of hyperviscosity occur. Ignoring this important therapeutic principle leads to a microcytic anemia that further complicates pregnancy. The ECG shows severe right ventricular hypertrophy. The chest radiograph is characterized by a normal-size heart and a concavity in the region where the pulmonary artery should be. As in all malformations of this general type, the lung fields are oligemic, showing small vessels throughout.

Most adults born with the tetralogy of Fallot and lesions with similar pathophysiology have undergone surgical treatment before reaching young adulthood. Children raised in developing countries are an important exception. Many patients have had surgery to close the VSD and relieve the pulmonary stenosis, constituting virtual “total repair” and rendering them potentially safe candidates for pregnancy and delivery. However, the operation is not curative. Significant arrhythmia and conduction defects that may eventually lead to the need for electronic cardiac pacing or an implantable defibrillator may occur years after an apparently successful operation. Other sequelae and residua include only partial relief of the right ventricular outflow obstruction and pulmonic regurgitation. This latter problem is usually well tolerated early but may lead to right-sided heart failure, necessitating reoperation. In addition, women with repaired tetralogy of Fallot and significant pulmonic regurgitation have a higher risk of decompensation during pregnancy.⁵²

The cyanotic patient with tetralogy of Fallot has special problems during pregnancy. The reduced systemic vascular resistance of pregnancy causes more blood to shunt from right to left, leaving less to flow to the pulmonary circulation. This intensifies hypoxemia and can lead to syncope or death. Maintenance of venous return is crucial. The most dangerous times for these women are late pregnancy and the early puerperium, because venous return is impeded by the large gravid uterus near term and by peripheral venous pooling after delivery. Pressure-graded elastic support hose are recommended. Blood loss during labor may compromise venous return, and blood volume must be promptly and adequately restored. Anesthetic considerations during delivery are discussed in detail in Chapter 70. Antibiotic prophylaxis should be used in these susceptible patients at delivery.

Because of the combined high maternal risk and high incidence of fetal loss, pregnancy is discouraged in women with uncorrected tetralogy of Fallot. The prognosis is particularly bleak in women with a history of repeated syncopal episodes, a hematocrit level greater than 60%, or a right ventricular systolic pressure greater than 120 mm Hg. If a young woman with untreated tetralogy of Fallot requests pre-pregnancy counseling, she should be advised to undergo surgical correction before pregnancy. Pregnancy does not represent a significantly increased risk for patients in whom the VSD has been patched and the pulmonary stenosis corrected.

COARCTATION OF THE AORTA

Coarctation of the aorta is a congenital defect in the area of the aorta where the ligamentum arteriosum and the left subclavian artery insert (the distal portion of the aortic arch). The malformation may be simple or complex, and it is either isolated or associated with PDA and other malformations, notably aortic stenosis and aortic regurgitation secondary to a bicuspid aortic valve. It may also occur in women with Turner syndrome. The lesion should be detected and treated surgically or by balloon dilation in infancy or childhood, but it may be present in women who are, or want to become, pregnant. Coarctation can be detected with echocardiography; both CT and MRI provide excellent visualization of the thoracic aorta (Fig. 52-11).

Typical features include the following:

- Upper extremity hypertension but lower extremity hypotension

Figure 52-11 Coarctation of the aorta. This magnetic resonance image from a young woman with hypertension shows the area of coarctation (*) in the proximal portion of the descending thoracic aorta (DA). AA, ascending aorta.

- Visible and palpable collateral arteries in the scapular area
- A late systolic murmur, usually loudest over the inter-scapular region
- Femoral pulses that lag behind the carotid pulses and are of diminished amplitude
- Notching of the inferior rib borders seen on the chest radiograph and resulting from erosion by arterial collaterals that bridge the coarctation

Electrocardiographic evidence of severe left ventricular hypertrophy strongly suggests associated aortic stenosis. Surgical grafting or percutaneous intravascular balloon dilation reduces the upper extremity hypertension, but blood pressure does not always return to normal, and hypertension may recur in later life.

Whenever possible, the operation should be performed before pregnancy; otherwise, the maternal mortality rate is approximately 3%. Coarctation is associated with congenital berry aneurysm of the circle of Willis and hemorrhagic stroke. The risk of stroke may increase during labor because of transient elevations in blood pressure. Patients are at risk for aortic dissection and infective endocarditis involving an abnormal aortic valve; these risks increase during pregnancy.⁵³ Hypertension often worsens as well.⁵⁴ Coarctation is also associated with an increased frequency of preeclampsia.³¹ The operation does not require cardiopulmonary bypass and can be carried out safely for the mother and with less fetal risk than accompanies open heart surgery with cardiopulmonary bypass. Although transvascular balloon dilation of aortic coarctation is a viable option for children and infants with coarctation, its use in adults is controversial.⁵⁵ The procedure is well accepted for treatment of postsurgical renarrowing of the coarctation, but

de novo balloon angioplasty carries a risk of aortic dissection and rupture. A number of centers are now performing balloon dilation with stent implantation for adults with unoperated aortic coarctation, but large, multicenter studies are not available.⁵⁶

If delivery must be undertaken in cases of unoperated coarctation, blood pressure can be titrated with β -adrenergic-blocking agents delivered by intravenous drip.

Other Congenital Cardiac Malformations

EBSTEIN ANOMALY

Ebstein anomaly is a malformation of the tricuspid valve in which the septal leaflet is displaced apically and the anterior leaflet is abnormally large in size. The deformed tricuspid valve apparatus may be significantly incompetent or stenotic, depending on the location of the anomalously placed cusps of the valve. In some cases, the malformation is an impediment to right ventricular outflow.

The clinical features are easily recognized by a cardiologist, and the echocardiogram is characteristic and reliable (Fig. 52-12; Video 52-5A,B). This syndrome is frequently associated with anomalous atrioventricular conduction pathways and with the Wolff-Parkinson-White syndrome. Patients may also have an ASD with right-to-left shunting and cyanosis. Supraventricular arrhythmias are also common.

The most favored treatment is reconstruction of the tricuspid valve, for which satisfactory techniques have now been developed. The operation should be performed before pregnancy is begun. Interruption of anomalous conduction pathways also can be performed during surgery.

The Mayo Clinic group⁵⁷ reported on 111 pregnancies in 44 women with Ebstein anomaly resulting in 95 live births, although most of the infants had low birth weight. Vaginal delivery was performed in 89% and cesarean section in 9%; 23 deliveries were premature. Nineteen pregnancies ended with

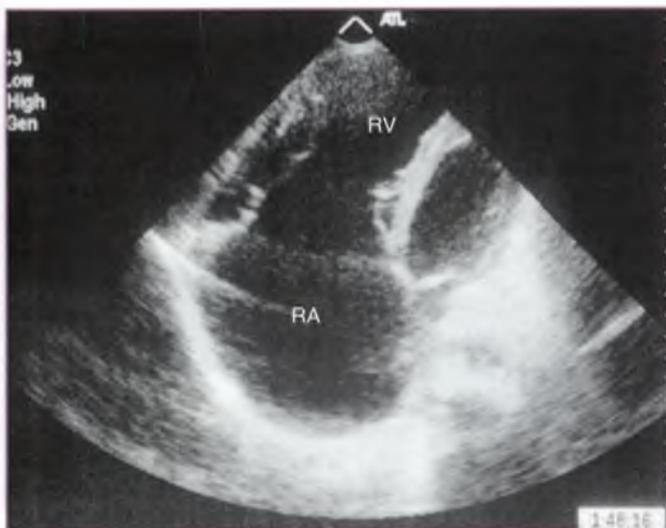

Figure 52-12 Ebstein anomaly. The right atrium (RA) and right ventricle (RV) are markedly dilated, and the tricuspid valve is displaced toward the cardiac apex.

spontaneous abortion, and seven ended with therapeutic abortion. Congenital heart disease occurred in 6% of the children of mothers with Ebstein anomaly.

CONGENITAL ATRIOVENTRICULAR BLOCK

Congenital atrioventricular block differs somewhat from heart block in adults. The pacemaker is usually junctional, and therefore the QRS complex is normal or only slightly widened and the ventricular rate is more rapid than in acquired complete atrioventricular block. Although these patients appear to do well during childhood and young adulthood, the lesion is associated with an unexpectedly high mortality rate. Therefore, treatment with a pacemaker is indicated in many cases.⁵⁸ The pacemaker used should be a dual-chamber and rate-responsive one, so that normal cardiovascular dynamics at rest and exercise are preserved. Patients who are untreated or who have received a pacemaker are at slight to no increased risk during pregnancy.

ADDITIONAL MALFORMATIONS

A number of other malformations may be present in women of childbearing age, including the following:

- Other left-to-right or right-to-left shunts
- Transposition of the great vessels
- Truncus arteriosus
- Single-ventricle double-outlet right ventricle
- Various obstructive lesions

The malformations may be multiple and complex. Survival to adulthood depends on at least partial correction, which may have been furnished by surgical operation or may be part of the malformation. For example, in D-type transposition of the great vessels, the aorta arises from the right ventricle, and the pulmonary artery from the left. Survival requires a shunt at some level (ASD, VSD, or PDA) so that oxygenated blood can enter the systemic circulation.

Some of these women with untreated and delicately balanced lesions bear children, but usually this is not wise to attempt. Transposition of the great vessels is now treated by anastomosis of the aorta to the morphologic left ventricle, and of the pulmonary artery to the morphologic right ventricle. Lesions such as single ventricle may be palliated by the Fontan procedure, in which venous return is connected directly to the pulmonary circulation, bypassing the right side of the heart. Neither procedure constitutes a cure, but successful pregnancy can occur.

In summary, patients should be evaluated and tracked by a cardiologist who is experienced in congenital heart disease, and by a maternal-fetal medicine specialist with knowledge and experience in managing pregnancy in women with congenital cardiac lesions.^{7,31}

Rheumatic Heart Disease

RHEUMATIC FEVER

Rheumatic fever is now distinctly uncommon in the United States, Canada, Western Europe, and Great Britain, but it is still prevalent in less economically developed countries. Young female immigrants to the Western world constitute a large proportion of the patients with a history of rheumatic fever. These

women are at risk of developing rheumatic valvular heart disease 10 to 20 years after the initial episode of rheumatic fever.

CHRONIC RHEUMATIC HEART DISEASE

In the United States, acute rheumatic fever with carditis has been uncommon for many years, and chronic rheumatic heart disease, which manifests years to decades after the episode of acute rheumatic fever, is becoming uncommon among the native childbearing population. Control of rheumatic fever has largely shifted the burden of rheumatic heart disease from teenagers to women in the third and fourth decades of life.

The characteristic lesion of rheumatic heart disease is mitral stenosis, and the next most common manifestation is the combination of mitral stenosis with aortic regurgitation. The mitral valve may become both stenotic and incompetent, and the valve may calcify. Pure mitral regurgitation is almost always nonrheumatic, except in young people with acute carditis. Similarly, aortic valve disease without mitral involvement is seldom rheumatic. Tricuspid regurgitation is a late secondary manifestation that occurs secondary to pulmonary hypertension and right ventricular enlargement.

MITRAL STENOSIS

The principal features are enlargement of the left atrium and right ventricle, a diastolic murmur at the cardiac apex, and pulmonary hypertension. Inflow to the left ventricle is impeded by the narrowed valve and can be accomplished only by an increased level of pressure in the left atrium (Figs. 52-13 and 52-14; Video 52-6). The faster the heart rate, the less time in diastole, and the less time for ventricular filling. Left atrial pressure therefore is further elevated by tachycardia. Atrial fibrillation eventually supervenes, causing a fall in cardiac output and escalation of left atrial hypertension, especially if the ventricular rate is not controlled. Atrial fibrillation substantially increases the probability of thrombus in the left atrial appendage and the threat of a subsequent embolic stroke.

Effect of Pregnancy

Pregnancy drastically stresses the circulation in women with severe mitral stenosis. The increased blood volume, heart rate, and cardiac output raise left atrial pressure to a level that causes severe pulmonary congestion, leading to progressive exertional dyspnea, orthopnea, paroxysmal nocturnal dyspnea, and pulmonary edema. Women who have not been receiving antenatal care often present initially with severe pulmonary edema during pregnancy. In long-standing cases, severe right-sided heart failure develops. Infective endocarditis, pulmonary embolism, and massive hemoptysis may also occur. The maternal risk for death is highest in the third trimester and in the puerperium.^{10,11}

Significant Mitral Stenosis without Heart Failure

Patients who have mitral stenosis without heart failure should be advised to undergo percutaneous balloon mitral valvuloplasty and to postpone pregnancy until after full recovery from the procedure. If they do not follow this advice and do become pregnant, one reasonable course in the first trimester may be pregnancy termination, followed by mitral valve operation and subsequent pregnancy planning. If this is not acceptable, the patient can be advised to remain under frequent close

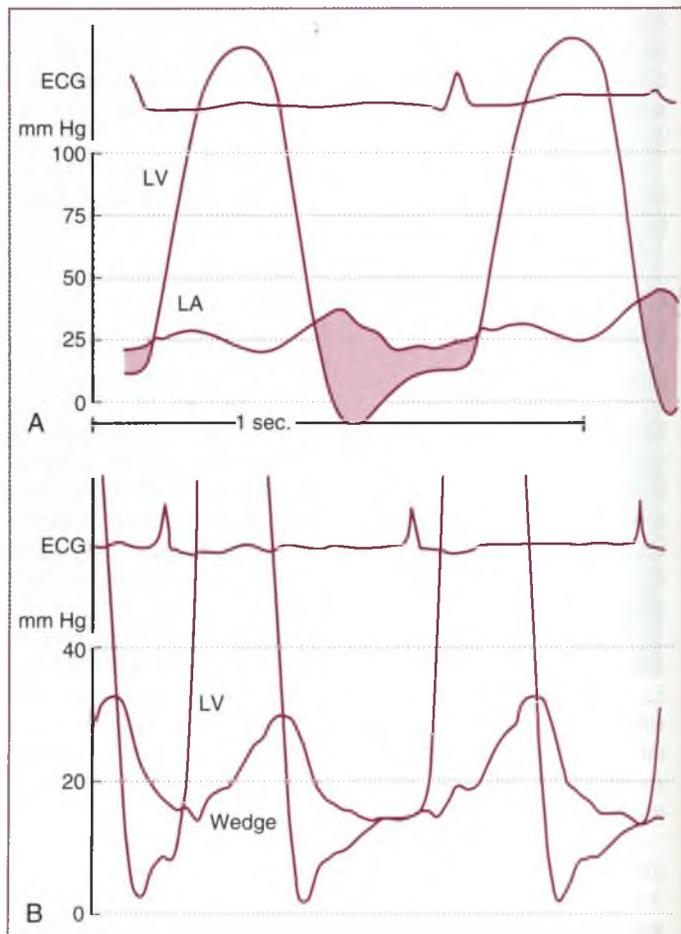

Figure 52-13 Hemodynamics of mitral valve disease. A, Mitral stenosis. The diastolic pressure gradient (shaded area) between the left atrium (LA) and left ventricle (LV) persists to end-diastole. B, Mitral regurgitation. Note the large systolic pressure wave of the pulmonary wedge pressure tracing. The diastolic pressure gradient is limited to early diastole. ECG, electrocardiogram.

Figure 52-14 Transesophageal echocardiographic image of mitral stenosis. During diastole, opening of the mitral valve is restricted by scarring and fusion of the leaflet tips. Characteristic doming of the leaflet is also present. AO, aorta; LA, left atrium; LV, left ventricle.

supervision by the cardiologist and obstetrician and to accept long periods of rest, prohibition of strenuous activity, salt restriction, and diuretic treatment. If this type of regimen is followed closely and is expertly supervised, maternal mortality is low.^{10,11} Atrial fibrillation signals the need for digitalis, a β -adrenergic blocking agent, or a calcium channel blocking agent to maintain a normal heart rate. More than one of these drugs may be needed to achieve the desired result without side effects. For patients with atrial fibrillation and significant mitral stenosis, anticoagulant treatment is recommended.

Depending on her course, the woman may have to spend many weeks in bed and should be admitted to the hospital well in advance of labor. The supine posture should be avoided as much as possible, and delivery in the left lateral decubitus position is desirable. The lithotomy position, with the patient on her back and her feet elevated in stirrups, is an invitation to pulmonary edema. The crisis of pulmonary edema may appear despite good management. Sedation (to drop the heart rate and promote cardiac filling and output) and diuretic treatment must then be followed by prompt delivery if the fetus is viable.

Percutaneous balloon valvuloplasty is a nonsurgical means to dilate mitral stenosis and is the current treatment of choice for most patients with symptomatic mitral stenosis.^{59,60} The procedure can be done during pregnancy if heart failure is severe, and it appears to be safer for the fetus than open mitral commissurotomy.⁶¹ Lead shielding should be used, because fluoroscopy is required to guide the balloon into the mitral orifice. Balloon valvuloplasty should be used with caution during pregnancy, and it should be reserved for women who are unresponsive to aggressive medical therapy.^{10,11} If possible, the procedure should be put off at least until after the first trimester. Patients with confirmed mitral stenosis and right-sided heart failure with severe pulmonary congestion should avoid pregnancy until after the valvular disease is corrected, because the risk of maternal mortality is high.

Mitral Valve Prolapse

In the past, a degree of prolapse of the mitral valve was considered so prevalent in the general population,⁶² particularly among young women, that authorities differed as to whether mitral valve prolapse (MVP) should be considered a normal variant or abnormal. More exacting echocardiographic criteria have yielded more realistic and much lower estimates of the prevalence of MVP (perhaps 1% of the female population).⁶³

True MVP occurs because portions of the mitral valve apparatus are redundant and, therefore, the leaflets balloon into the left atrium during systole. The leaflets may remain coapted during systole, or they may separate, causing a variable degree of mitral regurgitation. More severe prolapse may be caused by myxomatous degeneration of the mitral leaflets. These abnormalities of connective tissue may be isolated to the mitral valve, or they may be a part of Marfan syndrome (see later). MVP (and sometimes tricuspid valve prolapse) may be associated with congenital malformations, notably ASD.

Mitral regurgitation may be absent, intermittent, or permanent and may be of any degree of severity. Severe mitral regurgitation greatly enlarges the left atrium (Fig. 52-15; Video 52-7A,B) and ventricle and eventually leads to left ventricular failure and pulmonary hypertension, the latter less severe than with mitral stenosis.

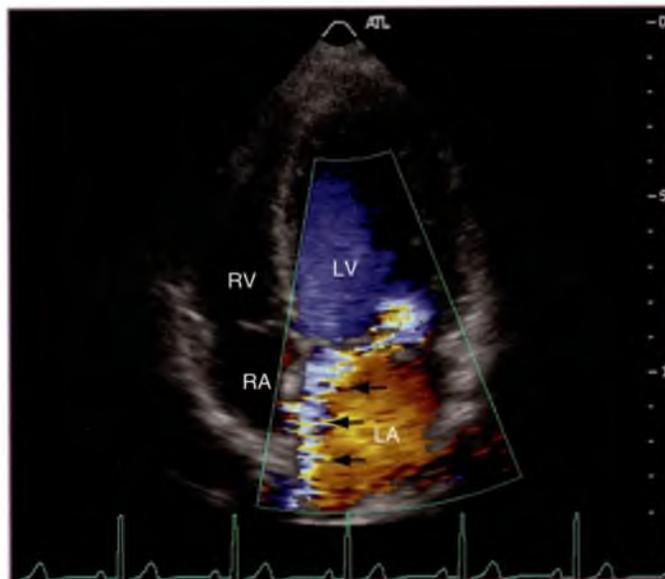

Figure 52-15 Transthoracic echocardiographic image of severe mitral regurgitation. During systole, the mitral valve does not coapt properly, and an eccentric jet of mitral regurgitation is present (arrows). LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Past reports have associated MVP with a number of disorders, including stroke, dysautonomia, panic attacks, anxiety, and transient ischemic attacks,^{64,65} but more recent studies^{66,67} have discounted almost all of these associations. The syndrome of myxomatous mitral valve degeneration with prolapse and mitral regurgitation is quite uncommon, and many women who were diagnosed with MVP more than 10 years ago do not have any actual pathology. Current guidelines do not recommend antibiotic prophylaxis for patients with uncomplicated mitral valve prolapse.

Some women with MVP complain of chest pain, which can be suggestive of angina pectoris. Although the coronary arteriogram is normal, T-wave inversions, especially in leads II, III, and aVF, are found in a small proportion, and the treadmill exercise test may induce ST-segment depression, indistinguishable from ischemia.⁶⁸

In most cases, the diagnosis of MVP is made by the physician providing pre-conception counseling and antenatal care. The examination reveals a systolic click occurring between the first and second heart sounds. The click may or may not be followed by a midsystolic or late systolic murmur. The click and murmur vary with the patient's posture and hydration status. In most patients, no other abnormality is found on clinical examination. Unless significant mitral regurgitation is present, the patient should be told that pregnancy, labor, and delivery will be safe and unaffected by the prolapse.

Patients with MVP and significant mitral regurgitation are far fewer in number than those with simple prolapse. The murmur is louder and longer, and it may become pansystolic. Clinical and laboratory evidence of enlargement of the left atrium and ventricle increases with increasing severity and duration of regurgitation. Even modest impairment of left ventricular function, especially if it is progressive, indicates that pregnancy may well precipitate heart failure and cannot be

lightly undertaken. More obvious left ventricular dysfunction (e.g., EF <40%) indicates that the woman should be strongly advised to avoid pregnancy. She should then be referred for complete cardiologic evaluation² and surgery to address the mitral regurgitation. In most cases of MVP, the valve can be repaired rather than replaced. It is important to appreciate that left ventricular function deteriorates after mitral valve replacement but may improve after mitral valve repair.⁶⁹ Thereafter, if the result is good and ventricular function is significantly improved, pregnancy may be begun successfully.

Chest pain and arrhythmias are best managed with β -adrenergic blockers such as atenolol or metoprolol. If symptoms are unusually pronounced, thyroid function tests should be checked as well. Because the gravid uterus and vasodilation may add to postural hypotension, the patient should be informed that she may experience lightheadedness, dizziness, or fainting, with prolonged standing during pregnancy.

MITRAL REGURGITATION NOT CAUSED BY PROLAPSE

In younger women, mitral regurgitation may be a result of rheumatic or congenital disease. In older women, mitral regurgitation is more often a manifestation of hypertension, ischemia, idiopathic myocardial disease, or infective endocarditis.

Most of the information regarding mitral regurgitation in prolapse also applies here. In older women, the valve is more likely to be calcified; fewer of the valves are amenable to repair and must be replaced. The problems posed by prosthetic valves in pregnant women are discussed later in this chapter; the hemodynamics are illustrated in Figure 52-13, and echocardiography is illustrated in Figure 52-15.

In patients with far-advanced left ventricular dysfunction or failure who have severe mitral regurgitation, it can be difficult to determine which is the cause and which the result. In either case, the patient with a greatly enlarged and hypokinetic ventricle must be advised against becoming pregnant. Most of the pregnancy would be spent in bed, the course would be punctuated by episodes of uncompensated congestive heart failure (any of which could prove fatal or require therapeutic abortion), and the risk to the fetus would exceed 50%.

Pregnancy in patients with mild or moderate mitral regurgitation can be managed safely with a conservative regimen of reduced physical activity, salt restriction, and low dosages of a diuretic agent. Low-dosage digoxin may be helpful if atrial fibrillation supervenes. As mentioned previously, severe mitral regurgitation indicates a need for repair or replacement of the valve when symptoms or early signs of declining ventricular function appear.^{2,70} Clearly, surgical treatment is best undertaken before pregnancy. If the woman is already pregnant, the physician should make every effort to help her to carry the pregnancy to term using strict medical measures. This course is particularly important if clinical, radiologic, and echocardiographic criteria suggest that the valve is irreparable and will require replacement in the future.

Aortic Valve Disease

AORTIC STENOSIS

(See also Aortic Stenosis under Congenital Obstructive Lesions, earlier.)

The etiologic mechanism of aortic stenosis is commonly degeneration, often of a congenitally bicuspid valve. The problem may be encountered in women a decade or more older than those with rheumatic or congenital aortic valve disease. The combination of aortic and mitral stenosis is usually caused by rheumatic heart disease. Critical aortic stenosis leads to severe left ventricular hypertrophy and, eventually, to left ventricular failure. Before overt heart failure develops, syncope or even sudden death may occur.

The characteristic findings include an ejection systolic murmur that is harsher and longer and peaks later than the normal ejection murmur of pregnancy. It is usually loudest at the second right intercostal space. If aortic stenosis is severe, the pulse upstroke is slow, and left ventricular hypertrophy is evident on the ECG. The echocardiogram is a more sensitive and more specific marker of left ventricular hypertrophy. Doppler echocardiographic measurement of blood flow velocity through the aortic valve permits reliable estimation of the systolic pressure drop across the valve, as well as calculation of the valve area. The hemodynamics are illustrated in Figure 52-16. The remodeling of the left ventricle in women is different from that in men. The concentric hypertrophy is more pronounced, the cavity is smaller, and systolic function is supranormal.

The left ventricle does not dilate until the ventricle fails, so a dilated ventricle in aortic stenosis is an ominous sign that calls for rapid intervention. In general, aortic valve replacement is preferred to percutaneous balloon aortic valvuloplasty, but open heart surgery presents a high risk to the fetus. For this

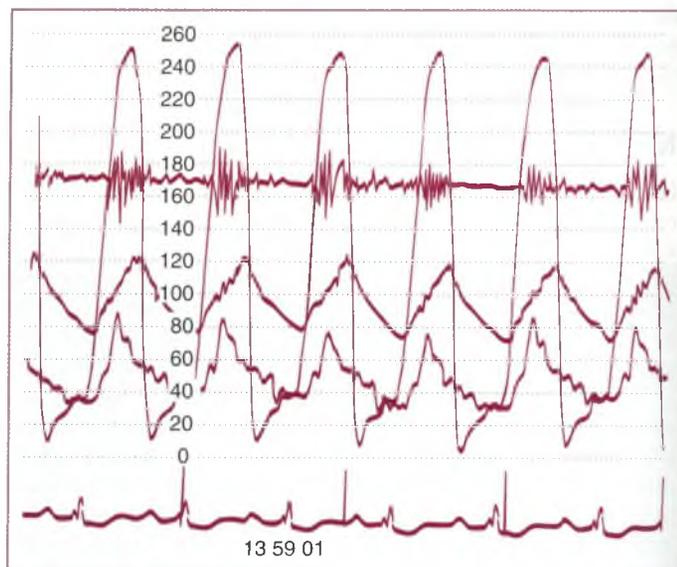

Figure 52-16 Hemodynamic data in aortic stenosis. Left ventricular pressure is 250/40 mm Hg (normal, 120/10 mm Hg). Aortic systolic pressure is 130 mm Hg lower than the left ventricular pressure and shows a slow upstroke and vibrations representing the systolic thrill. The record above the aortic pressure tracing is a phonocardiogram showing the systolic murmur. Also shown is the pulmonary wedge pressure (lowest pressure tracing), which is elevated to equal the left ventricular diastolic pressure. The bottom tracing is the electrocardiogram. (From Shabetai R, Adolph RJ: *Principles of cardiac catheterization*. In Fowler NO, editor: *Cardiac diagnosis and treatment*, Hagerstown, MD, 1980, Harper & Row.)

reason, some have advised balloon aortic valvuloplasty for treatment of aortic stenosis during pregnancy,⁷¹ but valve replacement will almost certainly have to be done soon after delivery.

Hemodynamic monitoring is recommended during labor in patients with moderate to severe aortic stenosis. Vaginal delivery is preferred, with assisted second stage of labor. If cesarean section is performed, some have suggested that general anesthesia is preferred.⁷² See Chapter 70 for more details regarding anesthesia management.

Pregnancy in women with a mechanical aortic valve replacement must be undertaken with great caution and meticulous management, because continuous anticoagulation is necessary (see Pregnancy in Patients with Artificial Heart Valves, later).

AORTIC REGURGITATION

The etiologic mechanism of aortic regurgitation is commonly rheumatic heart disease, in which case mitral stenosis often coexists. Other diseases, such as Marfan syndrome, bicuspid aortic valve, infective endocarditis, and systemic lupus erythematosus, also may cause severe aortic regurgitation. This valvular lesion imposes a volume rather than a pressure overload on the heart and, as such, is usually well tolerated in pregnancy and labor.¹⁵

The diagnosis is usually based on the finding of a typical, high-pitched, blowing diastolic murmur and can be quantified by Doppler echocardiography. Both pregnancy and aortic regurgitation contribute to hypervolemia and peripheral vasodilation. A prolonged course without decompensation is characteristic of chronic aortic regurgitation; once heart failure appears, however, the course may progress rapidly downhill.

Traditionally, aortic valve replacement is not recommended until symptoms of heart failure (most notably exertional dyspnea) occur or left ventricular dysfunction or enlargement is seen on echocardiography. Repair of aortic regurgitation is much less successful than repair of mitral regurgitation. For a woman who is contemplating pregnancy, the need for aortic valve replacement constitutes the grounds on which the medical advisor should caution against pregnancy and make the patient fully understand the consequences of choosing otherwise. If left ventricular dysfunction and heart failure are absent, carefully supervised pregnancy is in order, and the woman should be encouraged to complete her family before cardiac dysfunction and the need for valve replacement arise.

In many cases, the cause of aortic regurgitation is unclear. Special care must be taken to rule out aortic aneurysm or dissection, especially if aortic regurgitation is associated with Marfan syndrome or coarctation of the aorta, because these conditions can result in aortic rupture and constitute strong reasons to advise against pregnancy.

Drug-Induced Valvular Heart Disease

A recently recognized cause of deformity and regurgitation of the cardiac valves is ingestion of the drug combination fenfluramine-phentermine. The revelation of this side effect led to withdrawal of this drug combination from the market in the late 1990s. The mechanism of the effect of these drugs is unclear, and there is evidence that valvular lesions may sometimes gradually improve after discontinuation of the drugs.⁷³ In some cases, however, valve surgery has been necessary.⁷⁴

Cardiomyopathy

Cardiomyopathy is a disorder of myocardial structure or function. A number of forms exist, and several types that are seen in pregnant women are discussed here.⁷⁵

DILATED CARDIOMYOPATHY

In dilated cardiomyopathy, the cardiac chambers are severely dilated and the left ventricle is diffusely hypokinetic. Left ventricular wall tension is increased, and systolic pump function progressively declines. Consequently, cardiac output falls and filling pressures increase; both of these changes cause progressive dyspnea, edema, and fatigue. Serious ventricular arrhythmia develops in most cases.

Despite advances in treatment, the 5-year survival rate in patients with dilated cardiomyopathy and symptomatic heart failure approaches 50%. In some cases, however, improvement or even return to normal has been noted. Both ACE inhibitors and β -adrenergic blocking agents (most notably carvedilol) have been shown to slow the deterioration of left ventricular function in patients with congestive heart failure, and occasionally to actually improve the left ventricular EF.⁷⁶ In addition, some of the patients who recover may have had unrecognized myocarditis that did not progress to cardiomyopathy. Dilated cardiomyopathy may be the outcome of an autoimmune response to a myocardial injury, most commonly viral myocarditis. The exact role of alcohol is unclear, but it is at least a major aggravating factor in some cases.

Patients may have symptoms and signs of heart failure for which no cause can be found on clinical and laboratory examination. Weight is increased, the jugular venous pressure is elevated, and the heart is enlarged. An S_3 gallop is often present, frequently accompanied by the murmurs of mitral and tricuspid regurgitation, which develop as a consequence of cardiac dilation. The ECG is usually abnormal, often showing left ventricular hypertrophy or left bundle branch block. Echocardiography shows enlargement and hypocontractility of the ventricles. The patients are subject to mural thrombus in the cardiac chambers, with a consequent risk of stroke or pulmonary embolism. Established dilated cardiomyopathy, even when heart failure is compensated, is a contraindication to pregnancy. A recent study found that women with dilated cardiomyopathy who became pregnant had an adverse event (heart failure hospitalization, arrhythmia, stroke, myocardial infarction, and cardiac death) rate of 40% during pregnancy, and 70% at 18 months of follow-up.⁷⁷ There is also evidence that serum levels of B-type natriuretic peptide may help identify pregnant women with cardiomyopathy who are at high risk of cardiac events.⁷⁸

It was formerly thought that dilated cardiomyopathy was sporadic and not familial, but inherited cases have now been observed. It is estimated that 20% of cases are genetic in origin.¹³ Therefore, if an extensive family history of heart failure is present, the prospective mother and father should be informed of the potential risk of genetic transmission.

In a young woman with severe dilated cardiomyopathy, manifested by greatly impaired ventricular function and drastically reduced exercise capacity, cardiac transplantation should be considered. Successful pregnancy has been reported in women who have undergone heart or heart-lung transplantation.⁷⁹⁻⁸¹

PERIPARTUM CARDIOMYOPATHY

Peripartum cardiomyopathy (PPCM) is a form of dilated cardiomyopathy that occurs in the last month of pregnancy or during the first 5 months after delivery, in the absence of previous heart disease.⁸² The incidence in the United States is 1 case per 3000 to 4000 live births. Additional diagnostic criteria include a left ventricular EF of less than 45% and, most importantly, the absence of other identifiable causes of heart failure.⁸³ Whether the peripartum or postpartum state somehow constitutes the original myocardial insult or is an aggravating factor in individuals susceptible to cardiomyopathy for other reasons is not known.⁸⁴ It has been suggested that some cases are caused by active myocarditis,⁸⁵ but other investigators have reported that the incidence of myocarditis is the same in idiopathic cardiomyopathy and PPCM.⁸⁶ It is also possible that the stress of pregnancy may unmask an underlying cardiomyopathic process that might otherwise have manifested later in life.⁸⁷ This devastating disease can affect previously healthy young women and can cause unexpected sudden death (see Video 52-8 of a patient with a left ventricular EF of 20%).⁸⁸ Conditions associated with PPCM include older maternal age, hypertension, African-American race, and multiple-fetus pregnancies.⁸⁹ There is also growing evidence that subsets of PPCM may be genetic and may be initial manifestations of familial dilated cardiomyopathy.^{90,91}

The clinical course of PPCM is frustratingly variable and difficult to predict.⁹² About 20% of patients have a dramatic and fulminant downhill course and can be saved only with cardiac transplantation. Others, perhaps 30% to 50%, have partial recovery with persistence of some degree of cardiac dysfunction. The rest show remarkable recovery.⁸⁴ Apparently, the initial degree of left ventricular dysfunction does not predict the long-term outcome.⁹³ One study showed that cardiac function improved gradually over a 5-year period.⁹⁴ However, a recent review of cases in the United States found that women who do not show significant improvement in EF within 2 to 3 months of diagnosis usually do not recover cardiac function in the long term.⁸⁹

Women who recover from PPCM must be informed that cardiomyopathy may recur with a subsequent pregnancy. For some time, this risk has been believed to be 50%.⁹³ However, one report of four women who had PPCM with a previous pregnancy but whose hearts remained normal clinically and by echocardiography in a subsequent pregnancy indicated that the risk may be less.⁹⁵ The largest study to date of patients with a history of PPCM who subsequently became pregnant⁹⁶ showed that heart failure recurred in 20% of those patients whose EF had normalized after the previous pregnancy. None of these patients died during the study period. However, heart failure recurred in 40% of the patients who had persistent left ventricular dysfunction after their previous pregnancy, and the maternal mortality in this group was 19%. A study from Haiti of 15 women with PPCM showed a recurrence rate of almost 50% during a subsequent pregnancy.⁹⁷ Therefore, the risk of recurrent heart failure is high in women with PPCM, especially in those who do not have complete recovery of left ventricular function.

Treatment is similar to that for other patients with heart failure. Because ACE inhibitors are contraindicated during pregnancy, hydralazine is the vasodilator of choice. Recent small studies have shown improvements in EF and clinical outcomes

in patients with PPCM treated with the dopamine agonist bromocriptine.^{98,99} If cardiac dysfunction is severe, anticoagulation is usually recommended, given the prothrombotic tendency of pregnancy. Low-molecular-weight heparin (LMWH) is probably preferred to unfractionated heparin (warfarin is not recommended).⁹²

IDIOPATHIC HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy, which is usually inherited as an autosomal dominant trait with variable penetrance but sometimes is caused by a spontaneous mutation, is being recognized with increasing frequency. The phenotypes vary greatly. Left ventricular outflow tract obstruction may or may not be present, and the hypertrophy may be either symmetrical or asymmetrical. The chief symptoms are angina, dyspnea, arrhythmia, and syncope. Sudden death is a feature mostly confined to patients in whom the diagnosis is established in childhood or youth, patients with a history of syncope or ventricular arrhythmia, and patients with a family history of hypertrophic cardiomyopathy and sudden death. Recent research has shown that certain specific genetic defects place patients at great risk for sudden death.

When the disease is first detected in older adults, the course is more benign and sudden death is rare. Left ventricular hypertrophy is often apparent on clinical examination, and ECG and is invariably present on the echocardiogram. The echocardiographic findings are often diagnostic and include marked thickening of the ventricular septum, usually with less thickness of the other walls of the left ventricle (asymmetrical hypertrophy), and abnormal systolic anterior movement of the mitral valve (Fig. 52-17; Video 52-9A,B). The internal dimensions of the left ventricle are normal to small, and its contractility is increased.

An important feature in many cases is obstruction of the space between the ventricular septum and the anterior leaflet of the mitral valve. This space constitutes the left ventricular outflow tract. Outflow obstruction by the anterior mitral valve leaflet is worsened by increased inotropy, decreased heart size, and diminished peripheral vascular resistance. The normal fall in peripheral vascular resistance that accompanies pregnancy tends to increase outflow tract obstruction, although this effect may be compensated for by the physiologic increase in blood volume. In addition, vena caval obstruction in late pregnancy and blood loss at delivery, both of which may result in hypotension, can have a similar deleterious effect. Outflow tract obstruction may also be worsened by the increases in circulating catecholamine levels frequently encountered during labor and delivery. The Valsalva maneuver during the second stage of labor may greatly diminish heart size and increase outflow tract obstruction. Despite all these problems, however, most pregnant women with hypertrophic cardiomyopathy do tolerate labor and delivery.¹⁰⁰

There is a complex interplay between the hemodynamics of the cardiomyopathy and those of pregnancy, neither of which is constant. Exacerbation of symptoms¹⁰¹ and even sudden death¹⁰² have been reported during pregnancy in women with obstructive cardiomyopathy. Treatment is aimed at avoiding hypovolemia, maintaining venous return, and diminishing the force of myocardial contraction by avoiding anxiety, excitement, and strenuous activity.

Because left ventricular diastolic compliance can be greatly reduced in this disease, excessive or too rapid volume repletion

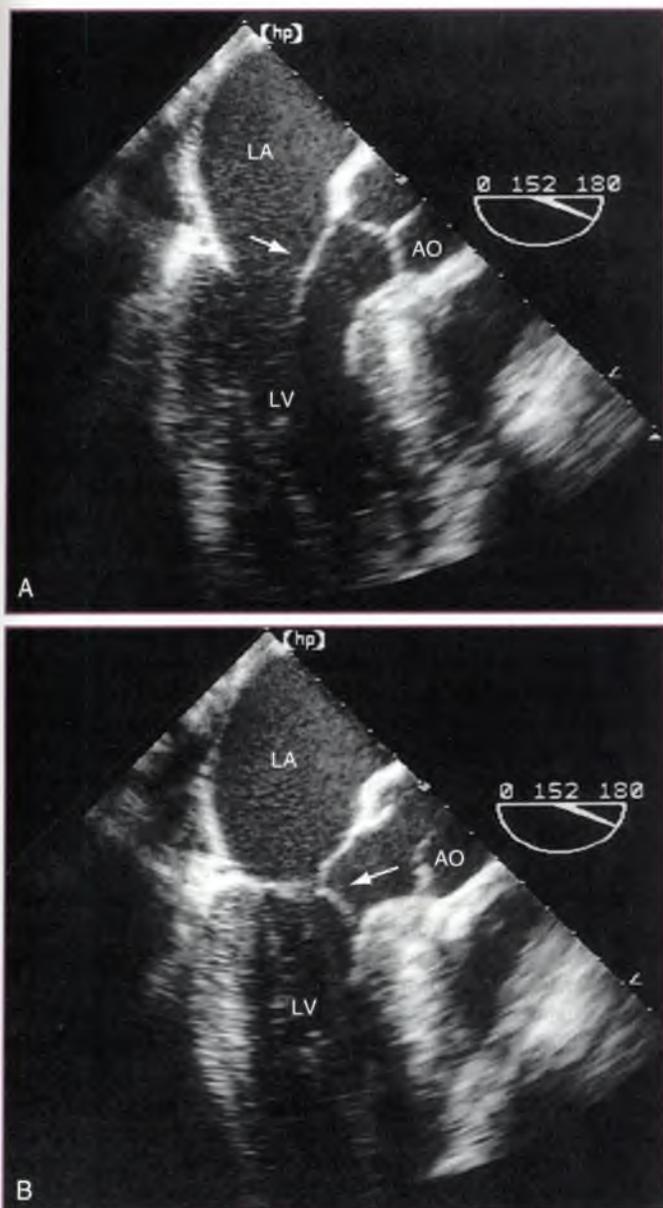

Figure 52-17 Transesophageal echocardiographic images of hypertrophic cardiomyopathy. **A**, During diastole the anterior leaflet of the mitral valve (arrow) is in a normal position. **B**, During systole the leaflet (arrow) is pulled by Venturi forces into the left ventricular outflow tract, causing obstruction to outflow. AO, aorta; LA, left atrium; LV, left ventricle.

can induce pulmonary edema. β -Adrenergic blockade is considered first-line pharmacologic therapy for symptomatic hypertrophic cardiomyopathy and can be continued or instituted during pregnancy. The dosage should be the minimal effective dosage needed to avoid excessive slowing of the fetal heart.

Esmolol can be given intravenously if the patient first presents with severe symptoms. Volume replacement and vasopressor therapy may be needed, along with β -adrenergic blockers. Calcium channel blockers, such as verapamil, have been shown to be effective in reducing symptoms, but they must be used cautiously because they can cause pulmonary edema in severe

cases. Nifedipine, because of its vasodilator properties, is best avoided.

Vaginal delivery is almost always appropriate in the absence of an obstetric indication for abdominal delivery. Impaired venous return is highly undesirable in hypertrophic cardiomyopathy and can be ameliorated by managing the second stage of labor with the patient in the left lateral decubitus position.

ACQUIRED IMMUNODEFICIENCY SYNDROME

Myocarditis or cardiomyopathy is frequently discovered on postmortem examination of patients with acquired immunodeficiency syndrome (AIDS).^{103,104} Symptomatic myocardial disease, although considerably less common, also occurs. If patients with full-blown AIDS are screened for cardiac involvement (e.g., by echocardiography), cardiac or pericardial involvement is found in almost 75% of the cases.¹⁰⁵ In some cases, these abnormalities are transient.¹⁰⁶ Myocarditis is usually caused by opportunistic infection, but in some cases hybridization studies have proved direct AIDS infection. Clinical findings range from occult ventricular dysfunction to severe uncompensated heart failure. Rarely, even Kaposi sarcoma has been detected in the heart or pericardium. Pericardial effusion, often occult, is one of the more common cardiac manifestations and suggests a worse prognosis.¹⁰⁷ Malignant lymphoma involving the myocardium and endocardium has been reported as well. In the current era of highly active antiretroviral therapy (HAART), myocardial involvement has become considerably less common in patients with human immunodeficiency virus (HIV) infection. However, some classes of antiretroviral drugs appear to cause dyslipidemia, and this can lead to an increased risk of coronary artery disease (CAD) and subsequent myocardial infarction.¹⁰⁸

Cardiac failure ranks low on the list of problems faced by the physician managing pregnancy complicated by AIDS. Nevertheless, physicians need to be on guard lest severe dilated cardiomyopathy, myocarditis, or cardiac tamponade develop, and the pregnant woman must be treated appropriately to prevent transmission of HIV to her offspring (see Chapter 51).

Coronary Artery Disease

Because premenopausal women enjoy substantial protection against coronary atherosclerosis,¹⁵ ischemic heart disease is rarely relevant to obstetric practice. However, CAD may be found in women of childbearing age when other risk factors, such as insulin-dependent diabetes, smoking, or severe dyslipidemia, overwhelm the natural protection they should normally enjoy. Lupus erythematosus, especially when treated with steroidal agents, may precipitate premature CAD. Coronary atherosclerosis appears in a significant proportion of patients who have received a cardiac transplant¹⁰⁹ and may be observed in familial lipid disorders. In the latter instance, the exact nature of the lipid disorder must be defined by detailed analysis of the patient's lipid chemistry and lipoproteins to enable the physician to provide an accurate forecast of the risk that the infant would inherit the lipid disorder and premature CAD. In women with CAD or severe dyslipidemia, oral contraceptives may be detrimental.¹¹⁰ In addition, spasm of anatomically normal coronary arteries leading to myocardial infarction has been reported.¹¹¹ Finally, as mentioned earlier, women with HIV

infection may develop dyslipidemia if they are on HAART, which can increase the risk of CAD.¹⁰⁸

CORONARY ARTERY DISSECTION

Spontaneous coronary artery dissection is quite rare and occurs chiefly in young women soon after pregnancy.^{112,113} Treatment has included placement of a stent, emergency coronary bypass surgery, and thrombolysis.¹¹⁴⁻¹¹⁷ Although coronary artery dissection is very uncommon, it is extremely important to consider this diagnosis whenever a woman presents with severe chest pain in the peripartum period. If the coronary artery dissection remains undetected, massive myocardial infarction and even death can occur.¹¹⁸ If the diagnosis is made expediently, however, outcome appears to be quite good, and long-term survival is expected.¹¹⁹

MANAGEMENT OF STABLE ANGINA PECTORIS

Women with CAD who experience angina pectoris only at high levels of exertion should be treated with β -adrenergic blocking drugs, aspirin, and lipid-lowering agents. In this setting, the likelihood of significant complications during pregnancy, labor, or delivery is low. If there is any question regarding the severity of myocardial ischemia, however, stress testing should be performed before pregnancy is attempted. Similarly, a woman who previously sustained a myocardial infarction but recovered without heart failure, significant left ventricular dysfunction, or unstable angina pectoris can also be advised that her pregnancy and labor should be relatively uncomplicated.

The major indications that pregnancy and labor would pose a significant risk to a woman with ischemic heart disease are the presence of overt heart failure, significant enlargement or dysfunction of the left ventricle, and ischemia at rest or provoked by mild exertion.

SEVERE MYOCARDIAL ISCHEMIC SYNDROMES: UNSTABLE ANGINA

The diagnosis of severe ischemia may be confirmed if angina occurs at rest or with mild exertion. This unstable angina frequently, but not necessarily, follows a period of classic stable angina pectoris. Unstable angina is a clear warning of the imminence of a major ischemic event, such as acute myocardial infarction or a fatal ventricular arrhythmia. Starting a pregnancy under these circumstances is not advisable, and aggressive treatment (including coronary angiography followed by percutaneous coronary intervention or coronary artery bypass surgery) is recommended. If the outcome is satisfactory, pregnancy can then be considered.

In some women with CAD, the clinical picture is less dramatic but a treadmill exercise test demonstrates that profound and dangerous ischemia can be precipitated by minimal exertion. If the treadmill test provokes an abnormal response at a low level of exercise, and particularly if this response is accompanied by either angina pectoris or a fall in blood pressure, the woman is at high risk for a serious and possibly fatal myocardial ischemic event and must not undertake pregnancy unless the myocardium can be revascularized.

Pregnant women who develop unstable ischemia require aggressive treatment in an intensive care unit. If the ischemia proves intractable, percutaneous coronary intervention (e.g.,

stenting) or bypass graft surgery will be necessary.¹²⁰ If possible, the coronary bypass operation should be performed without cardiopulmonary bypass to help decrease the risk to the fetus.¹²¹

MYOCARDIAL INFARCTION

Acute ST-elevation myocardial infarction complicates about 1 in 10,000 pregnancies.¹²² The highest incidence appears to occur in the third trimester and in older (>33 years) multigravidas. The maternal mortality rate is high (about 20%), and death usually occurs at the time of infarction or during labor and delivery.¹²³ Coronary angiography in this population demonstrated atherosclerosis in about 40% of cases, coronary thrombosis without atherosclerosis in 20%, and coronary dissection in 16%, but 30% had normal coronary arteries.¹²³ Treatment of acute myocardial infarction during pregnancy should include use of heparin and β -blockers (unless acute heart failure is present). The use of thrombolytics in pregnancy is controversial, because there is increased risk of maternal hemorrhage. Therefore, percutaneous coronary intervention (with stenting) is probably the procedure of choice. Clearly, this exposes the fetus to radiation, so extensive lead shielding should be used.

A remote myocardial infarction, followed by recovery without angina, major left ventricular dysfunction, or heart failure, should have little influence on pregnancy or labor. Patients should wait a year after an infarction before beginning a pregnancy. In many cases, coronary arteriography should be done first so that, if critical coronary stenoses are found, myocardial revascularization can be performed. Severe left ventricular damage and heart failure are contraindications to pregnancy.

For remote myocardial infarction without evidence of ischemia, heart failure, or severe left ventricular dysfunction, simple electrocardiographic monitoring suffices during labor. If a large myocardial infarction has occurred during pregnancy, then arterial blood pressure, central venous pressure, pulmonary arterial and pulmonary wedge pressure, and cardiac output should be monitored invasively. Monitoring should be continued until after the completion of labor, because maternal preload abruptly increases with the birth, after which substantial loss of blood can accompany delivery of the placenta.

Heart Failure

Chronic heart failure is a syndrome that develops when the heart cannot meet the metabolic requirements of the normally active individual. It may be defined as ventricular dysfunction causing dyspnea, fatigue, and sometimes arrhythmia. The lesion may be an intrinsic myocardial abnormality. Examples include myocarditis, the various cardiomyopathies, ischemic heart disease, other specific myocardial disorders (e.g., amyloidosis), and metabolic abnormalities (e.g., myxedema). Other causes include valvular disease, systemic and pulmonary hypertension, and congenital malformations. The myocardial response to chronic pressure overload is concentric hypertrophy with increased thickness of the ventricular walls; the response to chronic volume overload is dilation (eccentric hypertrophy). Contractile power is eventually diminished with either type of overload, resulting in decreased pump function of the heart. The clinical manifestations result in part from the abnormal loading conditions and in part from the damaged myocardium.

MANIFESTATIONS

The principal manifestations of heart failure are caused by increased left and right ventricular diastolic pressure, which engenders pulmonary and systemic congestion, and reduced cardiac output (during exercise or, in severe cases, at rest as well). The combined effects of inadequate cardiac output and congestion are dyspnea, fatigue, and edema. In the later stages of heart failure, these changes lead to progressive dysfunction of vital organs, principally the liver and kidneys. The prognosis of severe uncorrectable heart failure is quite poor, and pregnancy is absolutely contraindicated.

The critical clinical features that enable physicians to diagnose and monitor the course of heart failure are body weight, jugular venous pressure, the S_3 , cardiac size, radiologic evidence of pulmonary congestion, pulmonary rales, and peripheral edema. Echocardiography is an extremely useful tool for evaluating left ventricular function and prognosis in heart failure¹²⁴ and should be performed without delay if heart failure is suspected. Circulating B-type natriuretic peptide (BNP) is increased in congestive heart failure. Serum BNP levels provide an effective, inexpensive, and quickly available test for heart failure. The degree of BNP increase correlates with the severity of heart failure.¹²⁵

The presence of heart failure greatly limits physical activity and warrants several or all of the following treatments:

- Continuous, usually escalating courses of diuretic drugs
- β -Adrenergic receptor blockers
- ACE inhibitors (or, if these are not well tolerated, angiotensin receptor blockers)—note that these agents are contraindicated during pregnancy and should be replaced by hydralazine
- Salt restriction
- Digoxin

If heart failure is first discovered during pregnancy, episodes of cardiac decompensation that do not respond to adjustment of orally administered medicine necessitate admission to an intensive care unit. There, the effects of treatment on cardiac output, pulmonary arterial pressure, systemic venous pressure, and pulmonary wedge pressure, along with the maternal and fetal ECGs, can be monitored. If the hemodynamic parameters and clinical condition indicate continuing deterioration despite maximal medical therapy, emergency abdominal delivery may be necessary.

ASYMPTOMATIC LEFT VENTRICULAR DYSFUNCTION

There is a remarkable lack of correlation between symptoms of heart failure and objective evidence of left ventricular dysfunction.¹²⁶ For example, patients with chronic heart disease after myocardial infarction may have a considerably enlarged and extremely hypokinetic ventricle and yet be relatively free from symptoms. For this reason, any woman who has sustained myocardial damage should have left ventricular function assessed by echocardiography before deciding on pregnancy.

CARDIAC TRANSPLANTATION

Some women with advanced heart failure become successful recipients of a cardiac transplant. Successful pregnancy and delivery in patients with cardiac transplantation have been

reported.⁸¹ Medical treatment after transplantation is complex because of the immunosuppressive drug regimen and the uncertain long-term prognosis. Women should delay pregnancy for at least 1 year after cardiac transplantation, by which time the risk of acute rejection and the intensity of immunosuppression are considerably less.

Disturbances of Cardiac Rhythm

Isolated supraventricular and ventricular extrasystoles are very common, and no treatment is necessary. Pre-conception counseling is simplified by a clear appreciation of several general principles.

Arrhythmia that occurs in the absence of organic heart disease is almost always benign and is therefore not an indication for pharmacologic treatment unless the woman finds the symptoms intolerable. Reassuring her of the benign nature of this symptom is often all that is required. Sustained symptomatic arrhythmia, however, requires treatment, which can be pharmacologic or procedural (e.g., transcatheter ablation of an anomalous conduction pathway, insertion of an implantable cardiac defibrillator).

Pregnancy and labor should be safe except in the group with sustained ventricular arrhythmia, with its attendant risk of cardiac arrest and need for vigorous treatment. Pharmacologic treatment for serious arrhythmia is likely to include newer agents, such as amiodarone or sotalol, for which there is at best limited knowledge of potentially unfavorable effects on the fetus. Ideally, pregnancy should be postponed until the arrhythmia has been eliminated or at least controlled, preferably by nonpharmacologic means. If antiarrhythmic drugs must be used, whenever possible they should be those that have been used for several decades, allowing prediction of the fetal risk.

High-grade atrioventricular conduction disturbance (heart block), especially if it is symptomatic, is treated by artificial pacing, which should not influence pregnancy, labor, or the fetus. Electrical cardioversion or defibrillation of the mother's heart does not disturb or damage the fetal heart.¹²⁷

It is clearly desirable to evaluate disturbances of cardiac rhythm and conduction before pregnancy, proceeding to full electrophysiologic testing if indicated. This plan avoids exposing a fetus to potentially toxic antiarrhythmic agents and the radiation associated with electrophysiologic investigation.

Marfan Syndrome

Marfan syndrome is variably expressed and is inherited as an autosomal dominant trait. If it is left untreated, life expectancy is reduced by half in those who exhibit the classic syndrome. The basic defect is one of connective tissue, particularly fibrillin, and connective tissue weakness in the aorta causes the dangerous complications, most notably aortic dissection.¹²⁸

Symptoms and signs may include dyspnea and chest pain, an aortic diastolic murmur, and a midsystolic click. The best diagnostic test, and apparently the most critical one for determining the outcome of pregnancy, is the echocardiogram. More than 90% of patients have evidence of MVP, and 60% have echocardiographic evidence of aortic root dilation (Video 52-10).¹²⁹

Pregnancy is particularly dangerous for patients with this syndrome, because there appears to be a high risk of aortic

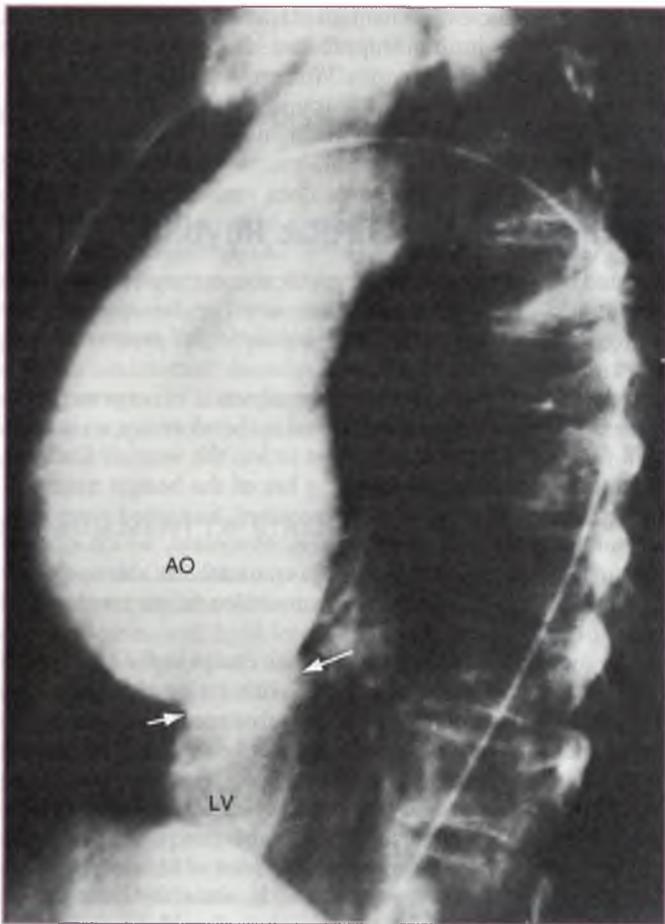

Figure 52-18 Aortic aneurysm. Aortogram showing an aneurysm of the ascending aorta (AO) with regurgitation of contrast through an incompetent aortic valve (arrows) into the left ventricle (LV). (From Shabetai R, Adolph RJ: *Principles of cardiac catheterization*. In Fowler NO, editor: *Cardiac diagnosis and treatment*, Hagerstown, MD, 1980, Harper & Row.)

rupture and dissection, especially if dilation of the aortic root is present.⁴⁷ Women with an aortic diameter exceeding 40 mm are at greatest risk for death during pregnancy.¹³⁰ A woman with Marfan syndrome who is considering pregnancy should be told that the risk for aortic dissection during pregnancy is approximately 1% if her ascending aortic diameter is less than 40 mm, and approximately 10% if it is greater than 40 mm.¹³¹ The physician should also make sure the woman understands the 50% risk of genetic transmission of Marfan syndrome to her children. Elective aortic root replacement should be recommended before pregnancy if the aortic root diameter is 50 mm or greater (European authorities recommend replacement for an aortic diameter of >47 mm).¹³¹

Deficiency of elastic tissue is the cause of myxomatous degeneration of the aortic and mitral valves and cystic medial necrosis of the aorta (Figs. 52-18 and 52-19). This abnormality translates to large aneurysms of the aortic root, multiple aneurysms elsewhere along the course of the aorta and great vessels, and severe aortic and mitral regurgitation with resulting heart failure. Surgery is indicated for rapidly expanding aneurysm or if dissection is evident. Pregnancy is poorly tolerated under

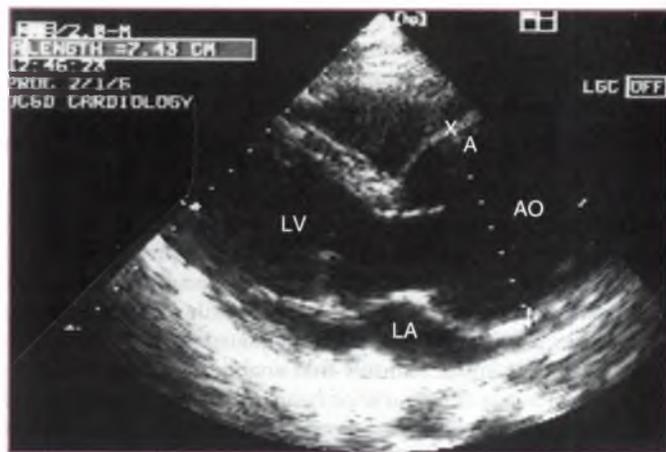

Figure 52-19 Marfan syndrome. The echocardiogram shows a markedly dilated aortic root, measuring 7.4 cm in diameter (normal, ≤ 3.5 cm). A, annulus diameter (7.43 cm); AO, aorta; LA, left atrium; LV, left ventricle.

these conditions, and labor may precipitate rupture of an aneurysm or aortic dissection.

If a woman with Marfan syndrome chooses to become pregnant, therapy is directed at markedly limiting physical activity, preventing hypertensive complications, and decreasing the pulsatile forces on the aortic wall with the use of a β -blocker. Long-acting β -blockers are indicated before, during, and after pregnancy in women with Marfan syndrome.¹³² Cesarean delivery is recommended to avoid the hemodynamic stress of labor.

Complex Cardiac Concerns for Pregnant Women

ARTIFICIAL HEART VALVES

Cardiology and obstetrics intersect in a most complex and challenging way when women with artificial heart valves are, or wish to become, pregnant. This could be the topic of an entire chapter. The discussion here covers three basic groups of patients:

1. Women contemplating pregnancy who are likely to need a valve replacement in the medium- to long-term future, such as women with moderate aortic or pulmonic stenosis, severe but asymptomatic mitral or aortic regurgitation with normal myocardial function, or mild to moderate mitral stenosis
2. Women who wish to become pregnant but have severe valve disease that must be addressed expediently, including those with severe aortic or mitral stenosis, severe mitral regurgitation with cardiac dysfunction, or severe aortic regurgitation with cardiac dysfunction
3. Women with mechanical valve replacements who become pregnant

The only group for whom no management controversy exists is the first.¹³³ Without question, women who are likely to need valve surgery in several years should be strongly encouraged to complete their childbearing as quickly as possible, so that they will not become members of the second or third group.

Women in the second group require valve replacement before pregnancy. In most adult patients younger than 65 or 70 years (but not in women who wish to become pregnant), mechanical prosthetic valves would be favored over biologic prostheses, because biologic valves have a shorter life span and deteriorate much more quickly than mechanical valves. This difference appears even more pronounced in younger patients; it was once thought that pregnancy itself hastened biologic valve deterioration, but this does not appear to be true.¹³⁴ In any case, younger patients with biologic valves will almost certainly require repeat surgery. With mechanical valves, however, the patient faces the requirement for lifelong anticoagulation and the resultant increase in risk for bleeding.

It is important to note that the anticoagulant of choice with a mechanical valve is warfarin, not heparin. Although heparin is clearly safer for the fetus,¹³⁵ it is not equivalent to warfarin in preventing thromboembolic complications (especially during the prothrombotic state of pregnancy). This has been shown in several studies and appears to be most striking in the case of single tilting-disk mechanical prostheses.^{8,24} Various reports have noted thromboembolic event rates of 12% to 24% in high-risk pregnant women with mechanical valves on unfractionated heparin or LMWH, which is more than double the risk for those on warfarin.^{133,136,137} Therefore, many experts agree that women who require valve surgery before pregnancy should receive a bioprosthetic valve—even though repeat surgery will be necessary in the future—because these valves have a much lower thromboembolic risk and do not usually require systemic anticoagulation. Women with normally functioning biologic valve replacements tolerate pregnancy well.

Management of the third group—women with mechanical cardiac valves who become pregnant—is the most difficult. A woman with a mechanical prosthetic heart valve should be counseled strongly that pregnancy is risky, primarily because of the risk for embolic phenomena. If the patient decides to proceed with pregnancy, warfarin is superior to heparin for preventing thromboemboli with mechanical valves (see Video 52-11A,B for examples of thrombi on a mechanical valve). However, warfarin is teratogenic and carries a 4% to 10% risk for warfarin embryopathy.^{138,139} This risk appears to be dosage dependent as well, and it appears to be highest during weeks 6 to 12 of pregnancy.²³ For these reasons, the U.S. manufacturer of Coumadin (warfarin) states that the drug is absolutely contraindicated during pregnancy. Although warfarin is used during pregnancy in Europe (after the first 12 weeks) and is recommended until the 35th week of pregnancy, American physicians face a particularly difficult dilemma because of the manufacturer's contraindication (even though this contradicts guidelines from acknowledged expert panels).^{2,10,11} In addition, many pregnant women would prefer to put themselves rather than the fetus at risk. Therefore, subcutaneous or intravenous heparin is used during pregnancy in many American women with mechanical heart valves, even though thromboembolic risk is higher.^{139,140} During treatment with unfractionated heparin or LMWH, the activated partial thromboplastin time (or anti-Xa heparin levels) must be monitored frequently. In addition, the dosage must be adjusted as the patient gains weight during pregnancy. There is some evidence that LMWH is superior to unfractionated heparin in nonpregnant patients with mechanical prostheses,¹⁴¹ and this approach has been used successfully for a number of pregnant patients.^{142,143} However, in a recent small study of enoxaparin in pregnant women with

prosthetic heart valves, two of eight patients developed prosthetic valve thrombosis leading to maternal and fetal death.¹⁴⁴ Although it is unclear, it is possible that these women did not receive adequate dosages of enoxaparin. Randomized trials have not been performed, and more information is needed before LMWH can be recommended over unfractionated heparin in this setting.¹⁴⁵

Table 52-3 and Box 52-4 show two currently proposed protocols for anticoagulation in the pregnant woman with a mechanical heart valve. Several authorities recommend using heparin through the first trimester, although continuous use of warfarin during the first trimester is an option in high-risk patients (particularly those with first-generation tilting-disk prostheses in the mitral position).^{10,11} The joint American College of Cardiology (ACC) and American Heart Association (AHA) Guidelines for the Management of Patients with Valvular Heart Disease² stress the importance of discussing the risks and benefits of various anticoagulation approaches with the patient, because she must be a full partner in her medical care. She must be informed that if she chooses to change from warfarin to heparin during the first trimester (or for the entire pregnancy), she has a higher risk for both thrombosis and bleeding, and any risk to her jeopardizes the baby as well. Table 52-3, from Elkayam and Bitar,¹¹ stratifies treatment options by risk for thrombosis and recommends consideration of continuing warfarin throughout the pregnancy (until week 35) for

BOX 52-4 RECOMMENDATIONS OF THE EIGHTH ACCP CONSENSUS CONFERENCE ON ANTITHROMBOTIC AND THROMBOLYTIC THERAPY FOR PROPHYLAXIS IN PREGNANT PATIENTS WITH MECHANICAL HEART VALVES

1. LMWH (SC, q12h) throughout pregnancy, with dosages adjusted to achieve the manufacturer's peak anti-Xa LMWH levels 4 hr after subcutaneous injection.
- OR
2. UFH (SC, q12h) throughout pregnancy, with dosages adjusted to keep the mid-interval aPTT at least twice control, or to attain an anti-Xa heparin level of 0.35 to 0.70 U/mL.
- OR
3. UFH or LMWH (in dosages described above) until the 13th week; at that point, warfarin is substituted and continued until close to delivery, when UFH or LMWH is resumed.

In women at very high risk of thromboembolism (e.g., those with older-generation mechanical valves in the mitral position), vitamin K antagonists can be used throughout pregnancy, with replacement by UFH or LMWH (in dosages described above) close to delivery, after a thorough discussion of the potential risks and benefits of this approach.

ACCP, American College of Chest Physicians; aPTT, activated partial thromboplastin time; LMWH, low-molecular-weight heparin; SC, subcutaneously; UFH, unfractionated heparin.

Data from Bates SM, Greer IA, Pabinger I, et al: *Venous thromboembolism, thrombophilia, antithrombotic therapy, and pregnancy: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th edition)*, Chest 133(6 Suppl):S844–S886, 2008.

patients with first-generation valves in the mitral position, atrial fibrillation, or a history of previous embolic events. The treatment options in Box 52-4, from the American College of Chest Physicians,¹⁴⁶ are somewhat simpler. The most recent ACC/AHA recommendations² are reproduced in Box 52-5.

During pregnancy, consultation and close follow-up with an experienced cardiologist is strongly recommended, as well as meticulous attention to blood coagulation testing. Because preterm labor occurs frequently in this group,²⁴ warfarin should be replaced by therapeutic dosages of subcutaneous heparin around the 35th week of gestation. If labor occurs while a patient is taking warfarin, cesarean section is recommended to avoid fetal cerebral hemorrhage during vaginal delivery.²

All patients with prosthetic heart valves require antibiotic prophylaxis for dental procedures but not during uncomplicated delivery. Prevention of prosthetic valve endocarditis is essential, because the mortality rate can reach 40%. The patient who experiences endocarditis with a prosthetic valve must receive aggressive antibiotic therapy and will often require valve replacement. Clearly, the risk to the fetus is exorbitant.

CARDIAC SURGERY

Whenever possible, any woman who requires cardiac surgery should undergo the procedure before becoming pregnant. Nevertheless, as explained previously, in rare instances a patient may require surgery during pregnancy. Valvular surgery has been performed successfully during pregnancy for many years, and patients have also undergone coronary artery bypass surgery and emergency aortic dissection repair. Cardiac surgery

BOX 52-5 AMERICAN COLLEGE OF CARDIOLOGY AND AMERICAN HEART ASSOCIATION RECOMMENDATIONS

CLASS I (RECOMMENDED THERAPY)

1. All pregnant patients with mechanical prosthetic valves must receive continuous therapeutic anticoagulation with frequent monitoring. (*Level of Evidence: B*)
2. For women requiring long-term warfarin therapy who are attempting pregnancy, pregnancy tests should be monitored, with discussions about subsequent anticoagulation therapy, so that anticoagulation can be continued uninterrupted when pregnancy is achieved. (*Level of Evidence: C*)
3. Pregnant patients with mechanical prosthetic valves who elect to stop warfarin between weeks 6 and 12 of gestation should receive continuous intravenous UFH, dosage-adjusted UFH, or dosage-adjusted subcutaneous LMWH. (*Level of Evidence: C*)
4. For pregnant patients with mechanical prosthetic valves, up to 36 weeks of gestation, the therapeutic choice of continuous intravenous or dosage-adjusted subcutaneous UFH, dosage-adjusted LMWH, or warfarin should be discussed fully. If continuous intravenous UFH is used, the fetal risk is lower, but the maternal risks of prosthetic valve thrombosis, systemic embolization, infection, osteoporosis, and heparin-induced thrombocytopenia are higher. (*Level of Evidence: C*)
5. In pregnant patients with mechanical prosthetic valves who receive dosage-adjusted LMWH, the LMWH should be administered twice daily subcutaneously to maintain the anti-Xa level between 0.7 and 1.2 U per mL 4 hr after administration. (*Level of Evidence: C*)
6. In pregnant patients with mechanical prosthetic valves who receive dosage-adjusted UFH, the aPTT should be at least twice control. (*Level of Evidence: C*)
7. In pregnant patients with mechanical prosthetic valves who receive warfarin, the INR goal should be 3.0 (range, 2.5 to 3.5). (*Level of Evidence: C*)
8. In pregnant patients with mechanical prosthetic valves, warfarin should be discontinued and continuous intravenous UFH given starting 2 to 3 weeks before planned delivery. (*Level of Evidence: C*)

CLASS IIA (REASONABLE THERAPY)

1. In patients with mechanical prosthetic valves, it is reasonable to avoid warfarin between weeks 6 and 12 of gestation because of the high risk for fetal defects. (*Level of Evidence: C*)
2. In patients with mechanical prosthetic valves, it is reasonable to resume UFH 4 to 6 hr after delivery, and to begin oral warfarin in the absence of significant bleeding. (*Level of Evidence: C*)
3. In patients with mechanical prosthetic valves, it is reasonable to give low-dosage aspirin (75 to 100 mg/day) in the second and third trimesters of pregnancy, in addition to anticoagulation with warfarin or heparin. (*Level of Evidence: C*)

CLASS III (THERAPY THAT IS NOT RECOMMENDED)

1. LMWH should not be administered to pregnant patients with mechanical prosthetic valves unless anti-Xa levels are monitored 4 to 6 hr after administration. (*Level of Evidence: C*)
2. Dipyridamole should not be used instead of aspirin as an alternative antiplatelet agent in pregnant patients.

aPPT, activated partial thromboplastin time; INR, international normalized ratio; LMWH, low-molecular-weight heparin; UFH, unfractionated heparin.

From Bonow RO, Carabello B, Chatterjee K, et al: *ACC/AHA 2008 guidelines for the management of patients with valvular heart disease*, Circulation 118:e523–e661, 2008.

during pregnancy does not appear to increase the maternal mortality risk.^{147,148} There is, however, a 10% to 15% risk for fetal mortality because of the nonpulsatile blood flow and hypotension associated with conventional cardiopulmonary bypass. Therefore, whenever possible, cardiac surgery should be performed without cardiopulmonary bypass. In addition, hypothermia should be avoided, because this appears to be especially dangerous to the fetus. In one study, fetal mortality was decreased by half when normothermic perfusion was used instead of hypothermic perfusion.¹⁴⁸ Hypothermia stimulates uterine contractions and impairs oxygen delivery to the fetus, mandating careful monitoring of the uterus and the fetal heart. The deleterious effect of hypothermia on umbilical blood flow has been documented by transvaginal ultrasonography.¹⁴⁹

Experimental studies suggest that fetal survival can be improved by the use of pulsatile perfusion, but results are not yet clear. If bypass is required for cardiac surgery at an immature gestational age, high-flow, high-pressure, normothermic perfusion should be instituted.¹⁵⁰ If possible, surgery should be postponed until the third trimester, when the fetal risk is considerably reduced. Fetal bradycardia is often seen during surgery and may require rapid treatment, usually with intravenous nitroprusside. In addition, preterm labor occurs more frequently in women undergoing cardiac surgery.

During surgery and in the immediate postoperative period, these patients should be monitored very closely. In general, use of intra-arterial and Swan-Ganz catheters and electrocardiographic monitoring of the woman and the fetus is recommended. Transesophageal echocardiography is also helpful in some cases and provides direct assessment of valvular and ventricular function. Maintenance of acceptable arterial oxygen levels and normal blood pressure, plus avoidance of hypothermia, are of utmost importance to the fetus.

PROPHYLACTIC ANTIBIOTICS

The most recent recommendations from the AHA regarding the use of prophylactic antibiotics represent a major departure from previous guidelines and are summarized here because of the importance of this information to those caring for women with heart disease. The most prominent aspect of the new guidelines is that antibiotics to prevent infective endocarditis (IE) are now recommended *only* for those patients deemed to be at the highest risk. These high-risk cardiac conditions include the following:

1. Prosthetic heart valve or prosthetic material used for cardiac valve repair
2. Previous IE
3. Congenital heart disease (CHD)
 - Unrepaired cyanotic CHD, including those with palliative shunts and conduits
 - Congenital heart defect completely repaired with prosthetic material or device, whether replaced by surgery or by catheter intervention, during the first 6 months after the procedure (during the process of endothelialization)
 - Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
4. Cardiac transplantation recipients who develop cardiac valvulopathy

The reader is referred to the AHA publication for additional details and the consensus panel's rationale.¹⁵¹

Coagulation Disorders in Pregnancy

MARC A. RODGER, MD, MSc | ROBERT M. SILVER, MD

Acquired and inherited disorders of the hemostatic system can produce hemorrhage and thrombosis.^{1,2} Inherited and acquired thrombophilias are associated with venous thromboembolism (VTE), the leading cause of maternal death in the United States, and they may be associated with placenta-mediated pregnancy complications. The hemostatic system and its modulators are reviewed in this chapter. We discuss the inherited and acquired disorders of platelet function, coagulation, and fibrinolysis and describe their impact on the mother and fetus. We provide an evidence-based approach to understanding the preventative and therapeutic alternatives for women challenged by these disorders in pregnancy.

Hemostatic System

The hemostatic system is designed to ensure that hemorrhage is avoided in the setting of vascular injury while the fluidity of blood is maintained in the intact circulation. After vascular injury, activation of the coagulation cascade and simultaneous platelet adhesion, activation, and aggregation are required to form the optimal fibrin-platelet plug to avoid or stop bleeding. The system is held in check by several factors. The endothelial cell lining covers a thrombogenic subendothelium and is vasodilatory. It is an active participant in the antiplatelet activation, anticoagulant, and fibrinolytic systems. The system also is managed by a potent series of circulating anticoagulant proteins and by a highly regulated fibrinolytic system.

Pregnancy introduces an additional challenge to this system because the risk of hemorrhage during placentation and the third stage of labor is high. The maternal hemostatic system has evolved to be prothrombotic on balance. Nonetheless, through a series of local and systemic adaptations, most pregnant women are able to balance these paradoxical requirements and achieve uncomplicated pregnancies.

PLATELET PLUG FORMATION

After vascular injury, platelets rolling and flowing in the bloodstream are primarily arrested at sites of endothelial disruption by the interaction of collagen in the subendothelium with circulating von Willebrand factor (vWF). Figure 53-1 schematically reviews platelet function. Attachment to collagen exposes sites on the vWF molecule that permit it to bind to the platelet glycoprotein complex (GpIb-IX-V) receptor,³ and vWF acts as glue between the platelets and the subendothelium. Platelets can also adhere to subendothelial collagen through their GpIa-IIa ($\alpha_2\beta_1$ integrin) and GpVI receptors. Deficiencies or defects in either receptor cause mild bleeding diatheses.

Adherent platelets are activated by collagen after binding to the GpVI receptor.⁴ This triggers receptor phosphorylation, leading to activation of phospholipase C, which generates inositol triphosphate and 1,2-diacylglycerol. Inositol triphosphate triggers a calcium flux, and 1,2-diacylglycerol activates protein kinase C, which triggers platelet secretory activity and activates various signaling pathways. Signaling promotes activation of the GpIIb-IIIa ($\alpha_{IIb}\beta_3$ integrin) receptor, a crucial step in subsequent platelet aggregation. Collagen promotes platelet adhesion and platelet activation. However, maximal platelet activation requires binding of thrombin to platelet type 1 and 4 protease-activated receptors (e.g., PAR-1, PAR-4).⁵ Platelet activation is also mediated by thromboxane A₂ (TXA₂) binding to its receptor (TBXA2R) and adenosine diphosphate (ADP) binding to its receptors (P2Y12 and P2Y1). TXA₂ and ADP are released by adjacent activated platelets. Collagen and these circulating agonists induce calcium-mediated formation of platelet pseudopodia, promoting further adhesion.

Platelet secretory activity includes the release of α -granules containing vWF, vitronectin, fibronectin, thrombospondin, partially activated factor V, fibrinogen, β -thromboglobulin, and platelet-derived growth factor, which enhance adhesion or promote clotting. Secretory activity also includes the release of dense granules containing ADP and serotonin, which enhance, respectively, platelet activation and vasoconstriction in damaged vessels. Calcium flux promotes the synthesis of TXA₂ by the sequential action of phospholipase A₂, cyclooxygenase-1 (COX-1), and TXA₂ synthase and its passive diffusion across platelet membranes to promote vasoconstriction and activation of adjacent platelets.⁴ Through an accumulation of activated platelets secreting platelet activators (e.g., ADP, TXA₂) and by enhancing thrombin generation (a potent platelet activator), a storm of platelet accumulation and activation ensues. Inhibition of COX-1-mediated TXA₂ synthesis by nonsteroidal anti-inflammatory drugs (NSAIDs) and aspirin (ASA) also can impair platelet function.

Platelet aggregation follows activation-induced conformational changes in the platelet membrane GpIIb-IIIa receptor, so-called inside-out signaling. The receptor forms a high-affinity bond to divalent fibrinogen molecules, which act as a glue between activated platelets. The same fibrinogen molecule is also able to bind to adjacent platelet GpIIb-IIIa receptors.⁶ Because these receptors are abundant (i.e., 40,000 to 80,000 copies), large platelet rosettes quickly form, reducing blood flow and sealing vascular leaks.⁴ Platelet activation and aggregation are prevented in intact endothelium by the latter's elaboration of prostacyclin, nitric oxide, and ADPase and by active blood flow that dilutes platelet activators. Cyclic adenosine

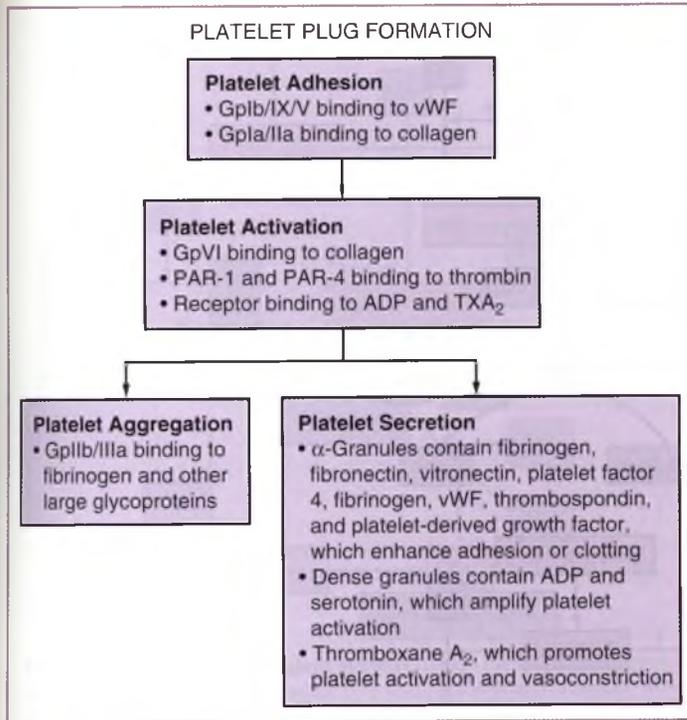

Figure 53-1 Schematic review of platelet function. ADP, adenosine diphosphate; Gp, glycoprotein; PAR, protease-activated receptor; TXA₂, thromboxane A₂; vWF, von Willebrand factor.

monophosphate (cAMP) inhibits platelet activation, which is the basis for the therapeutic effects of dipyridamole. Normal pregnancy is associated with a modest decline in platelet number^{7,8} and with evidence of progressive platelet activation.⁹

COAGULATION: FIBRIN PLUG FORMATION

Effective hemostasis requires the synergistic interaction of the coagulation cascade with platelet activation and aggregation. This synergism is in part mechanical, because fibrin and platelets together form an effective hemostatic plug after significant vascular disruption. However, biochemical synergism also occurs, because activated platelets contribute coagulation factors and form an ideal surface for thrombin generation. Conversely, optimal platelet activation and subsequent aggregation require exogenous thrombin generation (see Fig. 53-1). Avoidance of hemorrhage ultimately depends on the interplay between platelets and the coagulation cascade.

Understanding of the coagulation component of hemostasis has evolved rapidly in the past 2 decades. Coagulation is no longer thought of as a seemingly infinite cascade of enzymatic reactions occurring in the blood but rather as a highly localized cell surface phenomenon.¹⁰ Coagulation is initiated when sub-endothelial (extravascular) cells expressing tissue factor (TF), a cell membrane-bound glycoprotein, comes into contact with a small concentration of circulating activated factor VII (VIIa). TF is primarily expressed on the cell membranes of perivascular smooth muscle cells, fibroblasts, and tissue parenchymal cells, but it is not expressed on healthy endothelial cells. However, TF also circulates in the blood in very low concentrations as part

of cell-derived microparticles or in a truncated soluble form.^{8,11} Intrauterine survival is not possible in the absence of TF.¹²

After vascular disruption and in the presence of ionized calcium, perivascular cell TF comes into contact with plasma factor VIIa. Factor VIIa is unique in that it circulates in small quantities in activated form, which results from autoactivation after binding to TF or activation by factors IXa or Xa.¹³ Activation of factor VII to VIIa increases its catalytic activity more than 100-fold and ensures that factor VIIa is readily available to initiate coagulation when exposed to TF.

The complex of TF and factor VIIa activates factor X and factor IX. Factor Xa remains very active as long as it is bound to TF-VIIa in the cell membrane-bound prothrombinase complex (Xa/Va). However, when factor Xa diffuses away from the site of vascular injury, it is rapidly inhibited by tissue factor pathway inhibitor (TFPI) or antithrombin. This prevents inappropriate propagation of the thrombus throughout the vascular tree.¹⁰ Factor Xa bound to its cofactor, Va, which is generated from its inactive form by the action of factor Xa itself or by thrombin, forms the prothrombinase (Xa/Va) complex, which actively catalyzes the conversion of prothrombin (factor II) to thrombin (factor IIa). Partially activated factor Va also can be delivered to the site of coagulation initiation after its release from platelet α -granules (Fig. 53-2A).⁸ Thrombin converts fibrinogen to fibrin and activates platelets through binding PAR-1 and PAR-4 (see Fig. 53-2A).

After the initial TF-mediated reaction, the coagulation cascade is amplified in a propagation phase by an explosive positive-feedback loop of coagulation reactions that occur on adjacent activated platelets.¹⁰ Locally generated factor IXa diffuses to adjacent activated platelet membranes or to perturbed endothelial cell membranes, where it binds to factor VIIIa. This cofactor is directly activated by thrombin and is released from its vWF carrier molecule through the action of thrombin.¹⁰ The activated factor IXa/VIIIa complex (i.e., tenase complex) can then generate large amounts of factor Xa at these sites to further drive thrombin generation (see Fig. 53-2B). The significant hemorrhagic sequelae of hemophilia underscore the vital role played by tenase complex-mediated factor Xa generation in ensuring a sufficient thrombin burst for adequate hemostasis.¹⁰

The coagulation cascade can be amplified by the activation of factor XI to XIa by thrombin on activated platelet surfaces; factor XIa also activates factor IX (see Fig. 53-2C). The lack of significant hemorrhagic sequelae in patients with factor XI deficiency emphasizes that this mechanism has a less important role in the maintenance of hemostasis. Factor XIa has been described as having a booster function in coagulation.¹⁰

A third, theoretical coagulation amplification pathway may be mediated by circulating TF-bearing microparticles that bind to activated platelets at sites of vascular injury through the interaction between P-selectin glycoprotein ligand-1 on the microparticles and P-selectin on activated platelets.¹⁴ Together, the factor IXa, factor XIa, and TF-platelet surface events lead to additional factor Xa generation and to enhanced production of thrombin and fibrin. They also reflect the synergism that exists between platelet activation and the coagulation cascade.

The stable hemostatic plug is formed only when fibrin monomers self-polymerize and are cross-linked by thrombin-activated factor XIIIa (see Fig. 53-2D). This reaction highlights the dominant role that thrombin plays in the coagulation cascade: Thrombin activates platelets, generates fibrin, and

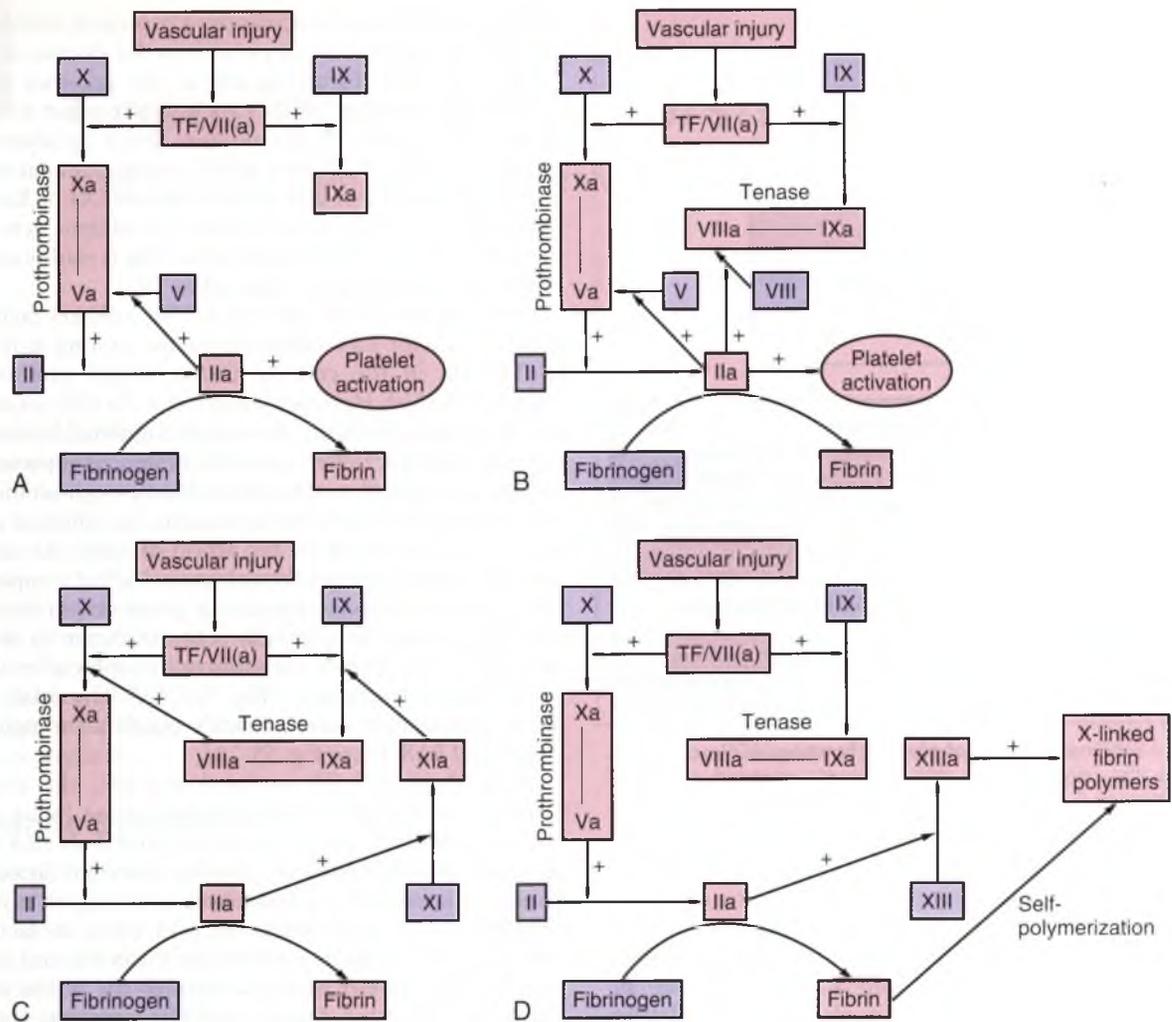

Figure 53-2 Fibrin plug formation. A, After vascular disruption, factor VII(a) binds to tissue factor (TF) to form the TF/VII(a) complex, which activates factor X and factor IX. Factor Xa binds to factor Va, which has been activated by thrombin (factor IIa) or released from platelet α -granules. The Xa/Va complex catalyzes the conversion of prothrombin (factor II) to thrombin (factor IIa), which converts fibrinogen to fibrin and activates platelets. B, The clotting cascade is amplified by clotting reactions that occur on adjacent activated platelets. Locally generated factor IXa binds to factor VIIIa, which is activated by thrombin. The factor IXa/VIIIa complex then generates factor Xa. C, Coagulation is further boosted by the thrombin-mediated activation of factor XI to factor XIa, which also activates factor IX. D, The stable hemostatic plug is formed when fibrin monomers self-polymerize and are cross-linked by thrombin-activated factor XIIIa.

activates the crucial clotting cofactors V and VIII, as well as the key clotting factors VII, XI, and XIII. This accounts for the primacy of antithrombin factors in preventing inappropriate intravascular clotting (e.g., thrombosis, disseminated intravascular coagulation [DIC]).

PREVENTION OF THROMBOSIS: THE ANTICOAGULANT SYSTEM

The hemostatic system must prevent hemorrhage after vascular injury and maintain the fluidity of the circulation in an intact vasculature. Thrombotic disease is a consequence of inappropriate or excess thrombin generation. As in preventing hemorrhage, avoidance of thrombosis depends on the synergistic interaction of platelets and the coagulant system. Coagulation is initiated locally at sites of vascular injury and amplified by the arrival, adherence, and activation of platelets. This local coagulation reaction is relatively protected from the dampening

effects of circulating endogenous anticoagulants because of its intensity and because it is shielded by the initial layer of adherent and activated platelets. However, maximal platelet activation occurs only after stimulation by subendothelial collagen and thrombin. As additional platelets aggregate on top of the initial layer of platelets, they become progressively less activated, and their coagulation reaction becomes more susceptible to the action of circulating inhibitors, attenuating the coagulation cascade.¹⁰

Prevention of DIC ultimately requires the presence of inhibitor molecules (Fig. 53-3). The first inhibitory molecule is TFPI, which forms a complex with TF, VIIa, and Xa (i.e., prothrombinase complex).¹⁵ TFPI is most effective distal to the initial site of clotting, and it can be bypassed by the generation of factors IXa and XIa.

Paralleling its pivotal role in initiating the hemostatic reaction, thrombin plays a central role in initiating the anticoagulant system. Thrombin binds to thrombomodulin on intact

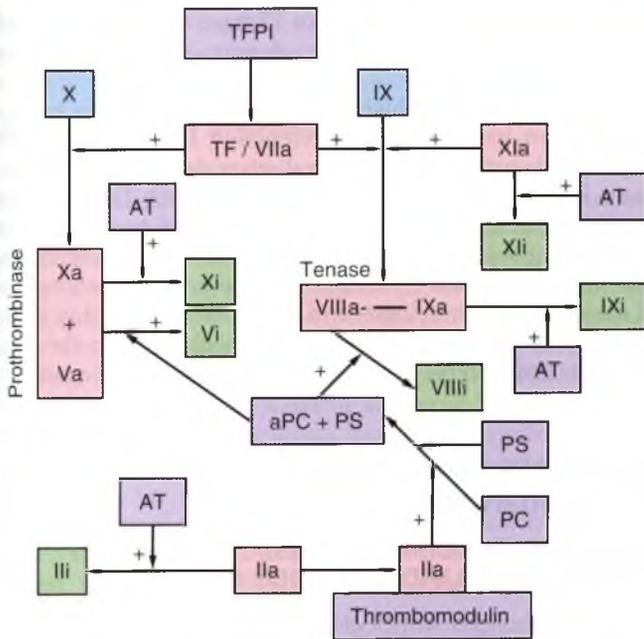

Figure 53-3 The anticoagulant system. Tissue factor pathway inhibitor (TFPI) binds with tissue factor (TF) and factor VIIa. Thrombin, after binding to thrombomodulin, can activate protein C (PC) when bound to the endothelial protein C receptor. Activated protein C (aPC) then binds to its cofactor, protein S (PS), to inactivate factors VIIIa and Va. Antithrombin (AT) potently inhibits factor Xa and thrombin.

downstream endothelial cells, and the resultant conformational change permits thrombin to activate protein C, in effect converting thrombin from a procoagulant molecule to an anticoagulant molecule. Protein C activation is enhanced when it is presented on the cell surface by the endothelial protein C receptor (PROCR, formerly designated EPCR), which is abundant in some circulatory compartments but not others. Activated protein C then inactivates Va and VIIa, thereby limiting coagulation. The latter reactions are enhanced by protein S, the cofactor of activated protein C.

Thrombomodulin also dampens coagulation by binding thrombin and removing it from participating in procoagulant reactions. The most potent inhibitor of factor Xa and thrombin is antithrombin (AT, previously known as antithrombin III [ATIII]) (see Fig. 53-3). AT can bind thrombin and factors Xa, IXa, and XIa and can inactivate them. AT binding to endothelial surface heparanoids or exogenous heparin, results in a conformational change that augments thrombin inactivation by AT more than 1000-fold, leading to downstream thrombin inactivation.¹⁶ Although thrombin generated at the initial site of vascular injury is relatively protected from AT, thrombin produced more distally on the surface of activated platelets is readily susceptible.¹⁰ Similar inhibitory mechanisms use heparin cofactor II and β_2 -macroglobulin.

RESTORATION OF BLOOD FLOW: FIBRINOLYSIS

Fibrinolysis permits the restoration of circulatory fluidity and serves as another barrier to widespread thrombosis (Fig. 53-4). The cross-linked fibrin polymer is degraded to fibrin degradation products, including D-dimer, by the action

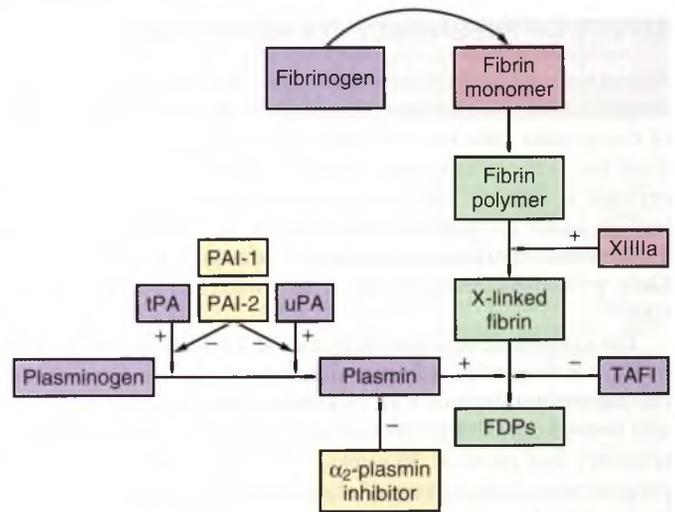

Figure 53-4 Fibrinolysis. The cross-linked fibrin polymer (X-linked fibrin), which was stabilized by thrombin (factor IIa)-activated factor XIIIa, is degraded to fibrin degradation products (FDPs) by the action of plasmin, which is generated by the proteolysis of plasminogen through tissue-type plasminogen activator (tPA) and urokinase-type plasminogen activator (uPA). To prevent excessive fibrinolysis, plasmin is inhibited by α_2 -plasmin inhibitor, and tPA and uPA are inhibited by plasminogen activator inhibitor type 1 (PAI-1) and type 2 (PAI-2). Thrombin-activated fibrinolysis inhibitor (TAFI), which is activated by the thrombin-thrombomodulin complex, cleaves terminal lysine residues from fibrin to render it resistant to plasmin.

of plasmin embedded in the fibrin clot.¹⁷ Plasmin is generated by the proteolysis of plasminogen by tissue-type plasminogen activator (tPA), which is released by intact endothelial cells. Endothelial cells also synthesize a second plasminogen activator, urokinase-type plasminogen activator (uPA), whose primary function is cell migration and extracellular matrix remodeling.

Fibrinolysis is modulated by a series of inhibitors. Plasmin is inhibited by β_2 -plasmin inhibitor, and like plasmin and plasminogen, it is bound to the fibrin clot, where it is positioned to prevent premature fibrinolysis. Platelets and endothelial cells release plasminogen activator inhibitor type 1 (PAI-1) in response to thrombin binding to PARs (e.g., PAR-1, PAR-4). The PAI-1 molecule inhibits tPA and uPA. In pregnancy, the decidua is also a very rich source of PAI-1,¹⁸ and the placenta can synthesize another antifibrinolytic molecule, plasminogen activator inhibitor type 2 (PAI-2). Fibrinolysis can also be inhibited by thrombin-activatable fibrinolysis inhibitor (TAFI, now designated plasma carboxypeptidase B2 [CPB2]). This carboxypeptidase cleaves terminal lysine residues from fibrin to render it resistant to plasmin. TAFI is activated by the thrombin-thrombomodulin complex.¹⁹ In the initial stages of clotting, platelets and endothelial cells release PAI-1, but after a delay, endothelial cells release tPA and uPA to promote fibrinolysis. This biologic process permits sequential clotting followed by fibrinolysis to restore vascular patency.

The fibrinolytic system can interact with the coagulation cascade. Fibrin degradation products inhibit the action of thrombin, which is a major source of hemorrhage in DIC. Moreover, PAI-1 bound to vitronectin and heparin also inhibits thrombin and factor Xa activity.²⁰

EFFECT OF PREGNANCY ON HEMOSTASIS

Pregnancy and delivery present unique and paradoxical challenges to a woman's hemostatic system. They also constitute one of the greatest risks for VTE that most young women will face. Until the 17th century, more than 10% of women died of hemorrhage at delivery, and peripartum hemorrhage remains the leading cause of maternal mortality in the developing world. This created enormous evolutionary selection pressure, which likely prompted development of the maternal prothrombotic state.²¹

The causal link between pregnancy and VTE is best explained by the Virchow triad, a framework that categorizes elements of the pathophysiology of VTE as venous stasis, vascular damage, and hypercoagulability. *Venous stasis*, which begins in the first trimester and peaks at 36 weeks,²² is thought to be caused by progesterone-induced venodilation, pelvic venous compression by the gravid uterus, and pulsatile compression of the left iliac vein by the right iliac artery.²² The latter may lead to the marked propensity for left leg deep venous thrombosis (DVT) in pregnancy (>80%).²³ DVT in pregnancy appears to more commonly arise from proximal veins (iliac and femoral) rather than calf veins, as is the usual pattern in nonpregnant patients, leading to a higher propensity for isolated iliac vein thrombosis and iliofemoral thrombosis in pregnant patients with DVT.²⁴ As a consequence of the tendency for more proximal location of thromboses during pregnancy, they are more likely to be associated with long-term postphlebotic syndrome.²⁵

During pregnancy, *vascular damage* to the pelvic vessels can be caused by venous distention. Vascular damage can occur after all types of deliveries.

Hypercoagulability occurs as the hemostatic system is progressively altered to prepare pregnant women for the hemostatic challenges of delivery. The modern consequence of this maternal hypercoagulable state is an increased risk of VTE. Two changes to the hemostatic system constitute the biologic mechanisms driving the maternal hypercoagulable state. First, anticoagulant activity of protein S is reduced, and activated protein C resistance increases.²⁶ Procoagulant activity is increased through higher levels of fibrinogen and factor V, IX, X and VIII levels, leading to increased thrombin production,²⁶ as measured by increased thrombin-antithrombin complexes, increased soluble fibrin, and prothrombin fragments 1 plus 2 levels.²⁷ Second, thrombus dissolution is reduced through decreased fibrinolysis from increased PAI-1 and PAI-2 activity and decreased tPA activity.²⁷ During the postpartum period, defined as the 6-week interval after delivery, the procoagulant maternal hemostatic system gradually returns to the nonpregnant state as evidenced by progressive normalization of markers of coagulation activation to pre-pregnancy levels.^{28,29}

Profound alterations occur in the local uterine coagulation, anticoagulant, and fibrinolytic systems to meet this hemostatic challenge. The uterine decidua is ideally positioned to regulate hemostasis during placentation and the third stage of labor. Progesterone augments expression of TF³⁰ and PAI-1¹⁸ on perivascular decidualized endometrial stromal cells. The crucial importance of the decidua in maintaining puerperal hemostasis is highlighted by the massive hemorrhage that accompanies obstetric conditions associated with impaired decidualization (e.g., ectopic and cesarean scar pregnancy, placenta previa, accreta). Decidual TF plays the primary role in mediating puerperal hemostasis. Transgenic TF-knockout mice rescued by the

expression of low levels of human TF have a 14% incidence of fatal postpartum hemorrhage despite far less invasive placentation.³¹

The extraordinarily high level of TF expression in human decidua can have a pathologic function if local hemostasis proves inadequate to contain spiral artery damage, and hemorrhage into the decidua occurs (i.e., abruption). This bleeding results in intense generation of thrombin and occasionally in frank hypofibrinogenemia and DIC. However, thrombin can also bind to decidual PAR-1 receptors to promote production of matrix metalloproteinases and cytokines, contributing to the tissue breakdown and inflammation associated with abruptio placentae and preterm premature rupture of the membranes.³²⁻³⁵

Disorders Promoting Thrombosis in Pregnancy

ACQUIRED THROMBOPHILIAS: ANTIPHOSPHOLIPID ANTIBODY SYNDROME

Antiphospholipid Antibodies

Antiphospholipid antibodies (aPLs) are a heterogeneous group of autoantibodies recognizing epitopes expressed by negatively charged phospholipids, proteins, or a phospholipid-protein complex. It is unclear which epitopes these antibodies bind to in vivo, but the most relevant appears to be the β_2 -glycoprotein-1, which has an affinity for negatively charged phospholipids and plays a regulatory role in coagulation. There are numerous aPLs, and there has been controversy regarding the best assays. There have been problems with interlaboratory variation, poor quality control, and a lack of standardization. Most of these problems have been addressed through a series of workshops, and most commercially available aPL assays are validated and reliable.³⁶ The three best characterized and standardized aPL assays are the lupus anticoagulant (LA), anticardiolipin antibodies (ACAs), and anti- β_2 -glycoprotein-1 antibodies.³⁷

LA is a misnomer for an antibody found in patients who need not have lupus and are not anticoagulated. The name was derived from the fact that the antibody interferes with phospholipid-dependent clotting assays, prolonging the assay clotting time and making it appear that the individual is anticoagulated. It was initially recognized in patients with lupus, accounting for the poor nomenclature. It can be detected by any of several phospholipid-dependent clotting tests, including the activated partial thromboplastin time, the dilute Russell viper venom time, the kaolin clotting time, and the plasma clotting time. It is necessary to do confirmatory testing because there are reasons other than LA for prolonged clotting times, such as a clotting factor deficiency or specific inhibitor. The assay for LA is interpreted as being *present* or *absent*.

ACAs are detected by a more traditional immunoassay. Results are reported as levels of antibody in GPL units for immunoglobulin G (IgG) or MPL units for immunoglobulin M (IgM). Medium or high positive levels of IgG antibodies are most strongly associated with the clinical disorders of antiphospholipid antibody syndrome (APS). This is typically at 40 GPL or higher.³⁸ The same is true for anti- β_2 -glycoprotein-1 antibodies, levels of which are reported in SGU and SMU units (e.g., ≥ 40 SGU).³⁸ As performed in most U.S. laboratories, LA is the aPL most specifically associated with APS.³⁹ However, most authorities advise testing for all three antibodies if APS is

suspected. Positive results for aPL may be transient, especially in the setting of infection. Testing should be repeated in 6 to 12 weeks to confirm the finding.³⁷

Antiphospholipid Antibody Syndrome

In a manner similar to that for lupus, the diagnosis of APS requires specific clinical features and supportive laboratory testing (Box 53-1).^{38,40} APS requires the presence of at least one clinical criterion (i.e., confirmed thrombosis or pregnancy morbidity) and one laboratory criterion (i.e., LA, ACA, or anti- β_2 -glycoprotein-1 antibody). However, the finding of thrombosis must take into account risk factors that lessen the certainty of the diagnosis (see Box 53-1). Uteroplacental insufficiency may be recognized by the sequelae of abnormal fetal surveillance tests suggesting fetal hypoxemia, abnormal Doppler velocimetry suggesting fetal hypoxemia, oligohydramnios (i.e., amniotic fluid index \pm 5 cm), or birth weight less than the 10th percentile in the absence of other causes for poor fetal growth. Diagnosis of APS should not be made if less than 12 weeks or more than 5 years separates the positive aPL test result and the clinical manifestation.

As with all syndromes, the relevance of a positive laboratory test in the absence of clinical features of the syndrome is uncertain. Some aPLs, especially low levels of the IgM isotype of ACAs, can be found in a few percent of healthy individuals.⁴¹ Many patients with APS also have systemic lupus erythematosus (SLE) and are considered to have secondary APS. APS in the absence of another autoimmune condition is primary APS.

Clinical Features

Medical Complications. A characteristic feature of thromboses associated with aPLs is that they can be venous or arterial. Approximately two thirds of the events are venous, and the most common site is deep in the lower extremity. Up to 50% of venous thromboses are pulmonary emboli, but thromboses in unusual locations also are common. It is estimated that aPLs are present in about 2% of individuals with unexplained thromboembolism.⁴² Arterial thromboses also are common; the most frequent type of arterial thrombosis in patients with APS is a cerebrovascular accident. Symptoms may include transient ischemic attacks and amaurosis fugax. Coronary occlusions and arterial thromboses in atypical sites also may occur. About 4% to 5% of cerebrovascular accidents in patients younger than 50 years of age are associated with aPLs.^{43,44}

A meta-analysis of 18 studies examining the thrombotic risk among SLE patients with LA found an odds ratio (OR) of 6.32 (95% confidence interval [CI], 3.71 to 10.78) for a venous thrombosis and an odds ratio of 11.6 (CI, 3.65 to 36.91) for recurrent venous thrombosis.⁴⁵ In contrast, ACAs were associated with lower odds ratios of 2.50 (CI, 1.51 to 4.14) for an acute VTE and 3.91 (CI, 1.14 to 13.38) for recurrent venous thrombosis. A meta-analysis of studies involving more than 7000 patients in the general population identified a range of odds ratios for arterial and venous thromboses in patients with LA: 8.6 to 10.8 and 4.1 to 16.2, respectively.³⁹ The comparable numbers for ACAs were 1 to 18 and 1 to 2.5. There appears to be a consistently greater risk of VTE associated with LA compared with isolated ACAs. Recurrence risks of up to 30% have been reported for affected patients, and long-term prophylaxis is required.⁴⁶ The risk of VTE in pregnancy and the puerperium for women with APS is uncertain but estimated to be between 5% and 12%.^{47,48}

BOX 53-1 REVISED CLASSIFICATION CRITERIA FOR DIAGNOSIS OF THE ANTIPHOSPHOLIPID ANTIBODY SYNDROME

CLINICAL CRITERIA*

1. Vascular thrombosis[†]: One or more clinical episodes of arterial, venous, or small-vessel thrombosis; any tissue or organ confirmed by objective, validated criteria (i.e., unequivocal findings of appropriate imaging studies or histopathology)
2. Pregnancy morbidity
 - a. One or more unexplained deaths of a morphologically normal fetus at or beyond 10 weeks' gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus, or
 - b. One or more premature births of a morphologically normal neonate before 34 weeks' gestation because of (i) eclampsia or severe preeclampsia or (ii) recognized uteroplacental insufficiency, or
 - c. Three or more unexplained consecutive euploid spontaneous abortions before 10 weeks' gestation, with maternal anatomic or hormonal abnormalities and paternal and parental chromosomal causes excluded

LABORATORY CRITERIA*

1. Lupus anticoagulant present in plasma on two or more occasions at least 12 weeks apart, detected according to the guidelines of the ISTH Scientific Subcommittee on Lupus Anticoagulants/Phospholipid-Dependent Antibodies
2. ACAs of the IgG or IgM isotype in serum or plasma, present in medium or high titers (i.e., >40 GPL or MPL, or >99th percentile), on two or more occasions at least 12 weeks apart as measured by a standardized ELISA
3. Anti- β_2 -glycoprotein-1 antibody or IgG or IgM isotype in serum or plasma (in a titer >99th percentile), present on two or more occasions at least 12 weeks apart as measured by a standardized ELISA according to recommended procedures

*A diagnosis of antiphospholipid antibody syndrome (APS) requires at least one clinical criterion and one laboratory criterion to be met.

[†]Coexisting inherited and acquired factors for thrombosis are not reasons for excluding patients from APS trials. However, two subgroups of APS patients should be recognized according to (1) the presence or (2) the absence of additional risk factors for thrombosis. Risk factors include older age (>55-year-old men, >65-year-old women), any risk factor for cardiovascular disease (e.g., hypertension, diabetes mellitus, elevated LDL or low HDL cholesterol, cigarette smoking, family history of premature cardiovascular disease, BMI \geq 30 kg/m², microalbuminuria, estimated GFR < 60 mL/min), inherited thrombophilias, oral contraceptive use, nephrotic syndrome, malignancy, immobilization, and surgery. Patients who fulfill these criteria should be stratified according to contributing causes of thrombosis.

[‡]Investigators are strongly advised to classify APS patients in studies as follows: I, more than one laboratory criterion present (any combination); IIa, lupus anticoagulant present alone; IIb, ACA present alone; IIc, anti- β_2 -glycoprotein-1 antibody present alone.

ACAs, anticardiolipin antibodies; BMI, body mass index; ELISA, enzyme-linked immunosorbent assay; GFR, glomerular filtration rate; GPL; IgG phospholipid units; HDL, high-density lipoprotein; IgG, immunoglobulin G; IgM, immunoglobulin M; ISTH, International Society on Thrombosis and Haemostasis; LDL, low-density lipoprotein; MPL, IgM phospholipid units.

Modified from Miyakis S, Lockshin MD, Atsumi D, et al: International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome (APS), *J Thromb Haemost* 4:295–306, 2006.

Autoimmune thrombocytopenia is a frequent medical complication of APS, occurring in almost one half of cases.⁴⁹ The condition is hard to distinguish from idiopathic thrombocytopenic purpura and is treated in a similar fashion. Other medical disorders associated with aPLs include autoimmune hemolytic anemia, livedo reticularis, chorea gravidarum, transverse myelitis, pyoderma-like leg ulcers, and cardiac valve disease. Some individuals have a life-threatening systemic illness—catastrophic APS—that is caused by multiple thromboses of the small and large vessels. Characterized by cardiopulmonary insufficiency, renal failure, and fever, catastrophic APS often occurs after delivery.^{50,51}

Obstetric Complications. The aPLs are associated with numerous obstetric complications, including recurrent pregnancy loss, fetal death, preeclampsia, intrauterine growth restriction (IUGR), abruption, and abnormal fetal test results. These conditions increase the risk of medically indicated preterm birth. In untreated patients, LA is associated with an odds ratio for fetal loss after the first trimester of 3.0 to 4.8.³⁹ The odds ratios for fetal loss for women with ACAs range from 0.86 to 20.0.³⁹ Detection of aPLs is more strongly associated with fetal death after 10 weeks' gestation than with early pregnancy loss (e.g., implantation failures, pre-embryonic losses, embryonic demises).⁵² At least 50% of pregnancy losses for patients with aPLs occur after the 10th week of gestation.⁵³ Compared with patients who have unexplained first-trimester spontaneous abortions without aPLs, those with antibodies more often have demonstrable embryonic cardiac activity (86% versus 43%; $P < .01$).⁵⁴ It is clear that aPLs are not associated with sporadic early pregnancy loss.⁵⁵ This is expected because most losses are caused by genetic abnormalities. There is some association between aPLs and recurrent and otherwise unexplained early pregnancy loss, but whether patients with recurrent early pregnancy loss truly have APS remains controversial.⁵⁶

The association between aPLs and infertility is uncertain. Increased levels of aPLs have been reported in women with infertility.^{57,58} However, a meta-analysis of seven studies of affected patients undergoing in vitro fertilization found no significant association between aPLs and clinical pregnancy (OR = 0.99; CI, 0.64 to 1.53) or live birth rate (OR = 1.07; CI, 0.66 to 1.75).⁵⁹ There is no evidence that treating patients who have aPLs with anticoagulant medications improves the outcomes of in vitro fertilization.⁶⁰

Women with APS who have pregnancies reaching viability are at increased risk for obstetric outcomes associated with abnormal placentation, such as preeclampsia and IUGR. Up to 50% of pregnant women with APS develop preeclampsia, and one third of pregnancies have IUGR.⁴⁷ Abnormal fetal heart rate tracings prompting cesarean delivery are also common. Conversely, most cases of preeclampsia and IUGR occur in women without aPLs. Although increased positive test results for aPLs have been reported for women with preeclampsia, especially for those with severe disease with onset before 34 weeks' gestation⁶¹ and IUGR, most large, retrospective and prospective studies have not found an association between these conditions and APS.⁶² This is not surprising, given the common occurrence of preeclampsia and IUGR and the relative infrequency of APS.

Pathophysiology

The mechanisms of thrombosis and pregnancy loss associated with aPLs are uncertain. Many mechanisms have been proposed

for aPL-mediated arterial and venous thrombosis. For example, aPLs directly inhibit the anticoagulant effects of anionic phospholipid-binding proteins such as β_2 -glycoprotein-1 and annexin V.^{63,64} The aPLs appear to inhibit thrombomodulin, activated protein C, and AT activity; to induce TE, PAI-1, and vWF expression in endothelial cells; and to augment platelet activation. These mechanisms may play a role in the pathophysiology of pregnancy complications. Although it is an oversimplification, thrombosis in the uteroplacental circulation may lead to placental infarction and insufficiency. Inflammation in the placenta appears to make an important contribution to abnormal pregnancy in women with APS. The activation of complement by aPLs was critical for aPL-induced pregnancy loss and IUGR in a murine model.^{65,66} Complement activation also has been reported in humans with APS.⁶⁷

Obstetric Management

The first consideration in the medical management of APS during pregnancy is whether the patient has had a prior thrombosis. All individuals with APS should undergo lifelong anticoagulation, typically with Coumadin. They should be treated with full anticoagulant doses of unfractionated heparin (UH) or low-molecular-weight heparin (LMWH) for the entire pregnancy, and anticoagulation with Coumadin is reinitiated after delivery. The optimal treatment for women with APS but no prior thrombosis is less clear. Most authorities advise using a thromboprophylactic dose of UH or LMWH during pregnancy through 6 weeks after delivery. This approach is used to reduce the risk of thrombosis and to improve the obstetric outcome. Appropriately designed trials have never been conducted with women who had medical and obstetric APS.⁴⁷ Given the small study sizes, weak study designs, lack of contemporary controls, and heterogeneity of the enrollment criteria and therapies employed, it is difficult to make definitive, evidence-based recommendations for treatment.⁶⁸ Chapter 44 provides a more detailed discussion of this topic.

Patients with APS and no prior thromboses are at long-term increased risk for thromboembolism. Most authorities advise against the use of estrogen-containing contraceptives in women with APS.⁶⁹ Progestin-containing agents are not contraindicated. The risk for non-obstetric complications such as thrombocytopenia and SLE also are increased. Counseling regarding non-obstetric issues and referral to an internist with expertise in APS is advised after delivery.

INHERITED THROMBOPHILIAS

Inherited thrombophilias are associated with VTE. However, the incidence of VTE among patients with an inherited thrombophilia depends on the potency of the thrombophilia and the exposure to other external risk factors (e.g., surgery, casts, immobilization, exogenous estrogen). Because thrombophilias predispose to the development of thrombosis in the slow-flow circulation of leg veins, the hypothesis that thrombophilias may lead to thrombosis in the slow-flow circulation of the placenta and to the consequent placenta-mediated complications appears plausible. However, this idea remains controversial and its application unclear for most thrombophilias and most pregnancy complications.⁷⁰

Early pregnancy is associated with a low-oxygen environment, with intervillous oxygen pressures of 17.9 ± 6.9 mm Hg at 8 to 10 weeks and rising to 60.7 ± 8.5 mm Hg at 12 to 13

weeks.⁷¹ Trophoblast plugging of the spiral arteries has been demonstrated in placental histologic studies before 10 weeks' gestation, and low Doppler flow is observed in the uteroplacental circulation before 10 weeks.⁷² The undetectable levels of superoxide dismutase in trophoblast before 10 weeks' gestation are consistent with a hypoxic state.⁷³ If factor V Leiden (FVL) or other thrombophilias are associated with early pregnancy loss, it is most likely through mechanisms other than placental thrombosis. Because most early pregnancy losses are associated with aneuploidy, thrombophilias are unlikely to play a role. In contrast, uteroplacental thrombosis after 9 weeks would be expected to reduce oxygen and nutrient delivery to a progressively larger embryo, accounting for the apparent link between FVL and other maternal thrombophilias and later adverse pregnancy outcomes.

Thrombin plays a central role in the coagulation component of hemostasis. It also appears that thrombin is necessary in normal placental development. TF, the most important initiator of coagulation, is constitutively expressed on almost all cells other than endothelial cells.⁷⁴ The maternal-fetal placental interface develops as the fetal-derived trophoblasts invade endometrial tissue.⁷⁵ The placental end product includes fetal trophoblastic tissue in direct contact with maternal blood in the intervillous space, which is fed by the spiral arteries that are offshoots of the maternal uterine artery.⁷⁵

Isermann and colleagues⁷⁶ demonstrated that knockout mice that do not express thrombomodulin on trophoblasts have inadequate placentation, which leads to embryonic lethality early in gestation. This embryonic lethality depends on TF expression on the trophoblast cells and thrombin generation. In thrombomodulin-deficient mice, embryonic lethality does not depend on fibrinogen and cannot be ameliorated with heparin. Giant trophoblast cells apoptose when exposed to fibrin degradation products, and trophoblast cell growth is arrested after engagement of PAR-2 and PAR-4. Because embryonic thrombomodulin deficiency is not associated with fibrin deposition in the developing placenta or placental thrombosis, mechanisms other than overt placental thrombosis must be responsible for embryonic lethality.⁷⁷ Li and coworkers showed that the embryonic lethality associated with deletion of the *PROCR* gene, which encodes an endothelial cell surface protein receptor for activated protein C that enhances activation of the protein, can be rescued by *PROCR* gene expression on trophoblasts and by genetically modifying TF expression.⁷⁸ Sood and

associates showed that PAR-4 deficiency in the mother or platelet deficiency can partially rescue thrombomodulin-deficient mice.⁷⁹

The net effect appears to be an autocrine loop whereby placental growth is enhanced by contact of maternal blood and fetal cells through the intermediary of the hemostatic system. Trophoblasts constitutively express TF (unlike endothelial cells) and have abundant thrombomodulin, PAR-1, and PROCR, and they are in contact with maternal blood. It is likely that thrombin, generated by contact of maternal blood and trophoblasts, binds to thrombomodulin, leading to the generation of activated protein C and its binding to PROCR. This complex then activates G protein-coupled protease-activated receptors PAR-1 and PAR-2, leading to cell signaling that promotes trophoblast cell growth and differentiation.⁸⁰ Thrombin can also bind to PAR-4 on maternal platelets and, through an unknown mechanism, influence trophoblast cell growth and differentiation.⁷⁹ Placental development and maternal hemostasis are intimately tied, but much remains to be discovered before it is appropriate to extrapolate this knowledge to clinical practice.

Factor V Leiden Mutation

Occurring in about 5% of Europeans and 0.8% of African Americans, FVL is the most common of the serious inheritable thrombophilias.^{81,82} The mutation is rare in African blacks, Chinese, Japanese, and other Asians. The mutation leads to a substitution of glutamine for arginine at position 506 at the site of proteolysis and inactivation by activated protein C. The FVL mutation is the leading cause of activated protein C resistance. The heterozygous state leads to a fivefold increased risk of VTE with a lifetime incidence of about 35%, whereas homozygous patients have a 25-fold increased risk with a lifetime VTE incidence of about 65% (Table 53-1). FVL thrombophilia is associated with approximately 40% of the VTE events among pregnant patients.⁸³ However, given the low prevalence of VTE in pregnancy and during the puerperium (1 case per 1400) and the high incidence of the mutation in the European-derived population, the risk of pregnancy-associated VTE among FVL heterozygotes without a personal history of VTE or an affected first-degree relative is less than 0.3%.⁸³ The risk appears to be at least 10% among pregnant women who have a personal history of VTE or an affected first-degree relative.⁸⁴ Pregnant homozygous patients without a personal history of VTE or an affected first-degree relative have a 1.5% risk of VTE in

TABLE 53-1 Inherited Thrombophilias Associated with Venous Thromboembolism in Pregnancy

Thrombophilia	Relative Risk of VTE (95% CI)	Probability (%) of VTE without or with a Personal History of VTE or a First-Degree Relative with VTE		
		Without	With	Reference
FVL (homozygous)	25.4 (8.8 to 66)	1.5	17	46
FVL (heterozygous)	5.3 (3.7 to 7.6)	0.20-0.26	10	45, 46
PGM (homozygous)	NA	2.8	>17	46
PGM (heterozygous)	6.1 (3.4 to 11.2)	0.37	>10	45, 46
FVL/PGM (double heterozygous)	84 (19 to 369)	4.7	NA	46
Antithrombin deficiency (<60% activity)	119	3.0-7.2	>40	46, 47
Protein S deficiency (<55% activity)	NA	<1	6.6	46, 47
Protein C deficiency (<50% activity)	13.0 (1.4 to 123)	0.8-1.7	2-8	46, 47

CI, confidence interval; FVL, factor V Leiden mutation; NA, not available; PGM, prothrombin gene mutation; VTE, venous thromboembolism.

pregnancy; if there is a personal or family history of VTE, the risk was 17% in one study (see Table 53-1). Screening can be done by assessing activated protein C resistance using a second-generation coagulation assay, followed by genotyping for the FVL mutation if the resistance is found in a pregnant or nonpregnant woman. Alternatively, patients can be genotyped for the FVL mutation.

FVL thrombophilia appears to be associated with early and late pregnancy loss. Individual case-control studies variably demonstrate an association between pregnancy loss and thrombophilia, but meta-analyses show a weak positive association.^{85,86} In a meta-analysis of 31 studies, FVL thrombophilia was associated with early (<13 weeks) pregnancy loss (OR = 2.01; CI, 1.13 to 3.58), but it was more strongly associated with late (>19 weeks), nonrecurrent fetal loss (OR = 3.26; CI, 1.82 to 5.83).⁸⁵ Multivariate analysis of a nested case-control study revealed an association between FVL thrombophilia and pregnancy loss after 10 weeks (OR = 3.46; CI, 2.53 to 4.72) but not for losses occurring between 3 and 9 weeks.⁸⁷ These results strongly suggest that FVL thrombophilia is associated with fetal (>9 weeks) but not embryonic (<9 weeks) losses.

Case-control studies may be limited by retrospective data collection, leading to potential bias in outcome classification and imperfect ascertainment of exposures and confounders, and by possible differential participation bias when more severe cases are recruited. Prospective cohort studies limit these potential biases but have limited power to detect weak associations.⁸⁸ Prospective cohort studies provide absolute risk estimates that can be used to counsel patients, whereas case-control studies provide only odds ratios for an exposure.

A systematic review and a meta-analysis of prospective cohort studies to estimate the risk of pregnancy loss in women with or without the FVL mutation was published in 2010.⁸⁹ The data extracted on pregnancy loss included spontaneous miscarriage (i.e., involuntary termination of pregnancy before 20 weeks' gestation, dated from the last menstrual period, or below a fetal weight of 500 g^{90,91}) and stillbirth (i.e., complete expulsion or extraction of a dead fetus at or after 20 weeks' gestation or when the fetal weight was at least 500 g in cases in which the gestational age was not known).⁹² Because most women were recruited in the late first trimester or second trimester, this meta-analysis provides limited information on early pregnancy loss. Seven studies reported information on pregnancy loss. Most studies included patients with spontaneous miscarriage or stillbirth as pregnancy losses, but there were important inconsistencies in the definition of this outcome. There was substantial statistical heterogeneity across studies ($I^2 = 51.0\%$; $P = .06$). The pooled odds ratio estimate from these seven studies is 1.52 (CI, 1.06 to 2.19) for a total of 16,959 women with an observed FVL mutation prevalence of 4.7%. This meta-analysis showed that FVL status was likely weakly associated with pregnancy loss after the first trimester. Despite demonstrating that the odds of pregnancy loss in women with the FVL mutation was 52% higher than for women without it, women with the mutation should be reassured that the absolute event rate for later pregnancy loss is low (4.2%) and is only slightly higher than the rate of later pregnancy loss in women without FVL thrombophilia (3.2%).

The correlation between FVL status and other later adverse pregnancy events is more controversial. In the early 1990s, Kupferminc and associates studied 110 women and reported a link between FVL mutation carriage and severe preeclampsia (OR =

5.3; CI, 1.8 to 15.6).⁹³ However, multiple case-control studies have failed to confirm a link between FVL positivity and moderate or severe preeclampsia.⁹⁴⁻⁹⁶ Dudding and Attia's meta-analysis estimated a 2.9-fold (CI, 2.0 to 4.3) increased risk of severe preeclampsia among FVL mutation carriers.⁹⁷ Similarly, Lin and August conducted a meta-analysis of 31 studies involving 7522 patients and reported pooled odds ratios of 1.81 (CI, 1.14 to 2.87) for FVL and all forms of preeclampsia and 2.24 (CI, 1.28 to 3.94) for FVL carriage and severe preeclampsia.⁹⁸ However, Kosmas and coauthors evaluated 19 studies involving 2742 hypertensive women and 2403 controls. Whereas the studies published before 2000 found a modest association between FVL thrombophilia and preeclampsia (OR = 3.16; CI, 2.04 to 4.92), those published after 2000 did not (OR = 0.97; CI, 0.61 to 1.54).⁹⁹ This suggests a reporting bias. Kahn and colleagues conducted a prospective, multicenter, cohort study of 5337 pregnant women, 113 of whom developed preeclampsia, and found that inherited thrombophilias, including FVL, occurred in only 14% of cases and 21% of controls (adjusted logistic regression OR = 0.6; CI, 0.3 to 1.3).¹⁰⁰

In a systematic review and meta-analysis of prospective cohort studies,¹⁰¹ the highest quality of evidence for association, data were extracted on preeclampsia, defined as systolic blood pressure of 140 mm Hg or higher or a diastolic blood pressure of 90 mm Hg or higher occurring after 20 weeks' gestation in a woman whose blood pressure had previously been normal, plus proteinuria, with excretion of 0.3 g or more of protein in a 24-hour urine specimen or proteinuria of $\geq 2+$ by dipstick.^{102,103} The cohorts were homogeneous and consistent in terms of participants, exposures, and outcomes. Participants were women with spontaneous singleton pregnancy in their first or second trimester, except for one study in which all patients were enrolled before 8 weeks' gestation.¹⁰⁴

In 10 studies that reported information on preeclampsia, harboring the FVL mutation did not significantly increase the risk of preeclampsia (estimated pooled OR = 1.23; CI, 0.89 to 1.70) among 21,833 total women with an FVL mutation prevalence of 4.9%. The absolute risk of preeclampsia in FVL-positive women was 3.8%, compared with 3.2% for FVL-negative women. There was no statistical heterogeneity across studies, and the definition of the outcome preeclampsia was fairly consistent across the studies. This meta-analysis had more than 90% power to detect an absolute increase of 2% (from control value of 3.2% to FVL value of 3.2% + 2% = 5.2%) in the rate of preeclampsia among women with the FVL mutation, but it did not detect an increased risk. This information should allow clinicians to provide reassurance to women with the FVL mutation that they are not at significantly increased risk for preeclampsia. However, it remains possible that there is an association between the FVL variant and severe or early-onset preeclampsia without an apparent association with unselected preeclampsia.

There is even less consistent evidence for an association between the FVL mutation and IUGR. A small case-control study reported a strong association between the FVL variant and IUGR (OR = 6.9; CI, 1.4 to 33.5) with a very wide confidence interval, reflecting the fact that there were only eight cases with the FVL mutation.¹⁰⁵ However, multiple, large, case-control and cohort studies have reported no statistically significant association between the FVL mutation and IUGR of less than the 10th or less than the 5th percentile.^{93,96,106} Howley and

colleagues conducted a systematic review of studies describing the association between the FVL mutation and IUGR; among 10 case-control studies meeting the selection criteria, there was a significant association between the FVL mutation and IUGR (OR = 2.7; CI, 1.3 to 5.5).¹⁰⁷ However, no association was found among five cohort studies, of which three were prospective and two retrospective (RR = 0.99; CI, 0.5 to 1.9). The investigators suggested that the putative association between IUGR and the FVL mutation was most likely driven by small, poor-quality studies that demonstrated extreme associations. Facco and colleagues also conducted a meta-analysis of case-control and cohort studies that examined the relationship between IUGR and carrying an FVL mutation and reported an odds ratio of 1.23 (CI, 1.04 to 1.44), but they observed that this linkage was mainly driven by the case-control studies, suggesting a publication bias.¹⁰⁸

In the systematic review and meta-analysis of prospective cohort studies previously described,¹⁰¹ data were extracted for a small-for-gestational-age (SGA) birth, which was defined as a birth weight less than the 10th percentile of population-specific birth weight adjusted for gender and gestational age, and for a severe SGA birth, defined as a birth weight less than 5th percentile of the population-specific and gender- and gestational age-adjusted birth weight.^{109,110} The cohorts were homogeneous and studies consistent in terms of participants, exposures, and outcomes. Participants were women with a spontaneous singleton pregnancy in the first or second trimester, except for one study in which all patients were enrolled before 8 weeks' gestation.¹⁰⁴ Seven studies reported information on SGA births and FVL thrombophilia.^{82,111-116} Occurrence of the FVL mutation did not significantly increase the risk of SGA (estimated pooled OR = 1.0; CI, 0.80 to 1.25) among 20,654 total women with an FVL mutation prevalence of 6.0%. The absolute risk of SGA births below the 10th percentile among women with the FVL variant was 6.5%, compared with 7.4% for FVL-negative women. Five studies reported FVL status and severe SGA status (i.e., birth weight below the 5th percentile)^{20,28-30,33} for a total of 12,936 women; FVL prevalence was 4.9%. The absolute risk of an SGA birth below the 5th percentile among FVL-positive women was 3.8%, compared with 4.3% for FVL-negative women. The combined odds ratio for this population showed no significant association between FVL status and SGA in the less than 5th percentile (pooled OR = 0.92; CI, 0.61 to 1.40). This study failed to demonstrate an association between FVL status and SGA but had more than 90% power to detect an absolute increase of 3% (from a control value of 7.4% to an FVL value of 7.4% + 3% = 10.4%) in the rate of SGA births (<10th percentile) among women with the FVL mutation. This finding should allow clinicians to provide reassurance to women positive for the FVL mutation that they are not at increased risk for giving birth to an SGA child.

Kupferminc and colleagues reported a modest association between positive FVL status and abruption (OR = 4.9; CI, 1.4 to 17.4).⁹³ A second case-control study found that 17 of 27 patients with abruption had activated protein C resistance, compared with 5 of 29 control subjects (OR = 8.16; CI, 3.6 to 12.75), and 8 patients were found to have the FVL mutation, compared with 1 control.¹¹⁷ Prochazka and associates conducted a retrospective case-control study among 180 women with placental abruption and 196 controls and found a significantly increased incidence of FVL carriage among cases compared with controls (14.1% versus 5.1%; OR = 3.0; CI, 1.4 to

6.7).¹¹⁸ Alfrevic and coworkers conducted a meta-analysis that revealed a strong association between placental abruption and homozygosity and heterozygosity for the FVL mutation (OR = 16.9; CI, 2.0 to 141.9 and OR = 6.7; CI, 2.0 to 21.6, respectively).¹¹⁹

In the previous meta-analysis of prospective cohort studies,¹⁰¹ five studies evaluated the association between the FVL mutation and placental abruption.^{82,104,111,113,114} These studies included 12,308 women with a pooled FVL mutation prevalence of 5.1%. The absolute risk of placental abruption in FVL-positive women was 1.3%, compared with 0.9% for FVL-negative women. The pooled odds ratio estimate for placental abruption among women with the FVL mutation (homozygous or heterozygous) was 1.85 (CI, 0.92 to 3.70). The moderate statistical heterogeneity ($I^2 = 33%$) identified may be attributable to the inconsistent and unclear definition of placental abruption across studies. The meta-analysis had inadequate power to detect a doubling of risk of placental abruption among women with FVL due to small sample sizes and low event rates limiting the conclusions regarding an association between FVL and placenta abruption. Further research is required to determine whether FVL status is truly associated with placental abruption.

In summary, there appears to be a modest association between the FVL mutation and pregnancy loss. However, no clear association exists between FVL status and preeclampsia or SGA births, although studies have been underpowered to definitely exclude a link with severe, early-onset preeclampsia, with severe SGA (<3%), or with placental abruption. A possible association between FVL status and abruption warrants further study. Although the FVL mutation is associated with pregnancy loss, most affected individuals without such prior obstetric complications are at low risk for subsequent adverse pregnancy outcomes. FVL and other thrombophilias should be thought of as a risk factor for rather than a cause of pregnancy loss and possibly other severe adverse outcomes, similar to risk factors such as maternal age and obesity.

Other Factor V Mutations

Other mutations in the factor V gene have been variably linked to maternal VTE and adverse pregnancy outcomes. The factor V HR2 haplotype (A4070G) decreases factor V cofactor activity in the activated protein C-mediated degradation of factor VIIIa; however, a meta-analysis demonstrated no statistically significant association between the HR2 haplotype and the risk of VTE (OR = 1.15; CI, 0.98 to 1.36).¹²⁰ There are conflicting reports about the linkage of the factor V HR2 haplotype and recurrent pregnancy loss. Zammiti and associates reported no association with losses before 8 weeks, but homozygosity for the factor V HR2 haplotype was associated with significant and independent risks of pregnancy loss during weeks 8 and 9, which increased during weeks 10 to 12 and culminated after 12 weeks.¹²¹ In contrast, Dillely and colleagues found no association between carriage of the factor V HR2 haplotype and pregnancy loss.¹²² The study sample sizes were too small to allow firm conclusions about the link between factor V HR2 haplotype and other adverse pregnancy outcomes.

Two other mutations in the factor V gene that occur at the second activated protein C cleavage site, factor V R306G Hong Kong and factor V R306T Cambridge, have been described but do not appear to be strongly associated with VTE.¹²³ The data are inadequate to assess any link between these mutations and adverse pregnancy outcomes.¹²¹

Prothrombin Gene Mutation

The prothrombin G20210A polymorphism is a point mutation causing a guanine to adenine switch at nucleotide position 20,210 in the 3'-untranslated region of the gene (*F2*).⁸¹ This nucleotide switch results in increased translation, possibly due to enhanced stability of messenger RNA (mRNA). As a consequence, there are increased circulating levels of prothrombin. Although the mutation occurs in only 2% to 3% of Europeans, it is associated with 17% of VTEs during pregnancy.⁸³ As was the case with FVL, the risk of VTE in pregnant patients who are heterozygous for the G20210A prothrombin gene mutation (PGM) but who do not have a personal or strong family history of VTE is less than 0.5%.⁸³ Pregnant PGM-heterozygous patients with a history of VTE have at least a 10% risk of VTE.⁸⁴ PGM-homozygous patients without a personal or strong family history have a 2.8% risk of VTE in pregnancy, whereas such a history probably confers a risk of at least 20% (see Table 53-1). Because the combination of FVL and PGM has synergistic hypercoagulable effects, double heterozygotes are at greater thrombotic risk than FVL or PGM homozygotes. Pregnant patients who are double heterozygotes without a personal or strong family history have a 4.7% risk of VTE.^{83,84}

The PGM has been associated with an increased risk of pregnancy loss in multiple case-control studies. One study reported the presence of the PGM in 7 of 80 patients with recurrent miscarriage, compared with 2 of 100 control patients (9% versus 2%; $P = .04$; OR = 4.7; CI, 0.9 to 23).¹²⁴ Finan and associates also found an association between PGM and recurrent abortion, with an odds ratio of 5.05 (CI, 1.14 to 23.2).¹²⁵ However, other studies have failed to identify a link.^{126,127} A 2004 meta-analysis of seven studies evaluating the correlation between PGM and recurrent pregnancy loss, defined as two or more losses in the first or second trimester, found a combined odds ratio of 2.0 (CI, 1.0 to 4.0).¹²⁸ Analogous to FVL, the association between PGM and pregnancy loss increases with increasing gestational age. In the meta-analysis by Rey and colleagues, an association was reported between PGM and recurrent loss before 13 weeks' gestation (OR = 2.3; CI, 1.2 to 4.79), but as with FVL, a stronger association was observed between PGM and recurrent fetal loss before 25 weeks (OR = 2.56; CI, 1.04 to 6.29).⁸⁵ PGM appears to fit the pattern displayed by FVL carriers of progressively greater risk of fetal loss with advancing gestation; however, these risks remain quite modest.

In a systematic review and meta-analysis of prospective cohort studies,¹⁰¹ the highest quality of evidence for association, only four studies evaluated the association of PGM and pregnancy loss; they reported a pooled odds ratio estimate of 1.13 and wide 95% confidence intervals (0.64 to 2.01). With a pooled PGM prevalence of 2.9% in a sample size of 9225, the meta-analysis had only 80% power to detect an absolute increase of more than 4% from the observed control group event pregnancy loss rate of 3.6%, and it therefore had limited power to detect important differences in the absolute risk of pregnancy loss (1% or 2%) among women with the PGM.

Other case-control studies and meta-analyses have failed to establish a link between PGM and preeclampsia or severe preeclampsia.^{93,96,98,129,130} In the meta-analysis of prospective cohort studies,¹⁰¹ six studies evaluated PGM status and preeclampsia and did not report a significant association between PGM (heterozygous or homozygous) and preeclampsia (pooled OR =

1.25; CI, 0.79 to 1.99) among 14,254 women with a PGM prevalence of 4.1%. The absolute risk of preeclampsia among women with the PGM was 3.5%, compared with 3.0% for PGM-negative women. The meta-analysis had more than 90% power to detect an absolute increase of 3% (from control value of 3.4% to the PGM value of 3.4% + 3.0% = 6.4%) in the rate of preeclampsia among women with PGM, but it did not detect an increased risk. This finding should allow clinicians to reassure women with these thrombophilias that they are not at significantly increased risk for preeclampsia. However, it remains possible that there is an association between the PGM and severe or early-onset preeclampsia without an apparent association with unselected preeclampsia. Further research is required to elucidate whether thrombophilias are associated with severe or early-onset preeclampsia.

A link between the PGM and SGA birth appears to have been excluded. Despite two small, positive studies,^{93,105} the large case-control study of Infante-Rivard and colleagues reported no link in heterozygotes between PGM and IUGR (OR = 0.92; CI, 0.36 to 2.35).¹⁰⁶ Similar results have been observed by others.¹³¹ In the meta-analysis of prospective cohort studies,¹⁰¹ five studies reported PGM status and SGA births below the 10th percentile¹¹³⁻¹¹⁶ among 17,287 total women with a PGM prevalence of 5.1%. The absolute risk of SGA births below the 10th percentile among women with PGM (heterozygous or homozygous) was 5.4%, compared with 5.7% for PGM-negative women. There was no significant association between PGM (heterozygous or homozygous) and SGA status below the 10th percentile (pooled OR = 1.25; CI, 0.92 to 1.70). The pooled odds ratio estimate of three studies reporting SGA births below the 5th percentile and PGM was 1.46 (CI, 0.81 to 2.62) among a total of 6285 women, with a prevalence of 3.3% for PGM. The prevalence of SGA births below the 5th percentile among women with PGM was 5.7%, compared with 4.3% for PGM-negative women. The meta-analysis had excellent power to detect an association, with more than 90% power to detect an absolute increase of 3% (from the control value of 5.4% to the PGM value of 5.4% + 3% = 8.4%) in the rate of SGA births (<10th percentile) among women with PGM, but it did not detect an increased risk. This information should allow clinicians to provide reassurance to women with PGM that they are not significantly more likely to give birth to an SGA child.

There are limited data on the association between PGM and abruptio. The case-control study of Kupferminc and coworkers found an association between the PGM and abruptio placentae (OR = 8.9; CI, 1.8 to 43),⁹³ whereas Prochazka and colleagues found no such link.¹¹⁸ Meta-analyses suggested a strong link between PGM heterozygosity and placental abruptio (OR = 28.9; CI, 3.5 to 236).¹¹⁹ In the meta-analysis of prospective cohort studies,¹⁰¹ the pooled odds ratio estimate for placental abruptio in women with the PGM (homozygous or heterozygous) was 2.02 (CI, 0.81 to 5.02), with moderate heterogeneity across studies ($I^2 = 49%$) and inadequate power to detect a doubling of risk of placental abruptio in women with the PGM.

In summary, there may be a weak association between the PGM and pregnancy loss and placental abruptio in case-control studies, but further prospective cohort studies are required to confirm this association. However, there does not appear to be a significant link between the PGM and SGA offspring or preeclampsia.

Hyperhomocysteinemia

Serum homocysteine levels are sensitive to dietary vitamin intake and are reduced by higher intakes of folic acid and vitamin B₁₂. Hyperhomocysteinemia can result from a number of mutations in the methionine metabolic pathway. Homozygosity for mutations in the methylenetetrahydrofolate reductase (*MTHFR*) gene is by far the most common cause. Homozygosity for the *MTHFR* C677T polymorphism occurs in 10% to 16% of all Europeans, and homozygosity for the A1298C mutation occurs in 4% to 6%.¹³² About 40% of whites are heterozygous for the C677T polymorphism, and most heterozygotes have normal levels of homocysteine. Moreover, because homocysteine levels decrease in pregnancy and U.S. diets are replete with folic acid supplementation, hyperhomocysteinemia is rare even among homozygotes. Although hyperhomocysteinemia is a risk factor for VTE (OR = 2.5; CI, 1.8 to 3.5),¹³³ *MTHFR* mutations do not appear to convey an increased risk for VTE in nonpregnant¹³⁴ or pregnant women.¹³⁵

As with thrombotic risk, meta-analyses suggest that elevated fasting homocysteine levels are more strongly associated with recurrent pregnancy loss (<16 weeks) than are *MTHFR* mutations, with an odds ratio of 2.7 (CI, 1.4 to 5.2) versus 1.4 (CI, 1.0 to 2.0), respectively.¹³⁶ The Hordaland Homocysteine Study assessed the relationship between plasma homocysteine values in 5883 women and their prior 14,492 pregnancy outcomes.¹³⁷ When the investigators compared the upper with the lower quartile of plasma homocysteine levels, elevated levels trended toward modest associations with preeclampsia (OR = 1.32; CI, 0.98 to 1.77), very low birth weight (OR = 2.01; CI, 1.23 to 3.27), and stillbirth (OR = 2.03; CI, 0.98 to 4.21), with various degrees of statistical significance determined by the method of analysis.¹³⁷ In contrast, a clear association was demonstrated between placental abruption and homocysteine levels greater than 15 $\mu\text{mol/L}$ (OR = 3.1; CI, 1.6 to 6.0), and a weaker but significant association was observed between homozygosity for the C677T *MTHFR* mutation and abruption (OR = 2.6; CI, 1.4 to 4.8).¹³⁸ A meta-analysis of these two risk factors found that hyperhomocysteinemia had a larger pooled odds ratio for abruption (OR = 5.3; CI, 1.8 to 15.9) than did homozygosity for the *MTHFR* mutation (OR = 2.3; CI, 1.1 to 4.9).¹³⁹

These studies suggest that hyperhomocysteinemia, but not merely the presence of *MTHFR* mutations, is linked to VTE and adverse pregnancy outcomes. Whereas homozygosity for *MTHFR* mutations is common in whites, hyperhomocysteinemia is rare. Screening for these mutations should be limited to those with a fasting homocysteine level greater than 12 mmol/L .¹³⁹

Antithrombin Deficiency

AT deficiency is the least common and the most thrombogenic of the heritable thrombophilias. More than 250 mutations have been identified in the AT gene, producing a highly variable phenotype. Disorders can be classified as type 1, those associated with reductions in antigen and activity; type 2, those associated with normal levels of antigen but decreased activity; and type 3, the rare homozygous deficiency associated with little or no activity.^{81,140} Complicating matters further, patients can acquire an AT deficiency due to liver impairment, increased consumption of AT associated with sepsis or DIC, or increased renal excretion in persons with severe nephrotic syndrome. Inherited and acquired AT deficiencies are associated with VTE.

Because screening for AT deficiency is done by assessing activity, its prevalence varies with the activity cutoff level employed (range, 0.02% to 1.1%). The recommended cutoff for abnormality is 50% activity, which is associated with a prevalence of 0.04% (1 of 2500 people).¹⁴⁰ Although it increases the risk of VTE up to 25-fold in the nonpregnant state,¹⁴⁰ because of its rarity, AT deficiency is associated with only 1% to 8% of VTE episodes.⁸¹ Pregnancy may increase its thrombogenic potential substantially (see Table 53-1). Moreover, use of a less stringent threshold yields a higher prevalence of AT deficiency among patients with VTE. For example, in one study, 19.3% of pregnant women with VTE had less than 80% AT activity,⁸³ but many of these cases might have been acquired due to clot-associated AT consumption. Conversely, the overall fraction of VTE in pregnancy associated with AT deficiency has been reported as 3% to 48%.^{83,141-143} The risk of VTE in pregnancy among AT-deficient patients most likely varies with a personal or family history (3% to 7% without such a history and up to 40% with such a history).⁸³

In the largest retrospective cohort study, AT deficiency was associated with a significantly increased risk of stillbirth after 28 weeks' gestation (OR = 5.2; CI, 1.5 to 18.1) but had a more modest association with miscarriage before 28 weeks (OR = 1.7; CI, 1.0 to 2.8).¹⁴⁴ Because of its rarity, there is a paucity of evidence concerning the link between AT deficiency and other adverse pregnancy outcomes. In a selected population referred to a maternal-fetal medicine academic practice, Roque and associates found it was associated with increased risks of IUGR (OR = 12.9; CI, 2.7 to 61), abruption (OR = 60; CI, 12 to 300), and preterm delivery (OR = 4.7; CI, 1.2 to 18).¹⁴⁵

Protein C Deficiency

Deficiency of protein C results from more than 160 distinct mutations, producing a highly variable phenotype. As occurs with AT deficiency, protein C deficiency can be associated with reductions in antigen and activity (type 1) or normal levels of antigen but decreased activity (type 2).⁸¹ The rare homozygous protein C deficiency results in neonatal purpura fulminans and a requirement for lifelong anticoagulation.¹⁴⁶ Activity levels can be ascertained by a functional (clotting) or chromogenic assay.

Estimates of prevalence and thrombotic risk reflect the cutoff values employed. Most laboratories use activity cutoff values of 50% to 60%, which are associated with prevalence estimates of 0.2% to 0.3% and relative risks for VTE of 6.5 to 12.5.^{81,140,147} The reported risk of VTE in pregnancy among protein C-deficient patients is 2% to 8%.^{141,148,149} Because of its rarity, there are few reports linking protein C deficiency to adverse pregnancy outcomes, and those that exist involve too few patients to allow firm conclusions.^{119,145} It is biologically plausible that protein C deficiency should pose risks of fetal loss and abruption analogous to those associated with the FVL mutation, but small sample sizes prevent firm conclusions regarding its link with preeclampsia or IUGR.

Protein S Deficiency

More than 130 mutations have been linked to deficiency of protein S.⁸¹ Most affected patients have low levels of total and free protein S antigen (type 1) or have only a low level of free protein S due to enhanced binding to the complement 4B-binding protein (type 2a). The latter condition is frequently caused by a serine 460 to proline mutation (i.e., protein S

Heerlen), which has been associated with the FVL or protein C mutation in about one half of affected patients.¹⁵⁰ As with protein C deficiency, homozygous protein S deficiency results in neonatal purpura fulminans.¹⁴⁶

Screening for protein S deficiency should not be done in pregnancy. Because protein S levels drop substantially during pregnancy and gestational age-specific levels have not been validated, testing during pregnancy leads to many false-positive results. Screening for protein S deficiency can be done with an activity assay, but this approach is associated with substantial interassay and intra-assay variability, in part because of frequently changing physiologic levels of complement 4B-binding protein.¹⁵¹ Detection of free protein S antigen levels lower than 55% in a nonpregnant woman is consistent with the diagnosis.^{151,152} Among patients with protein S deficiency and a strong family history of VTE, the risk of VTE in pregnancy is 6.6% (see Table 53-1).¹⁴⁸

The meta-analysis by Rey and colleagues reported an association between protein S deficiency and recurrent late (defined as more than 22, 23, or 27 weeks) fetal loss (OR = 14.7; CI, 0.99 to 218) and nonrecurrent fetal losses with the same gestational age criteria (OR = 7.4; CI, 1.3 to 43).⁸⁵ A second meta-analysis suggested an even stronger link between protein S deficiency and stillbirth (OR = 16.2; CI, 5.0 to 52), IUGR (OR = 10.2; CI, 1.1 to 91), and preeclampsia or eclampsia (OR = 12.7; CI, 4 to 39) but not with abruptio.¹¹⁹ The small sample sizes limit the ability to draw firm conclusions.

Mutations in Fibrinolytic Pathway Genes

Two polymorphisms (A675 4G/5G and A844G) in the promoter region of the PAI-1 gene have been described.¹⁵³ Homozygosity for the 4G/4G allele in the PAI-1 gene results in four instead of five consecutive guanine nucleotides in the promoter region, producing a site that is too small to permit repressor binding. Conversely, the A844G polymorphism affects a consensus sequence binding site for the regulatory protein ETS, enhancing PAI-1 gene transcription. The prevalence of the 4G/4G genotype in the general population is high, ranging from 23.5% to 32.3%.^{154,155} Most studies have not found an independent relationship between the 4G/4G polymorphism and the development of VTE in unselected patients.¹⁵⁶⁻¹⁵⁸ However, the 4G/4G genotype has been linked to an increased risk of VTE among patients with protein S deficiency or FVL mutation, suggesting that it plays an additive but not independent role in the pathogenesis of VTE.^{159,160} No relationship has been demonstrated between the A844G polymorphism and VTE.¹⁵⁶

There are limited data on the association between the 4G allele and a variety of adverse pregnancy outcomes. No statistically significant association was found between isolated homozygosity for the 4G/4G genotype and recurrent spontaneous abortion in several small studies.^{161,162} Several small studies have found modest positive associations between the 4G/4G genotype and some adverse pregnancy outcomes, sometimes in combination with other mutations.^{154,163,164} However, a prospective cohort study of more than 1700 nulliparas enrolled at a mean gestational age of 11.2 weeks found no increase in adverse pregnancy outcomes associated with heterozygosity or homozygosity for the 4G allele.¹⁶⁵

Polymorphisms have been described in the TAFI (*CPB2*) and tPA (*PLAT*) genes. However, no clear link has been established for either with increased VTE risk or adverse pregnancy outcomes.

Other Thrombophilic Mutations

The -455GtoA polymorphism in the fibrinogen β -chain gene (*FGB*) leads to increased plasma fibrinogen levels but an unclear thrombotic risk.¹⁶⁶ The apolipoprotein B R3500Q and E2/E3/E4 polymorphisms and the platelet receptor gene polymorphisms GpIIIa L33P and GpIa 807CtoT confer an uncertain VTE risk, although they may contribute to coronary and cerebral artery thrombosis, particularly in the presence of other risk factors, such as smoking, hypertension, obesity, and diabetes. The common hereditary hemochromatosis gene (*HFE* gene C282Y mutation) does not appear to be a risk factor for VTE, even when it occurs in patients with FVL.¹⁶⁷ An analysis of links between fetal loss and β -fibrinogen-455GtoA, between apolipoprotein B R3500Q and E2/E3/E4, and between GpIIIa L33P and *HFE* C282Y found no significant associations.¹⁶⁸

Polymorphisms have been described in the thrombomodulin (*THBD*), tissue factor pathway inhibitor (*TFPI*), and endothelial protein C receptor (*PROCR*) genes, but they have no or unknown thrombogenic potential.⁸¹ The Val34Leu polymorphism in the factor XIII gene (*F8*) is associated with increased activation by thrombin and a potentially thrombotic phenotype¹⁶⁹ but confers uncertain risks for VTE and adverse pregnancy outcome.

Summary

Many potentially thrombophilic polymorphisms are being uncovered at an ever-increasing pace. Although most of these mutations do not appear to be highly thrombogenic when present in isolation, they may exert an additive or synergistic effect on the thrombogenicity of other disorders. This may account for the finding of a very modest association between a given thrombophilic state (e.g., FVL, protein S deficiency) and the isolated occurrence of VTE or adverse pregnancy outcomes in low-risk populations, together with a far higher concordance rate within certain families.

SCREENING FOR THROMBOPHILIAS

Screening and Prevention of Venous Thromboembolism

Prevention requires optimal balancing of absolute increased bleeding risk from pharmacologic thromboprophylaxis and the absolute benefit of reduced VTE, which are serious but relatively uncommon. The focus must remain on known high-risk groups, with an understanding that recommendations for prophylaxis, even for high-risk groups, are based on a limited data set.

Patients with Prior Venous Thromboembolism but Not on Anticoagulants

Antepartum Prophylaxis. In a study of 125 women with a single prior VTE episode, Brill-Edwards and coworkers demonstrated that the lowest risk of recurrent VTE was for a subgroup of patients with previous VTE resulting from a temporary risk factor (i.e., provoked DVT) who did not have an identifiable thrombophilia (0 of 44 women had recurrences; CI, 0% to 8%).¹⁷⁰ Although they concluded that it was safe to withhold antepartum prophylaxis, given the small sample size and the 95% confidence interval of 0% to 8%, some experts recommend offering prophylaxis to this group. Several cases of recurrent VTE

have been reported for similar patients.¹⁷¹ The 9th edition of the American College of Chest Physicians *Evidence-Based Clinical Practice Guidelines* describes the antenatal and peripartum management of thrombophilia; it suggests that the occurrence of VTE in nonpregnant patients who are receiving estrogen-containing contraceptives is comparable with such events occurring in pregnancy.¹⁷² In either case, they recommend antepartum and postpartum prophylaxis in a subsequent pregnancy, regardless of thrombophilia status of women who had a VTE during a prior pregnancy or while taking estrogen-containing contraceptives.¹⁷³ The consensus is that antepartum prophylaxis should be recommended for women with a prior unprovoked VTE and identifiable thrombophilia with laboratory testing (1 of 10 women had antepartum recurrences [10%; CI, 0.3% to 44%]) and should be considered for all women with a prior VTE and identifiable thrombophilia with laboratory testing (2 of 21 women had antepartum recurrences [10%; CI, 1% to 30%]).

Postpartum Prophylaxis. All women with a prior VTE should receive postpartum prophylaxis based on a risk of postpartum recurrence of 2.4% (3 of 125; CI, 0.5% to 7.0%), which occurred despite all study participants being advised to use postpartum prophylaxis.¹⁷⁰ Two of the three events occurred after hospital discharge, arguing in favor of longer postpartum prophylaxis (i.e. 6 weeks).

Patients with Recent Venous Thromboembolism and on Anticoagulants. Vitamin K antagonists should be avoided in pregnancy because they are associated with congenital malformations (especially with exposure from 6 to 12 weeks) and with fetal and neonatal hemorrhage after second- and third-trimester exposure.¹⁷⁴ Women on vitamin K antagonists with a current or recent VTE should be counseled to discontinue oral anticoagulants as soon as they become pregnant (i.e., missed menses or positive urine pregnancy test). For women who become pregnant and have had a recent VTE, the urgency and aggressiveness of ongoing treatment should be dictated by the timing of the VTE. Full-dose therapeutic LMWH should be initiated immediately if the VTE occurred in the past month. Aggressive prophylaxis with three fourths of the usual treatment dose of LMWH should be used in the next 24 hours if the VTE occurred in the past 12 months, and if the VTE occurred more than 12 months earlier, a prophylactic dose should be considered. These recommendations are based on randomized controlled trial (RCT) evidence for malignancy-associated VTE, for which a three-fourth dose of LMWH was superior to warfarin for secondary VTE prophylaxis¹⁷⁵ and on findings for provoked VTE, for which prophylactic LMWH appeared to be equivalent to warfarin.¹⁷⁶

Identifiable Thrombophilia with Laboratory Testing but No Prior Venous Thromboembolism

Antepartum Prophylaxis. Although women with a thrombophilic mutation have a greater relative risk of developing VTE in the antepartum period, the standard of care is to observe most of them without prophylaxis. Several large, prospective cohort studies of pregnant women with FVL and the PGM but no prior VTE found a very low absolute risk of antepartum VTE without prophylaxis.^{114,177-179} However, in the rare patient with potent thrombophilia, such as double heterozygotes and type I AT deficiency, antepartum VTE prophylaxis is likely warranted.

Postpartum Prophylaxis. VTE prophylaxis should be considered while patients are in the hospital. Consideration should

also be given to screening pregnant women who have a strong family history (i.e., affected first-degree relative) of VTE. Because of the more than 10% risk of VTE in pregnancy among patients with this history and a thrombophilia (see Table 53-1), postpartum thromboprophylaxis is a reasonable option. Cost-effective screenings should be initially limited to the most common and most thrombogenic disorders, including FVL and PGM. Negative results should lead to evaluation of fasting homocysteine levels and protein C, protein S, and AT deficiencies.

Low-Molecular-Weight Heparin Dosing for Venous Thromboembolism Prevention in Pregnancy. The dosing regimen varies with the severity of the thrombophilia and the nature of the prior VTE episodes. For patients with a personal history of VTE and a less-threatening thrombogenic thrombophilia (e.g., FVL, PGM, hyperhomocysteinemia refractory to folate therapy, protein C or protein S deficiency), antepartum prophylaxis with prophylactic-dose LMWH is effective in preventing DVT in pregnant patients at risk. Regimens can include 5000 U of dalteparin given subcutaneously once daily or every 12 hours after 20 weeks' gestation or 30 mg of enoxaparin given subcutaneously every 12 hours or as 40 mg given subcutaneously once each day. For patients with highly thrombogenic thrombophilias (e.g., homozygotes or double heterozygotes for FVL and PGM, patients with AT deficiency or APS with prior VTE) and who have a personal history of VTE and for patients with recurrent VTE, a therapeutic (high-dose) unfractionated heparin or intermediate (one-half to three-fourth therapeutic dose) or full-dose LMWH should be used.

The goal of unfractionated heparin therapy is to obtain and maintain an activated partial thromboplastin time (aPTT) of 1.5 to 2.5 times control values or a plasma heparin concentration of 0.2 to 0.4 U/mL or an anti-factor Xa concentration of 0.4 to 0.7 U/mL. The aPTT should not be used to guide unfractionated heparin therapy in patients with prolonged aPTT values due to LAs. Full LMWH therapy consists of 1 mg/kg of enoxaparin given subcutaneously twice daily or a comparable dose of dalteparin (e.g., 100 U/kg U SQ every 12 hours). Intermediate doses are 50% to 75% of the full therapeutic dose. Barbour and colleagues evaluated whether the standard therapeutic doses of dalteparin maintained peak therapeutic levels of anticoagulation during pregnancy and reported that 85% (11 of 13) of patients required an upward dosage adjustment.¹⁸⁰ We suggest titrating either agent to maintain factor Xa levels at 0.5 to 1.0 U/mL 3 to 6 hours after injection but recognize that this approach is controversial and requires further research.

For all patients on therapeutic anticoagulants, an induction of labor helps to prevent the risk of labor occurring on full anticoagulation and likely reduces the risk of bleeding and optimizes anesthetic options. Recommendations for patients on therapeutic LMWH for VTE in the current pregnancy can be found in Chapter 54. For patients on therapeutic LMWH for other indications or intermediate-dose LMWH, the last dose of LMWH should be given 24 hours before induction, and a split dose of LMWH given every 12 hours should be restarted 12 to 24 hours after delivery. For patients on prophylactic LMWH, a decision must be made with the practitioner about how to proceed:

1. Discontinue the LMWH at 37 weeks' gestation to permit spontaneous vaginal delivery and keep all regional anesthetic options open but accept an increased risk of VTE in the short unprophylaxed interval.

2. Continue LMWH until term and accept that regional anesthetic options may be limited.
3. Continue LMWH until a planned induction to keep all regional anesthetic options open but accept the increased risk of maternal and child delivery complications associated with induction of labor.
4. Change to unfractionated heparin at 36 weeks' gestation and cease taking it with the onset of labor or rupture of the membranes. We favor this option in our usual practice.

Heparin and LMWH are associated with an increased risk of osteopenia. It seems prudent to advise the patient about axial skeleton weight-bearing exercise and calcium supplementation, although of unproven benefit. These medications also increase the risk for heparin-induced thrombocytopenia, which paradoxically is associated with thrombosis. With therapeutic doses of LMWH and with any dose of unfractionated heparin, platelet counts should be obtained after 3 to 4 days of therapy and intermittently for the first 2 weeks of treatment.¹⁸¹

When postpartum thromboprophylaxis is required, warfarin may be used rather than continuing LMWH. Warfarin is considered safe to take while breastfeeding. Doses are determined by monitoring the international normalized ratio (INR). To avoid paradoxical thrombosis and skin necrosis from warfarin's early, predominantly anti-protein C effect, it is critical to maintain unfractionated heparin or LMWH for a minimum of 5 days and until the INR is in the therapeutic range (2.0 to 3.0) for 2 consecutive days.

Screening and Prevention of Adverse Pregnancy Outcomes

As can be discerned from the preceding review, there appears to be a modest and consistent association between the major inherited and acquired thrombophilias (i.e., aPLs, FVL status, PGM, elevated fasting homocysteine levels, and protein C, protein S, and AT deficiencies) and pregnancy loss. There is a possible association between these thrombophilic states and abortion, but further study is required. No clear association exists between FVL or the other major thrombophilias and preeclampsia or SGA births, although studies have been underpowered to definitely exclude a link with severe early-onset preeclampsia or severe (<3rd percentile) SGA births.

These associations suggest that thromboprophylaxis (e.g., LMWH) could be of benefit in preventing pregnancy complications. As a first approach, we consider whether LMWH, regardless of the presence of thrombophilia, is beneficial in preventing placenta-mediated pregnancy complications.

Low-Molecular-Weight Heparin to Prevent Pregnancy Loss. We are fortunate to have multiple studies examining the efficacy of LMWH in women with recurrent miscarriage and no known thrombophilia. Although the findings of these studies are not uniform, they suggest no important treatment effect for anticoagulant prophylaxis. The trials with positive results include those led by Fawzy and Badawy.^{182,183} Both studies ($N = 447$) used small prophylactic doses of enoxaparin and demonstrated a positive treatment effect. The three negative trials were those led by Dolitzky,¹⁸⁴ Clark,¹⁸⁵ and Kaandorp¹⁸⁶ ($N = 696$), which compared higher doses of LMWH (i.e., doses used in orthopedic surgery prophylaxis) with no LMWH, and on balance, interventions started at earlier gestational ages. Most evidence suggests no treatment effect for LMWH in women

with recurrent pregnancy loss and no thrombophilia, and if a treatment effect existed, it was small. It is puzzling that the studies examining higher doses of prophylaxis had negative results but studies with positive results used lower doses of prophylaxis (i.e., negative dose-effect relationship).

Low-Molecular-Weight Heparin to Prevent Preeclampsia. Limited data suggest that anticoagulant prophylaxis may have the potential to prevent the recurrence of preeclampsia in subsequent pregnancies. However, heparin and LMWH should be considered experimental until additional studies can offer confirmation. A randomized trial comparing 5000 U/day of dalteparin given subcutaneously with no drug intervention in 80 women with angiotensin-converting enzyme deletion/deletion (ACE DD) polymorphism, no known thrombophilia, and a history of preeclampsia reported that the absolute risk of preeclampsia was reduced from 28.2% (11 of 39) in the no drug intervention group to 7.3% (3 of 41) in the dalteparin group.¹⁸⁷ However, the investigators thought that their study findings required confirmation in larger studies. A meta-analysis suggested that the ACE DD genotype protected against venous thrombosis and that it was not a thrombophilia.¹⁸⁸ This clinical trial was not registered, and the findings should not be generalized to women without the DD genotype.

A pilot randomized trial¹⁸⁹ compared 5000 U/day of dalteparin with no prophylaxis in 110 women without identifiable thrombophilia who had previously experienced one of the following: (1) severe preeclampsia necessitating delivery before 34 6/7 weeks, (2) unexplained birth weight less than the 5th percentile, (3) placental abruption necessitating delivery before 34 6/7 weeks or resulting in fetal death after 19 6/7 weeks, (4) unexplained fetal loss after 19 6/7 weeks, or (5) two prior unexplained fetal losses between 12 and 19 6/7 weeks. Dalteparin was associated with a lower rate of the composite primary outcome, which included severe preeclampsia, birth weight less than the 5th percentile, and major placental abruption leading to birth before 34 weeks or fetal death after 20 weeks. This composite outcome occurred for 5.5% of those in the dalteparin arm compared with 23.6% in the no prophylaxis arm (OR = 0.15; CI, 0.03 to 0.70; number needed to treat [NNT] = 5.5; $P = .016$). Although 63 nonthrombophilic women with prior severe preeclampsia were randomized in this study, the outcomes for this subgroup were not published. These results need to be interpreted with caution because the trial did not reach the intended sample size of 276 women, nor did the interim analysis of the primary outcome reach the preplanned level of statistical significance ($P < .005$). Stopping trials early due to apparent efficacy is known to exaggerate treatment benefits. Although the results were promising, additional studies are required to corroborate these findings.

Low-Molecular-Weight Heparin to Prevent Small-for-Gestational-Age Births. No randomized trials examining whether LMWH can prevent the recurrence of SGA births for women with or without thrombophilia have been published. Although there was a small subgroup (21) of nonthrombophilic women with SGA infants (<5th percentile) randomized in the study by Rey and colleagues,¹⁸⁹ data on the outcomes for this subgroup were not published.

Low-Molecular-Weight Heparin to Prevent Placental Abruptio. Limited data have shown no evidence of a durable benefit

for LMWH prophylaxis. An unblinded, single-center study by Gris and colleagues suggested that anticoagulant prophylaxis might be beneficial in preventing placenta-mediated pregnancy complications in women with a history of abruption.¹⁹⁰ From an initial group of 166 eligible women with prior objectively confirmed but nonlethal placental abruption without selection by thrombophilia, 160 consented to randomization to 4000 IU/day of enoxaparin until 36 weeks' gestation or to no drug intervention. The primary composite outcome consisted of any of the following: preeclampsia, birth weight less than the 5th percentile, confirmed placental abruption, or fetal demise after 20 weeks' gestation. The primary outcome was statistically significantly reduced from 31.3% (25 of 80) in the no-intervention group to 12.5% (10 of 80) in the enoxaparin group and was driven by the reduction in diagnosed preeclampsia. There were no differences in mean gestational age at delivery, mean birthweight, mean birth weight percentile for gestational age, birth weight less than the 5th percentile, or perinatal mortality.

Heparin or Low-Molecular-Weight Heparin to Prevent Pregnancy Loss in Women with Inherited Thrombophilia. The evidence supporting the use of antithrombotic therapy in women with inherited thrombophilia and pregnancy loss comes predominantly from observational studies that report good pregnancy outcomes for women when treated compared with their own prior untreated pregnancies or with historical or convenient untreated controls.¹⁹¹⁻¹⁹⁶ Overall, these reports found a significant improvement in live birth rates with antepartum thromboprophylaxis with heparin. However, these results are only hypothesis generating given the severe methodological limitations of the weak study designs. Three RCTs have evaluated the effect of LMWH for antepartum thromboprophylaxis in women with inherited thrombophilia and pregnancy loss.¹⁹⁷⁻¹⁹⁹ All three were limited by the absence of an untreated control arm. Gris and coworkers¹⁹⁷ compared 40 mg of enoxaparin given daily with 100 mg of ASA in 160 women with inherited thrombophilias (i.e., FVL, PGM, and protein S deficiency) and one prior pregnancy loss after 10 weeks' gestation. Enoxaparin resulted in a higher live birth rate (86%; 69 of 80) than ASA (29%; 23 of 80), with a very small number needed to treat (NNT = 1.7). The dramatic results are surprising because of the modest association between these thrombophilias and the risk of pregnancy loss in most studies, and they need to be validated before adoption of this method into routine clinical practice. Methodological limitations include inadequate concealment of allocation, which leads to an exaggerated treatment effect, and the lack of an untreated, no-intervention control group, which when coupled with the high rate of fetal loss in the ASA group (71%) raise the possibility that ASA was harmful. The unusually high rate of fetal loss after the 8th week (42.5%) compared with the 7% rate of fetal loss before the 8th week has led to skepticism about the external generalizability of this study's findings.

In the multicenter, prospective, randomized, open-label LIVE-ENOX trial reported by Brenner and coworkers,¹⁹⁸ two doses of enoxaparin (40 mg/day versus 80 mg/day) were compared in 166 women with thrombophilia and recurrent pregnancy loss. Live birth rates were similar in both arms (84.3% versus 78.3%, respectively) and were higher than expected given the inclusion of women with a history of recurrent pregnancy loss. The HepASA RCT¹⁹⁹ compared 5000 U/day of dalteparin plus 81 mg/day of ASA with 81 mg/day of ASA in women with

recurrent pregnancy loss (i.e., two or more consecutive, unexplained losses before 32 weeks' gestation) and inherited ($n = 19$) or acquired thrombophilia ($n = 30$ with aPLs and $n = 42$ with antinuclear antibody positivity). The live birth rates were 77.8% in the dalteparin/ASA group and 79.1% in the ASA group. However, this trial lacked the necessary power to detect clinically significant differences due to small sample size and much higher than expected live birth rates. Although anticoagulant prophylaxis has been examined in RCTs with primary inclusion criteria of thrombophilic (acquired or inherited) women with pregnancy loss, the data generated are methodologically limited and inadequate, preventing firm conclusions to be drawn. Further trials are required before adopting the use of anticoagulant prophylaxis in thrombophilic women with prior pregnancy loss.

Heparin or Low-Molecular-Weight Heparin to Prevent Recurrent Placenta-Mediated Pregnancy Complications in Women with Thrombophilia. The complete absence of RCT data examining anticoagulant prophylaxis in thrombophilic women with a history of preeclampsia, SGA births, or abruption lead us to conclude that the use of anticoagulant prophylaxis in these thrombophilic women should be considered experimental until proven otherwise.

RECOMMENDATIONS

Based on the previously described findings, we make the following recommendations:

1. Given its low toxicity, women with hyperhomocysteinemia should receive folic acid supplementation regardless of their antecedent VTE or obstetric history. Thromboprophylaxis recommendations should follow those of the clinical disorder or presentation (described later).
2. Patients with a highly thrombogenic thrombophilia (e.g., AT deficiency, FVL or PGM homozygotes or double heterozygotes), regardless of their obstetric history, should be offered prophylactic or intermediate doses of LMWH in the antepartum and postpartum periods.
3. It is unclear whether patients with prior severe or early-onset preeclampsia, severe SGA conditions, or major abruption in the absence of other known risk factors should be offered antepartum prophylaxis. We await confirmatory trials for this potentially important and promising therapeutic alternative.
4. LMWH should not be offered to women, with or without thrombophilia and with recurrent pregnancy loss to improve live birth rates.
5. There appears to be no justification for offering antepartum thromboprophylaxis to asymptomatic, otherwise low-risk women with less potent thrombophilias who have had prior episodes of preeclampsia, SGA births, or pregnancy loss. However, because of the possible association between inherited thrombophilias and placenta-mediated pregnancy complications, close maternal-fetal surveillance is appropriate. Fetal growth may be monitored with serial ultrasound examinations. Doppler flow studies of the umbilical artery may be used to assess the fetus in the setting of IUGR. Nonstress testing and biophysical profiles may be clinically appropriate at 36 weeks or earlier. Early delivery may be indicated for deteriorating maternal or fetal conditions. Surveillance can be

decreased if there is no evidence of placental insufficiency. Mothers should receive postpartum thromboprophylaxis to prevent VTE during this high-risk period.

ACQUIRED PLATELET DISORDERS

Primary Immune Thrombocytopenia

Primary immune thrombocytopenia, also known as idiopathic thrombocytopenic purpura (ITP) or autoimmune thrombocytopenic purpura, is defined as a platelet count of less than 100,000 cells/ μL .²⁰⁰ The syndrome of immunologically mediated thrombocytopenia is characterized by increased platelet destruction. IgG antibody binds to platelets, rendering them more susceptible to sequestration and premature destruction in the reticuloendothelial system, especially the spleen. The rate of destruction exceeds the compensatory ability of the bone marrow to produce new platelets, leading to thrombocytopenia. T-cell-mediated platelet destruction and impaired platelet production also play roles in the thrombocytopenia associated with ITP.^{201,202}

In adults, ITP is usually chronic. It may coexist with pregnancy, because the disease usually manifests in the second to third decade of life and is more common among women between 30 and 60 years of age.²⁰³ ITP is the most common autoimmune bleeding disorder encountered during pregnancy. The overall course is not consistently influenced by pregnancy, although women rarely experience repeated flares with each pregnancy. However, pregnancy may be adversely affected by ITP, and the primary risk is hemorrhage in the peripartum period. Because the placenta selectively transports maternal IgG antiplatelet antibodies into the fetal circulation, fetal thrombocytopenia also may occur.

Diagnosis. Most women with ITP have a history of petechiae, ecchymoses, easy bruising, menorrhagia, or other bleeding manifestations. The diagnosis is primarily one of exclusion and is based on the history, physical examination, complete blood cell (CBC) count, and examination of the peripheral blood smear.²⁰⁴ The CBC count is normal except for thrombocytopenia (platelet count $<100,000/\mu\text{L}$), and the smear may show an increased proportion of slightly enlarged platelets. The history and physical examination usually exclude other causes of thrombocytopenia. Rarely, a bone marrow biopsy is required to clarify the diagnosis. Typical bone marrow findings include increased numbers of immature megakaryocytes. Although the issue is controversial, many authorities do not routinely perform this procedure in typical cases of ITP, especially in women younger than 40 years of age.²⁰⁵

It can be difficult to distinguish ITP from other causes of maternal thrombocytopenia. The condition most commonly confused with ITP is *incidental thrombocytopenia of pregnancy*, also known as essential or gestational thrombocytopenia. Incidental thrombocytopenia of pregnancy is mild ($>70,000$ platelets/ μL), asymptomatic, and often first observed by the clinician after a CBC count obtained as part of a routine automated prenatal screening test.^{206,207} In contrast to ITP, incidental thrombocytopenia of pregnancy is common. It occurs in up to 5% of pregnant women and accounts for more than 70% of maternal thrombocytopenia.^{207,208} Individuals with incidental thrombocytopenia have no prior history of thrombocytopenia and are not at risk for bleeding complications or fetal thrombocytopenia. No special care is required for these women. Other

causes of maternal thrombocytopenia that should be considered are preeclampsia, pseudothrombocytopenia due to laboratory artifact, SLE, APS, human immunodeficiency virus (HIV) or hepatitis C virus infection, drug-induced thrombocytopenia, liver disease, bone marrow disorders, thrombotic thrombocytopenia, immunodeficiency states, hereditary thrombocytopenias, and DIC.

Numerous direct and indirect assays of antiplatelet antibodies have been developed to confirm the diagnosis of ITP. Most patients with ITP have platelet-associated immunoglobulin, and many also have circulating unbound antiplatelet antibodies. Levels of direct (platelet-associated) IgG have a strong inverse correlation with the maternal platelet count and intravascular platelet life span.²⁰⁹ Nonetheless, a negative result does not exclude a diagnosis of ITP.²¹⁰ Concentrations of indirect (circulating) antiplatelet antibodies less reliably predict maternal platelet counts. Although assays for direct and indirect antiplatelet antibodies are widely available, they are not recommended for the routine evaluation of maternal thrombocytopenia or ITP.²⁰⁴ Assays for antiplatelet antibodies are hampered by a variety of problems, including the use of several different assays, a large degree of interlaboratory variation, and a high background rate of platelet-associated IgG. Women with ITP cannot be distinguished from those with incidental thrombocytopenia of pregnancy on the basis of antiplatelet antibody testing.²¹¹

Maternal Considerations. The goal of maternal therapy during pregnancy is to minimize the risk of hemorrhage and to restore a normal platelet count. Asymptomatic pregnant women with ITP and platelet counts greater than 50,000/ μL do not require treatment. For nonpregnant patients, most authorities recommend treatment if the platelet count is lower than 10,000/ μL or in the presence of bleeding, but it is controversial whether a particular platelet count (e.g., $<50,000/\mu\text{L}$, $<30,000/\mu\text{L}$) is sufficient indication for therapy during pregnancy in asymptomatic women. A reasonable approach is to aim for a platelet count greater than 30,000/ μL throughout pregnancy and greater than 50,000/ μL near term.²¹²

The American Society of Hematology ITP Practice Guideline Panel²¹³ recommends treating pregnant women with platelet counts between 10,000 and 30,000/ μL during the second or third trimester. More aggressive treatment is often pursued close to the estimated due date in anticipation of potential bleeding, surgery, or the need for regional anesthesia. Some anesthesiologists may require a platelet count greater than 75,000 to 80,000/ μL before deeming the woman's condition safe for placement of an epidural catheter.²¹⁴ Although not an evidence-based level, most hematologists think that a platelet count higher than 50,000 cells/ μL is adequate for safe cesarean delivery.²¹²

Glucocorticoid Drugs. Glucocorticoid drugs have been the cornerstone of ITP therapy in pregnancy. Prednisone (0.5 to 2.0 mg/kg/day or the therapeutic equivalent) is the initial treatment of choice. Improvement usually occurs within 3 to 7 days and reaches a maximum within 2 to 3 weeks. Some increase in the platelet count occurs in 50% to more than 70% of patients, depending on the duration and intensity of therapy.²⁰⁴ Complete remission has been reported in 5% to 30% of cases.²⁰⁴ If platelet count improves, the steroid dose can be tapered by 10% to 20% per week until the lowest dosage required to maintain the platelet count at an acceptable level is reached.

It is uncertain how steroids improve platelet counts and decrease bleeding in patients with ITP. Proposed mechanisms of action²¹⁵ include increased platelet production, decreased production of antiplatelet antibodies and platelet-associated IgG, decreased clearance of antibody-coated platelets by the reticuloendothelial system, and decreased capillary fragility. Adverse effects of steroid use in pregnancy are well known and include glucose intolerance, osteoporosis, hypertension, psychosis, moon facies, and increased risk for premature rupture of the membranes. The dose and duration of therapy should be minimized accordingly. Although dexamethasone can be used to treat ITP, it is best avoided for chronic use in pregnancy because a metabolically active form of the drug reaches the fetus.

Intravenous Immune Globulin. Intravenous immune globulin (IVIG) is used in cases of ITP refractory to corticosteroids and in urgent circumstances, such as preoperatively, in the peripartum period, or when the platelet count is less than 10,000/ μL (<30,000/ μL in a bleeding patient). IVIG is a pooled concentrate of immunoglobulins collected from many donors. High doses of IVIG (1000 mg/kg/day for 2 to 5 days) usually induce a peak platelet count within 7 to 9 days. More than 80% of patients treated with this regimen have a peak platelet count greater than 50,000/ μL , and in 30%, the duration of the response lasts for more than 30 days.^{216,217} Although the mechanism of action is unclear, it seems to involve depression of antiplatelet antibody production, interference with antibody attachment to platelets, inhibition of macrophage receptor-mediated immune complex clearance, and blockage of Fc receptors in the reticuloendothelial system.²¹⁷⁻²¹⁹ In responders, only 2 or 3 days of IVIG therapy may be needed, and higher doses of 800 or 1000 mg/kg may suffice as a single or double infusion.²²⁰

Although IVIG had previously been associated with occasional hepatitis C transmission, the current purification process eliminates the risk of blood-borne infections. HIV transmission has never been associated with IVIG use. Untoward effects of IVIG include headache, chills, nausea, liver dysfunction, alopecia, transient neutropenia, flushing, autoimmune hemolytic anemia, and anaphylactic reactions in patients with IgA deficiencies.²²¹ There are no known adverse fetal effects. Because IVIG is extremely expensive, its use is best reserved for urgent cases and for ITP refractory to corticosteroids. Examples include a platelet count less than 5000/ μL despite treatment with steroids for several days, active bleeding, and extensive and progressive purpura.²⁰⁵

Rhesus Immune Globulin. Anti-Rh(D) immune globulin has been successfully used to treat ITP in RhD-positive individuals. Immune globulin against Rh(D) (75 $\mu\text{g}/\text{kg}$ of maternal weight) works as well as corticosteroids at initial presentation.²²² It is more costly than steroids but has fewer side effects. It may have some advantages over IVIG.²¹² Anti-Rh(D) is not typically used during pregnancy because of a theoretic risk of fetal erythrocyte destruction, although it would most likely bind maternal red blood cells before reaching the fetal circulation. Cases of successful and safe use of anti-Rh(D) during pregnancy in RhD-positive women have been reported.²²³

Platelet Transfusions. Platelet transfusions should be considered only as a temporary measure to control life-threatening hemorrhage or to prepare a patient for cesarean delivery or other surgery. Survival of transfused platelets is decreased in patients with ITP, because antiplatelet antibodies also bind to transfused platelets. The usual elevation in platelet count of

approximately 10,000/ μL per unit of a platelet concentrate is not achieved in patients with ITP. In one series, platelet transfusion increased the platelet count by at least 20,000/ μL in 42% of patients with ITP, and may reduce the rate of bleeding, especially when given concurrently with IVIG.^{224,225} A transfusion of 8 to 10 packs is sufficient in most cases.

Splenectomy. Complete remission is obtained in 80% of patients with ITP who undergo splenectomy. This operation, which removes the major sites of platelet destruction and antiplatelet antibody production, is usually avoided during pregnancy because of risks to the fetus and technical difficulties with the procedure. Nonetheless, splenectomy can be safely accomplished during pregnancy, ideally in the second trimester. It has been combined with cesarean delivery at term without reported morbidity. Splenectomy during pregnancy is appropriate for women with platelet counts lower than 10,000/ μL who are bleeding and have not responded to IVIG and steroids.²⁰⁴

Refractory Patients. Other drugs used to treat ITP, such as vinca alkaloids, colchicine, cyclophosphamide, danazol, rituximab, and thrombopoietin receptor antagonists are best avoided in pregnancy because of the potential for adverse effects on the fetus. Azathioprine and, rarely, cyclosporine may be considered in refractory cases.

Fetal Considerations. Because the placenta is permeable to circulating maternal antiplatelet IgG, fetal thrombocytopenia may occur with maternal ITP. Occasionally, this results in minor clinical bleeding, such as purpura, ecchymoses, hematuria, or melena. In rare cases, fetal thrombocytopenia can lead to intracranial hemorrhage (ICH), resulting in severe neurologic impairment or death. Avoiding ICH was the central issue in the obstetric management of ITP for many years.

Clinicians have tried a variety of strategies intended to minimize fetal bleeding problems in women with ITP, including maternal medical therapies and the use of cesarean delivery if the platelet count is below 50,000/ μL based on fetal scalp sampling or cordocentesis. However, fetal or neonatal ICH is rare with maternal ITP,^{208,226,227} and it is not clear that cesarean delivery prevents ICH.²²⁸⁻²³⁰

In summary, obstetric management of ITP remains controversial, but most investigators think that fetal scalp sampling, cordocentesis, and cesarean delivery contribute to cost and morbidity without preventing neonatal bleeding complications. ITP should be managed without determination of the fetal platelet count, and cesarean delivery should be reserved for the usual obstetric indications.^{226,228-230} Others think that the potential 1% risk of ICH warrants cesarean delivery in selected cases.^{204,231} Clinicians who favor interventional management use fetal scalp sampling to determine the fetal platelet count in pregnancies most at risk for thrombocytopenia (e.g., when there is a sibling with severe thrombocytopenia). The use of cordocentesis in the obstetric management of ITP is difficult to justify.

Delivery should be accomplished in a setting in which platelets, fresh-frozen plasma, and IVIG are available. A neonatologist or pediatrician familiar with the disorder should be present to promptly treat any hemorrhagic complications in the neonate. The platelet count of the affected newborn usually falls after delivery, and the lowest platelet count is not reached for several days.²³² Most infants are asymptomatic, and the thrombocytopenia is self-limited. Nonetheless, daily platelet counts should be obtained for several days. Although breastfeeding

early in the puerperium may theoretically cause neonatal thrombocytopenia, many women with ITP have done so without clinical sequelae.

Fetal or Neonatal Alloimmune Thrombocytopenia

In contrast to the minimal fetal risks in maternal ITP, fetal or neonatal alloimmune thrombocytopenia (AIT) is a serious and potentially life-threatening condition that affects about 1 of every 1000 live births among whites.²³³⁻²³⁶ Rates vary by ethnicity, and non-Hispanic blacks appear to be affected less frequently.²³⁷ The disorder occurs as the result of maternal alloimmunization against fetal platelet antigens that are lacking on the mother's own platelets; it is analogous to the hemolytic anemia caused by maternal alloimmunization against fetal erythrocyte antigens.

Several polymorphic, diallelic platelet antigen systems are responsible for AIT. Many of these antigen systems were simultaneously identified in different parts of the world and given different names. To minimize confusion, uniform nomenclature has been adopted to describe these antigen systems as human platelet antigens (e.g., HPA-1), with alleles designated as *a* or *b*.²³⁸ The most frequent cause of AIT among whites is sensitization against HPA-1a, also known as PLAT or Zwa. The antigens HPA-1a (PLA1) and HPA-1b (PLA2) are the product of polymorphic alleles that differ by a single base-pair change in the gene encoding the platelet glycoprotein GpIIb (integrin β_3).²³⁹ This causes a substitution of proline for leucine in the protein, resulting in antigenically distinct conformations. Among whites, 97% are HPA-1a positive, 69% are homozygous HPA-1a, and 28% are heterozygous.²⁴⁰ Several other antigens, including HPA-1b, HPA-5b (Br), HPA-3b (Bak), and HPA-4b (Yuk), also may cause AIT (Table 53-2). Among Asians, sensitization against HPA-4 is the most common cause of AIT.

Although approximately 1 in 42 pregnancies is incompatible for HPA-1a, AIT develops in only 1 of 10 cases.²³³ In some instances,²⁴¹ the disorder remains subclinical because the antiplatelet antibodies are not potent enough to induce thrombocytopenia in the infant.²⁴² In addition to antigen exposure, an immunologic susceptibility to HPA-1a sensitization may be required. Several HLA antigens have been associated with an increased risk of sensitization in incompatible pregnancies. Examples include Dw52a, DRB3*0101, and DQB1*0201.^{243,244} Associations between sensitization to other platelet antigens and HLA phenotypes are less well characterized, although DR6 has been linked to anti-HPA-5.²⁴⁵

In contrast to rhesus isoimmunization, neonatal AIT can occur during a first pregnancy without prior exposure to the offending antigen. The diagnosis is usually made after birth in an infant with unexplained severe thrombocytopenia, often associated with ecchymoses or petechiae.^{234,246} The most serious bleeding complication is ICH, which occurs in 10% to 20% of infants with AIT.^{246,247} It can occur in utero,²⁴⁸ and 25% to 50% of cases of ICH are detected by sonography before delivery.²⁴⁸ Characteristic sonographic findings include evidence of intracranial hematoma or hemorrhage and porencephalic cysts. Obstructive hydrocephalus also may occur. As with red cell alloimmunization, the condition tends to worsen throughout pregnancy and in subsequent pregnancies.^{247,249,250} AIT should be suspected in cases of otherwise unexplained fetal or neonatal thrombocytopenia, in utero or ex utero ICH, or porencephaly. Serologic evaluation should be performed

in an experienced laboratory with special interest and expertise in AIT.

In most cases, the diagnosis of AIT can be determined by testing the parents; testing of fetal or neonatal blood is confirmatory and occasionally helpful. Appropriate assays include serologic confirmation of maternal antiplatelet antibodies that are specific for paternal or for fetal or neonatal platelets. Individuals should undergo platelet typing with zygosity testing. This can be determined serologically or with DNA-based tests, because the genes and polymorphisms for HPAs recognized to cause AIT are well characterized. This approach is particularly useful for obstetric management, because fetal HPA typing can be accomplished with amniocytes.²⁵¹ Chorionic villus sampling should be avoided, because it may exacerbate the alloimmune reaction. Occasionally, results are ambiguous, and in some cases, an antigen incompatibility cannot be identified. The management of these difficult cases is best individualized and underscores the need for consultation with physicians and laboratories familiar with the disorder.

The natural history of AIT is difficult to ascertain, because it is usually unrecognized during first affected pregnancies, and subsequent pregnancies are influenced by therapeutic interventions. Nonetheless, several observations have been drawn from

a large cohort of 107 fetuses with AIT (97 with HPA-1a incompatibility) who were followed with serial cordocenteses to determine the fetal platelet count²⁵²:

1. The risk of AIT recurrence is extremely high and is 100% if the fetus has the HPA-1a antigen in a sensitized HPA-1a-negative mother.
2. Fetal thrombocytopenia caused by HPA-1a sensitization is often severe and can occur early in gestation. Of the patients studied, 50% had initial platelet counts of less than 20,000/ μ L. This included 21 (46%) of 46 fetuses tested before 24 weeks' gestation.
3. Having a sibling with antepartum ICH is a risk factor for the development of severe thrombocytopenia. However, neither a sibling platelet count nor a sibling with ICH recognized after delivery reliably predicts the initial fetal platelet count.
4. Thrombocytopenia uniformly worsens in untreated fetuses. Seven fetuses in this cohort had initial platelet counts higher than 80,000/ μ L and were not treated. All demonstrated rapid and substantial decreases in their platelet counts.

AIT associated with antigens other than HPA-1a is less well studied. In the large series reported by Bussel and colleagues, thrombocytopenia associated with anti-HPA-1a was more severe than AIT caused by other antigen incompatibilities.²⁵² Data regarding HPA-1a incompatibility cannot be generalized to other causes of AIT.

The explicit goal of the obstetric management of pregnancies at risk for AIT is to prevent ICH and its associated complications. As with ITP, antepartum management is controversial, and few randomized data are available to guide therapy. In contrast to ITP, the dramatically higher frequency of ICH associated with AIT justifies more aggressive interventions. Therapy must be initiated antenatally because of the risk of in utero ICH. If the diagnosis is uncertain, the risk of AIT should be confirmed by documentation of platelet incompatibility or maternal antiplatelet antibodies specific for paternal or fetal platelets. It is unnecessary to repeat testing in a family with a previously confirmed case of AIT. Traditionally, it was thought that antibody titers were poorly predictive of risk for the current pregnancy and need not be obtained after the diagnosis was secured. However, some investigators have suggested that antibody titers may be useful, and this issue remains controversial.²⁵³ If the father is heterozygous for the offending antigen, fetal genotyping should be accomplished with amniocytes. This strategy can prevent additional expensive and risky interventions in approximately 50% of cases. Since 2009, it has been possible to perform fetal genotyping using free fetal DNA in the maternal circulation.²⁵⁴

Proposed therapies to increase the fetal platelet count and prevent ICH include maternal treatment with steroids and IVIG,^{235,255-258} fetal treatment with IVIG,²⁵⁹⁻²⁶¹ and fetal platelet transfusions.²⁵⁰ However, no therapy is effective in all cases.

Administration of IVIG directly to the fetus has not consistently raised fetal platelet counts,^{262,263} but because only a few patients have been treated, lack of efficacy has not been proved. Platelet transfusions are effective,²⁶⁴ but the short half-life of transfused platelets necessitates weekly procedures. The potential risks involved with multiple transfusions and the potential for increased sensitization^{237,264,265} limit the attractiveness of this approach. Platelet transfusions are best reserved for severe cases refractory to other therapies.

Administration of IVIG to the mother appears to be the most consistently effective antenatal therapy for neonatal AIT. Bussel and colleagues demonstrated that weekly infusions of 1 g/kg maternal weight of IVIG often stabilize or increase the fetal platelet count.^{235,255,257} In a study of 55 women with neonatal AIT and thrombocytopenic fetuses, between 62% and 85% of fetuses responded to IVIG therapy, depending on how response was defined,²⁵⁵ and no fetus had ICH. In pregnancies treated with IVIG, ICH occurred in only 1 of more than 100 cases managed by Bussel and collaborators.²⁴⁹ The mechanism of action is uncertain, but it may be related to placental Fc receptor blockade, preventing active transport of antiplatelet antibodies across the placenta.²⁶⁷

Bussel and coworkers showed that low-dose dexamethasone therapy did not improve fetal platelet counts beyond the effect achieved with IVIG.²⁵⁶ Fetal platelet counts increased to a similar degree in AIT patients randomized to treatment with IVIG alone or IVIG plus 1.5 mg/day of dexamethasone.²⁵⁶ In contrast, 5 of 10 patients with no response to IVIG had increased fetal platelet counts after the addition of 60 mg/day of prednisone.²⁵⁶ They also found that fewer than one half of fetuses with platelet counts lower than 20,000/ μ L responded to the initial dose of IVIG.

This led to a parallel set of randomized trials, in which patients were stratified by level of risk for severe thrombocytopenia and ICH. The first trial, enrolling 40 women with a prior infant with ex utero ICH or a current fetus with a platelet count of less than 20,000/ μ L, randomized patients to treatment with 1 g/kg/wk of IVIG plus 1 mg/kg/day of prednisone or to 1 g/kg/wk of IVIG alone after cordocentesis performed at 20 weeks.²⁶⁸ IVIG and steroids increased the mean platelet count over 3 to 8 weeks by 67,100/ μ L, compared with 17,300/ μ L for IVIG alone ($P < .001$). The difference in treatment was more profound in the subgroup of cases with initial fetal platelet counts lower than 10,000/ μ L. In these cases, IVIG and prednisone increased the platelet count in 82% of cases, compared with 18% for IVIG alone.²⁶⁸

Thirty-nine women at lower risk for fetal ICH (i.e., no prior infant with ICH and current fetal platelet count $>20,000/\mu$ L) were randomized to treatment with IVIG (1 g/kg/wk) or lower-dose prednisone (0.5 mg/kg/day). The fetal responses to these two regimens were not significantly different.²⁴⁷ The same group also treated 15 women who had prior infants with in utero ICH with IVIG (1 or 2 g/kg/wk) beginning at 12 weeks' gestation. Therapy was intensified (i.e., increasing IVIG or adding steroids) if there was severe thrombocytopenia at 20 weeks. All fetuses responded adequately to intensified therapy, except one who had in utero ICH at 19 weeks' gestation.²³⁵

Berkowitz and colleagues reported results of an RCT comparing outcomes for 73 standard-risk (i.e., no prior infant with ICH) pregnancies for neonatal AIT treated with IVIG (2 g/kg/wk) or with IVIG (1 g/kg/wk) plus prednisone (0.5 mg/kg/day).²⁶⁸ Outcomes were excellent and similar in both groups, with no cases of ICH. Empiric therapy was started at 20 weeks' gestation, and cordocentesis was done once at 32 weeks. Salvage therapy (i.e., adding steroids or increasing the dose of IVIG) was done if the platelet count was lower than 50,000/ μ L.²⁶⁸ On balance, maternal side effects, including gestational diabetes mellitus, were worse in the group on high-dose IVIG alone.²⁶⁸

Berkowitz and coworkers reported outcomes for 37 pregnancies in 33 women with a prior child who had ICH.²⁶⁹ Patients were stratified into three groups based on the timing of the

ICH: extremely high risk (ICH before 28 weeks' gestation), very high risk (ICH between 28 and 36 weeks' gestation), and high risk (ICH in the perinatal period).²⁶⁹ They received 1 or 2 g/kg/wk of IVIG starting at 12 weeks' gestation. If the fetal platelet count was less than 30,000/ μ L (by cordocentesis), prednisone was added with or without more IVIG. Five of the 37 fetuses had ICH; three of these infants did well, with mild intraventricular hemorrhage or platelet counts higher than 100,000/ μ L. However, two were treatment failures; in one of these cases, treatment was initiated much later than prescribed by the protocol.²⁶⁹

Most authorities recommend cesarean delivery for fetuses with platelet counts of less than 50,000/ μ L,²³⁷ although vaginal delivery has never been shown to cause ICH, and cesarean delivery has never prevented it. The use of 50,000/ μ L as a platelet count cutoff is entirely arbitrary. Nonetheless, the substantial rate of ICH probably justifies cesarean delivery in pregnancies with severe AIT.

In the past, most investigators recommended cordocentesis to determine the fetal platelet count. This strategy avoids treatment of fetuses with normal platelet counts and provides feedback about treatment response in cases of thrombocytopenia. The drawback is the modest but clinically important risk of fetal hemorrhage after cordocentesis in the setting of severe neonatal AIT.^{237,247,270} Because of this risk, a case can be made to initiate therapy without knowledge of the fetal platelet count. Whether the benefits of fetal blood sampling outweigh the risks in most cases is controversial. Many clinicians transfuse 5 to 15 mL of packed, washed, and irradiated maternal platelets (obtained by plateletpheresis) at the time of cordocentesis.²⁷⁰ Although the efficacy of this approach is unproved, it may decrease the risk of bleeding complications at the time of the procedure. It is important to distinguish this use of platelets from platelet transfusions intended as primary therapy.

With increasing recognition of the risks of cordocentesis in fetuses with severe thrombocytopenia, most authorities do not advise fetal blood sampling early in gestation, when complications lead to death or very preterm birth. Berkowitz and colleagues have had excellent outcomes without early cordocentesis.²⁶⁸ Fetal blood sampling may be useful later in gestation (e.g., 32 weeks) to assess the potential need for salvage medical therapy or the safety of a trial of labor. Others, including many initial advocates of cordocentesis, think the procedure is unnecessary in the management of AIT.²⁷¹ Further studies should resolve some of these issues. Meanwhile, it seems prudent to individualize the management of each case and to limit or eliminate cordocentesis.

According to available data, it seems appropriate to stratify treatment based on the level of risk for neonatal AIT. Pacheco and coworkers have recently put forth state of the art recommendations using such an approach.²⁷¹

1. Stratum 1 includes families with an uncertain diagnosis (e.g., prior infant with thrombocytopenia, ICH but no specific HPA antibodies or incompatibility). These patients should be screened for maternal anti-HPA antibodies.
2. Stratum 2 includes confirmed AIT with a prior fetus having thrombocytopenia but not ICH. These pregnancies are treated with 1 g/kg/wk of IVIG and 0.5 mg/kg/day of prednisone or 2 g/kg/wk of IVIG starting at 20 weeks' gestation. They all receive empiric salvage therapy with both 2 g/kg/wk of IVIG and 0.5 mg/kg/day of

prednisone at 32 weeks' gestation. They have an elective cesarean delivery at 37 to 38 weeks' gestation with documented lung maturity, and cordocentesis is performed only if the patient desires a vaginal delivery.

3. Stratum 3 consists of women with confirmed AIT and a prior infant with antenatal ICH at 28 weeks' gestation or later or with peripartum ICH. These women start treatment with 1 g/kg/wk of IVIG at 12 weeks' gestation. Their treatment at 20 and 28 weeks is the same as for stratum 1. They deliver by cesarean at 35 to 36 weeks' gestation after documentation of lung maturity or undergo trial of labor after cordocentesis.
4. Stratum 4 includes women with a prior infant with antenatal intraventricular hemorrhage before 28 weeks' gestation. These women are treated with 2 g/kg/wk of IVIG at 12 weeks' gestation, and 0.5 mg/day of prednisone is added at 20 weeks' gestation. Delivery is the same as for women in stratum 3.²⁷¹

Population-wide screening for potential HPA incompatibility is not recommended.²³⁷ This approach would allow prevention of ICH in first pregnancies before recognition of the disease, but disadvantages include cost and potentially morbid interventions. Population-based screening has been conducted in parts of Norway.²³³ HPA-1 typing was done for more than 100,000 women, and HPA-1a-negative women were screened for antibodies against HPA-1a. Women with antibodies were delivered by elective cesarean at 36 to 38 weeks' gestation, and HPA-1b platelets were available for neonatal transfusion. As expected, 2.1% were HPA-1a negative, and 10.6% of these women (170) had anti-HPA-1a antibodies. There were 161 HPA-1a-positive offspring; 55 had severe thrombocytopenia, and 2 had ICH.²³³ This approach identified considerably more cases (53 per year) than traditional surveillance (i.e., referral based on symptomatic neonates; 7.5 cases per year).²⁷² Investigators report that this approach is cost-effective.²⁷³ Ongoing studies are addressing the efficacy and cost-effectiveness of these programs. Another clinical dilemma is the patient whose sister has had a pregnancy with AIT. It may be worthwhile to assess platelet antigen incompatibility, HLA phenotype, and in cases at risk based on these tests, fetal platelet count in these patients. However, we have not found such testing to be useful. Instead, we reassure these women that their prospective risk of AIT is low and explain that we are unsure about the clinical relevance of such testing.

Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

Thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS) are thrombotic microangiopathies that are characterized by thrombocytopenia, hemolytic anemia, and multisystem organ failure. They are rare entities, but they may occur during pregnancy, are life-threatening, and can be difficult to distinguish from HELLP syndrome (*hemolysis, elevated liver enzymes, and low platelets*) (Table 53-3). The estimated incidence is 1 case per 25,000 births.²⁷⁴ Early diagnosis and treatment are critical, because the mortality rate may be reduced by 90%.²⁷⁵

TTP is characterized by central nervous system (CNS) abnormalities, severe thrombocytopenia, and intravascular hemolytic anemia. The most common CNS abnormalities are headache, altered consciousness, seizures, and sensory-motor deficits. Renal dysfunction and fever also may occur. Individuals

with HUS have renal involvement as the major finding, as well as thrombocytopenia and hemolytic anemia. The conditions are difficult to distinguish from each other. Up to 50% of patients with HUS have CNS abnormalities, and renal dysfunction may occur in up to 80% of those with TTP. For this reason, the two disorders are often considered as a single entity.^{276,277} Some experts advise that the term *TTP* be used to refer to adults with the condition, with or without neurologic or renal abnormalities, and that *HUS* should refer to children with renal failure, typically after *Escherichia coli* infection.²⁷⁸

The pathophysiology of TTP and HUS is abnormal, and profound intravascular platelet aggregation leads to multiorgan ischemia. In HUS, this occurs predominantly in the kidney. The inciting event in TTP is uncertain. One possibility is an abnormal immune response, because the condition is associated with several autoimmune disorders. It is more common among women and non-Hispanic blacks, consistent with many other autoimmune conditions.²⁷⁹ Other possibilities are medications such as chemotherapy agents, viral infections, and perhaps pregnancy itself, although many individuals have no risk factors. Larger than average vWF multimers appear to contribute to the pathophysiology, promoting abnormal platelet aggregation.²⁸⁰ ADAMTS13, a plasma enzyme, cleaves these vWF multimers, preventing the formation of platelet clumps. ADAMTS13 activity may be absent in patients with TTP, making it a risk factor for the condition.²⁸¹ ADAMTS13 deficiency may be congenital,²⁸² or it may be acquired through the development of autoantibodies.²⁸³ HUS is most often seen in children after a diarrheal illness caused by *E. coli*. Hemolysin, often from verotoxin-producing strains of *E. coli*, attaches to receptors in renal

epithelium, leading to endothelial injury, platelet activation or aggregation, and ischemia.^{284,285} In adults, HUS is often precipitated by pregnancy, chemotherapy, or bone marrow transplantation. The recurrence risk is higher for adults and patients who do not have infectious diarrhea as an inciting event.

The diagnosis of these conditions is clinical, because there is no laboratory gold standard. The CBC count and peripheral blood smear confirm thrombocytopenia and microangiopathic hemolytic anemia (i.e., schistocytes, helmet cells, and burr cells). Lactate dehydrogenase (LDH) and bilirubin levels are elevated, indicating hemolysis. Levels of serum creatinine and blood urea nitrogen may be elevated, especially in HUS. Results of clotting studies are typically normal early in the disease process. However, secondary DIC may occur after tissue necrosis. Large multimers of vWF may be present in cases of TTP, and renal biopsy may show microvascular occlusions and intraglomerular platelet aggregates in HUS. ADAMTS13 activity may be decreased in TTP and HUS.²⁸¹ However, in many centers, results may not be available in a timely fashion.²⁸⁶ Both disorders are hard to distinguish from preeclampsia.^{286,287} Keiser and Martin and their colleagues reported that a high ratio of LDH to aspartate aminotransferase (AST) may differentiate patients with TTP from those with HELLP.^{288,289} Clinical signs and laboratory tests for differentiating these conditions are shown in Table 53-3.²⁹⁰ The distinction between preeclampsia and TTP or HUS is critical, because the former improves with delivery, but TTP and HUS require additional therapy.

Plasmapheresis has substantially increased the survival rate for those with TTP to about 80%.^{291,292} Efficacy is less certain for HUS, but good outcomes have been reported.^{289,291} The mechanism of action is unclear but may involve removal of platelet-aggregating agents, such as large vWF multimers, or autoantibodies against ADAMTS13. Additional treatment includes infusion of platelet-poor or cryoprecipitate-poor fresh-frozen plasma (30 mL/kg/day), which may replace ADAMTS13, reducing vWF multimer size and reducing platelet aggregation. Platelet transfusions should be avoided, because they may precipitate the disease.²⁷⁵ However, red blood cell transfusion is often necessary. Glucocorticoids or other immunosuppressive therapy may be useful (to reduce antibodies to ADAMTS13) and is recommended for patients who do not respond immediately to plasma exchange.²⁸¹ Efficacy is uncertain. Treatment should continue for several days after recovery. Refractory cases may benefit from cytotoxic immunosuppressive agents. These therapies are generally accepted for TTP. Therapy is similar for HUS, although efficacy is less certain. Individuals with HUS often require dialysis.

About 10% to 25% of TTP cases occur during pregnancy or the postpartum period. Pregnancy is considered to be a risk factor for TTP and HUS, perhaps because of physiologic reduction in ADAMTS13 levels, general hypercoagulability, and synergistic features with preeclampsia.^{293,294} HUS is more likely to occur in the peripartum or postpartum period. If TTP or HUS manifests during pregnancy, there is a risk of fetal mortality up to 33% due to severe maternal illness and placental insufficiency.^{295,296} Neonatal death may be caused by previsible delivery. If TTP or HUS occurs early in gestation, aggressive treatment with plasma infusions, plasmapheresis, and steroids should be initiated. Delivery of the fetus should be considered in refractory cases, because improvement has been reported in sporadic cases.²⁹⁰ At later gestational ages, delivery becomes a more attractive option. It is important to consider TTP and HUS in

cases of apparent preeclampsia or HELLP syndrome that do not improve within 48 to 72 hours after delivery.

It is important to counsel women about the recurrence risk for these conditions. In one small series of women with TTP or HUS in pregnancy, one half had at least one recurrence.²⁷⁴ Long-term morbidity and mortality rates were substantial. However, good outcomes and a lower recurrence risk have been reported in other series of subsequent pregnancies in women with prior TTP or HUS associated with pregnancy.^{297,298} Serial and prophylactic plasma exchange may be useful in women with prior TTP or HUS and persistent, severely reduced ADAMTS13 activity.^{298,299}

Drug-Induced Thrombocytopenia and Functional Platelet Defects

Drugs such as heparin and quinidine can cause thrombocytopenia. Functional platelet defects occur when there are normal numbers of platelets that do not function properly. Drugs are a common cause of this condition. Examples include ASA, NSAIDs, antimicrobial agents such as carbenicillin, and glyceryl guaiacolate, which is present in some cold remedies.

CONGENITAL PLATELET DISORDERS

Von Willebrand Disease

Laboratory studies indicate that von Willebrand disease (vWD) occurs in 1.3% of the population, making it the most common inherited bleeding disorder, but data based on clinical symptoms indicate a much lower prevalence.^{300,301} The von Willebrand molecule has several functions. It adheres to exposed subendothelium and to platelets, tethering them to sites of endothelial damage. The molecules bind to one another to create high-molecular-weight multimers to ensnare platelets, and they bind factor VIII, stabilizing it and prolonging its half-life in the circulation. The disease is caused by deficiencies or abnormalities in any of these functions.

Type I vWD, the most common variety, accounts for 80% of cases. It is usually inherited in an autosomal dominant fashion and is characterized by deficient quantities of structurally normal vWF. In type I vWD, platelets fail to aggregate in the presence of ristocetin.

Type II vWD is less common and may be transmitted in an autosomal recessive fashion. There are several subtypes of type II vWD, which is notable for vWF that does not function normally. Type IIA involves a deficiency of normal high-molecular-weight multimers of vWF, with consequently decreased affinity for platelets. Type IIB is characterized by vWF with an increased affinity for platelets due to an increased affinity for GpIb. The clinical disorder is similar to that caused by pseudo-vWD, which results from defective GpIb and leads to hyperactive platelet binding to vWF. Type IIM is notable for morphologically and qualitatively abnormal vWF with reduced interaction with GpIb. Type IIN is caused by vWF with impaired binding to factor VIII.

Type III vWD is an autosomal recessive trait and is the least common of the three types. Individuals with type III vWD have a severe deficiency of vWF, which causes factor VIII deficiency.

Some individuals have an acquired vWD in response to certain medical problems (e.g., congenital heart disease) or medications. vWD and its subtypes may be diagnosed with a variety of laboratory studies, as summarized in Table 53-4.³⁰²⁻³⁰⁴

Pregnancy increases the level of vWF and factor VIII, and patients are less likely to need therapy. Levels of vWF and factor VIII should be assessed in the third trimester in anticipation of delivery.^{305,306} Although of unproven efficacy, levels of 50 IU/dL should be reached before delivery and maintained for at least 3 to 5 days after delivery.³⁰⁵

A primary treatment for many women with vWD is 1-deamino-8-D-arginine vasopressin (DDAVP), which increases plasma factor VIII and vWF levels (Table 53-5).^{307,308} Response to DDAVP varies greatly among women with vWD, although most of those with type I disease have a favorable response. Some women with type IIA vWD also respond well to DDAVP. However, the drug should be avoided in women with type IIB disease, because it may cause thrombocytopenia.³⁰⁹ Patients with type III disease rarely respond. Ideally, an individual's response to DDAVP should be tested under nonurgent circumstances. A typical dose is 0.3 µg/kg to a maximum of 20 µg given subcutaneously or diluted in 50 to 100 mL of normal saline and given intravenously over 30 minutes. If the patient is not pregnant, the drug may be administered on day 1 of menses. A subjective decrease in flow is considered a positive response. If the patient is pregnant or not bleeding, the response is gauged by assessing a change in platelet count and vWF:ristocetin cofactor (RCoF) peak activity at 90 minutes after the administration of DDAVP. Adverse effects of DDAVP include headache, flushing, changes in blood pressure, fluid retention, and hyponatremia. The drug is pregnancy category B.

Replacement of clotting factors is the other standard treatment for vWD. In cases with circulating factor VIII (FVIII:C) or vWF levels less than 50 IU/dL, prophylactic treatment should be given to cover invasive procedures and delivery.³⁰⁸ Patients with low vWF levels and known positive responses to DDAVP or type I disease should be given prophylactic treatment with a single dose of DDAVP 60 minutes before anticipated delivery or at the time of cord clamping.³⁰⁸ Additional doses are of uncertain benefit and may be harmful. Special attention must be given to the possibility of fluid retention and hyponatremia when using DDAVP near the time of childbirth.³⁰¹ Women who do not respond to DDAVP may be treated with factor VIII/vWF plasma concentrate in the form of plasma, cryoprecipitate, Humate-P, and Koate-DVI. These products are typically labeled with vWF:Ac concentrations, indicating functional activity (Ac); 1 IU/kg of vWF:Ac increases the plasma level by 2.0 U/dL. Ideally, vWF:Ac levels should be 50% of normal (50 IU/dL) in prophylactic settings; 100% of normal is the goal in cases of bleeding or surgery. This level should be maintained for at least 3 days after vaginal delivery or 5 days after cesarean delivery.³⁰⁸ Some authorities advise that vWF concentrate be used as first-line therapy for peripartum women to avoid the risk of hyponatremia associated with DDAVP.³⁰⁵ Tranexamic acid also may be useful in controlling or preventing postpartum hemorrhage.³⁰⁸

Pregnancy is not contraindicated in women with vWD, but they should be informed about the potential for bleeding and the genetic implications.^{301,302,305} A large, epidemiologic study estimated the odds ratio of postpartum hemorrhage for women with vWD to be 1.5 (CI, 1.1 to 2.0).³¹⁰ The odds ratio for needing a blood transfusion was 4.7 (CI, 3.2 to 7.0), and 5 of 4067 women died, a rate 10-fold higher than in the general population.³¹⁰ The antepartum period is an ideal time to characterize the type of vWD and the response to DDAVP. If possible, a multidisciplinary team including a hematologist,

Disorder	Definition	Diagnostic Assays
Hemophilia A		
Severe	Factor VIII <2%	Prolonged aPTT, low factor VIII
Mild	Factor VIII = 2%-25%	Prolonged aPTT, low factor VIII
Carrier	Factor VIII ≈50%	aPTT usually normal, low factor VIII
Hemophilia B		
Severe	Factor IX <2%	Prolonged aPTT, low factor IX
Mild	Factor IX = 2%-25%	Prolonged aPTT, low factor IX
Carrier	Factor IX ≈ 50%	aPTT usually normal, low factor IX
Factor VII deficiency	Low factor VII	Prolonged INR, low factor VII
Factor X deficiency	Low factor X	Prolonged aPTT, prolonged INR, low factor X
Factor XI deficiency	Low factor XI	Prolonged aPTT, low factor XII
Factor XII deficiency	Low factor XII	Prolonged aPTT, low factor XII
Factor XIII deficiency	Low factor XIII	Normal aPTT and INR, low factor XIII
Hypofibrinogenemia	Low fibrinogen	Low fibrinogen
vWD		
Types I and III	Deficient (type I) or absent (type III) vWF	Absent vWF:RCoF and RIPA; platelets aggregate with bovine plasma
Type IIA	Qualitatively abnormal vWF: lack of HMW multimers	Multimeric analysis
Type IIB	Qualitatively abnormal vWF; spontaneously binds platelets; lack of HMW multimers	Platelets aggregate to 0.5 mg/mL of ristocetin; multimeric analysis, decreased platelets
Pseudo-vWD	Platelets spontaneously bind Gplb-IX-V complex	Absent vWF: RCoF activity; differentiated from vWD by no clumping to bovine plasma
Bernard-Soulier syndrome	Platelet Gplb is defective	Absent vWF: RCoF activity; differentiated from vWD by no clumping to bovine plasma
Secretion defects	Arachidonic acid and prostaglandin pathway abnormalities	Aspirin and NSAIDs are common causes; abnormal response to collagen; arachidonic acid; normal primary wave only
Storage pool deficiencies	Abnormal function or component deficiency of platelet granules (α , δ , or both)	Primary wave only; decreased collagen assay; variable arachidonic acid assay; mepacrine labeling
Glanzmann thrombasthenia	Gpllb-IIIa is absent, present in minimal amounts, or qualitatively abnormal	Platelets not activated by ADP, collagen, or arachidonic acid

ADP, adenosine diphosphate; aPTT, activated partial thromboplastin time; Gp, glycoprotein; HMW, high molecular weight; INR, international normalized ratio; NSAIDs, nonsteroidal anti-inflammatory drugs; RCoF, ristocetin cofactor; RIPA, ristocetin-induced platelet agglutination; vWD, von Willebrand disease; vWF, von Willebrand factor.

Disorder	Threshold for Treatment	Treatment
Hemophilia A	Bleeding; before delivery or procedures if factor VIII level <50 IU/dL	Factor VIII concentrate, cryoprecipitate, DDAVP
Hemophilia B	Bleeding; before delivery or procedures if factor IX level <50 IU/dL	Factor IX concentrate, cryoprecipitate
Factor VII deficiency	Bleeding; before delivery or procedures if factor VII level <50 IU/dL	rFVIIa, factor VII concentrate
Factor X deficiency	Bleeding; possibly before delivery or procedures	Factor IX concentrate, FFP
Factor XI deficiency	Bleeding; before delivery or procedures if factor XI level <15 IU/dL	Factor XI concentrate, FFP (do not exceed peak factor XI levels of 70 IU/dL)
Factor VII deficiency	?	?
Factor VIII deficiency	Bleeding; pregnancy	Factor VIII concentrate, FFP, cryoprecipitate (keep XIIIa antigen or activity >10% of normal)
Hypofibrinogenemia	Bleeding; fibrinogen <150 mg/dL; pregnancy	FFP, cryoprecipitate (keep fibrinogen >100 mg/dL)
vWD		
Type I	Bleeding	DDAVP (if favorable response), tranexamic acid, FFP, cryoprecipitate, Humate-P, Koate-DVI (goals are >50 IU/dL of vWF:Ac)
Type IIA	Bleeding; operative delivery; procedures	DDAVP (if favorable response), tranexamic acid, FFP, cryoprecipitate, Humate-P, Koate (goal is >50 IU/dL of vWF:Ac)
Type IIB	Bleeding; operative delivery; procedures	FFP, cryoprecipitate, Humate-P, Koate-DVI (goal is >50 IU/dL of vWF:Ac); DDAVP is contraindicated
Type IIN	Bleeding; operative delivery; procedures	FFP, cryoprecipitate, Humate-P, Koate (goal is >50 IU/dL of vWF:Ac)
Type IIM	Bleeding; operative delivery; procedures	FFP, cryoprecipitate, Humate-P, Koate (goal is >50 IU/dL of vWF:Ac)
Type III	Bleeding; all deliveries; procedures	FFP, cryoprecipitate, Humate-P, Koate-DVI (goal is >50 IU/dL of vWF:Ac); DDAVP is not effective
Bernard-Soulier syndrome	Bleeding (prophylaxis for delivery is controversial)	Platelet transfusion (possibly DDAVP, tranexamic acid, immune suppression, rFVIIa)
Storage pool deficiencies	Bleeding (prophylaxis for delivery is controversial)	Platelet transfusion; DDAVP (?)
Glanzmann thrombasthenia	Bleeding; delivery; procedures	Platelet transfusion; rFVIIa

DDAVP, desmopressin; FFP, fresh-frozen plasma; rFVIIa, recombinant activated factor VII; vWD, von Willebrand disease; vWF, von Willebrand factor.

TABLE 53-6 Prenatal Diagnosis of Congenital Bleeding and Platelet Disorders

Disorder	Tissue Required	Tests*	Comment
Hemophilia A	Amniocytes, fetal blood	Fetal gender; factor VII mutation analysis, linkage analysis (if family mutation is known); cord blood factor VIII levels	Because of the risk of bleeding, cordocentesis is reserved for cases in which genetic testing is nondiagnostic.
Hemophilia B	Amniocytes, fetal blood	Fetal gender; factor IX mutation analysis, linkage analysis (if family mutation is known); cord blood factor IX levels	Because of the risk of bleeding, cordocentesis is reserved for cases in which genetic testing is nondiagnostic.
Factor VII deficiency	Amniocytes, fetal blood	Factor VII mutation analysis, linkage analysis (if family mutation is known); cord blood factor VII levels	Because of the risk of bleeding, cordocentesis is reserved for cases in which genetic testing is nondiagnostic.
Factor X deficiency	Amniocytes, fetal blood	Factor X mutation analysis, linkage analysis (if family mutation is known); cord blood factor X levels	Because of the risk of bleeding, cordocentesis is reserved for cases in which genetic testing is nondiagnostic.
vWD (types I and III)	Amniocytes or fetal blood	Mutation analysis, linkage analysis (if family mutation known); vWF:RCoF	Because of the risk of bleeding, cordocentesis is reserved for cases in which genetic testing is nondiagnostic.
vWD (type II)	Amniocytes or fetal blood	Mutation analysis, linkage analysis, if family mutation known; vWF:RCoF	Because of the risk of bleeding, cordocentesis is reserved for cases in which genetic testing is nondiagnostic.
Bernard-Soulier syndrome	Amniocytes or fetal blood	Mutation analysis, linkage analysis (if family mutation known); vWF:RCoF; bovine plasma	Because of the risk of bleeding, cordocentesis is reserved for cases in which genetic testing is nondiagnostic. Cordocentesis is extremely hazardous if the fetus is positive for the mutation.
Glanzmann thrombasthenia	Amniocytes or fetal blood	Mutation analysis, linkage analysis (if family mutation known); functional assays; anti-GpIIb-IIIa antibody binding	Because of the risk of bleeding, cordocentesis is reserved for cases in which genetic testing is nondiagnostic. Cordocentesis is extremely hazardous if the fetus is positive for the mutation.
Gray platelet syndrome	Fetal blood	Microscopic analysis	Normal fetal platelets have α -granules.
Wiskott-Aldrich syndrome	Amniocytes or fetal blood	Mutation analysis, linkage analysis (if family mutation known); platelet size/volume	Because of the risk of bleeding, cordocentesis is reserved for cases in which genetic testing is nondiagnostic.
Chediak-Higashi syndrome	Fetal blood	Peroxidase stain of neutrophils	Proven successful in feline model
Hermansky-Pudlak syndrome	Amniocytes	Mutation analysis, linkage analysis (if family mutation known)	—

*Because genes and some mutations have been identified for deficiencies of factors X, XI, XII, and XIII and for fibrinogen, prenatal diagnosis using amniocytes may be possible. Cordocentesis also may be informative through the direct measurement of factor levels. Gp, glycoprotein; RCoF, ristocetin cofactor; vWD, von Willebrand disease; vWF, von Willebrand factor.

obstetrician, and anesthesiologist should coordinate care and a management plan.^{305,306,308} Prenatal diagnosis is possible in many cases, and genetic counseling should be offered to affected families (Table 53-6). This is especially pertinent for patients who are at risk of having a fetus with severe type III disease. At times, genetic testing of amniocytes or chorionic villi is possible in cases of known mutations or restriction fragment length polymorphisms.^{311,312} Cordocentesis to perform functional assays on fetal blood may be diagnostic, although results can be unreliable due to variable penetrance, and the risk of bleeding at cordocentesis is increased in affected cases.^{313,314} It may be helpful to assess levels of vWF antigen (vWF:Ag), vWF:Ac, and FVIII:C on a serial basis (e.g., the initial visit, at 28 and 34 weeks' gestation, and before invasive procedures and delivery).³⁰⁸ Factor VIII and vWF concentrates, DDAVP, skilled anesthesia personnel, and hematology consultants should be available at delivery, which may require referral to a tertiary care center.

In the past, neuraxial anesthesia was considered to be contraindicated in most women with vWD, but safe use of regional anesthesia has been reported in some of these cases.^{315,316} Regional anesthesia is thought to be safe if factor VIII and

vWF:RCoF levels are greater than 50 IU/dL, although this has not been proved.^{301,308,317} Cesarean delivery has been advised by some authorities in an attempt to avoid fetal bleeding.³¹⁸ However, the procedure is of unproven efficacy and bleeding has been reported in affected infants born by cesarean.³¹⁸ Given the unproven efficacy and the risk of maternal hemorrhage, elective cesarean delivery is not routinely advised in vWD cases.^{302,308} However, traumatic delivery, such as vacuum or rotational forceps, should be avoided. NSAIDs should not be used for postpartum analgesia. Neonates born to mothers with vWD should be tested to determine their vWF status. There is an increased risk of hemorrhage after delivery, even several weeks later. Frequent patient contact, monitoring of vWF levels, and prolonged prophylaxis may reduce this risk, but this has not been proved.³⁰¹

Bernard-Soulier Syndrome

Bernard-Soulier syndrome is usually transmitted in an autosomal recessive fashion. A family history is rare, although one variant appears to be autosomal dominant. Affected individuals have mucocutaneous bleeding due to a defect or deficiency in

the platelet glycoproteins that form a transmembrane complex (GpIb-IX-V) that binds vWF.³¹⁹ The result is platelets that cannot bind to subendothelial surface. Laboratory diagnosis includes a decreased number of relatively large platelets, absent ristocetin response, a failure of platelets to aggregate in response to bovine plasma, and decreased GpIb-IX-V complex density as measured by flow cytometry.³²⁰ Successful treatment requires platelet transfusion.

Prenatal diagnosis is possible in many cases and should be offered to families with a prior affected child. Because of previous platelet transfusions, affected mothers often are at risk for AIT. Cesarean delivery is controversial and should be reserved for obstetric indications.^{302,321} Regional anesthesia is contraindicated. Prophylactic platelet transfusion before delivery in this setting is also controversial because of the risk of AIT. This risk must be weighed against frequent antepartum, intrapartum, and postpartum hemorrhagic complications, especially after delivery.³²¹ A systematic review identified postpartum hemorrhage in 60% of pregnancies, with 50% requiring blood transfusion.³²² The use of HLA and platelet antigen–matched platelets may reduce the risk of AIT.

Several other strategies may reduce the risk of bleeding or may be used to treat bleeding after delivery in women with Bernard-Soulier syndrome. They include DDAVP, antifibrinolytic therapy with tranexamic acid, immune suppression to prolong platelet survival, and recombinant activated factor VII (rFVIIa).^{321,323–325} The optimal dose of rFVIIa is uncertain, but a dose of 90 to 120 µg/kg of body weight, repeated every 2 hours if there is a good response, has been recommended.³²¹

Disorders of Platelet Secretion

Disorders of platelet secretion include several rare conditions characterized by platelet storage pool deficiencies. These disorders involve deficient or abnormal platelet granules or their contents.

Gray Platelet Syndrome. Gray platelet syndrome is caused by a deficiency of α -granules in platelets and megakaryocytes. Platelet α -granules contain vWF, platelet factor 4, and platelet-derived growth factor. Characteristic gray-appearing platelets are observed on the peripheral smear or marrow aspirate after staining with Romanowsky solution. Treatment includes platelet transfusion, ideally with HLA-matched platelets. Good pregnancy outcomes have been reported for patients with gray platelet syndrome after platelet transfusion.^{326,327}

Delta Storage Pool Disease. Delta storage pool disease involves a deficiency in dense granules (δ -granules) in platelets containing ADP. Diagnosis is made by electron microscopy or by a ratio of adenosine triphosphate (ATP) to ADP that is greater than 3 to 1 in inactive platelets. Other disorders associated with δ storage pool disease include the Chediak-Higashi, Wiskott-Aldrich, thrombocytopenia with absent radii (TAR), and Hermansky-Pudlak syndromes.

Most patients with δ storage pool diseases respond to a platelet transfusion, although some may respond to DDAVP. Rarely, individuals have congenital or acquired abnormalities of δ - and α -granules (i.e., $\alpha\delta$ storage pool disease). A case of an uncomplicated pregnancy without treatment was reported in a patient with Chediak-Higashi syndrome.³²⁸ Wiskott-Aldrich syndrome is an X-linked immunodeficiency syndrome that is associated with early mortality. Prenatal diagnosis is possible and should

be offered to affected families.³²⁹ Thrombocytopenia associated with TAR typically resolves at 1 year of life. Prenatal diagnosis of the syndrome has been reported.³³⁰ Several pregnancies have been reported in women with Hermansky-Pudlak syndrome.^{331,332} This autosomal recessive condition is characterized by oculocutaneous albinism, platelet storage pool deficiency, and the accumulation of ceroid (a yellow, granular substance) in reticuloendothelial cells. It is common in some areas of Puerto Rico.^{331,332}

Glanzmann Thrombasthenia. Glanzmann thrombasthenia is an abnormality in the quantity or quality (or both) of the platelet membrane glycoprotein GpIIb-IIIa.³³³ The disease is transmitted in an autosomal recessive fashion and has been reported most often in Iraqi-Jewish and Arab populations in Israel, in Southern India, and among European Roma (gypsies).^{334,335} Patients with type 1 Glanzmann thrombasthenia lack detectable GpIIb-IIIa, whereas those with type 2 disease have only 10% to 20% of normal platelet surface GpIIb-IIIa.

These patients are at lifelong risk for bleeding and often require frequent platelet transfusions. Many develop alloimmune antibodies against platelet antigens, causing their pregnancies to be at risk for AIT.³³⁶ Women with a history of multiple platelet transfusions should undergo evaluation for parental platelet antigen incompatibility and the presence of specific antiplatelet antibodies for fetal antigens. Cordocentesis has been particularly risky in affected pregnancies and is best avoided. This makes prenatal diagnosis more difficult. In cases of known mutations, the fetal genotype may be obtained from amniocytes or chorionic villi; chorionic villus sampling should be avoided if the patient has antibodies.

The primary intrapartum treatment for Glanzmann thrombasthenia is platelet transfusion.^{337,338} If possible, type-specific platelets should be used to avoid platelet alloimmunization. If pooled platelets must be used in sensitized women, immunosuppressive therapy may prolong the life span and effectiveness of the platelets. Cesarean delivery should be reserved for the usual obstetric indications, including alloimmune thrombocytopenia. Postpartum hemorrhage is common and has been reported in 50% of pregnancies.³³⁹ Hormonal treatment and prolonged use of uterotonic agents may reduce the risk of this complication, although this approach is of unproven efficacy. The use of rFVIIa appears to be safe and relatively effective in patients with Glanzmann thrombasthenia,^{338,340,341} and it may prove to be an important tool for the treatment of this disease during pregnancy.

Bleeding Disorders

ACQUIRED BLEEDING DISORDERS

Factor VIII Inhibitors

The development of antibodies against factor VIII is a rare but serious acquired bleeding disorder.³⁴² The inciting event is unknown, but the condition often manifests in the postpartum period.³⁴³ Clinical features are similar to those seen in hemophilia. Diagnosis is made by prolonged clotting times that do not normalize in response to mixing studies using normal plasma. Demonstration of a specific factor VIII inhibitor and documentation of low levels of factor VIII in the plasma confirm the diagnosis.

Hemorrhage may be severe and may respond to activated prothrombin complex concentrate or rFVIIa (to bypass factor VIII pathways).³⁴¹⁻³⁴³ Mild cases often respond to DDAVP and factor VIII concentrates.³⁴³ Plasmapheresis or other immunosuppressive agents may be helpful in refractory cases.³⁴² The disease typically regresses spontaneously over time. Although IgG antibodies to factor VIII may develop, infants are rarely affected. The condition usually remits spontaneously, with or without the use of immunosuppressive therapy.³⁴³

CONGENITAL BLEEDING DISORDERS

Hemophilia A and Hemophilia B

Hemophilia A and B are caused by congenital deficiencies of factor VIII and IX, respectively. They are inherited in an X-linked recessive fashion. Affected female offspring are uncommon. Heterozygous carriers are usually asymptomatic. Rarely, a heterozygous girl has clinical symptoms of bleeding, perhaps because of skewed inactivation of the X chromosome containing the normal gene. Symptoms tend to be mild, and serious hemorrhage during labor and delivery is rare. Treatment may be accomplished with factor VIII concentrate or cryoprecipitate for hemophilia A and factor IX concentrate or fresh-frozen plasma for hemophilia B.³⁰⁸

Pregnancy issues often focus on the fetus or neonate because 50% of male offspring born to female carriers are affected. Carrier detection of hemophilia A may be accomplished using assays for factor VIII and is reliable during pregnancy. Prenatal diagnosis is feasible through factor VIII and IX gene mutation analysis or linkage analysis, or both.³¹² Rarely, cordocentesis may be used to detect an affected fetus by testing levels of factors VIII and IX, which are normally lower in a fetus than in an adult. However, this approach is reserved for cases in which genetic testing is not diagnostic, because the procedure is risky.³⁰⁸ Noninvasive prenatal diagnosis of hemophilia using free fetal DNA in maternal plasma has been reported.³⁴⁴ If this becomes commercially available, it will be an attractive option for prenatal diagnosis.

Levels of factor VIII or IX, or both, should be assessed at the initial pregnancy visit, at 28 and 34 weeks' gestation, and again at delivery.³⁰⁸ Recombinant factor VIII and IX should be used as the treatment of choice in pregnant carriers of hemophilia A and B, respectively. Treatment should be initiated in the setting of bleeding or factor VIII or IX levels lower than 50 IU/dL.³⁰⁸ DDAVP may be helpful in women with hemophilia A, but not in those with hemophilia B.

Regional anesthesia should be safe in women with normal coagulation studies and factor levels greater than 50 IU/dL. Vaginal delivery has not increased bleeding in affected male infants, and a trial of labor is a reasonable option in such cases.³⁴⁵ However, the optimal mode of delivery is controversial, and some authorities recommend elective cesarean delivery, which is a reasonable option.^{345,346} Fetal scalp electrodes, operative vaginal delivery with vacuum or forceps, and circumcision should be unequivocally avoided in male infants born to carriers of hemophilia A.³⁴⁵ Postnatal diagnosis may be established in newborns through assays of maternal and cord blood. Carriers of hemophilia B are detected by a factor IX assay. Levels of factor IX in carriers are usually decreased, although they may be normal. Delivery issues with hemophilia B are similar to those for hemophilia A.

Other Factor Deficiencies

Deficiencies of factors VII, X, XI, and XIII are uncommon hereditary bleeding disorders. Factor VII, X, and XIII deficiencies are probably autosomal recessive traits, whereas factor XI deficiency appears to be an incompletely autosomal-recessive trait.

Replacement with rFVIIa is the treatment of choice for women with factor VII deficiency.³⁴⁷ Factor X-deficient women may be treated with fresh-frozen plasma or factor IX concentrates to treat active bleeding.^{348,349} Prophylactic transfusion may be useful before vaginal or cesarean delivery.^{348,350} Individuals who are homozygous for factor XI deficiency have levels less than 20% of normal, whereas heterozygotes have levels that are 30% to 65% of normal.³⁵¹ Bleeding does not always correlate with factor XI concentrations, and heterozygotes may have minor bleeding problems. Most women do not experience hemorrhage during delivery,^{352,353} and it may be possible to stratify patients with the condition into bleeding and nonbleeding phenotypes.³⁵³ Prophylactic treatment is not required for all deliveries, and treatment may be reserved for excessive bleeding.^{352,353} This may be accomplished with fresh-frozen plasma given as a 10 mL/kg load followed by 5 mL/kg per day or through direct replacement with factor XI concentrate.

Factor XIII deficiency is rare but can lead to severe bleeding such as ICH after minor trauma and abnormal wound healing. Life-threatening umbilical cord stump hemorrhage has occurred in affected newborns. An increased risk of recurrent pregnancy loss also has been reported for women with factor XIII deficiency.³⁵⁴ It is thought to be the result of decidual bleeding, and successful pregnancy rarely occurs without treatment. Diagnosis is made by assessment of factor XIII (A and S subunits) or by dissolution of clot in 5 M urea. Treatment includes transfusion with factor XIII concentrate, fresh-frozen plasma, cryoprecipitate, or whole blood. Small amounts of plasma may provide adequate factor XIII for hemostasis. Although of uncertain efficacy, maintenance of XIIIa antigen or XIII activity at 10% is advised.³⁵⁴ This may require the administration of 1 vial of XIIIa concentrate (250 IU) every 7 days in early pregnancy, followed by 2 vials every 7 days after 23 weeks' gestation.^{354,355} Extra replacement (e.g., 4 vials) may be helpful at the time of delivery.³⁵⁴

Hypofibrinogenemia or Afibrinogenemia

Congenital hypofibrinogenemia is a rare, autosomal dominant condition characterized by bleeding and obstetric problems such as abruption, postpartum hemorrhage, and recurrent pregnancy loss.^{356,357} The condition is defined as the presence of structurally normal fibrinogen in concentrations of less than 150 mg/dL.³⁵⁶ Miscarriage at mid-gestation appears to be caused by perigestational hemorrhage.³⁵⁷ This is supported by data from transgenic mice lacking fibrinogen, which suffer uniform pregnancy loss at day 10.³⁵⁸ Pregnancy loss in these mice is corrected by the addition of fibrinogen. Dysfibrinogenemia has been weakly associated with hypercoagulability, rather than hypocoagulability.

Successful pregnancies in women with hypofibrinogenemia have been reported with the use of fresh-frozen plasma or cryoprecipitate to maintain fibrinogen levels greater than 100 to 150 mg/dL.^{356,357,359} Each unit of cryoprecipitate contains about 300 mg of fibrinogen, which raises the plasma concentration by approximately 6 mg/dL.

Factor XII Deficiency

Factor XII is involved in coagulation and fibrinolysis, and deficient individuals have been reported to be at increased risk for bleeding and thrombosis. However, it is not clear that this condition increases the risk for bleeding or thrombosis.³⁶⁰ The condition is of interest because it may be associated with recurrent pregnancy loss.^{361,362}

Plasminogen Activator Inhibitor 1 Deficiency

Individuals with elevated levels of PAI-1 are at increased risk for thrombosis and possibly for pregnancy loss. In contrast, deficiency of PAI-1 is associated with an increased risk of bleeding.³⁶³ The condition often manifests as menorrhagia and may

be responsive to aminocaproic acid.³⁶³ Low PAI-1 activity has been reported in 23% of patients referred for evaluation of bleeding diathesis, compared with 10% of controls (OR = 2.75; CI, 1.39 to 5.42).³⁶⁴ It may prove to be an important cause of abnormal bleeding. There are few data regarding pregnancy in women with PAI-1 deficiency, but a successful pregnancy has been reported.³⁶⁵

Tables 53-4, 53-5, and 53-6 compare the definitions, diagnoses, treatments, and prenatal diagnoses of platelet abnormalities and bleeding disorders.

Thromboembolic Disease in Pregnancy

ANN N. LEUNG, MD | CHARLES J. LOCKWOOD, MD, MHCM

Venous thromboembolism (VTE) accounts for almost 20% of pregnancy-related deaths in the United States.¹ A large retrospective cohort study of 268,525 patients over a 19-year period reported a VTE prevalence of 1 per 1627 births; of these cases, 77% involved deep venous thrombosis (DVT), and 23% involved acute pulmonary embolism (PE).² No antecedent history of VTE was present in 86% of these patients. Among nonpregnant adults who have fatal PE, 65% (95% confidence interval [CI], 40.8 to 84.6) die within 1 hour after onset.³ These findings underscore the need for a high index of suspicion, a sensitive and rapid diagnostic algorithm, and expeditious initiation of treatment in pregnant women with suspected VTE.

Among pregnant women, the DVT is localized to the lower extremities in 98.4% of cases, with the left leg affected in up to 80% of cases.² The occurrence of DVT is more common in the antepartum than in the postpartum period (74% versus 26%; $P < .001$), with a mean gestational age at diagnosis of 16.8 ± 2.4 weeks. Nearly 50% of antepartum DVT cases are detected by 15 weeks, 38% between 16 and 30 weeks, and only 12% after 30 weeks. In contrast, most PE is diagnosed in the postpartum period (60.5%) and are strongly associated with cesarean delivery (relative risk, 30.3; $P < .001$).²

Risk Factors

PREGNANCY AS A PROTHROMBOTIC STATE

Usually, VTE is a disease of aging, occurring in fewer than 1 of every 10,000 healthy women before 40 years of age.⁴ However, the risk for VTE is increased sixfold in pregnancy. Pregnancy induces this prothrombotic state in a number of ways. Compared with the nonpregnant state in women of reproductive age, pregnancy is associated with increases of 20% to 1000% in plasma concentrations of fibrinogen; factors VII, VIII, IX, X, and XII; and von Willebrand factor.⁵ In addition, activity of the anticoagulant factor, protein S, declines on average to 39% of normal levels in the second trimester and 31% of normal levels in the third trimester.⁶ As a consequence, pregnancy is associated with an increase in resistance to activated protein C. The net effect of these changes is an increase in thrombin generation, as measured by increased levels of fibrinopeptide A and the thrombin-antithrombin complex.⁷ Protein S levels drop even further after cesarean delivery or infection, helping to account for the high prevalence of PE after cesarean section. Levels of plasminogen activator inhibitor (PAI)-1, which inhibits clot lysis, increase threefold to fourfold during pregnancy, whereas plasma PAI-2 values, which are negligible before pregnancy, reach high concentrations at term as a result of production by the placenta.⁵ Thus, pregnancy is associated with increased thrombin-generating potential, decreased endogenous anticoagulant effects, and impaired fibrinolysis.

The occurrence of VTE in pregnancy is also promoted by venous stasis in the lower extremities resulting from compression of the inferior vena cava and pelvic veins by the enlarging uterus, compression of the left common iliac vein by the right iliac artery,⁸ and increases in deep vein capacitance caused by increased circulating levels of progesterone and local endothelial production of prostacyclin and nitric oxide.^{9,10}

RISK FACTORS NOT SPECIFIC TO PREGNANCY

Additional risk factors for VTE, not specific to, but potentially more common in, pregnancy, include vascular trauma, infection, obesity, severe proteinuria, and prolonged bed rest. Maternal age greater than 35 years doubles the risk for VTE in pregnancy.¹¹ One study found that among patients undergoing cesarean delivery who developed PE, 36% were older than 35 years and 55% were obese (body mass index, >29).¹²

Antiphospholipid antibody syndrome (APS) is associated with a 1% to 5% risk for VTE in pregnancy and the puerperium despite thromboprophylaxis.^{13,14} In a case-control study of 30 pregnant women with VTE versus matched controls who were subsequently analyzed for aPL, the prevalence of these antibodies was substantially increased in cases compared with controls (27% versus 3%; $P = .026$).¹⁵

The presence of an inherited thrombophilic disorder also increases the risk for VTE during pregnancy, particularly in the setting of a personal or strong family history. For example, the factor V Leiden (FVL) mutation is present in 40% of pregnant patients with VTE.^{16,17} However, because the prevalence of VTE in pregnancy is low (1/1600) and the incidence of heterozygosity for FVL in European populations is high (5%), the actual risk for VTE among gravidas who are without a personal history of VTE or an affected first-degree relative is less than 0.2% to 0.3%.^{16,17} With such a history, the risk for VTE in the antepartum or postpartum period is greater than 10%. Similar observations have been made for the other common inherited thrombophilias (Table 54-1).¹⁸⁻²²

The presence of thrombophilia can also affect the risk for recurrence of VTE among pregnant women. Brill-Edwards and colleagues prospectively followed 125 pregnant women with a prior VTE, 95 of whom were tested for thrombophilias including FVL; the prothrombin G20210A gene mutation (PGM); protein C, protein S, and antithrombin deficiencies; and the aPLs, anticardiolipin antibodies, and lupus anticoagulant.²³ The authors withheld antepartum thromboprophylaxis but employed it in the postpartum period. They noted an overall antepartum recurrence rate of 2.4% (95% CI, 0.2 to 6.9) but no recurrences in the 44 women without a detectable thrombophilia whose previous VTE was associated with a temporary risk factor (among which the authors included pregnancy itself). In contrast, the recurrence risk for VTE among the 25

thrombophilic patients was 16% (four patients) (odds ratio [OR], 6.5; 95% CI, 0.8 to 56.3). Therefore, it would appear prudent to test pregnant patients who have a history of VTE associated with a transient risk factor (e.g., fracture) for thrombophilias. Similarly, consideration should be given to screening pregnant women who have a strong family history (i.e., an affected first-degree relative) of VTE, particularly if they are likely to be exposed to risk factors such as prolonged immobilization or cesarean delivery.

Diagnosis and Evaluation of Venous Thromboembolism in Pregnancy

The clinical signs and symptoms of VTE are neither sensitive nor specific. Indeed, more than 90% of pregnant women in whom the diagnosis of either DVT or PE is suspected are unaffected.²⁴ Conversely, many of those ultimately diagnosed with VTE do not have classic features. To make an early diagnosis, clinicians must exercise a high index of suspicion and approach the diagnosis in a systematic fashion.

CLINICAL PRESENTATION

Only about one quarter of nonpregnant patients with unilateral extremity edema, erythema, warmth, pain, tenderness, and a positive Homans sign—the traditional hallmarks of DVT—prove to have the diagnosis when objective diagnostic tests are

performed.²⁵ The differential diagnosis includes a ruptured or strained muscle or tendon, cellulitis, knee joint injury, Baker cyst, cutaneous vasculitis, superficial thrombophlebitis, and lymphedema. The positive predictive value of these signs and symptoms increases substantially in patients at increased risk. However, no risk-assessment model has been prospectively validated in pregnancy. Chan and colleagues²⁶ have reported three objective variables (“LEFT”: symptoms in the left leg [L]; calf circumference difference ≥ 2 cm [E]; and first-trimester presentation [Ft]) to be highly predictive of DVT in pregnancy. In their retrospective study of 194 at-risk pregnant women without prior DVT, the condition was never diagnosed when not one of the three variables was present (0% [95% CI, 0 to 4.2]). When one or more variables were present, DVT was diagnosed in 16.4% of cases (95% CI, 10.5 to 24.7); with two or three variables, DVT was diagnosed in 58.3% of cases (95% CI, 35.8 to 75.5).

COMPRESSION ULTRASOUND

Compression ultrasound (CUS) with or without color Doppler imaging is the primary diagnostic modality for evaluating pregnant patients who are at risk for DVT. The test is performed by placing the ultrasound transducer over the common femoral vein, beginning at the inguinal ligament, and then moving down the leg to sequentially image the greater saphenous vein, the superficial and deep femoral veins, the popliteal vein, and

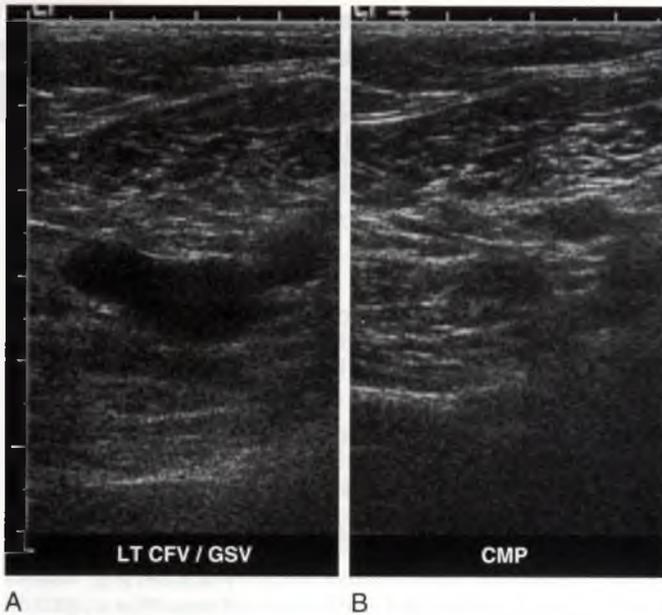

Figure 54-1 Patent vessel shown by compression of vessel lumen. Transverse ultrasound images of a 28-year-old woman in the second trimester of pregnancy performed at the level of the common femoral vein (CFV) and greater saphenous vein (GSV), with (A) and without (B) applied compression, demonstrates obliteration of vessel lumen on compression indicative of a patent vessel.

the deep calf veins including the anterior and posterior tibial and peroneal veins. Gentle pressure is applied with the probe to determine whether the vein under examination is compressible (Fig. 54-1). The most accurate ultrasonographic criterion for diagnosing DVT is noncompressibility of the venous lumen in a transverse plane^{27,28}; direct visualization of echogenic material in the venous lumen and loss of a normal phasic flow pattern are additional supportive findings. The sensitivity and specificity of CUS for proximal DVT are reported to be 95% and 98%, respectively, using contrast venography as the gold standard.²⁹ However, the accuracy in detection of isolated calf DVT is lower, largely because of the technical difficulty of visualizing all calf venous branches. A meta-analysis of 463 at-risk patients showed that indeterminate calf ultrasound examination rates range from 9.3% to 82.7%; in patients with diagnostic studies, CUS was found to have a sensitivity of 92.5% (95% CI, 81.8 to 97.9) and a specificity of 98.7% (95% CI, 95.5 to 99.9).³⁰ Despite clinical concern for proximal propagation of undetected calf vein thrombosis, preliminary studies suggest that a negative single complete ultrasound (including attempted visualization of calf veins) of the lower extremities may be a safe method to exclude DVT in the pregnant population. In a retrospective review of 118 pregnant or postpartum women with suspected DVT and a negative CUS, Le Gal and associates²⁹ found no recurrent thromboembolic events during a 3-month follow-up period. In a prospective study of 87 consecutive pregnant women with suspected DVT, no recurrent VTEs were documented in the 55 patients (63.2%) with negative CUS, although 6-week follow-up was available in only 43 patients (78.2%).³¹ These initial results of a low risk for recurrent VTE after a negative CUS in the pregnant population with suspected VTE are similar to outcomes observed in the nonpregnant population; a meta-analysis of seven studies with a total of 4731 patients

who had a negative whole-leg CUS examination showed a VTE recurrence rate of 0.57% (95% CI, 0.25 to 0.89) at 3-month follow-up.³²

MAGNETIC RESONANCE VENOGRAPHY

Because of the uncertain long-term effects of gadolinium on the fetus, contrast-enhanced magnetic resonance (MR) venography is relatively contraindicated in the pregnant population. In the nonpregnant population, the sensitivity and specificity of non-contrast MR venography for the diagnosis of proximal leg vein DVT have been reported to be 94.7% to 100% and 98% to 100%, respectively.³³⁻³⁵ The major advantage of noncontrast MR techniques over CUS is additional assessment of the pelvic veins.³³ In a small series of 24 nonpregnant patients, noncontrast MR venography using a steady-state precession technique yielded diagnostic assessment of calf veins in 81% of patients, with a sensitivity of 68% and specificity of 94% for DVT using contrast venography as the gold standard.³⁵

CONTRAST VENOGRAPHY

Before improvements in ultrasound and MR technology, contrast venography was the standard technique employed for the diagnosis of DVT. The procedure involved injecting a contrast agent into a superficial vein on the dorsum of the foot and allowing it to circulate into the deep venous system while radiographic images were obtained of the lower leg, thigh, and pelvis. The diagnosis required visualization of intraluminal filling defects observed on two or more views, or an abrupt cutoff of contrast material. It remains the most sensitive test for calf vein DVT. Although accurate, contrast venography has been essentially replaced by CUS and MR venography, which are less invasive, less painful, and not associated with radiation exposure.

D-DIMER ASSAYS

In the nonpregnant population with suspected DVT, a normal D-dimer level in a patient assessed by a clinical prediction rule to have a low pretest probability of having DVT is sufficient to safely exclude DVT with no further diagnostic testing required.³⁶ However, the role of D-dimer in excluding DVT in pregnancy is currently uncertain. The challenges in the application of D-dimer testing relate to the lack of a validated clinical prediction rule for DVT in the pregnant population, elevated D-dimer levels in pregnancy that occur in the absence of DVT, and the lack of prospective studies that validate the safety of this approach.^{37,38} Morse³⁹ measured D-dimer values in 48 women, aged 17 to 36 years, at 16, 26, and 34 weeks of gestation and compared these values to those of 34 healthy, nonpregnant controls. This author found a progressive increase in D-dimer concentrations across gestation (191 ± 25 ng/mL at 16 weeks, 393 ± 72 ng/mL at 26 weeks, and 544 ± 96 ng/mL at 34 weeks), all of which were significantly higher than the values in nonpregnant women (140 ± 58 ng/mL). Because the cutoff value for normal D-dimer levels at the author's hospital was 280 ng/mL, most pregnant patients would be considered positive. The author recommended new threshold ranges for 16 to 26 weeks (<465 ng/mL) and for 27 to 34 weeks (<640 ng/mL) of gestation.

Three prospective studies ($N = 389$) using a total of seven different commercially available assays have evaluated

the accuracy of D-dimer testing for the diagnosis for DVT in pregnancy.^{37,40,41} Each study showed D-dimer to be 100% sensitive for DVT, but the number of positive studies was low, and specificities ranged from 6% to 23% using standard cut-points for the different assays. Chan and coworkers³⁷ suggested that use of higher cut-points than those used in nonpregnant patients can improve the specificity of D-dimer assays for diagnosis of DVT in pregnancy without compromising sensitivity; however, this approach has not been validated in prospective management studies. There has been one case report of a negative D-dimer test in the setting of acute calf DVT in a postpartum woman.³⁸

EVALUATION ALGORITHMS FOR DEEP VEIN THROMBOSIS IN PREGNANCY

The cornerstone of evaluation for possible DVT in pregnant patients is CUS. A D-dimer assay may be used as a complementary test, but a negative result does not preclude the possibility of DVT.³⁸ Using CUS as the initial test, patients can be subsequently triaged on the basis of this test result, with clinical risk assessment determining the need for additional evaluations (Fig. 54-2). A positive CUS result prompts treatment. Follow-up of a negative CUS result depends on the patient's risk category. If it is low, the patient is discharged to routine follow-up. If it is moderate or high, she undergoes serial CUS or, if the index of suspicion is high enough, MR venography.

The diagnostic scheme in Figure 54-3 uses CUS and D-dimer testing without formal clinical risk assessment to triage patients. The combination of a negative D-dimer result and a negative CUS study is associated with a very low risk for DVT, and such patients are discharged to routine follow-up. A positive CUS, which is virtually always associated with a positive D-dimer test, prompts treatment. A negative CUS combined with a positive D-dimer test can be followed by routine follow-up, serial CUS, or MR venography, depending on the clinician's index of suspicion. It should be noted that D-dimer testing is likely to be

completely irrelevant in later stages of pregnancy and in puerperal and postoperative patients because of high false-positive rates. The diagnostic approach outlined in Figure 54-2 should be used in these settings.

The diagnosis of recurrent DVT in pregnancy presents a diagnostic challenge because CUS findings remain abnormal after an initial thrombus for up to 1 year in as many as 50% of patients.²⁵ In this setting, an increase of more than 2 mm in the compressed diameter of a previously involved vein, or a return to abnormal after earlier normalization of vein compressibility, has been reported to provide strong evidence of recurrent proximal thrombosis in the nonpregnant population.⁴² However, because a single CUS study does not exclude recurrent calf DVT (with potential for extension), performance of serial CUS studies should be considered in this high-risk population. Prandoni and colleagues⁴³ have reported a VTE recurrence rate of 1.3% (95% CI, 0.02 to 4.7) in 150 nonpregnant patients with suspected recurrent DVT and negative serial CUS studies performed at presentation and at days 2 (± 1) and 7 (± 1).

Acute Pulmonary Embolism

CLINICAL FINDINGS

Dyspnea and chest pain are the two most common symptoms of PE, and they occur with prevalences of 61% to 81% and 55% to 69%, respectively, in pregnant and postpartum women with ultimately confirmed PE.^{2,44} Associated signs and symptoms may include hypoxemia, tachycardia, tachypnea, hemoptysis, and sweating^{2,44}; hypotension and syncope are rare and usually indicate massive embolism.⁴⁵ Ideally, the initial step in the evaluation of any patient with suspected PE should be risk assessment. However, at present, there are no validated clinical prediction guidelines for determining pretest probability of PE in the pregnant population. The decision as to whom to refer for imaging evaluation is complicated, because some signs and symptoms, such as dyspnea, tachycardia, lightheadedness, orthostatic presyncope, and various chest wall complaints, may accompany normal pregnancy. Clinicians must generally rely on their clinical judgment and use a high index of suspicion.

NONSPECIFIC DIAGNOSTIC TESTS

Chest Radiography

Chest radiography can play an important role in the evaluation of pregnant patients with suspected PE. Although no radiographic findings are sensitive or specific for pulmonary embolism, using chest radiographs to select those patients with normal findings who should undergo a ventilation-perfusion (V/Q) scan can increase the percentage of definitive V/Q results (normal and high probability) in the pregnant population to 94% to 96%.⁴⁶⁻⁴⁹ In a study of 304 pregnant and postpartum women, patients with normal chest radiographs (Fig. 54-4A) were more likely to obtain a diagnostic result with a V/Q scan than with computed tomographic pulmonary angiography (CTPA) (94% versus 70%; $P < .01$); in contrast, patients with abnormal chest radiographs were more likely to have a higher nondiagnostic study rate on a V/Q scan than with CTPA (40% versus 16.4%; $P < .01$).⁵⁰ As an independent test, chest radiographs rarely allow a confident alternative diagnosis, but occasionally they can confirm clinically suspected alternative diagnoses such as pulmonary edema.

Electrocardiography

Electrocardiographic (ECG) changes have been reported to occur in 41% of pregnant and postpartum women with confirmed PE.⁴⁴ Truly characteristic ECG changes that reflect the hemodynamic sequelae of acute cor pulmonale characteristic of massive PE (e.g., $S_1Q_3T_3$ pattern, right bundle branch block, P-wave pulmonale, right-axis deviation) are uncommon and occurred in 26% of cases (22 of 86) in one small series.⁴⁴ Pregnancy-induced physiologic changes may mimic left heart strain (e.g., T inversions in the left precordial leads) and, therefore, may mask PE-induced right heart strain changes. On the other hand, some physiologic changes may simulate PE changes (e.g., physiologic Q waves in leads 3 and aVF), leading to false-positive results. For these reasons, the screening value of ECG in the setting of maternal acute PE is low. However, assessment of the maternal ECG may be useful for making decisions about how aggressively to pursue secondary diagnostic studies (see Evaluation Algorithm for Pulmonary Embolism, later).

Arterial Blood Gases

In young, nonpregnant patients, assessments of oxygen saturation and arterial blood gases are of limited value in the setting of acute PE, because PO_2 values greater than 80 mm Hg are found in 29% of such patients who are younger than 40 years.⁵¹ Because PO_2 levels are even higher in pregnant women, the tests are likely to produce even more false-negative results in pregnancy. In a small series of 17 pregnant women with confirmed PE, Powrie and associates⁵² found a normal alveolar-arterial gradient (<15 mm Hg) in 10 cases (59%). As is the case for maternal ECG, assessment of maternal oxygen saturation may be useful in deciding how aggressively to pursue secondary diagnostic studies (see Evaluation Algorithms for Pulmonary Embolism, later).

Echocardiography

Only 30% to 40% of nonpregnant patients with acute PE are found to have echocardiographic abnormalities suggestive of diagnoses such as right ventricular hypokinesia and dilation, abnormal motion of the interventricular septum, and tricuspid regurgitation.⁵³ Although of limited value in the diagnosis of PE, echocardiography can be used for rapid and accurate risk assessment, particularly when identifying patients who have a poor prognosis and require more aggressive interventions such as thrombolysis and embolectomy.⁵⁴

Transesophageal echocardiography (TEE), unlike transthoracic echocardiography (TTE), may allow direct visualization of a thrombus in the pulmonary arterial system, which avoids having to rely on the indirect signs previously described. However, TEE requires far more resources and operator skill than TTE and is easier to perform in an unconscious or sedated patient. In the nonpregnant population, TEE is reported to have 60% to 80% sensitivity and 95% to 100% specificity in the diagnosis of acute PE.⁵³ In a case report, intraoperative TEE was used to diagnose a right atrial thrombus during a cesarean delivery.⁵⁵

SPECIFIC DIAGNOSTIC TESTS

Ventilation-Perfusion Scans

In nonpregnant adults, V/Q scanning has been largely replaced by CTPA. However, V/Q scans are more useful for obtaining a

diagnosis in younger, otherwise healthy pregnant women than in older, nonpregnant patients, who frequently have cardiorespiratory comorbidities.⁴⁸ Because of this improved accuracy in pregnancy and because of concerns about maternal breast irradiation with CTPA, V/Q scans are preferred to CTPA for imaging in a pregnant woman with a normal chest radiograph.⁵⁶

The perfusion component of a V/Q scan requires injecting human albumin macroaggregates labeled with radioactive isotopes (e.g., technetium 99m) into the bloodstream, where they are deposited in the pulmonary capillary bed and imaged by a photoscanner. The ventilation component requires inhalation of radiolabeled (e.g., with xenon 133) aerosols, whose distribution in the alveolar space is assessed by a gamma camera. Comparison of the perfusion and ventilation scans produces characteristic patterns that can be used to assign diagnostic possibilities. Compared with CTPA, a V/Q scan is associated with a lower radiation dosage to the mother: the calculated dosages to breast and lung tissue have been estimated to range from 0.98 to 1.07 mGy and 5.7 to 13.5 mGy, respectively, with V/Q scan, compared with 10 to 60 mGy and 39.5 mGy, respectively, with CTPA.⁵⁷⁻⁶¹ Although there is no consensus in the literature as to whether a V/Q scan or CTPA delivers less radiation to the fetus, measured values for the two studies are low, roughly equivalent, and similar to the dosage (0.5 to 1 mGy) absorbed by the fetus from background radiation during the 9-month gestational period.⁶²⁻⁶⁴

Supportive evidence for the use of V/Q scans to evaluate for PE in pregnancy comes from four retrospective management studies that reported that the prevalence of diagnostic scan results (high probability, very low probability, and normal) ranges from 75% to 94%, with the upper value being observed in groups selected by normal chest radiography and no prior history of chronic obstructive pulmonary disease (see Fig. 54-4B).^{48,65-67} Combined ventilation and perfusion scans were performed in two studies,^{65,67} and the perfusion scan alone was performed in the other two studies.^{48,66} In the studies ($N = 195$) by Scarsbrooke and coworkers⁴⁸ and Shahir and colleagues,⁶⁶ all completed perfusion studies with results other than high probability had a 100% negative predictive value for PE. In the remaining two studies ($N = 211$), where anticoagulation was administered to some patients with normal and nondiagnostic results, no subsequent VTE was observed in untreated patients.^{65,67}

Computed Tomographic Pulmonary Angiography

In nonpregnant populations, CTPA has become firmly established as the first-line test for the diagnosis of PE (Fig. 54-5).⁶⁸ Two meta-analyses that reported outcome data on 4657 and 3089 patients with suspected PE and negative CTPA studies showed 3-month rates of subsequent VTE to be 1.4% (95% CI, 1.1 to 1.8) and 1.2% (95% CI, 0.8 to 1.8), respectively, and 3-month rates of fatal PE to be 0.51% (95% CI, 0.33 to 0.76) and 0.60% (95% CI, 0.40 to 1.1), respectively.^{69,70} These results compare very favorably with both a negative conventional pulmonary angiogram and a negative V/Q scan. There are limited outcome data for the pregnant population: a retrospective study of 96 pregnant women who were followed for 3 months after a negative CTPA reported a 3-month VTE recurrence rate of 1.0%.⁶⁶

Cross and colleagues compared CTPA with V/Q scans for the initial investigation of patients with suspected PE and

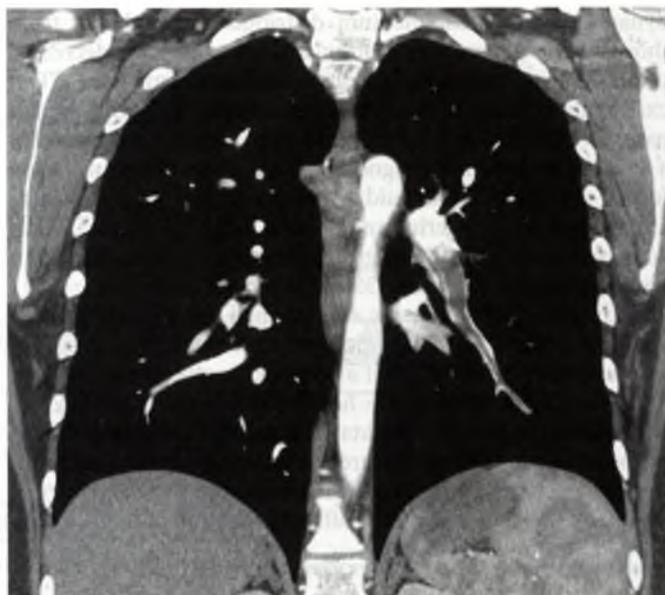

Figure 54-5 Pulmonary embolus. Coronal reformatted CT image of a 21-year-old woman in first trimester of pregnancy shows a pulmonary embolus in the pulmonary artery of the left lower lobe.

Figure 54-6 Interstitial pulmonary edema. Coronal reformatted CT image of a 32-year-old woman 3 days after delivery shows interlobular septal thickening (Kerley B lines) in the periphery of the lungs, consistent with interstitial pulmonary edema.

observed that definitive diagnoses of various etiologies were more frequent with CTPA (90% versus 54%; $P < .001$).⁷¹ Findings on CT suggestive of an alternative diagnosis are found in up to 13% of pregnant women and 39% of the general population who undergo a CTPA, with pulmonary edema (Fig. 54-6) and pneumonia being the two most commonly encountered entities.^{66,72}

Because of the increased cardiac output and blood volume associated with normal physiologic changes in pregnancy, the

dynamics of contrast medium distribution are altered from those of the general population and can result in decreased pulmonary arterial opacification. Technically inadequate CTPA examinations have been reported in 17% to 36% of pregnant patients in some studies.^{49,50,67,73} To maximize the likelihood of a technically adequate diagnostic study, protocol optimization for the pregnant state should be performed and should include automatic bolus triggering and use of a high iodine flux, usually achieved through both a high flow rate (4.5 to 6 mL/s) and a high iodine concentration (350 to 400 mg I/mL).⁷⁴

Iodinated contrast agents are classified as category B by the U.S. Food and Drug Administration (FDA), with no animal studies having demonstrated a teratogenic effect on the developing fetus. Although there has been concern regarding the potential induction of neonatal hypothyroidism as a result of exposure to free iodine, a retrospective study of 344 pregnant women who underwent a CTPA for suspected PE found normal thyroxine levels in all of their offspring at time of birth.⁷⁵

Magnetic Resonance Pulmonary Angiography

Gadolinium contrast agents are classified as category C by the FDA. Animal studies have demonstrated teratogenic effects but only at markedly increased dosages or after prolonged exposure.⁷⁶ In contrast, limited human observational studies have not documented adverse fetal effects.⁷⁷ However, because of the uncertain long-term effects of gadolinium on the fetus, contrast-enhanced MR pulmonary angiography (MRPA) is relatively contraindicated in the pregnant population. In a recent large multicenter prospective study,⁷⁸ gadolinium-enhanced MRPA was found to be technically inadequate in 25% of nonpregnant patients; in patients with technically adequate studies, MRPA had a sensitivity of 78% and a specificity of 99%. Data on performance of non-contrast-enhanced MRPA sequences for detection are sparse in the general population and nonexistent in the pregnant population. Using a real-time, steady-state, free-precession technique in 62 nonpregnant patients with suspected PE, Kluge and coworkers⁷⁹ reported a sensitivity of 85% and a specificity of 98%.

Pulmonary Angiography

Pulmonary angiography was long considered the definitive test for the diagnosis of PE. To perform this study, a catheter is usually placed in the right femoral, basilic, or right internal jugular vein. A PE is diagnosed by the finding of an intraluminal filling defect in a pulmonary artery visible on two views. In the general population, the procedure has a 0.5% mortality rate, a 1% major complication rate (e.g., respiratory distress requiring cardiopulmonary resuscitation or intubation, renal failure requiring dialysis, hematoma requiring transfusion), and a 5% minor complication rate.⁸⁰

In the general population, three studies have shown that a negative pulmonary angiogram is associated with a low frequency of recurrent PE (0% to 1.6%).⁸¹⁻⁸³ Although pulmonary angiography has traditionally been viewed as the reference standard in the diagnosis of PE, a retrospective review of 20 discordant cases in the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) II trial showed that pulmonary angiography is less sensitive than CTPA in the detection of emboli: digital subtraction angiography (DSA), a computer-assisted method that subtracts images of bone and soft tissue to optimize vessel viewing with contrast angiography, had one false-positive and 13 false-negative results, compared with only

two false-negative results with CTPA.⁸⁴ The largest missed thrombus using pulmonary angiography was subsegmental in eight patients, segmental in two patients, and lobar in three patients; using CT, the largest missed thrombus was subsegmental. Given its higher complication rate, lower sensitivity, and higher whole-body radiation dosage, pulmonary angiography has largely been superseded by CTPA as the definitive diagnostic tool in evaluation of PE in the general population. There are no studies that evaluate the performance of pulmonary angiography for the diagnosis of PE in pregnancy.

Evaluation of Lower Extremities for Deep Venous Thrombosis

The obvious reason to use CUS early in the diagnostic algorithm for PE is to avoid radiation-associated tests. A positive CUS establishes the need for anticoagulation. The prevalence of DVT in pregnant women who present with suspected PE is unknown; however, the prevalence of ultimately diagnosed PE in this population is low, ranging from 3% to 6%.^{48,50,65} In the general population with suspected PE, where the prevalence of PE ranges from 20% to 36% and the prevalence of DVT from 9% to 12%, the number of patients needed to undergo bilateral CUS to diagnose one clot (and avoid further workup) is around 11.^{85,86} In the pregnant population, the number needed to test is probably several-fold higher, given the lower prevalence of PE. Selecting women with signs and symptoms of DVT could increase the positive yield of CUS, as observed in the general population who present with suspected PE.⁸⁵ In two clinical studies ($N = 249$ and $N = 149$), the prevalence of DVT in pregnant women who presented with signs and symptoms of DVT were 7% and 9%.^{37,40}

D-Dimer Assays as a Screen for Pulmonary Embolism

In the nonpregnant population with suspected PE, a normal D-dimer level in a patient assessed by a clinical prediction rule to have a low or intermediate probability of having a PE is sufficient to safely exclude the diagnosis with no further diagnostic testing required.⁸⁷ Data for using the D-dimer test to exclude PE in pregnancy are sparse and limited. A retrospective study of 37 pregnant women with suspected PE who had both V/Q scans and D-dimer testing using an immunoturbidimetric assay reported a sensitivity of 73% and a specificity of 15% of D-dimer for PE⁸⁸; the negative likelihood ratio was 1.8, suggesting that a negative D-dimer test is inadequate to exclude PE. In addition, in two case reports that documented normal D-dimer levels in the setting of acute PE in pregnancy,^{89,90} one episode of PE occurred in the first trimester and the other in the third.

EVALUATION ALGORITHMS FOR PULMONARY EMBOLISM IN PREGNANCY

The considerable controversy regarding the optimal paradigm for diagnosing PE in pregnancy stems in large part from the low quality and very limited amount of direct evidence pertaining to diagnostic test accuracy and outcomes in the pregnant population. Consideration of the risks of radiation exposure associated with diagnostic imaging is also more complicated in pregnancy because of the presence of two at-risk individuals, the fetus and the mother.

Evidence-based guidelines developed by a multidisciplinary panel of major medical stakeholders and endorsed by the American Thoracic Society, the Society of Thoracic Radiology, and

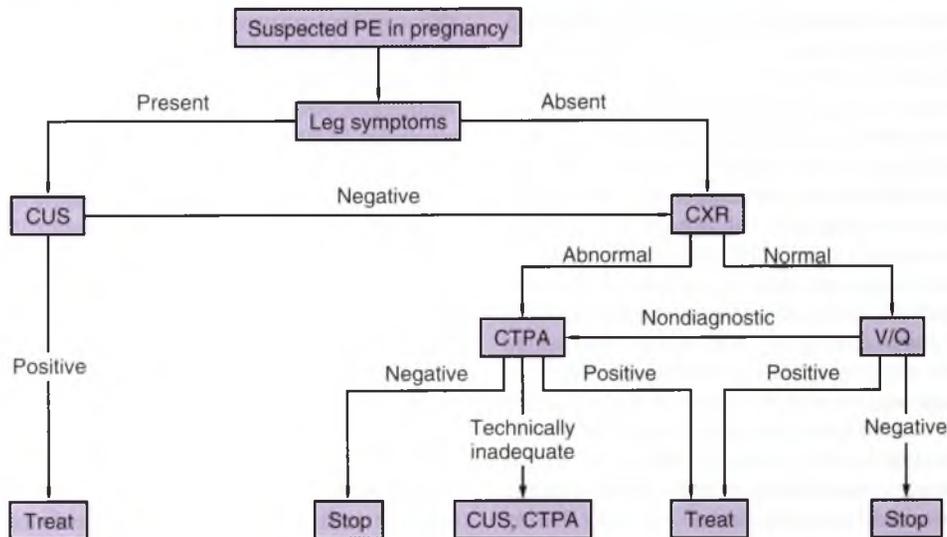

Figure 54-7 Diagnostic algorithm for pregnant patients with suspected pulmonary embolism (PE) and concomitant symptoms of deep venous thrombosis. CTPA, computed tomographic pulmonary angiography; CUS, compression ultrasound; CXR, chest radiograph; V/Q, ventilation-perfusion scan. (Reprinted with permission of the American Thoracic Society. Copyright © 2012, American Thoracic Society.)

the American College of Obstetricians and Gynecologists were published in 2011.⁵⁶ In the formulation of a recommended algorithm, the important outcomes were defined to be diagnostic accuracy and diagnostic yield. For each test, diagnostic yield was defined as the percentage of studies that were of an acceptable technical quality and provided the necessary information to establish a diagnosis. The panel also placed a high value on minimizing cumulative radiation dosage when determining the recommended sequence of tests (Fig. 54-7).

Panel members judged that the D-dimer test cannot currently be used to exclude PE in a pregnant woman with suspected PE; because of the additional cost and the delay to diagnosis, they gave a weak recommendation to not include it in the diagnostic algorithm. Because CUS has a low yield, it is recommended as the first diagnostic procedure only when the pregnant woman has concomitant signs and symptoms of DVT. Chest radiography is recommended as the first radiation-associated procedure, and it is used as a triage tool: women with a normal chest radiograph proceed to V/Q, whereas patients with an abnormal chest radiograph go to CTPA. Because of the potentially morbid consequences of undiagnosed PE, the suggestion for pregnant women who have a nondiagnostic V/Q scan is to undergo further diagnostic testing with CTPA rather than receive clinical management alone. Repeat CTPA in a pregnant woman who has already undergone one nondiagnostic study should be undertaken with caution unless review of the prior study reveals an opportunity for technical improvement that can increase the likelihood of a positive yield in a repeat study.

These guidelines were developed under the assumption that patients are stable and all studies are equally available. In real-life situations, when the patient is unstable or some studies are not available on a timely basis, panel members recommended consideration of empiric initiation of therapy and alternative diagnostic strategies (such as selection of CTPA over V/Q, or TEE in an intensive care setting). Because evidence documenting clear superiority of any one diagnostic test is lacking, the

values and preferences of a patient and her physician should determine the final choice and sequence of tests performed.

Treatment of Venous Thromboembolism in Pregnancy

Patients with new-onset VTE during pregnancy should receive therapeutic anticoagulation for a minimum of 6 months, including at least the first 6 weeks after delivery.^{91,92} During pregnancy, either low-molecular-weight heparin (LMWH) or unfractionated heparin (UFH) is a suitable anticoagulant, given their efficacy and safety profiles. Neither formulation crosses the placenta or poses teratogenic risks. After delivery, oral anticoagulation with warfarin may be started and is considered safe in breastfeeding mothers. The primary risks of long-term heparin therapy in pregnancy are hemorrhage and osteoporosis.

HEPARIN THERAPY

Low-Molecular-Weight Heparin

In nonpregnant patients, LMWH is now considered to be the drug of choice for both anticoagulant therapy and thromboprophylaxis of VTE. Meta-analyses of 23 studies including 9587 nonpregnant patients suggest that LMWH has fewer thrombotic complications than UFH (3.6% versus 5.3%; OR = 0.70; 95% CI, 0.57 to 8.5), produces a greater reduction in thrombus size (53% versus 45%; OR = 0.69; 95% CI, 0.59 to 0.81), and results in fewer major hemorrhages (1.1% versus 1.9%; OR = 0.58; 95% CI, 0.40 to 0.83) and fewer deaths (4.3% versus 5.8%; OR = 0.77; 95% CI, 0.63 to 0.93).⁹³ Although randomized clinical trials comparing the two formulations in the pregnant population have not been performed, LMWH has become the drug of choice with a well-established safety profile in pregnancy.^{91,92,94,95} LMWHs are associated with a low risk for

heparin-induced thrombocytopenia (HIT) (0% in >2000 pregnancies), a low risk for osteoporosis (0.04%; 95% CI, 0 to 0.2), and a low risk for bleeding (1.98%; 95% CI, 1.5 to 2.5).⁹⁶

There is currently no evidence to demonstrate the superiority of one LMWH over another. The initial therapeutic dosage varies with the specific agent.⁹⁴ Enoxaparin is given at a dosage of 1 mg (100 IU)/kg administered subcutaneously twice daily (i.e., every 12 hours). For tinzaparin, the dosage is 175 IU/kg administered subcutaneously once daily; dalteparin may be administered subcutaneously once daily (200 units/kg) or twice daily (100 IU/kg). Barbour and colleagues evaluated whether the standard twice-daily dosing of dalteparin maintained peak therapeutic levels of anticoagulation during pregnancy; in 85% of patients, dosage adjustments were required to maintain peak anti-Xa activity.⁹⁷ Given these data and the fact that pregnancy presents a period of rapidly changing volumes of distribution and fluctuating concentrations of heparin-binding proteins, it appears prudent to monitor anti-Xa activity during therapeutic treatment with LMWH in pregnant patients and to adjust the dosages to maintain therapeutic levels of anti-factor Xa between 0.5 and 1.0 IU/mL for twice-daily dosing and 1.0 to 1.5 IU/mL for once-daily dosing (LMWH levels drawn 4 hours after injection).⁹⁵ Prophylactic dosages can be initiated after 20 weeks of therapy and are as follows: enoxaparin, 40 mg once a day; tinzaparin, 2500 to 4500 IU once a day; and dalteparin, 2500 to 5000 IU once a day or 2500 IU twice a day. It is uncertain as to whether prophylactic LMWH warrants surveillance with anti-factor Xa levels,⁹⁵ but if done, the goal of surveillance should be an anti-factor Xa level of between 0.2 and 0.4 IU/mL.⁹⁴

Patients without current VTE who have antithrombin deficiency or antiphospholipid syndrome, and patients who are homozygotes or compound heterozygotes for the FVL or PGM mutation and have a prior VTE or affected first-degree relative, require therapeutic anticoagulation throughout pregnancy.⁹⁴ In our practice, except for antithrombin deficiency, pregnant patients with these highly thrombogenic thrombophilias who are without a personal or strong family history of VTE should receive subtherapeutic dosages of LMWH, with the goal of maintaining anti-factor Xa levels of 0.3 to 0.7 U/mL 4 hours after injection. For antithrombin deficiency, therapeutic levels of LMWH should be employed and antithrombin infusions used in labor.

Regional anesthesia is contraindicated within 24 hours after therapeutic LMWH administration because of the risk for epidural hematoma; therefore, we recommend switching to unfractionated heparin at 36 weeks, or earlier if preterm delivery is expected. However, vaginal or cesarean delivery occurring more than 12 hours after a prophylactic dose or 24 hours after a therapeutic dose of LMWH should not be associated with treatment-induced hemorrhage. If shorter intervals are encountered, protamine may partially reverse the anticoagulant effects of LMWH. The dosage is 1 mg of protamine for every 100 anti-Xa units of LMWH, but anti-factor Xa activity can be only partially (80%) reversed.⁹⁸

One of the most serious potential complications of heparin therapy is heparin-induced thrombocytopenia. This condition arises in 3% of nonpregnant patients given initial heparin therapy. Type 1 HIT occurs within a few days after initial heparin exposure, results from benign platelet clumping *in vitro*, is self-limited, is not associated with a significant risk for hemorrhage or thrombosis, and does not require cessation of

therapy. In contrast, type 2 HIT is a rare, immunoglobulin-mediated syndrome paradoxically associated with venous and arterial thrombosis that occurs 5 days to 3 weeks after initiation of therapy. Although the risk for HIT-2 is far lower in patients receiving LMWH than in those receiving UFH, platelet counts should still be checked at the start of treatment and then weekly for 3 weeks.⁹⁴ Because it can be difficult to differentiate the two entities, a 50% decline in platelet count from its pretreatment high should prompt cessation of therapy. The diagnosis of HIT-2 is confirmed by serotonin release assays, heparin-induced platelet aggregation test, and ELISA assays that detect the presence of antibodies to epitopes on platelet factor 4 (PF4)/heparin complexes.⁹⁹ If confirmed, all forms of heparin, including intravenous flushes, must be avoided.

Therapeutic Unfractionated Heparin

Hospitalization for the initiation of anticoagulation therapy may be indicated in cases of hemodynamic instability, large clots, or maternal comorbidities.¹⁰⁰ Intravenous UFH can be considered in the initial treatment of PE and when delivery, surgery, or thrombolysis may be necessary. The initial intravenous UFH dosage for pregnant patients with acute VTE should be determined with the use of a weight-based nomogram, and subsequent dosage modifications should be predicated on the activated partial thromboplastin time (aPTT) (Table 54-2). This regimen has been shown in nonpregnant patients to reduce recurrence rates.¹⁰¹

The overall goal is to obtain and maintain an aPTT of 1.5 to 2.5 times the control values. The aPTT should not be used to guide UFH therapy in patients with prolonged aPTT values caused by the presence of lupus anticoagulants. In these patients, plasma heparin activity can be measured by either a protamine sulfate or an anti-factor Xa chromogenic assay. Target plasma heparin concentrations of 0.2 to 0.4 U/mL are equivalent to anti-factor Xa concentrations of 0.4 to 0.7 U/mL. The usual duration of intravenous heparin therapy is 5 days, although

TABLE 54-2 Administration of Intravenous Heparin Using a Weight-Based Nomogram*

Activated Partial Thromboplastin Time (aPTT)	Adjustment
<35 sec (<1.2 × control)	Repeat 80 U/kg bolus, then increase infusion rate by 4 U/kg/hr
35-45 sec (1.2-1.5 × control)	Repeat 40 U/kg bolus, then increase infusion rate by 2 U/kg/hr
46-70 sec (1.6-2.3 × control)	No change in dosing
71-90 sec (2.4-3.0 × control)	Decrease infusion rate by 2 U/kg/hr
>90 sec (>3.0 × control)	Stop infusion for 1 hr, then restart original dosage decreased by 3 U/kg/hr

*Give bolus of 80 U/kg body weight, followed by a maintenance dosage of 18 U/kg/hr. Assess aPTT values every 4-6 hr and make adjustments on the basis of the aPTT obtained.

Adapted from Raschke RA, Reilly BM, Guidry JR, et al: The weight-based heparin dosing nomogram compared with a "standard care" nomogram: a randomized controlled trial, *Ann Intern Med* 119:874-881, 1993.

patients with large iliofemoral thromboses or massive PEs should receive heparin therapy for 7 to 10 days or until clinical improvement is noted.¹⁰² After hospital discharge, therapeutic dosages (10,000 units or more) are administered subcutaneously every 12 hours to maintain the aPTT at 1.5 to 2.5 times control values 6 hours after injection.

The standard prophylactic regimen of UFH used in pregnancy consists of 5000 units administered subcutaneously every 12 hours, increased by 2500 U in the second and third trimesters. However, Barbour and associates observed that this standard heparin regimen was inadequate to achieve the desired anti-factor Xa therapeutic range in five of nine second-trimester pregnancies and in 6 of 13 third-trimester pregnancies.¹⁰³ Therefore, careful assessment of anti-factor Xa levels 4 to 6 hours after injection is required to properly adjust the dosage.

If vaginal delivery or cesarean delivery occurs more than 4 hours after a prophylactic dose of UFH, the patient is not at significant risk for hemorrhagic complications. Patients receiving UFH who experience bleeding or require rapid reversal of the anticoagulant to effect delivery can be administered protamine sulfate by slow intravenous infusion of less than 20 mg/min, with no more than 50 mg given over 10 minutes. The amount of protamine needed to neutralize heparin is derived by determining the amount of residual heparin in the circulation, assuming a half-life for intravenously administered heparin of 45 minutes. Full neutralization of heparin activity would require 1 mg of protamine sulfate per 100 units of residual circulating heparin. If the heparin was administered subcutaneously, repeated small infusions of protamine are required. Finally, as noted earlier, antithrombin concentrates may be used in antithrombin-deficient patients in the peripartum period.

Postpartum Anticoagulation

LMWH or UFH can be restarted 4 to 6 hours after vaginal delivery or 6 to 12 hours after cesarean delivery. Postpartum patients should be started immediately on warfarin. The initial dosages of warfarin should be 5 mg for 2 days. Subsequent dosages are determined by monitoring the international normalized ratio (INR). To avoid paradoxical thrombosis and skin necrosis from warfarin's initial anti-protein C effect, it is critical to maintain these women on therapeutic dosages of UFH for a minimum of 5 days and until the INR has been at therapeutic levels (2.0 to 3.0) for 2 consecutive days. After an uncomplicated VTE during pregnancy, without other high-risk conditions such as APS or antithrombin deficiency, therapy should be continued in the postpartum period for 3 to 6 months. Because warfarin does not significantly accumulate in breast milk and does not induce an anticoagulant effect in the infant, it is not contraindicated in breastfeeding mothers.

Management of warfarin overdoses or hemorrhagic complications is guided by the severity of the problem. For example, if patients are found to have elevated INRs (>3.0) without bleeding, vitamin K can be given orally. However, if mild bleeding is present, vitamin K can be administered subcutaneously.¹⁰⁴ Normalization of the INR can occur within 6 hours after a 5-mg oral or subcutaneous dose of vitamin K. Larger dosages have a more rapid onset but render patients resistant to re-anticoagulation with warfarin. In the setting of significant hemorrhage, fresh-frozen plasma will replenish clotting factors and can be used with subcutaneous vitamin K to reverse the effects of warfarin.

COMPLEX PRESENTATIONS

Type 2 Heparin-Induced Thrombocytopenia

In patients with a history or new presentation of HIT-2, LMWH and UFH are contraindicated. Fondaparinux is an excellent alternative. It is a synthetic heparin pentasaccharide that complexes with the antithrombin binding site for heparin to permit the selective inactivation of factor Xa but not thrombin. Excretion is renal and the drug has a 15-hour half-life after a once-daily subcutaneous injection. Buller and associates conducted a randomized, double-blind trial of fondaparinux administered subcutaneously once a day at a dosage of 5.0 mg for patients weighing less than 50 kg, 7.5 mg for those weighing 50 to 100 kg, and 10.0 mg for those weighing more than 100 kg, versus enoxaparin among 2205 patients with acute symptomatic DVT.¹⁰⁵ No difference in recurrent VTE was observed between the groups. Fondaparinux is considered a pregnancy class B agent by the FDA. It has been used in a small number of pregnant patients without adverse sequelae, although it has been found to be present in umbilical-cord plasma at concentrations approximately 10% of those in the maternal plasma.¹⁰⁶ The levels are well below those required for effective anticoagulation. However, fondaparinux use in pregnant women is best limited to those patients with no clear therapeutic alternatives, such as patients with HIT-2 or a severe allergic reaction to heparin.

Thromboprophylaxis in Pregnant Patients with Mechanical Heart Valves

There remains considerable controversy concerning optimal management of VTE in pregnant women with mechanical heart valves. These patients are given warfarin when in the nonpregnant state. However, warfarin is loosely bound to albumin, readily crosses the placenta, and is associated with an increased rate of birth defects (OR = 3.86; 95% CI, 1.86 to 8.00) with exposure between 8 and 12 weeks' gestation.¹⁰⁷ The classic warfarin syndrome includes nasal hypoplasia, stippled epiphyses, and characteristic central nervous system defects including agenesis of the corpus callosum, Dandy-Walker malformation, midline cerebellar atrophy, and ventral midline dysplasia with optic atrophy. Maternal warfarin therapy after 12 weeks' gestation has been associated with fetal and placental hemorrhage, which can occur throughout pregnancy. For these reasons, the agent is usually avoided during pregnancy. However, it may be appropriate to use warfarin in pregnant patients who have a mechanical heart valve.⁹² Meta-analysis suggests that when warfarin is used throughout pregnancy, the cumulative risk for embryopathy is 6.4% (95% CI, 4.6 to 8.9), but the risk for valvular thrombosis is quite low (3.9%; 95% CI, 2.9 to 5.9).¹⁰⁸ In contrast, a regimen consisting of UFH for 6 to 12 weeks, followed by warfarin until 36 weeks and then by UFH until delivery, appears to reduce the fetal risk but is associated with substantially increased risk for valve thrombosis (9.2%; 95% CI, 5.9 to 13.9).

Warfarin is best employed in pregnant patients with mechanical heart valves when the dosage can be kept lower than 5 mg/day, because cohort studies suggest that this dosage is associated with a lower rate of fetal complications.¹⁰⁹ If warfarin is used in this setting, the target INR should be 2.5 to 3.5. Low-dosage aspirin should be used as an adjunct to warfarin, based on a study of antithrombotic therapy in high-risk patients with mechanical valves.¹¹⁰ Warfarin therapy should be stopped by 36

weeks, and unfractionated heparin should then be administered subcutaneously every 12 hours with dosages adjusted to keep the aPTT value at 2 times the control, or the anti-Xa heparin level at 0.35 to 0.7 U/mL.

LMWH has potential advantages over UFH in terms of the maternal side effect profile, and there is increasing use of LMWH in pregnant women with heart valves. However, treatment failures have been reported and have occurred mainly in patients who were either underdosed or inadequately monitored.^{111,112} The manufacturer of enoxaparin (Lovenox, Aventis, Bridgewater, NJ) specifically recommends against its use in this setting on the basis of a small number of reports to the FDA of valvular thrombosis in pregnant women treated with this drug, as well as by clinical outcomes in an open randomized study comparing enoxaparin with warfarin and UFH in pregnant women with prosthetic valves.⁹² This study was terminated after 12 of planned 110 patients were enrolled because of two deaths in the LMWH arm. Two cases of valvular thrombosis have been reported in the setting of therapeutic levels of anti-Xa.^{111,113} Some experts recommend that in addition to monitoring of peak anti-Xa levels 4 hours after injection, trough levels should also be monitored and maintained at the upper therapeutic range of 0.6 to 0.70 U/mL.¹¹³

Guidelines from the American College of Chest Physicians (ACCP) recommend that the decision about anticoagulant management in a pregnant woman with mechanical heart valve include an assessment of additional risk factors for thromboembolism, including valve type, position, and history of thromboembolism, and that the final decision be influenced strongly by patient preference.⁹² For pregnant women with mechanical heart valves, one of three regimens can be chosen: adjusted-dosage LMWH administered twice a day throughout pregnancy with monitoring to achieve an anti-Xa level of 1 U/mL (4 hours after injection); adjusted-dosage UFH throughout pregnancy administered subcutaneously twice a day in dosages adjusted to keep the mid-interval aPTT at least 2 times the control or to attain an anti-Xa heparin level of 0.35 to 0.70 U/mL; or UFH or LMWH until the 13th week with warfarin substitution until close to delivery when UFH or LMWH is resumed.⁹² In women judged to be at very high risk for thromboembolism for whom concerns exist about the efficacy and safety of LMWH or UFH in the dosages just described (e.g., older-generation prosthesis in the mitral position or history of thromboembolism), ACCP guidelines recommend warfarin throughout pregnancy with replacement by LMWH or UFH close to delivery, after a thorough discussion of the potential risks and benefits of this approach.

THROMBOLYTIC THERAPY

Although the mortality rate for expeditiously diagnosed and treated uncomplicated PE is less than 2% to 7%,¹¹⁴ rates higher than 50% have been reported for patients who were hemodynamically unstable at the time of presentation.¹¹⁵ This has led to more aggressive use of thrombolytic therapy in patients with PE. However, a Cochrane review of eight randomized controlled trials showed no difference in outcomes between thrombolytics compared with heparin alone or placebo and heparin with regard to death rate (OR = 0.89; 95% CI, 0.45 to 1.78), recurrence of PE (OR = 0.63; 95% CI, 0.33 to 1.20), major hemorrhagic events (OR = 1.61; 95% CI, 0.91 to 2.86), or minor hemorrhagic events (OR = 1.98; 95% CI, 0.68 to

5.75).¹¹⁶ Subgroup analysis performed in a meta-analysis of 11 randomized controlled trials showed that thrombolytic therapy compared with heparin was associated with a significant reduction in recurrent PE or death in trials that enrolled patients with major (hemodynamically unstable) PE (9.4% versus 19.0%; OR = 0.45; 95% CI, 0.22 to 0.92) but not in trials that excluded these patients (5.3% versus 4.8%; OR = 1.07; 95% CI, 0.50 to 2.30).¹¹⁷

Pregnancy poses special concerns for thrombolytic therapy because of the risk for abruption and puerperal hemorrhage. Turrentine and colleagues reviewed the outcomes of 172 pregnancies treated with thrombolytic therapy for a variety of indications and reported a maternal mortality rate of 1.2%, a fetal loss rate of 6%, and maternal hemorrhagic complications in 8%.¹¹⁸ Outcome data on treatment of massive embolism in the pregnant population are sparse. In a review that included 13 cases of pregnant women with massive PE treated with thrombolytics, there were no maternal deaths, four major bleeding complications (30.8%; 95% CI, 9.1 to 61.4), two fetal deaths (15.4%; 95% CI, 1.5 to 45.5), and five preterm deliveries (38.5%; 95% CI, 13.9 to 68.4).¹¹⁹ Four subsequent reported cases of pregnant women with massive PE treated with thrombolytics showed no treatment complications, with a delivery of a healthy baby in each case.^{120,121} In a review of eight cases of pregnant women who underwent surgical embolectomy for massive PE, there were no maternal deaths, three fetal deaths (37.5%; 95% CI, 8.5 to 75.5), and four preterm deliveries (50%; 95% CI, 15.7 to 84.3).¹¹⁹

Prevention of Venous Thromboembolism in Pregnancy

NONPHARMACOLOGIC PREVENTION

A Cochrane review of randomized controlled trials indicated that use of graduated compression stockings in hospitalized patients with prolonged medical immobilization, applied on the day before surgery or on the day of surgery and worn until discharge or restoration of full mobility, reduced the occurrence of DVT from 26% to 13% (OR = 0.35; CI, 0.26 to 0.47).¹²² A cohort study suggested that the use of graduated elastic compression stockings also reduced the prevalence of VTE in puerperal patients, from 4.3% to 0.9%.¹²³ In addition, graduated elastic compression stockings have been shown to increase femoral vein flow velocity in late pregnancy.¹²⁴

Meta-analysis in nonpregnant patients with high or moderate risk suggests that intermittent pneumatic compression devices decrease the relative risk for DVT by 62% compared with placebo, by 47% compared with graduated compression stockings, and by 48% compared with low-dosage UFH.¹²⁵ Because graduated elastic compression stockings and pneumatic compression stockings have no hemorrhagic risk and have been shown to be an effective means of DVT prophylaxis in surgical patients and possibly in pregnant patients, they should be strongly considered for prophylaxis in high-risk pregnant patients (e.g., those with obesity, thrombophilia, strong family history) who are admitted for labor or delivery or who require prolonged bed rest, and also in all pregnant patients undergoing elective or repeat cesarean delivery without prior labor. Caution must be exercised in their immediate preoperative use after labor, because DVT may have already formed and theoretically could be dislodged by either device. Finally, in

pregnancy, left-lateral decubitus positioning during the third trimester may also reduce the risk for VTE.

PHARMACOLOGIC PREVENTION

As noted, among pregnant patients who have had a previous VTE, recurrence risks are highly dependent on the presence of a thrombophilia and the nature of the risk factors associated with the prior thrombus.⁹⁴ Whereas VTE recurrences were not observed in women without detectable thrombophilias whose VTE was associated with a temporary risk factor, 5.9% of thrombophilic patients who did not receive thromboprophylaxis during pregnancy had an antepartum recurrence of VTE.²³ However, even the former group of patients requires postpartum thromboprophylaxis. In addition, it has been argued that thrombophilic patients who are without a personal history of VTE but who have an affected first-degree relative should also receive thromboprophylaxis during pregnancy and the postpartum period. Those with highly thrombogenic thrombophilias (e.g., antithrombin deficiency, homozygosity or joint heterozygosity for the FVL or PGM mutation) should receive both postpartum anticoagulation and therapeutic or subtherapeutic dosages of LMWH throughout pregnancy. However, such therapy does not appear to be justified during the antepartum period in patients with less thrombogenic thrombophilias (e.g., heterozygosity for FVL or PGM, protein C deficiency, protein S deficiency) who are without a personal or strong family history of VTE. However, these patients should receive postpartum anticoagulation if they require a cesarean delivery to reduce the risk for a fatal PE.

A very limited number of studies have assessed the value of perioperative thromboprophylaxis in cesarean delivery.^{126,127} However, perioperative thromboprophylaxis with LMWH or UFH may be appropriate for patients undergoing cesarean delivery who have a history of VTE and known highly

thrombogenic thrombophilia as well as those with mechanical heart valves.^{92,94}

INFERIOR VENA CAVA FILTERS

Inferior vena cava filters are designed for use in patients in whom anticoagulation is absolutely contraindicated, such as those with hemorrhagic stroke, recurrent or current hemorrhage, or recent surgery. This intervention appears to be appropriate in patients who have recurrent PE despite adequate anticoagulation and in those in whom a PE would probably be lethal (e.g., patients with pulmonary hypertension). Traditionally, pregnant patients with a history of HIT-2 were candidates for inferior vena cava filters, but the use of fondaparinux during pregnancy and the direct thrombin inhibitors (e.g., lepirudin) in the postpartum period has rendered this indication less absolute.¹²⁸ Although the use of filters is generally discouraged in younger patients, retrievable filters have been employed successfully in pregnant women and may prove ideal in this setting.¹²⁹

Summary

Acute PE remains a leading cause of maternal morbidity and mortality. Periods of maximal risk include the immediate puerperal perioperative period. Additional risk factors include prior VTE, positive family history, obesity, thrombophilias, infection, trauma, and immobilization. The prompt diagnosis of VTE requires assessment of clinical risk followed by initiation of the proper diagnostic algorithm. Treatment requires prompt initiation of LMWH or UFH. Prevention includes identification of high-risk patients and both nonpharmacologic and pharmacologic interventions.

Anemia and Pregnancy

SARAH J. KILPATRICK, MD, PhD

Anemia is defined as a hemoglobin (Hb) value less than the lower limit of normal that is not explained by the state of hydration. This definition has physiologic validity, in that it is the amount of Hb per unit volume of blood that determines the oxygen-carrying capacity of blood. The normal Hb level for the adult female is 14.0 ± 2.0 g/dL.¹ However, in pregnancy, because of the normal hemodilution of pregnancy, anemia is defined by the Centers for Disease Control and Prevention as an Hb concentration lower than 11 g/dL in the first and third trimesters, or lower than 10.5 g/dL in the second trimester.² According to the World Health organization (WHO), 20% to 52% of pregnant women are anemic.³ Defining anemia as an Hb level of less than 12 g/dL, the incidence of anemia was 6.9% in U.S. women less than 50 years old.⁴ The incidence of anemia was significantly higher in black than in white women, with an incidence of 24% versus 3%, respectively, and at least 20% of prenatal patients will be found to be anemic at some time during their pregnancy.⁴ In another study, 32% of women presenting at less than 7 weeks' gestation had an Hb value lower than 12 g/dL, suggesting that the prevalence of anemia is high.⁵

Clinical Presentation

Symptoms caused by anemia result from tissue hypoxia, the cardiovascular system's attempts to compensate for the anemia, or an underlying disease. Tissue hypoxia produces fatigue, light-headedness, weakness, and exertional dyspnea. Cardiovascular compensation leads to a hyperdynamic circulation, with attendant symptoms of palpitations and tachycardia. Clinical conditions commonly associated with anemia in pregnancy include multiple pregnancy, trophoblastic disease, chronic renal disease, chronic liver disease, and chronic infection. In obstetric patients, however, anemia is most commonly discovered not because of symptoms but because a complete blood count (CBC) is obtained as part of a routine laboratory evaluation, either at the initial prenatal visit or at repeat screening at 24 to 28 weeks' gestation.

Evaluation of Anemia

Anemia is not a diagnosis; rather, like fever or edema, it is a sign. The key issue in the evaluation of anemia is to define the underlying mechanism or pathologic process. Although a mild anemia caused by iron deficiency during pregnancy is of little consequence to either the mother or the fetus, a similarly mild anemia caused by carcinoma of the colon has grave implications. Furthermore, many anemias, such as the hemoglobinopathies and hereditary spherocytosis, have genetic implications.

Box 55-1 presents a classification of anemia based on the pathophysiologic mechanism involved. Although a mechanistic classification of anemia provides an exhaustive catalog of

diagnoses, it does not lend itself to a systematic investigation of an individual patient. Rather, when the patient is anemic, one wants to know (1) the morphology of the anemia and (2) the reticulocyte count. Determining the answers to these questions allows one to make a first approximation of a specific diagnosis and to answer the following questions:

1. What is the mechanism of the anemia?
2. Is there an underlying disease?
3. What treatment is appropriate?

The CBC and the reticulocyte count provide the answers to the first two questions. These data allow a morphologic classification of the anemia and indicate whether the marrow is hyperproliferative or hypoproliferative. The patient's Hb value is determined by converting the pigment to cyanmethemoglobin and quantitating the amount spectrophotometrically. The rest of the values are obtained by flow cytometry with an electronic cell counter.

On the basis of the size of the red blood cells (RBCs), anemia can be classified as microcytic, normocytic, or macrocytic. The appearance of the RBCs may also provide a clue to the mechanism of the anemia. For example, hypochromic microcytic cells associated with a low reticulocyte count suggest iron deficiency, thalassemia trait, sideroblastic anemia, or lead poisoning. Oval macrocytes combined with a low reticulocyte count and hypersegmented polymorphonuclear leukocytes suggest megaloblastic anemia (vitamin B₁₂ or folate deficiency). Oval microcytes and an elevated reticulocyte count are characteristic of hereditary spherocytosis. Various poikilocytes, such as sickle cells, acanthocytes, target cells, and schistocytes, suggest sickle cell disease, acanthocytosis, Hb C disease, and mechanical RBC destruction, respectively. Although the CBC is an excellent first step in the approximate diagnosis of anemia, additional studies are usually necessary to confirm the diagnosis. Table 55-1 lists laboratory studies frequently used in the evaluation of an anemic patient.

Serum Hb and serum haptoglobin levels are useful in defining intravascular hemolysis. If serum haptoglobin is absent or low in conjunction with an elevated serum Hb level, the presence of intravascular hemolysis is established. Undetectable haptoglobin values are virtually pathognomonic of hemolysis, except in the rare individuals with congenital haptoglobin deficiency. Further studies are necessary to rule in or rule out specific causes of intravascular hemolysis, such as severe autoimmune hemolytic anemia (direct Coombs test), paroxysmal nocturnal hemoglobinuria (PNH) (osmotic fragility), and hemoglobinopathies including sickle cell disease and thalassemia major (Hb electrophoresis).

Total bilirubin is elevated modestly in hemolytic anemia (rarely in excess of 4 mg/dL). The increase results predominantly from an increase in the indirect fraction. However, significant hemolysis can occur without an elevation in the

BOX 55-1 ANEMIA CLASSIFIED BY PATHOPHYSIOLOGIC MECHANISM

- I. Dilutional (expansion of the plasma volume)
 - A. Pregnancy
 - B. Hyperglobulinemia
 - C. Massive splenomegaly

RBC, red blood cell.

bilirubin. Therefore, the bilirubin level is helpful only when it is elevated.

The direct Coombs test uses anti-human immunoglobulin to detect immunoglobulins attached to the surface of RBCs. A positive test indicates an immune cause for a hemolytic anemia. In such cases, it is important to search for underlying causes of autoimmunity, such as connective tissue disease, lymphoma, carcinoma, and sarcoidosis. The diagnosis and management of glucose-6-phosphate dehydrogenase (G6PD) deficiency and of the various hemoglobinopathies are discussed later in this chapter.

The free erythrocyte protoporphyrin (FEP),⁶ plasma iron, plasma total iron-binding capacity (TIBC),⁷ and serum ferritin level^{8,9} are useful in establishing a diagnosis of iron deficiency. Protoporphyrin is generated in the penultimate step of heme synthesis, with iron subsequently incorporated into protoporphyrin to create heme. Iron deficiency causes elevated FEP $\mu\text{g}/\text{dL}$ whole blood. Serum ferritin correlates closely with body iron stores, and many investigators support the use of serum ferritin as the best single test in patients with anemia to make a diagnosis of iron deficiency anemia.^{8,10} A ferritin level of 12 $\mu\text{g}/\text{L}$ or lower is consistent with iron deficiency anemia, and some authors use values of less than 15 to 20 $\mu\text{g}/\text{L}$.¹¹ Plasma iron and serum ferritin levels are both increased after ingestion of iron.^{12,13} Therefore, iron therapy must be discontinued for 24 to 48 hours before these studies are carried out. In iron deficiency, the FEP increases approximately fivefold. Iron is transported in the plasma bound to transferrin. In the iron-deficient state, the plasma iron decreases, the TIBC increases, and the percentage of iron saturation decreases. In contrast, with chronic infection, both the plasma iron and the TIBC are decreased, but the percent saturation remains normal.

Serum folate, RBC folate, and serum vitamin B₁₂ levels are useful in defining the cause of macrocytic anemia. Because the RBC folate more accurately reflects the body's folate stores, many laboratories no longer offer the serum folate determination. The presence of serum intrinsic factor antibodies is specific for pernicious anemia. However, they are undetectable in approximately 40% of cases, so the absence of these antibodies does not rule out a diagnosis of pernicious anemia.

Although a bone marrow aspiration or biopsy can add much useful information, it is rarely done today in pregnant anemic women. In addition to providing a ratio of myeloid to erythroid production (normal, approximately 3:1), it provides a measure of iron stores, allows a differential count of myeloid and erythroid precursors, provides evidence of infiltration with neoplasm, and allows histologic and bacteriologic confirmation of infection.

Normal Hematologic Events Associated with Pregnancy

BLOOD VOLUME CHANGES

During pregnancy, there is normally a 36% increase in the blood volume, the maximum being reached at 34 weeks' gestation.¹⁴ The plasma volume increases by 47%, but the RBC mass increases only by 17%; the latter reaches its maximum at term. As shown in Figure 55-1, this disparity produces a relative hemodilution throughout pregnancy, which reaches its maximum between 28 and 34 weeks. Although this dilutional effect lowers the Hb, hematocrit (Hct), and RBC count, it causes

TABLE 55-1 Laboratory Studies Useful in Evaluation of Anemia

Laboratory Study	Reference Range
Red blood cell (RBC) count	4.0-5.2 $\times 10^{12}/\text{L}$
Mean corpuscular volume (MCV)	80-100 μm^3
Mean corpuscular hemoglobin concentration (MCHC)	31-36 g/dL
Reticulocyte count	48-152 $\times 10^9/\text{L}$ (0.5%-1.5%)
Serum (free) hemoglobin	1.0-5 mg/dL
Serum haptoglobin	30-200 mg/dL
Total bilirubin	0.1-1.2 mg/dL
Direct Coombs test	Negative
Hb electrophoresis	>98% A <3.5% A ₂ <2% F
Serum ferritin	>20 $\mu\text{g}/\text{L}$
Plasma iron	33-102 $\mu\text{g}/\text{dL}$
Plasma total iron-binding capacity	194-372 $\mu\text{g}/\text{dL}$
Transferrin saturation	16%-60%
Folate level	
Serum	>20 $\mu\text{g}/\text{L}$
Red blood cells	165 ng/mL
Serum vitamin B ₁₂	190-950 ng/L
Anti-intrinsic factor (AIF) antibody	Negative

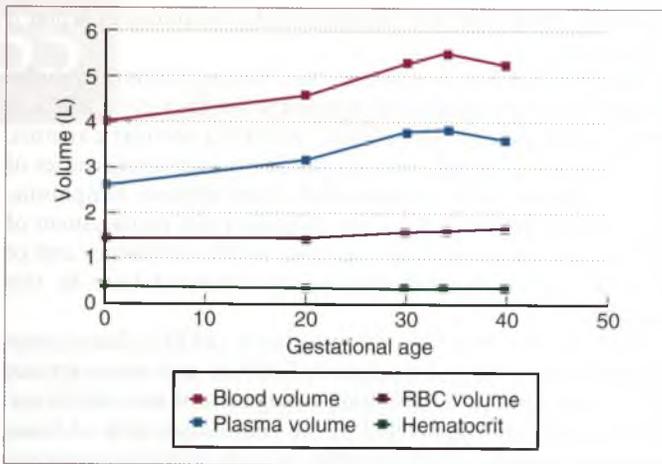

Figure 55-1 Hematologic changes during pregnancy. RBC, red blood cell. (Redrawn from Peck TM, Arias F: Hematologic changes associated with pregnancy, Clin Obstet 22:785, 1979.)

no change in the mean corpuscular volume or in the mean corpuscular Hb concentration. Therefore, serial evaluation of these two indices is useful in differentiating dilutional anemia from progressive iron deficiency anemia during pregnancy: In the former, the indices do not change; in the latter, they decrease progressively.

IRON KINETICS

The classic study by Scott and Pritchard showed that iron stores in healthy women are marginal at best.¹⁵ These authors evaluated iron stores in the bone marrow of healthy, white college students who had never been pregnant and had never donated blood. Approximately two thirds had minimal iron stores. In another study, almost 50% of healthy primigravidas had minimal iron stores in the marrow during the first trimester.¹⁶ Recent reports confirm continued high rates of iron deficiency.^{17,18} In a prospective report of more than 400 women in early pregnancy, one third of them had a ferritin level of less than 20 $\mu\text{g/L}$, and 15% of them had severe iron depletion with ferritin of less than 12 $\mu\text{g/L}$.¹⁷ In addition, despite the high rate of iron depletion, only 6% of the women with a ferritin level of less than 20 $\mu\text{g/L}$ also had anemia with an Hb level of less than 11 mg/L, suggesting that measuring only Hb is an inadequate screen for iron deficiency. The incidence of iron deficiency as measured by total body iron, which takes into account body weight, was 18% in the first trimester and rose to 29% by the third trimester in U.S. women in the National Health and Nutrition Examination Survey for 1999 to 2006.¹⁸

The major reason for poor iron stores in women is thought to be menstrual loss. Data from Monsen and associates indicated that the typical menstrual loss volume is 25 to 30 mL of whole blood.¹⁹ This is equivalent to 12 to 15 mg of elemental iron, because each milliliter of blood contains 0.5 mg of iron. To meet the iron loss accruing with menses alone, a woman must absorb 1.5 to 2.0 mg of elemental iron from her diet each day. Because only 10% of dietary iron is usually absorbed, and the average diet contains only 6 mg/1000 kcal, a woman's iron balance is precarious at best.

Pregnancy presents substantial demands on iron balance, exceeding that saved by 9 months of amenorrhea.¹⁶ Table 55-2

TABLE 55.2 Iron Requirements for Pregnancy

Required for	Average (mg)	Range (mg)
External iron loss	170	150-200
Expansion of red blood cell mass	450	200-600
Fetal iron	270	200-370
Iron in placenta and cord	90	30-170
Blood loss at delivery	150	90-310
Total requirement	980	580-1340
Requirement less red blood cell expansion	840	440-1050

lists the iron requirements for pregnancy. If available iron stores are insufficient to meet the demands of pregnancy, iron-deficient erythropoiesis results. In a prospective study of 35 nonanemic women, ferritin levels were measured before and during pregnancy to determine the relationship of iron stores to developing anemia.²⁰ Approximately 60% of the women with a ferritin concentration of less than 20 $\mu\text{g/L}$ before pregnancy were anemic by 20 weeks' gestation, compared with 25% of women with normal pre-pregnancy ferritin levels. Fenton and colleagues used serum ferritin levels to evaluate iron stores in pregnant women and found significantly higher ferritin levels in women who were receiving iron supplementation than in those who were not.²¹ The usual sequence of events in regard to iron deficiency is an absence of iron in the marrow followed by the development of abnormal plasma iron studies (transferin, ferritin, or FEP). The RBCs first become microcytic, then hypochromic. Finally, anemia develops.

Most women enter pregnancy with marginal iron stores. Pregnancy places a large demand on iron balance that cannot be met with the usual diet. In the absence of supplementation, iron deficiency will develop, and in many women anemia will also develop. Although supplementation with 60 mg of elemental iron per day during the second and third trimesters meets the daily requirement, a recent prospective study reported that despite a mean supplementation of 49 mg/day of iron, iron deficiency increased from 8% in the first trimester to 62% by the third trimester.²² However, it is clear that iron supplementation significantly, by as much as 73%, reduces the incidence of anemia.²³ The Institute of Medicine recommends that supplementation be offered only to women whose serum ferritin level is less than 20 $\mu\text{g/L}$.²⁴ Although this is a valid recommendation scientifically, the high cost of the screening limits its applicability.

The fetal compartment preferentially obtains iron, folate, and vitamin B₁₂ from—and at the expense of—the mother.²⁵⁻²⁷ Maternal iron is transferred to the fetus via serum transferrin. Transferrin binds to receptors on the apical surface of placental syncytiotrophoblast, where the iron is released and subsequently binds to ferritin in placenta cells. It is then transferred to apo-transferrin, which enters into the fetal circulation as holotransferrin. If maternal iron status is low, placental transferrin receptors increase to facilitate more uptake of iron by the placenta.²⁸

FOLATE

Folic acid, a water-soluble vitamin, is widely available in the diet. Dietary folates are, in fact, a family of compounds that appear as polyglutamates. In humans, the only source of folate

is the diet, and absorption occurs primarily in the proximal jejunum. Before folate can be absorbed, it must be reduced to the monoglutamate form.²⁹ Pancreatic conjugases in the intestine are responsible for this process. The activity of conjugase is decreased by use of anticonvulsants, oral contraceptives, alcohol, or sulfa drugs.³⁰ Therefore, in addition to an absolute diminution in dietary intake, the combination of increased need (e.g., multiple pregnancy, hemolytic anemia) and decreased absorption can lead to folate deficiency.^{27,31,32} Folate deficiency is defined as a serum level of less than 2.5 to 3.0 ng/mL.³³

The folate requirement of 50 µg/day for a nonpregnant woman increases to 300 to 500 µg/day during pregnancy.^{16,34} Because adequate folate intake before and during the first weeks of pregnancy reduces the occurrence of neural tube defects, all women considering pregnancy should consume 400 µg of folate per day.³⁵ One study estimated that a folate supplementation of 400 µg/day would reduce the risk of neural tube defects by 36%, and that 5 mg/day would reduce the risk by 85%.³⁶ If a previous pregnancy was complicated by a neural tube defect, the mother's intake of folate should be 4 mg/day in the next pregnancy, starting at least 4 weeks before conception and continuing through the first 3 months of pregnancy.^{35,37} When folate depletion occurs, the usual sequence of events is a decreased serum folate, hypersegmentation of polymorphonuclear leukocytes, a decrease in RBC folate, the appearance of ovalocytes in the blood, development of an abnormal marrow, and, finally, anemia.²⁹

VITAMIN B₁₂

Vitamin B₁₂, also abundantly available in the diet, is bound to animal protein. Absorption requires hydrochloric acid and pepsin to free the cobalamin molecule from protein. Intrinsic factor is also essential for absorption. After absorption, transport occurs via binding to transcobalamin II. Most of the vitamin B₁₂ is stored in the liver, and individuals typically have a 2- to 3-year store available (2 to 5 mg).⁷ Vitamin B₁₂ deficiency is defined by a serum level of less than 160 to 200 pg/mL.³³

Morphologic Classification of Anemia

MICROCYTIC ANEMIA

The microcytic anemias are characterized by abnormal Hb synthesis with normal RBC production. A logical progression of diagnostic steps requires, first, that iron deficiency anemia be ruled out. If iron deficiency anemia is diagnosed rather than ruled out, it is important to consider gastrointestinal bleeding as the cause, although it is rare in pregnant women. This can be accomplished by testing the stool for the presence of occult blood with guaiac or an equally sensitive reagent. If a microcytic anemia is not the result of iron deficiency, another cause should be sought, such as hemoglobinopathy, chronic infection, or one of the sideroblastic anemias. For this purpose, the following tests should be considered:

1. Hb electrophoresis
2. Plasma iron and TIBC
3. FEP
4. DNA probing for beta genes
5. Bone marrow examination

As noted, iron deficiency anemia is associated with decreased serum iron, increased TIBC (>400 µg/dL), reduced serum ferritin concentration (<20 µg/L), and elevated FEP. Because iron

deficiency is the most common anemia in pregnancy, it is reasonable and cost effective to screen all women with microcytic anemia with serum ferritin initially. A serum ferritin level of less than 20 µg/L is generally diagnostic of iron deficiency anemia. However, iron deficiency anemia may still be present when the serum ferritin level is greater than 20 µg/L, particularly in the setting of other conditions including chronic disease. Additional tests to confirm iron deficiency may be warranted in such settings. Anemia of chronic disorders is associated with decreased serum iron level and elevated FEP but paradoxically normal or increased ferritin and decreased TIBC. If the serum iron and TIBC are normal or increased and FEP is normal, the patient usually has thalassemia or a sideroblastic anemia. Hb electrophoresis and DNA probes are used to define the thalassemias, and ring sideroblasts are present in the bone marrow of individuals with hereditary or acquired sideroblastic anemia.

NORMOCYTIC ANEMIA

Because of the diverse nature of normocytic anemia, it is the most difficult type to evaluate. The reticulocyte count varies according to whether RBC production is increased, normal, or decreased. If erythropoiesis is increased, one must differentiate between hemorrhage and an increased rate of destruction. The blood smear may reveal a type of RBC shape that can be virtually diagnostic. Fragmented cells are seen in microangiopathic hemolysis—as in the HELLP syndrome (*hemolysis, elevated liver enzymes, low platelets*) and thrombotic thrombocytopenic purpura—and in association with prosthetic heart valves. Other types of poikilocytes identified include sickle cells, target cells, stomatocytes, ovalocytes, spherocytes, elliptocytes, and acanthocytes.

The Coombs test differentiates immune from nonimmune causes of hemolysis. Immune hemolysis is related to alloantibodies, drug-induced antibodies, and autoantibodies. Nonimmune causes of hemolysis include various hemoglobinopathies, hereditary disorders of the RBC membrane (spherocytosis and elliptocytosis), hereditary deficiency of an RBC enzyme, and the porphyrias. Acquired nonimmune hemolysis is caused by either PNH or lead poisoning.

Bone marrow examination is essential for the evaluation of patients who have hypoproliferative anemias with normal iron studies. If erythropoiesis is megaloblastic, folate or vitamin B₁₂ deficiency is a likely cause. If it is sideroblastic, both acquired and hereditary forms of sideroblastic anemia must be considered.

Finally, if erythropoiesis is normoblastic, etiologic mechanisms fall into two major categories. The first category has myeloid-to-erythroid production ratios greater than 4:1 and includes aplasia, bone marrow infiltration (e.g., chronic myeloid leukemia), effects of chronic diseases, and endocrine disorders such as hypothyroidism and hypopituitarism. In contrast, the myeloid-to-erythroid ratio is decreased (e.g., 2:1) when erythroid hyperplasia is present, as with relatively acute hemolysis.

MACROCYTIC ANEMIA

Macrocytic anemia is associated with either (1) an increased rate of RBC production and release of less than fully mature RBCs or (2) disorders of impaired DNA synthesis. Early use of a bone marrow examination is helpful in pointing the investigation in the correct direction. If maturation is megaloblastic, abnormal serum vitamin B₁₂ and RBC folate levels allow a diagnosis of vitamin B₁₂ or folate deficiency. If a diagnosis of folate

deficiency is confirmed, the various causes of decreased deconjugation of the polyglutamate and malabsorption must be considered. Folic acid, the polyglutamate present in food, must be deconjugated by intestinal enzymes for absorption. Causes of decreased deconjugation and hence poor absorption of folate include alcoholism, folate antagonists (methotrexate, pyrimethamine, trimethoprim). Other causes of malabsorption include pernicious anemia, which should be considered if anti-intrinsic factor antibodies are present. If anti-intrinsic factor antibodies are absent, a Schilling test is required to differentiate between pernicious anemia and a small-bowel malabsorption syndrome. The Schilling test is performed by oral loading with cobalt ^{58}Co -labeled cobalamin. Urinary excretion of cobalamin measured over 24 hours is then assessed. If abnormal excretion is noted (less than 10%), the test is repeated with ^{58}Co -labeled cobalamin bound to intrinsic factor. If pernicious anemia is present, excretion will normalize; if malabsorption is the cause, excretion will remain reduced. However, note that shortages of ^{58}Co -labeled cobalamin as well as certification issues have greatly limited the availability of this test in the United States. Celiac sprue, diagnosed by small-bowel biopsy, with villous atrophy is another malabsorption cause of folate deficiency.

Effects of Maternal Anemia on the Fetus

Although it has been traditionally taught that significant maternal anemia is associated with suboptimal fetal outcome, data supporting this concept are conflicting. Several studies, including a meta-analysis, reported a significant relationship between anemia early in pregnancy and preterm delivery but no significant association with small-for-gestational-age (SGA) neonates.³⁸⁻⁴¹ A more recent paper reported no significant relationship between anemia and preterm delivery, low-birth-weight infants, or maternal morbidity.⁴² Earlier studies reporting on maternal anemia and poor fetal outcome produced conflicting data.⁴³⁻⁴⁶ Studies in sheep showed that fetal oxygen consumption is maintained until the maternal Hct was reduced by more than 50%.⁴⁷ Therefore, maternal anemia needs to be severe to affect the fetus. However, there is a large body of international literature on the associations of neonatal and pediatric iron deficiency anemia with adverse outcomes including potential poor cognitive outcomes.^{3,48} It is not clear what proportion of this early life anemia is related to maternal iron deficiency during pregnancy, or whether there is any trimester-associated risk that is more highly associated with neonatal iron deficiency. A recent randomized study in a mouse model of several maternal iron-restriction diets concluded that maternal iron restriction, at a level that did not result in maternal anemia, beginning before conception and lasting through the first trimester was associated with a significant decrease in fetal iron stores and postnatal anemia compared with control.⁴⁸

Elevated Hb early in pregnancy has been associated with poor perinatal outcome, including stillbirth, low birth weight, and SGA neonates.^{42,49} In a case-control study, women with stillbirths had a significantly higher incidence of Hb levels that were higher than 14.5 g/dL than did control women without stillbirths.⁴⁹ Although the mechanism for this association is unknown, the authors hypothesized that high Hb may be a marker of inadequate plasma-volume expansion and hence

reduced blood flow to the intervillous space. An alternative explanation is that global placental dysfunction leads to reduced production of the steroid and peptide hormones responsible for maternal plasma volume expansion.

In Africa, Asia, and Latin America, the relative risk of maternal mortality with severe anemia (Hb <4.7 g/dL) was significantly elevated at 3.5 (confidence interval, 2.05 to 6.0), while moderate anemia (Hb 4.0 to 8.0 g/dL) was not associated with an increase in maternal mortality.⁵⁰ In a case series of 130 women with an Hb of less than 5 g/dL in the third trimester in India, more than half had a preterm delivery, more than 25% had postpartum hemorrhage, sepsis, or a stillbirth, and eight women died.⁵¹ The WHO estimated that 18% of maternal mortality is associated with anemia, the majority of which is iron deficiency anemia.⁵² However, these studies and others are fraught with confounders, including hemorrhage at delivery and lack of access to care, so it is difficult to know whether the key factor associated with these deaths was the baseline anemia. Therefore, although profound maternal anemia can have adverse effects on the mother and the fetus, the margin of safety appears to be large. It may be that the prevalence of severe anemia is too low in industrialized countries to see consistent associations with poor fetal or maternal outcomes.

Although there is no association between maternal third-trimester Hb and cord-blood Hb, maternal Hb or ferritin was significantly associated with cord-blood ferritin.^{28,53} In several studies, the umbilical cord-blood ferritin levels of infants whose mothers were iron deficient were reduced, compared with those of infants whose mothers were not iron deficient.^{21,54} Yet, infants whose ferritin levels were low were not anemic and had normal iron kinetics, and their serum ferritin values were not in the iron-deficient range. In a study of newborns of women with severe folate deficiency, Pritchard and colleagues found normal neonatal levels of folate.¹⁶

Colomer and colleagues found that 1-year-old infants had a 5.7-fold increase in risk for anemia if their mothers were anemic at delivery, compared with nonanemic mothers, even after the data were controlled for feeding practices and socioeconomic status.⁵⁵ In another interesting trial, iron supplementation in women who were not anemic in the first trimester was associated with a significant reduction in the incidence of birth weight less than 2500 g and in the incidence of SGA neonates.⁵⁶ This trial randomized nonanemic women to receive 30 mg ferrous sulfate or placebo by 20 weeks' gestation. Almost 17% of the placebo-treated women but only 4% of the iron-treated women had low-birth-weight neonates, and 18% and 7%, respectively, had babies that were SGA. These provocative results, indicating that improved iron reserves enhance fetal growth independent of anemia status, may be generalizable only to populations with a high incidence of smoking, because 36% to 40% of the women in each group smoked. However, another randomized trial of routine versus indicated (by an Hb level less than 10 g/dL) treatment with iron revealed no difference in perinatal outcome or long-term outcome, including subsequent pregnancies.⁵⁷

Specific Anemias

Space does not allow a detailed discussion of the diagnosis and treatment of literally hundreds of different anemias. Instead, a scheme of diagnostic studies that are useful in evaluating any anemia and a discussion of specific anemias that are commonly seen during pregnancy are presented.

IRON DEFICIENCY ANEMIA

Iron deficiency is the cause of 75% of all anemias in pregnancy, and its prevalence may be as high as 47%.⁵⁸⁻⁶⁰ Clinical symptoms include easy fatigue, lethargy, and headache. Pica, which may involve the ingestion of clay, dirt, ice, or starch, is a classic manifestation of iron deficiency and was significantly associated in one study with lower maternal Hb but not with adverse pregnancy outcomes.⁶¹ Clinical findings include pallor, glossitis, and cheilitis. Koilonychia has been associated with iron deficiency anemia but is a rare finding. The laboratory characteristics of iron deficiency anemia are a microcytic, hypochromic anemia with evidence of depleted iron stores, low plasma iron, high TIBC, low serum ferritin, or elevated FEP. If a bone marrow examination is performed, stainable iron is found to be markedly depleted or absent. Although iron supplementation has not been consistently shown to alter perinatal outcome, the Centers for Disease Control and Prevention strongly recommends screening and treatment of iron deficiency anemia in pregnancy.^{8,62,63} The rationale is that treatment maintains maternal iron stores and may be beneficial for neonatal iron stores.⁸

The specific treatment is oral iron, most commonly, in the United States, ferrous sulfate, 325 mg one to three times daily. The WHO recommends 60 mg iron daily with folic acid for all pregnant women but does note that 30 mg may be sufficient.³ A recent trial, in which 43% of the pregnant women had anemia, showed that 30 mg of iron with micronutrients had the same beneficial effect on hemoglobin as 60 mg without micronutrients.⁶⁴ Other iron preparations are more expensive and do not offer any advantage over ferrous sulfate if equal amounts of elemental iron are given. Reticulocytosis should be observed after 7 to 10 days of therapy, and the Hb can rise by as much as 1 g/wk in severely anemic individuals. Absorption from the gastrointestinal tract can be enhanced by the administration of 500 mg of ascorbic acid with each dose of iron. Gastrointestinal side effects associated with iron therapy include nausea, vomiting, abdominal cramps, diarrhea, and constipation. These symptoms correspond to the dose of elemental iron ingested; if symptoms are troublesome, the dose of iron should be reduced. Ferrous sulfate syrup (300 mg/5 mL) is an effective way of tailoring the dose to the patient's tolerance. Once the anemia has resolved, the patient should continue to receive iron therapy for an additional 6 months to replace iron stores. Vitamin B₆ deficiency should be considered in women unresponsive to oral iron therapy, as vitamin B₆ normally decreases in pregnancy and supplementation with B₆ and iron was associated with an increase in hemoglobin.⁶⁵

Parenteral administration of iron is rarely indicated and should be reserved for patients with a malabsorption syndrome and those who refuse to take oral iron and are significantly anemic (Hb <8.5 g/dL).⁶⁶ Currently, three parenteral forms of iron are approved for use in the United States: iron dextran, sodium ferric gluconate, and iron sucrose.⁶⁷ These are usually given intramuscularly or intravascularly, and, because severe anaphylaxis can occur in 1% of patients, a test dose should be administered first. In the absence of any reaction, daily injections of 2 mL (100 mg) can be administered until the full dose is reached. Iron dextran contains 50 mg of iron per milliliter and comes in 2-mL ampules. The required dose of iron dextran needed to correct anemia and replenish stores can be calculated as follows:⁶⁸

1. Milligrams of Fe needed = Hb deficit (in g/dL) × lean body wt (lb) + 1000, where the Hb deficit is calculated (for women) as 12 minus the patient's Hb value

2. Milliliters of iron dextran needed = milligrams of Fe needed divided by 50 mg/mL

Iron sucrose and sodium ferric gluconate preparations appear to have fewer adverse events, such as anaphylaxis, in part because of lower molecular weights.⁶⁷⁻⁶⁹ Oral iron was compared with intravenous iron sucrose in a randomized trial of pregnant women with Hb values of 8 to 10 g/dL, and the increase in Hb (2 g/dL) was the same in both groups at day 30.⁷⁰ In another, partially randomized study comparing oral iron with intramuscular iron dextran in anemic women, there was no significant difference in term Hb levels but a significant increase in ferritin in the group treated with intramuscular iron, compared with orally treated women.⁷¹ In contrast, another randomized trial comparing oral to intravenous iron sucrose found that the latter was associated with a significantly larger increase in Hb at 2 and 4 weeks and at delivery.⁷² However, at delivery, there was less than 1 mg/dL difference between the mean Hb values in the two groups. The authors reported no serious side effects in either group.

Subcutaneous erythropoietin with or without oral iron therapy or intravenous iron sucrose has been used successfully to treat severe iron deficiency anemia in pregnancy, with no significant risks to the mother.⁷³⁻⁷⁵ In one study of women for whom oral iron therapy had failed and who had an Hb value lower than 8.5 g/dL, the addition of erythropoietin to oral iron was associated with normalization of Hb in 2 weeks in 73% of the women.⁷⁴ Although there are no published reports of increased risk of thromboembolism in pregnant women on erythropoietin, erythropoietin is associated with such risk when administered to nonpregnant individuals, so this should be considered in the risk-benefit decision to use erythropoietin in pregnancy. Darbepoetin alfa, which has a longer half-life than erythropoietin, has also been used to successfully treat anemia after renal transplantation in a pregnant patient.⁷⁶

MEGALOBlastic ANEMIA

Megaloblastic anemia is the second most common nutritional anemia seen during pregnancy. Most commonly, folate deficiency is the cause, but a deficiency in vitamin B₁₂ must also be considered. Interestingly, although the incidence of iron deficiency anemia did not change between 1994 and 2002, the incidence of folate deficiency anemia in reproductive-age women decreased from 4.1% to less than 1.0%, or from one third of these anemias to less than 10% of anemias.⁴ The etiologies of these anemias are poor nutrition or decreased absorption, or both. With the increase in pregnancies occurring after bariatric surgery, it is possible that bariatric surgery may become a common cause of folate or B₁₂ deficiency in pregnant women in the United States.⁷⁷

Patients with folate deficiency present with the typical symptoms of anemia plus roughness of the skin and atrophic glossitis. The CBC reveals a macrocytic or normocytic, normochromic anemia with hypersegmentation of the polymorphonuclear leukocytes. The reticulocyte count is normal or low, and the white blood cell and platelet counts are frequently decreased. Bone marrow examination is not usually necessary for diagnosis, but if it is done, megaloblastic erythropoiesis is noted. The RBC folate level is decreased to less than 165 ng/mL (serum folate to less than 2 µg/L), and the vitamin B₁₂ level is normal. Treatment consists of oral folic acid administered in a dose of 1 mg/day. Parenteral folic acid may be indicated for individuals with malabsorption. A reticulocyte response should be seen in

48 to 72 hours, and the platelet count should normalize within a few days. The neutrophils normalize after 1 to 2 weeks.

In addition to anemia, women with vitamin B₁₂ deficiency may also manifest neurologic defects related to damage to the posterior columns of the spinal cord. It is critical that individuals with vitamin B₁₂ deficiency not be treated with folic acid alone. Such treatment may well improve the anemia, but it has absolutely no salutary effect on the neuropathy and may make it worse. As with folate deficiency, vitamin B₁₂ deficiency is associated with dietary deficiency, an increased requirement, or both. Except in strict vegetarians who avoid all animal products, dietary deficiency is rare.

The most common causes of vitamin B₁₂ deficiency are autoimmune inhibition of intrinsic factor production (pernicious anemia), inadequate production of intrinsic factor after gastrectomy, and the presence of a malabsorption syndrome. The morphologic features of B₁₂ deficiency are similar to those of folate deficiency. In this instance, the serum vitamin B₁₂ level is low and the folate level is normal. Because ineffective erythropoiesis is a prominent feature, evidence of low-grade hemolysis may be present (increased bilirubin and decreased haptoglobin). The measurement of anti-intrinsic factor antibodies is useful. Treatment consists of an intramuscular dose of 1 mg of vitamin B₁₂ every day for 1 week, then 1 mg every week for 4 weeks, and then 1 mg every month for the remainder of the patient's life in cases of pernicious anemia. A prompt reticulocyte response is anticipated after 3 to 5 days of therapy.

HEREDITARY SPHEROCYTOSIS AND ELLIPTOCYTOSIS

Spherocytosis is the most common form of inherited hemolytic anemia. The inheritance is autosomal dominant with variable penetrance. Hereditary spherocytosis (HS) is characterized by a structural defect in the erythrocyte membrane caused by several different molecular defects in the membrane proteins, including spectrin deficiency and ankyrin deficiency.⁷⁸ The classic characteristic is an increased RBC osmotic fragility. The prevalence of the disorder is two to three in 10,000, which implies around 1000 pregnancies annually in women with spherocytosis. A hemolytic crisis can be precipitated by many conditions, such as infection, trauma, and pregnancy itself.⁷⁹ A relationship between increased hemolysis and increased maternal blood volume and splenic blood flow has been proposed. An alternative suggestion is an increased osmotic fragility during the third trimester of pregnancy.⁸⁰

The diagnosis is suspected on the basis of family history and findings in the CBC and reticulocyte count that suggest a hyperproliferative anemia. Confirmation is obtained with the osmotic fragility test. Prenatal care of women with hereditary spherocytosis who have not had a splenectomy requires vigilance for hemolytic crisis, and folate supplementation to ensure adequate marrow function.⁸¹ A hemolytic crisis can be treated conservatively with replacement transfusions or with splenectomy. Because splenectomy is mechanically difficult to accomplish during the third trimester of pregnancy, it is sometimes preceded by delivery. In the absence of severe, untreated anemia, spherocytosis does not contribute to perinatal morbidity or mortality.

Hereditary elliptocytosis, also inherited as an autosomal-dominant trait, is a milder hemolytic state also caused by a structural defect in the RBC wall. The signs and symptoms are

similar to those of spherocytosis but are not as severe. Most cases detected during pregnancy have been successfully treated with supportive therapy alone.⁸²

AUTOIMMUNE HEMOLYTIC ANEMIA

The two major types of antibodies responsible for autoimmune hemolytic anemia are warm-reactive and cold-reactive antibodies. Most warm-reactive antibodies are of the immunoglobulin G (IgG) class and are directed against some component of the Rh system on the surface of the RBC. In contrast, most cold-reactive antibodies are IgM; they are usually anti-I or anti-i. Autoimmune hemolytic anemia with warm-reactive antibodies is frequently seen in association with various hematologic malignancies (chronic lymphocytic leukemia, lymphoma), lupus erythematosus, viral infections, and drug ingestion. Penicillin and alpha-methyldopa have been reported to cause autoimmune hemolytic anemia. Cold-reacting antibodies can be seen in association with mycoplasmal infections, infectious mononucleosis, and lymphoreticular neoplasms.

In a large number of cases, no specific inciting event can be identified.⁸³ The diagnosis is suspected when a hyperproliferative, macrocytic anemia is identified. The stained smear of peripheral blood often reveals microcytes, polychromatophilia, poikilocytosis, and the presence of normoblasts. Leukocytosis is frequently seen and is a result of marrow hyperactivity. The critical study to confirm the diagnosis is a positive direct Coombs test. Several case reports in the literature describe pregnancy-induced hemolytic anemia in which no etiology could be discerned, the disease was diagnosed during pregnancy, and spontaneous remission occurred after the delivery.^{84,85} One report described a woman in whom hemolytic anemia was diagnosed in three separate pregnancies; it was not responsive to either steroids or intravenous IgG therapy but resolved after delivery in all pregnancies.⁸⁴

Treatment of autoimmune hemolytic anemia is directed toward both the hemolytic process and the underlying disease. Blood transfusion, corticosteroid therapy, immunosuppression, and splenectomy are the most frequently used measures. Rituximab, a monoclonal anti-CD20 antibody, is a new second-line treatment, but its use for autoimmune hemolytic anemia in pregnancy has not been studied. It is a category C drug. In patients with warm-reactive antibodies, corticosteroid should be tried initially, because approximately 80% of patients respond dramatically. Splenectomy is an effective form of treatment in approximately 60% of patients with warm-reactive antibodies. If the disease is refractory to both corticosteroid therapy and splenectomy, a trial of immunosuppression is warranted. The treatment of cold-reactive antibodies depends on the severity of the hemolytic process. In patients with mild anemia, avoidance of cold temperatures is all that is required. Corticosteroid therapy and splenectomy are usually not effective if the majority of the RBC breakdown is intravascular. In patients with severe anemia, a trial of immunosuppression or plasmapheresis should be considered.

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

More than 20 different hereditary RBC enzyme defects have been described, most with an associated hemolytic anemia. Of these, only G6PD deficiency occurs with more than occasional

frequency. The genetic locus controlling G6PD synthesis is on the X chromosome, and males with an abnormal gene may suffer hemolysis, especially if they are exposed to oxidant drugs that stress the pentose phosphate pathway of the erythrocyte. Female heterozygotes are generally clinically unaffected by similar exposure. The G6PD activity of the RBCs in heterozygous females is usually intermediate between the activity in hemizygous males and that in unaffected subjects. However, some female carriers have normal G6PD activity, whereas others have activity that falls within the range seen in affected males. It has been proposed that this is consistent with the Lyon hypothesis, that one of the two X chromosomes of every female cell is randomly inactivated in early embryonic life and continues to be inactive throughout all cell divisions.⁸⁶ Therefore, a few heterozygous women may be severely deficient in G6PD activity, but most have sufficient activity to withstand added stress on this critical metabolic pathway in erythrocytes.

The ethnic groups in which variants of the deficiency occur with greatest frequency are blacks, Mediterranean populations, Sephardic and Asiatic Jews, and certain Asian populations. Of male African Americans in the United States, 12% are reported to be deficient in G6PD activity. Most affected individuals are hematologically normal unless they have been exposed to certain drugs or chemicals or have experienced metabolic disturbances or infections that precipitate an acute hemolytic episode. Most affected African Americans carry a variant with these properties. Their hemolytic episodes are relatively mild. Greeks, Sardinians, and Sephardic Jews are more likely to carry G6PD Mediterranean, in which hemolysis is characteristically more severe and favism (hemolysis induced by ingestion of fava beans) occurs. The G6PD-deficient African-American population has not been reported to experience favism.

It is relatively unusual for a pregnant woman to experience severe sequelae of G6PD deficiency. However, Silverstein and associates reported Hct levels of less than 30% in 62% of 180 G6PD-deficient women.⁸⁷ Prudence would argue against exposure of a known carrier to precipitants of hemolysis. Sulfonamides, sulfones, some antimalarials, nitrofurans, naphthalene, probenecid, para-aminosalicylic acid-isoniazid, and nalidixic acid are among the medications and commonly occurring environmental chemicals known to precipitate RBC destruction in at-risk individuals.

One report suggested an increased incidence of low-birth-weight infants born to G6PD-deficient mothers, but no correction for the effects of anemia or urinary tract infection was employed.⁸⁸ Affected male infants born of carrier females have a higher incidence of neonatal hyperbilirubinemia, sometimes severe, than normal infants, and careful observation of those at risk is strongly advised.⁸⁹ The incidence of severe jaundice in G6PD-deficient newborn male infants is approximately 5%, rising to 50% if there is a history of an icteric sibling.

If a hemolytic episode occurs during pregnancy because of G6PD deficiency in a female heterozygote or the very rare homozygote, management should include prompt discontinuation of any medication or other agent that may be responsible, treatment of any intercurrent illness, and, if clinically indicated, transfusion support. In patients with the variant common among African Americans, even in the male hemizygote, the G6PD activity of young RBCs is much higher than that of RBCs that have circulated for weeks and months. Old cells may be totally devoid of activity. Hence, the hemolytic episode, recognized early, is generally relatively mild and can be limited to the

oldest population of circulating RBCs if the inciting agent is eliminated. A comprehensive review of G6PD deficiency was published by Beutler.⁸⁶

APLASTIC AND HYPOPLASTIC ANEMIA

Aplastic anemia is characterized by pancytopenia in the presence of a hypocellular bone marrow. If it is left untreated, patients usually die from infection or bleeding. Three mechanisms have been postulated to explain the development of aplastic anemia: (1) insufficient stem cells resulting from an intrinsic defect or a reduction in number after exposure to a noxious agent, (2) the presence of a suppressor substance that inhibits maturation of the hematopoietic stem and progenitor cells, and (3) development of an autoimmune reaction that causes death of the stem cells.

Agents such as benzene, ionizing radiation, nitrogen mustard, antimetabolites, antimitotic agents, certain antibiotics, and toxic chemicals predictably lead to marrow aplasia. In another category are agents such as chloramphenicol, anticonvulsants, analgesics, and gold salts, which induce aplasia only occasionally. Finally, hundreds of agents of various types have been implicated in several cases as causes of aplastic anemia. In about 50% of the cases, however, careful search does not reveal any causative agent.

Holly described eight patients with hypoplastic anemia detected during pregnancy that remitted spontaneously after delivery.⁹⁰ The bone marrow was described as hypocellular with an increase in megakaryocytes. There are now many case reports and series of pregnancy-associated aplastic anemia, although they present a spectrum of clinical and bone marrow findings that makes it difficult to substantiate the existence of an aplastic anemia specifically related to pregnancy.⁹¹⁻⁹⁶ Many papers used the criteria delineated by Snyder and coworkers⁹⁶ as evidence that the disease was pregnancy related: identification of the disease after the onset of pregnancy; no other etiology of aplastic anemia; decrease in all blood cell counts and in Hb level; and hypoplastic bone marrow. However, recovery from the aplastic anemia was not universally documented after delivery, which raises the question of whether it is truly pregnancy related.^{92,94}

Patients with aplastic anemia seek medical attention because of symptoms related to profound anemia, bleeding, or infection. The CBC reveals pancytopenia with a hypoproliferative reticulocyte count. Examination of the bone marrow reveals hypoplasia with normoblastic erythropoiesis. Severe aplastic anemia is fatal for more than 50% of affected patients.⁹⁷

Bone marrow transplantation is now the treatment of choice, and long-term survival of 50% to 70% of patients can be expected. Alternatives include antithymocyte globulin, immunosuppressive therapy, and other supportive therapy (see later).⁹⁸ Survivors have had successful pregnancies after bone marrow transplantation.⁹⁹⁻¹⁰² The largest series examined pregnancy outcomes in 146 pregnancies occurring after treatment for aplastic anemia in 41 women.¹⁰¹ The outcomes for women treated with total-body irradiation and bone marrow transplantation were compared with those for women treated with high-dosage chemotherapy and bone marrow transplantation. The data demonstrated no increase in the incidence of congenital anomalies in infants. However, total-body irradiation was associated with an increased risk of spontaneous abortion. Twenty-five percent of the pregnancies ended with a preterm delivery or delivery of a low-birth-weight infant. Another paper

described pregnancy outcomes of 36 women with aplastic anemia who had been treated with immunosuppression before their pregnancy.¹⁰³ Only 11 of these women had complete remission before they became pregnant, and 19% of the total group had a relapse of their aplastic anemia during pregnancy that required transfusion. Two women died, one of whom also had PNH, and two women had eclampsia. The majority of the pregnancies resulted in live births, with a 14% prematurity rate. Several patients were treated with cyclosporine or corticosteroids during their pregnancy.

During pregnancy, supportive therapy remains the major objective, because bone marrow transplantation is relatively contraindicated in pregnancy. In recent years, with modern supportive therapy, the maternal mortality rate has been 15% or less, and more than 90% of patients survive in remission.^{92,94} Treatment consists of maintenance of Hb levels through periodic transfusion, prevention and treatment of infection, stimulation of hematopoiesis with androgens, splenectomy, intravenous immune globulin (IVIG), and intravenous steroids.¹⁰⁴ Two case reports described successful pregnancies with a combination of RBC and platelet transfusions, cyclosporine, human granulocyte colony-stimulating factor therapy, high-dosage intravenous prednisone, and IVIG.^{91,95} In a series of 14 women diagnosed during pregnancy, all of whom were treated with transfusions only, there were no deaths, and 10 of the women had normal pregnancy outcomes.⁹⁴ The four abnormal outcomes were spontaneous abortion, preterm delivery, preeclampsia, and intrauterine growth restriction (IUGR). Androgen therapy can be effective at stimulating erythropoiesis; however, androgens are contraindicated during pregnancy unless the fetus is demonstrated to be male. Androgenic agents commonly used include the anabolic steroids oxymetholone, nandrolone decanoate, and testosterone enanthate. Adrenocorticosteroids have also been widely used with some benefit. However, the remission rate with steroids is only 12%.

Because of anecdotal reports of complete remission after pregnancy termination, it is tempting to consider therapeutic abortion. However, thorough examination of the available literature indicates that abortion or premature termination of pregnancy is not associated with a more favorable outcome. The only reason to terminate pregnancy prematurely is inability to treat the patient satisfactorily during pregnancy with transfusion alone and a consequent need to proceed to marrow transplantation.

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Paroxysmal nocturnal hemoglobinuria was named for its characteristic nighttime hemolysis with dark early-morning urine. Hemolysis in PNH occurs as a result of a somatic mutation in the phosphatidylinositol glycan class A (*PIGA*) gene on the X chromosome. This enzyme mediates formation of phosphatidylinositol anchors for various transmembrane proteins, including inhibitors of the complement proteins.¹⁰⁵ These latter proteins are normally present in the RBC and protect against complement activation. Their reduction renders RBCs susceptible to intravascular hemolysis by complement. PNH usually begins insidiously, and there is no familial tendency. Considerable variability exists in the severity of the disease, and the classic presentation of hemoglobinuria is seen in only 25% of patients. Exacerbations of the hemolytic process are

precipitated by infection, menstruation, transfusion, surgery, and ingestion of iron.

The most serious complications are marrow aplasia, thrombosis, and infection. Thrombosis accounts for 50% of deaths in nonpregnant patients and often involves intraabdominal vessels, including Budd-Chiari syndrome resulting from hepatic vein thrombosis.^{106,107} Although anemia is the most prominent hematologic feature of PNH, leukopenia and thrombocytopenia also occur frequently. The diagnosis is based on tests including the sucrose hemolysis and acidified serum lysis tests, which demonstrate the sensitivity of the patient's RBCs to complement.

There are two excellent reviews of PNH in pregnancy.^{105,108} A review of 20 case reports and series encompassing 33 pregnancies in 24 women revealed several interesting features. One third of these cases were diagnosed for the first time during pregnancy, and 12% of the pregnancies were complicated by thromboembolism, with three fourths of the patients having Budd-Chiari syndrome or hepatic vein thrombus.¹⁰⁸ Half of these women died. In addition, there were two maternal deaths from infection, which means that five, or 21% of the 24 women with PNH, died in pregnancy or after the delivery. In addition, 73% had anemia or hemolysis during pregnancy, and 27% developed thrombocytopenia. In another review, the most common complication was venous thrombosis.¹⁰⁵ Although at least two pregnant or puerperal women developed a thromboembolism despite receiving thromboprophylaxis, experts continue to recommend thromboprophylaxis.^{105,108} This may be particularly challenging if the patient develops thrombocytopenia. There is one case report of a successful epidural placement during labor in a woman with PNH and a platelet count of 64,000/mL.¹⁰⁹ A more recent review of 25 pregnancies reported a high (4%) fetal demise rate and high preterm birth rate (29%).^{109a} Because of the extremely high maternal death and morbidity rates associated with PNH in pregnancy, careful detailed counseling should be provided to the woman before she considers pregnancy.

The optimal treatment of PNH is replacement of the abnormal stem cells with cells capable of producing the normal cellular components. This has been accomplished by bone marrow transplantation. The major therapeutic modalities during pregnancy are iron therapy, transfusions, corticosteroids, and androgen treatment (if the fetus is male).^{105,110,111} Iron can be administered orally to replace the considerable amount lost in the urine. However, in patients with significant iron deficiency, such treatment may lead to a burst of erythropoiesis, with delivery of a cohort of cells susceptible to the lytic action of complement. If a hemolytic episode follows iron therapy, it should be treated with either suppression of erythropoiesis by transfusion or suppression of hemolysis with corticosteroids. When acute hemolytic episodes occur, treatment is aimed at diminishing hemolysis and preventing complications.

Hemoglobinopathies

The hemoglobinopathies can be broadly divided into two general types. In the thalassemia syndromes, normal Hb is synthesized at an abnormally slow rate. In contrast, the structural hemoglobinopathies occur because of a specific change in the amino acid content of Hb. These structural changes may have either no effect or profound effects on the function of Hb, including instability of the molecule, reduced solubility, methemoglobinemia, and increased or decreased oxygen affinity.

THALASSEMIA SYNDROMES

The thalassemia syndromes are named and classified by the type of chain that is inadequately produced. The two most common types are alpha-thalassemia and beta-thalassemia, both of which affect the synthesis of Hb A. Reduced synthesis of gamma or delta chains and combinations in which two or more globin chains are affected are relatively rare. In each instance, the thalassemia is a quantitative disorder of globin synthesis.

Alpha-Thalassemia

In patients with alpha-thalassemia, one or more structural genes are physically absent from the genome. The various alpha-thalassemia genotypes are summarized in Figure 55-2. In blacks, the most common two-gene deletion state consists of one gene missing on each chromosome (trans). In Asians, most often both genes are missing from the same chromosome (cis). In the homozygous stage, all four genes are deleted and no chains are produced. In such cases, the fetus is unable

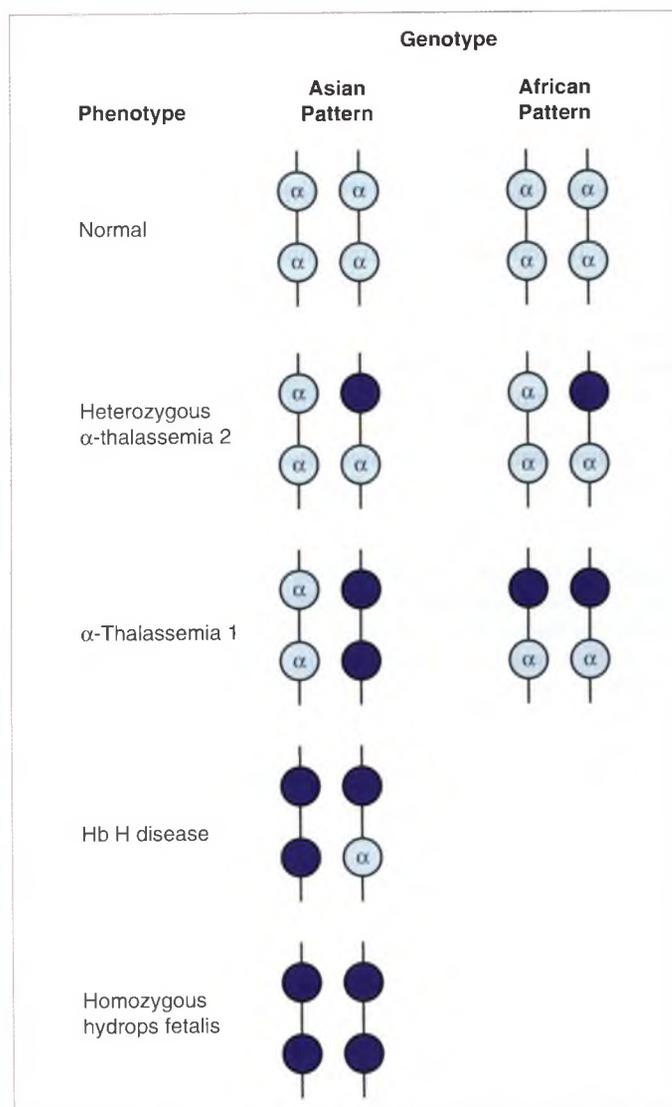

Figure 55-2 Genotypes of the various alpha-thalassemia syndromes. Hb H, hemoglobin H.

to synthesize normal Hb F or any adult hemoglobins. This deficiency results in high-output cardiac failure, hydrops fetalis, and stillbirth.¹¹²

The most severe form of alpha-thalassemia compatible with extrauterine life is Hb H disease, which results from deletion of three alpha genes. In these patients, abnormally high quantities of both Hb H (beta₄) and Hb Barts (gamma₄) accumulate. Because Hb H precipitates in the RBC, the cell is removed by the reticuloendothelial system, leading to a moderately severe hemolytic anemia. In alpha-thalassemia minor (also called alpha-thalassemia-1), two genes are deleted, resulting in a mild hypochromic, microcytic anemia that must be differentiated from iron deficiency. A single gene deletion (alpha-thalassemia-2) is clinically undetectable and is called the silent carrier state.

The diagnosis of alpha-thalassemia is presumptive by exclusion of iron deficiency and beta-thalassemia. Although alpha-thalassemia-1 minor does not present a hazard to the adult, there are serious genetic implications when a mating of two individuals with the trait occurs. Under these circumstances, a specific diagnosis can be made by using DNA analysis such as gap-polymerase chain reaction (gap-PCR) for common or known alpha-thalassemia deletions, or by using restriction endonuclease techniques or a DNA probe before undertaking antenatal diagnosis.^{113,114}

Beta-Thalassemia

Beta-thalassemia is autosomal recessive and is more common in people of Mediterranean, Middle Eastern, or Asian descent. The underproduction of beta-globin chains is caused by point mutations with single nucleotide substitution or oligonucleotide addition or deletion.¹¹⁵ The beta-globin gene is on chromosome 11. In homozygous beta-thalassemia, alpha-chain production is unimpeded, and these highly unstable chains accumulate and eventually precipitate; markedly ineffective erythropoiesis and severe hemolysis result in a condition known as beta-thalassemia major or Cooley anemia. In this homozygous form, the severity varies depending on whether beta-globin synthesis is reduced (beta⁺) or absent (beta⁰) (Table 55-3). The fetus is protected from severe disease by alpha-chain production. However, this protection disappears rapidly after birth, with the affected infant becoming anemic by 3 to 6 months of age. The infant has splenomegaly and requires blood transfusions every 3 to 4 weeks. Death typically occurs by the third decade of life and is usually the result of myocardial hemochromatosis. Female infants surviving until puberty are usually amenorrheic and have severely impaired fertility.^{116,117}

Beta-thalassemia minor (also called beta-thalassemia trait) results in a variable degree of illness, depending on the rate of beta-chain production. The characteristic findings include a relatively high RBC membrane rigidity, moderate to marked microcytosis, and a peripheral smear resembling that observed in iron deficiency. Hb electrophoresis characteristically shows an elevation of Hb A₂. Beta-thalassemia trait does not impair fertility, and the incidences of prematurity, low-birth-weight infants, and infants of abnormal SGA are identical to those in normal women.¹¹⁸ Nineteen women with beta-thalassemia major or intermedia (i.e., the compound heterozygous state) were followed through 22 pregnancies; 21 viable infants were delivered.¹¹⁹ These patients all had intensive treatment, including transfusions and iron-chelating agents, if necessary, before pregnancy or if their Hb concentration was greater than 7 g/dL.

TABLE 55-3 Hematologic and Clinical Aspects of the Thalassemia Syndromes

Condition	Hemoglobin (Hb) Pattern*				Clinical Severity
	Hb Level	Hb A ₂	Hb F	Other Hb	
HOMOZYGOTES					
Alpha-thalassemia	↓↓↓↓	0	0	80% Hb Barts, remainder Hb H and H Portland, some Hb A	Hydrops fetalis
Beta ⁺ -thalassemia	↓↓↓	Variable	↑↑	Some Hb A	Moderately severe Cooley anemia
Beta ⁰ -thalassemia	↓↓↓↓	Variable	↑↑↑	No Hb A	Severe Cooley anemia
Epsilon beta ⁰ -thalassemia	↓↓	0	100%	No Hb A	Thalassemia intermedia
HETEROZYGOTES					
Alpha-thalassemia silent carrier	N	N	N	1%-2% Hb Barts in cord blood at birth	N
Alpha-thalassemia trait	↓	N	N	5% Hb Barts in cord blood at birth	Very mild
Hb H disease	↓↓	N	N	4%-30% Hb H in adults; 25% Hb Barts in cord blood	Thalassemia intermedia
Beta ⁺ -thalassemia	↓ to ↓↓	↑	↑	None	Mild
Beta ⁰ -thalassemia	↓ to ↓↓	↓	↑↑↑	None	Mild

*Number of arrows indicates relative intensity of increase or decrease. ↑, increased; ↓, decreased; beta⁺, reduced beta-globin synthesis; beta⁰, absent beta-globin synthesis; epsilon beta⁰, both epsilon- and beta-globin synthesis reduced or absent; N, normal.

In addition, all women had a pre-pregnancy cardiac echocardiogram showing a left ventricular ejection fraction greater than 55%. These results suggest that women with well-managed, stable beta-thalassemia can do very well during pregnancy.¹¹⁹ The clinical characteristics and hematologic findings of the various thalassemias are summarized in Table 55-3.

Because of increased Asian immigration, the number of beta-thalassemia cases in the United States has risen, so maternal screening of appropriate women is important.¹²⁰ In California, cases of beta-thalassemia major, Hb E beta-thalassemia, and other combined structural Hb abnormalities are more common than phenylketonuria or galactosemia.¹²⁰ A suggestion for easy antenatal maternal screening for alpha- and beta-thalassemia is shown in Figure 55-3.^{118,121} A new and simple qualitative osmotic fragility test had very high sensitivity (100%) and specificity (73%) for diagnosing alpha- and beta-thalassemia trait in a high-prevalence population of pregnant women, prompting the authors to recommend using it for screening.¹²² Prenatal diagnosis, including preimplantation genetic diagnosis, is now available for beta-thalassemia by PCR techniques for mutation detection performed on fetal blood or fetal DNA obtained from amniocentesis or chorionic villus sampling.^{115,123-126}

STRUCTURAL HEMOGLOBINOPATHIES

Several hundred variants of alpha, beta, gamma, and delta chains have been identified. Most differ from normal chains by only one amino acid. The nomenclature and frequency of the most common hemoglobinopathies among African Americans are depicted in Table 55-4.¹²⁷ Confirmation of a diagnosis of a specific hemoglobinopathy requires identification of the abnormal Hb by means of Hb electrophoresis.

Sickle Cell Trait

Traditionally, women with sickle cell trait have been thought to do well during pregnancy and labor. However, new studies have reported conflicting results about increased morbidities in women with sickle trait.¹²⁸⁻¹³⁰ A case-control study from

Mississippi, in which women with or without the trait were matched for race, reported a significant decrease in gestational age at birth (33 versus 35 weeks), lower mean birth weight, and an increased rate of fetal death (9.7% versus 3.5%) in the women with sickle cell trait.¹²⁹ Furthermore, 42% of the fetal deaths in the sickle cell trait group were early deaths (16 to 20 weeks). In contrast, in a large cohort study of all African-American deliveries at one institution that compared those with and without maternal sickle cell trait, the trait was found to have a significant protective effect for preterm delivery at less than 32 weeks (0.9% versus 4.5%).¹²⁸ This protective effect was even more apparent in women with multiple gestations, with 0% versus 22% delivering before 32 weeks.

Because there is an increased rate of urinary tract infection among women with sickle cell trait, pregnant patients should be repeatedly screened for asymptomatic bacteriuria.¹³¹⁻¹³³ In a large case-control study of women with or without sickle cell trait who were matched for race, age, gestational age, and entry into prenatal care, there was no significant difference in the incidence of positive urine cultures (22% versus 19%).¹³⁰ However, pyelonephritis was significantly more common in the women with sickle cell trait (2.4% versus 0.7%). Another study suggested that the risk of preeclampsia was increased to 25% in those with the trait, compared with 10% in a sickle-negative control group.¹³⁴ These patients may become iron deficient, and iron supplementation during pregnancy is indicated.

Sickle Cell Anemia

Patients with sickle cell anemia (SCA) suffer from lifelong complications, in part as a result of the markedly shortened life span of their RBCs. Virtually all signs and symptoms of SCA result from hemolysis, vaso-occlusive disease, or an increased susceptibility to infection (Box 55-2). Clinical manifestations may affect growth and development, with growth restriction and skeletal changes secondary to expansion of the marrow cavity. Painful crises may occur in the long bones, abdomen, chest, or back. The cardiovascular manifestations are those of a

hyperdynamic circulation, and pulmonary signs may be secondary to either infection or vaso-occlusion. In addition to painful vaso-occlusive episodes, patients may exhibit hepatomegaly, signs and symptoms of hepatitis, cholecystitis, and painful splenic infarcts. Genitourinary signs include hyposthenuria (an impairment in the ability to concentrate the urine), hematuria, and pyelonephritis.

Most, but not all, research suggests that women with SCA have higher rates of obstetric-related morbidities such as pre-eclampsia, antepartum admissions, preterm delivery, and premature rupture of membranes than women without SCA.¹³⁵⁻¹³⁹ However, it is less clear whether pregnancy itself increases sickle cell–related morbidities. Rates of maternal morbidity from SCA were the same during pregnancy as in the nonpregnant state.¹⁴⁰ Series examining maternal deaths have been too small to determine whether there is an increased risk with SCA; however, pulmonary embolus or acute chest syndrome or both was the cause in five of seven deaths.¹⁴¹

It is not known whether the frequency of painful crises in women with SCA changes with pregnancy. In one large study, the average number of crises per patient per pregnancy was one to two, and other studies have suggested that 20% to 50% of affected pregnant women had crises.^{135,137,140,142,143} Treatment of crises is largely symptomatic, with the major objectives being to end a painful crisis and to combat infection. Hydration, oxygen therapy, and pain management are the cornerstones of managing a pain crisis. Acute chest syndrome is one of the most severe complications of SCA and can be very difficult to treat.

BOX 55-2 CLINICAL MANIFESTATIONS OF SICKLE CELL ANEMIA

- I. Growth and development
 - A. Retarded growth
 - B. Skeletal changes

 - A. Conjunctival vessel changes
 - B. Vitreous hemorrhage

It has been reported to occur in up to 20% of pregnancies.^{136,140,144} Urinary tract and pulmonary infections should be diagnosed promptly and treated vigorously with appropriate antibiotics. Transfusion therapy, particularly partial exchange transfusions, continues to be the cornerstone of treatment of symptomatic patients including women with acute chest syndrome, and those with crises and hemoglobin levels of less than 6 g/dL.^{138,145,146} The goal of partial exchange transfusions is to keep the Hb A level higher than 50% and the Hct greater than 25%.¹⁴⁷ A prospective randomized study of 72 patients with SCA showed no significant difference in perinatal outcome between women who were treated with prophylactic transfusions and those who received transfusions only if their Hb level fell to less than 6 g/dL, or the Hct to less than 18%.¹⁴³ However, this study did report a significant decrease in crises during pregnancy, from 50% to 14%, in the group receiving prophylactic transfusions. Similarly, despite routine prophylactic transfusions, women with SCA continued to experience significantly higher rates of preterm delivery, preeclampsia, and SGA fetuses, compared with matched controls without SCA.¹³⁷

Several studies documented no relationship between maternal anemia and risk for IUGR or perinatal death in women with SCA.^{136,148} Although fetal outcomes are generally good in pregnancies complicated by SCA, there continues to be an increased risk of prematurity and IUGR, with rates of each as high as

45%.^{135,137,140,149} Serial ultrasound studies should be done throughout pregnancy to confirm normal fetal growth. There are no prospective studies on the use of antepartum fetal testing in women with SCA, so this should be instituted at the discretion of the physician. In addition, preimplantation genetic diagnosis with PCR assays is available for patients with SCA.¹²³

In general, prenatal vitamins without iron should be given to women who are receiving multiple transfusions, but all women with SCA should have an additional folic acid supplement of 1.0 mg/day prescribed. The pneumococcal vaccine should be given if the patient has not had the vaccine within the past year. If the patient is on hydroxyurea, a drug used to manage SCA in nonpregnant women, it should be stopped because of possible teratogenic risk. However, despite a teratogenic effect in experimental animals, there were no reports of teratogenic effect in the more than 45 human pregnancies described in women who became pregnant while on hydroxyurea.^{138,150} During labor and delivery, the patient must remain well oxygenated and hydrated. If an exchange transfusion protocol has been used and the Hb A level is greater than 40%, painful crises are distinctly unusual.¹⁵¹ Finally, a retrospective study of 40 women with SCA reported that the initial prenatal white blood cell count was significantly higher in those who subsequently developed SCA-related complications ($11.2 \times 10^9/L$) during their pregnancy than in those who did not develop complications ($8 \times 10^9/L$).¹⁵²

Hemoglobin Sickle C Disease

Women who are doubly heterozygous for both the Hb S and the Hb C genes are said to have hemoglobin SC disease. Hb electrophoresis reveals approximately 60% Hb C and 40% Hb S. Patients with Hb SC disease typically have a normal habitus, a healthy childhood, and a normal life span. If a systematic screening program has not been used, the condition may first be detected in many women during the latter part of pregnancy, when a complication occurs. At the beginning of pregnancy, most women are mildly anemic and splenomegaly is present. Examination of a peripheral blood smear shows numerous target cells. Hb electrophoresis ensures the correct diagnosis.^{153,154}

During pregnancy, 40% to 60% of patients with Hb SC disease present as if they had SCA. In contrast to patients with SCA, those with Hb SC disease frequently experience rapid and severe anemic crises resulting from splenic sequestration. These patients also have a greater tendency to experience bone marrow necrosis with the release of fat-forming marrow emboli. The clinical manifestations of Hb SC disease are otherwise similar to those of SCA but milder, and the general management of symptomatic patients is identical. Considerations for the management of labor are the same as for patients with SCA. Women with Hb SC disease had a significantly increased risk of antepartum admission, preterm delivery, IUGR, and postpartum infection compared with women without sickle disease, but these risks were significantly less than those of the women with SCA.^{135,137} Similarly, Serjeant and associates reported that the rates of miscarriage, live-born delivery, and newborn weight less than 2500 g in women with Hb SC disease were similar to those for women with normal Hb and significantly better than those for women with SCA.¹⁵⁵ Rates of pain crises, acute chest syndrome, and urinary tract infections were similar for women with Hb SC disease and those with SCA.^{137,155} In one report 42% of the women with SCA had at least one

crisis during pregnancy compared with 36% of those women with SC disease.¹³⁷

Hemoglobin S–Beta-Thalassemia

Patients with Hb S–beta-thalassemia are heterozygous for the sickle cell and the beta-thalassemia genes, and in general about 10% of sickle cell disease is caused by Hb S–beta-thalassemia.¹²⁴ In addition to decreased beta-chain production, there is a variably increased production of Hb F and Hb A₂. Because of this variable production rate, Hb electrophoresis reveals a spectrum of Hb concentrations. Hb S may account for 70% to 95% of the Hb present, with Hb F rarely exceeding 20%.¹⁵⁶ Because of the thalassemia influence, the Hb S concentration exceeds the Hb A concentration. This is in sharp contrast to patients with sickle cell trait, in whom Hb A levels exceed the concentration of Hb S.

The diagnosis is made in an anemic patient by demonstrating increased Hb A₂ and Hb F levels in association with a level of Hb S exceeding that of Hb A. The peripheral smear reveals hypochromia and microcytosis with anisocytosis, poikilocytosis, basophilic stippling, and target cells. The clinical manifestations of this disorder parallel those of SCA but are generally milder. Painful crises may occur; however, these patients have a normal body habitus and frequently enjoy an uncompromised life span. The role of exchange transfusion should be similar to that in patients with SCA; that is, exchange transfusion should be reserved for the woman who experiences painful crises or whose anemia leads to an Hct lower than 25%.

Hemoglobin C Trait and Disease

Hemoglobin C trait is an asymptomatic trait without reproductive consequences. Target cells are found in the peripheral smear, but anemia is not present. Hb C disease, the homozygous state, is a mild disorder that usually is discovered during a medical evaluation. Mild hemolytic anemia with an Hct in the range of 25% to 35% is characteristic. The RBCs show microspherocytes and characteristic targeting. No increased morbidity or mortality is associated with pregnancy, and no specific therapy is indicated.

Hemoglobin E Disease

The recent immigration of Southeast Asians to the United States has resulted in an increase in the number of individuals with Hb E trait and disease. The clinical and laboratory manifestations of the various Hb E syndromes are outlined in Table 55-5.^{157,158} Most individuals have a mild microcytic anemia that is of no clinical significance, and no treatment is necessary. However, patients who are homozygous for Hb E have a greater

degree of microcytosis and are frequently anemic. Target cells are prominent. As with Hb C trait and disease, no specific therapy is required, and reproductive outcome is normal.

Anemias Associated with Systemic Disease

The normal bone marrow has the capacity to increase its RBC production sixfold to eightfold in response to anemia. This compensatory mechanism, which is responsible also for the increase in RBC mass in normal pregnancy, is triggered by tissue hypoxia and mediated by erythropoietin. The response may be absent or blunted in some circumstances, most commonly in patients with chronic disorders. Chronic infections, rheumatoid arthritis, and other inflammatory states are characterized by a mild normocytic, normochromic anemia (or sometimes a hypochromic, microcytic anemia) with low serum iron concentration, low transferrin level, inappropriately low reticulocyte count, and generous but poorly utilized stores of reticuloendothelial iron. Although the bone marrow is normally cellular, it does not respond appropriately to the mildly accelerated RBC destruction typical of chronic inflammation. Studies thus far have not determined whether the defect in erythropoiesis can be attributed to inadequate erythropoietin secretion. In the absence of pregnancy, the Hb concentration in these chronic states is frequently 9 to 10 g/dL, and the Hct concentration is approximately 30%. The hydremia of pregnancy may lower these values somewhat.

A similar but frequently more complicated anemia accompanies renal failure. Here, more often perhaps than in chronic inflammatory states, blood loss and hemolysis are contributory factors, and the serum iron and transferrin changes noted earlier are less regular. In many of these situations, diminished erythropoietin is important in the pathogenesis.

Renal failure and chronic inflammation are rare in pregnancy, so management of the associated anemias is seldom a clinical problem in obstetric patients. Occasionally, however, it is the anemia that calls attention to the underlying disease. These anemias do not respond to hematinic agents or steroid hormones (unless the adrenal steroids play some role in controlling the underlying disease, as in rheumatoid arthritis or lupus). Erythropoietin is useful in treating chronic renal disease and can often obviate the need for repeated RBC transfusion.¹⁵⁹

Malignancy and Pregnancy

DAVID COHN, MD | BHUVANESWARI RAMASWAMY, MD | KRISTIE BLUM, MD

Epidemiologic Overview of Cancer in Pregnancy

Cancer occurring during pregnancy is not rare. Approximately 1 in 1000 pregnant women are diagnosed with a new malignancy each year in the United States.¹ Cancer is one of the leading causes of nonaccidental death in the United States in women between the ages of 15 and 34 years, and it is the leading cause of death in women aged 35 to 54 years.² The most common malignancies in women 15 to 34 years old are malignant melanoma, breast cancer, leukemia, cervical cancer, central nervous system tumors, and non-Hodgkin lymphoma (NHL). Lung, colorectal, and ovarian cancer also are common in 35- to 54-year-old women.¹ Melanoma is estimated to occur in 1 of 1000, cervical cancer in 1 of 2000, Hodgkin lymphoma (HL) in 1 of 3000, breast cancer in 1 of 3000, ovarian cancer in 1 of 18,000, and leukemia in 1 of 75,000 pregnancies. However, these estimates are quite variable and are usually reported as incidence ranges (Table 56-1). The current social trend of delaying pregnancy into the later reproductive years will result in more cancers diagnosed during gestation.

The management of cancer in pregnancy is challenging and poses ethical and medical dilemmas. Limited prospective data are available, hindering the decision-making process. The goal of cancer therapy in pregnant women is to provide the best cancer care for the patient while minimizing the potential harm to the fetus.

Cancers in pregnancy are often categorized by the time of diagnosis: during the antenatal period, at the time of delivery, or up to 1 year after delivery. More than 50% of cancers complicating pregnancy are found within 1 year after delivery, and more than 25% are found in the antenatal period. Few are found at delivery.³

When a malignant neoplasm is diagnosed in pregnancy, the health of the mother and fetus must be considered. When cancer is diagnosed early in a desired pregnancy, the clinical situation is complex. If delaying treatment will not affect the maternal prognosis, treatment may be deferred until the fetus has achieved maturity. If the prognosis is expected to worsen with delayed treatment, the risks and benefits of more immediate treatment must be weighed against the risks to the pregnancy and the fetus. Given the complex management involved in the care of a pregnant patient with cancer, a multidisciplinary team is essential to ensure that the mother, family, and all members of the health care team are well informed about the risks, benefits, and alternatives of the treatment choices and modalities. In addition to the medical aspects of the care, management must be individualized to balance the ethical,

moral, spiritual, and cultural issues that complicate such a diagnosis.

Factors such as the hormonal milieu, increased vascularity, altered lymphatic drainage, and immune adaptations in pregnancy have historically been thought to increase the risk of malignancy and to increase the likelihood of a more aggressive course with poorer outcomes than would be expected in a nonpregnant woman. However, there is no evidence to suggest that pregnancy directly or indirectly affects the incidence or outcome of cancer. This chapter addresses the issues related to diagnosis and care for a pregnant patient with cancer.

Ovarian and Cervical Malignancies

OVARIAN CANCER

Epidemiology, Diagnosis, and Tumor Types

One of 18,000 pregnancies is complicated by an ovarian malignancy.^{4,6} Approximately 1 of 1000 pregnant women undergo exploratory surgery to evaluate an adnexal mass, and 1% to 3% of these masses are malignant.^{7,8} This incidence is lower than among nonpregnant women, probably because pregnancy occurs in younger women, in whom most ovarian masses are corpus luteum cysts or other benign simple cysts and most ovarian neoplasms are teratomas or cystadenomas.^{9,11} Most ovarian malignancies found in pregnancy are germ cell tumors, but the incidence of epithelial ovarian malignancies identified during pregnancy may increase as women defer childbearing later into their reproductive years.

Rarely, a woman presents with an advanced ovarian malignancy requiring extensive cytoreduction. If the malignancy is diagnosed when the fetal prognosis allows delivery or the patient does not wish to continue the pregnancy, immediate surgical exploration for cytoreduction and subsequent adjuvant treatment should be undertaken. If the pregnancy is desired and the fetus cannot be delivered, management is complex. In selected patients, antepartum bilateral oophorectomy and cytoreduction can be performed, with the pregnancy continuing and adjuvant treatment delayed until delivery. Management must be individualized for each patient based on her desire for future fertility, gestational age, and extent of disease. In selected patients, antepartum neoadjuvant (before surgery) chemotherapy administered until fetal maturity, followed by cytoreductive surgery at abdominal delivery, may be considered.

Germ cell cancer is the most common ovarian malignancy diagnosed in pregnancy; up to 30% of malignancies in pregnancy are dysgerminomas. They most often manifest with

TABLE 56-1 Incidence Ranges of Cancer Types in Pregnant Women

Cancer	Incidence (per no. gestations)
Malignant melanoma	1:1,000-1:10,000
Breast cancer	1:3,000-1:10,000
Cervical cancer	1:2,000-1:10,000
Lymphoma	1:1,000-1:6,000
Thyroid cancer	1:7,000
Colorectal cancer	1:13,000

BOX 56-1 COMPONENTS OF COMPREHENSIVE SURGICAL STAGING OF GYNECOLOGIC CANCERS

Sampling of pelvic cytology or ascites
 Ipsilateral salpingo-oophorectomy
 Hysterectomy and contralateral salpingo-oophorectomy (eliminated in selected patients)
 Peritoneal biopsies (e.g., anterior and posterior cul-de-sac, pelvic side walls, abdominal gutters, diaphragms)
 Biopsies of adhesions or other abnormalities
 Omentectomy
 Bilateral pelvic lymphadenectomy
 Bilateral aortic lymphadenectomy

torsion. The serum level of maternal lactate dehydrogenase (LDH), the tumor marker for dysgerminomas, is not altered by pregnancy, and it can serve as a marker for the disease during pregnancy.¹²

Standard management of a suspected ovarian dysgerminoma during pregnancy is surgery. Unilateral oophorectomy for diagnosis with comprehensive surgical staging (Box 56-1) with preservation of the contralateral ovary and uterus is recommended. Because 15% of dysgerminomas are bilateral, inspection of the contralateral ovary with biopsy or removal of abnormalities should be performed for therapeutic and prognostic reasons. Wedge resection or biopsy of a normal-appearing contralateral ovary is unnecessary because of the risk of increased adhesion formation and possible infertility. Patients with advanced dysgerminoma require chemotherapy with bleomycin, etoposide, and cisplatin (BEP regimen).

The prognosis for women with early-stage dysgerminoma is excellent. In women with advanced disease, approximately 10% of tumors will recur, but most are cured with chemotherapy or radiation therapy. The cure rate for women with early-stage disease is excellent.

Endodermal sinus tumors (i.e., yolk sac tumors) of the ovary are rare, aggressive tumors that confer a poor prognosis. These tumors are marked by increased serum levels of maternal α -fetoprotein (AFP), which may be elevated in normal and abnormal pregnancies. Nevertheless, an extremely elevated AFP level in an apparently normal pregnancy may be associated with an endodermal sinus tumor. Because of their aggressive nature, surgery is indicated for the diagnosis of an endodermal sinus tumor, and adjuvant chemotherapy is administered to all women with this diagnosis.

Sex cord-stromal tumors (mainly granulosa cell tumors and Sertoli-Leydig cell tumors) are rare ovarian cancers in

reproductive-age women and therefore rare in pregnancy. Independent of pregnancy, these tumors manifest with evidence of hormone excess (i.e., virilization or hyperestrogenism). During pregnancy, they more commonly manifest with hemorrhagic rupture leading to hemoperitoneum. Management includes unilateral oophorectomy and surgical staging. Adjuvant therapy is reserved for patients with advanced or recurrent disease.

For patients with ovarian cancer diagnosed during pregnancy, oncologic outcomes appear to be similar to those for patients who are not pregnant. However, the therapeutic plan must be modified by pregnancy in some circumstances.

Management of Adnexal Masses Occurring during Pregnancy

In the United States, 10% of women undergo surgery for an ovarian mass during their lifetime, and up to 20% of these masses are identified as malignant.¹³ The common use of obstetric ultrasonography has led to increased discovery of adnexal masses complicating gestation. Masses that once would have been found at the time of abdominal delivery, during the postpartum period, or later are now incidentally detected during a first- or second-trimester ultrasound examination. Approximately 0.2% to 2% of pregnancies are complicated by an adnexal mass, and 1% to 3% of these are malignant.^{4,9,14-18} These estimates are uncertain because many masses that are incidentally discovered regress, are not reported, or do not require or receive any intervention. Although many ovarian masses diagnosed during pregnancy are benign cysts that undergo spontaneous regression by the second trimester, some of these masses persist through the second trimester and beyond, potentially causing pregnancy-related complications and requiring surgical evaluation and intervention.

Approximately 75% of adnexal masses complicating pregnancy are simple cysts measuring less than 5 cm in diameter, and the remaining one fourth are simple or complex masses that exceed 5 cm in diameter. During pregnancy, 70% of ovarian masses spontaneously resolve by the early second trimester, becoming undetectable by 14 to 15 weeks' gestational age.^{9,16} Functional cysts are the most common, and dermoid cysts (i.e., benign cystic teratomas) are the most common neoplasm encountered in pregnancy. Other common benign masses include paraovarian cysts, endometriomas, leiomyomas, and benign neoplasms such as cystadenomas.⁸⁻¹¹

Adnexal masses larger than 8 cm in diameter are more often complicated by pain, torsion, rupture, or internal hemorrhage, compared with smaller lesions. Preterm labor, preterm premature rupture of membranes, obstruction of labor, and fetal death have rarely been observed.¹⁹⁻²¹ Ovarian torsion occurs most commonly in the late first or early second trimester, when the uterus is growing out of the true pelvis, and in the puerperium, when the uterus undergoes rapid involution. If clinical signs or symptoms consistent with torsion, rupture, or hemorrhage occur, emergent surgery is indicated independent of gestational age. In the case of an ovarian tumor larger than 8 cm in diameter in a woman who does not undergo surgery, the clinician and patient must be aware of the increased risk of complications and their symptoms.

In the non-emergent setting, the radiographic and ultrasonographic characteristics of the mass commonly have been used to guide management. Masses that appear to be simple and cystic in nature and are less than 6 cm in diameter have a low risk of malignancy (<1%); they can be observed without

surgery.^{9-11,19} Surgical exploration should be performed for masses that persist into the second trimester, are rapidly enlarging, exceed 8 cm in diameter, or appear malignant.¹³ Because levels of cancer antigen 125 (CA 125) usually are elevated during the beginning of pregnancy and persist throughout pregnancy, serum testing is unreliable for evaluating the risk of an epithelial malignancy. If the source of the mass is not clear, magnetic resonance imaging (MRI) can be employed to differentiate ovarian from extraovarian masses.

Surgical exploration for an ovarian mass is optimally undertaken at 16 to 20 weeks' gestation, when physiologic cysts have regressed and when, if an oophorectomy is required, the placenta has become hormonally functional and independent of the corpus luteum. If the mass is discovered in the late third trimester, evaluation, management, and surgical exploration may be deferred until or after delivery in some circumstances. If delivery is abdominal, diagnosis and potential staging can be undertaken at the time of cesarean section; if delivery is vaginal, surgery may be postponed, depending on the nature and appearance of the mass.

CERVICAL CANCER

According to the National Cancer Institute, an estimated 11,070 new cases of cervical cancer were diagnosed in the United States in 2008, with an estimated 3870 deaths from the disease.²² Invasive cervical cancer in pregnancy is uncommon, comprising only approximately 1% of total cervical cancers diagnosed, but pre-invasive cervical neoplasia is common in reproductive-age women, occurring in 5 to 50 of every 1000 pregnancies.²³⁻²⁵ The incidence of cervical cancer has declined because of implementation of the Papanicolaou (Pap) smear to screen for cervical dysplasia and cancer. The practicing obstetrician-gynecologist is more likely to encounter an abnormal Pap smear than invasive cervical cancer during pregnancy. Although Pap smears and routine screening are readily available in most developed countries, most women diagnosed with cervical cancer have not had appropriate screening. Pregnancy and prenatal care affords an opportunity to screen and treat many patients who would otherwise not access the health care system.

Cervical Intraepithelial Neoplasia

As many as 5% of pregnancies may be complicated by an abnormal Pap smear result.²⁵ Cervical cytology and physical examination are the principal forms of cervical cancer screening during pregnancy. Endocervical curettage should be avoided to prevent direct or indirect injury to the pregnancy, but an endocervical brush should be employed to increase the adequacy of the smear. This can increase the incidence of spotting after collection, but it appears to have no effect on the risk for serious adverse outcomes related to the pregnancy.²⁶ During pregnancy, the goal of evaluation of an abnormal Pap smear result and cervical dysplasia is determination of the extent of neoplasia; the aim is to rule out invasive cancer and allow therapy for pre-invasive disease to be deferred until after delivery.

The Bethesda system is the standard classification system for cervical neoplasia. It is used to guide management for patients with abnormal cervical cytology. Atypical squamous cells of uncertain significance (ASC-US) should be managed as in non-pregnant patients. Options include repeat cytologic examination at a close-interval follow-up visit, immediate colposcopy, or triage with high-risk human papillomavirus (HPV) testing.

Patients with an ASC-US Pap results without evidence of HPV infection can be evaluated after delivery. Cases in which a high-grade lesion cannot be excluded (ASC-H) usually are managed with colposcopy, although some clinicians use HPV status to triage these smears. Women who are found to have low- or high-grade squamous intraepithelial lesions (LSILs or HSILs) should undergo colposcopy to evaluate the extent and severity of neoplasia.²⁷

Pap smears revealing atypical glandular cells (AGCs), although rare in pregnancy, also warrant colposcopic examination. Pregnancy complicates the cytologic interpretation of AGC, because sloughed decidual cells, endocervical gland hyperplasia, and cells demonstrating an Arias-Stella reaction, all of which are benign, can occur in normal pregnancy. Compared with nonpregnant patients, for whom AGC is associated with malignancy in as many as 25% of cases, AGC found in pregnancy is less likely to indicate malignancy. However, the inability to perform an endocervical curettage and endometrial sampling limits the evaluation of AGC during pregnancy.

Colposcopic evaluation in pregnancy is facilitated by the eversion of the transformation zone. The procedure should be performed whenever indicated by the cytology results, regardless of pregnancy. The purpose of colposcopy in pregnancy is to exclude the presence of malignancy. Biopsies should be performed for any suspicious lesions seen at the time of colposcopic evaluation. Biopsies should be done only for the most suspicious areas, and taking many samples at one examination should be avoided.²⁸ Colposcopic diagnostic accuracy, with or without biopsy, is 95% to 99%, and complications are rare.²⁹ The most common complication associated with colposcopically directed biopsy is hemorrhage resulting from the increased vascularity of the cervix during pregnancy. Bleeding can be stopped by direct pressure to the site, with application of Monsel (ferric subsulfate) solution, silver nitrate, vaginal packing, and, rarely, suture ligation of vessels. Colposcopy and biopsy do not jeopardize the pregnancy as long as endocervical curettage is avoided.

Observation without therapy is appropriate for pregnant women with cervical dysplasia if invasive cervical cancer has been excluded by colposcopy (with or without biopsies).²⁹⁻³⁴ This approach is supported by the American Society of Colposcopy and Cervical Pathology (ASCCP).³⁵ Inadequate colposcopic evaluation is an indication for further evaluation with a cone biopsy in the nonpregnant patient, but pregnant women with an unsatisfactory initial colposcopic result may undergo repeat colposcopy in 6 to 12 weeks. Because the transformation zone undergoes further eversion as pregnancy progresses, a later examination may be satisfactory.³⁶ Treatment for cervical dysplasia such as laser therapy, cryotherapy, loop electrosurgical excision procedure (LEEP), and cone biopsy may therefore be deferred until the postpartum period. In women with biopsy-proven dysplasia identified during pregnancy who have no evidence of invasion by colposcopy, management may consist of serial colposcopy examinations with intermittent cervical cytology and expectant management of the pregnancy. Because regression of cervical dysplasia after pregnancy has been reported, withholding definitive treatment of this disease (in the absence of invasive cervical cancer) is appropriate. At 6 months after delivery, almost 70% of cervical intraepithelial neoplasia (CIN) type 2 and type 3 lesions have resolved,³³ which is higher than the rate for the nonpregnant population.^{33,37} For this reason, delay of definitive therapy until after delivery is

appropriate in a patient without evidence of invasive cervical cancer; however, the maximum interval from delivery until postpartum evaluation and management of cervical dysplasia has not been determined. Cervical cytology, colposcopy, directed biopsies, and endocervical curettage usually are performed at about the time of the 6-week postpartum evaluation.

In pregnant patients, LEEP and cone biopsies should be reserved for the exclusion of invasive disease. Risks of these procedures in pregnancy include cramping, bleeding, infection, preterm premature rupture of membranes, spontaneous abortion, preterm labor, and pregnancy loss. Complication rates are similar for LEEP and cone biopsy.³⁸ If a LEEP or cone biopsy is indicated to rule out malignancy, the safest time to perform the procedure seems to be in the middle of the second trimester, between 14 and 20 weeks, or after fetal maturity is documented. In an effort to minimize preterm delivery after cone biopsy, some physicians have advocated concurrent MacDonalld cerclage at the time of cone biopsy. Although there were no complications in the largest study of this strategy, only 17 patients were evaluated.³⁹

For patients with cervical dysplasia diagnosed during pregnancy without any clinical evidence of invasive cervical cancer, the route of delivery is not affected by the dysplasia. Some physicians have documented an increased rate of spontaneous remission of cervical cancer after vaginal delivery compared with cesarean delivery,⁴⁰ but others have not found this to be the case.⁴¹

Cervical Carcinoma

The occurrence of cervical carcinoma in pregnancy is rare, comprising only 1% of all cervical cancers diagnosed annually. However, because cervical cytology and examination are typically performed at the first prenatal visit, cervical cancer is one of the cancers most commonly diagnosed during pregnancy. Manifestation of cervical cancer during pregnancy is similar to that outside pregnancy, and most women present without symptoms. When detected in pregnancy, cervical cancer is usually at stage I due to increased surveillance. The most common symptom of cervical cancer in pregnancy is bleeding, especially after coitus. It is imperative for clinicians caring for pregnant women to recognize that vaginal bleeding is not necessarily related to the pregnancy and can be caused by other illnesses.

Pregnancy was once believed to alter the course of cervical cancer compared with nonpregnant cohorts, but there is no difference in survival or disease characteristics when matched cohorts are studied.^{37,42,43} However, when compared with nonpregnant counterparts, pregnant women with cervical cancer are much more likely to have stage I disease, and most have stage IB disease.^{42,44-47} Because of the physiologic and anatomic changes of pregnancy, induration or nodularity at the inferior cardinal ligament is less prominent, leading to underestimation of the stage and degree of tumor involvement. Nonetheless, pregnancy does not affect the survival rate for cervical cancer. The overall survival rate is 80%, compared with 82% in nonpregnant patients.⁴⁸

According to the International Federation of Gynecology and Obstetrics (FIGO), clinical staging of cervical cancer can include intravenous pyelography, chest radiography, cystoscopy, and sigmoidoscopy. Although not included in the FIGO staging system, intravenous contrast-enhanced computed tomography (CT) or positron emission tomography (PET) has often been

TABLE 56-2 Approximate Fetal Doses from Common Diagnostic Radiographic Procedures

Examination	Mean Dose (cGy)
Conventional x-ray examinations	
Abdomen (KUB)	0.24
Chest	0.001

Chest	<0.01
Head	<0.01

used for staging and treatment planning. The use and timing of these staging studies during pregnancy must be considered carefully because of the ionizing radiation exposure with CT and with fluoroscopy, which is used for barium enema and cystoscopy (Table 56-2). PET uses intravenous radioactively labeled fluorodeoxyglucose (¹⁸F-FDG). The fetal effects of this radioisotope are unknown, and therefore it should not be used during pregnancy. Chest radiography is acceptable during pregnancy with appropriate abdominal and pelvic shielding. In some case reports, MRI, which has been shown to be safe during pregnancy, has been used to define the extent of extracervical tumor spread.^{49,50}

After a stage has been established, management must be individualized. A multidisciplinary team, which may include a perinatologist, neonatologist, radiation oncologist, and gynecologic oncologist, must be recruited to counsel the patient regarding treatment options related to the stage, fetal status, and gestational age and to determine her desire to continue her pregnancy. In certain circumstances, treatment of the cancer is recommended despite the potential lethal effect of the therapy on the pregnancy. In others, treatment can be delayed until after delivery or until a gestational age at which delivery will not produce significant morbidity.

In pregnant women with a cervical biopsy suggesting microinvasive cervical cancer, a cervical cone biopsy must be performed to definitively establish the diagnosis. Women with stage IA1 cervical cancer (<3 mm of invasion, <7 mm of tumor breadth) can be monitored with periodic colposcopy and cytology, and the infant can be delivered when obstetrically indicated. Definitive management is deferred to the intrapartum (with cesarean hysterectomy) or the postpartum period. Surgical treatment for stage IA1 cervical cancer may include cervical conization (with negative margins) or extrafascial hysterectomy, depending on the desire for future fertility. Cone biopsy during pregnancy carries additional risks over that performed outside of pregnancy. The timing of cone biopsy during pregnancy is controversial, with some physicians reporting fetal loss

rates approximating 25% when conization is performed during the first trimester,⁵¹ whereas others have described the relative safety of early conization.⁵² Most agree, however, that the rates of fetal loss are less than 10% in the second trimester and non-existent in the third trimester. Blood loss associated with cone biopsy increases with increasing gestational age. For that reason, care must be taken in determining when a cone biopsy should be performed during pregnancy.

Limited data exist regarding the role of the LEEP during pregnancy.^{38,53} In the initial investigation, this technique was associated with maternal and fetal morbidity, blood transfusion, inadequate specimens, and residual disease in the conization specimen.³⁸ Further investigation of the relative safety and efficacy of LEEP compared with knife conization in pregnancy is required. When "microinvasive" cervical cancer is suggested by a cervical biopsy or invasive disease is suspected at colposcopy but not confirmed on biopsy, cervical conization is necessary, regardless of the duration of pregnancy. The procedure is optimally performed in the operating room, with a knife, after the period of organogenesis has passed and after appropriate counseling about the risks of fetal loss and transfusion. After conization with negative margins in a woman with confirmed pre-invasive disease or microinvasive carcinoma, follow-up colposcopy and possibly cytology can be used to monitor disease progression during pregnancy, with no alteration in the intrapartum management. For women who have completed child-bearing, cesarean hysterectomy or postpartum hysterectomy can be considered.

Although the approach is controversial, patients with cervical adenocarcinoma in situ or stage IA1 cervical adenocarcinoma with negative cone biopsy margins probably can be managed conservatively during their pregnancy, because most studies demonstrate a low risk of parametrial and lymphatic metastasis with early invasive cervical adenocarcinoma.⁵⁴⁻⁵⁶ However, there is a paucity of data regarding this disease during pregnancy.⁵⁷ Women with positive margins for dysplasia after conization during pregnancy must be counseled regarding the risk of current invasive disease, with management based on the risks and benefits of observation, repeat conization, or definitive therapy for possible invasive cervical cancer during pregnancy.

In women with stage IA2 or IB cervical cancer, identical oncologic outcomes have been reported with radiation therapy and with radical hysterectomy and lymphadenectomy in addition to adjuvant radiation therapy (possibly with concurrent radiosensitizing chemotherapy). The advantage of primary surgical management includes the ability to preserve ovarian function and to avoid the potential negative impact on sexual function imparted by radiation therapy. The diagnosis of a stage IA2 or IB cervical cancer during pregnancy does not change the potential therapies recommended. The initiation of treatment is the critical issue in the management of early cervical cancer during pregnancy, specifically related to the potential risk of delay of definitive therapy on cancer outcomes to minimize fetal morbidity and mortality. Case reports and small case series suggest that a moderate delay in definitive therapy is associated with oncologic outcomes similar to those in women treated promptly. Sood and colleagues⁵⁸ described 11 women whose definitive treatment for stage IA and IB cervical cancer was delayed by an average of 16 weeks (range, 3 to 32 weeks). All 11 women remained without evidence of disease and without apparent negative outcomes related to the delay in definitive

therapy during pregnancy. These and other reports of small series with a variety of treatment strategies suggest that a moderate delay of definitive therapy does not incur excessive risk. For this reason, women who are diagnosed with early cervical cancer at or beyond 20 weeks of pregnancy are commonly offered the option of delaying therapy until delivery later in pregnancy or after the birth. Women diagnosed with an early cervical cancer before 20 weeks should be informed of the risk of adverse oncologic outcomes related to delay of definitive therapy for their cervical cancer. However, the degree of risk is uncertain given the small number of patients for whom this management strategy has been reported. Thorough documentation of the risks of a decision to delay definitive treatment is imperative.

Immediate treatment options include radiation therapy and radical hysterectomy with lymphadenectomy for stage IA2 or IB disease. Irradiation usually leads to spontaneous abortion at a dose of 4000 cGy; evacuation of the uterus before therapy or in the absence of miscarriage from radiation therapy can be considered. For women who choose to delay therapy for the sake of fetal development, coordination of care with a perinatologist, neonatologist, and gynecologic oncologist is critical to determine the appropriate gestational age for delivery that balances the maternal oncologic risks with the fetal risks of prematurity. In a recent study, "late preterm" deliveries (before 37 weeks) in pregnant cancer patients were associated with neonatal intensive care stays in more than 50% of subjects.⁵⁹ Depending on the clinical extent of the cancer, delivery followed by pelvic irradiation in 2 to 3 weeks is one option. Alternatively, cesarean delivery followed immediately by radical hysterectomy and lymphadenectomy is often recommended for reproductive-age women with early cervical cancer to preserve ovarian and vaginal function compared with radiation therapy. At surgery, it may be appropriate to move the ovaries out of the potential radiation field (i.e., oophorectomy) in women who may need postoperative adjuvant teletherapy.

For women with advanced cervical cancer who present in the second half of pregnancy, delay of therapy for fetal maturity carries a small but unquantifiable risk of adverse cancer outcome. Cesarean delivery (to avoid delivery through a cervical tumor⁶⁰) followed by radiation therapy with concurrent chemotherapy usually is recommended. In the first trimester and early second trimester, delay of therapy may increase the risk of a poor oncologic outcome, and it is therefore recommended to begin treatment at the time of diagnosis, with ultimate sacrifice of the pregnancy as an unavoidable outcome. Evacuation of the uterus can be performed before irradiation or after radiation therapy if spontaneous miscarriage does not ensue. The anatomic distortion that occurs in pregnancy must be considered when planning radiotherapy to ensure the appropriate treatment fields. Patients who refuse immediate therapy for advanced cervical cancer during the first half of a pregnancy must be counseled regarding the potential impact on tumor growth and spread and the worsened prognosis. In selected patients, neoadjuvant chemotherapy (to decrease the risk of cancer progression during pregnancy) can be considered, with definitive chemoradiotherapy initiated after delivery. However, there are limited data to support this management strategy.⁶¹⁻⁶³

For those women who delay definitive therapy for their cervical cancer until the postpartum period, the mode of delivery remains controversial. For early-stage disease, there is no consensus on whether vaginal delivery affects survival and

prognosis. However, delivery through a bulky and friable cervical cancer leads to the potential risk of hemorrhage. Cervical cancer may recur at the episiotomy site, typically within 6 months after delivery.^{64,65} For these reasons, vaginal delivery should be reserved for appropriately counseled and carefully selected women with intraepithelial lesions and early-stage cancers. Women with cervical cancer who have delivered vaginally with episiotomy and later develop a lesion in the episiotomy should undergo biopsy to rule out recurrence at this site. For women with early cervical cancer whose primary therapy will be surgical, abdominal delivery with concurrent hysterectomy (i.e., extrafascial hysterectomy or radical hysterectomy and lymphadenectomy, depending on the tumor stage) is recommended.

In selected women with early cervical cancer, radical excision of the cervix (i.e., radical trachelectomy) and lymphadenectomy can be considered for definitive treatment of stage I cervical cancer with the potential to maintain future fertility. This procedure is usually performed in nonpregnant patients, but it has been reported during pregnancy.⁶⁶ After radical trachelectomy, oncologic outcomes appear favorable in women who have small squamous lesions without lymphovascular invasion. Although most women who attempt pregnancy after radical trachelectomy are able to conceive, pregnancy rates are decreased due to cervical dysfunction. The risk of preterm delivery is increased after radical trachelectomy, although most women deliver at term. Overall, approximately 2% develop recurrence, and 74% deliver a viable pregnancy (half of which deliver in the third trimester).⁶⁷⁻⁷² Recently, robotic radical trachelectomy has been reported to be feasible and associated with favorable outcomes.⁷³

Treatment of Cancer during Pregnancy

RADIATION THERAPY

Radiation during pregnancy may be used for diagnosis or therapy. Diagnostic radiation for cancer during pregnancy, in the form of x-rays, is used in chest radiography, CT for evaluation or staging of a cancer, and fluoroscopic techniques such as intravenous pyelography (IVP), retrograde pyelography, and barium enema. Radiographic imaging is often necessary for cancer diagnosis during pregnancy. The known risks of diagnostic radiation have to be balanced with the expected benefits of such imaging. Units of radiation are expressed as rad, millirad (mrad), gray (Gy), milligray (mGy), or centigray (cGy). These terms are units of absorbed dose and reflect the amount of energy deposited into a mass of tissue. One gray equals 1000 mGy or 100 rad. As it relates to pregnancy, the absorbed dose is the dose received by the entire fetus. Diagnostic radiation doses are less than 1 mGy (<0.1 cGy), and therapeutic radiation for cervical cancer delivers more than 4000 cGy to the fetus.

Because there is no dose of diagnostic radiation that is completely safe for the fetus, radiography should be avoided if possible during fetal development and minimized at all times during pregnancy. However, fetal tolerance to the level of radiation encountered in diagnostic procedures is greater than generally understood. Rarely does diagnostic radiography exceed the threshold of fetal tolerance during a pregnancy (see Table 56-2). At the time of conception, exposure of 10 cGy usually results in embryologic death. If the embryo survives, radiation-induced noncancer health effects are unlikely. At all stages of

gestation, radiation-induced noncancer health effects are not detectable for fetal doses at less than 5 cGy. From 16 weeks' gestation to birth, radiation-induced noncancer health effects are unlikely at less than 50 cGy. The risk of childhood cancer from prenatal radiation exposure is related to the amount of prenatal radiation exposure above the usual background. At a dose up to 5 cGy, the incidence of childhood cancer is 0.3% to 1%; at a dose of 5 to 50 cGy, the incidence is 1% to 6%; and at a dose greater than 50 cGy, the incidence is more than 6%.⁷⁴ At a dose of 5 to 50 cGy between 8 and 15 weeks after conception, growth retardation and mental retardation can occur, with severe mental retardation occurring in up to 20% of cases. At this dose, there are no noncancer health effects expected with exposure at 16 weeks to term. With doses higher than 50 cGy, these noncancer health effects are expected to be more severe and more common than with lower doses, and the health effects can occur even with exposure from 16 to 25 weeks. After 25 weeks, prenatal radiation exposure with doses greater than 50 cGy leads to fetal death in a dose-dependent manner.^{75,76} Given the rarity of diagnostic radiation dosages beyond the thresholds of fetal exposure, therapeutic abortion is rarely recommended for this reason alone. If many radiographic studies are required, the fetal radiation dose should be monitored. Increased use of MRI and ultrasonography, imaging modalities that do not employ ionizing radiation, may avoid concerns related to the fetal risks of imaging studies.

Therapeutic radiation for cervical cancer during pregnancy is lethal to a fetus. Radiation exposure while the fetus is in the uterus leads to fetal death, usually followed by spontaneous abortion. Pelvic radiotherapy for cervical cancer leads to sterility as a result of the direct cytotoxic effect on the endometrium and ovarian injury from standard pelvic doses for treating this cancer (usually greater than 4500 cGy). The threshold values for permanent and temporary sterility have not been clearly defined, but the risk of sterility is related to ovarian reserve (i.e., age at exposure) and dose. In women 40 years of age or older, 600 cGy can induce menopause. Adolescent girls treated with 2000 cGy fractionated over 5 to 6 weeks have a 95% likelihood of permanent sterility. With conventional therapeutic doses of radiation for cervical cancer, any field that includes the ovaries will cause sterility (Table 56-3).^{76a} Although the uterine effects cannot be avoided, transposing the ovaries out of the pelvic radiation field can preserve function in many women undergoing pelvic radiotherapy for cervical cancer.

CHEMOTHERAPY

The teratogenic effect of chemotherapy is inarguable. All chemotherapy agents used in the treatment of cancers are pregnancy category D, indicating that these agents have led to adverse effects in exposed fetuses. Although most cytotoxic agents have a molecular weight of less than 400 kDa, leading to fetal exposure by crossing through the placenta, the majority had never been tested in pregnant women at the time they were introduced into clinical practice. The effects of chemotherapeutic medications vary according to their mechanism of action and the gestational age of the fetus during their administration. Although there are few data regarding the use of cytotoxic chemotherapy during pregnancy for the treatment of gynecologic cancers, there is considerable literature about the use of these agents for treatment of with lymphomas and leukemias in pregnant women. These data indicate that fetal exposure to chemotherapeutic agents within 2 weeks after conception leads to spontaneous abortion or to no effect with subsequent normal development. Chemotherapeutic agents kill rapidly-dividing cells nonselectively in carcinomas and in the embryo or fetus.^{11,77} The most susceptible period is the first trimester, when organogenesis occurs.⁷⁸ During organogenesis, exposure to most cytotoxic chemotherapeutics carries a high incidence of congenital malformations.⁷⁹ Numerous uncontrolled, observational reports have described good fetal and maternal outcomes with administration of chemotherapy during the second and third trimesters,⁸⁰⁻⁸⁴ but increased intrauterine growth restriction, low birth weight, spontaneous abortion, and preterm labor are also reported.^{79,82,85}

Chemotherapy delivered near the time of delivery may cause concerns because of the risk of maternal myelosuppression with resultant neutropenia and thrombocytopenia. Furthermore, there may not be sufficient time for excretion of chemotherapy agents and their active metabolites from the fetus before delivery. The infant, after separation from the excretional function of the placenta and without mature hepatorenal excretion mechanisms, may experience adverse effects after birth. Other factors, such as maternal nutritional status, can alter protein binding and the serum free drug concentration, and the expanded plasma volume experienced during pregnancy also affects the pharmacokinetics of a chemotherapeutic agent. To minimize the maternal and fetal risks associated with chemotherapy in proximity to delivery, a careful delivery plan with input from the involved obstetrician, perinatologist, neonatologist, and oncologists must be made.

If chemotherapy for a gynecologic cancer is required during pregnancy, ovarian function is usually preserved, and future fertility should not be jeopardized. Long-term follow-up of children who were exposed to antineoplastic agents in utero found that exposed offspring usually have normal birth weights, educational performance, and reproductive capacity.⁸⁶⁻⁸⁹

SURGICAL PRINCIPLES

Pregnant women are not immune to processes that require surgical intervention, although fewer than 2% of women undergo surgery during pregnancy (with a small percentage of these undergoing a cancer surgery).⁹⁰ Because of their relative youth and general good health, pregnant women tolerate surgical procedures well, and obstetric outcomes are usually good after uncomplicated surgical procedures. Among 5405 women

undergoing nonobstetric surgical procedures, most performed in the second trimester, the rates of stillbirth and congenital anomalies were not different from those for pregnancies not associated with surgery, but low birth weight and preterm delivery were more common.⁹¹ An increased risk of preterm delivery has been reported after surgery in the first trimester, and the risk was increased with longer procedure times.⁹² If surgery is required during pregnancy, it should be performed, if possible, during the second trimester and under controlled circumstances. Urgent procedures performed during pregnancy should be carried out in an efficient, effective manner. In particular, abdominal surgery during pregnancy carries increased fetal risk compared with extraabdominal surgery.

Laparoscopic surgery is feasible and relatively safe during pregnancy.⁹³⁻⁹⁷ Laparoscopic procedures are associated with less pain in the postoperative period, reduced use of analgesics and tocolytics, and overall shorter lengths of bed rest and hospitalization compared with laparotomy. The most common indications for laparoscopic surgery during pregnancy are cholecystectomy, evaluation of an adnexal mass, and appendectomy.⁹⁸ Surgical risks inherent to minimally invasive surgery do not appear to be increased in pregnancy, and laparoscopic techniques in pregnant patients should not differ greatly from those in nonpregnant patients. As with open procedures, fetal heart tones should be obtained before and after the procedure. Continuous intraoperative fetal heart rate monitoring, if technically feasible, may be helpful to ensure satisfactory uterine blood flow in procedures when maternal blood loss is anticipated. A sustained fall in fetal heart rate may indicate decreased uterine perfusion that can be restored by repositioning the patient to relieve aortocaval compression or by expanding the intravascular volume. Nasogastric or orogastric decompression can be used to minimize insertion of ports into the stomach, and the patient should be placed in a leftward tilt to minimize aortocaval compression. The pneumoperitoneum should be established through an open technique to minimize the risk of uterine perforation or laceration. Rarely, insertion of the Veress needle used to establish the pneumoperitoneum into the uterus has led to fetal loss through the development of a pneumoamnion.⁹⁹ Ancillary ports should be placed carefully.

Because of an intraabdominal space that is progressively compromised, laparoscopy usually should be avoided after the late second trimester; however, this situation should be evaluated on a case-by-case basis. One possible risk of laparoscopy is that the developing fetus may be exposed to acidosis caused by maternal absorption of the carbon dioxide gas with subsequent hypercarbia and serum conversion to carbonic acid. Studies of fetal sheep have demonstrated that these animals have adequate compensatory response and placental reserve to tolerate insufflation, although one pregnant ewe died during establishment of the pneumoperitoneum.^{100,101} There have been no human reports of fetal loss attributable to acidosis caused by pneumoperitoneum, and this risk may be theoretical.

With any surgical approach during pregnancy (open or minimally invasive), the gravid uterus should be manipulated as little as possible to minimize the risk of spontaneous preterm labor, ruptured membranes, or other complications. Prophylactic tocolytics at the time of surgery in the second trimester do not decrease the risk of preterm labor or preterm delivery, but they may be beneficial in the third trimester.⁹² Specific oncologic procedures should be considered individually as to their relative safety during pregnancy. Whereas lumpectomy during

breast cancer surgery has been demonstrated to be safe, the use of vital dyes (methylene blue or lymphazurin) or of radionuclide technetium 99 (^{99}Tc) for this purpose has not been extensively evaluated. Nonetheless, they do appear safe in light of the fact that the radiation exposure of ^{99}Tc is less than 50 mGy,¹⁰² and the pharmacokinetics of methylene blue demonstrates limited fetal exposure.¹⁰³

Gestational Trophoblastic Neoplasia

Gestational trophoblastic neoplasia (GTN) is a spectrum of pregnancy-related conditions that have the potential for local invasion, distant metastasis, and death from disease. These conditions arise from abnormal fertilization and manifest as a missed abortion or a miscarriage or are concurrent with or follow a normal gestation. During the past 50 years, significant strides have been made in the diagnosis and treatment of GTN, and it is the most successfully treated gynecologic cancer and one of the most curable solid tumors in women. Full discussion of the diagnosis and treatment of GTN is beyond the scope of this text but can be found in texts of gynecologic oncology.

GTN is described here as it relates to ongoing pregnancies. As a pregnancy-related cancer, GTN can be diagnosed and monitored with serum levels of β -human chorionic gonadotropin (β -hCG). With the use of transvaginal ultrasonography, an intrauterine pregnancy can be diagnosed when the β -hCG level is 1500 to 2000 IU/mL (for singleton gestations). The threshold for transabdominal ultrasonography is higher—approximately 6500 IU/mL. When an abnormal pregnancy is diagnosed, GTN must be considered. The histologic spectrum of GTN includes partial and complete molar pregnancies, gestational choriocarcinoma, and placental-site trophoblastic tumors.

Molar pregnancy occurs in 1 of every 1000 pregnancies in the United States, and it is more common in women at the extremes of age for reproduction. Women most often present with amenorrhea, followed by vaginal bleeding in the first trimester. With the increasing use of transvaginal ultrasound in early pregnancy, it is rare for molar pregnancies to manifest later in the course of the disease, when hyperthyroidism, severe hyperemesis, and hypertension may occur. Often, patients complain of passage of vesicles from the uterus. These vesicles are usually seen on transvaginal ultrasound, and in the absence of a gestational sac or fetal parts, a diagnosis of partial molar pregnancy is usually made. Clinically, the uterus is larger than expected because of the molar pregnancy or the resultant ovarian thecal lutein cysts.

Included in the differential diagnosis of a positive serum β -hCG level in the absence of an intrauterine or extrauterine pregnancy must be phantom β -hCG syndrome,¹⁰⁴ in which circulating serum factors such as heterophilic antibodies or nonactive forms of β -hCG interact with the β -hCG antibody to create false-positive β -hCG results. These findings may lead to inappropriate initiation of therapy for GTN. This false β -hCG reading can be excluded by running a simultaneous urine sample for β -hCG, because these serum factors are not excreted in the urine. Alternatively, the serum can be serially diluted, with the expectation of a linear decrease in β -hCG levels in the case of a true-positive result. Because not all β -hCG testing platforms are susceptible to this false-positive result, the use of an alternative platform may exclude phantom β -hCG syndrome.^{104,105}

Molar pregnancy may coexist with a normal gestation in 1 of 20,000 to 100,000 pregnancies.¹⁰⁶ Coordinated care among the obstetrician, perinatologist, neonatologist, and gynecologic oncologist must ensue. These pregnancies are associated with a higher incidence of complications such as fetal death, vaginal bleeding, preeclampsia, and persistent GTN after evacuation. Historically, early pregnancy termination has been recommended to avoid complications. However, in the largest reported series,¹⁰⁶ 60% of women who chose to continue a normal pregnancy coexistent with a complete molar pregnancy experienced spontaneous abortion or fetal demise before 24 weeks, and 40% delivered a live infant at 24 weeks or later (most after 32 weeks). The rate of persistent GTN requiring chemotherapy was not different in women undergoing early pregnancy termination compared with those who did not terminate and no different from that experienced by patients with a singleton complete molar event in this series.¹⁰⁶

Pregnancy and Solid Tumors

BREAST CANCER IN PREGNANCY

Gestational or pregnancy-associated breast cancer is defined as breast cancer that is diagnosed during pregnancy, in the first postpartum year, or at any time during lactation. Physiologic changes in the breast make the diagnosis of breast cancer during pregnancy a challenge. Nevertheless, any discrete lump felt in the breast should be investigated further by a specialist breast team.

Epidemiology

Breast cancer is one of the malignancies most commonly encountered in pregnant women. The reported incidence ranges from 1.3¹⁰⁷ to 3.3² cases per 10,000 live births. Although only 0.2% to 3.8% of breast cancers diagnosed in women younger than 50 years of age are pregnancy associated, almost 10% to 20% of breast cancers diagnosed in women in their 30s are discovered during pregnancy.^{108,109} This pattern of prevalence is likely to change in the future with an increase in gestational breast cancers as more women delay childbearing.

Clinical Presentation and Diagnosis

The most common clinical presentation of breast cancer in pregnant and nonpregnant women is a painless lump in the breast. Occasionally, refusal by an infant to nurse from a lactating breast may signify an occult carcinoma; this has been described as the milk rejection sign.¹¹⁰ The physiologic changes in the breast during pregnancy and lactation result in engorgement and increased nodularity, which makes it a challenge for the patient and clinician to identify tumors by palpation. Such challenges result in diagnostic delays of 2 months or longer, which in part is responsible for the advanced stage at diagnosis in pregnant or lactating women. In a mathematical model assessing tumor progression over time, a 1-month delay in treatment of the primary tumor increased the risk of axillary metastases by 0.9% to 1.8%.¹¹¹ Clinicians therefore should perform a thorough breast examination at the initial prenatal visit and without hesitation thereafter.

The differential diagnosis of a breast mass in a pregnant or lactating woman is provided in Box 56-2. Although 80% of breast biopsies obtained from pregnant women are benign, it is important to biopsy any lump that is present for 2 to 4 weeks.¹¹²

Imaging. Mammography has a high false-negative rate during pregnancy, with sensitivity rates ranging from 63% to 78% in some studies.^{113,114} Mammography during pregnancy is safe because the average glandular dose to the breast for a two-view mammogram (200 to 400 mrad) results in a negligible radiation dose of only 0.4 mrad to the fetus.^{115,116} Fetal exposures less than 5 rad (50 mGy) are not thought to cause malformation (see Chapter 31),⁶³ and mammography still has a place in the evaluation of a breast mass in pregnancy.

Ultrasound is usually the preferred imaging modality to evaluate a breast mass in a pregnant woman. It is inexpensive, is safe for the fetus, and can distinguish between solid and cystic lesions in 97% of patients.¹¹⁷⁻¹¹⁹ If lymph nodes are palpable, axillary sonography with ultrasound-guided fine-needle aspiration biopsy should be done as part of staging evaluation.

The American Cancer Society recommends a screening MRI for women who have an approximately 20% to 25% or greater lifetime risk of breast cancer,¹²⁰ but there are no published data regarding the use of MRI to diagnose breast cancer during pregnancy. Although gadolinium-enhanced MRI is more sensitive than mammography for detection of invasive breast cancer, its use in pregnant women is limited by its passage across the placenta and reported association with fetal abnormalities in rats. MRI therefore is not recommended for the diagnosis of breast cancer during pregnancy. For postpartum women at the time of diagnosis, gadolinium-enhanced breast MRI may be considered if necessary.^{115,121} MRI may be used for staging evaluation in a pregnant woman as long as contrast is avoided (see later discussion).

Biopsy. Core-needle biopsy is the preferred method of tissue confirmation in pregnant women with suspected breast cancer.¹¹² This can be performed under local anesthesia and has no risks unique to pregnancy. Although fine-needle aspiration can be used, the proliferative changes induced by pregnancy may result in an indeterminate score requiring additional evaluation for diagnosis.^{122,123} The accuracy of interpretation of fine-needle aspiration biopsy depends on an experienced pathologist who is aware that the woman is pregnant.

One of the known, albeit rare, complications of such biopsies during lactation is the development of milk fistula.¹²⁴ Suspending breastfeeding before the biopsy decreases the incidence of milk fistula. Immunohistochemical stains for estrogen and progesterone receptors and for human epidermal growth factor receptor 2 (HER2 or ERBB2) should be performed on the biopsy tissue sample.

Staging

Evaluation. The tumor, node, and metastasis (TNM) staging system of the American Joint Committee on Cancer is appropriate for pregnant and nonpregnant women with breast cancer. Women with gestational breast cancer often present with later-stage disease than women who are not pregnant, which is attributable to the delay in diagnosis. A thorough history and physical examination of the breast and axillae are required to determine whether the woman needs a comprehensive staging workup.

Axillary Staging. Clinically palpable lymph nodes should be evaluated by ultrasound-guided fine-needle aspiration biopsy for pathologic confirmation. Sentinel lymph node biopsy has emerged as the standard technique in staging clinically node-negative women with early-stage breast cancer. Sentinel lymph node biopsy has not been fully evaluated in gestational breast cancer. Isosulphan blue dye should not be administered to pregnant women. Some small studies have reported that the use of double-filtered technetium sulfur colloid to map sentinel lymph nodes in pregnancy is safe, but no supporting larger studies have been reported.^{125,126,155} Sentinel lymph node biopsy is not recommended in women with gestational breast cancer outside of a clinical trial.¹²⁷

Distant Metastases. The three most common sites of distant metastasis in breast cancer are the lung, liver, and bone. As with nonpregnant women, women with gestational breast cancer who are asymptomatic and are clinically node negative do not require further formal staging because the yield in such patients is low. Complete radiologic staging evaluation should be considered in women with symptoms, women with clinically palpable nodes, and women with T3 or T4 lesions. Chest radiographs can be performed safely in pregnancy with abdominal shielding. Chest CT scans should be avoided. If further evaluation of the chest is required, MRI (without gadolinium) of the thorax is preferred. Abdominal ultrasound is the safest method to look for liver metastases in pregnancy, although MRI without contrast can be done if necessary.¹¹⁵ CT of the abdomen and pelvis is not preferred in pregnant women because the fetal radiation exposure approximates 250 mrad. For bony metastases, low-dose bone scans or MRI without contrast of the thoracic and lumbar spine is recommended.¹²⁸ Baker and colleagues¹²⁹ reported a “low-dose” bone scan with a fetal exposure of only 0.08 rad, compared with the standard 0.19 rad of a conventional bone scan. Maternal hydration and frequent voiding are required to reduce the fetal exposure to radiation resulting from accumulation of radionuclides in the maternal bladder. Plain skeletal radiographs including the spine and pelvis are acceptable and safe options for evaluation of bone; they expose the fetus to less than 1 rad (0.01 Gy). The other alternative to identify metastatic bony lesions is noncontrast MRI of the thoracic and lumbar spine. MRI is also the most sensitive and safe way to scan the brain for metastatic lesions.

Among the blood tests routinely obtained, alkaline phosphatase is not helpful. The level normally doubles or even quadruples during pregnancy, and it therefore cannot be used as an indicator for metastasis.¹³⁰

Pathology of Gestational Breast Cancer

Most breast cancers in pregnancy are poorly differentiated, infiltrating ductal carcinomas.¹³¹ Women with breast cancer in pregnancy have larger tumors and more frequently have nodal involvement, metastasis, and vascular invasion.^{109,132,133} Women with gestational breast cancer have a higher incidence of

inflammatory breast cancer and are 2.5 times more likely to have distant metastatic disease.¹³⁴ Breast cancers that are positive for estrogen or progesterone receptors are less common (25%) during pregnancy compared with the rate of 55% to 60% in nonpregnant premenopausal women.^{108,117,131,132} The high levels of circulating estrogen and progesterone in pregnancy may bind all the hormone receptor sites or downregulate them, resulting in negative receptor status in hormone binding assays. One series suggested that the proportion of hormone receptor-positive tumors in pregnant women is closer to the nonpregnant state when immunohistochemical methods are used.¹³⁵ Amplification of the *HER2* gene or increased expression of its ERBB2 protein (i.e., the oncoprotein fragment p105 is used in assays) is observed in approximately one fourth of breast cancers. Few studies have reported the incidence of this gene amplification in pregnant women with breast cancer, but most have quoted a higher incidence. For example, one series found that 7 (58%) of 12 gestational breast cancers were HER2 positive, compared with 16% of those in age-matched nonpregnant controls.¹³⁵ However, the percentage of HER2-positive tumors was similar to that for nonpregnant breast cancer patients in a prospective series of pregnant breast cancer patients.¹³¹

Treatment

The treatment of breast cancer during pregnancy should closely follow the guidelines recommended for women who are not pregnant. Treatment should be administered with a curative intent with minimal delay. Therapeutic decisions should be individualized, taking into consideration the gestational age, the stage of the disease, and the preferences of the patient and her family. Abortion is usually not recommended but may be considered for an individual patient during treatment planning.

Care by her obstetrician, perinatologist, and oncology team should be coordinated as described previously for women with leukemia, lymphoma, or solid tumors. Breast cancer occurring in the postpartum period is treated in the same way as breast cancer in a nonpregnant woman. Breastfeeding is contraindicated in patients who are receiving systemic therapy.

Locoregional Treatment. Surgery is the definitive treatment for pregnancy-associated breast cancer. Mastectomy with axillary dissection is traditionally considered the best choice for stage I, stage II, and some stage III breast cancers when the patient chooses to continue the pregnancy.^{136,137} Mastectomy eliminates the need for breast radiation therapy in stage I and II disease and therefore minimizes the risk associated with fetal radiation exposure. If breast reconstruction is desired, it should be delayed until after delivery, because prolonged surgery may increase fetal complications.

Breast-conservation surgery is a treatment option for women diagnosed in the late second trimester or early third trimester. Lumpectomy with axillary dissection is feasible in pregnancy. In such cases, radiation therapy to the entire ipsilateral breast is delayed until after delivery.¹³⁸ For women who present with locally advanced-stage disease, neoadjuvant chemotherapy can be considered before definitive surgery. The feasibility of breast-conservation surgery depends on the clinical response (Fig. 56-1).

Axillary dissection is an essential component of treatment and staging because nodal metastases are commonly found in pregnancy-associated breast cancer. Choice of systemic therapy also depends on comprehensive staging of the nodal involvement. Although sentinel lymph node biopsy is the preferred method of axillary staging in women with clinically

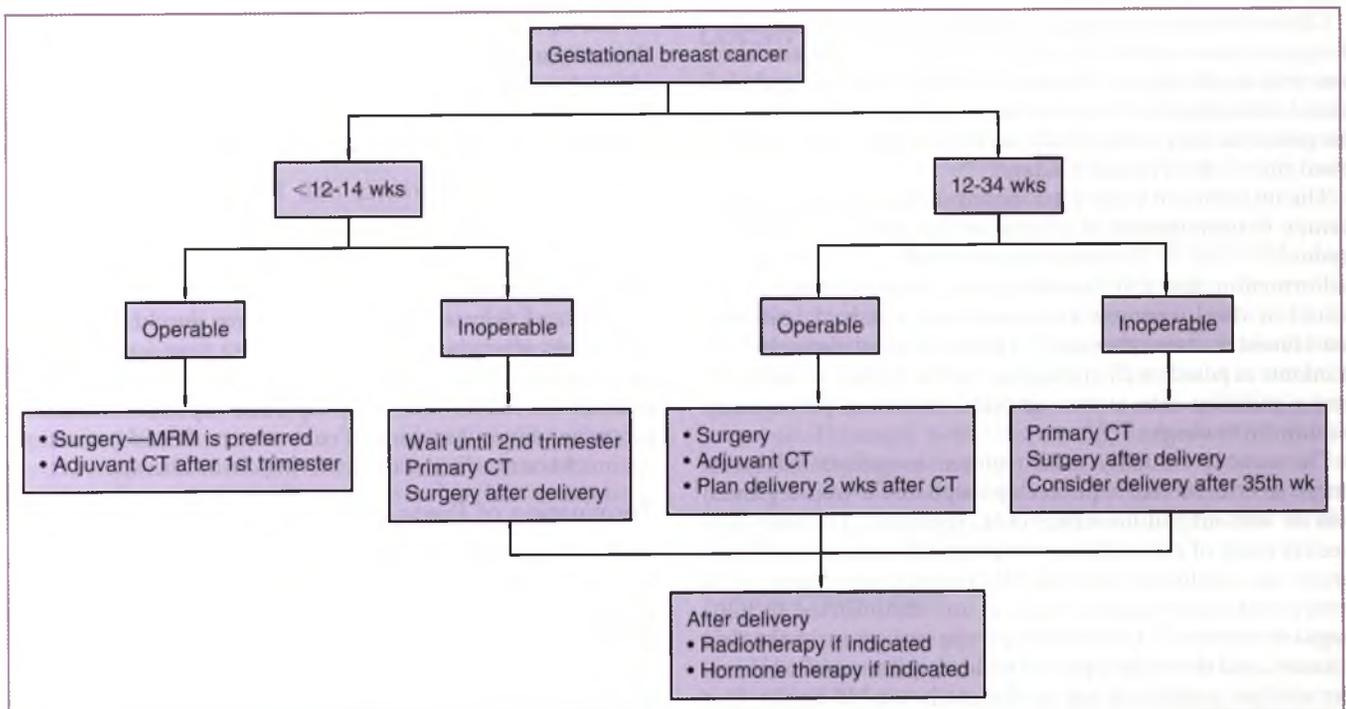

Figure 56-1 Algorithm for treatment of breast cancer in pregnancy. Neoadjuvant chemotherapy can be considered before definitive surgery for women who present with locally advanced-stage disease. Breast conservation surgery depends on the clinical response to therapy. CT, chemotherapy; MRM, modified radical mastectomy.

node-negative breast cancer, the safety and reliability of this procedure in pregnant women have not been established. Sentinel lymph node biopsy is not recommended for pregnant women with early-stage breast cancer.¹²⁷

Adjuvant radiation therapy improves local control of breast cancer and survival. The risks of teratogenicity and induction of childhood malignancies and hematologic disorders complicate but do not preclude the use of radiation therapy in the management of breast cancer in pregnancy.¹³⁹ In selected and appropriately counseled women, radiotherapy of breast cancer is possible with fetal doses that fall below the customary threshold for malformations (5 rad). The excess childhood cancer risk has been estimated as 6.57 cases per 10,000 children per rad per year.¹⁴⁰ For a typical treatment regimen approximating 50 Gy (5000 rad), radiation of the maternal breast or chest wall has been estimated to expose the fetus to as little as 0.1% to 0.3% of the total dose, or 0.05 to 0.15 Gy,¹²⁶ or as much as 3.9 to 15 rad in the first trimester and 20 rad in late third trimester.¹⁴¹ Some experts do not recommend radiation therapy during pregnancy,^{142,143} but each patient should be counseled based on her own circumstances.

Systemic Therapy. Adjuvant chemotherapy is recommended for all premenopausal patients with node-positive breast cancer or with tumors greater than 1 to 2 cm in diameter that are poorly differentiated. Most pregnancy-associated breast cancers fit in this category. All chemotherapeutic agents used in breast cancer have been categorized by the U.S. Food and Drug Administration as category D or X, indicating that teratogenic effects have occurred in humans (see Chapter 31). Information regarding the effects of chemotherapy administered during pregnancy is largely compiled from case reports and small case series. Dosing of chemotherapy during pregnancy is complicated by increased plasma volume, increased hepatorenal clearance, decreased serum albumin, and decreased gastric emptying, which increases absorption.¹⁴⁴

Chemotherapy exposure during the first trimester, the period of organogenesis, carries the greatest risk for spontaneous abortion, fetal death due to chromosomal abnormalities, and congenital abnormalities. Chemotherapy is usually deferred during this period as long as the health of the mother is not compromised due to the treatment delay.¹⁴⁵⁻¹⁴⁷

The incidence of congenital malformation is low if chemotherapy is administered to women in the second or third trimester.^{128,132,133,136,144,148} One review reported a 1.3% risk of fetal malformation for 150 women given chemotherapy in the second or third trimester, compared with a risk of 16% with first-trimester chemotherapy.¹⁴⁹ However, approximately 50% of infants exposed to chemotherapy in the second or third trimester manifest intrauterine growth restriction, prematurity, and low birth weight.^{150,151}

The most commonly used regimen in gestational breast cancer is doxorubicin with cyclophosphamide (AC regimen) with or without 5-fluorouracil (FAC regimen). The only prospective study of chemotherapy in pregnant women with breast cancer was conducted with the FAC regimen in a cohort of 24 women and used the same doses as are administered to non-pregnant women.¹³⁷ Chemotherapy was not given in the first trimester, and the study reported no birth defects in the infants. The median gestational age in this study was 38 weeks. It is unclear whether in utero exposure to anthracyclines is cardiotoxic to the fetus.

Methotrexate should be avoided in all stages of pregnancy because of the possibility of third spacing in the amniotic fluid and its abortifacient and teratogenic effects.^{147,149} Although several case reports have demonstrated the safety of administering taxanes during pregnancy, the long-term effects are unknown.^{152,153} The current international guidelines for use of chemotherapy in gestational breast cancer do not recommend the use of taxanes.¹⁵⁴ No data are available on the use of dose-dense therapy in pregnancy, and it is not recommended. Chemotherapy should be avoided for 3 to 4 weeks before delivery to preclude infectious complications caused by transient myelosuppression.

Addition of trastuzumab to adjuvant chemotherapy has made a significant impact on disease-free and overall survival in women with HER2-overexpressing breast cancers. Only four case reports of the use of trastuzumab in pregnancy have been published.¹⁵⁵⁻¹⁶⁰ Reversible oligohydramnios and reversible maternal heart failure were described. No fetal abnormalities have so far been reported.

In early-stage, node-negative, hormone receptor-positive breast cancer, oncologists use the Oncotype Dx assay, a 21-gene reverse transcriptase-polymerase chain reaction (RT-PCR) assay to predict the benefit from chemotherapy and endocrine therapy. This test provides useful information to decide whether chemotherapy is a necessary option for patients with a low risk of recurrence. There are no data regarding the predictive ability of this test in pregnancy-associated breast cancer. Thus, this test should be of value in appropriately selected patients with pregnancy-associated breast cancer. For women who have hormone receptor-positive breast cancer during pregnancy, endocrine therapy with tamoxifen or other selective estrogen receptor modulators is deferred until after delivery. These agents have been associated with vaginal bleeding, spontaneous abortion, birth defects, and fetal death.¹⁶¹⁻¹⁶³ Long-term effects of tamoxifen on female offspring are unknown.

Use of antiemetics such as promethazine, ondansetron, or dexamethasone is considered safe during pregnancy. Granulocyte colony-stimulating growth factor and erythropoietin have been safely used in pregnant patients, and their use should follow the general guidelines.

Monitoring of Pregnancy and Timing of Delivery

Pregnant women with breast cancer should be monitored closely by their obstetrician and oncologist. Gestational age should be accurately determined to plan the timing of chemotherapy and delivery. If possible, delivery should be planned 3 to 4 weeks after chemotherapy, allowing time for the recovery of cell counts. The timing of delivery is related to the maternal condition, need for further therapy, and expected neonatal and infant outcomes. As a general rule, women should be cautioned against breastfeeding while receiving chemotherapy.

Termination of Pregnancy

Early termination of pregnancy does not improve the outcome of breast cancer in pregnancy.¹⁶⁴ Some series suggest inferior outcomes in pregnant women with breast cancer who undergo elective termination compared with those who continue with the pregnancy.¹⁶⁵ Termination decisions should be individualized and depend on the patient's willingness to accept a possible risk to the fetus from cancer therapy, her overall prognosis, and the ability to care for the offspring.

Prognosis of Breast Cancer Associated with Pregnancy

The prognosis of breast cancer occurring during pregnancy has changed over the years. Current reports suggest similar survival rates for women with gestational breast cancers compared with age- and stage-matched control groups.^{133,164,166,167} In 1994, Petrek and associates¹⁶⁸ reported a 5-year survival rate of 82% for pregnant and nonpregnant women with node-negative breast cancer, 47% for node-positive pregnant women, and 59% for node-positive nonpregnant women.¹⁶⁸ However, other case-control studies have shown decreased survival for pregnant women with breast cancer.^{134,169,170} Some of these studies have lumped breast cancers occurring during pregnancy together with those occurring in the postpartum period, which may be the reason for the contradictory results.

Follow-up after Breast Cancer

Women with breast cancer occurring during pregnancy should be monitored for recurrence and long-term side effects of cancer therapy according to the guidelines recommended by the American Society of Clinical Oncology and the National Comprehensive Cancer Network (NCCN) for all women with breast cancer.

Pregnancy after Breast Cancer

The impact of future pregnancy in young women with breast cancer is uncertain. Three large, registry-based studies concluded that women who become pregnant after successful treatment of breast cancer do not have worse prognosis with regard to their cancer.^{148,171-173} Reports that the outcome of early breast cancer is improved in women with a subsequent pregnancy suggest a possible antitumor effect of pregnancy.¹⁷⁴⁻¹⁷⁶ Most recurrences of breast cancer occur within the first 2 years after initial treatment, and oncologists therefore recommend a delay of 2 to 3 years before contemplating pregnancy.¹⁷⁷

MALIGNANT MELANOMA IN PREGNANCY

Cutaneous melanoma is the most common malignancy encountered during pregnancy.^{178,179} Concerns regarding the possible relationship between melanoma and pregnancy arose from early reports of poor outcome of melanoma in pregnant women.¹⁸⁰ Melanoma occurring during pregnancy may be more advanced and is more likely to be located in sites associated with poorer prognosis.¹⁸¹⁻¹⁸³ Head, neck, and truncal lesions occurred in 43% of pregnant patients, compared with 38% of nonpregnant controls,¹⁸⁴ but other reports found no increase in poor prognostic locations in pregnancy. Pregnancy has been associated with increased tumor thickness in some reports.¹⁸⁴⁻¹⁸⁶ There may be a hormonal induction of proliferation of the cancerous melanoma cells in pregnancy, but no specific pregnancy-related hormone has been identified. The effect of pregnancy on tumor site and thickness remains unclear.

Historically, melanoma in pregnancy has been associated with a poorer prognosis, with several controlled studies reporting decreased survival rates compared with nonpregnant women.^{182,183,187,188} However, when cases are matched for site and stage, no significant difference in survival is observed. Trapeznikov and coworkers¹⁸⁸ reported the only study that showed a difference in survival rate despite matching by age, tumor site, and stage. At 10 years of follow-up, there was a statistically different survival rate of 26% for the pregnant group and 43% for the nonpregnant group in this study.¹⁸⁸

Other studies have not observed any significant differences in survival rates in pregnant women, but some have reported a shorter disease-free survival time for pregnant women,^{184-186,189,190} perhaps because of the shorter follow-up period in these studies. Three large, case-control studies of the prognosis of melanoma diagnosed during pregnancy did not show any difference in survival.¹⁹¹⁻¹⁹³ O'Meara and colleagues¹⁹³ used the records from the California Cancer Registry between 1991 and 1999 and reported no difference in survival between 303 patients with pregnancy-associated melanoma and 1799 age-matched nonpregnant controls. Most recently, the survival analysis in a Norwegian cohort of 42,511 women diagnosed with cancer in their reproductive period with 11.9 years' median follow-up reported no difference in cause-specific survival for melanoma between pregnant and nonpregnant women when controlled for Breslow thickness and tumor site.^{194,195}

Surgery is the only effective cure for melanoma. Recommendations should be based on the same prognostic factors (e.g., Breslow depth) established for a nonpregnant patient. In a pregnant woman diagnosed with early-stage melanoma, there is no reason to delay surgery. The risks of sentinel lymph node biopsy were discussed earlier (see "Staging"), and although small case reports of safe use of sentinel lymph node mapping have been published, it is not recommended outside of a clinical trial setting.¹²⁶ Chemotherapy does not offer sufficient benefit to the mother to warrant risk to the fetus. In pregnant women presenting with metastatic disease, the decision regarding termination of pregnancy and initiation of systemic therapy should be individualized according to the prognosis and the patient's wishes. There is very limited experience with the use of interferon, and the newer agents such as ipilimumab (a monoclonal antibody targeting CTLA-4) and vemurafenib (a mitogen-activated protein [MAP] kinase inhibitor) are classified as category C and D for use in pregnancy and hence currently not recommended.

COLON CANCER IN PREGNANCY

Colorectal cancer in pregnancy presents a diagnostic, therapeutic, and ethical challenge. Colorectal cancer in pregnancy is a rare event, with a reported incidence of 0.008% (1 in 13,000 pregnancies).¹⁹⁶ Approximately 300 cases have been reported in the literature. The mean age at diagnosis of colorectal cancer in pregnancy is 31 years (range, 16 to 48 years).¹⁹⁷ The management of colorectal cancer in pregnancy raises several ethical and medicolegal issues, because the treatment goals for the mother often conflict with the interests of the fetus. The diagnosis is particularly difficult because the common signs and symptoms of colon cancer are often attributed to the pregnancy. This results in advanced stages of the disease at diagnosis, with a correspondingly poor prognosis. Enhanced awareness among the medical community is needed to diagnose colon cancer earlier in pregnancy and thereby improve outcomes. A team approach involving experts in obstetrics, neonatology, gastrointestinal surgery, and medical oncology is required for optimal management.

Clinical Presentation

Common presenting signs and symptoms of colon cancer include abdominal pain, anemia, nausea, vomiting, constipation, abdominal mass, weight loss, and rectal bleeding. Many of these symptoms occur normally in pregnancy, and others, such as weight loss and an abdominal mass, can be masked by

pregnancy.¹⁹⁸ This diagnostic challenge often leads to delayed diagnosis and evaluation and to a poor prognosis for colorectal cancer in pregnancy. A review of 41 cases of colorectal cancer in pregnancy demonstrated that all of the patients presented with Duke class B or greater disease.¹⁹⁷

Predisposing Factors

Colorectal cancer is rare in young patients, and colorectal cancer in pregnancy designates a special group of young women who must have predisposing factors leading to this condition. Predisposing factors for colon cancer include hereditary nonpolyposis colorectal cancer (HNPCC or Lynch syndrome), familial adenomatous polyposis, Gardner syndrome, Peutz-Jeghers syndrome, and long-standing inflammatory bowel disease. However, in their review of 19 pregnant patients with colorectal cancer, Girard and coworkers¹⁹⁶ attributed these predisposing factors to only 4 patients.

Factors such as steroid hormones, TP53 protein abnormality, and cyclooxygenase-2 (COX-2) enzyme levels have been implicated in colorectal cancer in pregnancy. Between 20% and 54% of colon cancers have estrogen receptors, and some studies have also demonstrated progesterone receptors.¹⁹⁹ The role of these hormones in the progression of colon cancers has been related to the interaction between their receptors and other growth-signaling pathways.²⁰⁰ However, data to support an etiologic role of hormone receptors in colon cancer and circulating hormones are conflicting.

Diagnosis

Colonoscopy is the procedure of choice to obtain a biopsy and confirm a diagnosis in a nonpregnant patient with suspected colorectal cancer. However, pregnancy is a relative contraindication to colonoscopy. Possible adverse effects of colonoscopy in pregnant women include placental abruption from mechanical pressure on the uterus, fetal exposure to potential teratogenic medications, and fetal injury resulting from maternal hypoxia or hypotension.²⁰¹ The patient and her family should be fully informed about all potential risks to the mother and fetus, and informed consent should be obtained. The risks may be minimized with gentle abdominal compression during colonic intubation, use of meperidine instead of benzodiazepines, administration of oxygen to the mother, and antenatal fetal monitoring.²⁰²

Pregnant patients with persistent gastrointestinal symptoms should be evaluated by a specialist gastroenterologist with sigmoidoscopy as an alternate to colonoscopy. Most colorectal carcinomas diagnosed in pregnancy are rectal carcinomas; 86% of colorectal carcinomas diagnosed in pregnancy were below the peritoneal reflection in one review.¹⁸² The serum level of carcinoembryonic antigen (CEA) is a reliable laboratory test used for the diagnosis, prognosis, and monitoring of the colorectal cancer in pregnancy.²⁰³ Unfortunately, it is not a useful tool for screening because of its low sensitivity and specificity. Abdominal CT used for staging of colon cancer is contraindicated in pregnancy. Alternatives include ultrasound and MRI without contrast to assess the extent of the cancer in the abdomen and pelvis in a pregnant woman. Ultrasound has a sensitivity of 75% for detecting hepatic metastatic lesions.

Treatment

Management of colorectal cancer in pregnancy is influenced by the gestational age, tumor stage, and need for elective or emergent surgery. There are no universally accepted guidelines for

treatment. Goals of care are prompt initiation of treatment of the cancer and delivery of the infant as soon as neonatal outcomes are optimized. When colorectal cancer is diagnosed in the first 20 weeks of pregnancy, the recommended treatment is surgical removal of the tumor. However, colon cancer is rarely detected before 20 weeks' gestation, which explains the paucity of data on fetal outcome after colonic or rectal resections. Anecdotal reports have described birth of normal infants after such resections. Because of the controversial data regarding the risks of such resections to the pregnancy, termination of pregnancy and resection of the tumor constitute the recommended treatment.²⁰⁴ Delaying surgery until after delivery may result in significant tumor progression and is not recommended.

When the diagnosis is made after 20 weeks of pregnancy, surgery may be delayed until the fetal prognosis has improved. However, delay can result in progression of the cancer, increasing the mother's risks. The patient should be fully informed about these risks before making a decision to postpone surgery.

Colorectal cancer in pregnancy may be complicated by ovarian metastases, which are reported in 25% of pregnant patients but in only 3% to 8% of nonpregnant patients.^{205,206} Prophylactic bilateral salpingo-oophorectomy simultaneous with resection is recommended by some, but it is associated with an increased risk for spontaneous abortion. Bilateral wedge biopsies of the ovaries may be performed during surgery for pathologic examination and subsequent removal if the ovaries are involved.²⁰⁷

Adjuvant chemotherapy is recommended for stage II or III colorectal cancer. Chemotherapy cannot be administered in the first trimester but can be considered in the second or third trimester. The most commonly used agent is 5-fluorouracil, but its use in pregnancy has been associated with fetal abnormalities.²⁰⁸ Irinotecan, oxaliplatin, bevacizumab, and cetuximab are all newer agents used in the management of colorectal cancer, but experience with these agents in pregnancy is not well documented. Adjuvant radiation therapy is indicated in the management of Dukes B and C rectal cancers but is contraindicated in pregnancy. Radiation therapy should be employed postoperatively after delivery or elective abortion.

Prognosis

Colorectal cancer in pregnancy is associated with a poor prognosis. There are no reports of 5-year survivors of colorectal cancer diagnosed in pregnancy. Despite the poor prognosis, the stage-for-stage survival of women with colorectal cancer in pregnancy is similar to that of the general population.¹⁹⁷ Delay in diagnosis and advanced-stage disease at presentation most likely explain the overall poor prognosis in pregnancy. Gestational colon cancer also appears to worsen pregnancy outcomes. Woods and associates²⁰⁹ reported that 78% of pregnancies in women with colon cancer resulted in live births; deaths were attributed to prematurity and intrauterine demise. More recently, however, data from the California Cancer Registry of perinatal and cancer outcomes in pregnant women with colon cancer compared with age-matched nonpregnant women with colorectal cancer showed excellent neonatal and maternal outcomes.²¹⁰

Hematologic Malignancies during Pregnancy

Diagnosis and management of acute and chronic leukemias, NHL, and HL arising within the setting of pregnancy are difficult.

Approximately 1 of every 1000 to 6000 pregnancies is complicated by lymphoma,²¹¹ and 1 of 75,000 by leukemia.²¹² Because hematologic malignancy during pregnancy is rare and clinical trials in pregnancy are complicated by ethical dilemmas, there are few data to guide decisions about imaging, therapy, maternal toxicities, and gestational and postnatal complications.

Therapeutic options include observation, radiotherapy, chemotherapy, and termination of pregnancy. Several retrospective studies suggest that chemotherapy can often be safely administered during the second and third trimesters of pregnancy, and it should be considered in women with potentially curable and life-threatening leukemias and lymphomas.^{211,212} In women with aggressive and curable hematologic malignancies, delay in therapy can prevent remission, contribute to future disease relapse, and hasten maternal death.²¹² Chemotherapy during the second and third trimesters should therefore be considered for pregnant women with acute leukemia, HL, or Burkitt or diffuse large B-cell NHL. When chemotherapy poses a high risk to the fetus (e.g., in the first trimester in women with few clinical manifestations) or when the hematologic malignancy is incurable (e.g., indolent NHL, chronic leukemias), fetal toxicity can be limited by deferring treatment until later stages of the pregnancy or by using palliative chemotherapy or steroids during pregnancy. Regardless of the therapeutic approach, the management of a hematologic malignancy in a pregnant patient requires careful coordination and collaboration among medical oncologists, perinatologists, and neonatologists.

HODGKIN LYMPHOMA IN PREGNANCY

Epidemiology, Diagnosis, and Staging

HL is the fourth most common malignancy complicating pregnancy.²¹³ The relative frequency of HL in pregnancy is a function of the high incidence of HL in persons 15 to 34 years old. HL typically manifests as enlarging lymphadenopathy favoring the lymph nodes of the neck, mediastinum, and axillae. A contiguous pattern of spread of HL between lymphatic channels of the upper neck, chest, and mediastinum has been described,²¹⁴ with lymph node involvement tracking from the neck to the mediastinum and axilla before involvement of intraabdominal nodes or the spleen. Patients with mediastinal adenopathy often notice increasing shortness of breath or cough, symptoms common in normal pregnancies, which may delay diagnosis in pregnant women. Isolated subdiaphragmatic lymphadenopathy rarely occurs.

Diagnosis of HL requires excisional or core-needle biopsy, because the malignant Reed-Sternberg cells are often missed on fine-needle aspiration. Staging for HL follows the Ann Arbor staging system (Table 56-4) and usually requires CT of the chest, abdomen, and pelvis; bone marrow biopsy; and ¹⁸F-FDG PET. Bone marrow biopsy can be performed safely during pregnancy, but the fetal risks associated with ionizing radiation preclude the use of abdominal pelvic CT and PET in pregnant women. Typical staging of pregnant patients consists of a CT chest study with appropriate abdominal shielding and abdominal MRI to detect intraabdominal adenopathy. Because multiagent chemotherapy is used to treat early-stage and advanced-stage HL, accurate staging is less critical for the pregnant patient; the chemotherapy treats disease above and below the diaphragm. Few patients receive radiotherapy alone.

PET has been incorporated into response definitions for HL and aggressive NHL.²¹⁵ The use of PET improves the sensitivity

TABLE 56-4 Ann Arbor Staging System for Hodgkin Lymphoma and Non-Hodgkin Lymphoma

Stage*	Description
I	Involvement of a single lymph node region or lymphoid structure or involvement of a single extralymphatic site (I _e)
II	Involvement of two or more lymph node regions on the same side of the diaphragm, which may be accompanied by localized, contiguous involvement of an extralymphatic site or organ (II _e)
III	Involvement of lymph node regions on both sides of the diaphragm, which may also be accompanied by involvement of the spleen (III _s) or by localized contiguous involvement of an extralymphatic site or organ (III _e)
IV	Diffuse or disseminated involvement of one or more extralymphatic organs or tissues, with or without lymph node involvement

*The absence or presence of fever (>38°C), unexplained weight loss (>10% of body weight), or night sweats should be indicated by the suffix letters A or B, respectively (e.g., IIA, IIIB).

of traditional staging methods, and its results have prognostic significance during therapy.²¹⁶⁻²¹⁸ However, because it is contraindicated during pregnancy, PET scanning can be delayed until the completion of therapy and after delivery. Although a pre-therapy PET scan can facilitate the interpretation of post-therapy PET scans, a PET scan is not required at diagnosis for the management of patients with classic HL, because it is routinely avid for FDG.²¹⁵ At the conclusion of therapy, a PET scan is essential for persons with HL to confirm complete remission of a disease for which residual mediastinal masses may represent fibrosis or persistent disease. PET negativity correlates with disease-free survival.²¹⁶⁻²¹⁸ Although a PET scan cannot be used to stage a pregnant patient, it is performed for all patients after delivery on completion of therapy.

Therapy

Therapeutic options for pregnant patients with HL depend on clinical features, maternal wishes, fetal risks, the gestational age at diagnosis, and potential complications. Pregnancy has been associated with poor patient outcomes in HL, late presentation, minimal response to therapy, and short progression-free and overall survival times.²¹⁹⁻²²¹ However, these reports were likely confounded by delayed diagnosis and inferior therapy, because later series incorporating multiagent chemotherapy regimens into the treatment of HL in pregnant patients demonstrated response and survival outcomes comparable to those of non-pregnant patients.^{220,222-226}

Chemotherapy. During the first trimester, in women with painless adenopathy and without respiratory compromise or B symptoms (e.g., fevers, night sweats, weight loss >10%; see Table 56-4), therapy may be deferred until after the first trimester to minimize the risk of fetal teratogenicity. In women with symptoms, palliative measures such as corticosteroids or single-agent chemotherapy (i.e., vinblastine) may be necessary to control symptoms until the second trimester. Chemotherapy in the first trimester has been associated with fetal malformations, an increased risk of spontaneous abortion, and stillbirth.²²⁷⁻²³¹ In particular, antimetabolites (e.g., fluorouracil, gemcitabine,

fludarabine, cytarabine) and alkylating agents (e.g., busulfan, chlorambucil, cyclophosphamide, ifosfamide) should be avoided in the first trimester because of their teratogenic effects.^{211,231-233} The front-line chemotherapy regimen commonly used to treat HL is doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine (ABVD regimen), consisting of antitumor antibiotics and antimicrotubule agents. In some series, ABVD has been administered during the first trimester without fetal complications.^{86,234} However, because data to support the safe use of ABVD in the first trimester are limited and the potential for teratogenesis is significant, ABVD should be offered during the first trimester only after appropriate counseling when the health of the mother is at risk due to rapidly progressive disease. Palliative treatment of symptoms with steroids, single-agent treatment with vinblastine, and delayed therapy until the second trimester are preferable options.

Therapy for HL during the second and third trimesters consists primarily of chemotherapy. ABVD appears to be safe in the second and third trimesters of pregnancy,^{186,226,234} and because HL is potentially curable, the regimen should be offered to all patients unless delivery is expected within 2 to 3 weeks. Prolonged treatment delays may ultimately affect the prognosis of the mother and increase the risk for future relapse. In contrast to the first trimester, in which the potential fetal effects of chemotherapy include malformations and demise, multiagent chemotherapy in the second or third trimester primarily results in lower birth weights and pre-term labor, with rare reports of cardiac toxicity related to anthracycline (Adriamycin) therapy and neonatal myelosuppression complicated by respiratory distress or enterocolitis.^{231,235,236} One trial correlated cardiac toxicity with higher doses of the anthracycline; a dose per cycle of Adriamycin exceeding 70 mg/m² was associated with a 30-fold increase in fetal events.²³¹ However, with the ABVD regimen, the Adriamycin dose per cycle is only 50 mg/m². In at least one series with long-term follow-up of 3 to 19 years, children born to women who received chemotherapy during the first, second, or third trimester of pregnancy did not experience neurologic, psychologic, or immunologic effects, and they did not develop secondary malignancies.²³⁴ In one of the largest series evaluating lymphoma during pregnancy, the median birth weight of infants whose mothers received intrapartum chemotherapy was 2637 g, compared with 2212 g for mothers who deferred chemotherapy until after delivery.²²⁶ These reports offer some reassurance that standard doses of ABVD are probably safe when administered in the second or third trimester of pregnancy.

Radiotherapy. Before the advent of ABVD chemotherapy, radiotherapy with abdominal shielding was occasionally employed in pregnant women for the treatment of early-stage HL confined to the neck, mediastinum, or axilla. However, radiotherapy as a single modality has fallen out of favor in nonpregnant and pregnant patients, because chemotherapy alone or combined-modality regimens (e.g., ABVD and involved-field radiotherapy) have become the standard of care for early-stage and advanced-stage HL. Combined-modality regimens are more effective than radiation alone in early-stage HL, require limited doses and fields of radiation, and may have fewer late toxicities than previously employed extended fields of radiation.²³⁷

Most pregnant women cannot be adequately evaluated for intraabdominal involvement, because PET scans and abdominal CT are contraindicated; in these patients, radiotherapy

alone may undertreat those with undetected stage III or IV disease. Extended fields and higher doses of radiation have been associated with second malignancies, including breast and lung cancers, and with late cardiovascular disease in HL survivors.²³⁸⁻²⁴⁰ Radiotherapy fields encompassing the mediastinum or axilla ultimately include breast tissue and potentially increase the risk for late secondary breast cancers, particularly in women younger than 30 years of age.²³⁸ Radiotherapy alone therefore is considered only for selected patients (pregnant and nonpregnant) with stage I or II HL confined to the neck without B symptoms. In this setting, fetal exposure usually is less than 0.1 Gy (10 rad) with abdominal shielding.^{241,242} Mediastinal irradiation or mantle field irradiation (neck and mediastinum) typically leads to fetal radiation doses of 0.03 to 0.25 Gy, exceeding the recommended fetal radiation exposure of 0.1 Gy. When this dose is required for therapy, chemotherapy should be employed during pregnancy and, if necessary, radiotherapy delayed until after delivery.^{241,242}

Despite the fetal and maternal risks associated with radiotherapy, some patients will ultimately require radiotherapy for early-stage disease as part of combined-modality therapy regimens or to treat sites of initially bulky disease, where radiotherapy can minimize the risk of relapse.²⁴³ In these patients, ABVD chemotherapy is offered during the second and third trimesters of pregnancy, with radiotherapy withheld until the postpartum period.

NON-HODGKIN LYMPHOMA IN PREGNANCY

Epidemiology, Diagnosis, and Staging

The incidence of NHL during pregnancy is low, although the incidence of NHL in the general population has been steadily rising since the 1980s, increasing the likelihood of diagnosis during pregnancy.²⁴⁴ Studies of NHL during pregnancy are complicated by the number of subtypes of NHL—at least 30 based on the World Health Organization classification system of lymphoid malignancies,²⁴⁵ including B-cell, T-cell, NK-cell, and plasma cell neoplasms. As a result, the presenting features of the disease depend on the histologic subtype. Aggressive B-cell NHL subtypes (i.e., diffuse large B-cell; primary mediastinal B-cell; and Burkitt lymphomas)^{219,245,247} more commonly occur during pregnancy, because these diseases, more frequently than indolent or T-cell subtypes, affect younger patients. However, indolent NHL, including follicular and marginal zone lymphomas, T-cell lymphoma, and multiple myeloma, have also been reported during pregnancy.²⁴⁸⁻²⁵⁹

Diffuse large B-cell lymphoma is perhaps the most common NHL during pregnancy, followed by Burkitt lymphoma. Diffuse large B-cell lymphoma comprises 30% to 40% of all NHLs and can occur at any age. Common clinical presentations include lymphadenopathy, a mediastinal mass, involvement of a single extranodal site (e.g., bones, lung, liver), and B symptoms.^{211,245} Primary mediastinal large-cell lymphoma is a clinical variant of diffuse large B-cell lymphoma that has a female predominance, a large anterior mediastinal mass associated with dense fibrosis, and often involvement of other extranodal sites.^{245,260} A patient's presenting features often are related to compressive symptoms from the mediastinal mass, including dyspnea on exertion or superior vena cava syndrome.

Burkitt lymphoma is uncommon in adults, representing only 1% to 2% of all NHL subtypes, but it accounts for 30% to 50% of all childhood lymphomas.²³¹ The median age of adult

patients at presentation is 30 years, and as a result, Burkitt lymphoma is the second most common NHL manifesting during pregnancy.²⁶¹ Burkitt NHL frequently manifests in extranodal sites, often with intraabdominal masses arising from the mesenteric lymph nodes, bowel, kidney, liver, spleen, or ovaries. A high incidence of breast, cervical, uterine, and ovarian involvement by Burkitt NHL is reported in pregnant patients.^{247,258,262-266} Involvement of these organs is observed in nonpregnant patients with Burkitt lymphoma; however, the increased blood flow to the breast, ovary, cervix, and uterus during pregnancy may also contribute to this presentation.

As with HL, the diagnosis of NHL during pregnancy requires core-needle or excisional biopsy, because fine-needle aspiration is often insufficient to confirm the subtype of NHL.²⁶⁷ Routine staging of NHL, as in HL, follows the Ann Arbor staging system (see Table 56-4) and requires CT scans of the chest, abdomen, and pelvis; bone marrow biopsy; and occasionally a PET scan. Bone marrow biopsy, CT of the chest (with abdominal shielding), and MRI of the abdomen are typically employed for the pregnant patient with NHL to minimize fetal radiation exposure. PET, which is routinely performed for patients with aggressive NHL to determine therapeutic response and prognosis,²¹⁵⁻²¹⁸ can be deferred until the end of therapy and after delivery.

Therapy

Historically, coincident pregnancy at the time of a diagnosis of NHL was associated with poor patient outcomes.^{219,220,268-270} This may be attributed to the higher frequency of aggressive NHL subtypes in pregnant patients and to a reluctance to treat pregnant patients with the multiagent chemotherapy regimens necessary for long-term cure. The rarity of NHL and the variety of subtypes of NHL have made accurate assessment of outcomes during pregnancy difficult because of the unique prognosis, clinical outcome, and therapeutic approach for each NHL subtype. In several more recent retrospective series, pregnancy did not adversely influence patient outcomes when multiagent chemotherapy was administered during the second and third trimesters.^{226,230,246,271}

Treatment of Diffuse Large B-Cell Non-Hodgkin Lymphoma. Chemotherapy is the mainstay of therapy for most aggressive NHL subtypes. In nonpregnant patients with diffuse large B-cell lymphoma, three to six cycles of rituximab, cyclophosphamide, Adriamycin, vincristine, and prednisone (RCHOP regimen), with additional involved radiotherapy for early-stage or bulky NHL, is potentially curative. RCHOP has been safely administered during the second and third trimesters of pregnancy, with limited toxicity to the mother or fetus, with the exception of decreased birth weight, preterm labor, and fetal B-cell depletion.^{226,236,272,273} Rituximab, an anti-CD20 monoclonal antibody, specifically targets malignant and normal B cells bearing CD20. This agent can deplete normal B cells in treated patients for 3 to 6 months; however, this effect has not been associated with an increased incidence of infections.²⁷⁴ This same B-cell depletion is observed in infants whose mothers receive rituximab while pregnant, and the effect may persist for up to 4 months after birth with no consequent increase in infections.²⁷³

Because of the potential teratogenic effects of chemotherapy in the first trimester, combination chemotherapy with RCHOP is usually reserved until later trimesters for pregnant women with diffuse large B-cell or primary mediastinal large-cell NHL.

However, both are potentially curable malignancies, and therapy in the second and third trimesters should be considered after appropriate counseling. Deferring all therapy until after delivery can potentially compromise outcome, because these aggressive lymphomas progress quickly and the likelihood of cure decreases with advanced stages. For women with symptoms during the first trimester, palliative steroids may be administered until later stages of pregnancy, when chemotherapy administration is less risky. Radiotherapy is frequently administered after chemotherapy for women with early-stage or bulky disease, and it can be delayed until after delivery.

Treatment of Burkitt Non-Hodgkin Lymphoma. Treatment of Burkitt NHL during pregnancy is quite challenging. This malignancy is curable in up to 84% of young patients, but Burkitt lymphoma has a doubling time of 25 hours and can rapidly progress to involve the bone marrow or central nervous system, making observation until after delivery almost impossible. Alkylating agents, antimetabolites, antimicrotubule agents, and antitumor antibiotics are all incorporated into typical Burkitt lymphoma regimens, which include methotrexate, Adriamycin, cyclophosphamide, vincristine, ifosfamide, cytarabine, etoposide, and intrathecal chemotherapy.²⁶¹ Treatment with less aggressive regimens, including RCHOP, may adversely affect patient outcome. Therapy after relapse is frequently ineffective. Patients who relapse or progress during initial treatment require stem cell transplantation. Optimal and immediate treatment at diagnosis with multiagent chemotherapy is critical and potentially curative.

Although some series have reported safe administration of these multiagent regimens containing cyclophosphamide, doxorubicin, etoposide, vincristine, methotrexate, ifosfamide, and cytarabine (i.e., CODOX-M/IVAC) during pregnancy,^{226,271} such series are limited. Other physicians have recommended palliation with RCHOP until delivery, at which time aggressive, multiagent regimens can be administered.²⁷² These approaches may result in increased risk to the fetus or a increased risk of relapse for the mother.

All options, including termination of the pregnancy, must be weighed. Potential toxicities and disease outcomes must be discussed with the mother and the obstetric, oncology, and pediatric physicians. Treatment options during pregnancy for women with Burkitt NHL must be determined on an individual basis, but if the pregnancy is allowed to continue, strong consideration should be given to administration of multiagent chemotherapy with a clear understanding of the potential fetal risks associated with this approach, because this malignancy is potentially curable and can progress within days. However, because of the limited data regarding toxicities associated with these multiagent regimens, including profound and prolonged myelosuppression, termination of pregnancy is often recommended.

LEUKEMIA IN PREGNANCY

Epidemiology and Diagnosis

Acute leukemia complicates about 1 of every 75,000 pregnancies.^{212,275} Several subtypes of acute leukemia are recognized. They are separated on the basis of their cell of origin (i.e., myeloid and lymphoid) and cytogenetic abnormalities.²⁴⁵ The most commonly encountered acute leukemias during pregnancy are acute myeloid leukemia (AML), acute promyelocytic leukemia (APL), and acute lymphoid leukemia (ALL).

Presenting features include elevated white blood cell counts, neutropenia, anemia, thrombocytopenia, disseminated intravascular coagulation with associated bleeding or thrombosis (in APL), and occasionally lymphadenopathy (in ALL). The diagnosis of acute leukemia during pregnancy requires peripheral blood examination and bone marrow biopsy with flow cytometry and cytogenetic analysis.

Therapy

In a retrospective review of 37 women presenting with acute leukemia during pregnancy, the median age at diagnosis was 30 years (range, 19 to 45 years), and the gestational age at diagnosis was 23 weeks (range, 5 to 37 weeks).²⁷⁵ Twenty-four percent of patients presented during the first trimester, 27% during the second, and 49% during the third. Four (11%) of these cases were APL, 6 (16%) were ALL, and 27 (73%) were AML. In all cases, chemotherapy was initiated immediately, with therapeutic abortion recommended to those women presenting in the first trimester. Multiagent chemotherapy consisted of anthracycline (i.e., idarubicin or Adriamycin) and cytarabine for AML; anthracycline, cytarabine, and all-*trans*-retinoic acid for APL; and anthracycline, vincristine, cyclophosphamide, prednisone, and asparaginase for ALL. Ninety-two percent of the patients achieved a complete remission, and the 3-year disease-free survival rate reached 65%, which was similar to the rate for the nonpregnant population. Overall, 11 infants who were exposed to chemotherapy during the second or third trimester were delivered, and all developed normally, with no growth or developmental abnormalities or infectious complications.

A second large case series described the outcomes of 51 pregnant women diagnosed with acute leukemia between 1968 and 1986.²⁷⁶ In this series, AML accounted for 51% of cases, ALL for 33%, and APL for 8.5%, with 26% of patients presenting during the first trimester, 32% during the second, and 42% during the third. Among the 43 women diagnosed in the second or third trimester, 1 spontaneous abortion, 1 elective abortion, 2 stillbirths, 1 low-birth-weight infant, 18 premature births, and 20 term deliveries were reported. Only one congenital malformation (adherence of the iris to the cornea) occurred, and 3 of 39 infants had transient cytopenias. Among the 15 women treated during the first trimester, 3 infants had low birth weights, 7 were premature, 1 was stillborn, 2 were delivered at term, and 3 abortions occurred. One infant had esophageal atresia and anomalous inferior vena cava and eventually developed a neuroblastoma and thyroid carcinoma at age 14 years.

Fetal risk was highest with chemotherapy exposure in the first trimester; however, combination chemotherapy must be considered for pregnant patients with acute leukemia because of the likelihood of rapid disease progression and maternal complications without therapy. Potential risks from acute leukemia and its treatment during pregnancy include preterm delivery, low birth weight, disseminated intravascular coagulation, and maternal or fetal bleeding and infection due to thrombocytopenia and neutropenia.

The complete reference list is available online at www.expertconsult.com.

Renal Disorders

RAVI I. THADHANI, MD, MPH | MANISH R. MASKI, MD

A number of changes occur to renal function and overall renal physiology during pregnancy. Adaptations in normal pregnancy and alterations that occur in women with preexisting or new-onset kidney disease during pregnancy are the subject of Chapter 7. Although the outcomes for pregnant women with kidney disease and their offspring have improved, several conditions can lead to worsening kidney disease and, at times, kidney disease requiring dialysis. We begin this chapter with a brief overview of urinary tract infections, and then discuss one of the more common and devastating conditions of pregnancy that affect renal function—namely, preeclampsia and other conditions that resemble preeclampsia. We next describe acute and chronic renal disease in pregnancy, management of pregnant women receiving dialysis or with a renal allograft, and expected accompanying fetal outcomes and considerations in the management of infants born to women with kidney disease.

Urinary Tract Infection

Urinary tract infection (UTI) occurs in three forms during pregnancy: asymptomatic bacteriuria, cystitis, and pyelonephritis, the last of which is the most severe form. Although the 2% to 10% incidence of asymptomatic bacteriuria in pregnant women—defined as significant growth of a urinary bacterial isolate in the absence of symptoms—is the same as in sexually active nonpregnant women,¹ this condition more often results in ascending pyelonephritis in pregnancy. The reason for this increased risk has been attributed to the physiologic hydronephrosis and hydroureter of pregnancy, covered in detail elsewhere, as well as to the increased concentrations of amino acids and glucose in urine during pregnancy. Thus, whereas asymptomatic bacteriuria is usually benign and not treated with antibiotics in the nonpregnant state, acute pyelonephritis can result in up to 30% of pregnant women if left untreated and is associated with significant risks for morbidity and mortality for both the fetus and mother.^{2,3}

DIAGNOSIS OF URINARY TRACT INFECTIONS

The most common urinary pathogens associated with infection during pregnancy are present in the normal bowel flora. *Escherichia coli* is the primary pathogen in 65% to 80% of cases. Other pathogens include *Proteus mirabilis*, *Klebsiella pneumoniae*, *Enterobacter* species, *Staphylococcus saprophyticus*, and group B β -hemolytic streptococcus.⁴

Acute cystitis typically presents with dysuria, increased urinary frequency associated with urgency, and suprapubic discomfort. However, such symptoms may be unreliable in the latter portion of pregnancy, when many women experience increased urinary frequency, urgency, or suprapubic pressure

because of the increasing weight on the bladder from the gravid uterus. Acute pyelonephritis is typically characterized by fever and by flank pain with associated costovertebral-angle tenderness, with nausea, vomiting, and chills as common accompanying symptoms.⁵

The laboratory confirmation of any of the three forms of UTI relies on urine culture results demonstrating greater than 10^5 colony-forming units per milliliter (CFU/mL) of a single uropathogenic species. However, lower counts of bacteriuria may be significant in symptomatic women whose urine contains a slower-growing organism. In the cases of acute cystitis and pyelonephritis, urine microscopy usually reveals significant pyuria (i.e., urine leukocytes).

ASYMPTOMATIC BACTERIURIA AND CYSTITIS

As noted, asymptomatic bacteriuria in pregnancy can result in acute pyelonephritis in up to 30% of women if left untreated.^{2,3} Acute pyelonephritis, discussed in more detail later, is a serious infection that may result in significant fetal and maternal morbidity and mortality. A recent meta-analysis⁶ pooling 14 studies demonstrated that antibiotic treatment at the asymptomatic stage was effective in clearing bacteria (risk ratio [RR] = 0.25; 95% confidence interval [CI], 0.14 to 0.48) and in reducing the incidence of pyelonephritis (RR = 0.23; 95% CI, 0.13 to 0.41). Another meta-analysis of cohort studies showed that untreated asymptomatic bacteriuria in pregnancy significantly increased rates of low birth weight and preterm delivery: nonbacteriuric patients had only about two-thirds the risk (typical RR = 0.65; 95% CI, 0.57 to 0.74) of low birth weight and half the risk (RR = 0.50; 95% CI, 0.36 to 0.70) of preterm delivery compared with those with untreated asymptomatic bacteriuria.⁷

Thus, the American College of Obstetricians and Gynecologists currently supports the routine screening of pregnant women using urine dipstick, followed by urine culture when positive.⁸ Prompt empiric initiation of antibiotic therapy is warranted pending the return of culture sensitivities, which can then further guide therapy. The antibiotics considered safe in pregnancy and most often used are cephalosporins, amoxicillin, nitrofurantoin, and trimethoprim-sulfamethoxazole (although trimethoprim is contraindicated in the first trimester because of its association with neural tube defects).⁹ A recent meta-analysis that included 13 studies found that the cure rate was higher for a 4- to 7-day treatment regimen than for a 1-day regimen,¹⁰ but the optimal and cost-effective duration of therapy remains to be determined.

Women who have experienced two or more episodes of asymptomatic bacteriuria or cystitis may benefit from continued prophylactic antibiotics throughout the remainder of their pregnancy, guided by the antibiotic sensitivities of the most

recently isolated uropathogen.¹¹ Such prolonged antibiotic suppressive treatment has been shown to reduce the incidence of pyelonephritis,¹² but issues of antibiotic resistance remain a concern.

ACUTE PYELONEPHRITIS

Acute pyelonephritis is a serious infection that can lead to maternal septic shock, respiratory insufficiency secondary to pulmonary edema, disseminated intravascular coagulation, and acute kidney injury. Furthermore, acute pyelonephritis can stimulate uterine contractions and preterm labor, with considerable associated morbidity.¹³ These concerns underscore the current standard of care to both screen and treat women for asymptomatic bacteriuria.

Acute pyelonephritis is usually treated on an inpatient basis, with intravenous fluids and antibiotics. Monitoring of uterine activity and fetal heart rate may be indicated later in pregnancy. Some have advocated outpatient treatment for acute pyelonephritis in selected patients, and one randomized trial has suggested that this approach is safe and effective.¹⁴ The clinical decision clearly depends, however, on a particular patient's hemodynamic stability on presentation, ability to tolerate oral fluids, reliability to take medication as prescribed, and on the outpatient resources available for close follow-up.

Preeclampsia

Preeclampsia, a systemic syndrome of pregnancy characterized by new-onset hypertension and proteinuria after 20 weeks' gestation, affects 3% to 5% of all pregnancies and is a major cause of maternal, fetal, and neonatal morbidity and mortality worldwide.¹⁵ Preeclampsia when severe or when associated with HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome can lead to acute renal failure. However, only a minority of patients with severe preeclampsia require supportive hemodialysis for the management of acute renal failure.¹⁶ In women with severe preeclampsia and renal failure, major obstetric complications such as placental abruption are common and perinatal outcomes poor. A more extensive discussion of preeclampsia is the subject of Chapter 48.

Both glomerular filtration rate (GFR) and effective renal plasma flow decrease in preeclampsia.¹⁷ Because the decrement in filtration is less than 25%, and lower in mild cases, the GFR in women with preeclampsia often remains above values in nonpregnant women, despite morphologic evidence of ischemia and an obliterated urinary space. However, although functional decrements are usually mild or moderate and reverse rapidly after delivery, an occasional preeclamptic patient may progress to acute renal failure, especially when treatment or intervention is neglected or when there is associated severe obstetric hemorrhage. The mechanism (or mechanisms) responsible for the compromised renal function in preeclampsia may be related to renal vasoconstriction and to the glomerular endotheliosis noted on renal biopsies.

Evidence suggests that preeclampsia is primarily an endothelial disease that leads to development of hypertension, proteinuria, and progressive edema.¹⁵ Several studies have reported a strong association between altered circulating angiogenic factors and preeclampsia.¹⁸⁻²⁰ These factors include circulating antiangiogenic proteins such as soluble fms-like tyrosine kinase 1 (sFlt-1) and soluble endoglin, and the proangiogenic protein

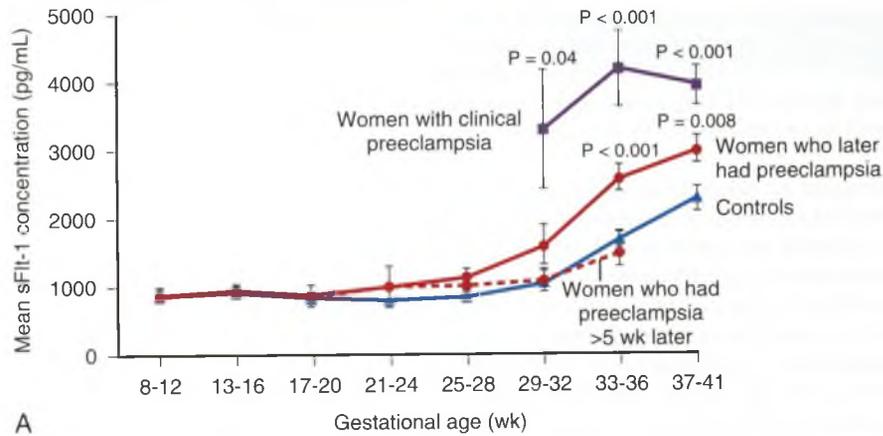

placental growth factor (PlGF). Abnormalities in these circulating angiogenic factors not only are present during clinical disease but also antedate clinical signs and symptoms by several weeks (Fig. 57-1).²¹ Levels of circulating angiogenic factors in patients with preeclampsia correlate with severe disease, including acute renal failure.¹⁸ These markers may be particularly useful in diagnosing preeclampsia in women with superimposed renal disease and in women with chronic hypertension.²² In addition, these angiogenic markers may be useful to differentiate HELLP syndrome from other causes of thrombocytopenia such as hemolytic uremic syndrome (HUS) or gestational thrombocytopenia.²³ One strategy that may neutralize or remove harmful angiogenic factors focuses on removing sFlt-1 by extracorporeal apheresis via peripheral veins, to decrease proteinuria and prolong pregnancy in patients with preterm preeclampsia.²⁴

The only current treatment for severe preeclampsia with acute renal failure is delivery of the placenta and the baby. Delivery of the placenta usually produces prompt improvement, although in a few cases, when the disease is severe and advancing rapidly, symptoms may persist and even progress for several days to weeks after delivery. Aggressive fluid challenges in women with preeclampsia are ill advised and increase the risk for pulmonary edema, because the intravascular space is small but full and leaky as a result of the widespread endothelial cell damage. Although follow-up studies in women with acute renal failure related to preeclampsia are limited, a minority of patients with the most severe renal injury will have permanent renal impairment that can progress after several years to end-stage renal disease (ESRD).²⁵

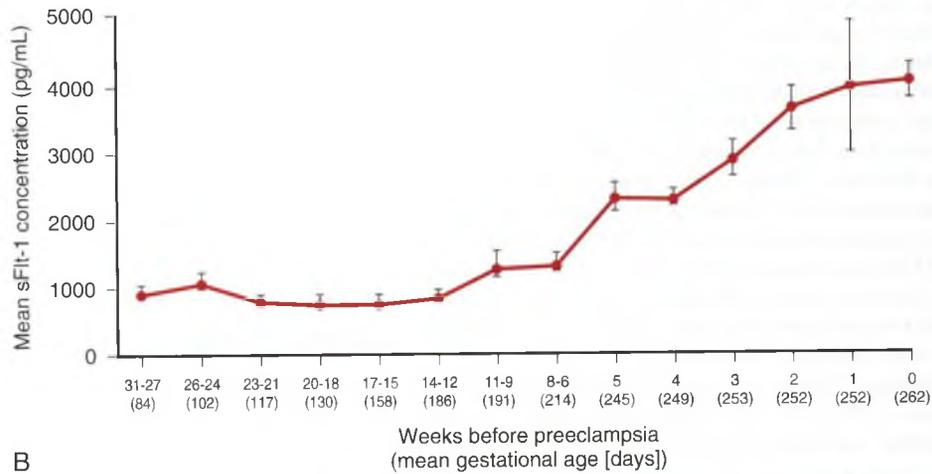

Postpartum hemorrhage may produce shock and cortical necrosis, and excessive saline infusions given to prevent acute kidney injury may trigger pulmonary edema or exacerbate hypertension. The use of nonsteroidal anti-inflammatory agents in the postpartum period should be avoided in patients with preeclampsia, as these agents can delay the resolution of renal failure and may be associated with persistent postpartum hypertension. Brief postpartum furosemide therapy for patients with severe preeclampsia has been shown to enhance recovery by normalizing blood pressure more rapidly and reducing the need for antihypertensive therapy.²⁶

PREECLAMPSIA AND FUTURE RISK OF CARDIOVASCULAR AND END-STAGE RENAL DISEASE

The signs and symptoms of preeclampsia resolve after delivery of the placenta, but women remain at high risk for future comorbidities including increased cardiovascular risk. One longitudinal study conducted in Norway described a 1.2-fold increased risk for death in women with preeclampsia compared with women without preeclampsia after a median follow-up of 13 years.²⁷ The risk was augmented to 2.7-fold in women with preterm preeclampsia, presumably because of the higher burden of disease that accompanies preterm as compared with term preeclampsia.²⁷ Moreover, the cardiovascular risk increased 8.1-fold in preterm preeclampsia compared with women without preeclampsia. A positive relationship of cardiovascular risk with disease severity was reported in another study, in which the relative risk for future cardiovascular risk over 14 years was 2 for mild, 2.99 for moderate, and 5.3 for severe preeclampsia.²⁸ Similarly, studies have linked preeclampsia with a higher risk

for other vascular diseases such as hypertension, cerebrovascular disease, venous thromboembolism, and even ESRD.^{25,29-32}

Despite the strong association between preeclampsia and vascular diseases, the exact pathophysiology remains controversial. Preeclampsia may itself cause permanent vascular injury or, alternatively, women with preeclampsia may have underlying risk factors for preeclampsia, cardiovascular disease, and ESRD. In a case-control study, women with higher blood pressures (even within normal range) and higher insulin and cholesterol levels early in pregnancy were more likely to develop preeclampsia later in that pregnancy, suggesting that derangements predisposing to hypertension, vascular disease, and renal disease preceded the preeclampsia.³³ Similarly, another study reported that more than 10% of patients with early-onset preeclampsia had previously unrecognized renal disease.³⁴ However, it is also likely that long-term renal dysfunction predisposes women to develop preeclampsia. The renal pathologic

characteristics in women with preeclampsia—endotheliosis and proteinuria—indicate acute glomerular damage. The remaining “scar” after such damage might heal incompletely, or the injury might progress in a small percentage of subjects to eventual development of chronic kidney disease.

Hemolytic Uremic Syndrome and Thrombotic Thrombocytopenic Purpura

Hemolytic uremic syndrome and thrombotic thrombocytopenic purpura (TTP) are two forms of thrombotic microangiopathy that can manifest during pregnancy. These syndromes have similar clinical presentations that include hemolytic anemia and marked thrombocytopenia, but prothrombin time, activated partial thromboplastin time, and fibrinogen levels are normal. Renal features can include renal failure, hypertension, and proteinuria. Although not universally present, additional

features that may be seen with TTP include neurologic impairment and fever, as well as involvement of other organs including the heart and intestines. TTP is characterized by an inherited or acquired deficiency in ADAMTS13, a metalloprotease that cleaves von Willebrand factor multimers to prevent formation of platelet thrombi.^{35,36}

Typical HUS is thought to result from the production of Shiga-like toxin in the setting of diarrheal illness due to *E. coli* (typically H7:O157), although associations with other bacterial infections have also been described.³⁷ By contrast, atypical HUS lacks the symptom of diarrhea and is more common in pregnancy. Atypical HUS may arise from inherited abnormalities or from acquired autoantibodies to regulators of the complement cascade. HUS or TTP is 10-fold more common in pregnant women than in the general population (occurring in up to 1 in 25,000 pregnancies); up to 10% of all patients with HUS or TTP are pregnant women,^{38,39} attributed in part to falling ADAMTS13 levels in pregnancy.⁴⁰ The risk for HUS or TTP increases as the pregnancy advances, with the majority of cases occurring either in the third trimester or after the birth.³⁹

Preeclampsia shares many similarities with HUS and TTP (Table 57-1). Both syndromes occur most frequently in the third trimester or in the immediate postpartum period and can include hypertension and proteinuria as part of the presenting syndrome. Severe preeclampsia, particularly if associated with HELLP syndrome, may be challenging to differentiate from HUS or TTP, as both can present with central nervous system changes and elevated levels of lactate dehydrogenase. Whereas HELLP and even normal pregnancy can be associated with low levels of ADAMTS13, severe deficiency (<5%) strongly suggests HUS or TTP.⁴¹ The time course after delivery may be helpful in differentiating between these syndromes, as preeclampsia typically improves with delivery, whereas HUS or TTP requires more directed therapy.⁴² However, acute renal failure associated with preeclampsia often becomes transiently worse before improving.¹⁶ Further complicating the diagnostic quandary is

the possibility that HELLP and HUS/TTP may coexist in the same patient and may even share similar underlying pathophysiological mechanisms.⁴³

MANAGEMENT OF HUS AND TTP

The mainstay of treatment for HUS and TTP is plasmapheresis, which has been associated with dramatic improvement in maternal survival. Despite this progress, HUS and TTP continue to carry a significant risk for maternal and fetal mortality.³⁹ Plasmapheresis may be helpful in removing autoantibodies to ADAMTS13, restoring depleted ADAMTS13, and clearing high-molecular-weight von Willebrand factor multimers.⁴⁴ Because of the possibility of an autoimmune etiology in many cases, corticosteroids are often used in conjunction with plasmapheresis, but the benefits have not been established in randomized trials.⁴⁵ The success of plasmapheresis in atypical HUS appears to be more limited, and there are high rates of progression to ESRD.⁴⁶ Nonetheless, in any patient with suspected HUS or TTP, plasmapheresis should be empirically used early in the clinical course, particularly in view of the limitations of diagnostic tests such as ADAMTS13.⁴⁷ Because atypical HUS and TTP are often associated with alterations in complement regulatory proteins, it is possible that agents that inhibit the complement cascade may be used to manage pregnant women with this condition.⁴⁸ The monoclonal antibody eculizumab, which binds to C5, has emerged as a promising treatment for atypical HUS and is now FDA approved for this indication.⁴⁹⁻⁵¹ Patients who develop pregnancy-associated HUS or TTP are also at risk for recurrence in subsequent pregnancies.⁵²

Acute Fatty Liver of Pregnancy

Acute fatty liver of pregnancy (AFLP) is an extremely rare complication that is estimated to occur in about 1 in 10,000 pregnancies.⁵³ These patients present with nausea and vomiting, jaundice, and abdominal pain. The histologic abnormalities consist of swollen hepatocytes filled with microvesicular fat and modest hepatocellular necrosis. A defect in fetal mitochondrial fatty acid oxidation due to mutations in the *HADHA* gene, which cause long-chain 3-hydroxyacyl CoA dehydrogenase deficiency, has been recently hypothesized as a risk factor for development of AFLP.⁵⁴ Acute renal failure can accompany AFLP in over half the patients, although the mechanism of renal failure is unclear.⁵⁵ The clinical features of AFLP may overlap with HELLP syndrome (see Table 57-1), so accurate diagnosis is critical. Management of AFLP includes early recognition, aggressive management of the coagulopathy, correction of hypoglycemia, and prompt delivery of the placenta and the fetus. The syndrome typically remits after the birth with no residual hepatic or renal impairment, although it can recur in subsequent pregnancies.

Acute Kidney Injury in Pregnancy

It has been estimated that the incidence of acute kidney injury (AKI) from obstetric causes is less than 1 in 20,000 pregnancies.⁵⁶ The most frequent cause of AKI in early pregnancy is pre-renal azotemia secondary to volume-depleting conditions, commonly hyperemesis gravidarum or nausea and vomiting associated with acute pyelonephritis. Clues to this diagnosis include a history of vomiting and physical signs of volume

depletion (e.g., orthostasis, flat neck veins, dry mucous membranes). The patient's laboratory studies may reveal an elevated blood urea nitrogen (BUN) level out of proportion to the elevation in creatinine.⁵⁷ Treatment with intravenous isotonic fluids results in normalization of renal function.

Although rare in developed countries, septic abortion remains an important clinical problem in underdeveloped countries and in those countries in which induced abortion is illegal or inadequately accessible.⁵⁸ Women with septic abortion typically present with vaginal bleeding, fever, and lower abdominal pain, usually within hours to days after the attempted abortion. AKI complicates up to 73% of cases of septic abortion,⁵⁹ and it is often characterized by anuria due to renal cortical necrosis.⁶⁰

The ovarian hyperstimulation syndrome (OHSS) can also be a cause of AKI early in pregnancy. Seen primarily in women undergoing ovulation induction with gonadotropins for infertility, OHSS results in increased vascular permeability leading to a shift of intravascular volume (third space loss) to serous spaces. Arterial vasodilation accompanies this intravascular hypovolemia,⁶¹ and in severe cases of OHSS the resultant renal hypoperfusion can lead to AKI.⁶²

Acute renal failure has been noted with accidental intravascular injection of hypertonic saline during intended intra-amniotic saline administration, with amniotic fluid embolism, and with diseases or accidents unrelated to the gestation such as drug ingestion, bacterial endocarditis, and incompatible blood transfusions.⁶³ Finally, gravidas with underlying renal disease and acute infectious pyelonephritis may be more liable to develop AKI.

The key issue in the treatment of AKI in pregnancy is restoration of fluid volume deficits, and, in later pregnancy, delivery of the baby and placenta as quickly as possible. No specific therapy has been shown to be effective in acute cortical necrosis except for dialysis when needed. Both peritoneal dialysis and hemodialysis have been used during pregnancy and are further described later.

Chronic Kidney Disease and Pregnancy

ASSESSMENT OF GLOMERULAR FILTRATION RATE

Chronic kidney disease (CKD) has classically been divided into five stages based on the GFR, as estimated by the modification of diet in renal disease (MDRD) equation. These stages were formalized in the Kidney Disease Outcomes Quality Initiative (K/DOQI) clinical practice guidelines for chronic kidney disease set forth by the National Kidney Foundation.⁶⁴ Stage 1 CKD represents kidney damage with normal or increased GFR (i.e., ≥ 90 mL/min/1.73 m²), and stages 2 through 5 represent progressively worsening GFR (Table 57-2).

Accurate estimation of the absolute value of GFR in pregnancy, however, can be quite difficult and is not usually necessary. For example, standard clearance methodologies that rely on timed urine collection are complicated by the dilated lower urinary tract in pregnancy, which can lead to a significant delay in the formation of urine compared with the collection of urine.⁶⁵ Standard equations for the estimation of GFR commonly used in nonpregnant women are also inaccurate. As noted, the MDRD equation is the most commonly used formula for the estimation of GFR; however, studies comparing GFR estimated by inulin clearance in early and late normal

TABLE 57-2 Stages of Chronic Kidney Disease

Stage	Description	Estimated GFR (mL/min/1.73 m ²)
1	Kidney damage with normal or increased GFR	≥ 90
2	Kidney damage with mildly reduced GFR	60-89
3	Moderately reduced GFR	30-59
4	Severely reduced GFR	15-29
5	End-stage renal failure	<15 or dialysis

GFR, glomerular filtration rate.

From National Kidney Foundation: *K/DOQI clinical practice guidelines for chronic kidney disease: evaluation, classification, and stratification*, Am J Kidney Dis 39(2 Suppl 1):S1-S266, 2002.

pregnancy and in pregnancies complicated by preeclampsia show that the MDRD equation significantly underestimates GFR in pregnancy and therefore cannot be recommended for use in routine clinical practice.^{66,67}

Therefore, to determine if renal function is deteriorating during pregnancy, the appropriate and typically used measurement is the change in the level of serum creatinine over the course of pregnancy. The average serum creatinine and BUN levels in pregnancy are 0.6 mg/dL (50 μ mol/L) and 9 mg/dL (3 mmol/L), respectively. Thus, a serum creatinine of 0.8 or 0.9 mg/dL, considered within normal limits in most nonpregnant adult women, should be further investigated for causes of kidney injury in pregnancy. In gravidas with established CKD, failure of the serum creatinine level to decrease from its baseline value as would be expected in pregnancy (and certainly any increase above baseline) suggests worsening renal function that requires further evaluation.

EFFECT OF PREGNANCY ON CHRONIC KIDNEY DISEASE PROGRESSION

Stages 1 and 2 Chronic Kidney Disease

Women with stages 1 and 2 CKD, in general, have successful pregnancies and do not have a worsened renal prognosis,⁶⁸ as long as blood pressure is well controlled and proteinuria is minimal. For example, one study analyzed data on 360 women with chronic glomerulonephritis and normal renal function over a 30-year period: 171 became pregnant and 189 did not.⁶⁹ After an average of 15 years (and as long as 30 years) of follow-up, no difference in the development of end-stage renal failure was noted between the two groups.

Stages 3 through 5 Chronic Kidney Disease

Unfortunately, the renal outlook for patients with stages 3 through 5 CKD is not as favorable. One of the largest studies examining renal outcomes in pregnant women with CKD was published in 1996 and included 82 pregnancies in 67 women with primary renal disease and a serum creatinine level of 1.4 mg/dL or greater, either before conception or in the first trimester.⁷⁰ Among these pregnancies, GFR was stable throughout pregnancy and to 6 months postpartum in 51%, it declined but returned to pre-pregnancy levels in 8%, it declined and persisted lower at 6 months in 31%, and it declined between 6 weeks postpartum and 6 months postpartum in 10%. The

likelihood of accelerated decline in renal function was greater in women whose first measured serum creatinine exceeded 2.0 mg/dL. Only 1 in 49 women with a serum creatinine level of 1.4 to 1.9 mg/dL experienced an accelerated decline, as opposed to 7 of 21 pregnancies in women with a baseline serum creatinine level of 2.0 mg/dL or greater. Eight women from the entire group progressed to ESRD within 1 year of pregnancy.

A more recent study of 49 women with a mean serum creatinine level of 2.1 mg/dL and mean GFR of 35 mL/min/1.73 m² at the time of conception demonstrated that the combined presence of a baseline GFR of less than 40 mL/min/1.73 m² and proteinuria of greater than 1 g/day predicted accelerated loss of GFR after delivery compared with before conception.⁷¹ The presence of both risk factors also predicted a shorter time to reducing GFR by one half, or the need to initiate dialysis.

Problems Associated with Specific Diseases of the Kidney

ACUTE AND CHRONIC GLOMERULONEPHRITIS

Acute glomerulonephritis may occur during any trimester of pregnancy; however, acute glomerulonephritis occurring for the first time during pregnancy is a very rare complication, with a reported incidence of approximately 0.05%.⁷² The clinical features of glomerulonephritis include hypertension and edema; thus, this condition may be difficult to distinguish from preeclampsia. Other features of acute glomerulonephritis may include fever and weight loss (especially if vasculitis is present), which are generally absent in patients with preeclampsia. Dysmorphic red blood cells or red blood cell casts in urine, which are characteristic of acute glomerulonephritis, further help in the differential diagnosis.

Although all categories of acute glomerulonephritis (anti-glomerular basement membrane antibody disease, immune

complex-mediated disease, and pauci-immune disease) have been reported in pregnancy, the most common reported pathology in pregnancy is IgA nephropathy.⁶⁸ Renal biopsy in pregnant patients remains challenging and is generally pursued only in cases of rapidly progressing glomerulonephritis or if accompanied by severe nephrotic syndrome before 32 weeks' gestation. Nevertheless, early in pregnancy, a renal biopsy may distinguish IgA nephropathy, for example, from preeclampsia, with which it is often confused (Fig. 57-2).

Biopsy after 32 weeks is not recommended, because beyond that, attaining a prone position becomes difficult for most patients. Studies on primary glomerulonephritis in pregnancy generally report that most of the pregnant patients had normal to nearly normal renal function,⁷³⁻⁷⁵ and fetal outcomes can be predicted by severity of hypertension, degree of proteinuria, and impairment of renal function.⁶⁸ Although the impact of pregnancy on glomerular disease progression has long been debated, the currently held view suggests that pregnancy does not influence the natural course of glomerulonephritis.⁷⁶ Treatment of glomerulonephritis in pregnancy should take into account the maternal and fetal effects of immunosuppressive agents. Corticosteroids and azathioprine are probably safer than cyclophosphamide and mycophenolate, which should be avoided unless absolutely necessary. In addition, close monitoring is needed, with a focus on blood pressure control and fluid balance.

NEPHROTIC SYNDROME

Nephrotic syndrome is characterized by the tetrad of edema, hypoalbuminemia (<3.0 g/dL), heavy proteinuria (generally >3.5 g/day), and hyperlipidemia. Although any of the conditions that can cause nephrotic syndrome in a nonpregnant adult patient may cause nephrotic syndrome in a pregnant woman (e.g., focal segmental glomerulosclerosis, IgA

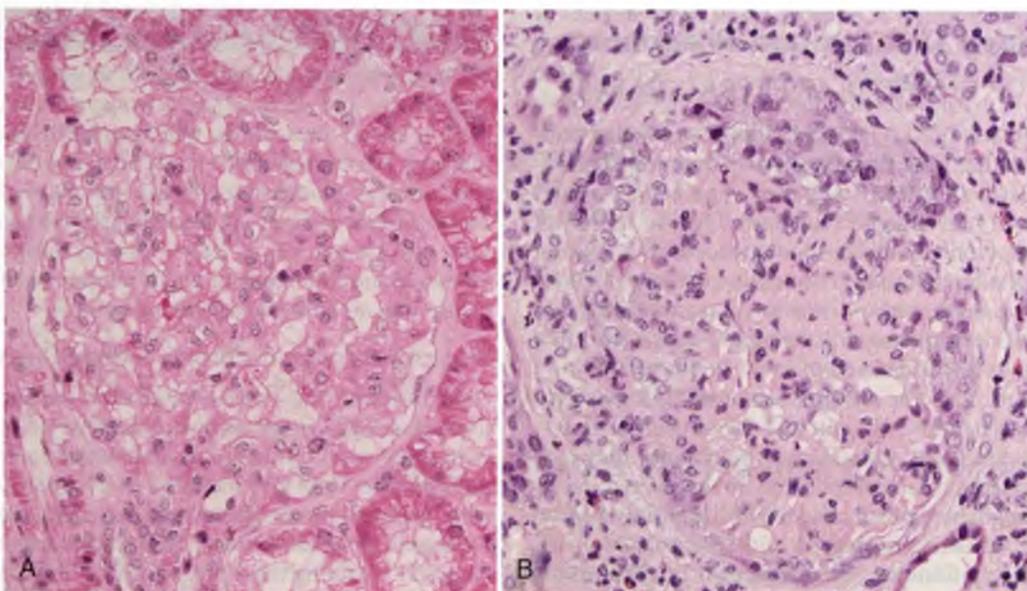

Figure 57-2 Renal biopsies of women with preeclampsia and IgA nephropathy. A, Biopsy for nephrotic-range proteinuria in a pregnant woman: glomerular endotheliosis (swelling of endothelial cells) indicates preeclampsia. B, Biopsy for nephrotic-range proteinuria at 17 weeks of pregnancy: sclerosing crescentic IgA (endocapillary and extracapillary proliferation) nephropathy. H&E, $\times 40$. (Courtesy of Isaac Stillman MD, Department of Pathology and Division of Nephrology, Beth Israel Deaconess Medical Center and Harvard Medical School.)

nephropathy, diabetes mellitus, systemic lupus erythematosus, hepatitis C, hepatitis B, human immunodeficiency virus infection, nonsteroidal anti-inflammatory medications), the most common cause of new-onset nephrotic syndrome in a pregnant patient remains preeclampsia.⁷⁷

Clues to the underlying etiology of nephrotic syndrome may be gathered from a careful history and physical examination (e.g., uncontrolled diabetes mellitus will suggest diabetic nephropathy), but when the etiology remains unclear, renal biopsy is required. This is especially important if the suspected diagnosis has definitive treatment options available. If indicated, renal biopsy should be performed before 32 weeks of gestation (as noted earlier).⁷⁸ The treatment of nephrotic syndrome in pregnancy includes measures to control edema such as salt restriction (with diuretics reserved for intractable cases of edema only), and management of the underlying condition. Pregnancy outcomes are generally good in the absence of hypertension and renal impairment.⁷⁹

DIABETIC NEPHROPATHY IN PREGNANCY

The incidence of diabetic nephropathy in pregnancy is likely to rise with the increasing prevalence of diabetes in women of childbearing age.⁸⁰ In patients with diabetes, there are several well-characterized sequential stages of renal dysfunction, and women with diabetes can be categorized into three groups: (1) those with preserved GFR and normal microalbuminuria (urinary albumin excretion of <20 mg/day); (2) those with preserved GFR and microalbuminuria (urinary albumin excretion of 30 to 300 mg/day); and (3) those with overt nephropathy (>300 mg of urinary albumin excretion per day).⁸¹ Once overt nephropathy develops, there is often a progressive decline in renal function, which, for many, culminates in ESRD. It is worth noting that diabetic women without microalbuminuria or elevated serum creatinine may have subclinical renal dysfunction.⁸¹ There is considerable evidence in nonpregnant individuals suggesting that control of blood sugar, control of hypertension, and therapy with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) can slow or halt the progression of diabetic renal disease.⁸²⁻⁹⁰ Unfortunately, both ACE inhibitors and ARBs are generally contraindicated in pregnancy because of their effects on the fetus.

Women with overt nephropathy are at risk for decline of renal function during pregnancy.⁹¹⁻⁹³ Whether this represents the natural course of their disease or a pregnancy-induced acceleration in renal deterioration remains to be shown. Several studies have attempted to identify prognostic factors that increase the risk for deterioration of renal function in women with overt diabetic nephropathy. Generally, the more severe the disease and the earlier it is manifest during pregnancy, the poorer the prognosis is. Creatinine clearance (GFR) less than 70 mL/min before pregnancy, creatinine clearance less than 90 mL/min before 20 weeks' gestation, urinary protein excretion greater than 1 g/day before 20 weeks' gestation, serum creatinine greater than 1.4 mg/dL, and failure to demonstrate an increase in GFR during the first and second trimesters have all been linked to an increased risk for the permanent decline of renal function during pregnancy.⁹¹⁻⁹³ Worsening hypertension and superimposed preeclampsia may play a role in the decline of renal function in these women. Appropriate counseling describing the risk for permanent renal deterioration during pregnancy should be conducted in women who have these risk factors.

Among women without overt nephropathy, pregnancy has not been shown to have a negative effect on the emergence and long-term progression of renal disease in those with diabetes. In the Diabetes Control and Complications Trial, whose study population consisted largely of subjects without nephropathy or microalbuminuria at baseline, women who had pregnancies during the follow-up period were no more likely to develop microalbuminuria or overt nephropathy than women who did not have pregnancies.⁹⁴ Three smaller studies also did not demonstrate any effect of pregnancy on the rate of decline in renal function or the progression of diabetic renal disease.⁹⁵⁻⁹⁷ However, diabetic women without overt nephropathy who develop preeclampsia may be more likely to develop nephropathy and ESRD in the future.^{98,99}

Pregnancy tends to promote proteinuria in all women, no matter the degree of antecedent renal dysfunction or albuminuria.¹⁰⁰⁻¹⁰³ Women with pregestational diabetes but without evidence of microalbuminuria before pregnancy may develop an exaggerated pregnancy-induced increase in protein excretion, which in many cases exceeds the 300 mg/day threshold otherwise considered normal.^{104,105} Pregnancy, by causing superimposed proteinuria, may unveil otherwise undetectable glomerular dysfunction in these women by leading them to exceed the maximum tubular reabsorption capacity for protein. In women with microalbuminuria that precedes the pregnancy, urinary protein excretion may increase 10-fold, with 20% to 30% of patients developing nephrotic-range proteinuria (>3.5 g/day) or nephrotic syndrome (or both).^{104,106-108} As in normo-albuminuric women, proteinuria usually resolves to pre-pregnancy levels in both women with microalbuminuria and women with overt diabetic nephropathy before pregnancy.^{104,105,108} The existence of exaggerated gestational proteinuria in women with pregestational diabetes is of interest clinically primarily because it substantially complicates the diagnosis of preeclampsia in these women.

Hypertension is a common complication of pregnancies in which the mother has diabetic nephropathy. Guidelines on the management of blood pressure in nonpregnant patients with diabetes cite a target blood pressure of 130/80 mm Hg in patients without evidence of renal dysfunction, and 125/75 mm Hg in patients with greater than 1 g/day of proteinuria or compromised renal function.¹⁰⁹ Blood pressure management in nonpregnant patients with diabetes should always include either an ACE inhibitor or ARB to reduce intraglomerular pressure and prevent the progression of diabetic renal disease. The blood pressure values targeted in nonpregnant patients with diabetes are much lower than blood pressure values typically targeted with medications in pregnant women (<160/100 mm Hg).¹¹⁰ Unfortunately, it is possible that the optimal maternal blood pressure for placental perfusion and fetal outcomes differs from the blood pressure that best protects the maternal kidneys from further damage. Thus, clinicians must balance the risk for maternal end-organ damage with the risk for inadequate placental perfusion. The American College of Obstetricians and Gynecologists recommends treating women with hypertension and evidence of end-organ damage, targeting blood pressures in the normal range.¹¹⁰ Observational studies demonstrate an association between poorly controlled blood pressures in early pregnancy and risk for adverse perinatal outcomes.¹¹¹ One center's experience suggests improved perinatal and maternal renal outcomes with initiation of hypertensive therapy targeting a blood pressure of less than

135/85 mm Hg and urinary albumin excretion of less than 300 mg/day,¹¹² but because of evidence in nondiabetic women suggesting inadequate placental perfusion with blood pressure targets in this range,^{113,114} no formal recommendation can be made regarding optimal blood pressure during pregnancy in women with diabetic nephropathy. ACE inhibitor and related medications that block the renin-angiotensin cascade, although a mainstay of therapy in diabetic nephropathy, are contraindicated in pregnancy because of the risk for congenital malformations in the first trimester, and because of the risk for fetal or neonatal renal failure or death in late pregnancy.^{115,116} Although the evidence base is modest, resulting in no compelling consensus, we recommend starting with labetalol and adding nifedipine, if needed, to control blood pressure in these patients.

Diabetic nephropathy is associated with a variety of perinatal complications. The high risk for complications once made pregnancy in this group contraindicated. Fortunately, outcomes have improved over time with advances in maternal and neonatal care. One larger case series on perinatal outcomes in women with diabetic nephropathy ($N = 45$) suggests that perinatal survival nears 100% despite substantial risk for preeclampsia (53%), cesarean delivery (80%), fetal growth restriction (11%), and preterm delivery at less than 36 weeks (51%).¹¹⁷ Of note, the risk for preeclampsia, lower neonatal birth weight, and preterm delivery was greater in women with serum creatinine greater than 1.5 mg/dL or proteinuria greater than 1 g/day before 20 weeks' gestation, or both.¹¹⁷ These complication rates are equal to or slightly better than those reported from similar case series published within the last 30 years.^{107,112,117-122} However, in one 20-year-old case series of women with more severe renal dysfunction before pregnancy (creatinine clearance <80 mL/min, and proteinuria >2 g/day), neonatal death occurred in two of five pregnancies studied,⁹¹ emphasizing that the degree of renal dysfunction at baseline is likely to be associated with a risk for perinatal complications.

LUPUS NEPHRITIS

Pregnancy increases the likelihood of lupus flare¹²³; however, these flares are not typically more severe than in nonpregnant patients. Although pregnancy per se does not increase the risk for lupus nephritis in a patient with preexisting lupus, lupus nephritis may appear during any trimester in pregnancy.¹²⁴ In general, lupus flares (either renal or extrarenal) have been reported in approximately 60% of lupus patients and are quite evenly distributed across all trimesters.^{124,125} Both lupus nephritis and antiphospholipid antibodies increase the risk for premature birth and maternal hypertension.¹²⁶ Although signs and symptoms of systemic lupus erythematosus may resemble those of preeclampsia, their histologic features on renal biopsy are quite distinct.

Management of lupus nephritis in this setting requires a multidisciplinary approach and remains a challenging task. First-line therapies include pulsed doses of corticosteroids or azathioprine, or both.¹²⁷ However, in severe cases, therapeutic termination and treatment with cyclophosphamide and mycophenolate mofetil (MMF) may be required to save the mother's life.^{127,128} Management of pregnant women with antiphospholipid antibody syndrome remains controversial. A recent meta-analysis of randomized controlled trials on this topic noted that a combination of unfractionated heparin and aspirin confers a significant benefit in live births.¹²⁹

GRANULOMATOSIS WITH POLYANGIITIS

Granulomatosis with polyangiitis (GPA) (formerly known as Wegener's granulomatosis) is an antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis of unclear etiology that predominantly shows involvement of respiratory tract and kidneys. Pregnancy in a patient with GPA is considered high risk because it has been associated with various complications including prematurity. About 40 cases of GPA in pregnancy have been reported in the literature.^{130,131} In 60% of cases, the disease was in remission at the beginning of pregnancy; in 30% of cases, the diagnosis was first established during pregnancy; and in the remaining cases, the disease was active at the beginning of pregnancy.¹³⁰ Because of this rarity, its management is individualized and the pregnancy outcome is variable. As with active disease in nonpregnant patients, prednisone alone is relatively ineffective, particularly for moderate to severe disease, and although remission can be induced by combined therapy with cyclophosphamide or MMF, this approach remains challenging because of the fetal risks.¹³²⁻¹³⁴ Cyclosporine and azathioprine may be safer options to consider, particularly in cases of mild disease.

POLYARTERITIS NODOSA

Polyarteritis nodosa (PAN), a medium-vessel vasculitis commonly associated with hepatitis B coinfection, is uncommon in pregnancy. Like other forms of vasculitis, PAN can be associated with hypertension, abdominal pain, weight loss, and proteinuria.^{131,135,136} A recent case series reported four cases of PAN in pregnant women, including one cutaneous form.¹³¹ In one case, the PAN was complicated by rupture of pancreatic artery microaneurysms during pregnancy; however, other cases did not show any flare during pregnancy.

SYSTEMIC SCLEROSIS

Systemic sclerosis is a rare disease characterized by circulation abnormalities (such as Raynaud's phenomenon) and abnormalities in multiple organ systems, including kidneys.¹³⁷ The effects of systemic sclerosis on pregnancy outcome remain unclear at this time; however, data are accumulating that suggest that patients with systemic sclerosis have more premature births and small-for-gestational-age (SGA) infants.¹³⁸ ACE inhibitors, which are the cornerstone of treatment for sclerodermal renal crisis, are contraindicated in pregnancy. Thus, management consists of intensive medical support, including dialysis.¹³⁹

REFLUX NEPHROPATHY

Reflux nephropathy is a relatively common condition in women of childbearing age. Many patients with reflux nephropathy may be asymptomatic, and it can be an incidental finding during regular pregnancy screens.¹⁴⁰ However, the impact of reflux nephropathy on both maternal and fetal health can be serious, with complications that include preeclampsia, worsening of renal function, and fetal loss.¹⁴¹ In pregnant patients with reflux nephropathy, urinary tract infections contribute to frequent morbidity, and studies report that acute pyelonephritis episodes occur more commonly in patients in whom

vesicoureteral reflux is still present at the time of conception, compared with patients who have undergone surgical correction before becoming pregnant.^{68,142}

Pre-pregnancy renal function and hypertension are significant predictors of pregnancy outcome in this setting. Pregnancy is most often successful when renal function is normal or near normal and hypertension is absent at conception.¹⁴¹ Fetal outcomes are also governed by the degree of renal impairment and the presence of significant first-trimester hypertension.¹⁴¹ Pregnant women with reflux nephropathy and diminished renal function require careful coordinated nephrologic and obstetric care so that complications can be immediately diagnosed and treated, and hypertension can be optimally controlled.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

It is not uncommon for patients with autosomal dominant polycystic kidney disease (ADPKD) to be entirely asymptomatic, with normal blood pressure and preserved renal function.^{143,144} For these normotensive patients with intact renal function, the pregnancy outcomes are favorable.¹⁴⁵ Pregnant women with ADPKD who are hypertensive are at high risk for preeclampsia as well as fetal complications such as prematurity.¹⁴⁵ These pregnancies need close monitoring for signs of uteroplacental insufficiency, such as intrauterine growth restriction (IUGR) and oligohydramnios.¹⁴⁶ Because the fetus of a parent with ADPKD has a 50% risk of being affected, a second-trimester prenatal ultrasound examination is indicated; moreover, all parents with ADPKD should undergo genetic counseling.¹⁴⁶ Because patients with ADPKD are at risk for intracranial aneurysms, those with a family history of intracranial aneurysms should undergo brain magnetic resonance imaging before conception to screen for such an aneurysm and correct it before pregnancy.⁶⁸

UROLITHIASIS

Symptomatic urolithiasis occurs with an incidence of one in every 1500 pregnancies, with 80% of cases occurring in the second and third trimesters.¹⁴⁷ The main signs and symptoms are flank pain (90%), hematuria (75% to 95%), gross hematuria (22% to 25%), and pyuria (40%).^{147,148} Most calculi are formed from calcium phosphate (~74%) and calcium oxalate (~26%).¹⁴⁹ Struvite (i.e., magnesium ammonium phosphate) stones also can occur, but they are much less common. Renal plasma flow increases during pregnancy, causing higher calcium excretion and an increase in urinary pH, but urine volume remains constant throughout pregnancy.¹⁵⁰ Urolithiasis incidence is similar in pregnant and nonpregnant women of childbearing age despite the hypercalciuria of pregnancy, possibly because of the concomitant increase in filtration of magnesium and other protecting substances during pregnancy.¹⁵¹

When urolithiasis is suspected, renal and pelvic ultrasounds, with sensitivities on the order of 60%, are the diagnostic studies of choice to avoid radiation exposure.^{147,152} Despite a negative sonographic evaluation, the patient may be treated for urolithiasis if clinical suspicion is high. If further diagnostic tests are needed, magnetic resonance urography should be considered. Low-dosage computer tomography has high sensitivity and specificity with relatively low risk for fetal harm, but it should be considered only if other measures are inconclusive.¹⁵³ Finally,

a limited intravenous pyelogram in a single abdominal radiograph after 5 minutes of intravenous contrast administration is another diagnostic option.¹⁴⁷

A conservative approach to treatment, including hydration, lying on the nonaffected side to relieve pressure, adequate antibiotic therapy, and pain management, is appropriate in most cases, as up to 75% to 80% of stones pass spontaneously as a result of the dilated state of the ureter in pregnancy.¹⁴⁷ The safest pain medication in pregnancy is acetaminophen, but epidural block has been used.¹⁵⁴ When sepsis, severe refractory pain, or obstruction develop in a single functioning kidney, further therapy such as cystoscopy with stent or nephrostomy tube placement is indicated.^{155,156} Use of an ultrasound-guided percutaneous nephrostomy tube is the preferred treatment for hydronephrosis, as this procedure is rapid and requires minimal local anesthesia and no radiation. Shock wave lithotripsy is contraindicated during pregnancy, although one small case series reported no adverse effects in six patients.¹⁵⁷

SOLITARY KIDNEY

Reasons for solitary kidney include either congenital absence or prior unilateral nephrectomy for conditions such as tumor or infection. In most patients, solitary kidney is an incidental finding when imaging is performed for another indication. Rarely, the gravid uterus may compress the unilateral ureter, leading to obstructive uropathy. Decompression of the ureter may be corrected by having the patient lie in an appropriate lateral position.¹⁵⁸

FETAL OUTCOMES IN THE PRESENCE OF CHRONIC KIDNEY DISEASE

Perinatal complications such as preterm labor, preeclampsia, SGA infants, and stillbirths are increased for all five stages of CKD, with risk increasing in parallel with the worsening degree of CKD.

With mild renal insufficiency, several authors report that pregnancies result in live births approximately 95% of the time^{159,160}; however, this was with an associated preterm delivery rate of 20% and an SGA birth weight rate of 24%. Preeclampsia is usually the indication for preterm delivery and has been diagnosed in 10% of reported pregnancies complicated by mild renal insufficiency.¹⁶⁰

Among women with a baseline serum creatinine level of 1.4 mg/dL or greater, the risk for prematurity is greatly increased, to 59% compared with a rate of 10% among the general population.^{70,161} Again, this increased rate of prematurity is largely secondary to intervention for preeclampsia and IUGR. In women with a serum creatinine level of 2.5 mg/dL or greater, the rate of preterm delivery is as high as 86%.¹⁶²

ANTENATAL COUNSELING AND CLINICAL STRATEGY

Because of the very real potential for worsening maternal renal function and the perinatal complications associated with maternal CKD, it is the clinician's responsibility to discuss these risks with such patients before conception. This will better allow women with CKD to make an informed decision regarding attempting pregnancy, and it will allow the development of a clinical evaluation and management plan after pregnancy

occurs. If unplanned pregnancy occurs, the discussion of these risks as soon as pregnancy is detected will help a woman with CKD to decide whether to continue the gestation.

Some clinicians advocate that pregnancy be avoided in women with a serum creatinine level of 1.4 mg/dL or greater, particularly if it is associated with difficult-to-control hypertension or significant proteinuria. Others use a serum creatinine level of 2.0 mg/dL as the level at which pregnancy is not recommended. Rather than focusing on specific cutoffs as the basis for a recommendation for or against pregnancy, each patient's decision to attempt (or to continue) a pregnancy must be individualized, and the ultimate choice resides with the patient. Particular considerations applicable to specific kidney diseases are discussed in more detail in this text, but in general, the following components should be part of the antenatal care plan.

FREQUENCY OF FOLLOW-UP DURING GESTATION

Pregnant women with CKD should be managed jointly by a nephrologist and an obstetrician-gynecologist who are familiar with the multiple interactions between renal disease and pregnancy. The frequency of prenatal visits should be determined by the degree of concern for deterioration in blood pressure control, renal function, and decreased fetal growth, with obstetric visits weekly during the third trimester. Monthly nephrology visits are appropriate, but the frequency may need to be increased if the patient's clinical status is changing with regard to blood pressure, renal function, or degree of proteinuria.

Blood Pressure Management

The choice of antihypertensive medications (discussed in detail elsewhere in this text) in pregnancy is very different from that in nonpregnant patients. Most notable is the contraindication of ACE inhibitors and ARBs in pregnancy, although these classes of medications are a staple in the management of CKD in nonpregnant women. Both classes of medications have been associated with impairment in fetal renal development and oligohydramnios, which can result in pulmonary hypoplasia and neonatal death as a result of respiratory failure.¹⁶³ Although first-trimester exposure to these classes of medications was not originally associated with an increased risk for fetal adverse events or congenital abnormalities,¹⁶⁴ more recent data suggest that these agents are not safe, even in early pregnancy.¹¹⁶ This 2006 epidemiologic study compared 209 infants exposed to ACE inhibitors in the first trimester and revealed an increase in the risk for major congenital malformations compared with infants exposed to no antihypertensive medications (RR = 2.7; 95% CI, 1.7 to 4.3; malformation rate, 7.1% versus 2.6%). The congenital anomalies with the highest relative risk were cardiovascular and central nervous system malformations.

Blood pressure in pregnant women should be closely monitored at every prenatal visit. Sudden appearance of hypertension after 20 weeks' gestation may indicate the development of preeclampsia, particularly if associated with either new-onset proteinuria or worsening of the patient's baseline proteinuria.

If preeclampsia is suspected, the goals of blood pressure management are considerably different from those in the nonpregnant population. Instead of seeking to minimize long-term cardiovascular complications, the primary goal is to maximize the likelihood of successful delivery of a healthy infant while minimizing the chance of acute maternal complications. Aggressive treatment of hypertension in pregnancy can compromise

placental blood flow and restrict fetal growth. For example, one meta-analysis demonstrated that treatment of mild to moderate hypertension in pregnancy was associated with an increased risk for SGA infants.¹¹⁴ Thus, antihypertensive therapy for preeclampsia is usually withheld unless the blood pressure rises above 150 to 160 mm Hg systolic or 100 to 110 mm Hg diastolic, above which the risk for maternal cerebral hemorrhage becomes significant.¹⁶⁵ Both the American College of Obstetricians and Gynecologists and the U.S. Preventive Services Task Force recommend the use of low-dosage aspirin for prevention of preeclampsia in high-risk women.^{166,167} Antiplatelet agents (e.g., aspirin) for preeclampsia prevention are discussed in further Chapters 40, 47, and 48.

Additional Management Principles

Monitoring for asymptomatic bacteriuria should be performed in pregnant women with CKD, as in all pregnant women, and promptly treated if discovered.

In addition to monitoring serum creatinine concentration at least monthly, proteinuria should be regularly assessed. Twenty-four-hour urine collection has been traditionally used for determination of the degree of proteinuria, but a protein-to-creatinine ratio in spot urine specimens has been shown to strongly correlate with 24-hour urine protein excretion in pregnancy.^{168,169} The spot urine protein-to-creatinine ratio has been routinely used in the nephrology community for years and probably should be more widely used in the obstetrics community.

Some clinicians advocate routine monitoring of the complete blood count and liver function tests for evidence of developing HELLP syndrome. Uric acid, which is elevated in preeclampsia primarily as a result of increased renal tubular urate absorption, may be a useful marker for the prediction of preeclampsia in women with CKD. In such patients, the criteria of new-onset hypertension and proteinuria are often impossible to apply, and a serum uric acid level greater than 5.5 mg/dL in the presence of stable creatinine can suggest superimposed preeclampsia.

Fetal surveillance for evidence of uteroplacental insufficiency with periodic ultrasound examinations for fetal growth may be supplemented with fetal heart rate monitoring as necessary to be assured of fetal well-being. Preterm delivery may be necessary for IUGR or nonreassuring results from fetal testing.

POSTPARTUM CARE AND FOLLOW-UP

Women with CKD should be followed closely in the postpartum period. Renal function and proteinuria should be measured routinely to evaluate whether resolution or potential worsening of these parameters has occurred. In women with preeclampsia superimposed on CKD, it may take up to 8 weeks for renal function and proteinuria to return to baseline values.

Blood pressure should be carefully followed and treated with appropriate medications to pre-pregnancy goals for patients with CKD. The ACE inhibitors captopril and enalapril have been reviewed by the American Academy of Pediatrics and deemed compatible with breastfeeding, but very low levels of these medications are present in breast milk and the infant may be susceptible to the hemodynamic effects of these medications.

Dialysis Patients and Pregnancy

End-stage renal disease in women of childbearing age is often accompanied by menstrual disturbances, anovulation, sexual

dysfunction, and infertility. Pregnancy in women on dialysis is therefore rare. However, despite these many disturbances, successful conception and delivery have been described in patients on chronic hemodialysis or on peritoneal dialysis. The frequency of pregnancies in women of childbearing age who are on dialysis is reportedly on the rise, increasing from a historic low of less than 1%, to 7% or even greater in recent reports from across the globe.¹⁷⁰⁻¹⁷² Whether this reflects improvements in dialysis and anemia management or publication bias is not clear.¹⁷³ What is clear, however, is that dialysis and pregnancy pose increased risks to both maternal and fetal health and thus require special consideration.

COUNSELING AND EARLY PREGNANCY ASSESSMENT

Because conception on dialysis is possible, albeit uncommon, women of childbearing age who are on dialysis ought to be counseled regarding the use of contraception should they not wish to become pregnant. For individuals on dialysis who desire and are considering pregnancy, the risks of such a decision should be explained. The conversation with the patient should include discussion about the increased risk for polyhydramnios, intrauterine growth restriction, preterm labor, and preeclampsia (Table 57-3).^{172,174}

Even when therapeutic termination of a pregnancy is excluded, there is generally only a 40% to 50% likelihood of successful infant survival, with better rates noted in patients who started dialysis after becoming pregnant and who receive intensive dialysis (up to 80% likelihood of infant survival in the latter scenario as reported from small case series) (see Table 57-3).¹⁷⁵⁻¹⁷⁹ Given the overall poor outcomes, many women may be better advised to wait until successful renal transplant can occur before considering conception. In the absence of a potential donor, however, many women do not have the option of a transplantation during their fertile years, and the management of pregnancy in the dialysis patient continues to remain relevant.

Adverse fetal outcomes are attributed to a number of ESRD-specific problems encountered by the pregnant patient.^{176,180} For example, polyhydramnios may result from fetal solute diuresis caused by a high placental BUN concentration. Surprisingly, some investigators have reported that fetal outcomes were better in the presence of polyhydramnios, possibly because this condition is evidence of adequate placental function.¹⁸¹ Shifts in acute fluid volume, electrolyte imbalance, and hypotension during hemodialysis impair the uteroplacental circulation.¹⁸⁰

TABLE 57-3 Estimates for Pregnancy Complications and Outcomes in Dialysis Patients

Pregnancy Complication	Estimate*
Polyhydramnios	33%-62%
Maternal hypertension	42%-80%
Cesarean section deliveries	46%-53%
Preterm delivery	85%
Average gestational age at delivery	32 weeks
INFANT SURVIVAL OUTCOME	
Conceived on dialysis	40%-50%
Conceived before dialysis	75%-80%

*Estimated from references cited in text.

Maternal hypertension and premature rupture of the fetal membranes are often implicated as a cause of premature delivery.¹⁸⁰

Because pregnancy in the dialysis patient is rare, it often surprises both patients and providers. Initially, pregnancy may become evident only by clinical features such as worsening anemia despite previously stable erythropoietin dosages or missed menstrual periods, which are relatively common in women with ESRD. Because β -human chorionic gonadotropin (β -hCG) is produced by somatic cells and excreted by the kidneys, its levels can increase in patients with ESRD even in the absence of pregnancy. Thus, suspected pregnancy in a woman with ESRD and elevated β -hCG should be verified with ultrasonography to determine the gestational age.

ANTENATAL CARE AND DIALYSIS

When pregnancy does occur in a woman on chronic dialysis, significant changes in dialysis management are required. Successful outcomes demand meticulous attention to ensure dialysis adequacy, fluid balance, blood pressure control, and optimal nutrition. This is best achieved using a multidisciplinary approach involving an experienced nephrologist, an obstetrician familiar with high-risk patients, a dialysis nurse, and a nutritionist (Table 57-4).¹⁷⁹

DIALYSIS ADEQUACY

It is now accepted that a longer duration of dialysis results in a longer gestation period and thus a higher birth weight, an

TABLE 57-4 Summary of Management Principles for the Pregnant Patient on Dialysis

Dialysis	If on hemodialysis, increase to at least 20 hr/wk If on peritoneal dialysis, increase exchange frequency and use lower exchange volumes Target blood urea nitrogen (BUN) to <50 mg/dL
Vitamins, minerals, nutrition	1-2 multivitamins daily Folate 1-5 mg daily 1.5-1.8 g protein/kg/day Calcium and phosphorus supplements or dialysate adjustments as indicated by weekly laboratory results Check 25-OH vitamin D every trimester; supplement if levels are low
Anemia	Replete iron stores Increase erythropoietin dosage to target hemoglobin to 10-11 g/L
Hypertension and volume	Target postdialysis blood pressure to <140/90 mm Hg Adjust estimated dry weight and ultrafiltration goals to account for normal weight gains of pregnancy (frequent volume assessment) Diuretics, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin II receptor blockers (ARBs) should be avoided

Information summarized from Giatras I, Levy DP, Malone FD, et al: Pregnancy during dialysis: case report and management guidelines, *Nephrol Dial Transplant* 13:3266-3272, 1998; and Hou S: Modification of dialysis regimens for pregnancy, *Int J Artif Organs* 25:823-826, 2002.

improved life expectancy, and fewer long-term complications.^{174,182,183} Current guidelines recommend increasing the weekly dialysis regimen to 20 or more hours per week and targeting the predialysis serum urea level to at least less than 50 mg/dL.^{68,174,184} Daily or long nocturnal dialysis¹⁸⁵ sessions provide the most realistic chance of achieving these goals. For example, one group used nocturnal home hemodialysis to provide intensified clearance after conception.¹⁸⁶ The amount of hemodialysis was increased from a weekly mean of 36 ± 10 to 48 ± 5 hours. Six live births after seven pregnancies (one pregnancy was electively terminated) were documented, with a mean gestational age of 36.2 ± 3 weeks and a mean birth weight of 2417.5 ± 657 g. Complications were minimal.

Volume

Management of volume status is challenging because the mother's dry weight increases throughout pregnancy. Nevertheless, vigilant efforts to avoid both hypovolemia and hypotension are warranted, as both can be damaging to the fetus. By mid-pregnancy, the classic weight gain of 0.5 to 1 kg/wk should be taken into account when considering dry weight and interdialysis weight gain, allowing appropriately tailored ultrafiltration goals. Because the pregnant dialysis patient will undergo frequent dialysis, the clinician should perform frequent physical examinations to evaluate for the presence of excess fluid unrelated to the pregnancy.

INTENSIFIED ANEMIA MANAGEMENT

The anemia of chronic kidney disease is further aggravated by the physiologic anemia of pregnancy. Thus, erythropoietin dosages should be adjusted to maintain the physiologic anemia of pregnancy (10 to 11 g/L).^{174,187} The use of erythropoietin during pregnancy has been demonstrated to be safe, with no documented increases in blood pressure or teratogenicity.^{174,187,188} The erythropoietin dosage may need to be increased by 50% to 100% to achieve targets.^{174,187} Furthermore, studies have demonstrated a positive correlation between maternal hemoglobin and a successful pregnancy.¹⁸² In addition to increased erythropoietin requirements, typical iron requirements exceed the usual 30 mg/day recommended for healthy pregnant women. Careful follow-up of complete blood count and iron stores can guide both intravenous erythropoietin and iron supplementation.

HYPERTENSION AND PREECLAMPSIA

It has been estimated that approximately 80% of women on hemodialysis who become pregnant will present with hypertension.¹⁷⁶ Elevated blood pressure should be treated to maintain a postdialysis systolic blood pressure of less than 140 mm Hg, and the diastolic blood pressure should range between 80 and 90 mm Hg.^{173,174} Blood pressure medications must be carefully reviewed to avoid drugs that are known to be toxic to the fetus, such as ACE inhibitors (as mentioned previously).

Exacerbation of hypertension is common, although the incidence of preeclampsia in dialysis patients is difficult to ascertain because of the inability to apply standard diagnostic criteria. In the absence of urine output revealing proteinuria, the diagnosis of preeclampsia relies on the assessment of worsening blood pressure. Other helpful clues might include alterations in placental blood flow (as seen in a Doppler ultrasound study), fetal

growth restriction, and abnormal laboratory results suggestive of the HELLP syndrome.

NUTRITION

Nutritional assessment and counseling may be necessary to ensure adequate protein and caloric intake as requirements intensify because of dialysis-related losses. For example, because amino acids are lost during dialysis, protein intake recommendations can increase to 1 to 1.5 g/kg of weight (if on hemodialysis) or to 1.8 g/kg of weight (if on peritoneal dialysis) per day. Because several water-soluble vitamins are also lost during dialysis and dialysis regimens are intensified overall during pregnancy, some suggest standard vitamin and supplement dosages should increase: for example, 1 to 5 mg folate per day and double the prescribed dosage of daily multivitamin.^{172,174,176}

PERITONEAL DIALYSIS PATIENTS AND PREGNANCY

The published experience with peritoneal dialysis and pregnancy is even more limited than that with hemodialysis; however, most authors do not recommend changing the dialysis technique after conception.^{172,173} Sequelae from peritonitis and hypertonic solutions may contribute to greater infertility, but once a woman is pregnant, several features of peritoneal dialysis make it a theoretically attractive renal replacement modality during the pregnancy^{172,173,177} for the following reasons:

- Less abrupt fluid and electrolyte shifts creating a more stable environment for the fetus
- Continuous allowance for extracellular fluid volume control so that blood pressure control is augmented
- Higher hemoglobin levels requiring less erythropoietin use

Although there appear to be no differences in outcome with the mode of renal replacement therapy (i.e., hemodialysis versus peritoneal dialysis), peritoneal dialysis is often accompanied by feelings of abdominal fullness or discomfort, and catheter drainage difficulties, necessitating a progressive decline in fill volumes and the need for frequent exchanges. It may therefore become difficult to achieve adequate dialysis. Preterm delivery, premature rupture of membranes, and stillbirths have also been documented to occur secondary to acute peritonitis in women who are undergoing peritoneal dialysis.

Renal Transplant and Pregnancy

End-stage renal disease causes hypothalamic-gonadal dysfunction that leaves most affected women of childbearing age infertile.^{173,189} However, within the first few months after renal transplantation, gonadal dysfunction reverses and female fertility generally returns.¹⁹⁰ The return of fertility is often seen as one of the major benefits of renal transplantation among women of childbearing age.

This section reviews the issues related to kidney donors, renal transplantation, and pregnancy, including the associated risks to the mother and fetus, strategies to increase the likelihood of a successful pregnancy while minimizing risk to the mother and renal allograft, management of the common immunosuppressant medications during and after pregnancy, management of acute allograft rejection, and issues related to labor and the subsequent neonatal period.

MATERNAL AND FETAL OUTCOMES AFTER KIDNEY DONATION

Pregnancy outcomes after kidney donation are an important topic, as many living kidney donors are women of childbearing age.¹⁹¹ After initial reports from small observational studies that kidney donation was associated with adverse outcomes, results from a large single-center survey of 663 pregnancies among 337 female kidney donors found that maternal and fetal outcomes did indeed significantly differ in pregnancies delivered before and after kidney donation.¹⁹² Pregnant women who had previously donated a kidney had a higher risk for preterm delivery and fetal loss than pregnant women who had not yet donated a kidney (Table 57-5). Similarly, pregnancy after kidney donation was associated with higher risk for gestational diabetes, gestational hypertension, proteinuria, and preeclampsia.¹⁹²

EFFECT OF PREGNANCY ON THE RENAL ALLOGRAFT

The vast majority of case-control studies performed over the years have not demonstrated an adverse effect of pregnancy on allograft function, provided that the baseline allograft function is normal and significant hypertension is not present. For example, a retrospective cohort study from the European Dialysis and Transplant Association compared 53 women (the cases) who had successful pregnancies, with a cohort of persons who had not been pregnant matched with regard to date of transplant and renal disease leading to transplant (the controls). Over 24 to 36 months of follow-up, the study found renal function unchanged in 67% of case-control pairs, and worse in both groups in 9% of pairs.¹⁹³ In 15% of pairs, the control had deterioration of renal function, and in 9% of pairs, the pregnant patient had deterioration of renal function. This group therefore concluded that pregnancy had no adverse effect on graft function.

Another matched cohort series published in 2006 matched each of 39 women who had had one or more pregnancies with

functioning renal allografts (total number of live births = 55) with three controls who had not been pregnant but matched with regard to 12 factors known to affect graft survival.¹⁹⁴ Graft (61.6%) and patient (84.8%) survival from transplantation to the end of follow-up (15 years) in the women who conceived after transplantation did not significantly differ from the rates observed in the matched control group (68.7% and 78.8%, respectively). There also were no between-group differences in long-term graft function. These authors concluded that pregnancy did not adversely affect long-term graft or patient survival.

Only one retrospective cohort series has suggested that pregnancy adversely affects allograft function.¹⁹⁵ In this study, 22 female transplant recipients with 29 total pregnancies were compared with 38 female controls matched for cause of renal failure, kidney source, immunosuppression, time from transplant, and serum creatinine levels. After 10 years of follow-up, graft survival was 100% in the control group and 69% in the group with pregnancies ($P < .005$). The difficulty of generalizing from this single study lies in the rarity of centers with a 10-year graft survival of 100%, as was observed in the control group.

Thus, the preponderance of the evidence indicates that the risk for irreversible loss of renal allograft function is minimal when the creatinine level is less than 1.5 mg/dL at the time of conception.¹⁹⁶ When the pre-conception creatinine level is greater than 1.5 mg/dL, however, the risk for irreversible loss of renal allograft function is increased during and after pregnancy.¹⁹⁷

EFFECT OF MATERNAL RENAL TRANSPLANTATION ON FETAL OUTCOMES

Three major registries, the U.S. National Transplantation Pregnancy Registry, the European Dialysis and Transplant Association Registry, and the U.K. Transplant Pregnancy Registry have collected data on pregnancy outcomes for more than 2000 pregnancies in women with solid-organ transplants.^{193,198,199} Results relating to major complications of pregnancy are very

TABLE 57-5 Fetal and Maternal Outcomes before and after Kidney Transplantation

	Pre-Donation Pregnancies	Post-Donation Pregnancies	Pre- and Post-Donation Pregnancies	P Value*
Number of donors	944	239	98	—
Number of pregnancies	2723	490	277	—
FETAL OUTCOMES				
Full-term birth	2305 (84.6%)	361 (73.7%)	262 (69.5%)	.0004
Prematurity	110 (4.0%)	35 (7.1%)	30 (8.0%)	.0004
Fetal loss	308 (11.3%)	94 (19.2%)	85 (22.6%)	<.0001
Death	15 (4.9%)	2 (2.1%)	3 (3.5%)	—
Miscarriage	240 (77.9%)	78 (83.0%)	69 (81.2%)	—
Abortion	5 (17.2%)	14 (14.9%)	13 (15.3%)	—
MATERNAL OUTCOMES				
Gestational diabetes	20 (0.7%)	13 (2.7%)	2 (0.5%)	.0001
Gestational hypertension	17 (0.6%)	28 (5.7%)	7 (1.9%)	<.0001
Preeclampsia or toxemia	23 (0.8%)	27 (5.5%)	7 (1.9%)	<.0001
Proteinuria	29 (1.1%)	21 (4.3%)	12 (3.2%)	<.0001

consistent across these registries. Approximately 22% of pregnancies among renal transplant recipients end in the first trimester, 13% resulting from miscarriage and the remaining from elective termination. For pregnancies that continue beyond the first trimester, more than 90% result in a successful maternal and fetal outcome. However, there is a substantial risk for low birth weight (25% to 50%) or preterm delivery (30% to 50%).²⁰⁰ Preeclampsia is the primary indication for preterm delivery, just as in women with CKD, complicating 25% to 30% of pregnancies in renal transplant recipients.^{197,200}

The rate of ectopic pregnancy may be slightly increased in women with a renal allograft, but it remains below 1%. Vaginal delivery is safe in this population and should be the default method of delivery, with cesarean section performed only for routine obstetric indications.²⁰¹

ANTENATAL COUNSELING AND CLINICAL STRATEGY

To maximize chances of a successful pregnancy, several factors need to be considered regarding how long to wait after transplantation before attempting pregnancy. Pregnancy within the first 6 to 12 months after transplantation is not recommended for the following important reasons: the risk for acute allograft rejection is relatively high, immunosuppressant medications are administered at higher dosages, and the risk for infection is greatest.

The American Society of Transplantation currently recommends that conception could be safely considered as early as 1 year after transplant if (1) graft function is adequate and stable (i.e., creatinine <1.5 mg/dL), with minimal to no proteinuria; (2) there have been no rejection episodes within the past year; and (3) maintenance immunosuppression is at low and stable dosages.²⁰¹

The need for close collaboration between the transplant nephrologist and the obstetrician familiar with high-risk patients in the management of women who become pregnant after transplantation cannot be overemphasized. Allograft function should be serially assessed and biopsy performed if there is a concern for acute rejection. The most common complication of pregnancy in transplant recipients is hypertension, which affects 30% to 75% of patients.¹⁹⁸ Hypertension is probably caused by a combination of underlying medical conditions and the use of calcineurin inhibitors (e.g., cyclosporine, tacrolimus) for immunosuppression. The American Society of Transplantation recommends that hypertension in pregnant renal transplant recipients should be managed aggressively, with target blood pressure close to normal—a goal that differs from somewhat higher blood pressure goals in women with hypertension in pregnancy in the absence of a transplant.²⁰¹

The risk for infections that have implications for the developing fetus, including cytomegalovirus (CMV), herpes simplex virus (HSV), and toxoplasmosis, is increased in the setting of chronic immunosuppression.

Current recommendations are to measure maternal blood titers of IgM and IgG antibodies against both CMV and *Toxoplasma* in each trimester.¹⁶⁴ If maternal serologic evidence suggests new or reactivated infection, diagnosis of fetal CMV infection is most accurately determined via polymerase chain reaction (PCR) for CMV DNA in amniotic fluid.²⁰² Treatment of fetal CMV infection with either antiviral medications or hyperimmunoglobulin therapy should be considered once the

diagnosis is made, although the overall efficacy of these treatments in preventing fetal disease is still being determined in clinical trials.

If maternal serologic evidence suggests toxoplasmosis primary infection (the usual scenario) or reactivation (less common), then conventional or real-time (if available) PCR of amniotic fluid for *Toxoplasma gondii* has been demonstrated as the best method for determination of fetal infection.²⁰³ Once fetal infection has been confirmed, treatment to reduce the risk for serious fetal neurologic sequelae is generally provided in the form of a pyrimethamine-sulfonamide combination or as spiramycin.

HSV is typically spread from an infected mother to child via exposure to viral particles as the fetus passes through the birth canal. Cesarean delivery can therefore reduce the risk for neonatal transmission in women with active lesions. Also, acyclovir has been safely used in pregnancy²⁰⁴ and should be used promptly to treat active maternal outbreaks of HSV during any trimester. In pregnant women without a transplantation who have a history of recurrent genital herpes, prophylactic acyclovir beginning at 36 weeks' gestation has been shown to reduce the risk for clinical recurrence at the time of delivery, the risk for cesarean delivery secondary to genital lesions, and the risk for HSV viral shedding at the time of delivery.²⁰⁵ These findings may also be applicable to pregnant women with renal allografts.

MANAGEMENT OF IMMUNOSUPPRESSION IN PREGNANCY

Because controlled studies on the developmental toxicity secondary to the commonly used immunosuppressant agents clearly cannot be performed for ethical reasons, most immunosuppressive agents fall within the U.S. Food and Drug Administration (FDA) category C (i.e., risks cannot be ruled out). Nevertheless, a significant amount of published data can inform decisions about the use of some of these agents safely in pregnancy (see Table 57-6).

Cyclosporine (or tacrolimus, although data for it are more limited) and steroids, with or without azathioprine, form the basis of immunosuppression during pregnancy. Corticosteroids at low to moderate dosages are generally considered to be safe²⁰⁶ but have been assigned as category C by the FDA. Given the chronic adrenal suppression associated with long-term steroid use, stress-dosage steroids are needed at the time of delivery and for 24 to 48 postpartum hours. Azathioprine is generally considered safe at dosages of less than 2 mg/kg/day. For azathioprine to become active, it must be converted to 6-mercaptopurine by the enzyme inosinate pyrophosphorylase, which the immature fetal liver lacks. Therefore, the fetus is relatively protected from the effects of the drug.¹⁶⁴ Both animal and human data suggest that lower dosages of the calcineurin inhibitors cyclosporine and tacrolimus are safe in pregnancy, without an increased incidence of congenital malformations, but with a possible increased rate of low birth weight.²⁰⁶ Serum levels of cyclosporine and tacrolimus can fluctuate significantly in pregnancy, as a result of decreased gastrointestinal absorption, increased volume of distribution, and increased GFR, with a concomitant risk for acute rejection. Hence, close monitoring of serum levels with dosage adjustment is required to maintain optimal levels.²⁰⁷

Sirolimus (FDA category C) is best avoided in pregnancy because it is teratogenic in rats at dosages used clinically,²⁰⁶ and the human data are very limited. It should be discontinued

preemptively in women of childbearing age who are not using contraception. MMF is associated with developmental toxicity, malformations, and intrauterine death in animal studies at therapeutic dosages. Limited human data suggest that MMF may be associated with spontaneous abortions and with major fetal malformations.²⁰⁸ In November 2007, the FDA modified the labeling of MMF and mycophenolic acid to change their pregnancy category from C to D (positive evidence of human fetal risk) and added a black box warning advising of the risks, including miscarriage, bilateral microtia or anotia, oral clefts, and other major malformations. Hence, MMF is contraindicated and sirolimus is best avoided in pregnancy.

MANAGEMENT OF ACUTE ALLOGRAFT REJECTION IN PREGNANCY

Serious acute rejection episodes occur in 6% of pregnant renal allograft recipients, which is not higher than that expected in nonpregnant renal allograft recipients. The diagnosis of acute rejection can be difficult, but it should be considered if fever, oliguria, graft tenderness, or deterioration in renal function is observed. Allograft biopsy is necessary for confirmation of the diagnosis before the initiation of therapy. High-dosage steroids have been the mainstay of treatment for acute allograft rejection during pregnancy.^{164,209} The data available on the safety of

TABLE 57-6 Safety of Commonly Used Immunosuppressive Agents for Chronic Kidney Disease in Pregnancy

Drug	Transplacental Passage	Human Teratogenicity	Fetal/Neonatal Effects	Safe in Pregnancy?	Safe in Breastfeeding?
Prednisolone	Limited, as most would be metabolized by the placenta	Possible increase in oral clefts	Rare, except at large dosages (cataract, adrenal insufficiency, infection)	Yes, with increased risk for preterm premature rupture of membranes at higher dosages	Yes, but breastfeeding is not encouraged if receiving >60 mg prednisolone daily
Azathioprine	Yes	Slightly increased risk for congenital malformations, specifically ventricular and atrial septal defects ²¹⁴	Fetal growth restriction, and dosage-related myelosuppression in the neonate ²¹⁴	Yes	Yes
Mycophenolate mofetil	Yes	Hypoplastic nails, shortened fifth fingers, diaphragmatic hernia, microtia (ear deformity), micrognathia, cleft lip and palate, and congenital heart defects ²²⁰	Yes	No. Stop at least 6 weeks before conception ²²⁰ and switch to a safer agent. Exceptional circumstance: with no other effective agent, continue treatment but counsel about teratogenicity.	No
Tacrolimus	Yes	No	Hyperkalemia and renal impairment	Yes. Increased risk for gestational diabetes. ¹⁹⁸ May need up to 40% increase in pre-pregnancy dosage because of increased clearance. Possible increase in low birth weight. ²⁰⁶	Probably possible ²²¹
Cyclophosphamide	Yes (animal data)	Yes	Chromosomal abnormalities and cytopenia	Yes (only after first trimester and only if there is life-threatening maternal disease)	No
Cyclosporine	Yes	No	Transient immune alterations	Yes. May need up to 40% increase in pre-pregnancy dosage because of increased clearance. Possible increase in low birth weight. ²⁰⁶	Probably possible*
Sirolimus	Not known	Not reported	None reported	No. Stop 12 weeks before conception ²²⁰ and switch to a safer agent (until more data regarding safety in pregnancy available).	Probably possible
Intravenous immunoglobulin	Yes	No	None reported	Yes	Yes
Rituximab	Yes (from 16 weeks of gestation)	Not reported	Yes. Neonatal B cell depletion reported.	Limit to severe disease	Inadequate data

*The American Academy of Pediatrics notes possible immune suppression with cyclosporine if used during lactation.²²⁶ Adapted with permission from Bramham K, Lightstone L: Pre-pregnancy counseling for women with chronic kidney disease, *J Nephrol* 25:450-459, 2012.

agents such as OKT-3, antithymocyte globulin, dacilizumab, and basiliximab are more limited.

POSTNATAL CONSIDERATIONS AFTER RENAL TRANSPLANT

Close maternal follow-up is required after pregnancy to monitor renal allograft function, as well as to monitor immunosuppressive medication levels that may be in flux secondary to the physiologic changes described earlier.

With regard to contraception, intrauterine devices are more likely to fail in women on immunosuppressive drugs because their efficacy depends on intact immunologic function.²¹⁰ The intrauterine devices may also increase the risk for intrauterine infections in women maintained on immunosuppression.²¹¹ Therefore, barrier methods and oral contraception formulations of progestin or combined estrogen and progestin are more often recommended.

PEDIATRIC MANAGEMENT

Preterm delivery and IUGR are the two most common problems for infants who deliver to women with CKD. In this population, the risk of developing an adverse fetal outcome (preterm delivery, neonatal or fetal death, low birth weight) has been shown to be at least two times higher than in normal healthy pregnant women.²¹² Because of obstetric concerns about increased maternal blood pressure, many infants are delivered before term. In addition, long-standing maternal hypertension may compromise placental blood flow, leading to impaired fetal growth. Development of superimposed preeclampsia has been identified as an important risk for adverse fetal outcome.¹⁸¹ Appropriate timing of delivery is a difficult decision, with the goal of balancing the infant's risks for diseases related to prematurity against maternal morbidity and mortality.

In addition to prematurity and IUGR, fetal exposure to ACE inhibitors, angiotensin II receptor blockers, and immunosuppressant drugs typically used in women with CKD, such as prednisone, azathioprine, cyclosporine and tacrolimus, are of concern. Epidemiologic studies have shown no increase in congenital anomalies with maternal steroid use, but chronic prednisone use has been associated with low birth weight and preterm rupture of membranes, leading to increased risk for chorioamnionitis and preterm delivery.²¹³ Use of prednisone during the first trimester of pregnancy has been associated with rare cases of cleft palate or cleft lip.²¹⁵ Neonatal adrenocortical

insufficiency and thymic hypoplasia are rare possible complications. Use of azathioprine has been associated with SGA infants and with dosage-related myelosuppression in the neonate.²¹⁴ Cyclosporine can also adversely affect fetal growth.²¹⁵ Anecdotal data exist that associate tacrolimus with oligoanuria and hypokalemia in the neonate.²¹⁶ Because of the concern for teratogenic effects of MMF,²¹⁷ sirolimus²¹⁸ and ACE inhibitors¹¹⁶ during early pregnancy, current recommendations are to discontinue their use before conception, and to lessen the use of other immunosuppressant medications to a minimal tolerable level.²¹⁹ A summary of the safety of commonly used immunosuppressant agents in pregnant women with CKD, consolidated from Østensen and colleagues¹²⁸ by Bramham and Lightstone,²¹⁹ is reprinted (with permission) in Table 57-6.^{220,221} The long-term sequelae of in utero exposure to immunosuppressants used for renal transplant is unknown; no differences in early childhood development have been noted in children of renal transplant–recipient mothers.²²²

BREASTFEEDING

Little is known about the quantities of the various immunosuppressive agents and their metabolites in breast milk, or what the potential effects on the infant may be. Although breastfeeding is generally discouraged in women taking immunosuppressive drugs, it may be considered possible (see Table 57-6) if women are informed about the associated risks.

Azathioprine does not appear in breast milk,²²³ but cyclosporine and tacrolimus do.²²⁴ Cyclosporine levels in breast milk are usually greater than those in a simultaneously taken blood sample.²²⁵ According to the American Academy of Pediatrics, possible immune suppression in the infant is a cause for concern when cyclosporine is used during lactation.²²⁶

Respiratory Diseases in Pregnancy

JANICE E. WHITTY, MD | MITCHELL P. DOMBROWSKI, MD

Proper functioning of the cardiorespiratory system is imperative to achieve adequate oxygenation of maternal and fetal tissues. The maternal cardiorespiratory system undergoes significant changes during gestation to optimize oxygen delivery to the fetus and maternal tissues. Pulmonary disease is one of the most frequent maternal complications during pregnancy, and it may result in significant morbidity or mortality for the mother and her fetus. Depending on the specific diagnosis, other maternal complications of pregnancy may have an adverse or a positive impact on the pulmonary function of the gravida.

In this chapter, we briefly review the physiologic adaptations of the respiratory system that occur during gestation. Specific respiratory diseases that occur in pregnancy and the effects of the disease on pregnancy, as well as the effects of pregnancy on the disease, are discussed. The obstetrician should realize that most of the diagnostic tests that are useful in evaluating pulmonary function during gestation are not harmful to the fetus, and, if indicated, they should be performed. Most medications used to treat respiratory disease in pregnancy are also well tolerated by the fetus. With few exceptions, the diagnostic and treatment algorithms for respiratory disease in a pregnant woman closely resemble those used for a nonpregnant woman.

Physiologic Changes of the Respiratory System

Because there is no increase in respiratory rate, the increase in maternal minute ventilation results from an increase in tidal volume.¹ The almost 50% increase in tidal volume occurs at the expense of an 18% decrease in the functional residual capacity. The resulting hyperventilation of pregnancy results in a compensated respiratory alkalosis (i.e., arterial partial pressure of carbon dioxide [P_{aCO_2}] ≤ 30 mm Hg) and a modest increase in arterial oxygenation tension (i.e., 101 to 104 mm Hg).² The P_{aCO_2} decreases early in pregnancy in parallel with the change in ventilation; however, a further progressive decrease in P_{aCO_2} may occur.³ The decrease in P_{aCO_2} is even greater at higher altitudes, where the mother exhibits compensatory hyperventilation in an attempt to maintain the arterial partial pressure of oxygen as high as possible. The decrease in P_{aCO_2} is matched by an equivalent increase in renal excretion of bicarbonate and thus a decrease in plasma bicarbonate concentration; therefore, arterial pH is not altered from the normal nonpregnant level of about 7.4.

It has been suggested that the hyperventilation of pregnancy results primarily from progesterone acting as a respiratory stimulant.⁴ Because hyperventilation has been observed during the

luteal phase of the menstrual cycle and progesterone can produce similar changes in nonpregnant women, it is likely that this phenomenon results from progestational influences.^{5,6} The P_{aCO_2} is linearly and inversely related to the log of the progesterone concentration.⁷ Wilbrand and colleagues⁸ reported that progesterone lowers the carbon dioxide threshold of the respiratory center. During pregnancy, the sensitivity of the respiratory center increases⁹ so that an increase in P_{aCO_2} of 1 mm Hg increases ventilation by 6 L/min in pregnancy, compared with 1.5 L/min in the nonpregnant state.^{1,10,11} It is possible that progesterone acts as a primary stimulant to the respiratory center independently of any change in carbon dioxide sensitivity or threshold.⁴ In addition to stimulating ventilation, progesterone may also increase levels of carbonic anhydrase B in the red blood cell.¹² Schenker and associates¹³ reported that carbonic anhydrase levels increase in pregnant patients and in women taking oral contraceptives. An increase in the carbonic anhydrase level facilitates carbon dioxide transfer and tends to decrease P_{aCO_2} independently of any change in ventilation. This respiratory stimulant effect of progesterone has been used in the treatment of respiratory failure and emphysema.^{6,14,15}

During gestation, ventilation is increased by the rise in tidal volume from approximately 500 to 700 mL in each breath.^{1,16-18} Because there is no change in respiratory rate, minute ventilation rises from about 7.5 to 10.5 L/min.^{11,17,19} Minute ventilation increases in the first trimester and remains at that level throughout pregnancy. The physiologic dead space is increased by about 60 mL in pregnancy. This may result from dilation of the small airways.¹¹ Residual volume is reduced by about 20%,¹⁶ from 1200 to 1000 mL.²⁰⁻²² The vital capacity, which is the maximum volume of gas that can be expired after a maximum inspiration, does not change in pregnancy.^{16,21-25}

Anatomic Changes of the Respiratory System

Observed changes in the configuration of the chest during pregnancy are in keeping with the findings of no change in vital capacity and a reduction in residual volume. The effect of pregnancy on pulmonary mechanics has been compared with the effect of a pneumoperitoneum. In both situations, the residual lung volume is decreased but ventilation remains unimpaired. Radiologic studies performed early in pregnancy have shown that the subcostal angle increases from 68 to 103 degrees before there is any mechanical pressure from the enlarging uterus.²⁶ The level of the diaphragm rises by about 4 cm, and the transverse diameter of the chest increases by 2 cm.²⁷⁻²⁹ These changes

account for the decrease in residual volume because the lungs are relatively compressed during forced expiration; however, the excursion of the diaphragm in respiration is increased by about 1.5 cm in pregnancy compared with the nonpregnant state.^{29,30}

Oxygen Delivery and Consumption

OXYGEN DELIVERY

All tissues require oxygen for the combustion of organic compounds to fuel cellular metabolism. The cardiopulmonary system delivers a continuous supply of oxygen and other essential substrates to tissues. Oxygen delivery depends on oxygenation of blood in the lungs, the oxygen-carrying capacity of the blood, and cardiac output.³¹ Under normal conditions, oxygen delivery exceeds oxygen consumption by about 75%.³² The amount of oxygen delivered is determined by the cardiac output (CO, in liters per minute) times the arterial oxygen content (CaO₂, in milliliters of O₂ per minute):

$$\text{Oxygen delivery} = \text{CO} \times \text{CaO}_2 \times 10 \text{ (700 to 1400 mL/min)}$$

The arterial oxygen content is determined by the amount of oxygen that is bound to hemoglobin (i.e., arterial blood saturation with oxygen [SaO₂]) and by the amount of oxygen that is dissolved in plasma (i.e., partial pressure of arterial oxygen [PaO₂ × 0.0031]):

$$\text{CaO}_2 = (\text{hemoglobin} \times 1.34 \times \text{SaO}_2) + (\text{PaO}_2 \times 0.0031) \\ \text{(16 to 22 mL} \times \text{O}_2/\text{dL)}$$

As can be seen in this formula, the amount of oxygen dissolved in plasma is negligible, and the arterial oxygen content therefore depends largely on hemoglobin concentration and arterial oxygen saturation. Oxygen delivery can be impaired by

conditions that affect arterial oxygen content or cardiac output (flow), or both. Anemia leads to low arterial oxygen content because of a lack of hemoglobin binding sites for oxygen. Carbon monoxide poisoning likewise decreases oxyhemoglobin because of blockage of binding sites for oxygen. The patient with hypoxemic respiratory failure does not have sufficient oxygen available to saturate the hemoglobin molecule. Desaturated hemoglobin is altered structurally such that it has a diminished affinity for oxygen.³³

The amount of oxygen available to tissues also is affected by the affinity of the hemoglobin molecule for oxygen. The oxyhemoglobin dissociation curve (Fig. 58-1) and the conditions that influence the binding of oxygen negatively or positively must be considered when attempts are made to maximize oxygen delivery.³⁴ An increase in the plasma pH level or a decrease in temperature or the concentration of 2,3-diphosphoglycerate can increase hemoglobin affinity for oxygen, shifting the curve to the left and resulting in diminished tissue oxygenation. If the plasma pH level decreases and the temperature or 2,3-diphosphoglycerate level increase, hemoglobin affinity for oxygen decreases, and more oxygen is available to tissues (see Fig. 58-1).³⁴

In certain clinical conditions, such as septic shock and adult respiratory distress syndrome, there is maldistribution of flow relative to oxygen demand, leading to diminished delivery and consumption of oxygen. The release of vasoactive substances is hypothesized to result in the loss of normal mechanisms of vascular autoregulation, producing regional and microcirculatory imbalances in blood flow.³⁵ This mismatching of blood flow with metabolic demand causes excessive blood flow to some areas and relative hypoperfusion of other areas, limiting optimal systemic use of oxygen.³⁵ The patient with diminished cardiac output resulting from hypovolemia or pump failure is

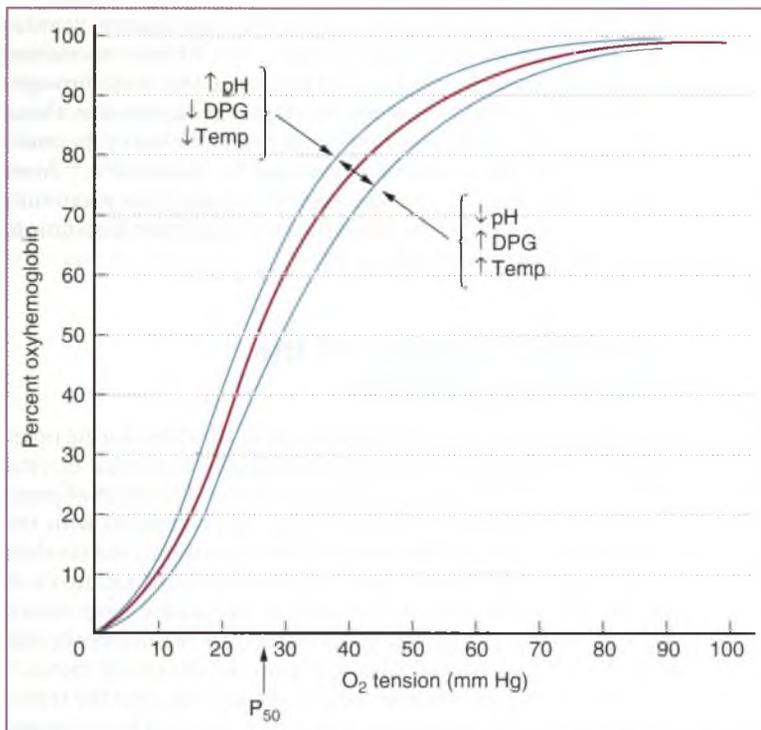

Figure 58-1 The oxygen-binding curve for human hemoglobin A under physiologic conditions (red curve). The affinity is shifted by changes in pH, diphosphoglycerate (DPG) concentration, and temperature. P₅₀ is the oxygen tension at one-half saturation.

unable to distribute oxygenated blood to tissues. Therapy directed at increasing the volume with normal saline, or with blood if the hemoglobin level is less than 10 g/dL, increases delivery of oxygen in the hypovolemic patient. The patient with cardiac failure may benefit from inotropic support and after-load reduction in addition to supplementation of intravascular volume.

RELATIONSHIP OF OXYGEN DELIVERY TO CONSUMPTION

Oxygen consumption is the product of the arteriovenous oxygen content difference ($C_{(a-v)O_2}$) and cardiac output. Under normal conditions, oxygen consumption is a direct function of the metabolic rate³⁶:

$$\text{Oxygen consumption} = C_{(a-v)O_2} \times CO \times 10 \\ (180 \text{ to } 280 \text{ mL/min})$$

The oxygen extraction ratio is the fraction of delivered oxygen that is actually consumed:

$$\text{Oxygen extraction ratio} = O_2 \text{ consumption} / O_2 \text{ delivery } (0.25)$$

The normal oxygen extraction ratio is about 25%. A rise in the oxygen extraction ratio is a compensatory mechanism used when oxygen delivery is inadequate for the level of metabolic activity. A subnormal value suggests flow maldistribution, peripheral diffusion defects, or functional shunting.³⁶ As the supply of oxygen is reduced, the fraction extracted from blood increases and oxygen consumption is maintained. If a severe reduction in oxygen delivery occurs, the limits of oxygen extraction are reached, tissues are unable to sustain aerobic energy production, and consumption decreases. The level of oxygen delivery at which oxygen consumption begins to decrease is called *critical oxygen delivery* (Fig. 58-2).³⁷ At the critical oxygen delivery level, tissues begin to use anaerobic glycolysis, with resultant lactate production and metabolic acidosis.³⁷ If oxygen deprivation continues, irreversible tissue damage and death ensue.

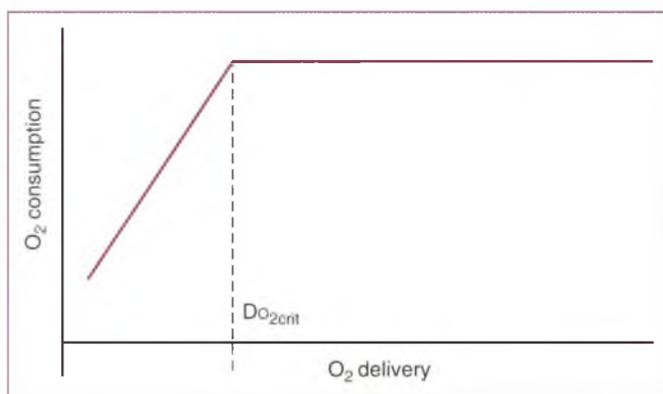

Figure 58-2 Relationship of oxygen consumption ($\dot{V}O_2$) and oxygen delivery (DO_2). At the point of critical oxygen delivery, tissues begin to use anaerobic glycolysis, with resultant lactate production and metabolic acidosis. If the oxygen deprivation continues, irreversible tissue damage and death ensue.

MIXED VENOUS OXYGENATION

The mixed venous oxygen tension and mixed venous oxygen saturation ($S\bar{V}O_2$) are parameters of tissue oxygenation.³⁷ The normal mixed venous oxygen tension is 40 mm Hg with a saturation of 73%. Saturations less than 60% are abnormally low. These parameters can be measured directly by obtaining a blood sample from the distal port of the pulmonary artery catheter. The $S\bar{V}O_2$ also can be measured continuously with special pulmonary artery catheters equipped with fiberoptics. Mixed venous oxygenation is a reliable parameter in the patient with hypoxemia or low cardiac output, but findings must be interpreted with caution. When the $S\bar{V}O_2$ is low, oxygen delivery can be assumed to be low. However, normal or high $S\bar{V}O_2$ values do not guarantee that tissues are well oxygenated. In conditions such as septic shock and adult respiratory distress syndrome, the maldistribution of systemic flow may lead to an abnormally high $S\bar{V}O_2$ value in the face of severe tissue hypoxia.³⁵ The oxygen dissociation curve must be considered when interpreting the $S\bar{V}O_2$ as an indicator of tissue oxygenation.³³ Conditions that result in a left shift of the curve cause the venous oxygen saturation to be normal or high, even when the mixed venous oxygen content is low. $S\bar{V}O_2$ is useful for monitoring trends in a particular patient, because a significant decrease occurs when oxygen delivery has decreased because of hypoxemia or a decrease in cardiac output.

OXYGEN DELIVERY AND CONSUMPTION IN PREGNANCY

The physiologic anemia of pregnancy results in a reduction in the hemoglobin concentration and arterial oxygen content. Oxygen delivery is maintained at or above normal despite this because of the 50% increase in cardiac output. The pregnant woman therefore depends on cardiac output for maintenance of oxygen delivery more than the nonpregnant patient.³⁸ Oxygen consumption increases steadily throughout pregnancy and is greatest at term, reaching an average of 331 mL/min at rest and 1167 mL/min with exercise.¹¹ During labor, oxygen consumption increases by 40% to 60%, and cardiac output increases by about 22%.^{39,40} Because oxygen delivery normally far exceeds consumption, the normal pregnant patient usually is able to maintain adequate delivery of oxygen to herself and her fetus, even during labor. When a pregnant patient has low oxygen delivery, she can very quickly reach the critical oxygen delivery level during labor, compromising herself and her fetus. The obstetrician therefore must make every effort to optimize oxygen delivery before allowing labor to begin in the compromised patient.

Pneumonia in Pregnancy

Pneumonia is fortunately a rare complication of pregnancy, occurring in 1 of 118 to 2288 deliveries.^{41,42} However, pneumonia contributes to considerable maternal mortality and is reportedly the most common non-obstetric infection to cause maternal mortality in the peripartum period.⁴³ Maternal mortality was as high as 24% before the introduction of antibiotic therapy.⁴⁴ Research reports have documented a dramatic decrease in maternal mortality from 0% to 4% with modern management and antibiotic therapy.^{42,45,46} Preterm delivery is a significant complication of pneumonia. Even with antibiotic therapy and modern management, preterm delivery continues to occur for 4% to 43% of gravidas who have pneumonia.^{42,45,46}

The increasing incidence of pneumonia in pregnancy may reflect the declining general health status of certain segments of the childbearing population (e.g., morbid obesity).⁴⁶ The epidemic of human immunodeficiency virus (HIV) infection has increased the number of mothers who are potentially at risk for opportunistic lung infections. HIV infection is also associated with increased risks of invasive pneumococcal disease (odds ratio [OR] = 41.8) and legionnaire disease (OR = 41.8).⁴⁷ HIV infection further predisposes the pregnant woman to the infectious complications of acquired immunodeficiency syndrome (AIDS).^{47,48} Reported incidence rates range from 97 to 290 cases per 1000 HIV-infected persons per year. HIV-infected persons are 7.8 times more likely to develop pneumonia than non-HIV-infected individuals with similar risk factors. Women with medical conditions that increase the risk for pulmonary infection, such as cystic fibrosis, are living to childbearing age more frequently than in the past. This disorder contributes to the increased incidence of pneumonia in pregnancy.

Pneumonia can complicate pregnancy at any time during gestation and may be associated with preterm birth, poor fetal growth, and perinatal loss. In an early report, 17 of 23 patients developed pneumonia between 25 and 36 weeks' gestation.⁴⁹ In that series, seven gravidas delivered during the course of their acute illness, and there were two maternal deaths. Another report described 39 cases of pneumonia in pregnancy.⁴⁵ Sixteen gravidas presented before 24 weeks' gestation, 15 between 25 and 36 weeks' gestation, and 8 after 36 weeks' gestation. Twenty-seven patients in this series were followed to completion of pregnancy; only two required delivery during the acute phase of pneumonia. Of these 27 patients, 3 suffered a fetal loss, and 24 delivered live fetuses, although there was one neonatal death resulting from prematurity.

Madinger and associates⁴² reported 25 cases of pneumonia occurring among 32,179 deliveries and observed that fetal and obstetric complications were much more common than in earlier studies. Preterm labor complicated 11 of 21 gestations. Eleven patients had pneumonia at the time of delivery. Preterm delivery was more likely for women who had bacteremia, needed mechanical ventilation, and had a serious underlying maternal disease. In addition to the complication of preterm labor, there were three perinatal deaths in this series. Berkowitz and LaSala⁴⁶ reported 25 patients with pneumonia complicating pregnancy; 14 women had term deliveries, one delivered preterm, three had a voluntary termination of pregnancy, three had term deliveries of growth-restricted infants, and four were lost to follow-up. Birth weight was significantly lower in the study group in this series (2770 ± 224 g versus 3173 ± 99 g in the control group; $P < .01$). In this series, pneumonia complicated 1 of 367 deliveries. The investigators attributed the increase in the incidence of pneumonia in this population to a decline in general health status, including anemia, a significant incidence of cocaine use (52% versus 10% of the general population), and HIV positivity (24% versus 2% of the general population) in the study group.

BACTERIOLOGY

Most series describing pneumonia complicating pregnancy have used incomplete methodologies to diagnose the etiologic pathogens for pneumonia, relying primarily on cultures of blood and sputum. In most cases, no pathogen was identified; however, pneumococcus and *Haemophilus influenzae* remain the most common identifiable causes of pneumonia in

pregnancy.^{42,45,46} Because comprehensive serologic testing has rarely been done, the true incidences of viral, *Legionella*, and *Mycoplasma pneumoniae* in pregnancy are difficult to estimate. The data presented by Benedetti, Madinger, Berkowitz, and their respective colleagues all support pneumococcus as the predominant pathogen causing pneumonia in pregnancy, and *H. influenzae* as the second most common organism.^{42,45,46} In the series of Berkowitz and LaSala,⁴⁶ one patient was infected with *Legionella* species.

Pneumonia in pregnancy has several causes, including mumps, infectious mononucleosis, swine influenza, influenza A, varicella, coccidioidomycosis, and other fungi.⁵⁰ Varicella pneumonia can complicate primary varicella infections in 5.2% to 9%⁵¹ of infections in pregnancy, compared with 0.3% to 1.8% in the nonpregnant population.⁵² Influenza A has a higher mortality rate among pregnant women than among nonpregnant patients.⁵³ The increase in virulence of viral infections reported in pregnancy may result from the alterations in maternal immune status that characterize pregnancy, including reduced lymphocyte proliferative response, reduced cell-mediated cytotoxicity by lymphocytes, and a decrease in the number of helper T lymphocytes.^{53,54} Viral pneumonias can also be complicated by superimposed bacterial infection, particularly pneumococcus.

ASPIRATION PNEUMONIA

Mendelson syndrome describes chemical pneumonitis resulting from the aspiration of gastric contents in pregnancy. Chemical pneumonitis can be superinfected with pathogens present in the oropharynx and gastric juices, primarily anaerobes and gram-negative bacteria.⁴⁵ Mendelson's original report of aspiration⁵⁵ consisted of 44,016 nonfasted obstetric patients between 1932 and 1945, and more than half had received "operative intervention" with ether by mask without endotracheal intubation. He described aspiration in 66 cases (rate of 1 case per 667 patients). Although several of the patients were critically ill from their aspirations, most recovered within 24 to 36 hours, and only two died from this complication (rate of 1 death per 22,008 patients). A review described 37,282 vaginal deliveries: 85% were performed with general anesthesia by mask and without intubation, and 65% to 75% had ingested liquids or solid food within 4 hours of onset of labor.⁵⁶ The investigators found five mild cases of aspiration (1 per 7456 patients) with no sequelae.⁵⁶ Another report described one occurrence of "mild aspiration" without adverse outcome among 1870 women undergoing nonintubated peripartum surgery with intravenous ketamine, benzodiazepines, barbiturates, fentanyl, or some combination of these drugs.⁵⁷ Soreide and colleagues⁵⁸ observed four episodes of aspiration each during 36,800 deliveries and 3600 cesarean sections with no mortality. On the basis of these data, most hospitals permit free intake of clear liquids during labor. The risk of aspiration, pneumonia, and death from general anesthesia appears to be very low. This may reflect the use of modern techniques and therapy to reduce gastric pH.

BACTERIAL PNEUMONIA

Streptococcus pneumoniae (pneumococcus) is the most common bacterial pathogen that causes pneumonia in pregnancy, and *H. influenzae* is the next most common. These pneumonias typically manifest as an acute illness accompanied by fever, chills,

Figure 58-3 Right lower lobe pneumonia. Lobar consolidation in the right lower lobe is consistent with pneumococcal pneumonia.

and a purulent, productive cough and are seen as a lobar pattern on the chest radiograph (Fig. 58-3). Streptococcal pneumonia produces a “rusty” sputum, with gram-positive diplococci on Gram stain, and it demonstrates asymmetrical consolidation with air bronchograms on the chest radiograph.⁵⁴ *H. influenzae* is a gram-negative coccobacillus that produces consolidation with air bronchograms, often in the upper lobes.⁵⁴ Less common bacterial pathogens include *Klebsiella pneumoniae*, which is a gram-negative rod that causes extensive tissue destruction, with air bronchograms, pleural effusion, and cavitation seen on the chest radiograph. Patients with *Staphylococcus aureus* pneumonia present with pleuritis, chest pain, purulent sputum, and consolidation without air bronchograms identified on the chest radiograph.⁵⁴

Patients infected with atypical pneumonia pathogens, such as *Mycoplasma pneumoniae*, *Legionella pneumophila*, and *Chlamydia pneumoniae* (TWAR agent), present with gradual onset of symptoms. They have a lower temperature, appear less ill, and have mucoid sputum, and a patchy or interstitial infiltrate is seen on the chest radiograph. The severity of the findings on the chest radiograph is usually out of proportion to the mild clinical symptoms. *M. pneumoniae* is the most common organism responsible for atypical pneumonia and is best detected by the presence of cold agglutinins, which appear in about 70% of cases.

The normal physiologic changes in the respiratory system associated with pregnancy result in a loss of ventilatory reserve. Coupled with the immunosuppression that accompanies pregnancy, this puts the mother and fetus at great risk from respiratory infection. Any gravida suspected of having pneumonia should be managed aggressively. The pregnant patient should

be admitted to the hospital and a thorough investigation undertaken to determine the cause. One study examined 133 women admitted with pneumonia during pregnancy using protocols based on the British Thoracic Society and American Thoracic Society admission guidelines for management of nonpregnant individuals. The investigators reported that if the American Thoracic Society guidelines were used, 25% of the pregnant women with pneumonia could have avoided admission. Using the American criteria, none of the gravidas who would have been managed as an outpatient had any complications. If the British Thoracic Society guidelines had been used, 66% of the pregnant women in this group would have been assigned to outpatient therapy. However, 14% would have required readmission for complications. Most of the 133 women who were hospitalized with pneumonia in this study did not receive a chest radiograph for confirmation of the diagnosis. This limits the value of the study for guiding admission criteria for pneumonia in pregnancy. Until additional information is available, admission for all pregnant women with pneumonia is still recommended.

The workup should include a physical examination, arterial blood gas determinations, a chest radiograph, sputum Gram stain and culture, and blood cultures. Several studies have called into question the use of cultures to identify the microbes of community-acquired pneumonia. Success rates for identification of the bacterial cause with cultures range from 2.1% to approximately 50%. Review of available clinical data reflects an overall reliance on clinical judgment and the patient’s response to treatment to guide therapy. Other tests that do not require culture and are more sensitive and specific are available to identify the cause of pneumonia. An assay approved by the U.S. Food and Drug Administration (FDA) for pneumococcal urinary antigen has been assessed in several studies. The sensitivity for identifying pneumococcal disease in adults is reportedly 60% to 90%, with a specificity close to 100%. In one study, the pneumococcal antigen was detected in 26% of patients in whom no pathogens had been identified. This finding suggests that cases that are undiagnosed by standard test can be identified with the assay. In this study, 10% of samples from patients with pneumonia caused by other agents were positive on the pneumococcal assay, indicating a potential problem with specificity. If the response to therapy directed at pneumococcus is inadequate, coverage for other potential pathogens should be added.

The test for *Legionella* urinary antigen has a sensitivity of 70% and specificity of 90% for serogroup 1. This is especially useful in the United States and Europe, because about 85% of *Legionella* isolates are serogroup 1. *Legionella* is a common cause of severe community-acquired pneumonia. The urinary antigen for serogroup 1 should be considered for any patient requiring admission into an intensive care unit (ICU) for pneumonia.

Percutaneous-transsthoracic needle aspiration has been advocated as a valuable and safe method to increase the chance of establishing the causative agent for pneumonia. This test should be reserved for use in compromised individuals, suspected tuberculosis in the absence of a productive cough, selected cases of chronic pneumonia, pneumonia associated with neoplasm or a foreign body, suspected *Pneumocystis jiroveci* pneumonia, and suspected conditions that necessitate lung biopsy. Cold agglutinins and *Legionella* titers may also be useful. Empiric antibiotic coverage should be started, usually

with a third-generation cephalosporin such as ceftriaxone or cefotaxime. *Legionella* pneumonia has a high mortality rate and sometimes manifests with consolidation, mimicking pneumococcal pneumonia. It is recommended that a macrolide, such as azithromycin, be added to the empiric therapy. Dual coverage has been demonstrated to improve response to therapy even for abbreviated macrolide regimens. This may reflect the added anti-inflammatory effect of the macrolides. Azithromycin administration is an independent predictor of a positive outcome and reduced length of hospital stay for patients with mild to moderate community-acquired pneumonia. The use of macrolides to treat community-acquired pneumonia should be limited when possible, because their use has also been associated with increased penicillin resistance by *S. pneumoniae*.

When admission for pneumonia is required, there is evidence that inpatient and 30-day mortality rates have been reduced when antibiotics are administered in less than 8 hours. Current U.S. federal standards require that the first dose of antibiotics be administered within 4 hours of arrival to the hospital. After the results of the sputum culture, blood cultures, Gram stain, and serum studies are obtained and a pathogen has been identified, antibiotic therapy can be directed toward the identified cause. The third-generation cephalosporins are effective agents for most pathogens causing a community-acquired pneumonia. They are also effective against penicillin-resistant *S. pneumoniae*. The quinolones as a class should be avoided in pregnancy because they may damage developing fetal cartilage. However, with the emergence of highly resistant bacterial pneumonia, their use may be lifesaving and therefore justified in specific circumstances. The respiratory quinolones are effective against highly penicillin-resistant *S. pneumoniae* strains, and their use does not increase resistance. The respiratory quinolones include levofloxacin, gatifloxacin, and moxifloxacin. These agents are ideal for community-acquired pneumonia because they are highly active against penicillin-resistant strains of *S. pneumoniae*. They are also active against *Legionella* and the other atypical pulmonary pathogens. Another advantage is a favorable pharmacokinetic profile, such that blood or lung levels are the same whether the drug is administered orally or intravenously. Arguments against more extensive respiratory quinolone use are based on concerns about the potential for developing resistance, the variable incidence of *Legionella*, and cost. An additional caveat is that the respiratory quinolones are only partially effective against *Mycobacterium tuberculosis*. Evaluation for this infection should be done when considering the use of quinolones for pneumonia. If community-acquired methicillin-resistant *S. aureus* (CA-MRSA) pneumonia is suspected, vancomycin or linezolid should be added to empiric therapy.⁵⁹ CA-MRSA is also susceptible to fluoroquinolones and trimethoprim-sulfamethoxazole and is often resistant only to beta-lactam antibiotics. Additional therapy with clindamycin can be considered, as it has been shown to reduce production of staphylococcal exotoxins.

In addition to antibiotic therapy, oxygen supplementation should be given. Frequent arterial blood gas measurements should be obtained to maintain partial pressure of oxygen at 70 mm Hg, a level necessary to ensure adequate fetal oxygenation. Arterial saturation also can be monitored with pulse oximetry. When the gravida is afebrile for 48 hours and has signs of clinical improvement, an oral cephalosporin can be started and intravenous therapy discontinued. A total of 10 to 14 days of treatment should be completed.

Pneumonia in pregnancy can be complicated by respiratory failure requiring mechanical ventilation. If this occurs, team management should include the obstetrician, a maternal-fetal medicine specialist, and an intensivist. In addition to meticulous management of the gravida's respiratory status, she should be maintained in the left lateral recumbent position to improve uteroplacental perfusion. The viable fetus should be monitored with continuous fetal monitoring. If positive end-expiratory pressure greater than 10 cm H₂O is required to maintain oxygenation, central monitoring with a pulmonary artery catheter should be instituted to adequately monitor volume status and maintain maternal and uteroplacental perfusion. There is no evidence that elective delivery results in overall improvement in respiratory function,⁶⁰ so it should be reserved for the usual obstetric indications. However, if there is evidence of fetal compromise or profound maternal compromise and impending demise, delivery should be accomplished.

Pneumococcal polysaccharide vaccination prevents pneumococcal pneumonia in otherwise healthy populations with an efficacy of 65% to 84%. The vaccine is safe in pregnancy and should be administered to high-risk gravidas. Those at high risk include individuals with sickle cell disease with autosplenectomy, patients who have had a surgical splenectomy, and individuals who are immunosuppressed. Several studies have demonstrated an additional advantage to maternal immunization with the pneumococcal vaccine: a significant transplacental transmission of vaccine-specific antibodies in infants, measured at birth and at 2 months. Colostrum and breast milk antibodies are also significantly increased in women who have received the pneumococcal vaccine.

VIRAL PNEUMONIAS

Influenza

An estimated 4 million cases of pneumonia and influenza occur annually in the United States, and it is the sixth leading cause of death.⁶¹ In contrast to the general population, pregnant women seem to be at higher risk for influenza pneumonia.^{62,63} Epidemiologic data from the 1918 to 1919 influenza A pandemic revealed a maternal mortality rate that approached 50% for pregnant women with influenza pneumonia.^{64,65} Three types of influenza virus can cause human disease—A, B, and C—but most epidemic infections are caused by influenza A.⁵⁰ Influenza A typically has an acute onset after a 1- to 4-day incubation period and first manifests as high fever, coryza, headache, malaise, and cough. In uncomplicated cases, results of the chest examination and chest radiograph are normal.⁵⁰ If symptoms persist longer than 5 days, especially in a pregnant woman, complications should be suspected. Pneumonia may complicate influenza as the result of secondary bacterial infection or viral infection of the lung parenchyma.⁵⁰ In the epidemic of 1957, autopsies demonstrated that pregnant women died most commonly of fulminant viral pneumonia, whereas nonpregnant patients died most often of secondary bacterial infection.⁶⁶

A large, nested, case-control study evaluated the rate of influenza-related complications over 17 influenza seasons among women enrolled in the Tennessee Medicaid system. This study demonstrated a high risk for hospitalization for influenza-related reasons in low-risk pregnant women during the last trimester of pregnancy. The study authors estimated that 25 of 10,000 women in the third trimester during the influenza

season are hospitalized with influenza-related complications. A later, matched-cohort study using the administrative database of pregnant women enrolled in the Tennessee Medicaid system examined pregnant women between the ages of 25 and 44 years hospitalized with respiratory illness during the 1985 to 1993 influenza seasons. In this population of pregnant women, those with asthma accounted for one half of all respiratory-related hospitalizations during the influenza season. Among pregnant women with diagnosis of asthma, 6% required respiratory hospitalization during the influenza season (OR = 10.63; 95% confidence interval [CI], 8.61 to 13.83) compared with women without a medical comorbidity. This study detected no significant increases in adverse perinatal outcome associated with respiratory hospitalization during flu season. Data on pandemic 2009 influenza A (H1N1) suggest that pregnant women had an increased risk of hospitalization and death. Pregnant women with treatment more than 4 days after symptom onset were more likely to be admitted to an ICU than those treated within 2 days after symptom onset. Therefore, a high index of suspicion, early diagnosis, and empiric treatment for suspected influenza are warranted in pregnancy.⁶⁷

Primary influenza pneumonia is characterized by rapid progression from a unilateral infiltrate to diffuse bilateral disease. The gravida may develop fulminant respiratory failure requiring mechanical ventilation and positive end-expiratory pressure. Aggressive therapy is indicated when pneumonia complicates influenza in pregnancy. Antibiotics should be started and directed at the likely pathogens that can cause secondary infection, including *S. aureus*, pneumococcus, *H. influenzae*, and certain enteric gram-negative bacteria. Antiviral agents, such as oseltamivir and zanamivir, should also be considered.⁶⁸ It has been recommended that the influenza vaccine be given routinely to all gravidas in all trimesters of pregnancy to prevent the occurrence of influenza and the development of pneumonia. Women at high risk for pulmonary complications, such as those with asthma, chronic obstructive pulmonary disease, cystic fibrosis, and splenectomy, should be vaccinated early in pregnancy to prevent the occurrence of influenza and the development of secondary pneumonia. In addition to maternal protection, prospective studies have demonstrated higher cord blood levels of antibody to influenza in infants born to mothers immunized during pregnancy. There is a delay in the onset and decrease in severity of influenza in infants born with higher antibody levels.

Varicella

Varicella-zoster virus is a DNA virus that usually causes a benign, self-limited illness in children, but it may infect up to 2% of all adults.⁶⁹ Varicella infection occurs in 0.7 of every 1000 pregnancies.⁷⁰ Pregnancy may increase the likelihood of varicella pneumonia, complicating the primary infection.⁵² Treatment with acyclovir is safe in pregnancy.⁷¹ In one report,⁵² there was one intrauterine fetal death. Another report⁵¹ documented a 5.2% incidence of varicella pneumonia among gravidas with varicella-zoster infection. The investigators also reported that gravidas who smoke or manifest more than 100 skin lesions are more likely to develop pneumonia.⁵¹ Varicella pneumonia occurs most often in the third trimester, and the infection is likely to be severe.^{52,72,73} The maternal mortality rate for varicella pneumonia may be as high as 35% to 40%, compared with 11% to 17% for nonpregnant individuals.^{52,73} Although one review reported a decreased mortality rate, with only three deaths

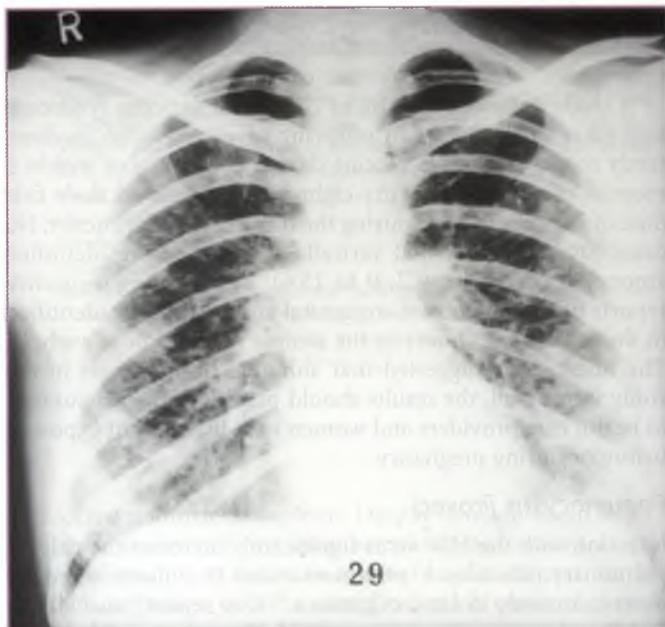

Figure 58-4 Varicella pneumonia. The chest radiograph demonstrates bilateral nodular and interstitial pneumonia of varicella pneumonia.

among 28 women with varicella pneumonia,⁷² another study documented a maternal mortality rate of 35%.⁵² However, a later report documented 100% survival among 18 gravidas with varicella pneumonia who were treated with acyclovir.⁵¹ In this report, there was one intrauterine fetal death at 25 weeks' gestation in a woman with varicella. In one report of 312 pregnancies, there was no increase in the number of birth defects and no consistent pattern of congenital abnormalities. In another report, 17 infants were delivered beyond 36 weeks' gestation, and there was no evidence of neonatal varicella.⁵¹

Varicella pneumonia usually manifests 2 to 5 days after the onset of fever, rash, and malaise and is heralded by the onset of pulmonary symptoms, including cough, dyspnea, pruritic chest pain, and hemoptysis.⁵² The severity of the illness varies from asymptomatic radiographic abnormalities to fulminant pneumonitis and respiratory failure (Fig. 58-4).⁵²

All gravidas with varicella pneumonia should be aggressively treated with antiviral therapy and admitted to the ICU for close observation or intubation if indicated. Acyclovir, a DNA polymerase inhibitor, should be started. The early use of acyclovir was associated with an improved hospital course after the fifth day and a lower mean temperature, lower respiratory rate, and improved oxygenation.⁵² Treatment with acyclovir is safe in pregnancy. Among 312 pregnancies, there was no increase in the number of birth defects and no consistent pattern of congenital abnormalities.⁷³ A dosage of 7.5 mg/kg given intravenously every 8 hours has been recommended.⁷⁴

Varicella vaccine is an attenuated live virus vaccine that was added to the universal childhood immunization schedule in the United States in 1995. The program of universal childhood vaccination against varicella in the United States has resulted in a sharp decline in the rate of death from varicella. However, varicella vaccine is not recommended for use in pregnancy. The overall decline in incidence of adult varicella infection because

of childhood vaccination will probably result in a decreased incidence of varicella infection and varicella pneumonia during pregnancy.

A study⁷⁵ assessed the risk of congenital varicella syndrome and other birth defects in offspring of women who inadvertently received varicella vaccine during pregnancy or within 3 months of conception. Fifty-eight women received their first dose of varicella vaccine during the first or second trimester. No cases (0%) of congenital varicella syndrome were identified among 56 live births (CI, 0 to 15.6). Among the prospective reports of live births, five congenital anomalies were identified in the susceptible cohort or the sample population as a whole. The investigator suggested that although the numbers in the study were small, the results should provide some reassurance to health care providers and women with inadvertent exposure before or during pregnancy.

Pneumocystis jiroveci

Infection with the HIV virus significantly increases the risk for pulmonary infection. *S. pneumoniae* and *H. influenzae* are the most commonly isolated organisms.⁷⁵ One report⁷⁶ also identified *Pseudomonas aeruginosa* as a significant cause of bacterial pneumonia in HIV-infected individuals. *Pneumocystis* pneumonia, an AIDS-defining illness, occurs more frequently when the helper-T-cell count (CD4⁺) is less than 200 cells/mm³. *Pneumocystis jiroveci* pneumonia (PJP), formerly designated *Pneumocystis carinii* pneumonia (PCP), is the most common of the serious opportunistic infections in pregnant women infected with HIV.^{77,78} *P. jiroveci* is the number one cause of pregnancy-associated AIDS deaths in the United States.⁷⁹ Initial reports of PJP in pregnancy described a 100% maternal mortality rate.^{47,77,80-82} However, in a 2001 review of 22 cases of PJP in pregnancy, the mortality rate was 50% (11 of 22 patients).⁸³ However, the mortality rate is still higher than that reported for HIV-infected nonpregnant individuals.⁸³ In that series, respiratory failure developed in 13 patients, and 59% required mechanical ventilation. The survival rate of gravidas requiring mechanical ventilation was 31%. In this series, maternal and fetal outcomes were better in cases of PJP that occurred during the third trimester of pregnancy.

A high index of suspicion is necessary when gravidas at risk for HIV infection present with symptoms such as weight loss, fatigue, fever, tachypnea, dyspnea, and nonproductive cough.⁷⁷ The onset of disease can be insidious, including normal radiographic findings, and it can then proceed to rapid deterioration.⁷⁷ When the chest radiograph is positive, it typically exhibits bilateral alveolar disease in the perihilar regions and lower lung fields (Fig. 58-5), which can progress to include the entire parenchyma.⁷⁷ Diagnosis can be accomplished by means of sputum silver stains, bronchial aspiration, or bronchoscope-directed biopsy.⁸⁴ Lung biopsy is recommended for definitive diagnosis.⁸⁰

Therapy for PJP in pregnancy includes trimethoprim-sulfamethoxazole (TMP-SMX), which is a category C drug. Gravidas with a history of PJP, a CD4⁺ lymphocyte count of less than 200/mm³, or oral pharyngeal candidiasis should receive prophylaxis.⁸⁵ TMP-SMX is the drug of choice and may provide cross-protection against toxoplasmosis and other bacterial infections.⁸⁶ The usual dosage is one double-strength tablet (150 mg/m² of TMP and 750 mg/m² of SMX) given three times each week. Adverse reactions such as drug allergy, nausea, fever, neutropenia, anemia, thrombocytopenia, and elevated

Figure 58-5 *Pneumocystis jiroveci* pneumonia (PJP). Bilateral alveolar disease is consistent with PJP pneumonia.

transaminase levels have been reported in 20% to 30% of nonpregnant individuals receiving TMP-SMX therapy.⁸⁶ Complete blood cell count with a differential cell count and liver function tests should be obtained every 6 to 8 weeks to monitor for toxicity. Other regimens used for prophylaxis for individuals with intolerance to TMP-SMX include aerosolized pentamidine (300 mg every month by Respigard II nebulizer) or dapsone (100 mg once daily). Hussain and colleagues⁸⁷ found that the survival rate for patients treated with SMX alone was 71% (5 of 7 patients) and that the rate with SMX and steroids was 60% (3 of 5 patients); the overall survival rate for both groups was 66.6% (8 of 12 patients). The investigators concluded that PJP has a more aggressive course during pregnancy, with increased morbidity and mortality.⁸⁷ However, treatment with SMX compared with other therapies may result in improved outcome. They also caution that withholding appropriate PJP prophylaxis may adversely affect maternal and fetal outcomes.⁸⁷

Initiation of therapy during the antepartum period can also prevent the rare occurrence of perinatally transmitted PJP.⁸⁶ When a gravida is demonstrating symptoms consistent with a possible infection, a diligent search should be conducted to quickly identify PJP as the cause of pneumonia. When PJP is untreated, the maternal mortality rate can approach 100%. In summary, PJP pneumonia remains a dreaded complication of HIV infection and an AIDS-defining illness. There is a very high maternal and fetal mortality rate when PJP complicates pregnancy. Primary prophylaxis against *Pneumocystis* pneumonia with TMP-SMX in HIV-infected adults, including pregnant women and patients receiving highly active antiretroviral therapy, should begin when the CD4⁺ cell count is less than 200 cells/mm³ or there is a history of oropharyngeal candidiasis.

Prophylaxis should be discontinued when the CD4⁺ cell count increases to more than 200 cells/mm³ for a period of 3 months.

Tuberculosis in Pregnancy

Tuberculosis kills more than 1 million women per year worldwide, and it is estimated that 646 million women and girls are already infected with tuberculosis. In women between 15 and 44 years old in developing countries, tuberculosis is the third most common cause of morbidity and mortality combined, and tuberculosis kills more women than any other infectious disease, including malaria and AIDS.

Epidemiologic information shows differences between men and women in prevalence of infection, rate of progression from infection to disease, incidence of clinical disease, and mortality resulting from tuberculosis. Case-notification rates from countries with a high prevalence of tuberculosis suggest that it may be less common among women.⁸⁸ Seventy percent more smear-positive male than female tuberculosis patients are diagnosed every year and reported to the World Health Organization.⁸⁸ Differences between men and women have also been shown in the development and outcome of active disease, with female cases having a higher rate of progression from infection to disease and a higher case-fatality rate.⁸⁹ The conclusion of a research workshop on sex and tuberculosis was that a combination of biologic and social factors is responsible for these differences.⁸⁸

The incidence of tuberculosis in the United States began to decline in the early part of the 20th century and fell steadily until 1953, when the introduction of isoniazid (INH) led to a dramatic decrease in the number of cases, from 84,000 cases in 1953 to 22,255 cases in 1984.⁹⁰ However, since 1984, there have been significant changes in tuberculosis morbidity trends. From 1985 through 1991, reported cases of tuberculosis increased by 18%, representing approximately 39,000 more cases than expected had the previous downward trend continued. This increase results from many factors, including the HIV epidemic, deterioration in the health care infrastructure, and more cases among immigrants.^{90,91} Between 1985 and 1992, the number of tuberculosis cases among women of childbearing age increased by 40%.⁹² One report described tuberculosis-complicated pregnancies in 94.8 cases per 100,000 deliveries between 1991 and 1992.⁹³

The emergence of drug-resistant tuberculosis has become a serious concern. In New York City in 1991, 33% of tuberculosis cases were resistant to at least one drug, and 19% were resistant to INH and rifampin. Multidrug resistance is an additional problem. Many centers advocate directly observed therapy in the treatment of multidrug-resistant disease. Pregnancy complicates treatment of multidrug-resistant tuberculosis for the following reasons⁹⁴:

- Several antimycobacterial drugs are contraindicated during gestation.
- Patients and physicians may fear the effects of chest radiography on the fetus.
- Untreated, infectious, multidrug-resistant tuberculosis may be vertically and laterally transmitted.

In one report,⁹⁴ three patients had disease resulting from multidrug-resistant *M. tuberculosis*, and one had disease resulting from multidrug-resistant *Mycobacterium bovis*. Only one patient began retreatment during pregnancy because her organism was susceptible to three antituberculosis drugs that were

BOX 58-1 HIGH-RISK FACTORS FOR TUBERCULOSIS

Human immunodeficiency virus infection
 Close contact with persons known or suspected to have tuberculosis
 Medical risk factors known to increase risk for disease if infected
 Birth in a country with high tuberculosis prevalence
 Medically underserved status
 Low income
 Alcohol addiction
 Intravenous drug use
 Residency in a long-term care facility (e.g., correctional institution, mental institution, nursing home or facility)
 Health professionals working in high-risk health care facilities

considered nontoxic to the fetus. Despite concern about teratogenicity of the second-line antituberculosis medications, careful timing of treatment initiation resulted in clinical cure for the mothers, regardless of some complications because of chronic tuberculosis or therapy. In this series, all infants were born healthy and remained free of tuberculosis.⁹⁴

DIAGNOSIS

Most gravidas with tuberculosis in pregnancy are asymptomatic. All gravidas at high risk for tuberculosis (Box 58-1) should be screened with subcutaneous administration of intermediate-strength purified protein derivative (PPD). If anergy is suspected, control antigens such as candidal, mumps, or tetanus toxoid should be used.⁹⁵ The sensitivity of the PPD is 90% to 99% for exposure to tuberculosis. The tine test should not be used for screening because of its low sensitivity.

The onset of the recent tuberculosis epidemic stimulated the need for rapid diagnostic tests using molecular biology methods to detect *M. tuberculosis* in clinical specimens. Two direct amplification tests have been approved by the FDA: the *Mycobacterium tuberculosis* Direct (MTD) Test (Gen-Probe, San Diego, CA) and the Amplicor *Mycobacterium tuberculosis* (MTB) Test (Roche Diagnostic Systems, Branchburg, NJ). Both tests amplify and detect *M. tuberculosis* 16S ribosomal DNA.⁹⁶ When testing acid-fast, stained smear-positive respiratory specimens, each test has a sensitivity of greater than 95% and a specificity of essentially 100% for detecting the *M. tuberculosis* complex.^{97,98} When testing acid-fast, stained smear-negative respiratory specimens, the specificity remains greater than 95%, but the sensitivity ranges from 40% to 77%.^{97,98} These tests are FDA approved only for testing acid-fast, stained smear-positive respiratory specimens obtained from untreated patients or those who have received no more than 7 days of antituberculosis therapy. The PPD remains the most commonly used screening test for tuberculosis.

Immigrants from areas where tuberculosis is endemic may have received the bacillus Calmette-Guérin (BCG) vaccine, and they are likely to have a positive response to the PPD. However, this reactivity should wane over time. The PPD should be used to screen these patients for tuberculosis unless their skin tests are known to be positive.⁹⁵ If BCG vaccine was given 10 years earlier and the PPD is positive with a skin test reaction of 10 mm or more, the individual should be considered infected with tuberculosis and managed accordingly.⁹⁵

Figure 58-6 Chest radiograph of pulmonary tuberculosis. Radiographic findings may include adenopathy, multinodular infiltrates, cavitation, loss of volume in the upper lobes, and upper medial retraction of hilar markings.

Women with a positive PPD skin test result must be evaluated for active tuberculosis with a thorough physical examination for extrapulmonary disease, and a chest radiograph after they are beyond the first trimester.⁵⁴ Symptoms of active tuberculosis include cough (74%), weight loss (41%), fever (30%), malaise and fatigue (30%), and hemoptysis (19%).⁹⁹ Individuals with active pulmonary tuberculosis may have radiographic findings, including adenopathy, multinodular infiltrates, cavitation, loss of volume in the upper lobes, and upper medial retraction of hilar markings (Fig. 58-6). The finding of acid-fast bacilli in early-morning sputum specimens confirms the diagnosis of pulmonary tuberculosis. At least three early-morning sputum samples should be examined for the presence of acid-fast bacilli. If sputum cannot be produced, sputum induction, gastric washings, or diagnostic bronchoscopy may be indicated.

Extrapulmonary tuberculosis occurs in up to 16% of cases in the United States; however, the pattern may occur in 60% to 70% of all patients with AIDS.¹⁰⁰ Extrapulmonary sites include lymph nodes, bone, kidneys, intestine, meninges, breasts, and endometrium. Extrapulmonary tuberculosis appears to be rare in pregnancy.¹⁰¹ When it is confined to the lymph nodes, it has no effect on obstetric outcomes, but tuberculosis at other extrapulmonary sites does adversely affect the outcome of pregnancy.¹⁰² Jana and colleagues¹⁰² documented that tuberculosis lymphadenitis did not affect the course of pregnancy, labor, or perinatal outcome. However, compared with control women, the 21 women with tubercular involvement of other extrapulmonary sites had higher rates of antenatal hospitalization (24% versus 2%; $P < .0001$), infants with low Apgar scores (≤ 6) soon after birth (19% versus 3%; $P = .01$), and low-birth-weight (< 2500 g) infants (33% versus 11%; $P = .01$). Rarely,

mycobacteria invade the uteroplacental circulation, and congenital tuberculosis results.^{49,92,103} The diagnosis of congenital tuberculosis is based on one of the following factors⁹²:

- Demonstration of primary hepatic complex or cavitating hepatic granuloma by percutaneous liver biopsy at birth
- Infection of the maternal genital tract or placenta
- Lesions seen in the first week of life
- Exclusion of the possibility of postnatal transmission by a thorough investigation of all contacts, including attendants

PREVENTION

Most gravidas with a positive PPD result are asymptomatic during pregnancy and have no evidence of active disease; they are classified as infected without active disease. The risk of progression to active disease is highest in the first 2 years of conversion. It is important to prevent the onset of active disease while minimizing maternal and fetal risk. An algorithm for management of the positive PPD is presented in Figure 58-7.^{104,105} In women with a known recent conversion (within 2 years) to a positive PPD result and no evidence of active disease, the recommended prophylaxis is INH (300 mg/day), starting after the first trimester and continuing for 6 to 9 months.⁵⁴ Under base-case assumptions in a Markov decision-analysis model, the fewest cases of tuberculosis in the cohort occurred with antepartum treatment (1400 per 100,000), compared with no treatment (3300 per 100,000) or postpartum treatment (1800 per 100,000).¹⁰⁶ Antepartum treatment resulted in a marginal increase in life expectancy because of the prevented INH-related hepatitis and deaths, compared with no treatment or postpartum treatment. Antepartum treatment was the least expensive.¹⁰⁶ Isoniazid should be accompanied by pyridoxine (vitamin B₆) supplementation (50 mg/day) to prevent the peripheral neuropathy that is associated with INH treatment. Women with an unknown or prolonged duration of PPD positivity (> 2 years) should receive INH (300 mg/day) for 6 to 9 months after delivery. Isoniazid prophylaxis is not recommended for women older than 35 years who have an unknown or prolonged PPD positivity in the absence of active disease. The use of INH is discouraged in this group because of an increased risk for hepatotoxicity. Isoniazid is associated with hepatitis in pregnant and nonpregnant adults. However, monthly monitoring of liver function tests may prevent this adverse outcome. Among individuals receiving INH, 10% to 20% will develop mildly elevated values detected on liver function tests. These changes resolve after the drug is discontinued.¹⁰⁷

Recently, three randomized controlled trials have shown that a new combination regimen of INH and rifapentine administered weekly for 12 weeks as directly observed therapy is as effective for preventing TB as other regimens and is more likely to be completed than the U.S. standard regimen of 9 months of INH daily without direct observation of compliance.¹⁰⁸ However, this therapy is not recommended in pregnancy because its safety has not been studied.

TREATMENT

The gravida with active tuberculosis should be treated initially with INH (300 mg/day) combined with rifampin (600 mg/day) (Table 58-1).¹⁰⁹ Resistant disease may begin with the initial infection with resistant strains (33%), or it can develop during

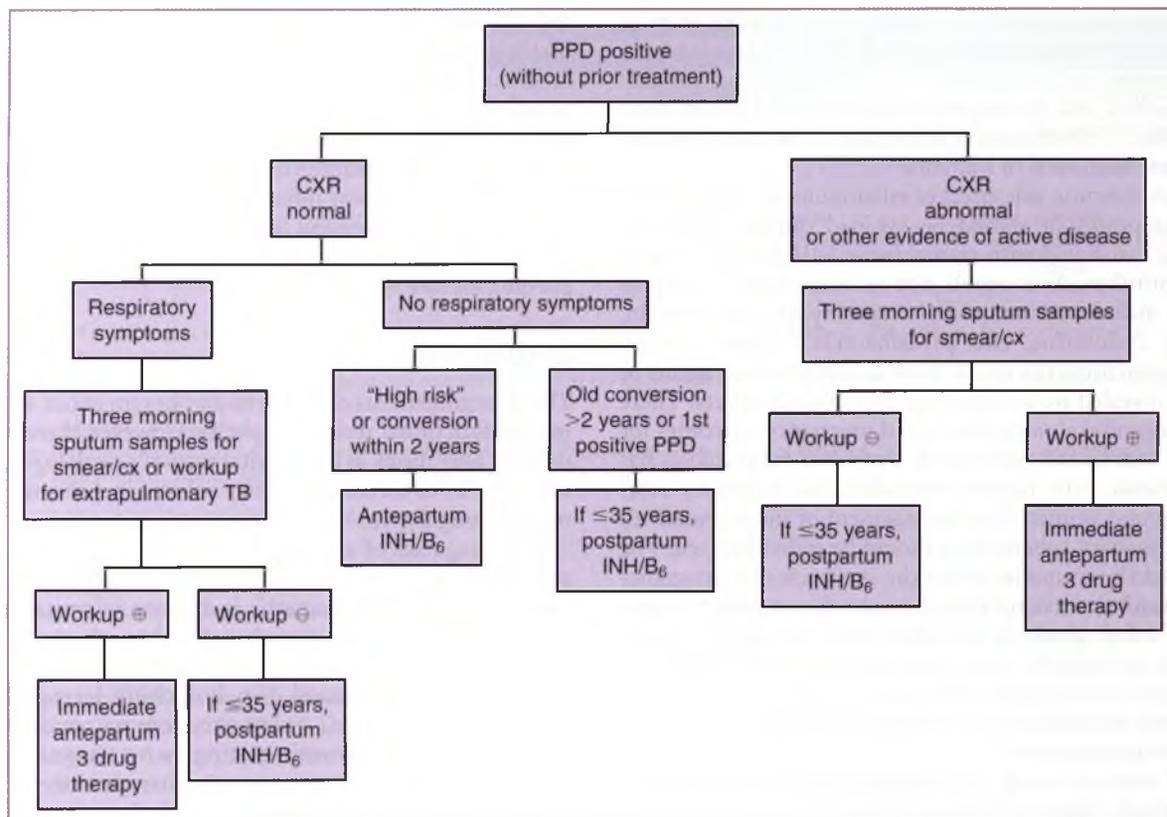

Figure 58-7 Algorithm for the management of a patient with a positive purified protein derivative (PPD) result. In women with known conversion within the past 2 years to a positive PPD result and no evidence of active disease, the recommended prophylaxis is 300 mg of isoniazid (INH) per day, starting after the first trimester and continuing for 6 to 9 months. B₆, pyridoxine; cx, culture; CXR, chest radiograph; TB, tuberculosis.

TABLE 58-1 Antituberculosis Drugs

Drug	Dosage Route	Daily Dose	Weekly Dose	Major Adverse Reactions
FIRST-LINE DRUGS (FOR INITIAL TREATMENT)				
Isoniazid	PO, IM	10 mg/kg, up to 300 mg	15 mg/kg, up to 900 mg	Hepatic enzyme elevation, peripheral neuropathy, hepatitis, hypersensitivity
Rifampin	PO	10 mg/kg, up to 600 mg	10 mg/kg, up to 600 mg	Orange discoloration of secretions and urine; nausea, vomiting, hepatitis, febrile reaction, purpura (rare)
Pyrazinamide	PO	15-30 mg/kg, up to 2 g	50-70 mg/kg, twice	Hepatotoxicity, hyperuricemia, arthralgias, rash, gastrointestinal upset
Ethambutol	PO	15 mg/kg, up to 2.5 g	50 mg/kg	Optic neuritis (decreased red-green color discrimination, decreased visual acuity), rash
Streptomycin	IM	15 mg/kg, up to 1 g	25-30 mg/kg, up to 1 g	Ototoxicity, nephrotoxicity
SECOND-LINE DRUGS (DAILY THERAPY)				
Capreomycin	IM	15-30 mg/kg, up to 1 g	—	Auditory, vestibular, and renal toxicity
Kanamycin	IM	15-30 mg/kg, up to 1 g	—	Auditory and renal toxicity, rare vestibular toxicity
Ethionamide	PO	15-20 mg/kg, up to 1 g	—	Gastrointestinal disturbance, hepatotoxicity, hypersensitivity
<i>p</i> -Amino-salicylic acid	PO	150 mg/kg, up to 1 g	—	Gastrointestinal disturbance, hypersensitivity, hepatotoxicity, sodium load
Cycloserine	PO	15-20 mg/kg, up to 1 g	—	Psychosis, convulsions, rash

IM, intramuscularly; PO, orally.

therapy.¹¹⁰ The development of resistance is more likely in individuals who are noncompliant with therapy. If resistance to INH is identified or anticipated, 2.5 g of ethambutol per day should be added, and the treatment period should be extended to 18 months.¹¹¹ Ethambutol is teratogenic in animals, but this effect has not been seen in humans.

The most common side effect of ethambutol therapy is optic neuritis. Streptomycin should be avoided during pregnancy because it is associated with cranial nerve VIII damage in neonates.¹¹² Antituberculous agents not recommended for use in pregnancy include ethionamide, streptomycin, capreomycin, kanamycin, cycloserine, and pyrazinamide.⁵⁴ However, case reports documenting the use of these antituberculous agents in pregnancy revealed no adverse fetal or neonatal effects. There were no congenital abnormalities, and pregnancy outcomes for the treated individuals were good. Untreated tuberculosis has been associated with higher morbidity and mortality rates among pregnant women. The management of the gravida with multidrug-resistant tuberculosis should be individualized. The patient should be counseled about the small risk of teratogenicity and should understand that the risk of postpartum transmission of tuberculosis to the infant may be higher among those born to patients with drug-resistant tuberculosis. In patients with active disease at the time of delivery, separation of the mother and newborn should be accomplished to prevent infection of the newborn.

Women who are being treated with antituberculous drugs may breastfeed. Only 0.75% to 2.3% of INH and 0.05% of rifampin is excreted into breast milk. Ethambutol excretion into breast milk is also minimal. However, if the infant is concurrently taking oral antituberculous therapy, excessive drug levels may be reached in the neonate, and breastfeeding should be avoided. Breastfed infants of women taking INH should receive a multivitamin supplement that includes pyridoxine.⁵⁴ Neonates of women taking antituberculous therapy should have a PPD skin test at birth and again when 3 months old. Infants born to women with active tuberculosis at the time of delivery should receive INH prophylaxis (10 mg/kg/day) until maternal disease has been inactive for 3 months as evidenced by negative maternal sputum cultures.⁵⁴ Infants of women with multidrug-resistant tuberculosis should probably be placed with an alternative caregiver until there is no evidence of active disease in the mother. The newborn should also receive BCG vaccine and INH prophylaxis.⁹⁴ Active tuberculosis in the neonate should be treated appropriately with INH and rifampin immediately on diagnosis, or with multiagent therapy if drug-resistant organisms are identified. Infants and children who are at high risk for intimate and prolonged exposure to untreated or ineffectively treated persons should receive the BCG vaccine.¹¹³

In summary, high-risk gravidas should be screened for tuberculosis and treated appropriately with INH prophylaxis for infection without overt disease and with dual antituberculous therapy for active disease. The newborn also should be screened for evidence of tuberculosis. Proper screening and therapy will lead to a good outcome for the mother and infant in most cases.

Asthma in Pregnancy

Asthma may be the most common potentially serious medical condition to complicate pregnancy.^{114,115} It is characterized by chronic airway inflammation with increased airway

responsiveness to a variety of stimuli, and airway obstruction that is partially or completely reversible.¹¹⁵ Approximately 4% to 8% of pregnancies are complicated by asthma.^{114,115} The prevalence and morbidity rates for asthma are increasing, but the mortality rate has decreased in recent years.

Insight into the pathogenesis of asthma has changed with the recognition that airway inflammation occurs in almost all cases. The medical management for asthma emphasizes treatment of airway inflammation to decrease airway responsiveness and prevent asthma symptoms.

DIAGNOSIS

The enlarging uterus elevates the diaphragm about 4 cm, reducing the functional residual capacity. However, there are no significant alterations in forced vital capacity, peak expiratory flow rate (PEFR) or forced expiratory volume in 1 second (FEV₁) in normal pregnancies.^{114,116}

The diagnosis of asthma is usually straightforward, as most patients have a history of asthma antedating pregnancy. The common alternative diagnosis is dyspnea of pregnancy, which is not associated with cough, wheezing, chest tightness, or airway obstruction. Other potential diagnoses include cough due to reflux or postnasal drip, bronchitis, laryngeal dysfunction, hyperventilation, pulmonary edema, and pulmonary embolism.¹¹⁴⁻¹¹⁶ Diagnostic testing is warranted in patients whose clinical picture or response to therapy is atypical, or who present with respiratory symptoms during pregnancy in the absence of a history of asthma. The demonstration of a reduced FEV₁ or a 12% or greater improvement in FEV₁ after the administration of inhaled albuterol confirms a diagnosis of asthma.¹¹⁴⁻¹¹⁶ Methacholine testing is contraindicated during pregnancy because of the lack of data on safety. In a small study, exhaled nitric oxide was significantly reduced among pregnant women with asthma compared with healthy pregnant controls.¹¹⁷

Patients with persistent asthma who have not previously been tested for allergies may undergo blood testing for specific IgE antibodies to allergens such as dust mites, cockroaches, mold spores, and pets. Skin tests are not generally recommended during pregnancy because skin testing with potent antigens may be associated with systemic reactions.

The National Asthma Education and Prevention Program (NAEPP)¹¹⁴ Expert Panel Report defined asthma as mild intermittent, and as mild, moderate, and severe persistent (Table 58-2). Current asthma control should be assessed according to the frequency and severity of symptoms, including interference with sleep and normal activity, the frequency of use of rescue therapy, the history of exacerbations requiring the use of systemic corticosteroids, and the results of pulmonary function tests. Spirometry is the preferred method of assessing pulmonary function, but PEFR is an acceptable alternative. Patients who have asthma that is well controlled and who are not receiving controller medications can be classified as having intermittent rather than persistent asthma. Using the Juniper Quality of Life Questionnaire, asthma-specific quality of life in early pregnancy was found to be related to subsequent asthma morbidity but not to perinatal outcomes.¹¹⁸

EFFECTS OF PREGNANCY ON ASTHMA

Asthma has been associated with considerable maternal morbidity. In a large, prospective study of pregnant women, those

TABLE 58-2 Classification of Asthma Severity and Control in Pregnant Patients

Sign or Symptom	Well Controlled*		Not Well Controlled*	
	Intermittent [†]	Mild Persistent [†]	Moderate Persistent [†]	Severe Persistent [†]
Symptom frequency/short-acting β -agonist use	≤ 2 days/wk	>2 days/wk but not daily	Daily symptoms	Throughout the day
Nighttime awakening	$\leq 2 \times /mo$	$>2 \times /mo$	$>1 \times /wk$	$\geq 4 \times /wk$
Interference with normal activities	None	Minor limitation	Some limitation	Extremely limited
FEV ₁ or peak flow (% predicted/ personal best)	$>80\%$	$>80\%$	60%-80%	$<60\%$

*Asthma control: Assess in patients on long-term-control medications to determine whether step-up, step-down, or no change in therapy is indicated.

[†]Asthma severity: Assess severity for patients who are not on long-term-control medications. See Table 58-5 to choose controller therapy based on severity.

FEV₁, expiratory volume in 1 second.

Modified from National Asthma Education and Prevention Program: Expert panel report 3: guidelines for the diagnosis and management of asthma—full report 2007. www.nhlbi.nih.gov/guidelines/asthma/asthgdln.pdf. Accessed December 2, 2012.

with mild asthma had an exacerbation rate of 12.6% and a hospitalization rate of 2.3%, those with moderate asthma had an exacerbation rate of 25.7% and a hospitalization rate of 6.8%, and severe asthmatics had an exacerbation rate of 51.9% and a hospitalization rate of 26.9%.¹¹⁹ The effects of pregnancy on asthma vary. In a large, prospective study, 23% improved and 30% became worse during pregnancy.¹¹⁹ One of the most important conclusions of this study is that pregnant women with mild or even well-controlled asthma should be monitored by PEFr and FEV₁ testing during pregnancy.

EFFECTS OF ASTHMA ON PREGNANCY

Women with asthma have been reported to have higher risks for several complications of pregnancy, including preeclampsia, preterm birth, low birth weight or intrauterine growth restriction, and perinatal mortality, even after adjustment for potential confounders.¹²⁰ A significant increase in congenital malformations has been associated with exacerbations during the first trimester.¹²¹ Although residual confounding or common pathogenic factors may explain some of these associations, observational data showing strong associations between poor asthma control (based on symptoms, pulmonary function, or exacerbations) and these increased risks suggest potential benefits of better asthma control in pregnancy in terms of improved pregnancy outcomes.¹²⁰⁻¹²⁴

Prospective studies of the effects of asthma during pregnancy have generally shown excellent perinatal outcomes.^{122,125-132} Preterm birth after less than 37 weeks' gestation was increased among asthmatics who had severe disease or required oral corticosteroids; preeclampsia and small-for-gestational-age fetuses were increased among those with daily symptoms; and the rate of cesarean delivery was increased among those with daily symptoms and among those with moderate or severe asthma.^{122,130} Although these studies show that women with asthma can have excellent maternal and perinatal outcomes, some caveats are called for in the interpretation. These prospective studies tended to find fewer significant adverse associations, possibly because of better asthma surveillance and active asthma management. In addition, women who enroll in research studies tend to be more compliant and better motivated than the general public. Also, the failure to find more adverse outcomes

among women with severe asthma may be a function of the relatively small numbers and the resulting lack of statistical power. Nonetheless, these prospective studies are reassuring in their consensus of good pregnancy outcomes among women with asthma. These findings do not contradict the possibility that suboptimal control of asthma during pregnancy is associated with increased risk to the mother or baby.¹³⁰ In fact, a significant relationship has been reported between lower FEV₁ during pregnancy and increased risk of low birth weight and prematurity.¹³³

MANAGEMENT APPROACHES

The ultimate goal of asthma therapy during pregnancy is to maintain adequate oxygenation of the fetus by preventing hypoxic episodes in the mother. Other goals include achievement of minimal or no maternal symptoms day or night, minimal or no exacerbations, no limitations of activities, maintenance of normal or near-normal pulmonary function, minimal use of short-acting β_2 -agonists, and minimal or no adverse effects from medications. Consultation or co-management with an asthma specialist is appropriate for evaluation of the role of allergy and irritants, complete pulmonary function studies, or evaluation of the medication plan if there are complications in achieving the goals of therapy or if the patient has severe asthma. A team approach is helpful if more than one clinician is managing the asthma and the pregnancy. The effective management of asthma during pregnancy relies on four integral components: objective assessment, trigger avoidance, patient education, and pharmacologic therapy.

Objective Measures for Assessment and Monitoring

Subjective measures of lung function by the patient or physician provide insensitive and inaccurate assessments of airway hyperresponsiveness, airway inflammation, and asthma severity. The FEV₁ value after a maximal inspiration is the single best measure of pulmonary function. When adjusted for confounders, a mean FEV₁ less than 80% of the predicted value has been significantly associated with increased preterm delivery at less than 32 weeks and at less than 37 weeks, and with a birth weight of less than 2500 g.¹³³ However, measurement of FEV₁ requires a spirometer. The PEFr correlates well with the FEV₁, and it can

be measured reliably with inexpensive, disposable, portable peak flow meters.

PEFR monitoring by the patient provides valuable insight into the course of asthma throughout the day, it assesses circadian variation in pulmonary function, and it helps detect early signs of deterioration so that timely therapy can be instituted. Patients with persistent asthma should be evaluated at least monthly, and those with moderate to severe asthma should have daily PEFr monitoring.¹¹⁴ In a pregnant woman, the typical PEFr should be 380 to 550 L/min. She should establish her “personal best” PEFr and then calculate her individualized PEFr zones. The green zone is more than 80% of the personal best, the yellow zone is between 50% and 80%, and the red zone is less than 50%.

Avoiding or Controlling Asthma Triggers

Limiting adverse environmental exposures during pregnancy is important for controlling asthma. Irritants and allergens that provoke acute symptoms also increase airway inflammation and hyper-responsiveness. Avoiding or controlling such triggers can reduce asthma symptoms, airway hyper-responsiveness, and the need for medical therapy.¹¹⁶ Association of asthma with allergies is common; 75% to 85% of patients with asthma have positive skin test results for common allergens, including animal dander, house dust mites, cockroach antigens, pollens, and molds. Other common nonimmunologic triggers include tobacco smoke, strong odors, air pollutants, food additives such as sulfites, and certain drugs, including aspirin and β -blockers. Another trigger can be strenuous physical activity. For some patients, exercise-induced asthma can be avoided with inhalation of albuterol 10 to 30 minutes before exercise.

Specific measures for avoiding asthma triggers include removing carpeting, using an allergen-impermeable mattress and pillow covers, weekly washing of bedding in hot water, avoiding tobacco smoke, inhibiting mite and mold growth by reducing humidity, and leaving the house when it is being vacuumed. Allergic women should at least keep furry pets out of the bedroom; ideal animal dander control involves removing the pet from the home. Cockroaches can be controlled by poison baits or bait traps and eliminating exposed food or garbage.

The use of allergen immunotherapy, or “allergy shots,” has been shown to be effective in improving asthma in allergic patients.¹¹⁶ However, anaphylaxis is a risk of allergy injections, especially early in the course of immunotherapy when the dosage is being escalated, and anaphylaxis during pregnancy has been associated with fetal and maternal death. In a patient who is receiving a maintenance or near-maintenance dosage, not experiencing adverse reactions to the injections, and apparently deriving clinical benefit, continuation of immunotherapy is recommended.¹¹⁴ In such patients, a dosage reduction may be considered to further decrease the chance of anaphylaxis. Risk-benefit considerations do not usually favor *beginning* allergy shots during pregnancy.

Patient Education

All patients should be educated about the relationship between asthma and pregnancy, and they should be taught about self-treatment, including inhaler techniques, adherence to medication, and control of potential environmental triggers. They should know that discontinuation of medications during pregnancy is associated with more severe asthma for all categories of asthma severity.¹³⁴ Physicians should discuss self-reported

adherence to treatment with controller medication and, if needed, address barriers to optimal adherence (e.g., cost, convenience, concern about side effects). Active smoking, but not passive smoking, has been associated with increased asthma symptoms and fetal growth abnormalities.¹³⁵ Women who smoke should be strongly encouraged to quit. Advice on environmental control measures for reducing exposure to allergens can be provided on the basis of the results of allergy testing.

Patients should be provided with a schedule for maintenance medications and dosages of rescue therapy for increased symptoms. They should understand when and how to increase controller medications, when and how to use prednisone (for those with previous prednisone use or poorly controlled asthma), how to recognize a severe exacerbation, and when and how to seek urgent or emergency care. Patients should be aware that controlling asthma during pregnancy is especially important for the well-being of the fetus. They should have a basic understanding of the medical management of asthma during pregnancy, including self-monitoring of PEFrs and the correct use of inhalers. They should be instructed on proper PEFr technique—for example, to make the measurement while standing, and to take a maximal inspiration and note the reading on the peak flow meter. Women should also be instructed to avoid and control other asthma triggers, as described earlier.

Pharmacologic Therapy

The goals of asthma therapy include relieving bronchospasm, protecting the airways from irritant stimuli, mitigating pulmonary and inflammatory responses to an allergen exposure, and resolving the inflammatory process in the airways, all of which lead to improved pulmonary function with reduced airway hyper-responsiveness. The step-care approach is based on using the smallest amount of drug intervention possible to control the severity of a patient’s asthma.

It is safer for pregnant women with asthma to be treated with asthma medications than it is for them to have asthma symptoms and exacerbations.¹¹⁴ Current pharmacologic therapy emphasizes treatment of airway inflammation to decrease airway hyper-responsiveness and prevent asthma symptoms. Typical dosages of commonly used asthma medications are listed in Table 58-3. Low, medium, and high dosages of inhaled corticosteroids are provided in Table 58-4.

Medications for asthma are divided into long-term controllers that prevent asthma manifestations (inhaled corticosteroids, long-acting β -agonists, leukotriene modifiers, prednisone, and theophylline) and rescue therapy (primarily albuterol) to provide quick relief of symptoms. The protective effect of appropriate pharmacologic therapy is strongest among pregnant women with mild intermittent or mild persistent asthma.¹³⁴

Women who have previously been prescribed asthma medications should be asked about their use so as to classify their current level of therapy according to a step-care approach and to assess potential adherence problems and barriers. Adherence to inhaled corticosteroids has been reported to be poor in many studies. For example, reported adherence rates were approximately 50% in one study of asthmatic adults; decreased adherence was associated with an increased frequency of asthma exacerbations in this study.¹³⁶ Women with asthma have been reported to decrease their inhaled corticosteroid use during early pregnancy compared with their pre-pregnancy use, perhaps because of their reported concern about the safety of

TABLE 58-3 Typical Dosages of Asthma Medications

Drug	Dosage
Albuterol MDI, 90 µg/puff	2-6 puffs, as needed
Salmeterol DPI	1 puff bid
Fluticasone/salmeterol (Advair) DPI	1 inhalation bid, dose depends on severity of asthma
Montelukast	10-mg tablet at night
Zafirlukast	20 mg twice daily
Prednisone	20-60 mg/day for active symptoms
Theophylline	Start 200 mg bid orally, target serum levels of 5-12 µg/mL (decrease dosage by half if treated with erythromycin or cimetidine)
Ipratropium MDI	2-3 puffs every 6 hr
Ipratropium nebulizer	1 mL (0.25 mg) every 6 hr

DPI, dry powder inhaler; MDI, metered-dose inhaler.

TABLE 58-4 Examples of Comparative Daily Doses for Inhaled Corticosteroids

Drug	Low Daily Dosage	Medium Daily Dosage	High Daily Dosage
Beclomethasone HFA 40 or 80 µg/puff	80-240 µg	240-480 µg	>480 µg
Budesonide DPI 90, 180, or 200 µg/inhalation	180-600 µg	600-1200 µg	>1200 µg
Flunisolide 250 µg/puff	500-1000 µg	1000-2000 µg	>2000 µg
Fluticasone MDI: 44, 110, or 220 µg/puff DPI: 50, 100, or 250 µg/inhalation	88-264 µg 100-300 µg	264-440 µg 300-500 µg	>440 µg >500 µg
Triamcinolone acetonide 75 µg/puff	300-750 µg	750-1500 µg	>1500 µg
Mometasone DPI 200 µg/inhalation	200 µg	400 µg	>400 µg

DPI, dry powder inhaler; HFA, hydrofluoroalkane; MDI, metered-dose inhaler.

The total daily dosage is usually divided and given twice a day. Some doses may contain more than package labeling for the high-dosage range. From National Asthma Education and Prevention Program: Expert panel report 3: guidelines for the diagnosis and management of asthma—full report 2007. www.nhlbi.nih.gov/guidelines/asthma/asthgdln.pdf. Accessed December 2, 2012.

inhaled corticosteroids during pregnancy. Moreover, a substantial proportion of asthma exacerbations during pregnancy have been associated with nonadherence to inhaled corticosteroids.¹²⁴ Finding out about past medications, their effectiveness, and any side effects can help the physician with subsequent management decisions and with assessing adherence.

Step Therapy. The step-care approach to therapy increases the number and frequency of medications with increasing asthma severity.^{114,116} Based on clinical trials in patients with varying degrees of asthma severity, medications are considered to be “preferred” or “alternative” at each step of therapy (Table 58-5). Patients not responding optimally to treatment should be stepped up to more intensive medical therapy. Patients with asthma that is not well controlled should generally be stepped up one step, and those whose asthma is very poorly controlled should be stepped up two steps. Once control is achieved and sustained for several months, a step-down approach can be considered, but it should be undertaken cautiously and gradually to avoid compromising the stability of the asthma control. For some patients, it may be prudent to postpone until after the birth attempts to reduce therapy that is effectively controlling the asthma.¹¹⁴ When a patient had a favorable response to an

alternative drug before becoming pregnant, she can be appropriately maintained on that therapy. However, when initiating new treatment for asthma during pregnancy, preferred medications should be considered rather than alternative treatment options.¹¹⁴

Patients with asthma exacerbations may require oral corticosteroids. In such cases, a short course of oral prednisone (40 to 60 mg/day in a single or two divided doses for 3 to 10 days) is recommended.¹¹⁶

Inhaled Corticosteroids. Inhaled corticosteroids are the preferred treatment for the management of all levels of persistent asthma during pregnancy.¹¹⁴ Because almost all patients have airway inflammation, inhaled corticosteroids have been advocated as first-line therapy for those with mild asthma.¹¹⁴ The use of inhaled corticosteroids among nonpregnant asthmatics has been associated with a marked reduction in fatal and near-fatal episodes of asthma. Inhaled corticosteroids produce clinically important improvements in bronchial hyper-responsiveness that appear to be dosage-related and include prevention of increased bronchial hyper-responsiveness after seasonal exposure to allergen. Continued administration is effective in reducing the immediate pulmonary response to an allergen challenge.

TABLE 58-5 Step-Care Approach to Asthma Therapy during Pregnancy

Step	Preferred Controller Medication	Alternative Controller Medication
1	None	—
2	Low-dose inhaled corticosteroid	LTRA, theophylline or cromolyn
3*	Medium-dose inhaled corticosteroid	Low-dose inhaled corticosteroid plus LABA, LTRA, or theophylline
4	Medium-dose inhaled corticosteroid plus LABA	Medium-dose inhaled corticosteroid plus either LTRA or theophylline
5	High-dose inhaled corticosteroid plus LABA	—
6	High-dose inhaled corticosteroid plus LABA plus oral prednisone	—

*Step 3 is modified here to reflect the choice of a medium-dose inhaled corticosteroid over a low-dose inhaled corticosteroid plus a LABA because of the lack of safety data on the use of LABA during pregnancy.

LABA, long-acting β -agonist; LTRA, leukotriene-receptor antagonist. Modified from National Asthma Education and Prevention Program: Expert panel report 3: guidelines for the diagnosis and management of asthma—full report 2007. www.nhlbi.nih.gov/guidelines/asthma/asthgdln.pdf. Accessed December 2, 2012.

In a prospective observational study of 504 pregnant women with asthma, 177 patients were not initially treated with inhaled corticosteroids.¹²⁸ This cohort had a 17% rate of acute exacerbation compared with only a 4% rate among those treated with inhaled corticosteroids from the start of pregnancy. Prescribing inhaled beclomethasone in addition to oral corticosteroids and inhaled β -agonists at the time of discharge after hospitalization for asthma results in fewer subsequent readmissions for asthma as compared with oral corticosteroids and inhaled β -agonists alone.¹³⁷

The NAEPP2 found no evidence linking inhaled corticosteroid use with increases in congenital malformations or adverse perinatal outcomes.¹¹⁴ Included among these studies was the Swedish Medical Birth Registry, which had 2014 infants whose mothers had used inhaled budesonide in early pregnancy.¹³⁸ Because there are more data on using budesonide during pregnancy than on using other inhaled corticosteroids, the NAEPP considered budesonide to be a preferred medication. However, if a woman's asthma was well controlled by a different inhaled corticosteroid before pregnancy, it seems reasonable to continue that medication during pregnancy. All inhaled corticosteroids are labeled by the FDA as pregnancy class C except budesonide, which is class B.

Inhaled β_2 -Agonists. As-needed use of inhaled β_2 -agonists is currently recommended for all levels of asthma during pregnancy.¹¹⁴ Albuterol provides a rapid onset of relief of acute bronchospasm via smooth muscle relaxation. β_2 -agonists are associated with tremor, tachycardia, and palpitations. They do not block the development of airway hyper-responsiveness. An increased frequency of bronchodilator use could be an indicator of the need for additional anti-inflammatory therapy. On the basis of a NAEPP review of six published studies with 1599

women with asthma who took β_2 -agonists during pregnancy, appropriate β_2 -agonist use appears to be safe.¹¹⁴ Additionally, in a large prospective study, no significant relationship was found between the use of inhaled β_2 -agonists ($n = 1828$) and adverse pregnancy outcomes.¹³⁹

Salmeterol and formoterol are long-acting β -agonist (LABA) preparations. Data on the safety of LABAs during human pregnancy are lacking, but safety is considered likely on the basis of the inhalational route and the generally reassuring data for short-acting β -agonists.¹¹⁴ LABA drugs should be used only in combination with inhaled corticosteroids during pregnancy. They are more effective than leukotriene receptor antagonists or theophylline as add-on therapy to inhaled corticosteroids.¹¹⁵ The efficacy of these drugs during pregnancy is largely extrapolated from studies performed in nonpregnant patients.

Theophylline. Theophylline is an alternative treatment for mild persistent asthma and an adjunctive treatment for the management of moderate and severe persistent asthma during pregnancy.¹⁴⁰ Subjective symptoms of adverse theophylline effects, including insomnia, heartburn, palpitations, and nausea, may be difficult to differentiate from typical pregnancy symptoms. High dosages have caused jitteriness, tachycardia, and vomiting in mothers and neonates. Dosage guidelines have recommended that serum theophylline concentrations be maintained at 5 to 12 $\mu\text{g/mL}$ during pregnancy.¹⁴⁰ Theophylline can have significant interactions with other drugs, which can cause decreased clearance with resultant toxicity. For example, cimetidine can cause a 70% increase in serum levels, and erythromycin can increase theophylline serum levels by 35%.

The main advantage of theophylline is the long duration of action—10 to 12 hours for sustained-release preparations—which is especially useful in the management of nocturnal asthma. Theophylline is indicated only for chronic therapy and is not effective for the treatment of acute exacerbations during pregnancy.¹³⁶ Theophylline has anti-inflammatory actions that may be mediated by inhibition of leukotriene production and its capacity to stimulate prostaglandin E_2 production.¹⁴¹ Theophylline may potentiate the efficacy of inhaled corticosteroids.¹⁴²

The NAEPP reviewed eight human studies that had a total of 660 women with asthma who took theophylline during pregnancy.¹⁴⁰ These studies and clinical experience confirm the safety of theophylline at a serum concentration of 5 to 12 $\mu\text{g/mL}$ during pregnancy. In a randomized controlled trial, there were no differences in asthma exacerbations or perinatal outcomes in a cohort receiving theophylline compared with the cohort receiving inhaled beclomethasone.¹³⁰ However, the theophylline cohort reported significantly more side effects, discontinuation of the study medication, and an increased proportion of women with an FEV₁ of less than 80% of the predicted value.

Leukotriene Mediators. Leukotrienes are arachidonic acid metabolites that have been implicated in transducing bronchospasm, mucous secretion, and increased vascular permeability. Bronchoconstriction associated with aspirin ingestion can be blocked by leukotriene receptor antagonists. The leukotriene receptor antagonists zafirlukast (Accolate) and montelukast are pregnancy category B drugs. Zileuton is not currently recommended because of the limited human safety data and non-reassuring animal data.¹¹⁴ Leukotriene receptor antagonists

provide an alternative treatment for mild persistent asthma and an adjunctive treatment for the management of moderate and severe persistent asthma during pregnancy.¹¹⁴ Although human data are limited for the use of leukotriene receptor antagonists in pregnancy, their use has not been associated with an increase in congenital anomalies.^{123,143} Leukotriene modifiers are less effective as single agents than inhaled corticosteroids and less effective than LABA agents as add-on therapy.¹¹⁶

Omalizumab. Omalizumab is a humanized monoclonal antibody to immunoglobulin E and is in pregnancy category B. An ongoing registry (sponsored by Genentech) of the use of omalizumab during pregnancy does not yet have sufficient numbers to provide any definitive information. Because of the lack of safety data and a potential risk of anaphylaxis, treatment with omalizumab should not be initiated during pregnancy. However, it seems reasonable to continue omalizumab for women with severe asthma who become pregnant.

Oral Corticosteroids. The NAEPP Working Group reviewed eight human studies, including one report of two meta-analyses.¹¹⁴ Most subjects in these studies did not take oral corticosteroids for asthma, and the length, timing, and dosages of the drugs were not well described. The panel concluded that findings from the evidence are conflicting. Oral corticosteroid use during the first trimester of pregnancy is associated with a threefold increased risk for isolated cleft lip with or without cleft palate. Because the background incidence is about 0.1%, the excess risk attributable to oral steroids is 0.2% to 0.3%.¹⁴³ Oral corticosteroid use by pregnant patients who have asthma has been associated with an increased incidence of preeclampsia, preterm delivery, and low birth weight.^{122,139,144} A prospective study found that use of systemic corticosteroids resulted in a deficit of about 200 g in birth weight compared with controls and those treated with β_2 -agonists exclusively.¹⁴⁵ However, it is difficult to separate the effects of the oral corticosteroids on these outcomes from the effects of severe or uncontrolled asthma.

Because of the uncertainties in these data and the definite risks of severe, uncontrolled asthma to the mother and fetus, the NAEPP recommends the use of oral corticosteroids when indicated for the long-term management of severe asthma or exacerbations during pregnancy.¹¹⁴ For the treatment of acute exacerbations, prednisone, methylprednisolone, or prednisolone may be given (40 to 80 mg per day in one or two divided doses).¹¹⁶ If the patient is unresponsive to the initial treatments listed in Box 58-2, consider adjunctive treatment such as magnesium sulfate for severe exacerbations. In a retrospective study, pregnant asthmatic women were found to be undertreated with systemic corticosteroids when compared with nonpregnant patients in an emergency department; they were also nearly four times more likely to return to the same emergency department within 2 weeks for asthma symptoms.¹⁴⁶

Management of Allergic Rhinitis and Gastric Reflux Exacerbating Asthma

Rhinitis, sinusitis, and gastroesophageal reflux may exacerbate asthma symptoms, and their management should be considered an integral aspect of asthma care. Intranasal corticosteroids are the most effective medications for control of allergic rhinitis. Loratadine (Claritin) or cetirizine (Zyrtec) are recommended

second-generation antihistamines. Because oral decongestant ingestion during the first trimester has been associated with gastroschisis, inhaled decongestants or inhaled corticosteroids should be considered before use of oral decongestants.¹¹⁴ Immunotherapy is considered safe during pregnancy, but because of the risk of anaphylaxis, initiation of immunotherapy is not recommended during pregnancy.

ANTENATAL MANAGEMENT

In general, data are lacking to guide the optimal obstetric management of the woman with asthma, and recommendations are based on extrapolation of data from other clinical settings and expert opinion. Women with asthma should be offered influenza vaccination as appropriate. Those with asthma that is not well controlled should be considered to be at risk for pregnancy complications and may benefit from increased fetal surveillance. Adverse outcomes may be more common if asthma severity is underestimated and the asthma undertreated. The first prenatal visit should include a detailed medical history with attention to medical conditions that can complicate the management of asthma, including rhinitis, sinusitis, reflux, or depression. The patient should be questioned about her smoking history and the presence and severity of symptoms, episodes of nocturnal asthma, the number of days of work missed, and emergency care visits related to asthma. Asthma severity should be determined and control efforts planned (see Table 58-2). The type and amount of asthma medications, including the number of puffs of albuterol used each day, should be noted.

Scheduling of prenatal visits for gravidas with moderate or severe asthma should be based on clinical judgment. In addition to routine care, monthly or more frequent evaluations of asthma history (i.e., emergency visits, hospital admissions, symptom frequency, severity, nocturnal symptoms, and medication dosages and compliance) and pulmonary function (i.e., FEV₁ or PEF_R) are recommended. Patients should be instructed on proper dosages and administration of their asthma medications.

Daily PEF_R monitoring should be considered for patients with moderate to severe asthma and especially for patients who have difficulty perceiving signs of worsening asthma.¹⁴⁰ It may be helpful to maintain an asthma diary containing a daily record of symptoms, PEF_R measurements, activity limitations, medical contacts initiated, and regular and as-needed medications taken. Identifying and avoiding asthma triggers can lead to improved maternal well-being and reduced need for medications. Specific recommendations can be made for appropriate environmental controls on the basis of the patient's history of exposure and, when available, skin test reactivity to asthma triggers.

Women with asthma that is not well controlled may benefit from additional fetal surveillance in the form of ultrasound examinations and antenatal fetal testing. Because asthma has been associated with intrauterine growth restriction and preterm birth, it is useful to establish pregnancy dating accurately by first-trimester ultrasound when possible. In the opinion of NAEPP,¹¹⁴ the evaluation of fetal activity and growth by serial ultrasound examinations may be considered for women who have suboptimally controlled asthma, for those with moderate to severe asthma (starting at 32 weeks), and after recovery from a severe asthma exacerbation. The intensity of antenatal surveillance of fetal well-being should be considered

BOX 58-2 EMERGENCY DEPARTMENT AND HOSPITAL-BASED MANAGEMENT OF ASTHMA EXACERBATION**INITIAL ASSESSMENT AND TREATMENT**

- History and examination (auscultation, use of accessory muscles, heart rate, respiratory rate), peak expiratory flow rate (PEFR) or forced expiratory volume in 1 second (FEV₁), oxygen saturation, and other tests as indicated, or
- Initiate fetal assessment (consider fetal monitoring and/or biophysical profile if fetus is potentially viable)
- Albuterol by metered-dose inhaler or nebulizer (0.25 to 0.5 mg), up to three doses in first hour
- Oral corticosteroid if no immediate response or if patient recently treated with systemic corticosteroid
- Oxygen to maintain saturation >95%
- Repeat assessment: symptoms, physical examination, PEFR, oxygen saturation
- Continue albuterol every 60 minutes for 1 to 3 hours provided there is improvement
- If severe exacerbation (FEV₁ or PEFR <50% with severe symptoms at rest), then
 - High-dose albuterol by nebulization every 20 minutes, or 10 to 15 mg/hr administered continuously for 1 hour
 - And inhaled ipratropium bromide
 - And systemic corticosteroid

REPEAT ASSESSMENT

- Symptoms, physical examination, PEFR, oxygen saturation, other tests as needed
- Continue fetal assessment

GOOD RESPONSE

- FEV₁ or PEFR ≥70%
- Response sustained 60 minutes after last treatment
- No distress
- Physical examination normal
- Reassuring fetal status
- Discharge home

INCOMPLETE RESPONSE

- FEV₁ or PEFR ≥50% but <70%
- Mild or moderate symptoms
- Continue fetal assessment until patient stabilized

- Monitor FEV₁ or PEFR, oxygen saturation, pulse
- Continue inhaled albuterol and oxygen
- Inhaled ipratropium bromide nebulizer (0.5 mg every 20 min for three doses)
- Systemic (oral or intravenous) corticosteroid (40 to 80 mg/day in one or two doses)
- Individualize decision for hospitalization

POOR RESPONSE

- FEV₁ or PEFR <50%
- PCO₂ >42 mm Hg
- Physical examination: symptoms severe, drowsiness, confusion
- Continue fetal assessment
- Admit to intensive care unit (ICU)

IMPENDING OR ACTUAL RESPIRATORY ARREST

- Admit to ICU
- Intubation and mechanical ventilation with 100% oxygen
- Nebulized albuterol plus inhaled ipratropium bromide
- Intravenous corticosteroid

INTENSIVE CARE UNIT

- Inhaled albuterol hourly or continuously plus inhaled ipratropium bromide
- Intravenous corticosteroid
- Oxygen
- Possible intubation and mechanical ventilation
- Continue fetal assessment until patient is stabilized

DISCHARGE HOME

- Continue treatment with albuterol
- Oral systemic corticosteroid if indicated
- Initiate or continue inhaled corticosteroid until review at medical follow-up
- Patient education
 - Review medicine use
 - Review/initiate action plan
 - Recommend close medical follow-up

Modified from National Asthma Education and Prevention Program Expert Panel Report: Managing asthma during pregnancy: recommendations for pharmacologic treatment—2004 update, J Allergy Clin Immunol 115:34–46, 2005.

on the basis of the severity of the asthma and any other high-risk features of the pregnancy. All patients should be instructed to be attentive to fetal activity.

Home Management of Asthma Exacerbations

An asthma exacerbation that causes minimal problems for the mother may have severe sequelae for the fetus. An abnormal fetal heart rate tracing may be the initial manifestation of an asthmatic exacerbation. A maternal Po₂ value of less than 60 mm Hg or a hemoglobin saturation of less than 90% may be associated with profound fetal hypoxia. Asthma exacerbations in pregnancy should be aggressively managed. Patients should be given an individualized guide for decision making and rescue management, and they should be educated to recognize signs and symptoms of early asthma exacerbations, such as coughing, chest tightness, dyspnea, or wheezing, or by a 20% decrease in the PEFR. Early recognition enables prompt institution of home rescue treatment to avoid maternal and fetal hypoxia. Patients should use inhaled albuterol (two to four puffs) every 20 minutes for up to 1 hour (Box 58-3). The response is considered to be good if symptoms are resolved or

become subjectively mild, normal activities can be resumed, and the PEFR is more than 70% of the personal best value. The patient should seek further medical attention if the response is incomplete or if fetal activity is decreased.

Hospital and Clinic Management

The principal goal of hospital and clinic management should be the prevention of hypoxia. Measurement of oxygenation by pulse oximetry is essential, and arterial blood gas determinations should be obtained if oxygen saturation remains less than 95%. Chest radiographs are usually not needed. Continuous electronic fetal monitoring should be initiated if gestation has advanced to the point of potential fetal viability. Nebulized albuterol should be delivered with oxygen, 2.5 to 5 mg every 20 minutes for three doses and then 2.5 to 10 mg every 1 to 4 hours as needed; for severe exacerbations, give 10 to 15 mg/hr administered continuously.¹¹⁴ Occasionally, nebulized treatment is not effective because the patient is moving air poorly; in such cases, terbutaline (0.25 mg) can be administered subcutaneously every 15 minutes for three doses. The patient should be assessed by auscultation and FEV₁ or PEFR before and after

BOX 58-3 HOME MANAGEMENT OF ACUTE ASTHMA EXACERBATIONS**INITIAL APPROACH**

Use albuterol metered-dose inhaler (MDI) 2 to 4 puffs, and measure peak expiratory flow rate (PEFR).

POOR RESPONSE

PEFR <50% of predicted, or severe wheezing and shortness of breath, or decreased fetal movement: Repeat albuterol 2 to 4 puffs by MDI and obtain emergency care.

INCOMPLETE RESPONSE

PEFR is 50% to 80% of predicted, or persistent wheezing and shortness of breath: Repeat albuterol MDI treatment 2 to 4 puffs at 20-min intervals up to two more times. If repeat PEFR is 50% to 80% of predicted, or if fetal movement is decreased, contact caregiver or go for emergency care.

GOOD RESPONSE

PEFR >80% predicted, no wheezing or shortness of breath, and fetus is moving normally: May continue inhaled albuterol MDI treatment 2 to 4 puffs every 3 to 4 hours as needed.

Modified from National Asthma Education and Prevention Program Expert Panel Report: Managing asthma during pregnancy: recommendations for pharmacologic treatment—2004 update, J Allergy Clin Immunol 115:34–46, 2005.

each bronchodilator treatment. Guidelines for the management of asthma exacerbations are presented in Box 58-2.

Labor and Delivery Management

Asthma medications should not be discontinued during labor and delivery. Although asthma is usually quiescent during labor, consideration should be given to assessing PEFRs on admission and at 12-hour intervals for those with persistent asthma. The patient should be kept hydrated and should receive adequate analgesia to decrease the risk of bronchospasm.

It is commonly recommended that women who are currently taking systemic corticosteroids or who have received several short courses of systemic corticosteroids during pregnancy receive intravenous corticosteroids (e.g., hydrocortisone at a dosage of 100 mg every 8 hours) during labor and for 24 hours after delivery to prevent an adrenal crisis.¹²⁰

An elective delivery should be postponed if the patient is having an exacerbation. It is rarely necessary to perform a cesarean section for an acute asthma exacerbation. Maternal compromise and fetal compromise usually respond to aggressive medical management. Prostaglandin (PG) E₂ or E₁ can be used for cervical ripening, the management of spontaneous or induced abortions, or postpartum hemorrhage, although the patient's respiratory status should be monitored.¹⁴⁷ Carboprost (15-methyl PGF_{2α}) and ergonovine and methylergonovine (Methergine) can cause bronchospasm.¹¹⁵ Magnesium sulfate is a bronchodilator, but indomethacin can induce bronchospasm in the aspirin-sensitive patient. There are no reports of the use of calcium channel blockers for tocolysis among patients with asthma, although an association with bronchospasm has not been observed with wide clinical use.

Lumbar anesthesia has the benefit of reducing oxygen consumption and minute ventilation during labor.¹¹⁵ A 2% incidence of bronchospasm has been reported with regional

anesthesia.¹¹⁵ Communication between the obstetric, anesthetic, and pediatric caregivers is important for optimal care.

Breastfeeding

Only small amounts of asthma medications enter breast milk. Prednisone, theophylline, antihistamines, beclomethasone, β₂-agonists, and cromolyn are not considered to be contraindications for breastfeeding.¹¹⁴ However, among sensitive individuals, theophylline may cause toxic effects in the neonate, including vomiting, feeding difficulties, jitteriness, and cardiac arrhythmias.

SUMMARY AND RECOMMENDATIONS

1. It is safer for pregnant women to be treated with asthma medications than it is for them to have asthma symptoms and exacerbations.
2. Inhaled corticosteroids are the preferred treatment for persistent asthma.
3. Inhaled albuterol is recommended rescue therapy.
4. Clinical evaluation of asthma includes subjective assessments and pulmonary function tests.
5. Identifying and controlling or avoiding such factors as allergens and irritants, particularly tobacco smoke, can lead to improved maternal well-being with less need for medication.
6. The goal of asthma therapy is maintenance of (near) normal pulmonary function.
7. Step-care therapy uses the principle of tailoring medical therapy to asthma severity.
8. Maintenance allergen immunotherapy may be continued during pregnancy.
9. Women taking asthma medication may breastfeed.

Restrictive Lung Disease in Pregnancy**CLINICAL MANIFESTATIONS**

Restrictive ventilatory defects occur when lung expansion is limited because of alterations in the lung parenchyma or because of abnormalities in the pleura, the chest wall, or the neuromuscular apparatus.¹⁴⁸ These conditions are characterized by a reduction in lung volumes and an increase in the ratio of FEV₁ to forced vital capacity.¹⁴⁹ The interstitial lung diseases include idiopathic pulmonary fibrosis, sarcoidosis, hypersensitivity pneumonitis, pneumomycosis, drug-induced lung disease, and connective tissue disease. Additional conditions that cause a restrictive ventilatory defect include pleural and chest wall diseases and extrathoracic conditions such as obesity, peritonitis, and ascites.¹⁴⁹

Restrictive lung disease in pregnancy has not been well studied, and little is known about the effects of restrictive lung disease on the outcome of pregnancy or the effects of pregnancy on the disease process. One study presented data on nine pregnant women with interstitial and restrictive lung disease who were prospectively managed.¹⁵⁰ Diagnoses included idiopathic pulmonary fibrosis, hypersensitivity pneumonitis, sarcoidosis, kyphoscoliosis, and multiple pulmonary emboli. Three of the gravidas had severe disease characterized by a vital capacity of no more than 1.5 L (50% of predicted) or a diffusing capacity of no more than 50% of predicted. Five of the patients had exercise-induced oxygen desaturation, and four required

supplemental oxygen. In this group, one patient had an adverse outcome and was delivered at 31 weeks. She subsequently required mechanical ventilation for 72 hours. All other patients were delivered at or beyond 36 weeks with no adverse intrapartum or postpartum complications. All infants were at or above the 30th percentile for growth.¹⁵⁰ The investigators concluded that restrictive lung disease was well tolerated in pregnancy. However, exercise intolerance is common, and these patients may require early oxygen supplementations.¹⁵⁰

SARCOIDOSIS

Sarcoidosis is a systemic granulomatosis disease of undetermined origin that often affects young adults. Pregnancy outcome for most patients with sarcoidosis is good.^{151,152} In one study, 35 pregnancies in 18 patients with sarcoidosis were evaluated retrospectively.¹⁵¹ There was no effect of the disease process during pregnancy in nine patients, improvement was demonstrated in six patients, and there was a worsening of the disease in three patients. During the postpartum period, no relapse occurred in 15 patients; however, progression of the disease continued in three women. Another retrospective study assessed 15 pregnancies complicated by maternal sarcoidosis over a 10-year period.¹⁵² Eleven of these patients remained stable, two experienced disease progression, and two died because of complications of severe sarcoidosis. In this group, factors indicating a poor prognosis included parenchymal lesions identified on the chest radiograph, advanced radiographic staging, advanced maternal age, low inflammatory activity, requirement for drugs other than steroids, and the presence of extrapulmonary sarcoidosis.¹⁵² Both patients who succumbed during gestation had severe disease at the onset of pregnancy. The overall cesarean section rate was 40%, and 4 (27%) of 15 infants weighed less than 2500 g. None of the patients developed preeclampsia. One explanation for the commonly observed improvement in sarcoidosis may be the increased concentration of circulating corticosteroids during pregnancy. However, because sarcoidosis improves spontaneously in many nonpregnant patients, the improvement may be coincident with pregnancy.

Maycock and associates¹⁵³ reported 16 pregnancies in 10 patients with sarcoidosis. Eight of these patients showed improvement in at least some of the manifestations of sarcoidosis during the antepartum period. In two patients, no effect was seen. A recurrence of the abnormal findings was observed in the postpartum period within several months after delivery in approximately half of the patients. Some had new manifestations of sarcoidosis not previously observed. Another study examined 17 pregnancies in 10 patients and concluded that pregnancy had no consistent effect on the course of the disease.¹⁵⁴ Scadding¹⁵⁵ separated patients into three categories based on characteristic patterns on their chest radiographs. When the lesions on the chest radiograph had resolved before pregnancy, radiographs remained normal throughout gestation. In women with radiographic changes before pregnancy, resolution continued throughout the prenatal period. Patients with inactive fibrotic residual disease had stable chest radiographs, and those with active disease tended to have partial or complete resolution of those changes during pregnancy. However, most patients in the latter group experienced exacerbation of the disease within 3 to 6 months after delivery.

Patients with pulmonary hypertension complicating restrictive lung disease may have a mortality rate as high as 50%

during gestation. These patients need close monitoring during the labor, delivery, and postpartum periods. Invasive monitoring with a pulmonary artery catheter may be indicated to optimize cardiorespiratory function. Gravidas with restrictive lung disease, including pulmonary sarcoidosis, may benefit from early institution of steroid therapy for evidence of worsening pulmonary status. Individuals with evidence of severe disease need close monitoring and may require supplemental oxygen therapy during gestation.

During labor, consideration should be given to the early use of epidural anesthesia if it is not contraindicated. The early institution of pain management in this population can minimize pain, decrease the sympathetic response, and decrease oxygen consumption during labor and delivery. The use of general anesthesia should be avoided, if possible, because these patients may develop pulmonary complications after general anesthesia, including pneumonia and difficulty weaning from the ventilator. Close fetal surveillance throughout gestation is indicated because impaired oxygenation may lead to impaired fetal growth and the development of fetal heart rate abnormalities during labor and delivery.

An additional consideration is the need to counsel all women with restrictive lung disease about the potential for continued impairment of their respiratory status during pregnancy, particularly if their respiratory status is deteriorating when they conceive. The woman with clinical signs consistent with pulmonary hypertension or severe restrictive disease should be cautioned about the possibility of maternal mortality resulting from worsening pulmonary function during gestation.

In summary, although the literature on restrictive lung disease in pregnancy is limited, it supports the conclusion that most patients with restrictive lung disease complicating pregnancy, including those with pulmonary sarcoidosis, can have a favorable pregnancy outcome. However, the clinician should keep in mind that patients with restrictive lung disease can have worsening of their clinical condition and may succumb during gestation.

Cystic Fibrosis in Pregnancy

Cystic fibrosis (CF) involves the exocrine glands and epithelial tissues of the pancreas, sweat glands, and mucous glands in the respiratory, digestive, and reproductive tracts. Chronic obstructive pulmonary disease, pancreatic exocrine insufficiency, and elevated levels of sweat electrolytes are present in most patients with CF.¹⁵⁶ The disease is genetically transmitted and has an autosomal recessive pattern of inheritance. The CF gene was identified and cloned in 1989. It is localized to chromosome 7, and the molecular defect accounting for most cases has been identified.¹⁵⁷⁻¹⁵⁹ In the United States, approximately 4% of the white population are heterozygous carriers of the CF gene. The disease occurs in 1 of 3200 white live births.¹⁶⁰

Morbidity and mortality in patients with CF usually result from progressive chronic bronchial pulmonary disease. Pregnancy and the attendant physiologic changes can stress the pulmonary, cardiovascular, and nutritional status of women with CF. The purpose of this section is to familiarize the obstetrician and gynecologist with the physiologic effects of this complex disease, the impact of the disease on pregnancy, and the effect of pregnancy on the disease.

Survival for patients with CF has increased dramatically since 1940. According to the Cystic Fibrosis Foundation's Patient

Registry (www.cff.org), survival in 2006 had increased to 37 years. More than 40% of all people with CF in the United States are 18 years or older.¹⁵⁶ This increase in survival of patients with CF most likely reflects earlier diagnosis and intervention and the advances in antibiotic therapy and nutritional support. Recent novel therapy in CF has been directed at specific mutations in the cystic fibrosis transmembrane regulator (CFTR). A new drug, ivacaftor (Kalydeco), has been approved by the FDA for patients with CF who have a G551D mutation in the CFTR. Ivacaftor was associated with improvements in lung function at 2 weeks that were sustained through 48 weeks in these patients.¹⁶¹ This type of therapy directed at other CFTR mutations may increase survival in the future. Because of the improvements in care, more women with CF are entering reproductive age. Unlike men with CF who are infertile for the most part, women with CF are often fertile.

The first case of CF complicating pregnancy was reported in 1960, and a total of 13 pregnancies in 10 patients with CF were reported in 1966.^{162,163} Cohen and colleagues¹⁶⁴ conducted a survey of 119 CF centers in the United States and Canada and identified a total of 129 pregnancies in 100 women by 1976. Hilman and colleagues¹⁵⁶ surveyed reports from 127 CF centers in the United States between 1976 and 1982. A total of 191 pregnancies were reported during this period in women with CF who were between 16 and 36 years old, with a mean age of 22.6 years.¹⁵⁶ The annual number of CF pregnancies reported to the Cystic Fibrosis Patient Registry doubled between 1986 and 1990, with 52 pregnancies reported in 1986, compared with 111 pregnancies reported in 1990. In 2006, 209 women with CF were pregnant. Because the number of women with CF achieving pregnancy is steadily increasing, it is imperative that the obstetrician be familiar with the disease.

OUTCOME OF PREGNANCY IN CYSTIC FIBROSIS

The physiologic changes associated with pregnancy are well tolerated by healthy gravidas, but those with CF may adapt poorly. During pregnancy, there is an increase in resting minute ventilation, which at term may approach 150% of control values.¹⁶⁵ Enlargement of the abdominal contents and upward displacement of the diaphragm leads to a decrease in functional residual volume and a decrease in residual volume.¹⁶⁵ Pregnancy is also accompanied by subtle alterations in gas exchange with widening of the alveolar-arterial oxygen gradient that is most pronounced in the supine position.¹⁶⁵ Alterations in pulmonary function are of little consequence in the normal pregnant woman, but in the gravida with CF, these changes may contribute to respiratory decompensation that can lead to an increase in morbidity and mortality for the mother and the fetus. Women with CF and advanced lung disease may also have pulmonary hypertension, increasing the risk of maternal mortality.

Nutritional requirements are increased during pregnancy, with approximately 300 kcal/day in additional fuel needed to meet the requirements of mother and fetus.¹⁶⁶ Most patients with CF have pancreatic exocrine insufficiency. Digestive enzymes and bicarbonate ions are diminished, resulting in maldigestion, malabsorption, and malnutrition.¹⁶⁶ Gastrointestinal manifestations of CF include steatorrhea, abdominal pain, distal intestinal obstruction syndrome, and rectal prolapse. Gastroesophageal reflux, peptic ulcer disease, acute pancreatitis, and intussusception occur to different degrees in patients with

CF. Partial or complete obstruction of the gastrointestinal tract in older children and adults, also known as distal obstruction syndrome, can be precipitated by dehydration, a change in eating habits, a change in enzyme brand or dose, or immobility. It is treated with a combination of laxatives and enemas. Patients with CF are encouraged to eat a diet that provides 120% to 150% of the recommended energy intake of normal age- and sex-matched controls. This is only a guideline, because in practice, the energy requirement for a patient with CF is that of their ideal body weight when malabsorption has been minimized. Research done by the United Kingdom Dieticians Cystic Fibrosis Interest Group found that women with CF who received preconception counseling had a significantly greater mean maternal weight gain and significantly heavier infants than women who had not received preconception advice.¹⁶⁷

Grand and colleagues¹⁶³ reported 13 pregnancies in 10 women with CF. Of these, five women had a progressive decline in their pulmonary function, and two of these five died of cor pulmonale in the immediate postpartum period. Pregnancy was well tolerated in 5 of 10 women, two of whom went on to have subsequent pregnancies that were similarly well tolerated.¹⁶² In this study, the pregravid pulmonary status of the patient was the most important predictor of outcome. However, there was no quantification of pulmonary function. A case report by Novy and colleagues¹⁶⁸ described pulmonary function and gas exchange in a pregnant woman with CF. The patient had severe disease as evidenced by a vital capacity of only 0.72 L and a Pao₂ of 50 mm Hg at presentation. The patient suffered a progressive increase in residual volume and decline in vital capacity that was accompanied by worsening hypoxemia and hypercapnia, resulting in respiratory distress and right-sided heart failure in the early postpartum period.¹⁶⁸ On the basis of the experience with this patient and a review of the literature, the investigators recommended therapeutic abortion for any patient demonstrating progressive pulmonary deterioration and hypoxemia despite maximal medical management.¹⁶⁸

In 1980, Cohen and associates¹⁶⁴ described 100 patients and a total of 129 pregnancies. Ninety-seven pregnancies (75%) were completed, and 89% of these women delivered viable infants. Twenty-seven percent of these fetuses were delivered preterm. There were 11 perinatal deaths and no congenital anomalies. In this study, 65% of patients required antibiotic therapy before delivery. In 1983, Palmer and colleagues¹⁶⁹ retrospectively reviewed the pre-pregnancy status of eight women with CF who subsequently completed 11 pregnancies. They found that five women tolerated pregnancy without difficulty but that three had irreversible deterioration in their clinical status. The investigators identified four maternal factors that predicted outcome: clinical status (i.e., Shwachman score), nutritional status (i.e., percent of predicted weight for height), the extent of chest radiologic abnormalities (i.e., Brasfield chest radiographic score), and the magnitude of pulmonary function impairment. Women with good clinical study results, good nutritional status (i.e., within 15% of their predicted ideal body weight for height), nearly normal chest radiographs, and only mild obstructive lung disease tolerated pregnancy well without deterioration.¹⁶⁹

Several reports suggest that patients with mild CF, good nutritional status, and less impairment of lung function tolerate pregnancy well. However, those with poor clinical status, malnutrition, hepatic dysfunction, or advanced lung disease are at increased risk from pregnancy.¹⁷⁰⁻¹⁷² Kent and Farquharson¹⁷²

reviewed the literature and reported on 217 pregnancies. In this series, the frequency of preterm delivery was 24.3%, and the perinatal death rate was 7.9%. Poor outcomes were associated with a maternal weight gain of less than 4.5 kg and a forced vital capacity of less than 50% of the predicted value. Edenborough and colleagues¹⁷³ also described pregnancies in women with CF. There were 18 live births (81.8%), one third of which were preterm deliveries, and 18.2% of patients had abortions. There were four maternal deaths within 3.2 years after delivery. In this series, lung function tests were performed before delivery, immediately after delivery, and after pregnancy. The investigators demonstrated declines of 13% in FEV₁ and 11% in forced vital capacity during pregnancy. Most patients returned to baseline pulmonary function after pregnancy. Although most of the women in this series tolerated pregnancy well, those with moderate to severe lung disease (i.e., FEV₁ <60% of the predicted value) more often had preterm infants and had increased loss of lung function compared with those with milder disease.¹⁷³

In two series, pre-pregnancy FEV₁ was found to be the most useful predictor of outcomes in pregnant women with CF.^{173,174} There was also a positive correlation of pre-pregnancy FEV₁ with maternal survival. For the 72 pregnancies identified, the outcomes were known for 69: There were 48 live births (70%), of which 22 were premature (46%); 14 therapeutic abortions (20%), and 7 miscarriages (10%). There were no stillbirths, neonatal deaths, or early maternal deaths. Three major fetal anomalies were seen, but no infant had CF. Another report similarly documented the outcome of 72 pregnancies with CF.¹⁷⁵

A recent case report and review of the literature of 523 pregnancies in 401 women reported a preterm birth rate of 24%, spontaneous abortion in 6.2%, and therapeutic abortion in 10%.¹⁷⁶ In this series, indirect maternal death occurred in seven patients. The authors noted that pregnancy was more complicated in the second pregnancy than in the first. They also reported pre-pregnancy lung function, lung function deterioration, CF-related diabetes, and weight gain as parameters to consider when counseling about the potential outcome of pregnancy in women with CF.¹⁷⁶

Pulmonary involvement in CF includes chronic infection of the airways and bronchiectasis. There is selective infection with certain microorganisms, such as *S. aureus*, *H. influenzae*, *P. aeruginosa*, and *Burkholderia cepacia*. In one report, three of four deaths during pregnancy occurred in gravidas colonized with *B. cepacia*.¹⁷⁷ Gilljam and associates¹⁷⁸ reported outcomes for a cohort of pregnancies for women with CF from 1963 to 1998. For 92 pregnancies in 54 women, there were 11 miscarriages and 7 therapeutic abortions. Forty-nine women gave birth to 74 children. The mean follow-up time was 11 ± 8 years. One patient was lost to follow-up shortly after delivery, and one was lost after 12 years. The overall mortality rate was 19% (9 of 48 patients). Absence of *B. cepacia* ($P < .001$), pancreatic sufficiency ($P = .01$), and pre-pregnancy FEV₁ more than 50% of the predicted value ($P = .03$) were associated with better survival rates. When adjusted for the same parameters, pregnancy did not affect survival compared with the entire adult female CF population. The decline in FEV₁ was comparable to that in the total CF population. Three women had diabetes mellitus, and seven developed gestational diabetes. There were six preterm infants and one neonatal death. CF was diagnosed in two children. Gilljam and coworkers¹⁷⁸ concluded that the maternal and fetal outcomes were good for most women with CF. Risk factors for mortality are similar to those for the nonpregnant CF

population. Pregnancies should be planned so that there is an opportunity for counseling and optimization of the medical condition. Good communication between the CF team and the obstetrician is important.¹⁷⁸

A review of 10 pregnancies in 10 lung transplant recipients with CF documented nine live births and one therapeutic abortion. Of the nine, five were preterm births, all of whom were well at follow-up. Three transplant recipients developed rejection during the pregnancy, and one had had evidence of rejection prior to conception. These four women died within 38 months of delivery. Pregnancy in lung transplant patients with CF is feasible but carries a high risk of maternal mortality.¹⁷⁹

COUNSELING PREGNANT WOMEN WITH CYSTIC FIBROSIS

Women with CF should be advised about the potential adverse effects of pregnancy on maternal health status. Factors that may predict poor outcome include pre-pregnancy evidence of poor nutritional status, significant pulmonary disease with hypoxemia, and pulmonary hypertension. Liver disease and diabetes mellitus are also poor prognostic factors. Gravidas with poor nutritional status, pulmonary hypertension (e.g., cor pulmonale), and deteriorating pulmonary function early in gestation should consider therapeutic abortion, because the risk of maternal mortality may be unacceptably high.

The woman with CF who is considering pregnancy should consider the need for strong psychosocial and physical support after delivery. The rigors of child rearing may add to the risk of maternal deterioration during this period. Her family should be willing to provide physical and emotional support and should be aware of the potential for deterioration in the mother's health and the potential for maternal mortality. The requirements of caring for a potentially preterm, growth-restricted neonate, with all of its attendant morbidities and potential mortality, should be discussed. In the long term, the woman and her family should consider the fact that her life expectancy may be shortened by CF, and plans should be made for rearing of the child in the event of maternal death.

MANAGEMENT OF THE PREGNANCY COMPLICATED BY CYSTIC FIBROSIS

Care of the gravida with CF should be a coordinated team effort. Physicians familiar with the complications and management of CF should be included, as well as a maternal-fetal medicine specialist and neonatal team.

The gravida should be assessed for potential risk factors, such as severe lung disease, pulmonary hypertension, poor nutritional status, pancreatic failure, and liver disease, preferably before attempting gestation but certainly during the early months of pregnancy. Gravidas should be advised to be 90% of ideal body weight before conception, if possible. A weight gain of 11 to 12 kg is recommended.¹⁵⁶ Frequent monitoring is suggested for weight; levels of blood glucose, hemoglobin, total protein, serum albumin, and fat-soluble vitamins A and E; and prothrombin time.¹⁵⁶ At each visit, the history of caloric intake and symptoms of mal-digestion and malabsorption should be taken, and pancreatic enzymes should be adjusted if needed. Patients who are unable to achieve adequate weight gain through oral nutritional supplements may be given nocturnal enteral nasogastric tube feeding. In this situation, the risk of aspiration should be considered,

especially in patients with a history of gastroesophageal reflux, which is common in patients with CF.¹⁵⁶ If malnutrition is severe, parenteral hyperalimentation may be necessary for successful completion of the pregnancy.¹⁸⁰

Baseline pulmonary function should be assessed, preferably before conception. Assessment should include forced vital capacity, FEV₁, lung volumes, pulse oximetry, and arterial blood gas measurements, if indicated. These values should be serially monitored during gestation, and deterioration in pulmonary function should be addressed immediately. An echocardiogram can assess the patient for underlying pulmonary hypertension and cor pulmonale. If pulmonary hypertension or cor pulmonale is diagnosed, the gravida should be advised about the high risk of maternal mortality.

Early recognition and prompt treatment of pulmonary infections is important in the management of the pregnant woman with CF. Treatment includes intravenous antibiotics in the appropriate dosage, keeping in mind the increased clearance of these drugs because of pregnancy and CF. Plasma levels of aminoglycosides should be monitored and adjusted as indicated by the results. Chest physical therapy and bronchial drainage are also important components of the management of pulmonary infections in CF. Because *P. aeruginosa* is the most frequently isolated bacterium associated with chronic endobronchitis and bronchiectasis, antibiotic regimens should include coverage for this organism.

If the patient with CF has pancreatic insufficiency and diabetes mellitus, careful monitoring of blood glucose levels and insulin therapy are indicated. Pancreatic enzymes may need to be replaced to optimize the patient's nutritional status. Because of malabsorption of fats and frequent use of antibiotics, the patient with CF is prone to vitamin K deficiency. The prothrombin time should be checked regularly, and parenteral vitamin K should be administered if the prothrombin time is elevated.

The fetus of a woman with CF is at risk for uteroplacental insufficiency and intrauterine growth restriction. The maternal nutritional status and weight gain during pregnancy affect fetal growth. Nonstress testing should be started at 32 weeks' gestation or sooner if there is evidence of fetal compromise. If there is evidence of severe fetal compromise, delivery should be accomplished. Likewise, evidence of profound maternal

deterioration, such as a marked and sustained decline in pulmonary function, development of right-sided heart failure, refractory hypoxemia, and progressive hypercapnia and respiratory acidosis, may be maternal indications for early delivery. If the fetus is potentially viable, the administration of betamethasone may be beneficial. Vaginal delivery should be attempted when possible.

Labor, delivery, and the postpartum period can be particularly dangerous for the patient with CF. The augmentation in cardiac output stresses the cardiovascular system and can lead to cardiopulmonary failure in the patient with pulmonary hypertension and cor pulmonale. These patients are also more likely to develop right-sided heart failure. Heart failure should be treated with aggressive diuresis and supplemental oxygen. Management may be optimized by insertion of a pulmonary artery catheter to monitor right- and left-sided filling pressures. Pain control can reduce the sympathetic response to labor and tachycardia. This benefits the patient who is demonstrating pulmonary or cardiac compromise. In the patient with a normal partial thromboplastin time, insertion of an epidural catheter for continuous epidural analgesia may be beneficial. This is also useful in the event a cesarean delivery is indicated, because general anesthesia and its possible effects on pulmonary function can be avoided. If general anesthesia is needed, preoperative anticholinergic agents should be avoided because they tend to promote drying and inspissation of airway secretions. Close fetal surveillance is essential because the fetus might have been suffering from uteroplacental insufficiency during gestation and is more prone to develop evidence of compromise during labor. Delivery by cesarean section should be reserved for the usual obstetric indications.

In summary, more women with CF are living to childbearing age and are capable of conceiving. Clinical experience has demonstrated that pregnancy in women with mild CF is well tolerated. Women with severe disease have an associated increase in maternal and fetal morbidity and mortality. The potential risk to any woman with CF desiring pregnancy should be assessed and discussed in detail with the patient and her family.

Diabetes in Pregnancy

THOMAS R. MOORE, MD | SYLVIE HAUGUEL-DE MOUZON, PhD |
PATRICK CATALANO, MD

Global Prevalence of Diabetes

An epidemic of diabetes and obesity is sweeping the globe, largely because of marked shifts in dietary practices and reduced physical activity, and has even overtaken many countries formerly considered immune to obesity. In 2011, 366 million people worldwide had diabetes; by 2030, that number is projected to almost double to 552 million.¹ In India, sub-Saharan Africa, and Latin America, diabetes prevalence is projected to increase by 150% to 160%. The number of people with type 2 diabetes is increasing in every country, with 80% of those afflicted living in low- and middle-income countries.

In 2011, diabetes caused 4.6 million deaths, generated at least US \$465 billion in health care expenditures, and accounted for 11% of total health care expenditures in adults aged 20 to 79 years²:

- The World Health Organization (WHO) predicts that developing countries will bear the brunt of this epidemic in the 21st century, with the majority of people with diabetes living in low- and middle-income countries.
- An estimated 285 million people, corresponding to 6.4% of the world's adult population, were living with diabetes in 2010. The number is expected to grow to 438 million by 2030, corresponding to 7.8% of the adult population.
- The global prevalence of diabetes is 6.4% but varies regionally, from 10.2% in the western Pacific to 3.8% in Africa. Africa is expected to experience the greatest increase because of rising affluence in that region.

In the United States, approximately 20 million people have been diagnosed with diabetes (Fig. 59-1), and almost 2 million were newly diagnosed in 2010. About 215,000 people younger than 20 years of age had diabetes (type 1 or type 2) in 2010. In 2005–2008, based on fasting glucose or glycosylated hemoglobin (Hb A_{1c}) levels, 35% of U.S. adults aged 20 years or older had prediabetes (as did 50% of adults aged 65 years or older). Applying this percentage to the entire U.S. population in 2010, an estimated 79 million American adults aged 20 years or older have prediabetes. Approximately 10% of them have overt diabetes, but there is a strong overrepresentation of this disease among certain ethnic groups, including 12.6% of non-Hispanic blacks, 11.8% of Hispanic and Latino Americans, and 14.2% of Native Americans.^{3,4}

The prevalence of diabetes is projected to increase from 10% in 2010 to between 21% and 33% of the U.S. adult population by 2050.⁵ The reasons for this increase are thought to include the aging of the U.S. population, increasing numbers of persons in higher-prevalence minority groups, and the fact that people with diabetes are living longer.

EPIDEMIOLOGY OF DIABETES IN U.S. WOMEN

Studies suggest that the prevalence of diabetes among women of childbearing age is increasing in the United States.^{6,7} This trend will have a profound impact on obstetrics and pediatrics in the next 2 decades and beyond. Increased outreach efforts to provide care to the populations experiencing rising rates of pregestational diabetes will be necessary if a significant increase in maternal and newborn morbidity is to be avoided. When offspring of diabetic mothers are compared with those of weight-matched (nondiabetic) controls, the risk of serious birth injury is doubled, the likelihood of cesarean section is tripled, and the incidence of newborn intensive care unit admission is quadrupled.⁸

Before the 20th century, pregnancy in a woman with insulin-dependent diabetes portended death of the mother, the child, or both. Today, centers providing meticulous metabolic and obstetric surveillance report perinatal loss rates approaching but still higher than those seen in the nondiabetic population.^{9,10} Despite steadily falling perinatal mortality rates (Fig. 59-2) fetal and neonatal mortality remain threefold or fourfold higher for mothers with type 1 or type 2 diabetes than for the normoglycemic population. Congenital fetal anomalies, many of them life-threatening and debilitating, remain three to four times more common in diabetic pregnancies than in nondiabetic pregnancies.¹¹ Macrosomia and birth injury occur several times more frequently in offspring of diabetic pregnancies. Studies indicate that the magnitude of such risks is proportional to the degree of maternal hyperglycemia.¹² To a great extent, the excessive fetal and neonatal morbidity of diabetes in pregnancy is preventable or at least reducible by meticulous prenatal and intrapartum care. This chapter reviews the pathophysiology of this complex group of disorders and identifies the obstetric interventions that can improve outcome.

Classification of Diabetes Mellitus

Diagnostic and classification criteria for diabetes are issued and updated periodically by the American Diabetes Association (ADA).¹³ The classification includes four clinical types:

- Type 1 diabetes mellitus (T1DM), which results from pancreatic beta cell destruction usually leading to absolute insulin deficiency
- Type 2 diabetes mellitus (T2DM), which results from a progressive insulin secretory defect on the background of insulin resistance
- Other specific types of diabetes from other causes, such as genetic defects in beta cell function, genetic defects in

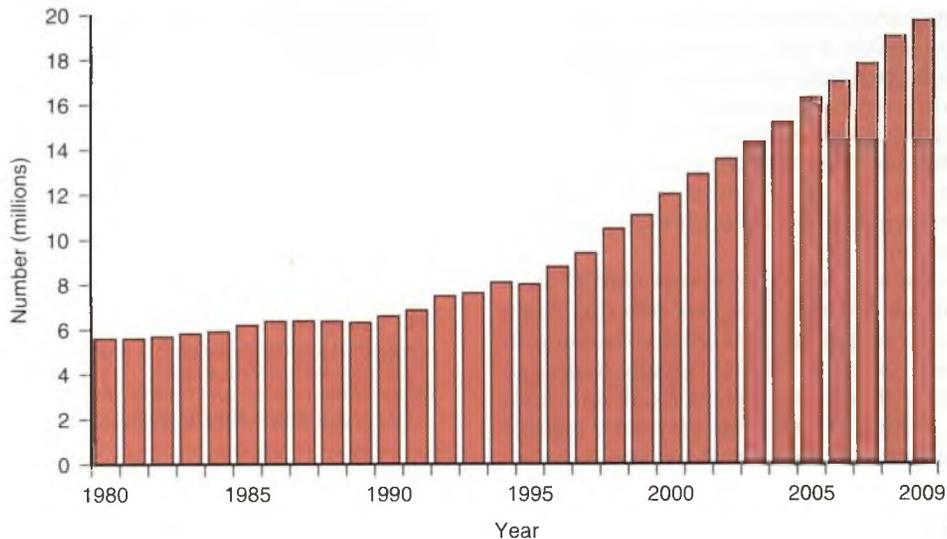

Figure 59-1 Number of U.S. residents with diagnosed diabetes, 1980-2009. (Data from Centers for Disease Control and Prevention, National Center for Health Statistics, Division of Health Interview Statistics, National Health Interview Survey.)

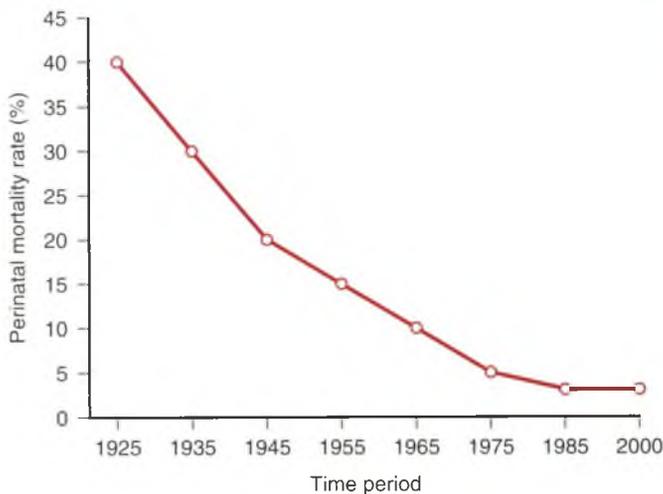

Figure 59-2 Perinatal mortality rates per 1000 births in pregnancies complicated by type 1 diabetes, 1925-2000. (From Landon MB, Catalano PM, Gabbe SG: *Diabetes mellitus*. insulin action, diseases of the exocrine pancreas (e.g., cystic fibrosis, chronic pancreatitis), and drug- or chemical-induced conditions (e.g., treatment of HIV/AIDS, organ transplantation)

- Gestational diabetes mellitus (GDM), which is defined as diabetes diagnosed during pregnancy that is not clearly overt diabetes.

Criteria for the diagnosis of diabetes in nonpregnant adults are shown in Box 59-1.¹³

TYPE 1 DIABETES

T1DM is a chronic autoimmune disease in which destruction of or damage to the beta cells in the islets of Langerhans results

BOX 59-1 CRITERIA FOR THE DIAGNOSIS OF DIABETES

An Hb A_{1c} level $\geq 6.5\%$. The test should be performed in a laboratory using a method that is NGSP certified and standardized to the DCCT assay.*

OR

An FPG measurement ≥ 126 mg/dL (7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 hr.*

OR

A 2-hr plasma glucose measurement ≥ 200 mg/dL (11.1 mmol/L) during an OGTT. The test should be performed as described by the WHO, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.*

OR

In a patient with classic symptoms of hyperglycemia or hyperglycemic crisis, a random plasma glucose level ≥ 200 mg/dL (11.1 mmol/L)

*In the absence of unequivocal hyperglycemia, result should be confirmed by repeat testing.

DCCT, Diabetes Control and Complications Trial; FPG, fasting plasma glucose; Hb A_{1c}, glycosylated hemoglobin; NGSP, National Glycohemoglobin Standardization Program; OGTT, oral glucose tolerance test; WHO, World Health Organization.

Adapted from American Diabetes Association: *Standards of medical care in diabetes—2012*, *Diabetes Care* 35(Suppl 1): S11–S63, 2012.

in insulin deficiency and hyperglycemia. T1DM accounts for approximately 5% to 10% of patients diagnosed with diabetes in the general population. However, T1DM may represent a relatively greater proportion of women in the reproductive age group with nongestational diabetes because of the relatively earlier age at onset of T1DM compared with T2DM.

As noted, T1DM results from a cell-mediated autoimmune destruction of the beta cells of the pancreas. Markers of the immune response include islet cell autoantibodies, autoantibodies to insulin, autoantibodies to glutamic acid decarboxylase (GAD2, formerly designated GAD65), and autoantibodies to

the tyrosine phosphatase IA-2. It is now clear that T1DM occurs in genetically susceptible individuals, in concert with an environmental trigger. Current genetic data point toward the following as susceptibility genes: human leukocyte antigen (HLA), insulin, the protein tyrosine phosphatase PTPN22, interleukin 2 receptor alpha (IL2Ra), and cytotoxic T-lymphocyte-associated protein 4 (CTLA4). Epidemiologic and other studies suggest a triggering role for enteroviruses, whereas other microorganisms might provide protection.¹⁴

T1DM usually is characterized by an abrupt clinical onset after a period of immune destruction of beta cells that might have been in progress for some time. Beta cell destruction continues after the clinical onset of diabetes, usually leading to absolute insulinopenia with resultant lifelong requirements for insulin replacement. Although T1DM was previously referred to as juvenile-onset diabetes, it can occur at any age.

TYPE 2 DIABETES

T2DM involves a loss of balance between insulin sensitivity and insulin (i.e., beta cell) response. The relationship between these two factors can be expressed as the disposition index (i.e., the normal inverse relationship between the two factors can be expressed as a constant). A decline in the disposition index is associated with the development of T2DM. Both insulin resistance and beta cell dysfunction exist in individuals who develop T2DM. There is little agreement about whether beta cell dysfunction is an independent event or coincident with declining insulin sensitivity and whether the abnormalities are causally linked.

Decreased insulin sensitivity and inadequate insulin response lead to an increase in circulating glucose concentrations, and decreased insulin sensitivity in individuals with T2DM results in the inability of insulin to suppress lipolysis in adipose tissue. Many predisposing factors are related to decreased insulin sensitivity including obesity, a sedentary lifestyle, family history and epigenetics, puberty, advancing age, and, of particular concern to the obstetrician, the maternal hormonal environment of pregnancy.¹⁵ Although it was formerly believed that T2DM was primarily a disorder of older individuals, there has been a significant increase in the prevalence of T2DM among children and adolescents since 1990.^{16,17}

The contribution of population obesity to the rise in T2DM cannot be overestimated. Approximately two thirds of the population in the United States are overweight or obese.¹⁸ Obesity—particularly central obesity, which is estimated by waist circumference—is a well-described risk factor. This increase in visceral obesity affects hepatic metabolic function and is a rich source of cytokines and inflammatory factors, which are recognized as contributing to increasing insulin resistance.

PREDIABETES

Although the 75-g, 2-hour oral glucose tolerance test (OGTT) is the most sensitive and specific diagnostic test for T2DM, the fasting plasma glucose (FPG) test is often used as a first-line diagnostic test because of its ease of administration and reproducibility, particularly in the nongravid population. Because the onset of T2DM is usually insidious, hyperglycemia insufficient to satisfy the diagnostic criteria for diabetes is often categorized as impaired fasting glucose (IFG) (100 to 125 mg/dL) or, if the 75-g OGTT is employed, as impaired glucose tolerance (IGT) (2-hour glucose level of 140 to 199 mg/dL).

BOX 59-2 DIAGNOSTIC CRITERIA FOR PREDIABETES*

IFG: An FPG measurement of 100 to 125 mg/dL (5.6 to 6.9 mmol/L)
OR
IGT: A 2-hr plasma glucose measurement in the 75-g OGTT of 140 to 199 mg/dL (7.8 to 11.0 mmol/L)
OR
An Hb A_{1c} level of 5.7% to 6.4%

*For all three tests, risk is continuous, extending below the lower limit of the range and becoming disproportionately greater at the higher end of the range.

FPG, fasting plasma glucose; Hb A_{1c}, glycosylated hemoglobin; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; OGTT, oral glucose tolerance test.

Adapted from American Diabetes Association: *Standards of medical care in diabetes—2012*, Diabetes Care 35(Suppl 1):S11–S63, 2012.

As for intermediate values of Hb A_{1c}, a systematic review of 16 cohort studies demonstrated that those with an A_{1c} between 5.5% and 6.0% had a risk of overt diabetes within 5 years ranging from 9% to 25%. Those with an A_{1c} of 6.0% to 6.5% had a 5-year risk of developing diabetes of 25% to 50% and relative risk (RR) 20 times higher than those with an A_{1c} of 5.0%.¹⁹

Persons with IFG, IGT, or intermediate elevations in Hb A_{1c} (i.e., 5.7% to 6.4%) have been officially designated as having *prediabetes* because of the associated high risk for the development of T2DM within the next 5 years (Box 59-2). However, the management of pregnant women who are found to have prediabetes is controversial (see “Gestational Diabetes”).

GESTATIONAL DIABETES

GDM is defined as diabetes diagnosed during pregnancy that is not clearly overt diabetes. The underlying pathophysiology of GDM in most instances is similar to that observed for T2DM: an inability to maintain an adequate insulin response because of the significant decreases in insulin sensitivity with advancing gestation. About 2% to 13% of women diagnosed as having GDM have detectable antibodies directed against specific beta cell antigens. Some of these deficiencies are population dependent. Other patients diagnosed with GDM have genetic variants that have been identified as causes of diabetes in the general population, including autosomal dominant and maternal or mitochondrial inheritance patterns.^{20,21}

It is estimated that 3% to 25% of a population of pregnant women will be diagnosed with GDM.²² This is not surprising, because GDM is the precursor to T2DM for many women, based on ethnicity-specific increases in insulin resistance and rising obesity in women of reproductive age. Clinical recognition of GDM is important because therapy can reduce pregnancy complications and potentially reduce long-term sequelae in the offspring.

In the past, diagnosis of GDM was based on John O’Sullivan’s work in the 1960s with the 3-hour, 100-g OGTT.²³ The O’Sullivan criteria for blood glucose levels after oral glucose loading were established to serve as a risk predictor for the likelihood of development of T2DM in the mother after delivery. The limits chosen for the 3-hour 100-g OGTT were somewhat arbitrarily statistically defined to yield a group of women in the top 98th percentile of glucose response. The definition of “abnormal” did not

BOX 59-3 IADPSG RECOMMENDATIONS: STRATEGY FOR THE DETECTION AND DIAGNOSIS OF HYPERGLYCEMIC DISORDERS IN PREGNANCY*

FIRST PRENATAL VISIT

Measure FPG, Hb A_{1c}, or random plasma glucose on all or only high-risk women[†]

If results indicate overt diabetes as defined in Table 59-1:

Treat and follow-up as for preexisting diabetes

If results not diagnostic of overt diabetes:

and FPG ≥ 5.1 mmol/L (92 mg/dL) but < 7.0 mmol/L (126 mg/dL), diagnose as GDM

and FPG < 5.1 mmol/L (92 mg/dL), test for GDM from 24 to 28 weeks' gestation with a 75-g OGTT[‡]

24-28 WEEKS' GESTATION: DIAGNOSIS OF GDM

Perform 2-hr 75-g OGTT after overnight fast for all women not previously found to have overt diabetes or GDM during testing earlier in this pregnancy

Overt diabetes if FPG ≥ 7.0 mmol/L (126 mg/dL)

GDM if one or more values equals or exceeds thresholds indicated in Table 59-1

Normal if all values on OGTT are less than thresholds indicated in Table 59-1

*To be applied to women without known diabetes antedating pregnancy. Postpartum glucose testing should be performed for all women diagnosed with overt diabetes during pregnancy or with GDM.

[†]The decision to perform blood testing for evaluation of glycemia on all pregnant women or only on women with characteristics indicating a high risk for diabetes is to be made on the basis of the background frequency of abnormal glucose metabolism in the population and on local circumstances.

[‡]The panel concluded that there have been insufficient studies performed to know whether there is a benefit of generalized testing to diagnose and treat GDM before the usual window of 24-28 weeks' gestation.

FPG, fasting plasma glucose; Hb A_{1c}, glycosylated hemoglobin; GDM, gestational diabetes mellitus; IADPSG, International Association of Diabetes and Pregnancy Study Groups; OGTT, oral glucose tolerance test.

Adapted from International Association of Diabetes and Pregnancy Study Groups Consensus Panel: *Recommendations on the diagnosis and classification of hyperglycemia in pregnancy*, Diabetes Care 33:676-682, 2010.

consider correlation with neonatal or fetal outcome, which clearly is the most significant morbidity associated with GDM. Other problems with use of the 3-hour OGTT included the propensity for patient emesis after such a large glucose load, which invalidated the test. This led to the development of the two-step testing regimen used widely in the United States, which involves a 50-g "challenge" pre-test followed by the 100-g OGTT only if the initial result is abnormal. However, the two-step diagnostic system inherently imposes delay in diagnosis of GDM and has a relatively high false-negative rate (10% to 20%).

In 2010, the International Association of Diabetes and Pregnancy Study Groups (IADPSG) recommended new criteria for the diagnosis of GDM.²⁴ These criteria (Box 59-3 and Table 59-1) were based largely on the results of a large (25,000 participants) multinational observational trial known as the Hyperglycemia and Adverse Pregnancy Outcome Study (HAPO),²⁵ which meticulously tracked adverse pregnancy and neonatal outcomes. The new IADPSG criteria were based primarily on the perinatal risks of excessive values ($>90\%$

TABLE 59-1 Threshold Values for the Diagnosis of GDM and Overt Diabetes in Pregnancy (IADPSG)

Glucose Measure	Glucose Concentration Threshold	Cumulative % of HAPO Cohort Equaling or Exceeding Threshold
GDM*		
FPG	5.1 mmol/L (92 mg/dL)	8.3
1-hr Plasma glucose	10.0 mmol/L (180 mg/dL)	14.0
2-hr Plasma glucose	8.5 mmol/L (153 mg/dL)	16.1
OVERT DIABETES		
FPG [†]	7.0 mmol/L (126 mg/dL)	
Hb A _{1c} [†]	6.5% (DCCT/UKPDS standardized)	
Random plasma glucose [‡]	11.1 mmol/L (200 mg/dL)	

*One or more of these values from a 75-g OGTT must be equaled or exceeded for the diagnosis of GDM.

[†]One of these must be met to identify the patient as having overt diabetes in pregnancy.

[‡]If a random plasma glucose is the initial measure, the tentative diagnosis of overt diabetes in pregnancy should be confirmed by FPG or Hb A_{1c} using a DCCT/UKPDS-standardized assay. DCCT/UKPDS, Diabetes Control and Complications Trial/United Kingdom Prospective Diabetes Study; FPG, fasting plasma glucose; GDM, gestational diabetes mellitus; HAPO, Hyperglycemia and Adverse Pregnancy Outcome Study; IADPSG, International Association of Diabetes and Pregnancy Study Groups; OGTT, oral glucose tolerance test.

From International Association of Diabetes and Pregnancy Study Groups Consensus Panel: *Recommendations on the diagnosis and classification of hyperglycemia in pregnancy*, Diabetes Care 33:676-682, 2010.

percentiles) for newborn birth weight, body fat, and cord C-peptide level, adjusted for confounding variables.

Further, in recognition of the alarming increase in incidence of obesity and T2DM in the world population, particularly among women of reproductive age, the IADPSG noted that the diagnosis of GDM inevitably includes women with unrecognized *pregestational diabetes*. These women are at increased risk for congenital anomalies in their offspring; complications of diabetes during their pregnancy, including retinopathy and nephropathy; and need for treatment after delivery.²⁴ Because of the potential risk to the mother and fetus, screening for overt diabetes (based on Hb A_{1c} $> 6.5\%$ and FPG > 126 mg/dL) is recommended early in the pregnancy to provide the opportunity to optimize pregnancy outcome. If the results indicate overt diabetes, treatment should be as for preexisting diabetes. If the first-trimester results are not diagnostic of overt diabetes but the FPG level is between 92 and 125 mg/dL, IADPSG recommends treating those women as having GDM. For those whose first-trimester tests are diagnostic of neither overt diabetes nor GDM, a 75-g, 2-hour OGTT is recommended between 24 and 28 weeks' gestation.

The new IADPSG criteria for GDM diagnosis have been adopted widely globally and in the United States by the ADA,¹³ but substantial controversy remains because of the increased numbers of women with GDM who will be diagnosed—up to 18%, from 8% to 10% with the 3-hour OGTT system. Currently, the American College of Obstetricians and Gynecologists (ACOG) has not endorsed the IADPSG recommendations.

Because of the controversy regarding the optimal approach for diagnosis of GDM, the National Institutes of Health convened a Consensus Conference in 2013. The goal was to determine what diagnostic approach, if any, should be recommended after evaluating the benefits and harms of screening for GDM, the effects of different screening tests for GDM, the effects of different screening and diagnostic thresholds on outcomes for mothers and their offspring, and the potential benefits and risks of treatment of GDM.

As part of the Consensus Conference process, an Evidence Report/Technology Assessment was produced.²⁶ This document, which identified 97 relevant studies (6 randomized controlled trials [RCTs], 63 prospective cohort studies, and 28 retrospective cohort studies), concluded that there are clear, continuous, positive associations between increasing glucose concentrations and macrosomia, primary cesarean section, and increasing plasma glucose on a 75-g or 100-g OGTT but that clear thresholds for increased risk were not found. The 50-g oral glucose challenge test had a high negative predictive value but a suboptimal positive predictive value. The reduction in preeclampsia and macrosomia with treatment of GDM was affirmed, but the investigators found no evidence of reduced neonatal hypoglycemia or improved downstream metabolic outcomes.

Based on these considerations, the panel of 19 experts in the fields of obstetrics, diabetes, and biostatistics concluded that although there may be benefits from standardization of a GDM diagnostic protocol between the United States and the world, at present there is insufficient evidence to adopt the IADPSG one-step approach. They supported the continued use of the two-step protocol while recommending further study, including a cost-benefit comparison with the one-step test and research examining the potential short- and long-term benefits and risks for mother and child.²⁷ Accordingly, ACOG subsequently issued a practice bulletin affirming the continued use of the two-step protocol for diagnosis of GDM.^{27a} This protocol involves:

- Early pregnancy screening of women at high risk for pregestational diabetes and GDM (Box 59-4)
- At 24 to 28 weeks, uniform screening for GDM via a two-step regimen consisting of:
 - A 50-g, 1-hour glucose challenge test, which may be administered in the fasting or nonfasting state. A threshold value of ≥ 135 mg/dL or ≥ 140 mg/dL can be used at the discretion of the provider.
 - For glucose challenge test results exceeding the selected threshold, a 100-g, 3-hour OGTT is performed. Two abnormal values meeting or exceeding the values shown in Table 59-2 are required for the diagnosis.

GENETIC AND OTHER CAUSES OF DIABETES

The ADA's fourth classification of diabetes, comprising specific types of diabetes attributed to "other causes," includes genetic defects in insulin action, diseases of the exocrine pancreas (e.g., cystic fibrosis), and drug- or chemical-induced diabetes, such as occurs in the treatment of HIV infection or after organ transplantation. One well-characterized genetic defect that is often included under the heading of maturity-onset diabetes of the young (MODY), is the glucokinase mutation described by Hattersley and colleagues.²⁸ Because glucokinase phosphorylates glucose to glucose-6 phosphate in the pancreas and liver, a heterozygous glucokinase mutation results in hyperglycemia, usually with a mildly elevated FPG level.

BOX 59-4 EARLY SCREENING STRATEGY FOR DETECTING GESTATIONAL DIABETES

Women with the following risk factors are candidates for early screening:

- Previous medical history of gestational diabetes mellitus
 - Known impaired glucose metabolism
 - Obesity (body mass index ≥ 30 [calculated as weight in kilograms divided by height in meters squared])
- If gestational diabetes mellitus is not diagnosed, blood glucose testing should be repeated at 24 to 48 weeks of gestation.

From American College of Obstetricians and Gynecologists: *Gestational diabetes mellitus. Practice Bulletin No. 137, Obstet Gynecol 122:406–416, 2013.*

TABLE 59-2 Three-Hour 100-g Oral Glucose Tolerance Test for Gestational Diabetes

Assessment for GDM	Plasma Glucose Level after a 100-g Glucose Load mg/dL (mmol/L)
Fasting	95 (5.3)
1 hr	180 (10.0)
2 hr	155 (8.6)
3 hr	140 (7.8)

TEST PREREQUISITES

- 1-hr, 50-g glucose challenge result ≥ 135 or 140 mg/dL
- Overnight fast of 8-14 hr
- Carbohydrate loading for 3 days, including ≥ 150 g of carbohydrate
- Seated, not smoking during the test
- Two or more values must be met or exceeded for a diagnosis of GDM

GDM, gestational diabetes mellitus.

From American College of Obstetricians and Gynecologists: *Gestational diabetes mellitus. Practice Bulletin No. 137, Obstet Gynecol 122:406–416, 2013.*

It is estimated that 5% of pregnant women with GDM have this mutation.²⁹ If the heterozygous mutation is present in the fetus, then the altered glucose sensing by the fetal pancreas will result in a decrease in insulin secretion. Insulin is a primary stimulus for growth in the fetus, and any defect in fetal insulin secretion results in decreased fetal growth and possible intrauterine growth restriction (IUGR). Depending on whether the mother or fetus, or both, have a defect in the glucokinase gene, the phenotype of the infant can vary from IUGR through normal fetal growth and to macrosomia.

Maternal-Fetal Metabolism in Normal and Diabetic Pregnancy

Significant changes in maternal metabolism occur during a normal pregnancy. These include changes in maternal nutrient metabolism (i.e., carbohydrate, lipid, and protein metabolism) and changes in factors such as energy expenditure. The overall goal of these maternal metabolic adaptations is to prepare the woman's body to meet the increased energy needs of the mother and growth of the fetus in the latter third of pregnancy, when approximately 70% of fetal growth takes place.³⁰ However, these pregnancy metabolic changes take place on the background of

a woman's pregestational metabolic status. For example, if a woman is healthy and lean before conception, there is an increased need to store adipose tissue in early pregnancy (to meet the increased energy demands of late gestation) and to develop insulin resistance in late gestation (to provide nutrients for the growing fetus). If a woman is obese before conception, there is little need to gain additional adipose tissue, but there is the requirement to provide nutrients for the fetal growth in late gestation.

NORMAL GLUCOSE-TOLERANT PREGNANCY

Glucose homeostasis is primarily a balance between insulin resistance and insulin secretion. The alterations in insulin resistance affect endogenous glucose production (primarily hepatic glucose metabolism) and peripheral glucose metabolism, which takes place in skeletal muscle. In the lean pregnant woman with normal glucose tolerance, there is a significant 30% increase in basal hepatic glucose production by the third trimester of pregnancy (Fig. 59-3). This is associated with a significant increase in basal or fasting insulin concentrations (Fig. 59-4).³¹ A decrease in FPG concentrations most likely results from increasing plasma volumes in early gestation and increased fetoplacental utilization in late pregnancy. In the postprandial state, increasing insulin concentrations enhance glucose uptake into skeletal muscle and adipose tissue and almost completely suppress hepatic glucose production. Although this is the case in lean women, obese women, even those with normal glucose tolerance, have a decreased ability for insulin to completely suppress hepatic glucose production in late pregnancy.³² These data support the concept of decreased insulin sensitivity in late gestation that is more severe in obese women compared with non-obese counterparts.

Peripheral insulin resistance is defined as the decreased ability of insulin to affect glucose uptake primarily in skeletal muscle and to a lesser degree in adipose tissue. Various methods are used to assess insulin sensitivity *in vivo*, including mathematical models of fasting glucose and insulin modeling (e.g.,

homeostasis model assessment [HOMA], OGTT),^{33,34} the intravenous glucose tolerance test, and the gold standard, the hyperinsulinemic-euglycemic clamp.³⁵ Most of these measures have identified a significant 50% to 60% decrease in insulin sensitivity in late gestation.³⁶

The changes in insulin sensitivity during gestation reflect the woman's pregravid insulin sensitivity status. Lean women usually have greater pregravid insulin sensitivity compared with overweight or obese women. These differences manifest before pregnancy, and when evaluated against the metabolic background of pregnancy, the relationships are similar in late pregnancy, albeit reduced by approximately 50% to 60% (see Fig. 59-4). The decreases in insulin sensitivity in late pregnancy are accompanied by an increase in insulin response. The insulin response to a glucose load increases approximately threefold compared with pregravid measures (Fig. 59-5).

PREGNANCY COMPLICATED BY DIABETES

Alterations in glucose metabolism in women with diabetes have been most extensively examined in women with GDM; alterations are probably very similar in women with T2DM but with increased insulin resistance and further decompensation of beta cell function. In both lean and obese women with GDM and mildly elevated FPG levels, there is an increase in basal endogenous glucose production, similar to that observed in subjects with normal glucose tolerance, although fasting insulin concentrations, particularly in late gestation, are greater than in normal glucose-tolerant women (Fig. 59-6).³⁷ However, with insulin infusion, the ability of insulin to suppress endogenous glucose production is decreased in women with GDM compared with a matched control group (approximately 80% versus 95%).

If insulin sensitivity is estimated before conception or after delivery, there is a significant decrease in women who go

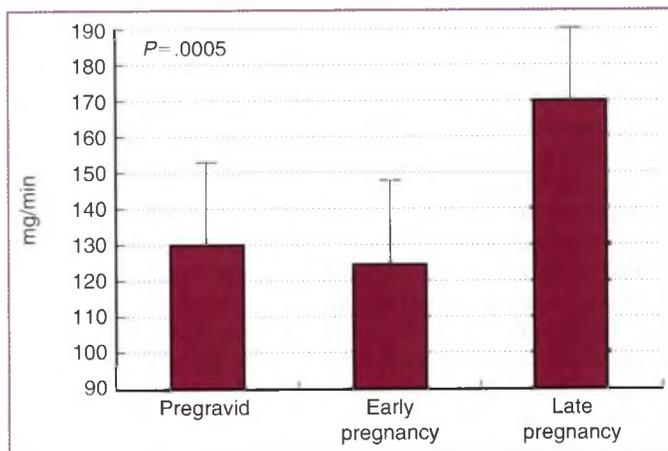

Figure 59-3 Alterations in glucose production. Changes in first phase (A) and second phase (B) insulin response from the pregravid state through early (12 to 14 weeks) and late (34 to 36 weeks) pregnancy, as measured during an intravenous glucose tolerance test (mean \pm SD). The asterisk indicates change over time from pregravid status through late pregnancy (ANOVA). (Adapted from Catalano PM, Tyzbir ED, Roman NM, et al: Longitudinal changes in insulin release and insulin resistance in non-obese pregnant women, *Am J Obstet Gynecol* 165:1667–1672, 1991.)

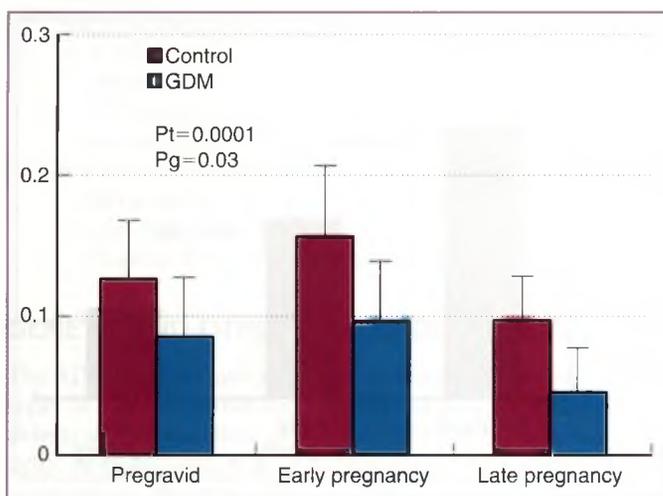

Figure 59-6 Alterations in insulin sensitivity. Longitudinal changes in insulin sensitivity during clamp $40 \text{ mU}\cdot\text{m}^{-2}\cdot\text{min}^{-1}$ insulin infusion in obese women (mean \pm SD). GDM, gestational diabetes mellitus; Pg, difference between groups; Pt, individual longitudinal changes with time. (Adapted from Catalano PM, Huston L, Amini SB, Kalhan SC: Longitudinal changes in glucose metabolism during pregnancy in obese women with normal glucose tolerance and gestational diabetes, *Am J Obstet Gynecol* 180:903–916, 1999.)

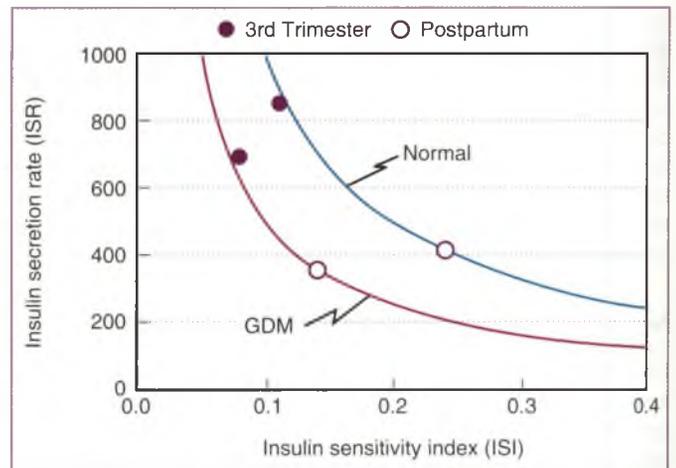

Figure 59-7 Insulin sensitivity and secretion relationships in normal women and women with gestational diabetes mellitus (GDM). Prehepatic insulin secretion was assessed during steady-state hyperglycemia using plasma insulin and C-peptide concentrations and C-peptide kinetics in individual patients. (From Buchanan TA: Pancreatic β -cell defects in gestational diabetes: implications for the pathogenesis and prevention of type 2 diabetes, *J Clin Endocrinol Metab* 86:989–993, 2001.)

on to develop GDM, compared with normal glucose-tolerant women.³⁸ During pregnancy, the percentage decrease in insulin sensitivity is approximately the same in women with GDM as in matched controls (i.e., 50% to 60%). The decreased insulin sensitivity observed during pregnancy in the woman who develops GDM is a function of her pregravid metabolic status. The increased glucose concentrations represent the inability of pancreatic beta cells to normalize glucose levels (Fig. 59-7).

The relationship between insulin sensitivity and insulin response has been characterized as a hyperbolic curve or, when multiplied, as the disposition index. A curve that is “shifted to the left” can be plotted for individuals who go on to develop GDM. Whether insulin resistance precedes beta cell defects or occurs concomitantly is not known with certainty. However, Buchanan proposed that insulin resistance causes beta cell dysfunction in susceptible individuals.³⁹ The increased risk of T2DM in women who formerly had GDM may be a function of decreasing insulin sensitivity (i.e., worsening insulin resistance) exacerbated by increasing age, adiposity, and the inability of the beta cells to fully compensate.

Scant data are available on changes in glucose metabolism in women with T1DM. Schmitz and coworkers evaluated the longitudinal changes in insulin sensitivity in women with T1DM in early and late pregnancy and after delivery and showed a 50% decrease in insulin sensitivity in late gestation.⁴⁰ There was no significant difference in insulin sensitivity in these women in early pregnancy or within 1 week of delivery compared with nonpregnant women with T1DM. Based on the available data, women with T1DM have similar alterations in insulin sensitivity as are observed in women with normal glucose tolerance.

The longitudinal changes in insulin requirements during pregnancy in women with well-controlled T1DM before conception were recently reported by Garcia-Patterson and colleagues.⁴¹ There were variable changes in insulin requirements in early gestation, with decreases between 9 and 18 weeks’

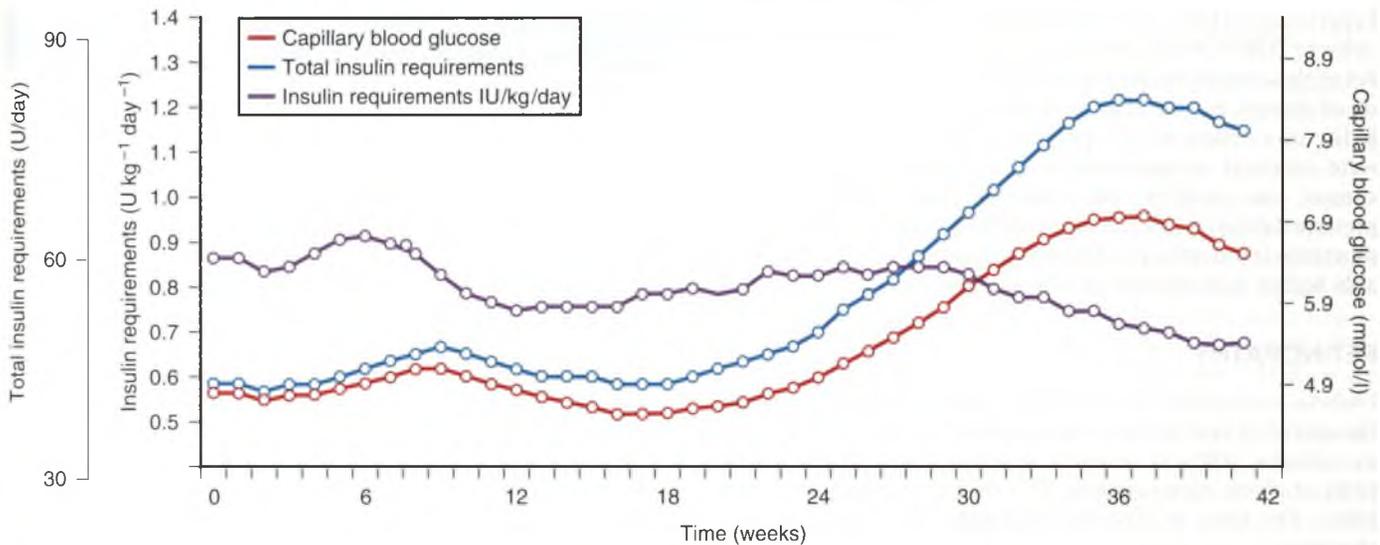

Figure 59-8 Mean insulin requirements and self-monitored blood glucose levels in pregnant women with type 1 diabetes. (From Garcia-Patterson A, Gich I, Amini SB, et al: *Insulin requirements throughout pregnancy in women with type 1 diabetes mellitus: three changes of direction*, *Diabetologia* 53:446–451, 2010.)

gestation. The greatest increase was observed between 16 and 37 weeks, with a gradual decline thereafter (Fig. 59-8). These changes in insulin requirements in women with well-controlled T1DM support the earlier observations of variable changes in insulin sensitivity in early gestation and a significant decrease in insulin sensitivity in late gestation.

MECHANISMS OF INSULIN RESISTANCE

Insulin resistance is defined as a condition in which physiologic insulin concentrations elicit decreased biologic response in target tissues. The action of insulin in target cells requires the orchestrated activation of complex molecular steps. Autophosphorylation of the insulin receptor on tyrosine residues is the initial mandatory step allowing recruitment and activation of downstream effectors such as insulin receptor substrate-1 (IRS-1). The mechanisms responsible for pregnancy-induced insulin resistance have been characterized at the molecular level. In normal pregnancy, the ability of the insulin receptor to transduce an intracellular signal is diminished. In late pregnancy, skeletal muscle IRS-1 content is lower than in nonpregnant women.⁴² The downregulation of IRS-1 closely parallels the decreased ability of insulin to stimulate 2-deoxyglucose uptake in skeletal muscle. In GDM, the insulin receptor also displays a decreased ability to undergo tyrosine phosphorylation. The decreased receptor phosphorylation, which results in 25% less glucose transport activity, is not found in pregnant women with normal glucose tolerance.

The insulin resistance of pregnancy is almost completely reversed shortly after delivery, consistent with the marked decrease in insulin requirements clinically in women managed on insulin.⁴³ The placenta has long been suspected of producing hormonal factors related to these adaptations in maternal metabolism. The strongest candidates include maternal cortisol and placenta-derived hormones such as human placental lactogen (HPL), progesterone, and estrogen.^{43–46} Tumor necrosis factor- α (TNF- α) and other cytokines produced by the placenta can be released locally as well as in the maternal systemic circulation.⁴⁵

Despite decades of intensive research, direct proof of how placental factors modify insulin action in maternal tissues has not been obtained. The role of TNF- α in insulin resistance was first revealed in studies investigating how TNF- α impairs insulin action.⁴⁷ Since then, a wide variety of factors, including nutrients such as fatty acids and amino acids, have been found to induce insulin resistance through IRS-1 serine phosphorylation.⁴⁸ In pregnant women, circulating TNF- α concentrations had an inverse correlation with insulin sensitivity, as estimated from clamp studies.⁴⁹ In the third trimester, increased circulating free fatty acids may also contribute to the insulin resistance.⁵⁰

The cooperation of inflammatory and metabolic factors in blunting the effects of insulin has recently gained attention. The term “metabolic inflammation” is applied to situations of low-grade chronic inflammation observed in several metabolic disorders such as obesity and diabetes.⁵¹ Adipose tissue plays an essential role in initiation of the inflammatory response. Not only is it a storage depot for excess calories, but it also actively releases fatty acids and secretes a variety of adipocytokines. Pregnancy in a woman with obesity and GDM is a state of metabolic inflammation.⁵² Macrophages originating from the maternal systemic circulation invade maternal adipose tissue and the placenta, increasing local and systemic release of pro-inflammatory cytokines.⁵³

Altogether, these observations suggest that in pregnancy the expanding adipose tissue mass is a primary cause of systemic insulin resistance and that the resulting altered homeostasis, inflammation, and insulin resistance propagate to skeletal muscle and the liver.⁵⁴

Complications of Diabetes during Pregnancy

MATERNAL MORBIDITY

Women with pregestational diabetes are at risk for a number of obstetric and medical complications, with significantly elevated odds ratios (ORs) compared to nondiabetic gravidas for

hypertension (OR = 14.2), preeclampsia (OR = 3.4) cesarean delivery (OR = 11.3), and preterm delivery (OR = 4.4).⁵⁵ The RR of these problems is proportional to the duration and severity of disease. Evers and coworkers reported on maternal morbidity in a cohort of 323 pregnant women with T1DM who were followed prospectively in the Netherlands.⁵⁶ Glycemic control was excellent, but rates of preeclampsia (12.7%), preterm delivery (32%), cesarean delivery (44%), and maternal mortality (60 deaths per 100,000 pregnancies) were considerably higher than in the nondiabetic population.

RETINOPATHY

Diabetic retinopathy is the leading cause of blindness between the ages of 24 and 64 years. Some form of retinopathy is present in virtually 100% of women who have had T1DM for 25 years or more; approximately 20% of these women are legally blind. The topic of diabetic retinopathy has been reviewed elsewhere.⁵⁷

The pattern of progression of diabetic retinopathy is relatively predictable. It proceeds from mild nonproliferative abnormalities, which are associated with increased vascular permeability; to moderate and severe nonproliferative diabetic retinopathy, which is characterized by vascular closure; to proliferative diabetic retinopathy, which is characterized by the growth of new blood vessels on the retina and posterior surface of the vitreous. Vision loss from diabetic retinopathy results from several mechanisms. First, central vision may be impaired by macular edema or capillary nonperfusion. Second, the new blood vessels of proliferative diabetic retinopathy and contraction of the accompanying fibrous tissue can distort the retina and lead to tractional retinal detachment, producing severe and often irreversible vision loss. Third, the new blood vessels may bleed, adding the further complication of preretinal or vitreous hemorrhage.

Although past studies suggested that rapid induction of glycemic control in early pregnancy stimulates retinal vascular proliferation,⁵⁸ later investigations showed that the severity and duration of diabetes before pregnancy have a greater effect. Temple and colleagues studied 179 women with pregestational T1DM, performing dilated fundal examination at the first prenatal visit and at 24 and 34 weeks' gestation. Progression to proliferative diabetic retinopathy occurred in only 2.2% of their subjects, and moderate progression occurred in 2.8%. However, progression was significantly greater in women who had had diabetes for more than 10 years (10% versus 0%).⁵⁹

Further, trials failed to show any acceleration in microvascular complications when pregnant and nonpregnant diabetic subjects were closely followed and compared.⁶⁰ In the study by Arun and Taylor, 59 women who had T1DM with a mean duration of 14.4 ± 8.2 years, a mean age at pregnancy of 29.8 ± 5.5 years, and a mean Hb A_{1c} value of $8.2 \pm 2.0\%$ before pregnancy with tighter control during pregnancy. Four women required laser therapy during pregnancy, but none required laser subsequently. Baseline retinopathy status was the only independent risk factor that predicted progression of retinopathy.

Screening for retinopathy by a qualified ophthalmologist is recommended before pregnancy and again during the first trimester for patients with pregestational diabetes because of the demonstrated effectiveness of laser photocoagulation therapy in arresting progression. Patients with minimal disease should be re-examined yearly after delivery. Those with significant retinal pathology may require monthly follow-up.¹³ In patients

TABLE 59-3 Categories of Diabetic Renal Disease

Category*	Albumin-to-Creatinine Ratio ($\mu\text{g}/\text{mg}$) [†]
Normal	<30
Microalbuminuria	30-299
Macroalbuminuria	>300

*Categories of diabetic nephropathy are distinguished by the level of urinary protein excretion. Two of three collections in a 3- to 6-month period should be abnormal for a diagnosis of microalbuminuria or nephropathy.

[†]The ratio of albumin to creatinine is determined by random spot collection.

with macular edema, Michaelides and associates⁶¹ showed that use of intravitreal anti-vascular endothelial growth factor (anti-VEGF) agents provided superior improvement in visual acuity compared with laser photocoagulation. However, use of this agent in pregnant women has been limited to case reports, several of which have documented miscarriage after intraocular injection.⁶²

NEPHROPATHY

Diabetes is the most common cause of end-stage renal disease (ESRD) in the United States and Europe. In the United States, diabetes is the leading cause of kidney failure, accounting for 44% of all new cases of kidney failure in 2008. In that year, a total of 202,290 people with ESRD due to diabetes were living on chronic dialysis or with a kidney transplant.⁴

The pathophysiology of diabetic renal disease is incompletely understood, but several factors play a role, including genetic susceptibility, control of hyperglycemia, and the duration and severity of coexisting hypertension. Additional insults, such as repeated urinary tract infections, excessive glycogen deposition, glycosylation, and papillary necrosis, all hasten deterioration of renal function. The kidney is normal at the onset of diabetes, but within a few years glomerular basement membrane thickening can be identified. By 5 years, there is expansion of the glomerular mesangium, resulting in diffuse diabetic glomerulosclerosis. All patients with marked mesangial expansion exhibit proteinuria exceeding 400 mg in 24 hours. The peak incidence of nephropathy occurs after about 16 years of diabetes.

Categories of Diabetic Nephropathy

Categories of diabetic nephropathy are distinguished by the level of urinary protein excretion. Table 59-3 shows normal values and the current clinical criteria for microalbuminuria and nephropathy. Screening for microalbuminuria can be performed by three methods: measurement of the albumin-to-creatinine ratio in a random spot collection; 24-hour urine collection with serum creatinine, allowing the simultaneous measurement of creatinine clearance; and timed (4-hour or overnight) collection. The first method is preferred because it is the easiest to carry out in an ambulatory setting and it provides adequately accurate information.

Effect of Pregnancy on Progression of Nephropathy

Although some clinicians discourage pregnancy in women with diabetic renal disease because of concerns about permanent

renal deterioration as a result of the pregnancy, recent data consistently indicate that pregnancy does not measurably alter the time course of diabetic renal disease.

Progression of diabetic nephropathy is closely related to the degree of glycemic control. To the extent that most women have better glycemic control during pregnancy, delay or slowing of renal function deterioration can be expected. A study of renal function for 4 years before and 4 years after pregnancy in 11 patients with diabetic nephropathy⁶³ showed that the gradual rise in serum creatinine over that period was unaffected by the intervening pregnancy. Imbasciati and coworkers performed a longitudinal study of 58 women with chronic renal disease whose mean serum creatinine level was 6 mg/dL at the start and 6 mg/dL at the end of pregnancy. Although women with glomerular filtration rates slower than 40 mL/min and proteinuria greater than 1 g/day had increased risk of delivering a low-birth-weight child, even those with worse values had similarly modest changes in renal function when after- and before-pregnancy indices were compared.⁶⁴

Young and associates⁶⁵ monitored 32 diabetic women without nephropathy (group I) and 11 diabetic women with nephropathy (group II) through pregnancy and for 1 year after delivery. In both groups, there was an increase in urinary albumin excretion during pregnancy (592 versus 119 mg/24 hr, respectively; $P = .0001$) but no difference in postpartum albuminuria, creatinine, or creatinine clearance compared to antepartum values. Group II had higher prevalences of chronic hypertension (72.7% versus 21.9%, $P = .004$), preeclampsia (63.6% versus 6.3%, $P = .0003$), and lower gestational age at delivery (36 versus 38 weeks, $P = .003$), but pregnancy was not associated with development or progression of diabetic nephropathy.

Rossing and colleagues⁶⁶ evaluated the effect of pregnancy on deterioration of renal function in 93 women older than 20 years of age. They compared groups of never-pregnant and ever-pregnant women who received similar medical therapy and who had similar degrees of renal function at the start of the study. The results are shown in Figure 59-9. Based on this excellent prospective study, it is evident that pregnancy neither alters the time course of renal disease nor increases the likelihood of transition to ESRD.

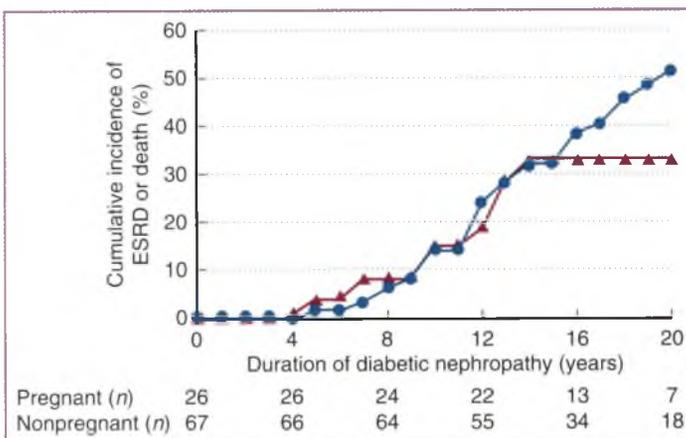

Figure 59-9 End-stage renal disease (ESRD). Cumulative incidence of ESRD in ever-pregnant women (triangles) and never-pregnant women (circles). (From Rossing K, Jacobsen P, Hommel E, et al: Pregnancy and progression of diabetic nephropathy, *Diabetologia* 45:36–41, 2002.)

Renal Dialysis in Pregnant Women with Diabetes

Although women receiving dialysis for ESRD are often amenorrheic or anovulatory, pregnancies have become increasingly common during therapy (3% to 7%).⁶⁷ However, the prognosis for pregnancy in diabetic women with ESRD managed on dialysis continues to be exceedingly poor, with fetal loss rates remaining in the range of 30% to 50%. Neonatal death rates are between 5% and 15%, and fewer than one half of pregnancies among women with ESRD result in viable children. About 60% of births are premature, often because of uncontrollable hypertension, renal failure, or fetal growth failure. Among the 20% to 25% of pregnancies ending in live births, 40% of babies are severely growth restricted.

A major practical problem with achieving a successful pregnancy outcome while on hemodialysis is proper maintenance of maternal vascular volume. Dialysis teams are accustomed to removing significant vascular volume at each session. However, during a normal pregnancy, there is a progressive expansion in vascular volume of at least 20% to 30% above nonpregnant values from 8 to 30 weeks' gestation. This volume augmentation is required to maintain uteroplacental perfusion and fetal growth. Pregnancies in which vascular volume does not increase appropriately have high incidences of IUGR and stillbirth. Difficulties with vascular underfill (e.g., hypotension, poor fetal growth, asphyxia) and overfill (e.g., hypertension) are common in pregnant patients on hemodialysis and often are difficult to rectify.

The poor prognosis associated with hemodialysis combined with other considerations has prompted increased interest in continuous ambulatory peritoneal dialysis. Although fluid and chemical balance is constant and heparinization is not necessary, intrauterine deaths, abruption, prematurity, hypertension, and fetal distress still occur. The best strategy for most diabetic women on dialysis who desire pregnancy is to undergo kidney transplantation.

Renal Transplantation and Diabetic Pregnancy

Successful pregnancy after renal transplantation is now a reality. Deshpande and colleagues performed a systematic review and meta-analysis of articles published between 2000 and 2010 consisting of 50 studies with 4706 pregnancies in 3570 transplant recipients.⁶⁸ The overall rates of live birth and miscarriage were comparable or better than those of the general U.S. population (74% versus 67% and 14% versus 17%, respectively). However, complications of preeclampsia (27%), GDM (8%), cesarean delivery (57%), and preterm delivery (46%) were higher than in the general population (4%, 4%, 32%, and 13%, respectively). Outcomes were more favorable in those pregnancies with lower mean maternal age, and obstetric complications were more frequent with a shorter mean interval between transplantation and pregnancy.

CARDIOVASCULAR COMPLICATIONS

Cardiovascular complications experienced by pregnant women with diabetes include chronic hypertension, pregnancy-induced hypertension, and, rarely, atherosclerotic heart disease. In composite studies of all types of diabetic pregnancies, the incidence of hypertensive disorders during pregnancy varied from 15% to 30%, with the rate of hypertension increased fourfold over that for the nondiabetic population.⁶⁹

Chronic Hypertension

Chronic hypertension (i.e., blood pressure $\geq 140/90$ mm Hg before 20 weeks' gestation)⁷⁰ complicates 10% to 20% of pregnancies in diabetic women and up to 40% of those in diabetic women with preexisting renal or retinal vascular disease. The perinatal problems encountered with chronic hypertension include IUGR, maternal stroke, preeclampsia, and abruptio placentae. In women with pregestational diabetes, the prevalence of chronic hypertension increases with duration of diabetes and is closely associated with nephropathy.⁷¹

The Diabetes in Early Pregnancy (DIEP) study reported that women with T1DM have higher mean blood pressures throughout pregnancy than do normal controls.⁷² In a significant proportion of patients, this difference is probably evidence of underlying renal compromise. Preexisting chronic hypertension should be suspected if the diabetic patient's systolic blood pressure exceeds 130/80 mm Hg before the third trimester. The diagnosis is strengthened if the mean blood pressure fails to decline normally in the late second trimester, the blood urea nitrogen level is greater than 10 mg/dL, the serum creatinine concentration is greater than 1 mg/dL, creatinine clearance is less than 100 mL/min, or a combination of these factors is present.

Preeclampsia

Preeclampsia occurs two to four times as frequently in women with pregestational diabetes as in those without diabetes. The risk of developing preeclampsia is proportional to the duration of diabetes before pregnancy, the preexistence of nephropathy and hypertension, and the level of glycemic control when the pregnancy began.⁷³ More than one third of pregnant women who have had diabetes for longer than 20 years develop this condition. Using White's classification of severity and duration of diabetes (Table 59-4), Sibai and associates reported that

patients with White class B diabetes have a risk profile similar to that of nondiabetic patients, whereas women with evidence of renal or retinal vasculopathy (White class D, F, or R) have a 50% excess risk of hypertensive complications compared to women without hypertension.⁷⁴

Renal function assessments should be performed in each trimester in women with overt diabetic vascular disease and in those who have had diabetes for longer than 10 years. Significant proteinuria, plasma uric acid levels greater than 6 mg/dL, or evidence of HELLP syndrome (*hemolysis, elevated liver enzymes, and low platelets*) should prompt a workup for preeclampsia.

Heart Disease

Although it is uncommon, atherosclerotic heart disease may afflict diabetic patients in the later reproductive years. For diabetic women with cardiac involvement, pregnancy outcome is dismal, with a maternal mortality rate of 50% or higher and perinatal loss rates approaching 30%.⁷⁵ Recognition of cardiac compromise in pregnant women with diabetes may be difficult because of the decrease in exercise tolerance that occurs during normal pregnancy. Compromised cardiac function may also be difficult to detect in patients who are restricted to bed rest for hypertension or poor fetal growth. It is prudent to obtain a detailed cardiovascular history in all diabetic patients and to consider electrocardiography and maternal echocardiography in patients who have T1DM and are older than 30 years of age and in patients who have had diabetes for 10 years or longer. With intensive monitoring, successful pregnancy is possible, albeit hazardous, for women with significant cardiac disease.⁷⁶

DIABETIC KETOACIDOSIS

Diabetic ketoacidosis (DKA) during pregnancy is a medical emergency for the mother and the fetus. Pregnant women with T1DM are at increased risk for DKA, although the incidence and morbidity of this complication have decreased from 20% or more in the older literature to approximately 1% to 2% in later reports.⁷⁷ The rate of intrauterine fetal death, formerly as high as 35% with DKA during pregnancy, has dropped to 10% or less.

Precipitating factors for ketoacidosis include pulmonary, urinary, or soft tissue infections; poor compliance; and unrecognized new onset of diabetes. Because severe DKA threatens the life of the mother and fetus, prompt treatment is essential. Fetal well-being in particular is in jeopardy until maternal metabolic homeostasis is reestablished. High levels of plasma glucose and ketones are readily transported to the fetus, which may be unable to secrete sufficient quantities of insulin to prevent DKA in utero.

DKA derives from inadequate insulin action and functional hypoglycemia at the target tissue level. This leads to increased hepatic glucose release but decreased or absent tissue disposal of glucose. Glucose-lacking tissues release ketone bodies, and vascular hyperglycemia promotes osmotic diuresis. Over time, the diuresis causes profound vascular volume depletion and loss of electrolytes. The release of stress hormones (i.e., catecholamines, glucagon, growth hormone, and cortisol) further impairs insulin action and contributes to insulin resistance. Left unchecked, this cycle of dehydration, tissue hypoglycemia, and electrolyte depletion can lead to multisystem collapse, coma, and death.

TABLE 59-4 The White Classification of Diabetes in Pregnancy

White Class	Age at Onset (yr)	Duration (yr)	Complications
A	Any	Any	Diagnosed before pregnancy; no vascular disease
B	>20	or <10	No vascular disease
C	10-19	or 10-19	No vascular disease
D	<10	or >20	Background retinopathy only or hypertension
E			Calcification of pelvic arteries (no longer used)
F			Nephropathy (>500 mg of proteinuria per day)
H			Arteriosclerotic heart disease
R			Proliferative retinopathy or vitreous hemorrhage
T			After renal transplantation

Adapted from Hare JW, White P: Gestational diabetes and the White classification, *Diabetes Care* 3:394-396, 1980. Copyright © 1980 by the American Diabetes Association.

Early in the illness, hyperglycemia and ketosis are moderate. If hyperglycemia is not corrected, diuresis, dehydration, and hyperosmolality follow. Pregnant women in the early stages of ketoacidosis respond quickly to appropriate treatment of the initiating cause (e.g., broad-spectrum antibiotics), additional doses of regular insulin, and volume replacement.

Patients with advanced DKA usually present with typical findings, including hyperventilation, normal or obtunded mental state (depending on the severity of the acidosis), dehydration, hypotension, and a fruity odor to the breath. Abdominal pain and vomiting may be prominent symptoms. The diagnosis of DKA is confirmed by the presence of hyperglycemia (glucose >200-300 mg/dL) and base deficit of -4 mEq/L or greater.

As many as one third of patients in the early or very late stages of DKA have initial blood glucose levels lower than 200 mg/dL. A pregnant diabetic patient with a history of poor food intake or vomiting for longer than 12 to 16 hours should have a thorough workup for DKA, including a complete blood cell count and electrolyte determinations. A serum bicarbonate level lower than 18 mg/dL or an anion gap exceeding 10 to 15 mEq/L should prompt performance of an arterial blood gas analysis. In all cases of DKA, the diagnosis is confirmed by arterial blood gases demonstrating a metabolic acidemia with base excess exceeding -4 mEq/L.⁷⁸

Table 59-5 contains a protocol for treatment of DKA. The important steps in management include the following:

- Search for and treat the precipitating cause. Typical initiators include pyelonephritis and pulmonary or gastrointestinal viral infections.
- Perform volume resuscitation that is both vigorous (3 to 4 L of physiologic intravenous fluid over the first 2 hours) and sustained (a total of 6 to 8 L is frequently required over the first 24 hours). The patient will continue to generate vascular volume deficits until her glucose levels and acidosis are largely resolved. A physiologic fluid such as 0.9% NaCl or lactated Ringer solution should be used and continued until the acidosis is substantially corrected.

Potassium chloride should be added to the infusate when the plasma potassium level nears the lower limit of normal.

- Use insulin to correct hyperglycemia. Although intermittent injections may be used, a continuous infusion of regular or short-acting insulin (i.e., lispro or aspart) allows frequent adjustments. When given as a continuous infusion, insulin 1 to 2 units/hr gradually corrects the patient's glucose abnormality over 4 to 8 hours. Attempts to normalize plasma glucose levels rapidly (i.e., in less than 2 to 3 hours) may result in hypoglycemia and physiologic counterregulatory responses.
- Monitor serum bicarbonate levels and arterial blood gas base deficits every 1 to 3 hours to guide management. Even after the plasma glucose level is normalized, acidemia may persist, as evidenced by continuing abnormalities in the patient's electrolyte concentrations. Unless volume therapy is continued until the patient's electrolyte stores and plasma concentrations have substantially returned to normal, DKA may reappear, and the cycle of metabolic derangement will be renewed.

If DKA occurs after 24 weeks' gestation, the status of the fetus should be continuously monitored by fetal heart rate monitoring or a biophysical profile, or both. However, even if the fetal status is questionable during the phase of therapeutic volume and plasma glucose correction, emergency cesarean delivery should be avoided. Usually, correction of the maternal metabolic disorder is effective in normalizing fetal status. Nevertheless, if a reasonable effort has been expended in correcting the maternal metabolic disorder and the fetal status remains a concern, delivery should not be delayed if the maternal condition is stable.

FETAL MORBIDITY AND MORTALITY

The rate of perinatal mortality in diabetic pregnancy has decreased 30-fold since the discovery of insulin in 1922 and the institution of intensive obstetric and infant care in the 1970s. Improved techniques of maintaining maternal euglycemia have

TABLE 59-5 Treatment Protocol for Diabetic Ketoacidosis*

Measures	Initial Phase (6-24 hr)	Recovery Phase
General	Search for initiating cause of ketoacidosis. Insert bladder catheter. If patient is unconscious, establish nasogastric tube.	Continue treatment of initiating cause. Remove bladder catheter when vascular volume is replaced.
Fluids	Administer 0.9% NaCl at 1000 mL/hr \times 2 hr and then 500 mL/hr until 5-8 L has been infused.	Continue 0.9% NaCl at 100 mL/hr for at least 48 hr to avoid return of ketoacidosis.
Insulin	Administer 20 U of insulin by IV bolus and then 5-10 U/hr by IV infusion.	When acidosis is resolved and plasma glucose is <160 mg/dL, reduce insulin infusion to 0.7-2.0 U/hr. Return to patient's prior SC insulin dosing after plasma glucose has been stable for at least 12 hr.
Glucose	When plasma glucose is <250 mg/dL, add 5% dextrose to 0.9% NaCl.	
Potassium	If serum K ⁺ level is normal or low, infuse KCl at 20 mEq/hr. If serum K ⁺ level is high, wait until K ⁺ is normal, then administer KCl at 20 mEq/hr.	Use oral potassium supplementation for 1 wk.
Bicarbonate	Measure serum K ⁺ level every 2-4 hr. If pH is <7.1, add one ampule of bicarbonate (50 mEq) to IV; repeat until pH is >7.1.	

*These are general guidelines. Because there may be wide variation in individual patient needs, there is no substitute for careful monitoring of each patient, particularly in the initial phase of therapy.

IM, intramuscular; IV, intravenous; KCl, potassium chloride; NaCl, sodium chloride; SC, subcutaneous.

Adapted from American College of Obstetricians and Gynecologists (ACOG): *Clinical management guidelines for obstetrician-gynecologists: pregestational diabetes mellitus*. ACOG practice bulletin no. 60, March 2005, *Obstet Gynecol* 105:675-685, 2005.

led to later timing of delivery and reduced iatrogenic respiratory distress syndrome. Nevertheless, the perinatal mortality rates reported for diabetic women remain approximately three times those observed in the nondiabetic population, with congenital malformations, respiratory distress syndrome, and extreme prematurity accounting for the majority. Recognizing these risks, many experts have recommended early delivery (at 37 to 38 weeks) to optimize fetal outcome.

However, in 2011, the Society for Maternal-Fetal Medicine (SMFM) and the Eunice Kennedy Shriver National Institutes of Child Health and Human Development (NICHD) held a conference addressing the issues of late preterm and early term birth. If GDM is well controlled on diet or pharmacologic therapy and the estimated fetal weight is less than the 90th percentile, one need not consider early term delivery. If GDM or preexisting diabetes is complicated by conditions that increase the risk for the mother (e.g., severe preeclampsia) or the fetus (non-reassuring fetal status), the timing of delivery should be based on the underlying medical or obstetric condition. If a woman with GDM or preexisting diabetes has poor glycemic control despite reasonable efforts or is noncompliant with management, consideration should be given to late preterm or early term delivery after evaluation of the risks and benefits of continuing the pregnancy. Even among women with excellent glycemic control, delivery at term increases the risk of fetal demise, fetal macrosomia, and birth injury.⁷⁹ Additional prospective data are needed to better understand the short- and long-term risks and benefits of this obstetric dilemma.

Miscarriage

Studies of miscarriage rates from several decades ago indicated an increased incidence of spontaneous abortion among women with pregestational diabetes, especially those with poor glucose control during the periconceptional period. Given the well-documented association between congenital anomalies and hyperglycemia, such a finding is not surprising. In 1984, Miodovnik and coworkers⁸⁰ prospectively studied spontaneous abortion in diabetic pregnancy as stratified by White's classification. They found an increasing rate among patients with more advanced classes of diabetes: Rates for White classes C, D, and F were 25%, 44%, and 22%, respectively, compared with a 15% expected rate in the nondiabetic population. Later studies of populations with better preconceptional glycemic control reported miscarriage rates similar to those in the nondiabetic population, indicating that diabetic women with excellent glycemic control have a risk of miscarriage equivalent to that in women without diabetes.⁸¹

These studies can be used to encourage patients who have not yet conceived to achieve excellent glycemic control. Patients who present in early pregnancy with normal glycohemoglobin values can be reassured that the overall elevation in risk of miscarriage is modest. However, for patients with glycohemoglobin values 2 to 3 standard deviations above the norm, intense early pregnancy surveillance is indicated.

Congenital Anomalies

Among women with overt diabetes before conception, the risk of a structural anomaly in the fetus is increased threefold to eightfold, compared with the 1% to 2% risk for the general population.⁸² There is no increase in birth defects among offspring of diabetic fathers and nondiabetic women or in women who develop GDM after the first trimester, indicating that

glycemic control during embryogenesis is the main factor in the genesis of diabetes-associated birth defects. A classic report by Miller and associates⁸³ compared the frequency of congenital anomalies in patients with normal or high first-trimester maternal glycohemoglobin levels and found only a 3.4% rate of anomalies with an Hb A_{1C} value lower than 8.5%, whereas the rate of malformations in patients with poorer glycemic control in the periconceptional period (Hb A_{1C} >8.5%) was 22.4%.

Bell and coworkers studied 1677 pregnant women with diabetes and more than 400,000 controls.⁸⁴ The rate of nonchromosomal major congenital anomalies in women with diabetes was 71.6 per 1000 pregnancies (95% confidence interval [CI], 59.6 to 84.9), an RR of 3.8 (CI, 3.2 to 4.5) compared with women without diabetes. There was a threefold to sixfold increased risk across all common anomaly groups. In multivariate analysis, periconceptional glycemic control (adjusted OR [aOR] = 1.3; [CI, 1.2 to 1.4] per 1% [11 mmol/L] linear increase in Hb A_{1C} above 6.3% [45 mmol/L]) and preexisting nephropathy (aOR = 2.5; CI, 1.1 to 5.3) were independent predictors of congenital anomaly. Unadjusted risk was higher for women who did not take folate. The typical congenital anomalies observed in diabetic pregnancies and their frequency of occurrence are listed in Table 59-6.

Pathogenesis. The mechanism by which hyperglycemia disturbs embryonic development is multifactorial. The glucose transporter GLUT2 plays a prominent role in mediating embryonic glucotoxicity.⁸⁵ A variety of environmental changes with teratologic consequences for diabetic embryopathy have been identified. Diabetic teratogenesis has been associated with oxidative stress,⁸⁶ enhanced lipid peroxidation,⁸⁷ decreased antioxidative defense capacity,⁸⁸ and sorbitol accumulation.⁸⁹ Along these lines, high doses of vitamins C and E decreased fetal dysmorphogenesis to nondiabetic levels in vivo and in rat embryo culture.^{90,91}

Likewise, addition of prostaglandin inhibitors to cultures of mouse embryos prevented glucose-induced embryopathy.⁹² The underlying biochemical and molecular mechanisms of diabetic embryopathy have started to be deciphered.⁹³ Disturbed arachidonic acid metabolism, alteration in activity of protein kinase C,⁹⁴ increased apoptosis,⁹⁵ and enhanced JNK1 and JNK2 activity⁹⁶ have been well documented. Decreased expression of the gene *PAX3* is central to the appearance of neural tube defects.⁹⁶ Recent studies have indicated that the detrimental effect of *PAX3* in embryos during a diabetic pregnancy are mediated by adenosine monophosphate-activated protein kinase (AMPK) signaling pathways.⁹⁷

TABLE 59-6 Congenital Malformations in Infants of Insulin-Dependent Diabetic Mothers

Anomaly	Approximate Relative Risk	Percent Risk (%)
All cardiac defects	18	8.5
All central nervous system anomalies	16	5.3

Prevention. Because the critical time for teratogenesis is during the period 3 to 6 weeks after conception, nutritional and metabolic intervention must be instituted preconceptionally to be effective. Several clinical trials of preconceptional metabolic care have demonstrated that malformation rates equivalent to those in the general population can be achieved with meticulous glycemic control.

Wahabi and colleagues analyzed 12 cohort studies with low or medium risk of bias involving 2502 women with diabetes who did or did not participate in preconception care. Their results showed that preconceptional care was effective in reducing the occurrence of congenital malformations (RR = 0.25; CI, 0.15 to 0.42); preterm delivery (RR = 0.70; CI, 0.55 to 0.90); and perinatal mortality (RR = 0.35; CI, 0.15 to 0.82). In these studies, preconception care lowered Hb A_{1c} in the first trimester of pregnancy by an average of 2.43% (CI, 2.27 to 2.58) and reduced diabetes-related congenital malformations, preterm delivery, and maternal hyperglycemia.⁹⁸

Van Beynum and coworkers, in a case-control study assembled over a 10-year period (1996-2005), compared mothers who delivered infants with isolated heart defects ($n = 611$) and controls from the general population ($n = 2401$).⁹⁹ Folic acid was taken as a supplement or as a multivitamin in a dose of at least 400 μg daily. Those receiving periconceptional folic acid had an OR for all types of congenital heart defects of 0.82 (CI, 0.68 to 0.98) relative to other malformations. The estimated OR for congenital heart defects of folic acid supplementation was 0.74 (CI, 0.62 to 0.88) compared with the general population. These results demonstrated that periconceptional folic acid use was related to a reduction of approximately 20% in the prevalence of any congenital heart defect.

Intrauterine Growth Restriction

Although the weights of infants of diabetic mothers usually are skewed into the upper range, IUGR occurs with significant frequency in diabetic pregnancies, especially in women with underlying vascular disease. Additional factors that increase the risk for IUGR in a diabetic pregnancy include the higher incidence of structural anomalies and maternal hypertension.

Asymmetric IUGR is encountered most frequently in diabetic patients with vasculopathy (i.e., retinal, renal, or chronic hypertension). This association suggests that uteroplacental vasculopathy may promote restricted fetal growth in these patients.¹⁰⁰ Patients with poor glycemic control and frequent episodes of ketosis and hypoglycemia are also prone to preeclampsia and poor fetal growth. Whether IUGR results from poor maternal-placental blood flow or intrinsically poor placental function is unresolved.

Fetal Macrosomia

Macrosomia has been defined using various criteria, such as birth weight greater than the 90th percentile for gestational age, gender, and race; birth weight greater than 4000 g; and estimates of neonatal adiposity based on body composition measures. As early as 1923, research by Moulton¹⁰¹ described variability in weight among different mammalian species that was attributed to the amount of adipose tissue or fat mass rather than lean body mass. Using autopsy data and chemical analysis of 169 stillbirths, Sparks¹⁰² described a relatively comparable rate of accretion of lean body mass in fetuses that were small for gestational age (SGA), average for gestational age (AGA), and large for gestational age (LGA), but he found

considerable variation in the accretion of fetal fat in utero. The human fetus at term has the greatest percentage of body fat (approximately 10% to 12%) when compared with other mammals. Furthermore, although fetal adipose tissue accounts for a mean of only 10% to 14% of birth weight, between 40% and 60% of the variance in birth weight can be attributed to variation in fetal adiposity.

Growth Dynamics. The increased growth of the mother is composed primarily of total body water and adipose tissue in early gestation. Relative to the fetoplacental unit, the human placenta attains most of its growth by the middle of the second trimester. In contrast, approximately 70% of fetal growth occurs over the last third of gestation (1000 g at 28 weeks to 3500 g at term). Yang and associates⁸ reported that infants of diabetic mothers have increased growth rates above that observed in normoglycemic pregnancies. Ogata and colleagues,¹⁰³ using serial ultrasound measures of the fetuses of diabetic mothers, described an increase in the rate of abdominal circumference growth after 24 weeks' gestation. The increase in growth appears to affect primarily insulin-sensitive tissues such as the subcutaneous fat included in measures of abdominal circumference.¹⁰⁴ Ninety-five percent of the variance in fetal abdominal circumference can be accounted for by subcutaneous fat rather than intraabdominal measures such as liver size. This is consistent with the inability of the fetal liver to store much glycogen in early third trimester. Reece and coworkers showed that fetuses of diabetic mothers have normal growth of lean body mass such as head and skeletal growth, even when there is marked hyperglycemia.¹⁰⁵ In longitudinal ultrasound studies, Bernstein and associates reported that fetal fat and lean body mass demonstrate unique growth profiles. These unique ultrasound profiles potentially provide a more sensitive marker of abnormal fetal growth, particularly in infants of women with diabetes, based on the increased fat mass rather than lean mass of these neonates.¹⁰⁶ Body composition studies by Catalano and colleagues showed that birth weight at delivery alone, even when AGA, may not be a sensitive enough measure of fetal growth in the infant of the diabetic mother.¹⁰⁷ They reported that although there were no significant differences in birth weight or lean body mass, the infants of women with GDM had increased fat mass and increased percentage of body fat compared with a normoglycemic control group (Table 59-7).

Pathophysiology of Fetal Overgrowth.

Maternal Glucose Concentrations. Because glucose is the most easily measured nutrient and marker of diabetes, most studies evaluating the effect of diabetes on fetal growth have used measures of glucose as a reference. In the DIEP study, birth weight correlated best with second- and third-trimester postprandial glucose measures. When 2-hour postmeal glucose measures averaged 120 mg/dL or less, approximately 20% of infants were macrosomic, but when 2-hour postprandial glucose measures averaged up to 160 mg/dL, the rate of macrosomia reached 35%.¹⁰⁸ Similarly, Combs and coworkers reported that macrosomia was significantly associated with postprandial glucose levels between 29 and 32 weeks' gestation.¹⁰⁹

In contrast, Persson and associates showed that FPG concentrations account for 12% of the variance in birth weight and correlate best with estimates of neonatal fat.¹¹⁰ Uvena-Celebrezze and colleagues found that the strongest correlation was between FPG and neonatal adiposity, rather than

Increased fetal adiposity: a very sensitive marker of abnormal in utero development, *Am J Obstet Gynecol* 189:1698–1704, 2003.

postprandial measures.¹¹¹ The results of the HAPO study showed that the fasting as well as the 1- and 2-hour glucose values at the time of the OGTT at 24 to 32 weeks' gestation had a significant linear correlation with both birth weight and fetal estimates of adiposity.¹¹² The variation in results may reflect differences in study design, patient populations, or estimates of neonatal adiposity. However, there is agreement that glucose concentrations during pregnancy are strongly related to birth weight and adiposity.

Fetal Insulin Concentrations. Based on the early work of Pedersen, fetal insulin has long been considered an anabolic factor driving in utero fetal growth.¹¹³ Experimental data gathered from nonhuman primates showed evidence of fetal overgrowth when rhesus monkeys were implanted with a pump that delivered continuous, increasing insulin concentrations to the fetus independent of the mother's metabolic condition.⁹² In contrast, when genetic mutations such as glucokinase deficiencies exist only in the fetus, the inability of the beta cell to respond to increasing glucose concentrations results in IUGR.

Many studies have confirmed the correlation of increased cord insulin concentrations with fetal macrosomia. Schwartz and associates found that umbilical cord insulin concentrations at delivery correlated with the degree of macrosomia.⁹⁰ Cordocentesis studies in the late third trimester showed that the ratio of fetal plasma insulin to glucose and the degree of macrosomia were strongly correlated.⁹¹ Krew and colleagues reported that amniotic fluid C-peptide measures at term had a strong correlation with fetal adiposity but not with lean body mass.¹¹⁴

In addition to data linking increased fetal insulin concentrations with macrosomia in late pregnancy, there is also evidence for altered metabolic function in early gestation. Carpenter and colleagues¹¹⁵ reported that elevated amniotic fluid insulin concentrations obtained from normoglycemic patients at 14 to 20 weeks' gestation and adjusted for maternal age and weight correlated with the likelihood of subsequently diagnosed GDM. These data support the concept that the underlying pathophysiology of GDM and fetal macrosomia may exist earlier in gestation than is routinely screened for, consistent with subclinical pregravid maternal metabolic disturbances.

Role of the Placenta in Fetal Overgrowth

Nutrients. All nutrients required for fetal growth and development are delivered through the placenta. Hence, transplacental fluxes are ultimate determinants of fetal nutrient availability. The macrosomic fetus of a woman with GDM is generally fatter than the fetus of a lean woman due to excess accrual of adipose tissue in response to excess nutrient supply. Glucose and lipids have long been known to provide the primary fetal energy fuels for growth and tissue accretion.¹¹⁶ Adipogenic pathways from glucose and lipid substrates are well described, but their relative contributions to adipose tissue accretion in the human fetus is unknown. Numerous studies in human and animal models have shown that maternal hyperglycemia with or without diabetes is associated with increased fetal adiposity. On the other hand, clinical and molecular studies have also suggested the potential contribution of lipids as adipogenic substrates in fetal macrosomia.¹¹⁷ Maternal obesity that is associated with only modest and sometimes no glucose intolerance but marked dyslipidemia is evolving as a leading pathology for high fetal adiposity at birth.¹¹⁸ Neonatal adiposity is poorly correlated with the severity of maternal hyperglycemia in diabetic pregnancy, and fetal macrosomia occurs despite satisfactory glycemic control in many diabetic women.¹¹⁹ In a pregnancy complicated with diabetes, the placenta exhibits modifications in multiple lipid pathways with activation of genes controlling placental lipid transport and synthesis of triglycerides.¹²⁰

Activation of this class of genes may be instrumental in increasing transplacental lipid fluxes and thereby increasing delivery of adipogenic lipid substrates for fetal fat accretion. Because hyperinsulinemia is a hallmark of fetal macrosomia, the combination of high fatty acids and high insulin levels has been viewed as favoring fetal fat accumulation. Along these lines, data from multiple studies suggest that hyperinsulinemia may be one of the driving forces responsible for facilitating the uptake and esterification of fatty acids in the fetal adipocyte.

Growth Factors and Cytokines. There has been considerable interest in the role of insulin-like growth factors (IGFs) in fetal growth. Members of the IGF family have been implicated in abnormalities of increased and decreased fetal growth in humans. IGF-1 and the ratio of IGF-2 to the IGF-2 soluble receptor have been positively correlated with the ponderal index.¹²¹ There is also direct evidence from rodent knockout models. Baker and coworkers reported that null mutations for the *IGF1* or *IGF2* gene decreased neonatal weight by 40% in mice; the effect of both genes is additive.¹²² Liu and associates previously reported that IGF-1, IGF-2, and IGF-binding protein-3 (IGFBP-3) were significantly elevated in women with T1DM or T2DM compared with a control group.¹²³ These data are consistent with the findings of other investigators, including measurements of these proteins in women with T1DM and T2DM.^{124,125}

Roth and colleagues reported that cord levels of IGF-1 were significantly greater in macrosomic infants of diabetic mothers than in nonmacrosomic infants of glucose-tolerant or diabetic mothers.¹²⁶ Radaelli and coworkers showed that there was a strong negative correlation between maternal circulating IGFBP-1 and lean body mass in infants.¹²⁷ The study authors speculated that IGFBP-1 might influence fetal growth by affecting IGF-mediated placental nutrient transport, particularly of glucose or amino acids rather than lipids. Decreased IGFBP-1 levels are in keeping with a potential negative transcriptional regulation of the *IGFBP1* gene by insulin.

Maternal Obesity. Obesity is an epidemic in developed countries and in the developing world.¹²⁸ In the United States, the prevalence of obesity, defined as a body mass index (BMI) greater than 30, rose to 33.8% in 2007-2008. During the same period, the prevalence of obesity in women was 35.5%.¹²⁹ The proportion of women who were overweight or obese (BMI ≥ 25) was 64.1%. The risk of obesity varies with race and ethnicity and has increased most among African Americans and Hispanics, the same populations that are most at risk for T2DM.

Several studies have suggested that maternal obesity before conception has an independent effect on fetal macrosomia. Vohr and associates analyzed various risk factors for neonatal macrosomia in women with GDM compared with obese and normal-weight controls.¹³⁰ Pre-pregnancy weight and weight gain during pregnancy were significant predictors for infants of GDM and control mothers. Catalano and colleagues¹³¹ performed a stepwise logistic regression analysis on data for 220 infants of mothers with normal glucose tolerance and 195 infants of mothers with GDM (Table 59-8). Gestational age at term had the strongest correlation with birth weight and lean body mass. In contrast, maternal pregravid BMI had the strongest correlation (approximately 7%) with fat mass and percent body fat. Although almost 50% of the infants had GDM, only 2% of the variance was correlated with fat mass. These data

support an effect of maternal pregravid obesity on fetal growth, particularly fat mass, independent of treated GDM.

Other Fuels. Many factors are related to fetal overgrowth in the infant of a woman with diabetes. The significant decreases in insulin sensitivity in late gestation affect the metabolism of glucose, lipids, and amino acids. Although we clinically focus on glucose, other nutrients most probably contribute to fetal overgrowth. This concept is consistent with the hypothesis of fuel-mediated teratogenesis first proposed by Freinkel in 1980.¹³² Circulating amino acid concentrations reflect the balance between protein breakdown and synthesis. Duggleby and Jackson estimated that there is a 15% increase in protein synthesis during the second trimester and a further 25% increase in the third trimester compared with levels in nonpregnant women.¹³³ These differences appear to have a strong relationship to fetal growth, particularly lean body mass.

Butte and coworkers¹³⁴ and Metzger and associates¹³⁵ independently reported higher amino acid concentrations in women with GDM compared with normoglycemic controls. Zimmer and colleagues reported no significant difference in amino acid turnover in women with GDM compared with a control group.¹³⁶ However, they found that hyperinsulinemia was required to maintain normal amino acid turnover in women with GDM. Kalhan and coworkers reported that leucine turnover and oxidation were greater in obese women with GDM than in less obese control subjects.¹³⁷ The increased insulin concentrations required to maintain appropriate amino acid levels in women with diabetes may be another manifestation of the increased insulin resistance in pregnant women with GDM.

Knopp and associates found a twofold to fourfold increase in triglyceride concentrations and a 25% to 50% increase in cholesterol during gestation.¹³⁸ This group also reported a further increase in concentrations of triglyceride and high-density lipoprotein cholesterol in pregnant T2DM and GDM patients.¹³⁹ Similarly, Xiang and colleagues⁵⁰ described increased basal free fatty acid concentrations in Hispanic women with GDM during the third trimester when compared with a matched nondiabetic control group. Knopp and coworkers also reported that mid-trimester triglyceride concentrations were a better predictor of macrosomia than glucose values during the glucose tolerance test.¹⁴⁰ Similarly, Kitajima and colleagues examined lipid profiles in women with an abnormal glucose challenge test in pregnancy and reported that triglycerides had a significant correlation with birth weight, even after adjusting for significant covariables.¹⁴¹ More recently, Ute Schaffer-Graf and colleagues reported that in women with well-controlled GDM at 28 weeks, maternal triglycerides and free fatty acids were strong predictors of fetal growth.¹⁴² Consistent with the concept that metabolism in early pregnancy metabolism affects fetal growth, there is a strong correlation of maternal triglycerides and fetal adiposity not only in late pregnancy but also before conception and in early gestation. Although lipid transport from mother to fetus is not well understood, maternal lipid metabolism may play a significant role in fetal growth, particularly in accrual of adipose tissue.

Birth Injury

Birth injury is more common among the offspring of diabetic mothers, and macrosomic fetuses are at the highest risk.¹⁴³ The most common birth injuries associated with diabetes are brachial plexus palsy, facial nerve injury, humerus or clavicle fracture, and cephalohematoma. The level of glycemic control is

strongly correlated with the risk of shoulder dystocia and birth injury, presumably because increasing levels of hyperglycemia are associated with greater fetal fat deposition. Athukorala and associates studied women with GDM and found a positive relationship between the severity of maternal fasting hyperglycemia and the incidence of shoulder dystocia, with a doubling of risk with each 1-mmol/L increase in the FPG value on the OGTT.¹⁴⁴ Shoulder dystocia occurs more often in diabetic deliveries that require operative vaginal assistance (Fig. 59-10).

Most birth injuries occurring in infants of diabetic mothers are associated with difficult vaginal delivery and shoulder dystocia. Although shoulder dystocia occurs in 0.3% to 0.5% of vaginal deliveries among normal pregnant women, the incidence is twofold to fourfold higher for women with diabetes because the excessive fetal fat deposition in poorly controlled diabetic pregnancies causes the fetal shoulder and abdominal dimensions to become excessive. Although one half of shoulder dystocias occur in infants of normal birth weight (2500 to 4000 g), the incidence of shoulder dystocia rises 10-fold to 5% to 7% among infants weighing 4000 g or more. However, if maternal diabetes is present, the risk at each birth-weight class is increased fivefold.¹⁴⁵ These risks are further magnified if a forceps or vacuum delivery is performed.¹⁴⁶

Although it would be desirable to predict shoulder dystocia on the basis of warning signs during labor such as labor protraction, suspected macrosomia, or the need for midpelvic forceps delivery, fewer than 30% of these events can be predicted from clinical factors.^{147,148}

Illuminating findings regarding the role of maternal insulin resistance and glucose levels in the development of fetal obesity were reported by Metzger and associates in the HAPO study.²⁵ At 15 centers in nine countries, more than 25,000 women underwent a 75-g OGTT at 24 to 32 weeks' gestation. Subjects were excluded from the study if the OGTT was diagnostic of

GDM (FPG >105 mg/dL or 2-hour plasma glucose level >200 mg/dL). The study group consisted of women who had glucose responses lower than the cutoff values for the 75-g OGTT for GDM. For outcome measures, the investigators evaluated the number of cases in the cohort with birth weight greater than the 90th percentile, primary cesarean delivery, or clinical neonatal hypoglycemia. As a measure of in utero hyperinsulinemia, they obtained cord-blood serum C-peptide measurements at delivery and reported the frequency when greater than the 90th percentile.

Figures 59-11 and 59-12 show that the odds of fetal obesity (birth weight >90th percentile for gestational age) and high umbilical C-peptide levels were highly correlated with the glucose levels obtained during the essentially negative 75-g OGTT.²⁵ The odds of having a newborn with birth weight greater than the 90th percentile when the maternal FPG value was 95 to 104 mg/dL were three to five times greater than in women whose FPG was less than 75 mg/dL. Even when FPG levels were near but technically lower than the Carpenter-Coustan cutoff for GDM (90 to 94 mg/dL), the odds of high birth weight were almost triple those found in the lowest-category group.

The relationship between OGTT glucose levels and the odds of abnormal newborn outcomes in this study were linear, with no clear point on the risk curve where a cutoff might conveniently be assigned.²⁵ When category 7 (FPG \geq 100 mg/dL and the 2-hour glucose level after 75-g OGTT \geq 178 mg/dL) was compared with category 1 (FPG <75 mg and the 2-hour glucose level after 75-g OGTT \leq 90 mg/dL), the aOR for primary cesarean delivery was 1.86, and that for neonatal hypoglycemia was 1.29; these values were statistically significant, but less strongly positive.

The results of the HAPO study raise significant questions regarding screening for GDM. It is clear that women who score near, but below, almost any cutoff for glucose response have a higher risk of fetal macrosomia, cesarean delivery, and newborn morbidity as well as higher maternal morbidity than women in the lowest category. Because the relationship between glucose response and morbidity seems to be linear, the criterion for setting cutoffs may have to be based on cost-benefit/cost-effectiveness analyses rather than simple health improvement values. Lowering the FPG cutoff to 90 mg/dL would approximately double the number of women worldwide diagnosed as having GDM.

NEONATAL MORBIDITY AND MORTALITY

Polycythemia and Hyperviscosity

Polycythemia (i.e., central venous hemoglobin concentration >20 g/dL or hematocrit >65%) occurs in 5% to 10% of infants of diabetic mothers and is apparently related to glycemic control. Hyperglycemia is a powerful stimulus for fetal erythropoietin production, which is probably mediated by decreased fetal oxygen tension.¹⁴⁹ If left untreated, neonatal polycythemia may lead to jaundice and kernicterus or promote vascular sludging, ischemia, and infarction of vital tissues, including the kidneys and central nervous system.

Neonatal Hypoglycemia

Approximately 15% to 25% of neonates delivered from women with diabetes during gestation develop hypoglycemia during

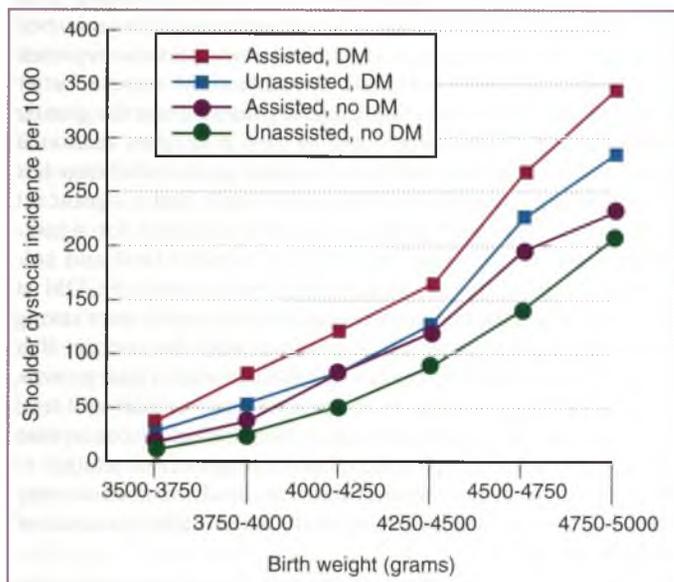

Figure 59-10 Risk of shoulder dystocia by diabetes status and instrumental delivery. Shoulder dystocia occurred more often in diabetic deliveries that required operative vaginal assistance and in fetuses above the 90th percentile of birth weight for age. DM, diabetes mellitus. Percentages are shown for birth weight, body fat, and umbilical cord C-peptide level. (Data from HAPO Study Cooperative Research Group, Metzger BE, Lowe LP, Dyer AR, et al: *Hyperglycemia and adverse pregnancy outcomes*, *N Engl J Med* 358:1991–2002, 2008.)

the immediate newborn period.¹⁵⁰ Neonatal hypoglycemia is less common when tight glycemic control is maintained during pregnancy and in labor.¹⁵¹ A detailed study by Taylor and associates found no correlation between the likelihood of neonatal hypoglycemia and Hb A_{1c} levels, whereas mean maternal glucose levels during labor were strongly predictive.¹⁵² Because unrecognized postnatal hypoglycemia may lead to neonatal seizures, coma, and brain damage, it is imperative that the team caring for the neonate follow a protocol of frequent postnatal glucose monitoring until metabolic stability is ensured.

Neonatal Hypocalcemia and Hyperbilirubinemia

Low levels of serum calcium (<7 mg/100 mL) have been reported in up to 50% of infants of diabetic mothers during the first 3 days of life, although later series demonstrated an incidence of 5% or less with better-managed pregnancies.¹⁵³ Neonatal hyperbilirubinemia occurs in approximately 25% of infants of diabetic mothers, a rate approximately double that for normal infants, with prematurity and polycythemia being the primary contributing factors. Close monitoring of the newborn infants of diabetic mothers is necessary to avoid the further morbidity of kernicterus, seizures, and neurologic damage.

Hypertrophic and Congestive Cardiomyopathy

In some macrosomic, plethoric infants of mothers with poorly controlled diabetes, a thickened myocardium and significant asymmetric septal hypertrophy have been described.

The prevalence of clinical and subclinical asymmetric septal hypertrophy in infants of diabetic mothers has been estimated to be as high as 30% at birth, with resolution by 1 year of age.¹⁵⁴ Kjos and colleagues found that cardiac dysfunction associated with this entity often leads to respiratory distress, which may be mistaken for hyaline membrane disease.¹⁵⁵ Russell and coworkers noted that stillborn infants of diabetic mothers, when compared with appropriately grown stillborn infants of nondiabetic mothers and adjusted for birth weight, had heavier hearts and thicker ventricular free wall measurements, indicating that extremes of hypertrophic cardiomyopathy with maternal diabetes may lead to intrauterine fetal demise.¹⁵⁶

Infants of diabetic mothers who manifest cardiorespiratory dysfunction in the neonatal period may have congestive or hypertrophic cardiomyopathy rather than surfactant-deficient pulmonary disease. This condition is often unrecognized. Echocardiograms show a hypercontractile, thickened myocardium, often with septal hypertrophy disproportionate to the ventricular free walls. The ventricular chambers are often smaller than normal, and there may be anterior systolic motion of the mitral valve, producing left ventricular outflow tract obstruction.¹⁵⁷

Neonatal septal hypertrophy may be a response to chronic hyperglycemia. The maternal level of IGF-1, which is elevated in suboptimally controlled diabetic pregnancies, is significantly elevated in neonates with asymmetric septal hypertrophy. Because IGF-1 does not cross the placenta, it may exert its action through binding to the IGF-1 receptor on the placenta.¹⁵⁸ Halse and coworkers found that the level of B-type natriuretic

protein (BNP), a marker for congestive cardiac failure, is elevated in neonates whose mothers had poor glycemic control during the third trimester.¹⁵⁹

Septal hypertrophy can be identified antenatally with sonography.¹⁶⁰ Cooper and coworkers performed serial fetal echocardiography on 61 pregnant, diabetic women, demonstrating excessive ventricular septal thickness in those fetuses that were diagnosed postnatally with asymmetric septal hypertrophy.¹⁶¹ When the newborns with asymmetric septal hypertrophy were compared with normal infants, birth weights (4009 versus 3457 g; $P < .01$) and maternal glycosylated hemoglobin levels (6.7% versus 5.7%) were higher in the infants with cardiomyopathy.

Respiratory Distress Syndrome

Until recently, respiratory distress syndrome (RDS) was the most common and most serious disease in infants of diabetic mothers. In the 1970s, improved prenatal maternal management of diabetes and new techniques in obstetrics for timing and mode of delivery resulted in a dramatic decline in its incidence, from 31% to 3%.¹⁶² However, even when matched by gestational week of pregnancy, infants of diabetic mothers are many more times as likely as infants from normal pregnancies to develop RDS.

The increased susceptibility to RDS may result from altered production of alveolar surfactant or abnormal pulmonary function. Kulovich and Gluck reported delayed timing of phospholipid production in diabetic pregnancy, as indicated by a delay in the appearance of phosphatidylglycerol in the amniotic fluid.¹⁶³ Landon and coworkers reported that fetal lung maturity occurred later in pregnancies with poor glycemic control (mean plasma glucose level >110 mg/dL), regardless of the class of diabetes.¹⁶⁴ These findings were confirmed by Moore,¹⁶⁵ who demonstrated no differences in the rate of rise of the ratio of amniotic fluid lecithin to sphingomyelin by type of diabetes or degree of glucose control but found that amniotic fluid phosphatidylglycerol was delayed approximately 1.5 weeks in women with pregestational diabetes or GDM compared with controls (Fig. 59-13). The delay in phosphatidylglycerol was associated with an earlier and higher peak in the level of phosphatidylinositol, suggesting that elevated maternal plasma levels of myoinositol in diabetic women may inhibit or delay the production of phosphatidylglycerol in the fetus.

The near-term infant of a mother with poorly controlled diabetes is more likely to have neonatal respiratory dysfunction than is the infant of a nondiabetic mother. The observations of Moore¹⁶⁵ indicate that the average nondiabetic fetus achieves pulmonary maturity at 34 to 35 weeks' gestation, with more than 99% of normal newborns having a mature phospholipid profile by 37 weeks. In diabetic pregnancy, however, it cannot be assumed that lung maturity exists until approximately 10 days after the time observed in nondiabetics (i.e., 38 to 39 gestational weeks). Delivery contemplated before 39 weeks' gestation for other than compelling fetal or maternal indications should take into account the risks of poor neonatal transition compared with concerns regarding in utero fetal demise or hypoxic injury.

LONG-TERM RISKS FOR THE FETUS

Over the past decade, the concept of perinatal programming of the fetus, termed developmental origins of health and disease

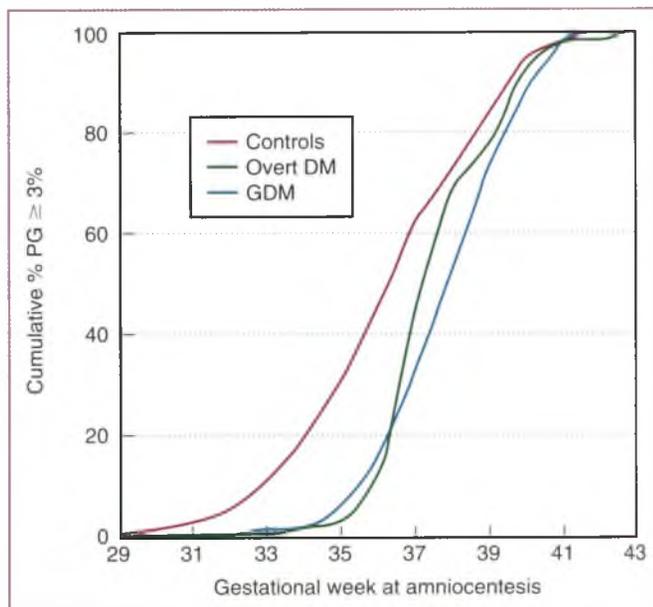

Figure 59-13 Delay in fetal pulmonary phosphatidylglycerol. The delay in fetal pulmonary phosphatidylglycerol was associated with a sustained peak in phosphatidylinositol in diabetic pregnancy, suggesting that elevated maternal plasma levels of myoinositol in a diabetic woman may inhibit or delay the production of phosphatidylglycerol in the fetus. DM, diabetes mellitus; GDM, gestational diabetes mellitus; PG, phosphatidylglycerol. (From Moore TR: A comparison of amniotic fluid fetal pulmonary phospholipids in normal and diabetic pregnancy, *Am J Obstet Gynecol* 186:641-650, 2002.)

(DOHaD), has gained greater acceptance.¹⁶⁶ As first described by Barker and colleagues, infants born SGA or growth restricted had an increased risk of developing the metabolic syndrome (diabetes, hypertension, dyslipidemia, and obesity) as adults.¹⁶⁷ However, evidence also pointed toward an increase in adolescent and adult obesity among infants born LGA or macrosomic, particularly to women who had diabetes or were obese. In animal studies, Van Assche and Aerts reported that diabetes in the mother, but not the father, increased the risk of metabolic dysfunction through the third generation.¹⁶⁸ In the Pima Indian community, Pettitt and colleagues first reported that the risk of obesity¹⁶⁹ and subsequent T2DM¹⁷⁰ was greater in offspring of mothers with a diagnosis of diabetes during pregnancy compared with siblings born to the same women before the onset of maternal diabetes.

There has been abundant evidence linking higher birth weights to increased obesity in adolescents and adults.¹⁷¹ Large cohort studies such as the Nurses Health Study¹⁷² and the Health Professional Follow-up Study¹⁷³ reported a J-shaped curve (i.e., a slightly greater BMI among subjects born small but a much greater prevalence of overweight and obesity among those born large). The increased prevalence of adolescent obesity is related to an increased risk of metabolic syndrome. The increased incidence of obesity accounts for much of the 33% increase in T2DM, particularly among the young. Between 50% and 90% of adolescents with T2DM have a BMI greater than 27, and 25% of obese children between 4 and 10 years old have impaired glucose tolerance.¹⁷⁴

The epidemic of obesity and subsequent risk for diabetes and components of the metabolic syndrome may begin in utero

with fetal overgrowth and adiposity.¹⁷⁵ A retrospective cohort study by Whitaker reported that children who were born to obese mothers (BMI >30 in the first trimester) were twice as likely to be obese when they were 2 years old.¹⁷⁶ If a woman had a BMI of 30 or greater during the first trimester, the prevalences of childhood obesity (BMI >95th percentile based on criteria of the Centers for Disease Control and Prevention [CDC]) at ages 2, 3, and 4 years were 15.1%, 20.6%, and 24.1%, respectively. This was between 2.4 and 2.7 times the prevalence of obesity observed in children of mothers whose BMI values were in the normal range (18.5 to 24.9).

Maternal pregravid weight and diabetes have independent effects on birth weight. In the HAPO study,¹¹² increasing maternal pregravid weight from normal or underweight to obese increased the mean birth weight by 174 g in women with normal glucose tolerance and by 339 g in those with GDM. Similarly, among normal-weight and underweight women, birth weights were increased by 164 g in infants born to mothers with GDM versus normal glucose tolerance and by 339 g in infants of obese mothers with normal glucose tolerance versus obese GDM.¹¹² These data emphasize the independent and additive effects of maternal obesity and GDM on fetal growth.

The risk for development of the metabolic syndrome in adolescents of obese and GDM women was addressed by Boney and colleagues in a longitudinal cohort study of AGA and LGA infants.¹⁷⁷ Children who were LGA at birth had an increased hazard ratio (HR) for metabolic syndrome (HR = 2.19; CI, 1.25 to 3.82; $P = .01$) by age 11 years, as did children of obese women (HR = 1.81; CI, 1.03 to 3.19; $P = .04$). The presence of maternal GDM was not independently significant, but the risk for developing metabolic syndrome was significantly different between LGA and AGA offspring of mothers with GDM by age 11 years (RR = 3.6). In another prospective, longitudinal cohort study, Catalano and associates¹⁷⁸ reported that maternal pregravid BMI, independent of maternal glucose status or birth weight, was the strongest predictor of childhood obesity. Maternal pregravid BMI accounted for 17.6% of the variance in percentage body fat among children at 6 to 10 years of age.

CHILDHOOD NEUROLOGIC ABNORMALITIES

Several reports have suggested an increased prevalence of childhood neurodevelopmental abnormalities in offspring of diabetic mothers.¹⁷⁹ Ornoy and associates assessed IQ scores on the Wechsler Intelligence Scale for Children-Revised (WISC-R) and Bender tests of children born to diabetic mothers.¹⁸⁰ No differences were found between the study groups in various sensorimotor functions compared with controls, but the children of diabetic mothers performed less well than controls in fine and gross motor functions, and they scored lower on the Pollack taper test, which is designed to detect inattention and hyperactivity.

Preconceptional Management of Pregestational Diabetes

Although widely underused, preconceptional care programs have consistently been associated with decreased perinatal morbidity and mortality.¹⁸¹ Patients enrolled in preconceptional diabetes-management programs obtain earlier prenatal care and have lower Hb A_{1c} values in the first trimester, as shown by Wahabi and coworkers, who conducted a systematic review of

preconceptional care of women with pregestational diabetes comprising 24 studies. Preconception care lowered Hb A_{1c} by a mean of 2.43% (CI, 2.27 to 2.58) and was effective in markedly reducing the rates of congenital malformation (RR = 0.25; CI, 0.15 to 0.42), preterm delivery (RR = 0.70; CI, 0.55 to 0.90), and perinatal mortality (RR = 0.35; CI, 0.15 to 0.82) compared to women without such care.⁹⁸ A number of expert bodies have provided guidance regarding the content of preconceptional care. These recommendations have been summarized by Mahmud and Mazza (Box 59-5).¹⁸²

RISK ASSESSMENT

Several factors should be emphasized in preconceptional diabetes risk assessment¹⁸³:

- Glycemic control should be assessed directly from glucose logs or meter downloads and by glycosylated hemoglobin levels.
- For patients who have had diabetes for 10 years or longer, an electrocardiogram, an echocardiogram, and microalbuminuria and serum creatinine studies should be considered.
- Because retinopathy can progress during pregnancy, the patient should establish a relationship with a qualified ophthalmologist. A baseline retinal evaluation should be completed within the year before conception, with laser photocoagulation performed if needed. Previous laser or anti-VEGF treatment is not a contraindication to pregnancy and may preclude significant hemorrhage during pregnancy.
- Thyroid function (i.e., thyroid-stimulating hormone and free thyroxine levels) should be evaluated and corrected as necessary in all patients with T1DM because of the frequent coincidence of autoimmune thyroid disease and diabetes.
- Prenatal supplementation of folic acid (1-4 mg daily) should be prescribed for a minimum of 3 months before conception, because folate supplementation significantly reduces the risk of congenital neural tube defects.¹⁸⁴
- The patient's occupational, financial, and personal situation should be reviewed, because job and family pressures can become barriers to achieving and maintaining excellent glycemic control.
- In patients with pre-pregnancy hypertension or proteinuria, particular emphasis should be given to defining support systems that permit extended bed rest in the third trimester, if it should become necessary.
- The patient's preconception medications should be reviewed and altered to avoid teratogenicity and potential embryonic toxicity. Statins are pregnancy category X drugs and should be discontinued before conception. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) should be discontinued before conception because of first-trimester teratogenicity and fetal renal toxicity in the second half of pregnancy. Among oral antidiabetic agents used by women of reproductive age, metformin and acarbose are classified as pregnancy category B, although systematic data on safety are lacking. All other agents are category C drugs, and unless the potential risks and benefits of oral antidiabetic agents in the preconception period have been carefully weighed, they usually should be discontinued in pregnancy.

BOX 59-5 SUMMARY OF RECOMMENDATIONS FOR PRECONCEPTION CARE AMONG DIABETIC WOMEN

1. Use a multidisciplinary preconception care team, which may include an obstetrician, endocrinologist, family physician, diabetic educator, and dietitian.
2. Perform a full medical and obstetric evaluation in the preconception period to assess risks.
3. Evaluate and treat diabetic complications before pregnancy, including
 - Retinopathy: diagnostic examination for all women with pregestational diabetes
 - Nephropathy: diagnostic examination for all women with pregestational diabetes
 - Neuropathy: diagnostic examination for symptomatic women
 - Cardiovascular disease: diagnostic examination for symptomatic women
 - Hypertension: diagnostic examination for hypertensive women (>130 mm Hg systolic or >80 mm Hg diastolic)
4. Measure and optimize thyroid hormone levels in women with type 1 diabetes.
5. Review all current medications, and change the following to a form of therapy that has less fetal risk:
 - Angiotensin-converting enzyme (ACE) inhibitors
 - Angiotensin II receptor blockers (ARBs)
 - Statins
 - Diuretics
 - β -Blockers
6. Assess level of metabolic control. Measure Hb A_{1c} monthly until control is achieved. Hb A_{1c} should remain below 7%, and lower if possible.
7. Manage blood glucose levels:
 - Work to achieve optimal pregnancy glycemic goals preconceptionally: premeal, bedtime, and overnight glucose levels, 60-99 mg/dL; 1-hr or 2-hr postprandial glucose levels, 100-129 mg/dL.
- Higher glucose targets may be used in patients with hypoglycemia unawareness or the inability to cope with intensified management.
- Maintain glucose levels without hypoglycemia. Educate on hypoglycemia awareness and management.
- Insulin should be prescribed to achieve target blood glucose levels.
8. Commence folate supplementation, 1-4 mg daily from before conception until 12 weeks' gestation to minimize congenital anomalies.
9. Provide counseling:
 - Inform about risks of miscarriage, congenital malformation, and perinatal mortality with poor metabolic control and unplanned pregnancy. Inform about how DM affects pregnancy and how pregnancy affects DM.
 - Encourage smoking cessation and reduction in alcohol intake.
 - Encourage regular exercise and management of weight to achieve a BMI <27.
 - Encourage a diet with complex carbohydrates, soluble fiber, and reduced levels of saturated fats.
10. Use effective contraception until target blood glucose control is achieved before conception.
11. Contraindications to pregnancy:
 - Hb A_{1c} >10%
 - Impaired renal function with creatinine >0.2 mmol/L (increased risk of progression to dialysis during pregnancy)

BMI, body mass index; DM, diabetes mellitus.

METABOLIC MANAGEMENT

The goal of preconceptional metabolic management is to achieve an Hb A_{1c} level within the normal range before conception using a safe and reliable medication regimen that permits a smooth transition through the first trimester. The patient should be skilled in managing her glucose levels in a narrow range well before pregnancy begins, so that the inevitable insulin adjustments necessitated by the appetite, metabolic, and activity changes of early pregnancy can be accomplished smoothly.

A regimen of regular monitoring of preprandial and postprandial capillary glucose levels should be instituted. Although there are no data indicating that postprandial glucose monitoring is required before pregnancy to achieve adequate control, monitoring these levels increases the preconceptional woman's awareness of the interaction of dietary content and quality with postprandial glycemic excursions.¹⁸⁵ The insulin regimen should result in a smooth glucose profile throughout the day, with no hypoglycemia between meals or at night.

ORAL HYPOGLYCEMIC AGENTS

Many women with T2DM use one or more oral agents for glycemic control—typically metformin and a sulfonylurea or thiazolidinedione. Despite the lack of evidence of teratogenicity

for most of these agents, none is recommended for use in pregnancy, and standard practice is to transition these patients to insulin management before conception.

A possible exception is the use of metformin in infertile patients with polycystic ovary syndrome (PCOS), which has been reported to lead to higher conception rates, lower miscarriage rates, and higher live birth rates.¹⁸⁶ However, a systematic review of metformin use in conjunction with assisted reproduction procedures failed to show a benefit for miscarriage and successful pregnancy.¹⁸⁷ Another systematic review found an improvement in miscarriage rates but no other effect on outcome (e.g., live birth rates)¹⁸⁸ for women with PCOS, oligomenorrhea or amenorrhea, and subfertility.

Metformin readily crosses the placenta, exposing the fetus to concentrations approaching those in the maternal circulation. A study of maternal and fetal pharmacodynamics was performed by Charles and coworkers,¹⁸⁹ who obtained maternal and cord blood samples in the third trimester from metformin takers with GDM or T2DM. Mean metformin concentrations in cord and maternal plasma were 0.81 and 1.2 mg/L, respectively, with a half-life in maternal plasma of 5.1 hours.

With regard to potential teratogenicity associated with metformin use in pregnancy, Gilbert and associates performed a meta-analysis of eight available studies.¹⁹⁰ The malformation rate in the disease-matched control group was

approximately 7.2%, statistically significantly higher than the rate found in the metformin group (1.7%). After adjustment for confounders, first-trimester metformin treatment was associated with a statistically significant 57% reduction in birth defects.

The sequelae of metformin exposure (i.e., effects on neonatal obesity and insulin resistance) remain unclear. One randomized trial evaluating metformin versus insulin in the treatment of GDM found no significant differences in the composite primary outcomes of neonatal hypoglycemia, respiratory distress, need for phototherapy, birth trauma, 5-minute Apgar score <7, or prematurity.¹⁹¹ In a 2-year follow-up of this trial, the children exposed to metformin had larger measures of subcutaneous fat, but overall there was no difference in total fat mass or percentage body fat as assessed by bioimpedance.¹⁹²

Finally, the concentrations of metformin in breast milk are generally low, and the mean infant exposure to metformin has been reported to be 0.28% to 1.08% of the weight-normalized maternal dose. No adverse effects on blood glucose of nursing infants have been reported.¹⁹³

ANTIHYPERTENSIVE MEDICATIONS

Hypertension is a common comorbidity of diabetes and is found in 20% to 30% of women who have had diabetes for longer than 10 years. Although treatment of modest degrees of hypertension (<160 mm Hg systolic) during pregnancy has not been shown to be beneficial in improving perinatal outcome, treatment in diabetic women, both during pregnancy and before conception, is recommended if the blood pressure is consistently higher than 130/80 mm Hg.¹³ The U.K. Prospective Diabetes Study and the Hypertension Optimal Treatment trial¹⁹⁴ demonstrated improved outcomes, especially in stroke prevention, for patients assigned to lower blood pressure targets.

Patients frequently enter the preconception period taking one or more antihypertensive medications. In preconceptional and pregnant patients with diabetes and chronic hypertension, blood pressure target goals of 110/65 to 129/79 mm Hg are recommended in the interest of long-term maternal health and minimizing impaired fetal growth. Blood pressure medications that are safe for pregnancy should be added sequentially until target blood pressure levels are achieved. Such agents include methyldopa, long-acting calcium channel blockers, and selected β -adrenergic blockers. However, as noted earlier, ACE inhibitors and ARBs are contraindicated in pregnancy because of associated embryopathy and fetopathy and should be stopped when pregnancy is anticipated.¹⁹⁵ Effective contraception should be used by women treated with these agents.

Metabolic Management of Pregestational Diabetes in Pregnancy

The primary goals of metabolic management (i.e., glycemic monitoring, dietary regulation, and insulin therapy) in diabetic pregnancy are to prevent or minimize the postnatal sequelae of diabetes: macrosomia, shoulder dystocia, birth injury, and postnatal metabolic instability in the newborn. A secondary goal is to reduce the risk of pediatric and adult metabolic syndrome in the offspring. If this goal is to be achieved, glycemic control must be instituted early and aggressively.

PRINCIPLES OF MEDICAL NUTRITIONAL THERAPY

There is a surprising lack of well-controlled research on the optimal diet for lean or obese women with diabetes. Most recommendations regarding dietary therapy are based on common sense and experience. Because women with all types of diabetes experience inadequate insulin action after feeding, the goal of medical nutritional therapy is to avoid single, large meals containing foods with a high percentage of simple carbohydrates that release glucose rapidly from the maternal gut. Three major meals and three snacks are preferred, because this multiple-feeding regimen limits the amount of calories presented to the bloodstream during any given interval. The use of nonglycemic foods that release calories from the gut slowly also improves metabolic control. Examples include foods with complex carbohydrates and fiber, such as whole-grain breads and legumes. Carbohydrates should account for no more than 50% of the diet, with protein and fats equally accounting for the remainder.

Medical nutritional therapy should be supervised by a trained professional—ideally, a registered dietitian. In many programs, dietary counseling is capably provided by a certified diabetes educator. In any case, formal dietary assessment and counseling should be provided at several points during the pregnancy to design a dietary prescription that can provide adequate quantity and distribution of calories and nutrients to meet the needs of the pregnancy and support achieving the plasma glucose targets that have been established. For obese women (BMI ≥ 30), a 30% to 33% calorie restriction (to 25 kcal/kg of actual weight per day or less) has been shown to reduce hyperglycemia and plasma triglycerides with no increase in ketonuria.

Low-Glycemic Foods

Manipulation of the type of carbohydrate in the diet can provide additional benefits in glycemic control. Crapo and coauthors¹⁹⁶ compared the blood glucose excursions induced by the ingestion of 50 g of carbohydrate from dextrose, rice, potatoes, corn, and bread. They observed that the highest glucose response occurred with dextrose and potatoes, with much lower peaks occurring after intake of corn or rice. This led to the concept of classifying foods by a glycemic index related to their tendency to induce hyperglycemia. In general, low-glycemic foods, such as complex (rather than simple) carbohydrates and those with higher soluble fiber content, are associated with a more gradual release of glucose into the bloodstream.

Formal dietary consultation at periodic intervals during pregnancy improves metabolic control.¹⁹⁷ Timing and content of meals should be reviewed at each visit together with the patient's individual food preferences. In all pregnant women, the continuing fetal consumption of glucose from the maternal bloodstream results in a steady downward drift in maternal glucose levels unless feeding occurs. In patients taking insulin or oral hypoglycemics, prolonged periods (>4 hours) without food intake increase the risk of hypoglycemic episodes. In these patients, a rather rigid schedule of three meals plus snacks (at mid-morning, mid-afternoon, and bedtime) is often necessary to achieve smooth control. Because insulin resistance changes dynamically during pregnancy, the dietary prescription must be continually adjusted according to the patient's weight gain, insulin requirement, and pattern of exercise.

Avoiding Nocturnal Hypoglycemia

Unopposed action of intermediate-acting insulin during the hours of sleep frequently results in nocturnal hypoglycemia at 3 to 4 AM in individuals with T1DM. Reducing the insulin dose to avoid this complication typically leads to unacceptably high glucose levels on rising at 6 to 8 AM, whereas adding a bedtime snack helps to moderate the effect of bedtime insulin and sustain glucose levels during the night. The snack should contain a minimum of 25 g of complex carbohydrate and enough protein or fat to help prolong release from the gut during the hours of sleep.

Avoiding Ketosis

The issue of maternal ketosis and its potential effect on childhood mental performance is a source of continuing controversy. Churchill and associates¹⁹⁸ reported that ketonuria during pregnancy is associated with impairment of neuropsychological development in the offspring. This report has resulted in admonitions to avoid caloric reduction in any pregnant woman. The methodology of this study has been criticized, however, because the ketonuria data were acquired from many different hospitals by having a nurse obtain a single urine sample for ketone testing on the day of delivery.

Coetzee and colleagues¹⁹⁹ found morning ketonuria in 19% of women with insulin-independent diabetes on a 1000-calorie diet, 14% of those on a 1400- to 1800-calorie diet, and 7% of normal pregnant women on a free diet. There were no untoward neonatal events in infants of any of the ketonuric mothers.

There may be a difference between starvation ketosis and the ketosis that develops with poorly controlled diabetes. Ketonuria develops in 10% to 20% of normal pregnancies after an overnight fast and may protect the fetus from starvation in the nondiabetic mother. In the final analysis, significant maternal ketonemia resulting in maternal acidemia is probably unfavorable for the mother and fetus. The small degrees of ketosis that occur in many pregnant women, including those with diabetes, are unlikely to lead to measurable deficits in the newborn.

Weight Management

In 2009, the Institute of Medicine (IOM) revised their guidelines for weight gain in pregnancy. The previous (1990) guidelines were focused on prevention of the small or growth-restricted fetus. However, with the increase in obesity among women of reproductive age, the guidelines were revised with the goal of addressing short- and long-term issues related to gestational weight gain for both the mother and her offspring.²⁰⁰ The weight gain guidelines apply to women with normal glucose tolerance as well as to women with diabetes complicating pregnancy (Table 59-9).

Data pertaining to weight gain in pregnant women with diabetes is limited. Excessive gestational weight gain is weakly associated with the development of GDM. Some authors have endorsed less gestational weight gain than was recommended by the IOM, particularly in obese women, because, according to some epidemiologic reports, it leads to decreased risk of preeclampsia, cesarean delivery, and LGA neonates.²⁰¹ Others have actually recommended weight loss during pregnancy for overweight and obese women to decrease the risk of short- and long-term outcomes including SGA, LGA, preterm delivery, postpartum weight retention, and childhood obesity.²⁰² The only prospective RCT was designed to determine, in a small

number of women, the effect of a moderate (30%) decrease in energy restriction in decreasing the need for insulin therapy and the incidence of macrosomia in GDM.²⁰³ However, the energy restriction between the two groups was not significantly different (6845 versus 6579 kJ). Furthermore, there were no differences in need for insulin therapy or in birth weight between the intervention and control groups. These data emphasize the need for additional prospective, longitudinal studies to address this important facet of management of diabetes in pregnancy.

PRINCIPLES OF GLUCOSE MONITORING

Glycosylated Hemoglobin

Measurements of glycohemoglobin have proved to be a useful index of glycemic control over the long term (4 to 6 weeks), providing a numeric index of the patient's overall compliance and an indication of her average plasma glucose level over the past 30 to 60 days. Table 59-10 shows the relationship between Hb A_{1c} and plasma glucose. Although assessing Hb A_{1c} levels every 4 to 6 weeks during pregnancy rarely alters management significantly, it can provide the patient with a score by which she can rate the success of her hourly efforts to keep her blood

glucose levels within a narrow range. Glycohemoglobin levels are too crude to guide adjustments in insulin dosage.

Self-Monitoring of Blood Glucose Levels

The availability of capillary glucose chemical test strips has revolutionized the management of diabetes, and they should be considered the standard of care for pregnancy monitoring. The discipline of measuring and recording blood glucose levels before and after meals has a positive effect on improving glycemic control.

Timing of Capillary Glucose Monitoring. The frequency and timing of self-monitoring of blood glucose should be individualized (Table 59-11). However, because postprandial values have a strong correlation with fetal growth, checking after meals is essential. The DIEP study reported that when postprandial glucose values averaged 120 mg/dL, approximately 20% of infants were macrosomic, whereas a modest 30% rise in postprandial glucose levels to a mean level of 160 mg/dL resulted in a 35% rate of macrosomia.²⁰⁴ Similar results emphasizing postprandial blood glucose monitoring were reported by de Veciana and associates.²⁰⁵ In the HAPO study, FPG levels during the OGTT, as well as the 1- and 2-hour glucose concentrations, were strong correlates with fetal birth weight and adiposity.²⁵ In a retrospective study, Uvena-Celebrezze reported that home FPG monitoring had the strongest correlation with fetal adiposity ($r = 0.71$; $P < .01$).¹¹¹

With these facts in mind, a typical glucose monitoring schedule involves capillary glucose checks on rising in the morning, 1 or 2 hours after breakfast, before and after lunch, before dinner, and at bedtime. For patients taking intermediate- or long-acting medication at bedtime, measuring the capillary glucose level between 3 and 4 AM (the lowest glucose level

of the day) two to three times per week is helpful in interpreting the morning glucose values.

Target Capillary Glucose Levels. Controversy exists about whether the target glucose levels to be maintained during diabetic pregnancy should be designed to limit macrosomia or to closely mimic nondiabetic pregnancy profiles.

Regarding glucose targets for women with GDM, the recommendations from the Fifth International Workshop-Conference on Gestational Diabetes in 2007 were to target maternal capillary glucose concentrations as follows²⁰⁶: preprandial, less than 95 mg/dL (5.3 mmol/L); and postprandial, less than 140 mg/dL (7.8 mmol/L) at 1 hour or less than 120 mg/dL (6.7 mmol/L) at 2 hours.

For women with pregestational T1DM or T2DM, a 2012 consensus statement recommended the following as optimal glycemic goals if they can be achieved without excessive hypoglycemia¹⁸⁶: premeal, bedtime, and overnight glucose, 60 to 99 mg/dL (3.3 to 5.4 mmol/L); peak postprandial glucose, 100 to 129 mg/dL (5.4 to 7.1 mmol/L); Hb A_{1c}, less than 6.0%.

Data are available describing normal glucose variations during pregnancy in nondiabetic gravidas. Parretti and coworkers²⁰⁷ profiled normal pregnant women on an *ad libitum* diet twice monthly during the third trimester, measuring preprandial and postprandial glucose levels with capillary glucose meters. The results of the 95th percentile of the plasma glucose excursions are shown in Figure 59-14. Fasting and premeal plasma glucose levels were usually lower than 80 mg/dL and often lower than 70 mg/dL. Peak postprandial plasma glucose values rarely exceeded 110 mg/dL. Yogev and colleagues²⁰⁸ obtained continuous glucose information from nondiabetic pregnant women using a sensor that monitored interstitial fluid glucose levels and found similar results. The range of normal glucose levels occurring in nondiabetic pregnancy reported by these two sources are summarized in Table 59-12.

In consideration of these facts, the target plasma glucose values to be used during pregnancy management in women with diabetes should range from 65 to 95 mg/dL preprandially and should not exceed 130 to 140 mg/dL postprandially at 1 hour. Superb glycemic control requires attention to preprandial and postprandial glucose levels.

TABLE 59-11 Timing of Home Capillary Glucose Monitoring

Capillary Glucose Assessment	Advantage	Disadvantage
Preprandial	Permits prospective adjustment of food intake, supplementation of preprandial insulin	Preprandial or fasting glucose levels correlate poorly with fetal morbidity. Significant postprandial hyperglycemia may go undetected.
Postprandial	Permits supplementation of insulin to reduce postprandial glucose overshoots; improved postprandial control correlates with improved fetal or neonatal outcome.	Results are obtained after food intake.
Bedtime	Permits adjustment of calories at bedtime snack, adjustment of bedtime insulin.	—
3-4 AM	Enables detection of nocturnal hypoglycemia.	Interrupts sleep, may increase stress.

PRINCIPLES OF INSULIN THERAPY

Despite the fact that no available insulin delivery method approaches the precise secretion of the hormone from the human pancreas, the judicious use of modern insulins can mimic those patterns remarkably well. The goal of exogenous insulin therapy during pregnancy is to achieve diurnal glucose excursions similar to those of nondiabetic pregnant women. Given that in normal pregnant women the postprandial blood glucose excursions are maintained within a relatively narrow range (70 to 120 mg/dL), the task of reproducing this profile requires meticulous daily attention by both patient and physician.

As pregnancy progresses, the increasing fetal demand for glucose results in lower fasting and between-meal blood glucose levels, increasing the risk of symptomatic hypoglycemia. Upward adjustment of short-acting insulins to control postprandial glucose surges within the target range only exacerbates the tendency toward interprandial hypoglycemia. Any insulin regimen for pregnant women requires combinations and timing

TABLE 59-13 Insulin Preparations and Pharmacokinetics

Insulin Preparation	Time to Peak Action (hr)*	Total Duration of Action (hr)*	Comment
Insulin lispro (Humalog)	1	2	Onset within 10 min of injection; no need to delay meal onset after injection
Insulin aspart (Novolog)	1	2	Onset within 10 min of injection; no need to delay meal onset after injection
Regular insulin	2	4	Good coverage of individual meals if injected 20 min before eating; increased risk of postprandial hypoglycemia with unopposed action 2-3 hr after eating
NPH insulin	4	8	Provides intermediate-acting control; give on rising and at bedtime; risk of 3 AM hypoglycemia
Insulin detemir (Levemir)	7	20	Provides a useful peak 7 hr after injection; can be used at bedtime to suppress fasting glucose
Insulin glargine (Lantus)	5	<24	Prolonged flat action profile; limited pregnancy experience; increased risk of nocturnal hypoglycemia or undertreatment during the day

*Times are approximate in typical pregnant women with diabetes.

of insulin injections different from those that would be effective in the nonpregnant state. The regimens must be modified continually as the patient progresses from the first to the third trimester and as insulin resistance rises. The regimen should always be matched to the patient's unique physiology, work, rest, and food intake schedule.

Types of Insulin

The types of insulin frequently used in diabetes control are listed in Table 59-13. Several insulins are available for use, but most have not been extensively evaluated in pregnancy. They include the short-acting insulins lispro (Humalog) and aspart (Novolog) and the newer, very-long-acting, molecularly

modified insulins detemir (Levemir) and glargine (Lantus). The activity profiles of the intermediate- and long-acting insulins are shown in Figure 59-15.

Typical Insulin Regimens

Flexibility is important in dosing and adjusting insulin during pregnancy. Although most patients find it necessary to organize their mealtimes and physical activity around their insulin regimen, changes in the timing of insulin injections and the types of insulin used are frequently necessary to match lifestyle and occupational needs and to optimize glycemic control. It is also helpful to understand the trends in basal and bolus insulin as pregnancy progresses. Expected changes in insulin requirements across gestation were assessed by Roeder and colleagues²⁰⁹

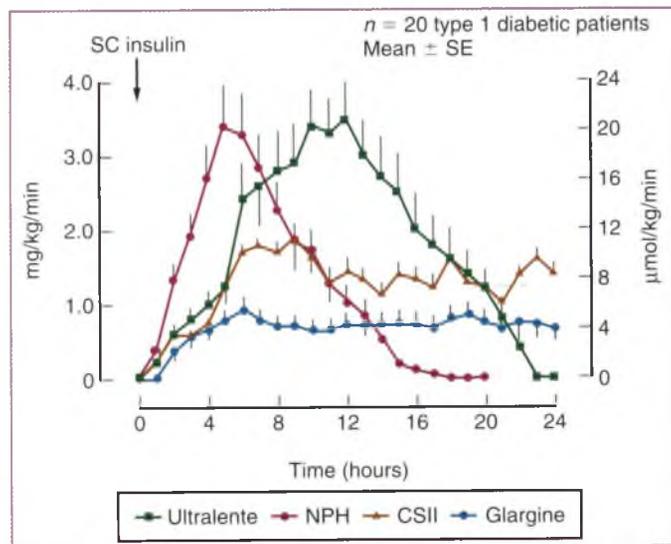

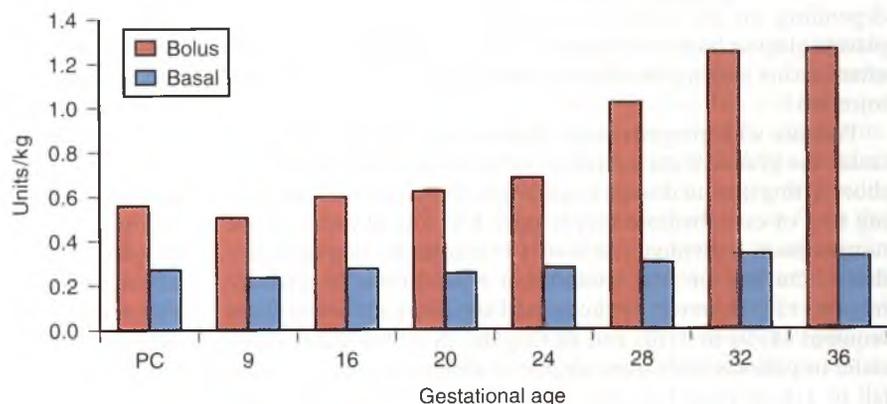

Figure 59-15 Activity profiles of intermediate- and long-acting insulins. The kinetics of NPH, Ultralente, glargine (Lantus), and continuous subcutaneous insulin infusion with lispro insulin are graphed. The curves show the glucose infusion rate necessary to maintain plasma glucose at 130 mg/dL. CSII, continuous subcutaneous insulin infusion; SC, subcutaneous; SE, standard error. (From Lepore M, Pampanelli S, Fanelli C, et al: *Pharmacokinetics and pharmacodynamics of subcutaneous injection of long-acting human insulin analog glargine, NPH insulin, and Ultralente human insulin and continuous subcutaneous infusion of insulin lispro*, *Diabetes* 49:2142–2148, 2000. Figure 59-16 Changes in bolus and basal insulin requirements for women with type 1 diabetes across gestation. PC, preconception. (From Roeder HA, Moore TR, Ramos GA: *Insulin pump dosing across gestation in women with well-controlled type 1 diabetes mellitus*, *Am J Obstet Gynecol* 207:324.e1–324.e5, 2012.)

in women with excellent glycemic control before, during, and after the pregnancy (Fig. 59-16). In the first trimester, total insulin dose declined by 15% at 10 weeks, then rose progressively toward a peak at 32 to 36 weeks. The total daily dose of insulin almost tripled (280%) from preconception to term (33.3 ± 7.8 U/day to 93.5 ± 27.9 U/day at delivery). Basal rates rose modestly (50% increase), from 16.2 ± 6.5 U/day to 24.0 ± 9 U/day, whereas bolus insulin doses quadrupled, from 17.1 ± 6.1 U/day to 69.5 ± 29.6 U/day ($P < .0001$). Bolus insulin increased from approximately 50% of the total daily dose of insulin before conception to 75% of the total daily dose at 36 weeks' gestation.

The following guidelines and examples can help in managing and adjusting insulin during pregnancy:

1. In the first trimester from week 6 to week 10, progressively reduce the insulin dose by a total of 10% to 25% to avoid hypoglycemia. Reduced physical activity and caloric intake associated with the appetite changes and fatigue of early pregnancy lead to increased insulin effectiveness and interprandial hypoglycemia. After approximately 11 weeks, it is typical to begin increasing insulin doses again as the insulin resistance mediated by rising placental hormones begins its linear and progressive increase toward 36 weeks' gestation.
2. A typical total insulin dose is 0.6 U/kg in the first trimester, but this must be increased weekly or every other week with pregnancy duration from the second trimester onward. In women with T1DM, insulin increases markedly over the nonpregnant baseline by the end of pregnancy. In insulin-resistant T2DM, 300% to 400% increases are not unusual. Insulin requirements normally peak at 36 weeks' gestation and drop significantly thereafter.
3. The kinetics of NPH insulin are such that care must be taken to time its peak action at 5 to 7 AM and avoid peaking at 4 AM, when maternal glucose levels are lowest. For many women, who may be taking NPH at "bedtime" (8 or 9 PM), NPH will peak at 4 AM, exposing the mother and fetus to nocturnal hypoglycemia. It is often better to administer NPH at a set time between 10 PM and midnight, not the less accurate timing of "bedtime," to optimize needed NPH peak action during the hours of 5 to 7 AM.
4. A combination of short- and intermediate-acting insulins can be employed to maintain glucose levels in an acceptable range. A typical regimen involves intermediate-acting

insulin (NPH) before breakfast and at 10 PM, with injections of short-acting insulin before breakfast and before dinner. Approximately two thirds of the daily insulin dose is given in the morning and one third in the afternoon and at bedtime. For example, the regimen may be 20 U of NPH plus 10 U of regular insulin in the morning, 8 U of regular insulin with dinner, and 8 U of NPH at 10 PM. The morning dose of NPH covers the periods before and after lunch. Avoid NPH injections at dinnertime, because the peak will occur at 2 to 3 AM, creating symptomatic hypoglycemia.

5. Short-acting insulins (lispro or aspart) are preferred during diabetic pregnancy. Compared with regular insulin, the peak serum lispro concentration is three times higher, the time to peak is 4.2 times shorter, the absorption rate constant is double, and the duration of action is one half as long.²¹⁰ These kinetics allow the patient to inject insulin just before eating, rather than having to delay eating for 20 to 30 minutes to allow regular insulin to begin its effect.
6. The use of insulin glargine during pregnancy potentially provides a stable, basal insulin release throughout the 24-hour day. The safety of glargine in pregnancy was addressed in systematic review of eight studies involving a total of 702 women with pregestational diabetes or GDM in pregnancy treated with either insulin glargine ($n = 331$) or NPH insulin ($n = 371$); no statistically significant differences in studied fetal outcomes were found with the use of insulin glargine compared to NPH insulin.¹⁵³

Although the relatively flat activity profile of glargine is attractive, the dose must be regulated to avoid excessive basal insulin action during the night and resulting hypoglycemia. During the day, when insulin resistance and insulin requirements are higher, the basal rate low enough to avoid nocturnal hypoglycemia is usually inadequate, and NPH must be added. As shown in Figure 59-14, the nocturnal low glucose level (typically at 4 AM) decreases as the third trimester progresses. Great care must be exercised in using glargine to avoid severe nocturnal hypoglycemia.

Carbohydrate Counting and Insulin Corrections

Intermediate- and long-acting insulins should be adjusted no more frequently than weekly or biweekly to maintain preprandial plasma glucose levels in the target range (60 to 99 mg/dL). However, with short-acting insulins, glycemic control is better when the patient is able to vary, within a reasonable range, the insulin dose she uses to cover a meal depending on its calorie or carbohydrate content and the plasma glucose level existing at the time she begins eating. This often means varying the short-acting insulin dosage with every injection.

Patients with pregestational diabetes are usually taught to count the grams of carbohydrate in their meals and adjust the short-acting insulin dosage accordingly. A typical meal containing 60 g of carbohydrate may require 4 to 6 U of lispro in the nonpregnant individual (ratio of 1 U insulin to 15 g carbohydrate). During the first trimester, a typical ratio is approximately 1:12. However, by the second trimester, more insulin is required (1:10 to 1:6), and during the third trimester, especially in patients with some degree of insulin resistance, ratios fall to 1:6 or even 1:2. The clinician should anticipate these

increases in insulin requirement as pregnancy progresses, because patients often interpret them as errors or failure on their part.

Carbohydrate counting has limits in accuracy due to miscalculation of carbohydrate content and individual differences in glucose uptake dynamics that may result in erratic control. During pregnancy, many women regiment their food quantity, content, and timing so that carbohydrate calculations are within a reasonably narrow range.

Women with pregestational diabetes are frequently taught how to perform preprandial and postprandial insulin corrections. A typical regimen is to add 1 to 2 U lispro for every 50 mg/dL that the glucose level is out of target range. A preprandial glucose level of 130 mg/dL would require 1 U lispro more than the prescribed dose for that meal. As pregnancy progresses, corrections increase from 1 per 50 mg/dL to 1 per 20 mg/dL. However, the patient must be instructed not to take more than 4 correction units in a single bolus during pregnancy; instead, she should retest the glucose level in 1 to 2 hours and apply an additional correction at that time.

Use of Continuous Subcutaneous Insulin Infusion

Most of the principles described to enhance and smooth glycemic control by manipulating the timing, quantity, and type of insulin can be used with greater facility with continuous subcutaneous insulin infusion (CSII) delivered by a programmable pump. These devices, which infuse insulin by means of a convenient catheter placed into the subcutaneous tissue near the abdomen, can be programmed to provide varying basal and bolus levels of insulin at differing times of day, which change smoothly even while the patient sleeps or exercises.

However, the value of CSII in improving outcomes remains unclear. Cummins and associates performed a systematic review of 74 studies comparing nonpregnant adults using CSII with those using multiple daily injections.²¹¹ The following benefits of CSII were significant: lower Hb A_{1c} levels; reduced swings in blood glucose levels and in problems due to the dawn phenomenon; fewer hypoglycemic episodes; reduction in total insulin dose per day; improved quality of life, including lowered chronic fear of severe hypoglycemia; and more flexibility of lifestyle.

Bruttomesso and colleagues conducted a retrospective study of two comparable groups of women with T1DM, 100 of whom were using CSII and 44 of whom were using multiple daily injections. Metabolic control improved during pregnancy in both groups, but good control was reached earlier among patients using CSII. At parturition, patients using CSII had lower Hb A_{1c} levels ($6.2 \pm 0.7\%$ versus $6.5 \pm 0.8\%$; $P = .02$) and required less insulin ($P < .01$). However, maternal and neonatal outcomes did not differ.²¹² Similar findings of improved Hb A_{1c} levels with CSII versus multiple daily injections were reported by Gonzalez-Romero and coworkers, again with no differences in maternal or neonatal outcomes.²¹³

A properly designed insulin pump infusion scheme allows convenient tailoring of the insulin administration profile to the patient's individual metabolic and lifestyle rhythms. A sample regimen is shown in Table 59-14. The lowest infusion rate of the day is between 11 PM and 4 AM, when the pump is set at about 70% of the mean rate needed during the day. The basal rate must be increased to 1.3 to 1.5 times the mean daily rate between 5 AM and 9 AM to provide extra insulin coverage for the high insulin-resistance period as the day begins (dawn effect). For the remainder of the day (9 AM to 10 PM), a steady

TABLE 59-14 Typical Second-Trimester Continuous Administration Profile Using a Subcutaneous Insulin Infusion Pump

Time	Basal Rate (U/hr)	Bolus (U/g of carbohydrates)	Comment
12 midnight	0.6	—	Lower basal rate for sleep
5 AM	1.5	—	Higher basal rate opposes the "dawn effect" of rising serum glucose from 4 to 6 AM
7 AM	—	1:6	Prebreakfast bolus
9 AM	1.0	—	Lower basal rate to match increased physical activity, decreased insulin needs
12 noon	—	1:8	Prelunch bolus
6 PM	—	1:8	Predinner bolus
10 PM	0.6	—	Lower basal rate for sleep

mean infusion rate is usually sufficient. Insulin boluses, programmed to limit the postprandial excursion to less than 130 to 140 mg/dL, are given as often as needed. The enhanced ability for the patient to administer extra insulin doses without syringes and insulin vials is of great value in improving the smoothness of glycemic control.

Treating Gestational Diabetes with Insulin

Clinicians and patients are reluctant to start insulin in patients with GDM, but this intervention may be essential if macrosomia is to be reduced or avoided. Because the period of accelerated fetal growth velocity and fat accretion occurs from 28 to 34 weeks of gestation, delaying definitive therapy with repeated attempts to correct a suboptimal glucose profile with dietary adjustments may, by 33 to 34 weeks, have missed the time when glycemic intervention is likely to moderate fetal growth. It is reasonable to allow a 1- to 2-week trial of dietary management before resorting to other measures, but waiting longer does not significantly increase the likelihood of good control. McFarland and colleagues showed that approximately 50% of patients achieved good glycemic control during the first 2 weeks of dietary therapy, but by the 4th week, only an additional 10% attained acceptable blood glucose levels.²¹⁴

The value of insulin in managing GDM was reported by Crowther and associates,²¹⁵ who randomly assigned 1000 women with GDM to insulin or no medical therapy in the Australian Carbohydrate Intolerance Study in Pregnant Women (ACHOIS trial). Controls (women with normal OGTT results) comprised a third group. In the insulin group, glucose levels were maintained at less than 99 mg/dL before meals and less than 126 mg/dL 2 hours postprandially. The rate of serious perinatal complications was significantly lower among infants in the insulin group compared with the routine-care group (1% versus 4%). The umbilical cord serum insulin value and insulin-to-glucose ratio, which provide an indicator of fetal hyperglycemia, were similar in the three groups, but leptin concentration, an indicator of fetal fat mass, was lower in the insulin-treated

group ($P < .02$). This result suggests that treatment of GDM using diet, blood glucose monitoring, and, if necessary, insulin influences the fetal adipoinular axis, which may reduce the risk of childhood and adult obesity later in life.

Landon and colleagues²¹⁶ performed a multicenter randomized trial of dietary and insulin therapy compared with no treatment in women with mild GDM defined as an FPG value lower than 95 mg/dL (5.3 mmol/L) but an abnormal 3-hour, 100-g OGTT result. A total of 958 women at 24 to 31 weeks' gestation were randomized. The control group had usual prenatal care, whereas the treatment group received dietary intervention, self-monitoring of blood glucose, and insulin therapy. The primary outcome was a composite of stillbirth or perinatal death and neonatal complications, including hyperbilirubinemia, hypoglycemia, hyperinsulinemia, and birth trauma. No significant difference was found between treatment and control groups in the frequency of the composite outcome (32.4% and 37.0%, respectively; $P = .14$), but there were statistically significant reductions with treatment in several secondary outcomes, including mean birth weight (3302 versus 3408 g), neonatal fat mass (427 versus 464 g), frequency of LGA infants (7.1% versus 14.5%), birth weight greater than 4000 g (5.9% versus 14.3%), shoulder dystocia (1.5% versus 4.0%), and cesarean delivery (26.9% versus 33.8%). Treatment of GDM, compared with usual care, was also associated with reduced rates of preeclampsia and gestational hypertension (combined rate for the two conditions, 8.6% versus 13.6%; $P = .01$). Taken together, these two randomized trials indicate that intervention to treat GDM improves both maternal and neonatal outcomes.

The specific insulin regimen employed in managing GDM should be designed to address the patient's individual glucose profile, because some women require insulin only to prevent fasting morning hyperglycemia and others only for postprandial excursions. Typically, one to several postprandial glucose levels become consistently above target as the patient's ability to compensate for rising insulin resistance becomes inadequate with diet alone. In such cases, administration of short-acting insulin such as lispro or aspart (4 to 8 U to start) before meals is helpful. If more than 10 U of short-acting insulin is needed before the noon meal, adding a 6- to 8-U dose of NPH before breakfast may help to achieve smoother control. If the FPG rises above 90 to 95 mg/dL, 4 to 6 U of NPH insulin should be administered between 10 to 11 P.M. The doses are scaled up as necessary, twice weekly or more often, to keep glucose levels within the target range.

USE OF ORAL HYPOGLYCEMIC AGENTS

Maintaining glucose levels within the target range requires meticulous attention to diet and physical activity. For many patients, injecting insulin frequently is impossible, and there are many initiatives to augment glucose control with oral agents, particularly in patients with insulin-resistant T2DM. An ideal treatment would reduce insulin resistance, improve insulin secretion or action, and delay the uptake of glucose from the gut. Current strategies are aimed at augmentation of insulin supply (i.e., sulfonylurea and insulin therapy), amelioration of insulin resistance (i.e., exercise, weight loss, and metformin and troglitazone therapy), and limitation of postprandial glucose excursions (i.e., complex carbohydrates plus protein, acarbose therapy).

Pharmacology and Safety

Sulfonylurea compounds, commonly prescribed for patients with T2DM, have been considered to be contraindicated during pregnancy based on evidence of safety and efficacy. Few rigorously designed trials have been performed to assess these agents during pregnancy. Reports of fetal anomalies have been largely anecdotal. When Towner and coworkers²¹⁷ evaluated the frequency of birth defects in fetuses of patients who took oral hypoglycemics during the periconceptional period, they found that the first-trimester glycohemoglobin level and duration of diabetes were strongly associated with fetal congenital anomalies but that use of an oral hypoglycemic agent was not.

Use of glyburide, a second-generation oral sulfonylurea available in the United States since 1984, has become widespread because of its ability to enhance pancreatic insulin secretion as well as target tissue insulin sensitivity. As adjunctive therapy, glyburide can reduce the daily dosage for those who require large amounts of insulin. The safety of glyburide use in pregnancy was assessed by Nicholson and Baptiste-Roberts, who examined eight RCTs comparing glyburide with insulin.²¹⁸ Key findings included the following:

- Maternal glycemic control and cesarean delivery rates did not differ significantly between the insulin and glyburide groups.
- Insulin treatment was associated with an average 95-g lower infant birth weight, which was not statistically or clinically significant.
- Few congenital anomalies were reported in either group.

Metformin has also gained increasing acceptance for treatment of GDM. Metformin is frequently used in patients with PCOS and T2DM to improve insulin sensitivity and fertility. The safety profile of metformin in the first trimester and its apparent lack of teratogenicity have been well documented in patients who achieved pregnancy while undergoing treatment.²¹⁹

Nicholson and Baptiste-Roberts also evaluated two RCTs comparing metformin to insulin therapy for GDM.²¹⁸ Key findings included the following:

- Glycemic control did not differ between the metformin and insulin groups.
- Neonatal hypoglycemia was more frequent in the insulin group.
- No differences in rates of congenital anomalies were noted.

At present, use of metformin or glyburide in pregnancy has not been associated with clear risk to mother or neonate, compared with insulin therapy. Large-scale outcome studies in mothers and neonates are clearly needed, however.

Glyburide Therapy

A unique characteristic of glyburide that allows its use in pregnancy is its minimal transport across the human placenta. This has been attributed to its high maternal protein binding, its rapid clearance rate, and the role of placental efflux transporters such as the breast cancer resistance protein.²²⁰

Based on findings consistently showing minimal transfer of glyburide across the placenta, Langer and colleagues designed a randomized trial to compare this oral agent with insulin in patients with GDM.²²¹ They randomized 404 women with second- and third-trimester singleton GDM pregnancies to glyburide versus insulin treatment. At the conclusion of the trial, there was no difference between the groups in mean maternal blood glucose, percentage of LGA infants (12% and 13%,

respectively), birth weight 4000 g or greater (7% and 4%), or neonatal complications (pulmonary complications, 8% and 6%; hypoglycemia, 9% and 6%; admission to neonatal intensive care unit, 6% and 7%; fetal anomalies, 2% and 2%). Only 4% of the glyburide group required insulin therapy. Glyburide was not detected in the cord serum of any infant in the glyburide group. The mean glyburide dose was 9.2 mg. Only 82% of the patients receiving glyburide and 88% of those receiving insulin achieved the target level of glycemic control, representing a GDM treatment “failure rate” of 12% to 18%, regardless of therapy.

Beyond this single encouraging study, further nonrandomized experience with more than 1000 patients exposed to glyburide during pregnancy has been reported (as summarized by Moore²²² and by Rosenn²²³). For example, Chmait and coworkers,²²⁴ reported that 19% of patients managed on glyburide required adjunctive insulin therapy to keep glucose values in the target range. The adjunctive insulin rate was higher for women diagnosed earlier in pregnancy (20 versus 27 weeks; $P < .05$).

In another study, Jacobson and coworkers²²⁵ performed a retrospective cohort comparison of glyburide and insulin treatment of GDM. There were no statistically significant differences in gestational age at delivery, mode of delivery, birth weight, percentage of LGA infants, or percentage of macrosomic infants. The rate of preeclampsia was twice as high in the glyburide group (12% versus 6%; $P < .02$), but women in the glyburide group had significantly lower FPG and postprandial blood glucose levels. The glyburide group also more frequently achieved target glycemic levels (86% versus 63%; $P < .001$). The failure rate (i.e., transfer to insulin) was 12%.

Finally, Dhulkotia and associates analyzed six RCTs that compared oral hypoglycemic and insulin therapy for GDM, comprising 1388 subjects.²²⁶ No significant differences were found in maternal FPG level or postprandial glycemic control. Use of oral hypoglycemic agents was not associated with increased risk of neonatal hypoglycemia, increased birth weight, cesarean delivery rate, or incidence of LGA infants.

The recommended glyburide dosing regimen is based largely on animal studies and a few human studies of nonpregnant subjects. Yin and associates²²⁷ studied the glucose and insulin responses to glyburide in a group of nonpregnant, nondiabetic subjects. After a 5-mg oral dose, serum glyburide levels peaked at 2.75 hours and had sustained levels with a half-life ranging from 2 to 4 hours, considerably shorter than the quoted half-life of 10 hours. Given the larger volume of distribution in pregnancy and the faster renal clearance of medications, the current dosing recommendations may be very conservative.²²⁸

Based on these data, glyburide should be taken at least 30 minutes (preferably 60 minutes) before a meal so that the peak action (2.5 hours after dosing) coincides with the postprandial glucose surge, which peaks at 60 to 75 minutes. Because of its extended duration of action, glyburide taken at 10 to 11 PM is effective in lowering FPG levels in the morning. Significant interprandial hypoglycemia can occur with glyburide, and patients should carry glucose tablets with them at all times as a precaution. The maximum dose is 20 mg per day, and no more than 7.5 mg should be taken at a single time.

Metformin

Because of the putative beneficial effect of metformin on first-trimester miscarriage, many patients with PCOS enter prenatal care taking this medication. The efficacy of continuing metformin beyond the first trimester was evaluated by Vanky and associates

in 257 women with PCOS.²²⁹ Subjects were randomly assigned to receive either metformin or placebo from first trimester to delivery. Preeclampsia, preterm delivery, and GDM prevalence were not different between the groups. Women in the metformin group gained less weight during pregnancy than those in the placebo group, but there was no difference in fetal birth weight. Therefore, there seems to be little evidence to justify continuing metformin after the first trimester in the absence of GDM.

However, once GDM has been diagnosed, metformin has been shown to be equivalent to insulin in effectiveness.¹⁹¹ To test the relative effectiveness of metformin versus glyburide for treatment of GDM, Moore and colleagues²³⁰ randomized 149 patients with GDM and found that mean FPG and 2-hour postprandial blood glucose levels were not statistically different. However 34.7% of the metformin group, versus 16.2% of the glyburide group, required supplemental insulin therapy ($P = .01$). In that study, the failure rate of metformin was 2.1 times higher than the failure rate of glyburide. A similarly high failure rate for metformin (46%) was reported by Rowan and coworkers.¹⁹¹ Recommended dosing of oral metformin begins with 500 mg twice daily (approximately every 12 hours), increasing as needed to achieve glucose target values to a maximum of 2500 mg/day.

α -Glucosidase Inhibitors

The α -glucosidase inhibitors, another class of oral agents, reversibly inhibit pancreatic amylase and α -glucosidase enzymes in the small intestine, delaying cleavage of complex sugars to monosaccharides and reducing the increase of blood glucose levels after a meal. Although these agents offer promise in pregnant women because of limited uptake from the gut, only a few studies of the drugs in pregnancy are available. Bertini and colleagues²³¹ compared treatment with insulin ($n = 27$), glyburide ($n = 24$), and acarbose ($n = 19$) in women with GDM. No difference was observed in maternal glucose levels or in mean birth weight, although the rates of LGA fetuses were 3.7%, 25%, and 10.5% for the three groups, respectively. Neonatal hypoglycemia was observed in eight newborns, six of whom were from the glyburide group. Glucose control was not achieved in five (20.8%) of the patients using glyburide and in eight (42.1%) of the patients using acarbose. Acarbose is given before meals, initially in an oral dose of 25 mg three times daily up to a maximum of 100 mg three times daily.

Pregnancy Management in the Diabetic Patient and Fetus

FETAL SURVEILLANCE

The goals of third-trimester management of diabetic pregnancy are to prevent stillbirth and asphyxia while optimizing the opportunity for a safe vaginal delivery. This involves monitoring fetal growth to determine the proper timing and route of delivery and testing for fetal well-being at frequent intervals.

A regimen for fetal surveillance throughout pregnancy is provided in Table 59-15. The goals are to accomplish the following:

- Verify fetal viability in the first trimester
- Validate fetal structural integrity in the second trimester
- Monitor fetal growth during most of the third trimester
- Ensure fetal well-being in the late third trimester

A variety of fetal biophysical tests are available, including fetal heart rate testing, fetal movement counting, ultrasound

TABLE 59-15 Fetal Surveillance in Type 1 and Type 2 Diabetic Pregnancies

Weeks of Gestation	Test
Preconception	Maternal glycemic control
8-10	Sonographic crown-rump measurement
16	Maternal serum α -fetoprotein level to screen for neural tube defects
18-20	High-resolution sonography to detect congenital anomalies
20-22	Fetal cardiac echography in cases of suboptimal cardiac imaging during mid-trimester fetal anatomy scanning or poor diabetic control (Hb A _{1c} $\geq 10\%$) in the first trimester
28	Baseline sonographic growth assessment of the fetus; daily fetal movement counting by the mother
32	Repeat sonography for fetal growth
34	Biophysical testing: either twice weekly nonstress test with amniotic fluid assessment or weekly biophysical profile
36	Estimation of fetal weight, head and abdominal circumference percentiles by sonography
37-38	Amniocentesis and delivery for patients with poor glucose monitoring compliance, persistently poor glycemic control, or suspicious findings on fetal biophysical testing
39-40	Delivery without amniocentesis for patients in good glycemic control

Hb A_{1c}, glycosylated hemoglobin.

TABLE 59-16 Tests of Fetal Well-Being

Test	Frequency	Reassuring Result	Comment
Fetal movement counting	Every night from 28 wk	10 movements in <60 min	Performed in all patients
Nonstress test	Twice weekly	2 heart-rate accelerations in 20 min	Begin at 28-34 wk in medication-dependent diabetes; start at 36 wk in diet-controlled gestational diabetes
Contraction stress test	Weekly	No heart-rate decelerations in response to 3 contractions in 10 min	Same as for nonstress test
Ultrasound biophysical profile	Weekly	Score of 8 in 30 min	3 movements = 2 1 flexion = 2 30-sec breathing = 2 2-cm amniotic fluid = 2

biophysical scoring, and fetal Doppler studies. These tests are summarized in Table 59-16.

Testing should be initiated early enough to avoid the risk of stillbirth but not so early that a high rate of false-positive results is encountered. Because the risk of fetal death is roughly

AC as a single measure ($P = .03$). A similar analysis of 36 formulas performed by Hoopmann and coworkers²³⁶ compared detection and false-positive rates for birth weights of greater than 4000 g and greater than 4500 g. The sensitivity values were 29% and 22%, respectively, and the false-positive rates were 12% and 7%. Therefore, whereas the formulas can be said to provide a statistical estimate of birth weight when performed near delivery, the confidence intervals are wide, encompassing as much as a pound above or below the actual birth weight.

Considering the inaccuracy of weight prediction from a single set of sonographic measurements, serial analysis of parameters every 2 to 4 weeks is commonly used. However, trended serial EFW calculations or percentiles appear to be no better than a single estimate performed near term. Predictions based on the average of serial EFWs, linear extrapolation from two estimates, or extrapolation by second-order equations fitted to four estimates were no better than the prediction from the last estimate before delivery.²³⁷

In view of the inadequate methods used to diagnose macrosomia antenatally, the widespread practice of estimating fetal weight using ultrasound near term in diabetic pregnancy must be questioned. Parry and colleagues²³⁸ compared the cesarean rate for neonates falsely diagnosed on ultrasound as macrosomic (i.e., false positives) with the rate for those correctly diagnosed as non-macrosomic (i.e., true negatives). They found that the cesarean rate was significantly higher among the false-positive macrosomics than among the true negatives (42.3% versus 24.3%).

Predicting Shoulder Dystocia

Because of the asymmetric adipose deposition around the fetal chest and trunk, macrosomic infants of women with diabetes are at high risk for shoulder dystocia and injury (see Fig. 59-10). However, prediction of this risk is not possible with adequate precision to avoid excessive unnecessary interventions.²³⁹

In a subanalysis of the ACHOIS trial, Athukorala and associates¹⁴⁴ identified a linear increase in the risk of shoulder dystocia in relation to FPG level on the glucose tolerance test, with an 18-mg/dL (1-mmol) increase in the fasting OGTT result leading to an RR of 2.09 (CI, 1.03 to 4.25). As reported by others, shoulder dystocia was 10-fold more common with operative vaginal delivery of GDM infants. However, there was no clear cutoff for glucose tolerance test fasting value that was adequately predictive of shoulder dystocia.

There is no clinical method of reliably identifying the fetus who is likely to experience shoulder dystocia and injury during birth without an unacceptably high false-positive rate. Between 8% and 20% of fetuses from diabetic pregnancy weighing 4500 g or more at birth have shoulder dystocia; 15% to 30% of these have recognizable brachial plexus injury, and 5% to 15% of those injuries result in permanent deficit. However, approximately 443 to 489 cesarean deliveries would have to be performed for suspected macrosomia to prevent one case of permanent injury from shoulder dystocia.²⁴⁰

Delivery Timing

Timing of delivery should minimize neonatal morbidity and mortality while maximizing the likelihood of vaginal delivery. Delaying delivery to as near the estimated due date as possible increases cervical ripeness and improves the chances of vaginal birth. However, the risks of fetal macrosomia, birth injury, and fetal death increase as the due date approaches. Earlier delivery

may reduce the risk of shoulder dystocia, but the increase in failed labor inductions and neonatal respiratory distress is appreciable.

Kjos and associates performed the only existing RCT to assess whether the cesarean delivery rate can be reduced by expectant management versus induction at 38 weeks in women with diabetes.²⁴¹ Although there was an increase in LGA infants (23% versus 10%; $P < .02$) in the expectantly managed group, there was no significant difference in the cesarean delivery rate.

An additional consideration is the risk of fetal death and perinatal asphyxia which can lead to neonatal death. Both of these rise with advancing gestation. Rosenstein and colleagues²⁴² performed a retrospective cohort study of women with GDM delivering at 36 to 42 weeks' gestational age in California from 1997 through 2006. A composite mortality rate was developed to estimate the risk of expectant management at each gestational age; this rate incorporated the stillbirth risk during each week of continuing pregnancy plus the infant mortality risk at the gestational age 1 week hence. With GDM, the risk of expectant management was lower than the risk of delivery at 36 weeks (17.4 versus 19.3 per 10,000), but at 39 weeks, the risk of expectant management exceeded that of delivery (RR = 1.8; CI, 1.2 to 2.6) (Fig. 59-18).

When all these factors are considered, the optimal time for delivery of most diabetic pregnancies is between 39 and 40 weeks. However, coexisting maternal hypertension, suboptimal glucose control, or suspicious fetal biophysical testing results are important cofactors that may influence decisions regarding

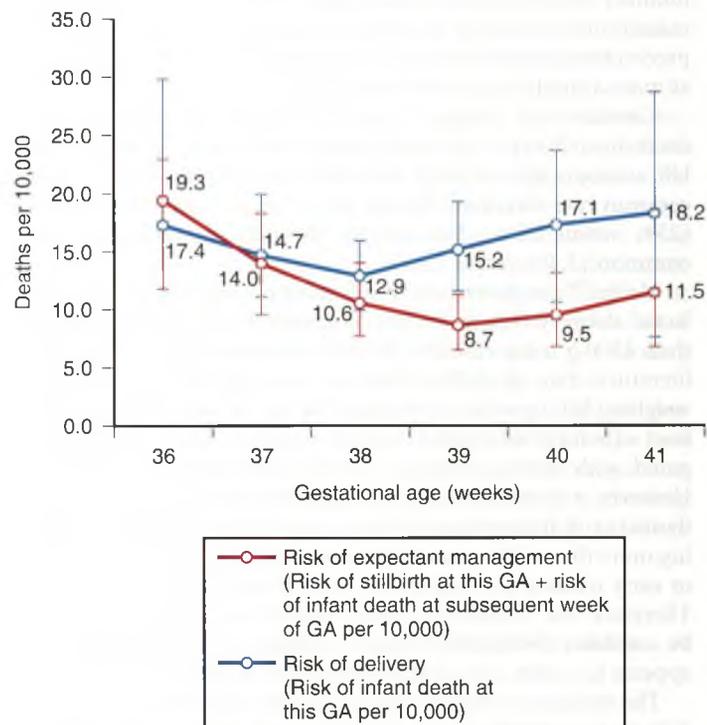

Figure 59-18 Mortality risk of expectant management compared with delivery in women with gestational diabetes mellitus. GA, gestational age. (From Rosenstein MG, Cheng YW, Snowden JM, et al: The risk of stillbirth and infant death stratified by gestational age in women with gestational diabetes, *Am J Obstet Gynecol* 206:309.e1-309.e7, 2012.)

delivery timing.⁷⁹ Because of the apparent delay in fetal lung maturity in diabetic pregnancies, delivery before 39 weeks' gestation should be performed only for compelling maternal or fetal reasons.

It may be tempting to consider early delivery in a diabetic pregnancy with "impending macrosomia" identified on ultrasonography. Because fetal growth between 37 and 40 weeks' gestation in a 90th-percentile fetus is approximately 100 to 150 g per week, inducing labor 2 weeks early may reduce the risk of shoulder dystocia in some cases.

Fetal lung maturity should be verified in all patients delivered before 38 weeks by the presence of greater than 3% phosphatidylglycerol or the equivalent on an amniocentesis specimen. If obstetric dating is suboptimal, amniocentesis should be performed. After more than 40 weeks, the benefits of continued conservative management are less than the danger of fetal compromise. Induction of labor before 42 weeks in diabetic pregnancy is prudent regardless of the readiness of the cervix.

Labor or Cesarean Delivery

ACOG²⁴³ has recommended that primary cesarean delivery be discussed with diabetic gravidas with an EFW greater than 4500 g. This may reduce the risk of shoulder dystocia to some degree for an individual patient, but the effect on the larger obstetric population is less clear.

Gonen and associates²⁴⁴ retrospectively assessed the impact of a policy of elective cesarean in cases with an EFW greater than 4500 g. With more than 16,000 deliveries, macrosomia was correctly predicted using EFW in only 18% of cases. Of the 115 undiagnosed macrosomic cases, 13 infants were delivered by emergency cesarean and 86% were delivered vaginally. Three infants (3%) with macrosomia and 14 infants (0.1%) without macrosomia sustained brachial plexus injury. Their policy of preemptive cesarean for an EFW greater than 4500 g prevented at most a single case of brachial palsy.

Conway and Langer²⁴⁵ prospectively performed elective cesarean delivery in diabetic women with an EFW of 4250 g. Ultrasonography correctly identified macrosomia in 87%. The cesarean rate increased slightly after the protocol was initiated (25% versus 22%), but overall, shoulder dystocia was less common (2.4% versus 1.1%).

Herbst²⁴⁶ conducted a cost-effectiveness analysis of "prophylactic" delivery (i.e., induction or cesarean) for an EFW greater than 4500 g using risk and benefit estimates from the medical literature. For an infant from a normoglycemic pregnancy weighing 4500 g or more, routine obstetric management was the least expensive alternative (\$4014 per injury-free child) compared with elective cesarean (\$5212) and induction (\$5165). However, a sensitivity analysis suggested that with a shoulder dystocia risk higher than 10% (as is the case with a fetus weighing more than 4500 g in a diabetic pregnancy), primary cesarean or early induction is somewhat more financially advantageous. Therefore, the current recommendation that cesarean delivery be considered when fetal weight is suspected to exceed 4500 g appears to confer a modest improvement in neonatal outcome.

The decision to attempt vaginal delivery or perform a cesarean delivery is inevitably based on limited and somewhat unreliable data. The patient's obstetric history, the best EFW, and the fetal adipose profile (i.e., abdomen larger than head) should all be considered. Midpelvic operative deliveries should be avoided when macrosomia is suspected, and low pelvic or even outlet operative deliveries must be approached with extreme caution if

labor is protracted. With an EFW greater than 4500 g, a prolonged second stage of labor or arrest of descent in the second stage is an indication for cesarean delivery. Most large series of diabetic pregnancies have reported a rate of 30% to 50% for cesarean delivery. The best means by which this rate can be lowered is by early and strict glycemic control in pregnancy. Conducting long labor inductions in patients with a large fetus and a marginal pelvis may increase, rather than lower, morbidity and costs.

INTRAPARTUM GLYCEMIC MANAGEMENT

Perinatal asphyxia and neonatal hypoglycemia correlate with maternal hyperglycemia during labor.²⁴⁷ Strict maternal euglycemia during labor does not guarantee newborn metabolic stability in infants with macrosomia and islet cell hypertrophy. The use of a combined insulin and glucose infusion during labor maintains the maternal plasma glucose level in a narrow range (80 to 110 mg/dL) and reduces the incidence of neonatal hypoglycemia.²⁴⁸ A protocol for continuous insulin infusion in labor is outlined in Table 59-17. Typical infusion rates are 5% dextrose in lactated Ringer solution at a rate of 100 mL/hr and lispro or aspart insulin at 0.5 to 1 U/hr. If a glucose and insulin infusion is not given, intermittent short-acting insulin can be given subcutaneously in response to glucose excursions outside the target range (90 to 110 mg/dL).

Capillary blood glucose is monitored hourly in patients with diabetes. For patients with diet-controlled GDM or mild T2DM, avoidance of dextrose in all intravenous fluids during labor usually maintains excellent glucose control.

When cesarean delivery is planned in a woman with diabetes, the procedure should be performed early in the day to avoid prolonged periods of fasting. On the night before surgery,

TABLE 59-17 Intrapartum Maternal Glycemic Control

INSULIN INFUSION METHOD

1. Withhold AM insulin injection.
2. Begin and continue glucose infusion (5% dextrose in water) at 100 mL/hr throughout labor.
3. Begin infusion of regular insulin at 0.5 U/hr.
4. Begin oxytocin as needed.
5. Monitor maternal glucose levels hourly using a capillary reflectance meter at bedside or laboratory determinations, or both.
6. Adjust insulin infusion.

Plasma/Capillary Glucose (mg/dL)	Infusion Rate (U/hr)
<80	Insulin off
80-100	0.5*
101-140	1.0
141-180	1.5
181-220	2.0*
>220	2.5*

INTERMITTENT SUBCUTANEOUS INJECTION METHOD

1. Give one half of the usual insulin dose in AM.
2. Begin and continue glucose infusion (5% dextrose in water) at 100 mL/hr throughout labor.
3. Begin oxytocin as needed.
4. Monitor maternal glucose levels hourly using a capillary reflectance meter at bedside or laboratory determinations, or both.
5. Administer regular insulin in small doses (2-5 U) to maintain glucose levels of 80-120 mg/dL.

*Intravenous bolus of 2-5 units when the rate increases.

patients should be instructed to take their full dose of NPH or glyburide. No morning insulin or glyburide should be taken. A glucose-containing intravenous line should be established promptly on arrival at the hospital, with short-acting insulin given as intravenous boluses on a sliding scale as needed every 1 to 4 hours to maintain the maternal plasma glucose level in the range of 80 to 160 mg/dL.

POSTPARTUM METABOLIC MANAGEMENT

In the recovery room and after delivery, short-acting insulin can be given subcutaneously to women with T2DM, using a sliding scale, until a regular diet is established. The basal and bolus insulin doses required after delivery are typically 30% to 50% of the preprandial doses required during pregnancy just before delivery. T1DM patients require more intensive glucose monitoring after delivery, because many experience a “honeymoon” phase in which insulin requirements fall dramatically. The glucose-insulin intravenous infusion should be continued in T1DM patients, especially those who have had a cesarean delivery, until the diet has normalized.

Management of the Neonate

NEONATAL TRANSITIONAL MANAGEMENT

Unmonitored and uncorrected neonatal hypoglycemia can lead to neonatal seizures, brain damage, and death. The degree of hypoglycemia correlates roughly with the degree of maternal glycemic control during the 6 weeks before birth. Pancreatic hypertrophy and chronic fetal hyperinsulinemia—holdovers from the chronically glucose-rich intrauterine environment—can lead to significant hypoglycemia after the umbilical supply of nutrients is interrupted by delivery. Infants of diabetic mothers also appear to have disorders of catecholamine and glucagon metabolism and have diminished capability to mount normal compensatory responses to hypoglycemia. The current recommendations specify frequent blood glucose checks and early oral feeding whenever possible (ideally from the breast), with infusion of intravenous glucose if oral measures prove insufficient. Chertok and associates compared the neonatal glucose levels of infants of mothers with GDM who were breastfed in the delivery room with those of infants fed later.²⁴⁹ They found that infants who were breastfed in the delivery room had a significantly lower rate of borderline hypoglycemia than those who were not breastfed in the early postpartum period (10% versus 28%), and they had significantly higher mean blood glucose levels compared to infants who were not breastfed in the delivery room (57 versus 48 mg/dL; $P = .03$). Additionally, breastfed infants had a significantly higher mean blood glucose level than those who were given formula for their first feeding, indicating that early breastfeeding may promote glycemic stability in infants born to women with GDM.

Ordinarily, if neonatal blood glucose levels fall into the hypoglycemic range, they can be controlled satisfactorily with

an infusion of 10% glucose. If greater amounts of glucose are required, bolus administration of 5 mL/kg of 10% glucose is recommended, with gradually increasing concentrations of glucose administered every 30 to 60 minutes, if necessary.

BREASTFEEDING

Considering the number of perinatal complications experienced by many women with diabetes (e.g., preeclampsia, macrosomia-induced cesarean delivery, neonatal hypoglycemia), achieving a high rate of breastfeeding may seem to be a superfluous goal. However, mounting evidence indicates that breastfed infants have a much lower risk of developing obesity, cardiometabolic disease, and diabetes than do those exposed to the proteins in infant formula.^{250,251} Pettitt and associates²⁵⁰ found that children who were exclusively breastfed had significantly lower rates of non-insulin-dependent diabetes mellitus than did those who were exclusively bottle-fed in all age groups. The OR for diabetes in exclusively breastfed persons, compared with exclusively formula-fed individuals, was 0.41 (CI, 0.18 to 0.93).

For women with GDM, lactation has a beneficial effect on postpartum glycemic status. Gunderson and coworkers found that, on 75-g 2-hour OGTT postpartum testing, exclusively breastfeeding women had lower FPG levels and lower prevalence of T2DM and prediabetes.²⁵³

Most neonatologists maintain strict monitoring of glucose levels in newborn infants of diabetic mothers for at least 4 to 6 hours (frequently 24 hours), often necessitating admission to a newborn special care unit. This early separation of mother and neonate impedes breastfeeding and infant attachment, and it may delay the onset of lactogenesis in the diabetic mother. Delayed lactogenesis in women with insulin-dependent diabetes tends to occur in those with poor metabolic control.

The actual techniques of infant nursing require some modification in women with overt diabetes, especially insulinopenic patients with T1DM. Increased maternal calorie and fluid intake is necessary to maintain milk supply in all women. The calorie expenditure during nursing and for the 30 to 45 minutes thereafter (probably during post-nursing lactogenesis) may precipitate severe hypoglycemia if compensatory calories are not ingested. This is especially common during nursing late at night. Breastfeeding women with T1DM should be encouraged to take in fluids and food (100 to 300 calories per feeding episode) while nursing to avoid reactive hypoglycemia.

Studies of breastfeeding women with diabetes indicate that lactation, even for a short duration, has a beneficial effect on overall maternal glucose and lipid metabolism. For postpartum women who have GDM during their pregnancies, breastfeeding may offer a practical, low-cost intervention that helps to reduce or delay the risk of subsequent diabetes.

Thyroid Disease and Pregnancy

SHAHLA NADER, MD

Thyroid disorders are among the most common endocrinopathies in young women of childbearing age. In large areas of the world, iodine deficiency is the predominant cause of these disorders. In the Western Hemisphere, these disorders are most often related to altered immunity. The hormonal and immunologic perturbations of pregnancy and the postpartum period and the dependence of the fetus on maternal iodine and thyroid hormone have profound influences on maternal thyroid function and consequently on fetal well-being. Appropriate antepartum and postpartum care requires a basic knowledge of thyroid function, its alteration in pregnancy, and the more common thyroid diseases affecting women in the setting of pregnancy, all of which are addressed in this chapter. The combination of thyroid disease and pregnancy has been the topic of a recent review,¹ and the Endocrine Society and American Thyroid Association (ATA) guidelines for management of thyroid dysfunction during pregnancy and after delivery have been published.^{2,3}

Maternal-Fetal Thyroid Physiology

NORMAL THYROID PHYSIOLOGY

The thyroid gland is located in the anterior neck below the hyoid bone and above the sternal notch. Consisting of two lobes and connected by the isthmus, it weighs approximately 20 to 25 g. Each lobe is divided into lobules, each of which contains 20 to 40 follicles. The follicle consists of follicular cells, which surround a glycoprotein material called *colloid*.

The hypothalamic-pituitary axis governs the production of thyroid hormone by the follicular cells. Tonic stimulation of thyrotropin-releasing hormone (TRH) is required to maintain normal thyroid function, and hypothalamic injury or disruption of the stalk results in hypothyroidism. TRH, a tripeptide, is produced in the paraventricular nucleus of the hypothalamus, and its local production as determined by mRNA is inversely related to concentrations of circulating thyroid hormones. Traversing the pituitary stalk, TRH is delivered to the pituitary thyrotroph by the pituitary portal circulation, and it affects the production and release of thyrotropin (i.e., thyroid-stimulating hormone [TSH]). A glycoprotein, TSH is composed of α - and β -subunits, and the β -subunit confers specificity. Control of TSH secretion occurs by negative feedback (e.g., from circulating thyroid hormone, somatostatin, dopamine) or by stimulation by TRH.

Thyroid gland production of thyroxine (T_4) and triiodothyronine (T_3) is regulated by TSH. On binding to its receptor, TSH induces thyroid growth, differentiation, and all phases of iodine metabolism from uptake of iodine to secretion of the two

thyroid hormones. In the nonpregnant state, the gland takes up 80 to 100 μg of iodine daily. Dietary iodine is reduced to iodide, which is absorbed and cleared by the kidney (80%) and thyroid (20%). Iodide is actively trapped by the thyroid and is the rate-limiting step in hormone biosynthesis. The iodide is converted back to iodine and organified by binding to tyrosyl residues, which are part of the glycoprotein thyroglobulin. This process requires the enzyme thyroid peroxidase. Iodination can give rise to monoiodotyrosine or diiodotyrosine, with the ratio depending on prevailing iodine availability. Coupling of two diiodotyrosine molecules forms T_4 , and one diiodotyrosine and one monoiodotyrosine form T_3 . Thyroglobulin is extruded into the colloid space at the center of the follicle, and thyroid hormone is stored as colloid.

Hormone secretion by thyroid cells, which is also under TSH control, involves digestion of thyroglobulin and extrusion of T_4 and T_3 into the capillaries. Daily secretion rates approximate 90 μg of T_4 and 30 μg of T_3 . Both circulate highly bound to protein (mainly thyroxine-binding globulin [TBG]), with less than 1% in free form (i.e., 0.3% of T_3 and 0.03% of T_4). Other binding proteins include thyroxine-binding prealbumin and albumin. The free form of hormone enters cells and is active.

Whereas T_4 completely originates in the thyroid, only approximately 20% of T_3 comes directly from the thyroid. Thyroxine is metabolized in most tissues (particularly in the liver and kidneys) to T_3 by deiodination. It is also metabolized to reverse T_3 , a metabolically inactive hormone. Removal of an iodine by 5'-monodeiodination from the outer ring of T_4 results in T_3 , which is metabolically active. When iodine is removed from the inner ring, reverse T_3 is produced (e-Fig. 60-1). Type I and type II monodeiodinases catalyze the formation of T_3 , whereas reverse T_3 is catalyzed by type III monodeiodinase. Normally, approximately 35% of T_4 is converted to T_3 , and 40% is converted to reverse T_3 , but this balance is shifted in favor of the metabolically inert reverse T_3 in illness, starvation, or other catabolic states.^{4,5} About 80% of circulating T_3 is derived from peripheral conversion. The half-life of T_4 is 1 week; 5 to 6 weeks are necessary before a change in dose of T_4 therapy is reflected in steady-state T_4 values. The half-life of T_3 is 1 day.

Free thyroid hormone enters the cell and binds to nuclear receptors and in this way signals its cellular responses.⁶ The affinity of T_3 for nuclear receptors is tenfold that of T_4 , which helps to explain the greater biologic activity of T_3 . Thyroid hormone receptors belong to a large superfamily of nuclear-hormone receptors that include the steroid hormone, vitamin D, and retinoic acid receptors. Thyroid hormones have diverse effects on cellular growth, development, and metabolism. The major effects of thyroid hormones are genomic, stimulating

transcription and translation of new proteins in a concentration- and time-dependent manner.

MATERNAL THYROID PHYSIOLOGY

Pregnancy alters the thyroid economy. Lazarus reviewed the hormonal changes of pregnancy, which result in profound alterations in the biochemical parameters of thyroid function.⁷

Three series of events occur at different times during gestation. Starting in the first half of gestation and continuing until term, there is an increase in TBG, a direct effect of increasing circulating estrogen concentrations. Basal levels increase twofold to threefold. This increase is accompanied by a trend toward lower free hormone concentrations (T_4 and T_3), which results in stimulation of the hypothalamic-pituitary-thyroid axis. Under conditions of iodine sufficiency, the decrease in free hormone levels is marginal (10% to 15% on average). When the supply of iodine is insufficient, more pronounced effects occur (discussed later). There is usually a trend toward a slight increase in TSH between the first trimester and term.

The second event takes place transiently during the first trimester and is a consequence of thyroid stimulation by increasing concentrations of human chorionic gonadotropin (hCG). As hCG peaks late in the first trimester, there is partial inhibition of the pituitary and transient lowering of TSH levels between 8 and 14 weeks' gestation (Fig. 60-2). In about 20% of women, the TSH level falls below the lower limit of normal, and they often have significantly higher hCG concentrations.⁸ The stimulatory action of hCG has been broadly quantified; an increment of 10,000 IU/L is associated with lowering of the basal TSH level by 0.1 mU/L. In most normal pregnancies, this is of minor consequence.⁹

In the third series of events, alterations in the peripheral metabolism of thyroid hormone occur throughout pregnancy but are more prominent in the second half. Three enzymes deiodinate thyroid hormones: types I, II, and III deiodinases. Type I is not significantly modified. Type II, which is expressed in the placenta, can maintain T_3 production locally, which can be critical when maternal T_4 concentrations are reduced. Type III is also found abundantly in the placenta, and it catalyzes the conversion of T_4 to reverse T_3 and conversion of T_3 to T_2 . This abundance may explain the low T_3 and high reverse T_3 concentrations characteristic of fetal thyroid hormone metabolism.¹⁰

These physiologic adaptations to pregnancy, which are depicted in Figure 60-3, are attained without difficulty by the normal thyroid gland in a state of iodine sufficiency. This does not apply when thyroid function is compromised or iodine supply is insufficient.

IODINE DEFICIENCY AND GOITER

Increased vascularity and some glandular hyperplasia can result in mild thyroid enlargement, but frank goiter occurs because of iodine deficiency or other thyroid disease. Although iodine deficiency is usually not a problem in the United States, Japan, and parts of Europe, 1 to 1.5 billion people in the world are at risk, with 500 million living in areas of overt iodine deficiency. The World Health Organization recommends 150 μg of iodine per day for adults and 250 μg for pregnant and lactating women, and the latter was endorsed by the Endocrine Society guidelines.² Renal iodine clearance is increased during pregnancy, and in the latter part of gestation, a significant amount of iodine is

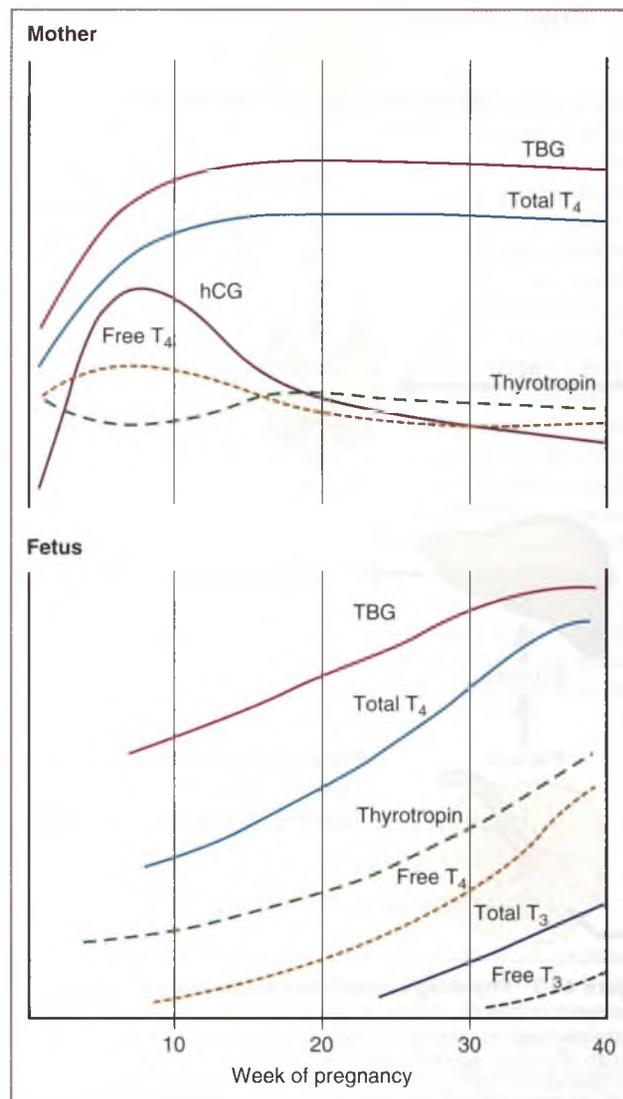

Figure 60-2 Relative changes in maternal and fetal thyroid function during pregnancy. The effects of pregnancy on the mother include a marked and early increase in hepatic production of thyroxine-binding globulin (TBG) and placental production of human chorionic gonadotropin (hCG). The increased serum level of TBG increases total serum concentrations of thyroxine (T_4). The thyrotropin-like activity of hCG stimulates maternal T_4 secretion. The transient hCG-induced increase in the serum level of free T_4 inhibits maternal secretion of thyrotropin. T_3 , triiodothyronine. (From Burrow GN, Fisher DA, Larsen PR: Maternal and fetal thyroid function, *N Engl J Med* 331:1072, 1994. Reprinted by permission.)

diverted toward the fetoplacental unit to allow the fetal thyroid to produce its own thyroid hormones. This physiologic adaptation occurs easily with minimal hypothyroxinemia and no goiter formation in areas of iodine sufficiency. Through hypothalamic-pituitary feedback, borderline iodine intake chronically enhances thyroid stimulation. The iodine deficiency manifests as greater hypothyroxinemia, which increases TSH and thyroglobulin levels and produces thyroid hypertrophy (e-Fig. 60-4).

In a study of otherwise healthy pregnant women living under conditions of relative iodine restriction, thyroid volume, as assessed by ultrasonography, increased an average of 30% during pregnancy.¹¹ In a selected group of these women with goitrogenesis, follow-up a year after delivery did not show a

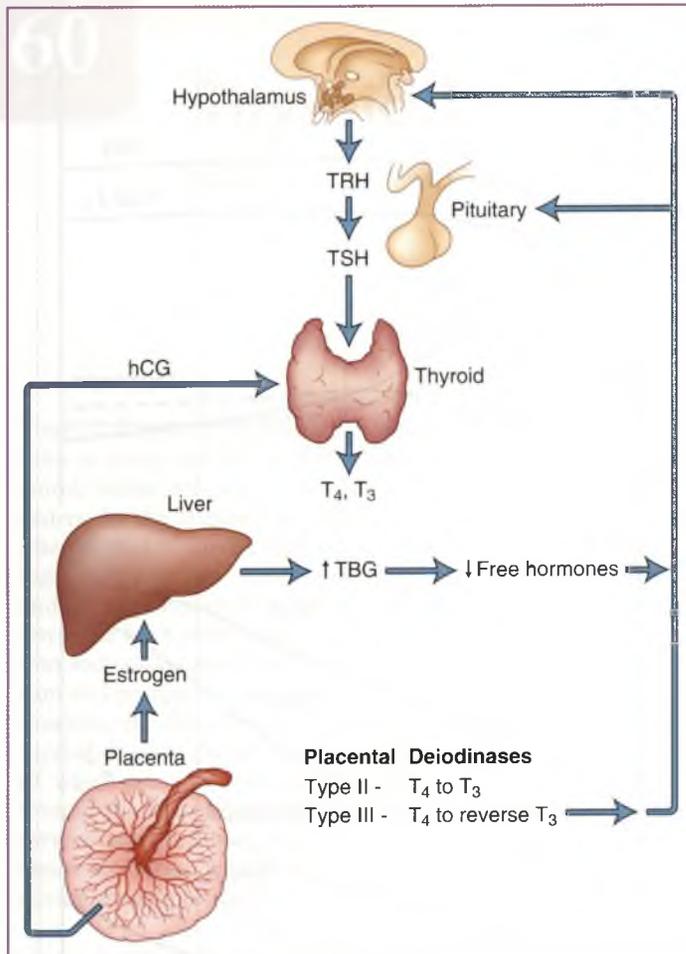

Figure 60-3 Physiologic adaptation to pregnancy. Schematic representation of the physiologic adaptation to pregnancy shows increased thyroxine-binding globulin (TBG) concentrations, increased levels of human chorionic gonadotropin (hCG) with its thyrotropin-like activity, and alterations in the peripheral metabolism of thyroid hormones in the placenta. TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone; T₄, thyroxine; T₃, triiodothyronine. (Adapted from Glinner D: *What happens to the normal thyroid during pregnancy?* *Thyroid* 9:631, 1999.)

return of thyroid volumes to those found in early pregnancy. Iodine intake should also be increased after delivery, especially in breastfeeding women. Ultrasonography revealed that thyroid volume was 38% larger in neonates of untreated mothers compared with neonates of mothers treated with iodine supplementation.¹² Neurodevelopmental outcomes were improved for children whose mothers were moderately deficient and who received iodine supplementation early in pregnancy.¹³ Even in mild iodine deficiency, prolonged iodized salt improved maternal thyroid economy and reduced the risk of maternal thyroid insufficiency during gestation.¹⁴ Iodine content of prenatal vitamins in the United States was evaluated and often found to be discordant with the labeled amount; it was recommended that only potassium iodide be used.¹⁵

In addition to iodine deficiency, goiter in pregnancy can be related to the following conditions:

- Graves disease
- Hashimoto thyroiditis

- Excessive iodine intake
- Lymphocytic thyroiditis
- Thyroid cancer
- Lymphoma
- Therapy with lithium or thionamides

In the United States, clinical studies of pregnant women and nonpregnant controls have not revealed an increase in goiter during pregnancy.¹⁶ Ultrasound studies from other areas replete with iodine have confirmed these findings.¹⁷

IODINE METABOLISM IN PREGNANCY

Although radioactive iodine is absolutely contraindicated in pregnancy, early studies using iodine 132 (¹³²I) showed a three-fold increase in thyroid iodine clearance in pregnant women. Another set of studies enrolling 25 pregnant women also revealed increased radioactive iodine uptake during pregnancy compared with the nonpregnant or postpartum state.¹⁸ The mean renal iodine clearance almost doubles because of increased renal blood flow and an increase in the glomerular filtration rate of as much as 50%. If iodine excretion is greater than 100 μg in a 24-hour period, the patient's iodine intake is assumed to be sufficient.¹⁹

Placental-Fetal Thyroid Physiology

The thyroid gland forms as a midline outpouching of the anterior pharyngeal floor, migrates caudally, and reaches its final position by 7 weeks' gestation. Lateral contributions from the fourth and fifth pharyngeal pouches give it its bilateral shape by 8 to 9 weeks' gestation. Active trapping of iodide is detectable by week 12, and the first indication of T₄ production is detectable by week 14. Hypothalamic TRH is detectable at weeks 8 to 9, and the pituitary portal circulation is functional by weeks 10 to 12. Until mid-gestation, fetal TSH and T₄ concentrations remain low. At 18 to 20 weeks' gestation, the fetal thyroid gland's iodine uptake and serum T₄ concentrations begin to increase.²⁰ Concentrations of T₄ increase from 2 μg/dL at 20 weeks to 10 μg/dL at term, with increasing TBG concentrations contributing to this rise. Similarly, free fetal T₄ concentrations increase from 0.1 ng/dL at 12 weeks' gestation to 1.5 ng/dL near term. Increases in T₃ and free T₃ are smaller, presumably because of the availability of placental type III deiodinase, which converts T₄ rapidly to reverse T₃. The fetal serum T₃ concentration increases from 6 ng/dL at 12 weeks' gestation to 45 ng/dL near term. Fetal serum TSH levels increase from 4 to 8 mU/L between weeks 12 and term.^{21,22} In summary, most fetal T₄ is inactivated to reverse T₃. The availability of T₃ (from T₄ conversion or direct fetal thyroid secretion) is limited. Fetal tissues that depend on T₃ for development (e.g., brain structures) are supplied by local T₄ to T₃ conversion catalyzed by type II deiodinase.^{22,23}

PLACENTAL TRANSFER OF THYROID HORMONES

Although earlier studies suggested only limited T₄ and T₃ transfer through the placenta, later studies have shown that T₄ can be found in first-trimester coelomic fluid by 6 weeks' gestation. Nuclear T₃ receptors can be identified in the brain of 10-week-old fetuses, and they increase tenfold by 16 weeks' gestation before the fetal thyroid becomes fully functional.²⁴ These studies suggest that maternal T₄ transfer occurs early in gestation and

that low levels of T_4 are sustained in the fetus at this time.²⁵ Vulsma and colleagues²⁶ reported that cord serum T_4 levels in hypothyroid neonates with glandular agenesis represented as much as 30% of normal circulating values, a strong indication of maternal T_4 transfer, although this has not been a uniform finding.²⁷

It appears that the first phase of maximum growth velocity of developing brain structures—neuronal multiplication and organization occurring during the second trimester—corresponds to a phase during which the supply of thyroid hormones to the fetus is almost exclusively of maternal origin.²⁰ In the second phase of maximum fetal brain growth velocity, occurring from the third trimester to 2 to 3 years postnatally, the supply of thyroid hormone is of fetal and neonatal origin. Low maternal thyroxine concentrations in the second trimester can result in irreversible neurologic deficit in offspring. When it occurs later, the damage to the fetal brain is less and is partially reversible. The need for T_3 by mid-gestation for development of the human cerebral cortex was also demonstrated by Kester and associates.²⁸ Concentrations of TSH, T_4 , T_3 , and reverse T_3 are measurable in the amniotic fluid and correlate with the fetal rather than maternal serum levels.

NEONATAL THYROID FUNCTION

Immediately after birth, there is a surge of TRH and TSH that is followed by an increase in T_3 (from increased T_4 to T_3 conversion) and a moderate increase in T_4 levels.¹⁰ Within a few days, the increased TSH falls to adult levels through T_4 and T_3 negative-feedback inhibition. Neonatal T_4 and T_3 concentrations return to normal adult levels within 4 to 6 weeks.²⁹ Transient hyperthyroxinemia can be triggered by neonatal cooling and may represent an adaptation of thermogenesis to extrauterine life.^{30,31}

In premature neonates, free T_4 levels are low, TSH levels are normal (adult), and T_4 levels are related to gestational age. The clinical consequence of this transient hypothalamic hypothyroidism is unknown, but it has been associated with impaired neurologic and mental development.^{32,34}

PLACENTAL TRANSFER OF DRUGS AFFECTING THYROID FUNCTION

The potential influence of the placenta on fetal thyroid and neurologic development is evident by the ready transfer of several agents that affect thyroid function,^{35,36} including the following:

- Iodine
- Thionamides
- β -Adrenergic receptor blockers
- Somatostatin
- Exogenous TRH
- Dopamine agonists and antagonists
- Thyroid-stimulating immunoglobulins and other antibodies

TSH does not cross the placenta. TRH and corticosteroid administered antenatally before 32 weeks' gestation stimulates T_4 release and decreases the frequency of chronic lung disease among neonates.³⁷ Intra-amniotic administration of T_4 in the preterm setting increases fetal maturation, as reflected by an increase in the lecithin-to-sphingomyelin ratio and a decrease in respiratory distress syndrome of the newborn.³⁸

Pregnancy, the Immune System, and Thyroid Disease

Chapter 6 offers a detailed review of pregnancy immunology. The fetus, with its complete set of paternal antigens, survives because of adjustments in the maternal-placental-fetal immune systems. This immunologic compromise of pregnancy is orchestrated primarily by the placental tissues and passaged fetal cells that are able to modulate the local and systemic maternal immune responses.^{39,40} Autoimmune responses are usually reduced in pregnancy, as evidenced by amelioration of Graves disease, rheumatoid arthritis, and multiple sclerosis.^{41,42} Although there is a shift from proinflammatory type 1 helper T cell (T_H1) cytokines to T_H2 cytokines, driven perhaps by progesterone,⁴³ it is occurring against a background of reduced B-cell reactivity. The reduced B-cell responses are likely orchestrated by placental sex steroids, which are powerful negative regulators of B-cell activity. Whereas most of the immune changes in pregnancy return to normal by 12 months after delivery, there is a marked increase after most pregnancies in many different types of autoantibody secretion and an exacerbation of autoimmune disease. In most studies, total immunoglobulin G and autoantibody levels rise above pre-pregnancy levels during the first 6 months after delivery, suggesting continuing nonspecific immune stimulation.³⁹

Laboratory Evaluation of Thyroid Function during Pregnancy

THYROTROPIN AND THYROID HORMONES

Total T_4 and total T_3 levels are elevated because of increased TBG production and reduced clearance induced by the hyperestrogenic state of pregnancy. The normal reference range for total T_4 should be adjusted by a factor of 1.5 for pregnant patients.⁴⁴ The T_3 resin uptake (i.e., indirect laboratory measure of available TBG binding sites) is reduced in pregnancy because increased TBG binding sites take up more of the added T_3 , leaving less to bind to resin. The free thyroxine index, which is a product of the total T_4 and T_3 resin uptake, usually falls to within the normal range in pregnancy.

Third-generation TSH and free T_4 assessments are often used to evaluate thyroid function in pregnancy. However, automated free T_4 assays are sensitive to the alternations in binding proteins that occur in pregnancy and can falsely elevate or lower the free T_4 assay result. The free T_4 , as measured by equilibrium dialysis, is not affected by these protein changes. The measurement of free thyroxine (T_4) by two different immunoassays were so misleading that 57% to 68% of pregnant subjects were diagnosed incorrectly as having hypothyroxinemia in the report.⁴⁴ Immunoassays of free T_4 should be used with caution during pregnancy until their interpretation is improved and validated. If needed, a free T_4 index using the product of total T_4 and T_3 resin uptake should be used. Alternatively, the nonpregnant T_4 range can be adapted in the second and third trimester by multiplying this range by 1.5-fold.⁴⁴ This was specifically recommended by the Endocrine Society, with use of the free T_4 index as an alternative.² The ATA recommends measurement of T_4 in the ultrafiltrate of serum employing online extraction, liquid chromatography, and tandem mass spectrometry. They further suggest that if this is not available, another measure or estimate

of free T_4 should be used while remaining aware of the limitations of each method.³ These methodologies were addressed in depth by Soldin after the publication of the Endocrine Society guidelines because the guidelines did not have a section on thyroid hormone testing.⁴⁵

If TSH is suppressed, suggesting overproduction of thyroid hormones, the free T_3 level can be determined. The third-generation TSH assays can differentiate profound from marginal suppression. Trimester-specific TSH concentrations were obtained by Dashe and colleagues,⁴⁶ who determined these concentrations at each point during gestation in singleton and twin pregnancies. They constructed nomograms for both using regression analysis and showed significantly lower TSH concentrations in the first trimester. These levels were lower in twin pregnancies, as would be expected from the known effects of hCG. Values were converted to multiples of the median for singleton pregnancies at each week of gestation, and they suggested that values expressed this way might facilitate comparison across laboratories and populations.

In another study, using sensitive TSH assays, 9% of nonsymptomatic first-trimester women were found to have TSH values higher than 0.05 mIU/L (i.e., lower limit of assay detection) but less than 0.4 mIU/L, and another 9% had TSH values below the detection limit.⁸ The ATA guidelines recommend the use of trimester-specific reference ranges for TSH, as defined in populations with optimal iodine intake, and if trimester-specific ranges are not available, the following are recommended: 0.1 to 2.5 mIU/L in the first trimester, 0.2 to 3.0 mIU/L in the second trimester, and 0.3 to 3.0 mIU/L in the third trimester.³ Free T_3 and T_4 concentrations can be in the high-normal range early in pregnancy because of the stimulatory effects of hCG. Free T_4 levels tend to fall through the rest of pregnancy and occasionally to levels below those of nonpregnant women.¹ Table 60-1 outlines factors that influence TBG and therefore total hormone concentrations.

Resistance to thyroid hormone is a rare condition encompassing several defects. The pituitary and other peripheral tissues can manifest this resistance. These patients present with an increased free T_4 concentration along with an inappropriately elevated or nonsuppressed TSH, and they may have goiters. Whereas patients with thyroid hormone resistance have normal α -subunit concentrations, patients with TSH-secreting tumors (i.e., differential diagnosis of thyroid hormone resistance) often have elevated serum α -subunit levels.⁴⁷ In a case reported by Anselmo and colleagues,⁴⁸ transient thyrotoxicosis occurred during pregnancy in a woman with resistance to thyroid hormone caused by a mutation in the thyroid receptor- β gene (*THRB*). This thyrotoxicosis manifested clinically by hypermetabolic features and paralleled the rise and peak of hCG concentrations. Symptoms ameliorated and thyroid hormone

concentrations declined as pregnancy progressed and hCG concentrations fell.

Concern has been raised regarding unaffected fetuses of mothers with thyroid hormone resistance. Outcomes of pregnancies in an extended Azorean family with resistance to thyroid hormone were analyzed. Miscarriages were found to be more common, and unaffected infants born to affected mothers had lower birth weights, demonstrating a direct toxic effect of thyroid hormone excess on the fetus.⁴⁹ Approach to the patient with thyroid hormone resistance was discussed by Weiss and colleagues.⁵⁰ For correct management and if the thyroid hormone receptor mutation is known in the mother, the fetus can be genotyped from DNA obtained at amniocentesis.

THYROTROPIN RECEPTOR ANTIBODIES

Several functional types of TSH receptor antibodies are recognized. Some antibodies promote gland function (i.e., thyroid-stimulating immunoglobulins [TSIs]), some inhibit binding of TSH to its receptor (i.e., thyroid-binding inhibitory immunoglobulins [TBIs]), and some enhance or inhibit thyroid growth. These antibodies can be measured by a variety of bioassays and receptor assays. For example, maternal production of TSIs causes maternal Graves disease. TSIs are transferred across the placenta and can lead to neonatal Graves disease. Excess TBIs can cause maternal and neonatal hypothyroidism.

ANTITHYROID ANTIBODIES

The two most commonly determined antithyroid antibodies are those to thyroglobulin and to thyroid peroxidase (anti-TPO).⁵¹ Among nonpregnant women, the incidence of anti-TPO antibodies is about 3%, with the incidence ranging from 5% to 15% among pregnant women. A substantial proportion of women with positive anti-TPO antibodies in early pregnancy develop postpartum thyroiditis.^{52,53}

DRUGS AND THYROID FUNCTION

Box 60-1 outlines drug effects on thyroid function and metabolism, absorption of thyroid hormones, and interpretation of thyroid function tests. Iodine and lithium inhibit thyroid function. Propranolol and ipodate block T_4 to T_3 conversion, as do glucocorticoids; however, glucocorticoids also reduce release of TSH from the pituitary, as do dopamine, dopamine agonists, and somatostatin. The antiepileptic medication phenytoin reduces total T_4 levels (up to 30%) by inhibiting the binding of thyroid hormones to binding proteins and increasing T_4 clearance. Ferrous sulfate, aluminum hydroxide, and sucralfate may inhibit thyroid hormone absorption substantially—an important interaction in pregnant women who are taking iron and thyroid hormones.

Amiodarone, an iodine-rich drug, has been used in pregnancy to treat maternal or fetal tachyarrhythmias. Amiodarone is transferred across the placenta, exposing the fetus to the drug and an iodine overload. Because the fetus does not acquire the capacity to escape the acute Wolff-Chaikoff effect (i.e., decrease in peroxidase activity and organification that follow iodine excess) until late in gestation, the iodine overload can cause fetal or neonatal hypothyroidism and goiter. Among 64 pregnancies in which amiodarone was given to the mother, 17% of progeny developed goitrous or nongoitrous hypothyroidism. Hypothyroidism was transient, although a few of the infants were treated

TABLE 60-1 Factors Influencing Thyroxine-Binding Globulin (TBG)

Factors Increasing TBG Levels	Factors Decreasing TBG Levels
Oral contraceptives	Testosterone
Pregnancy	Nephrotic syndrome

short term with thyroid hormones. Only two newborns had transient hyperthyroxinemia. Although breastfeeding resulted in substantial infant amiodarone ingestion, it did not cause major changes in neonatal thyroid function. The study authors concluded that amiodarone should be used only when tachyarrhythmias are unresponsive to other drugs and are life-threatening and that hypothyroid neonates (and perhaps the fetus in utero) should be treated. It is prudent to monitor the infants of breastfeeding mothers who continue to use the medication.⁵⁴

NONTHYROID ILLNESS AND THYROID FUNCTION

Nonthyroid illness has been the topic of various reviews and commentaries.^{4,5,55} Severely ill patients can manifest thyroid function test abnormalities that may correlate with functional inhibition of the hypothalamic-pituitary-thyroid axis, impaired T₄ to T₃ conversion (a constant accompaniment of nonthyroid illness), and abnormalities in binding and clearance of thyroid hormone. Reverse T₃ levels are substantially elevated because of increased T₄ to reverse T₃ conversion and impaired metabolic clearance of reverse T₃. TSH concentrations can be low, normal, or elevated, although they are seldom higher than 20 mU/L.⁵⁵ The more severe the illness, the lower the T₄ values, and this relationship has been used as a prognostic indicator because a low T₄ value correlates well with a fatal outcome.⁵⁶ The best test for assessing thyroid function in severely or chronically ill

patients is the free T₄ concentration. Despite the low T₃ and total T₄ state, this situation does not represent true hypothyroidism but rather is an adaptation to stress, and it should not be treated.

Thyroid Dysfunction and Reproductive Disorders

Thyroid hormones are important for normal reproductive function. Deficiency of thyroid hormone can result in delayed sexual development. As reviewed by Winters and Berga⁵⁷ and Krassas,⁵⁸ all women with infertility and menstrual disturbances should have thyroid function tests for T₄, T₃, and TSH. Women with type 1 diabetes, who have a relatively high incidence of hypothyroidism, should undergo screening before conception. This topic has been reviewed by Krassas and colleagues.⁵⁹

HYPERTHYROIDISM

Hyperthyroidism has been linked to oligomenorrhea, hypomenorrhea, amenorrhea, and infertility, although many thyrotoxic women remain ovulatory. In one survey, only 21.5% of 214 thyrotoxic patients had menstrual disturbances, compared with 50% to 60% in older series.⁶⁰ Thyroxine upregulates the production of sex hormone-binding globulin. Elevated levels of circulating testosterone and estrogen may be observed, and the clearance of testosterone is reduced. Gonadotropin concentrations can be tonically elevated.^{61,62} The substantial weight loss seen in some hyperthyroid patients can affect the hypothalamic-pituitary-gonadal axis and can contribute to the infertility of severe hyperthyroidism.

HYPOTHYROIDISM

Hypothyroidism in fetal life does not affect the development of the reproductive tract, but during childhood, it leads to sexual immaturity and usually a delay in puberty, followed by anovulatory cycles. Almost 25% of women with untreated hypothyroidism have menstrual irregularities. Menorrhagia occurs frequently and can reflect interference with the endometrial maturational process and response to ovarian steroids; it usually responds to thyroxine treatment.⁶³ The increased miscarriage rate for hypothyroid patients may reflect disrupted endometrial maturation. Through increased TRH levels, hypothyroidism can be associated with hyperprolactinemia, which can disrupt reproductive function and menstrual cyclicity⁶⁴ and lead to oligomenorrhea or amenorrhea. Galactorrhea can sometimes be seen in this setting, as can elevated levels of luteinizing hormone that may result from diminished dopamine secretion.⁶⁵

Women with hypothyroidism have diminished rates of metabolic clearance of androstenedione and estrone and an increase in peripheral aromatization. Plasma concentrations of testosterone and estradiol are decreased because of diminished binding activity, but their unbound fractions are increased. Several studies have suggested an increased risk of miscarriage in the setting of thyroid antibodies, even in the face of a euthyroid status. A meta-analysis confirmed the increased risk of miscarriage in euthyroid women with thyroid autoimmunity with a pooled relative risk of 2.31 in 14 cohort studies.⁶⁶ Although previous studies did not demonstrate benefit in using T₄ to treat euthyroid women with recurrent spontaneous abortions,^{67,68} benefit was shown by Negro and colleagues⁶⁹ in a

group of 115 antibody-positive women, one half of whom received thyroxine. Treatment decreased the rates of miscarriages and prematurity by 75% and 69%, respectively. An accompanying editorial⁷⁰ reaffirmed the statistical strength of the association between miscarriages and autoimmune thyroid disease. Because there is no reason to believe that thyroxine treatment altered autoimmunity, it was thought that the subtle deficiency in thyroid hormone concentration or reduced ability of maternal thyroid function to adapt adequately in women with autoimmune thyroid disease was the main reason for the beneficial effects of thyroid hormone administration.

ATA guidelines³ state that there is insufficient evidence to recommend for or against screening for thyroid antibodies or for treatment in the first trimester of pregnancy with T₄ or intravenous immunoglobulin in euthyroid women with sporadic or recurrent abortion or in women undergoing in vitro fertilization. The Endocrine Society did not recommend such screening or treatment.² Overt hypothyroidism has been associated with increased spontaneous abortion, premature delivery, low-birth-weight (LBW) infants, fetal distress in labor, and perhaps gestation-induced hypertension and placental abruption. The link between subclinical hypothyroidism and such outcomes is less evident (discussed later).

RADIOIODINE AND GONADAL FUNCTION

The prevalence of infertility, premature births, miscarriage, and genetic damage in the offspring of women treated with radioactive iodine for thyrotoxicosis does not seem to be increased.⁷¹ Although doses of ¹³¹I for thyroid cancer may be associated with subsequent menstrual irregularities in approximately 30% of patients, exposure to radioiodine does not appear to reduce fecundity.⁷² In a large study, Schlumberger and associates⁷³ obtained data on 2113 pregnancies conceived after exposure to 30 to 100 mCi of radioiodine given for thyroid cancer. The incidences of stillbirths, preterm labor, LBW infants, congenital malformations, and death during the first year of life were not significantly different between pregnancies conceived before or after radioiodine therapy. The miscarriage rate in an update was not significantly different in treated or untreated women.⁷⁴ In a 2011 article, Sioka and Fotopoulos reported similar conclusions.⁷⁵

All women need pregnancy tests before ¹³¹I treatment. Treatment late in the first trimester and in the second trimester may result in irreversible hypothyroidism in the fetus. Lactating mothers who have received diagnostic or therapeutic doses of ¹³¹I should not breastfeed their infants. The use of radioiodine in pregnancy has been reviewed by Gorman⁷⁶ and Berlin.⁷⁷

Hyperthyroidism

SIGNS AND SYMPTOMS

The prevalence of hyperthyroidism in pregnant women ranges from 0.05% to 0.2%.⁷⁸ The signs and symptoms of mild to moderate hyperthyroidism—heat intolerance, diaphoresis, fatigue, anxiety, emotional lability, tachycardia, and a wide pulse pressure—can be mimicked by the hypermetabolic state of normal pregnancy. However, weight loss, tachycardia greater than 100 beats/min, and diffuse goiter are features that may suggest hyperthyroidism. Graves ophthalmopathy can be helpful but does not necessarily indicate active thyrotoxicosis.⁷⁹ Gastrointestinal

symptoms such as severe nausea and excessive vomiting can accompany thyrotoxicosis in pregnancy, as can diarrhea, myopathy, lymphadenopathy, and congestive heart failure.

DIAGNOSIS

Biochemical confirmation of the hyperthyroid state can be obtained through laboratory measurement of free T₄, free T₃, and TSH levels. Typically, elevated values for free T₄ and T₃ and greatly suppressed TSH values are found, but a normal free T₄ level can be seen in cases of T₃ toxicosis. Other laboratory features include normochromic, normocytic anemia; mild neutropenia; elevated levels of liver enzymes and alkaline phosphatase; and mild hypercalcemia. Patients may test positive for antithyroid antibodies (i.e., antithyroglobulin and antithyroid peroxidase), but they are not specific to Graves disease. TSIs are considered to be the antibodies specific to Graves disease, and they can be measured by bioassays or receptor assays.⁸⁰

DIFFERENTIAL DIAGNOSIS

Causes of hyperthyroidism are outlined in Box 60-2. Approximately 90% to 95% of hyperthyroid pregnant women have Graves disease, which can be diagnosed with certainty in a thyrotoxic pregnant woman who has diffuse thyromegaly with a bruit and ophthalmopathy. Whereas excess circulating thyroid hormones cause lid retraction and lid lag, proptosis and external ocular muscle palsies reflect the infiltrative ophthalmopathy of Graves disease. Graves disease is an autoimmune disease mediated by antibodies (i.e., TSIs) that activate the TSH receptor and stimulate thyroid follicular cells. It affects 3% of women of reproductive age.⁸¹

TREATMENT

The outcome of treatment before pregnancy is better than that of treatment during pregnancy,⁸² and hyperthyroidism is therefore best treated before conception. If untreated or treated inadequately, women may have more complications during pregnancy and delivery. Very mild cases of hyperthyroidism, with adequate weight gain and appropriate obstetric progress, may be followed carefully, but moderate or severe cases must be treated. In a retrospective study of 60 thyrotoxic pregnant women, rates of preterm delivery, perinatal mortality, and maternal heart failure were significantly increased among

BOX 60-2 CAUSES OF HYPERTHYROIDISM IN PREGNANCY

- Graves disease
- Toxic adenoma
- Toxic multinodular goiter
- Hyperemesis gravidarum
- Gestational trophoblastic disease
- TSH-producing pituitary tumor
- Metastatic follicular cell carcinoma
- Exogenous T₄ and T₃
- De Quervain (subacute) thyroiditis
- Painless lymphocytic thyroiditis
- Struma ovarii

TSH, thyroid-stimulating hormone; T₃, L-triiodothyronine; T₄, L-thyroxine.

women who remained thyrotoxic. Thyroid hormone status at delivery correlated directly with pregnancy outcome.⁸² In another study by Momotani and Ito,⁸³ hyperthyroidism at conception was associated with a 25% rate of abortion and 15% rate of premature delivery, compared with 14% and 10%, respectively, for euthyroid patients. Preeclampsia has also been associated with uncontrolled hyperthyroidism.⁸⁴

Thionamide Therapy

Thionamide therapy has been reviewed by Clark and associates.⁸⁵ The thionamides inhibit the iodination of thyroglobulin and thyroglobulin synthesis by competing with iodine for the enzyme peroxidase. Propylthiouracil (PTU) (but not methimazole) also inhibits the conversion of T_4 to T_3 .

The goal of therapy is to control the hyperthyroidism without causing fetal or neonatal hypothyroidism. Maternal free T_4 should be maintained in the high-normal range or total T_4 at 1.5 times the upper limit of normal (nonpregnant) range. Until recently, PTU was considered the drug of choice in young women who may become pregnant and in pregnant patients with hyperthyroidism. This preference was based on reports of methimazole embryopathy that was not seen with PTU, although a later report linked PTU with cutis aplasia, a scalp deformity.⁸⁶ Reports describing higher hepatotoxicity profiles for PTU compared with methimazole, especially in children and adolescents, have raised concern regarding the use of PTU in the management of hyperthyroidism even in pregnant patients.^{87,88} These concerns had to be balanced by the known embryopathy associated with methimazole. The transplacental passage of the two drugs is similar.⁸⁹ Methimazole may cause cutis aplasia, a scalp deformity.⁹⁰⁻⁹² Although rare, there are reports of methimazole and carbimazole embryopathy with choanal atresia, tracheoesophageal fistula, and facial anomalies.⁹³⁻⁹⁶

The U.S. Food and Drug Administration advises health care professionals to reserve PTU for patients in the first trimester of pregnancy or for those who are intolerant of or allergic to methimazole. When switching from PTU to methimazole, thyroid function should be assessed after 2 weeks and then at 2- to 4-week intervals. Methimazole may also be used if PTU is not available or the patient has an adverse response to PTU. The new Endocrine Society and ATA guidelines also recommend PTU in the first trimester.^{2,3} PTU is given every 8 hours at doses of 100 to 150 mg (300 to 450 mg total daily dosage) according to thyrotoxicosis severity. Equivalent doses of PTU relative to methimazole are 10:1 or 15:1 (100 mg of PTU is equivalent to 7.5 to 10 mg of methimazole).³ Usual starting doses are up to 300 mg of PTU and up to 20 mg of methimazole. The occasional patient may require higher doses because the risk of uncontrolled hyperthyroidism is greater than that of high-dose PTU or methimazole.⁸² It can take 6 to 8 weeks for major clinical effects to manifest.

After the patient is euthyroid (reflected by monthly free T_4 and free T_3 values), the dose of antithyroid drugs should be tapered (e.g., halved), with further reduction as the pregnancy progresses. For many patients, antithyroid drugs can be discontinued by 32 to 36 weeks' gestation, because remission of Graves disease during pregnancy is commonly observed, although relapse often occurs after delivery. It has been suggested that a change from stimulatory to blocking antibody activity may contribute to this remission.⁹⁷

Maternal side effects of PTU or methimazole treatment can include rash ($\leq 5\%$), pruritus, drug-related fever, hepatitis, a

lupus-like syndrome, and bronchospasm. The alternative thionamide can be used, although cross-sensitivity occurs in 50% of patients. Agranulocytosis, which is the most serious side effect, develops in only 0.1%, occurring especially in older women and those receiving higher doses. All patients experiencing fever or unexpected sore throat on therapy should discontinue the drug and have white blood cell count monitoring. Agranulocytosis is a contraindication to further thionamide therapy; the blood count gradually improves over days or weeks.

The risks of untreated hyperthyroidism need to be considered in relation to the risk of antithyroid medications. The risks appear to correlate with the control and severity of the hyperthyroidism. In a study of hyperthyroid pregnant women, the odds ratio for LBW infants was 2.4 for those treated during pregnancy and 9.2 for those uncontrolled during pregnancy compared with a group of women who were euthyroid and remained so. Similarly, prematurity was more common in the hyperthyroid group; the odds ratio was 2.8 for the controlled group and 16.5 for the uncontrolled group. Similar findings were reported for preeclampsia, with an odds ratio of 4.7 for the controlled group,⁸⁴ and confirmed by a later study.⁹⁸ Higher frequencies of small-for-gestational-age births, congestive heart failure, and stillbirths have been found.^{82,99} It is uncertain whether untreated Graves disease is associated with a higher frequency of congenital malformation.¹⁰⁰

Infants of mothers receiving thionamides should be evaluated ultrasonographically for signs of hypothyroidism, such as goiter, bradycardia, and intrauterine growth restriction. If needed, cordocentesis may be performed and fetal thyroid function determined; reference ranges have been reported.¹⁰¹ Doses of thionamides should be adjusted to keep free T_4 level in the upper-normal range and TSH level less than 0.5 mU/L during pregnancy to avoid hypothyroidism in the fetus. The drugs can often be stopped in late gestation.

PTU is not significantly concentrated in breast milk (10% of serum) and does not appear to affect the infant's thyroid hormone levels in any major way. Methimazole also does not appear to affect subsequent somatic or intellectual growth in children exposed to it during lactation.^{102,103} Antithyroid medication should be taken just after breastfeeding, allowing a 3- to 4-hour interval before the woman lactates again. In patients who are in remission, the postpartum period of a subsequent pregnancy is significantly associated with relapse of Graves disease compared with those without a subsequent pregnancy.¹⁰⁴

β -Blockers

β -Blockers are useful for the control of adrenergic symptoms, particularly maternal heart rate. Propranolol is commonly used in doses of 20 to 40 mg two or three times daily, and it inhibits T_4 to T_3 conversion. Alternatively, other β -blockers may be used (except atenolol, which is category D),¹ and in an emergency, esmolol, an ultrashort-acting, cardioselective, intravenous β -blocker, has been used successfully.¹⁰⁵ Prolonged therapy with β -blockers can be associated with intrauterine growth restriction, fetal bradycardia, and hypoglycemia.

Iodides

Iodides decrease circulating T_4 and T_3 levels by up to 50% within 10 days by acutely inhibiting the release of stored hormone. Their use is appropriate in combination with thionamides (which should be started before the iodide) and

β -blockers in patients with severe thyrotoxicosis or thyroid storm. A saturated solution of potassium iodide (SSKI) is administered as 5 drops every 8 hours. Sodium ipodate, a radiographic contrast agent, is an alternative that has the added benefit of inhibiting conversion of T_4 to T_3 . Its safety in pregnancy has not been documented.

Because iodides cross the placenta readily, they should be used for no longer than 2 weeks, or fetal goiter can result. Inadvertent use of iodides also follows use of Betadine cleansing solutions, iodine-containing bronchodilators, and the drug amiodarone.

^{131}I thyroid ablation is contraindicated in pregnancy because the radioactive iodine is concentrated in the fetal thyroid after 10 to 12 weeks' gestation. If a woman inadvertently receives ^{131}I during pregnancy, SSKI should be given immediately along with PTU or methimazole to block organification and reduce radiation exposure to the fetal thyroid by a factor of 100 and to the fetal whole body by a factor of 10. To be of benefit, SSKI and thionamide treatment must be given within 7 to 10 days of exposure.⁷⁶

Surgery

In selected cases of thyrotoxicosis, surgery can be performed in the pregnant patient if the patient has severe reactions to thionamides, persistently high doses are required, or the patient is noncompliant with uncontrolled hyperthyroidism. Two weeks of low-dose iodine therapy, such as one or two drops of SSKI daily, can reduce gland vascularity preoperatively. Surgery is best performed in the second trimester, although it can be done in the first or third trimester. The risks are those of anesthesia, hypoparathyroidism, and recurrent laryngeal nerve paralysis.

Thyroid Storm Therapy

Thyroid storm is a life-threatening exacerbation of thyrotoxicosis. Criteria for its diagnosis have been introduced,¹⁰⁶ and the classic findings are various degrees of thermoregulatory dysfunction, central nervous system effects (e.g., agitation, delirium, coma), gastrointestinal dysfunction, and cardiovascular problems manifesting as tachycardia or heart failure. For example, a patient with a temperature of 102°F who is agitated and tachycardic with a pulse rate exceeding 130 beats/min would be diagnosed with thyroid storm. Although it rarely occurs in pregnancy, it may be precipitated by labor

and delivery, cesarean section, infection, or preeclampsia.¹⁰⁷ Thyrotoxic cardiomyopathy may also lead to heart failure in pregnancy.¹⁰⁸ Intensive care treatment with fluid and nutritional support is necessary for thyroid storm and heart failure. A loading dose of 600 mg of PTU may be given orally or through a nasogastric tube, and 200 to 300 mg of PTU is continued every 6 hours. An hour after the initial dose of PTU, iodine is given as 2 to 5 drops of SSKI every 8 hours (or 500 to 1000 mg of intravenous sodium iodide every 8 hours) to inhibit thyroid hormone release. If the patient is iodine allergic, lithium (300 mg every 6 hours) is an alternative. Dexamethasone (2 mg every 6 hours for four doses) is given to block T_4 to T_3 conversion. For tachycardia exceeding 120 beats/min, β -blockers such as propranolol (20 to 80 mg every 4 to 6 hours), labetalol, or esmolol may be used. Table 60-2 summarizes the management of thyroid storm.

OTHER FORMS OF HYPERTHYROIDISM

Subclinical Hyperthyroidism

Subclinical hyperthyroidism, as defined by suppressed TSH and normal free T_4 and free T_3 levels, is seen in pregnancy. In a study by Casey and associates,¹⁰⁹ 1.7% of women screened had subclinical hyperthyroidism, which they defined as TSH values at or below the 2.5th percentile for gestational age and a free T_4 level of 1.75 ng/dL or less. Rates of pregnancy complications, morbidity, and mortality were not increased among these women, and it was recommended that treatment in pregnancy was unwarranted.

Fetal and Neonatal Hyperthyroidism

Hyperthyroidism in fetuses and neonates is usually produced by transplacental passage of TSIs and activation of the fetal thyroid, occurring in 1% of offspring of these women. Although they are a common component of active Graves disease, the antibodies can continue to be present in the maternal circulation after surgical (e-Fig. 60-5) or radioactive iodine ablation or even in patients with Hashimoto thyroiditis.

Maternal TSI levels in excess of 300% of control values predict fetal hyperthyroidism⁹⁹ and should be measured at 20 to 22 weeks in mothers with current Graves disease, prior treatment for the disease with radioactive ^{131}I or thyroidectomy, a previous neonate with Graves disease, or those with previously

TABLE 60-2 Treatment of Thyroid Storm

Treatment	Rationale and Cautions	Dosage
General care	Intensive management achieved with intravenous fluid hydration and nutritional support	
Propylthiouracil		Initial: 600 mg orally or crushed and given by NG tube Maintenance: 200-300 mg every 6 hr given orally or by NG tube
Iodide	Initial dose to be given 1 hr after start of PTU	2-5 drops of supersaturated solution of potassium iodide every 8 hr or 500-1000 mg of intravenous sodium iodide infusion every 12 hr
Lithium carbonate	Used if patient is allergic to iodine	300 mg every 6 hr
Dexamethasone	Given to block T_4 to T_3 conversion	2 mg every 6 hr for four doses
β -Blockers	Given to control tachycardia ≥ 120 beats/min (use cautiously if patient in heart failure)	IV propranolol at 1 mg/min up to several doses until blockade is achieved and concurrent 20-80 mg of propranolol (PO or NG tube) every 6 hr or IV loading dose of 250-500 $\mu\text{g}/\text{kg}$ of esmolol, followed by infusion at 50-100 $\mu\text{g}/\text{kg}/\text{min}$

IV, intravenous; NG, nasogastric; PO, orally; PTU, propylthiouracil.

elevated receptor antibodies.² The assay used should be a functional one, because TSH-receptor antibodies are heterogeneous and can stimulate or block the TSH receptor.^{99,110} Neonatal syndromes have been caused by transplacental passage of stimulating and blocking antibodies.^{111,112} In women with receptor antibodies twofold to threefold normal and in those treated with antithyroid drugs, fetal thyroid dysfunction should be screened for during the fetal anatomy ultrasound done at 18 to 22 weeks and repeated as indicated. Evidence of fetal thyroid dysfunction is discussed in the following sections.

Fetal Thyrotoxicosis. Features of fetal thyrotoxicosis include a heart rate greater than 160 beats/min, growth retardation, advanced bone age, and craniosynostosis, all of which can be detected by ultrasound examination.¹¹³ Occasionally, nonimmune fetal hydrops and fetal death occur with associated diminished subcutaneous fat and thyroid enlargement. In utero, most cases are likely treated by the antithyroid drugs given to the mother. However, this problem can arise if the mother is euthyroid but has elevated levels of TSIs.¹¹⁴ Cordocentesis can be used for diagnosis and for monitoring therapy. A combination of antithyroid drugs and T₄ treats the fetal hyperthyroidism while keeping the mother euthyroid. Umbilical cord sampling can be considered if there is doubt about fetal thyroid disease.

Neonatal Thyrotoxicosis. All newborns of mothers with Graves disease should be evaluated for thyroid dysfunction. Features of thyrotoxicosis in the neonate include hyperkinesis, diarrhea, poor weight gain, vomiting, exophthalmos, arrhythmias, cardiac failure, systemic and pulmonary hypertension, hepatosplenomegaly, thrombocytopenia, and craniosynostosis. The infant should be examined immediately after birth. Cord blood reflects the in utero environment, and by day 2 of life, the maternal antithyroid drug effects have receded. Affected neonates are treated with antithyroid drugs, β -blockers, iodine, and glucocorticoids and digoxin, as needed. Iodate may be preferable because it blocks T₄ to T₃ conversion. Remission by 20 weeks is common, and it usually occurs by 48 weeks; occasionally, there is persistent disease when there is a strong family history of Graves disease.

Other mechanisms of fetal and neonatal hyperthyroidism include activating mutations of the stimulatory G protein in McCune-Albright syndrome and activating mutations of the TSH receptor.^{115,116}

Hyperthyroidism Related to Human Chorionic Gonadotropin

When hyperthyroidism is diagnosed during the first trimester, the physician has a challenging differential diagnosis, usually that of Graves disease versus hCG-mediated hyperthyroidism. The role of hCG as a thyroid stimulator of pregnancy was reviewed in an editorial by Hershman.¹¹⁷ Molecular variants of hCG with increased thyrotropic potency include basic molecules with reduced sialic acid content, truncated molecules lacking the C-terminal tail, or molecules in which the 47-48 peptide bond in the β -subunit loop is nicked. This relationship is further complicated by differences in clearance rates for different hCG glycoforms.¹¹⁸ In vivo thyrotropic activity is regulated by the glycoforms and the plasma half-life.

The hCG concentrations peak at 6 to 12 weeks and then decline to a plateau after 18 to 20 weeks. The stimulation of thyroid hormone production can suppress the TSH to low or reduced

values in up to 20% of normal pregnancies. Twin pregnancies can be associated with biochemical hyperthyroidism,⁹ as may pregnancies complicated by trophoblastic disease. Several clinical scenarios can arise and are described in the following sections.

Gestational Transient Thyrotoxicosis. Gestational transient thyrotoxicosis (GTT) occurs in the first trimester in women without a personal or family history of autoimmune disease. It results directly from hCG stimulation of the thyroid. Glinier and colleagues⁸ found an overall prevalence of GTT of 2.4% in a prospective cohort study between 8 and 14 weeks' gestation. Symptoms compatible with thyrotoxicosis were often present, and elevated free T₄ concentrations were found. The GTT was transient, paralleled the decline in hCG, and usually did not require treatment. The thyroid gland was not enlarged. Occasionally, β -blockers were used. GTT was not associated with a less favorable outcome of pregnancy.

Hyperemesis Gravidarum. Hyperemesis gravidarum is a serious pregnancy complication associated with weight loss and severe dehydration that often necessitates hospitalization.¹¹⁹ Biochemical hyperthyroidism is found in most women with this condition.^{120,121} Goodwin and colleagues¹²⁰ found that the severity of disease varied directly with the hCG concentration, but Wilson and associates¹²¹ did not find such a correlation. As in the case of GTT, certain hCG fractions may be more important than total hCG as thyroid stimulators. The duration of the hyperthyroidism varies widely from 1 to 10 weeks but is usually self-limited. Vomiting and normalization of T₄ levels occur by 20 weeks, although TSH may remain suppressed a little longer. Treatment is usually supportive, consisting of correction of dehydration, use of antiemetics, and occasional administration of parenteral nutrition. The vomiting may not be controlled by normalization of thyroid hormones. The Endocrine Society guidelines recommend serum total T₃ testing and use of β -blockers at the discretion of the obstetrician.² In more refractory patients, PTU therapy can be attempted if tolerated; methimazole suppositories can also be used.

Gestational Trophoblastic Disease. Hydatidiform mole and choriocarcinoma can be associated with hCG levels that are greater than 1000 times normal, and they commonly cause hyperthyroidism. The thyroid is usually not enlarged. Treatment of the hydatidiform mole or choriocarcinoma restores thyroid function to normal. The thyroid overactivity may be potentially life-threatening.^{122,123} Treatment with antithyroid drugs and β -blockers may be necessary, however, before surgical treatment of the mole.¹²⁴

Recurrent Gestational Hyperthyroidism. Cases of recurrent gestational hyperthyroidism have been described.^{125,126} In the case described by Rodien and colleagues,¹²⁶ hyperthyroidism was caused by a mutant TSH receptor that was hypersensitive to hCG.

Uncommon Causes of Hyperthyroidism

Much less common causes of hyperthyroidism include thyrotoxicosis factitia (i.e., ingestion of exogenous hormone surreptitiously). In these cases, serum thyroglobulin, which is produced by the thyroid, is suppressed.¹²⁷ Women with large, nodular goiters may have hyperthyroidism from autonomously functioning nodules within such goiters. Alternatively, women can have hyperthyroidism from a single toxic adenoma. If either of

these entities is diagnosed during pregnancy, the correct treatment is control of hyperthyroidism with antithyroid drugs until definitive treatment (i.e., surgery or radioactive iodine) can be administered after delivery. Even less common causes of hyperthyroidism in pregnancy are listed in Box 60-2.

Hypothyroidism

IODINE DEFICIENCY

Although iodine deficiency is rare in the United States, it is a common cause of maternal, fetal, and neonatal hypothyroidism in the world, where 1 to 1.5 billion are at risk and 500 million live in areas of overt iodine deficiency. Worldwide, it is the most common cause of mental retardation. A schematic representation of the clinical conditions that can affect thyroid function in the mother, fetus, or fetomaternal unit is provided in e-Figure 60-6.

Iodine deficiency and hypothyroidism in pregnancy continue to be a worldwide problem worthy of resolution, a topic that has been a subject of numerous reviews.¹²⁸⁻¹³¹ Even in the United States, iodine intake has declined, and 15% of women of childbearing age and 7% of pregnant women were found to have urinary iodine excretions below 50 µg/L, indicative of moderate iodine deficiency.¹³²

Pregnancy is an environmental trigger for the thyroid machinery, inducing changes in people who live in geographic areas that have iodine deficiency. Four biochemical markers related to iodine and hypothyroidism are useful for following the changes induced:

1. Relative hypothyroxinemia
2. Preferential T₃ secretion as reflected by an elevated T₃/T₄ molar ratio
3. Increased TSH levels after the first trimester, progressing until term
4. Supranormal thyroglobulin concentrations correlating with gestational goitrogenesis

Goitrogenesis can occur in the fetus, indicating the exquisite sensitivity of the fetal thyroid gland to the consequences of maternal iodine deficiency. This process can start during the earliest stages of fetal thyroid development. It occurs against a background of low initial maternal intrathyroid iodine stores, the increased need for iodine after pregnancy occurs, and an insufficiency of iodine intake throughout the gestation.

It appears that maternal thyroxine, traversing the placenta during the first trimester and subsequently, is necessary for fetal brain development. Even before fetal thyroid hormone synthesis, T₃ receptors are found in fetal brain tissues, and local conversion of T₄ to T₃ can occur. Iodine deficiency perpetuates the process, because the fetus is less able to synthesize thyroid hormones even when the fetal thyroid has developed.

Severe iodine deficiency (i.e., intake of 20 to 25 µg/day) can produce endemic cretinism, which has a prevalence up to 15% in severely affected populations. These infants are characterized by severe mental retardation with a neurologic picture that includes deaf-mutism, squint, and pyramidal and extrapyramidal syndromes. There are few clinical signs of thyroid failure. A remarkable exception to this picture has emerged from Africa, where the cretins have less mental retardation and fewer neurologic deficits. The clinical picture is that of severe thyroid failure with dwarfism, delayed sexual maturation, and myxedema. Thyroid function is grossly impaired.

The consensus is that the neurologic picture of endemic cretinism results from insults to the developing brain, occurring sometimes during the first trimester (in the case of deafness) and mostly during the second trimester, with the cerebellar abnormalities resulting from postnatal insult. This profile is supported by the observation that the full picture can be prevented only when the iodine deficiency is corrected before the second trimester and optimally before conception.¹³³ In Africa, iodine deficiency is complicated by selenium deficiency. The deficiency of selenium leads to accumulation of peroxide, and excess peroxide leads to destruction of thyroid cells and hypothyroidism.¹³⁴ Selenium deficiency also induces monodeiodinase I (a selenoenzyme) deficiency, resulting in reduced T₄ to T₃ conversion and increased availability of maternal T₄ for the fetal brain. This protective mechanism may prevent the development of neurologic cretinism, and the combined iodine-selenium deficiency prevalent in Africa may help explain the predominance of the myxedematous type observed there.

Neurologic abnormalities and mental retardation depend ultimately on the timing and severity of the brain insult. Endemic cretinism constitutes only the extreme expression of the spectrum of physical and intellectual abnormalities. In a meta-analysis of 18 studies in areas of iodine deficiency, it appeared to be responsible for an IQ loss of 13.5 points.¹³⁵ Even borderline iodine deficiency, as seen in Europe, can be accompanied by impaired school achievements by apparently normal children, as reviewed by Glinoe.¹²⁸

Actions taken to eradicate iodine deficiency have prevented the occurrence of mental retardation in millions of infants throughout the world. In a study by Xue-Yi and coauthors¹³⁶ of a severely iodine-deficient area of the Xinjiang region of China, iodine was administered to pregnant women. The prevalence of moderate or severe neurologic abnormalities among 120 infants whose mothers received iodine in the first or second trimester was 2%, compared with 9% (of 952 infants) when the mothers received iodine in the third trimester (*P* = .008). Although treatment in the third trimester did not improve neurologic status, head growth and developmental quotients improved slightly.

The importance of thyroid hormone to fetal and neonatal well-being and development was highlighted by a remarkable case of an infant born to a mother with strongly positive test results for TSH receptor-blocking antibodies. The mother was profoundly hypothyroid when tested after delivery. The infant, who was delivered by cesarean section because of bradycardia, was also profoundly hypothyroid and required intubation. Her brain size was reduced, and her auditory brainstem response was absent at 2 months of age. The audiogram at age 4 years revealed sensorineural deafness. At age 6 years, motor development was the same as at age 4 months. She required T₄ for 8 months until the antibody effect had worn off. Her physical growth was normal. The outcome of severe thyroid hormone deficiency in utero was fetal distress, permanent auditory deficit, brain atrophy, and severely impaired neuromotor development despite adequate neonatal treatment.¹³⁷

The Institute of Medicine of the National Academy of Sciences has set the iodine requirement as 110 µg for infants 0 to 6 months old, 130 µg for infants 7 to 12 months old, 90 µg for children 1 to 8 years old, 120 µg for those 9 to 13 years old, and 150 µg for those older than 13 years. The recommended intake for pregnancy and lactation is 250 µg/day. Even higher intakes (300 to 400 µg/day) have been suggested.¹³⁸

SIGNS AND SYMPTOMS

In one report, hypothyroidism occurred with a frequency of 1 case in 1600 to 2000 deliveries.⁶⁷ However, population screening studies have revealed a higher incidence. In a U.S. study, serum TSH levels were determined in 2000 women between gestational weeks 15 and 18; 49 (2.5%) had TSH levels greater than or equal to 6 mU/L, and positive thyroid antibodies were found in 58% of these 49 women, compared with 11% of control euthyroid pregnant women.¹³⁹ In a Japanese study, only 0.29% had an elevated TSH level.¹⁴⁰ In another U.S. study, 1 infant in 1629 deliveries had hypothyroidism.¹⁴¹

Women with hypothyroidism have higher pregnancy complication rates. As well as miscarriages, complications include preeclampsia, placental abruption, low birth weight, prematurity, and stillbirth.¹⁴² Gestational hypertension is also more common.¹⁴¹ These outcomes can be improved with early therapy.

The symptoms of hypothyroidism are insidious and can be masked by the hypermetabolic state of pregnancy. Symptoms can include modest weight gain, decrease in exercise capacity, lethargy, and intolerance to cold. In moderately symptomatic patients, constipation, hoarseness, hair loss, brittle nails, and dry skin also can occur. Physical signs may include a goiter, a thyroidectomy scar, and delay in the relaxation phase of deep tendon reflexes.

Laboratory confirmation is obtained from an elevated TSH level, with or without a suppressed free T_4 value. Test results for thyroid autoantibodies (i.e., antithyroglobulin and antithyroid peroxidase) may be positive. Other laboratory abnormalities can include elevated levels of creatine phosphokinase, cholesterol, and carotene and liver function abnormalities. Patients may have macrocytic or normochromic, normocytic anemia. Hypothyroidism may occur more frequently in pregnant women with type I diabetes, and T_4 replacement therapy can increase insulin requirements.¹⁴³

DIFFERENTIAL DIAGNOSIS

Hashimoto thyroiditis (i.e., chronic lymphocytic thyroiditis), an autoimmune disease, is the most common cause of hypothyroidism and can occur in 8% to 10% of women of reproductive age. It is characterized by the presence of antithyroid antibodies, and the patient may have a goiter. Titers of antithyroglobulin are elevated in 50% to 70% of patients, and almost all have antithyroid peroxidase antibodies.⁵³ The goiter is firm, diffusely enlarged, and painless, and the gland is infiltrated by lymphocytes and plasma cells. Many patients with Hashimoto thyroiditis are initially euthyroid but can subsequently develop hypothyroidism. The thyroid gland can be atrophic, and the test result for antibodies can be negative—so-called idiopathic hypothyroidism. Patients with other autoimmune diseases also can develop Hashimoto thyroiditis.

Other important and common causes of hypothyroidism include ^{131}I therapy, ablation for Graves disease, and thyroidectomy (e.g., for thyroid cancer). Of patients who receive ^{131}I therapy, 10% to 20% are hypothyroid within the first 6 months, and 2% to 4% become hypothyroid each year thereafter.¹⁴⁴ Hypothyroidism can result from subacute viral thyroiditis and, much less commonly, from suppurative thyroiditis.

Drugs that inhibit the synthesis of thyroid hormones include thionamide, iodides, and lithium. Carbamazepine, phenytoin, and rifampin can increase thyroid hormone clearance.

Aluminum hydroxide, cholestyramine, and most importantly, ferrous sulfate and sucralfate can interfere with the intestinal absorption of thyroxine, and they should not be overlooked.

Hypothyroidism resulting from hypothalamic or pituitary disease is rare but can occur in the setting of pituitary tumors, after pituitary surgery or irradiation, and in Sheehan syndrome and lymphocytic hypophysitis, an autoimmune disease with a predilection for women, especially in the setting of pregnancy (see Chapter 61). In secondary hypothyroidism, the TSH level may be low or normal, but the free T_4 level is low.

TREATMENT

Prompt treatment is mandated for hypothyroidism, which is defined as a high TSH level with a suppressed free T_4 concentration or a TSH level higher than 10 mIU/L irrespective of the free T_4 level.³ A dose of 0.1 to 0.15 mg of T_4 per day should be initiated. Other thyroid preparations, such as T_3 or desiccated thyroid should not be used.³ The dose is adjusted every 4 weeks until the TSH concentration is in the lower end of the normal range or within the trimester-specific reference range.^{2,3} In women with little or no functioning thyroid tissue, a dose of 2 $\mu\text{g}/\text{kg}/\text{day}$ may be required.

Women who are euthyroid on T_4 should adjust their dose because the requirements for thyroid hormone increase as early as the fifth week of gestation. The patient can be instructed to increase her dose by two extra doses per week and be checked a few weeks later.^{3,145} The amount of dose increase may depend on the cause. For example, women who have had total thyroidectomy may need a greater increase than women with mild hypothyroidism. Increased dosage requirements may plateau by the 20th week,¹⁴⁶ but the need for increased dosage may occur as late as the third trimester in about one third of patients.² In a review of 77 pregnancies in 65 hypothyroid women, serum TSH levels became abnormal in 70% of women with prior ^{131}I ablation therapy and in 47% of women with chronic thyroiditis. When data from other studies were pooled, overall TSH levels increased above normal in 45% with a mean daily thyroxine dose of 146 μg .^{147,148} It was estimated that the increment in dose could be predicted according to the TSH value at the first evaluation. The TSH concentration should be determined again 4 to 6 weeks after dose adjustment.

Increased T_4 requirements may reflect a real increased demand for T_4 in pregnancy¹⁴⁹ in patients whose thyroid reserve is compromised, and in some cases, iron therapy may be the cause. Ferrous sulfate interferes with T_4 absorption and should be taken at a different time of day from thyroxine therapy, at least 4 hours apart.^{2,150} Patients with thyroid cancer whose target TSH concentration is below the normal range almost uniformly require an increased dose to maintain their suppressed TSH levels, and they should be followed closely.¹⁵⁰ After delivery, the dose should be reduced to pre-pregnancy levels in all patients, and the TSH concentration should be measured 6 to 8 weeks later.

The topic of thyroid hormone and intellectual development has received widespread publicity and has been the subject of many articles and reviews.^{128,151,152} In 1969, Man and Jones¹⁵³ studied a cohort of 1349 children and concluded that mild maternal hypothyroidism alone was associated with lower IQ levels in the offspring. In 1990, Matsuura and Konishi¹⁵⁴ documented that fetal brain development is affected adversely when both mother and fetus have hypothyroidism caused by chronic autoimmune thyroiditis. With the background of this

information and the associations of iodine deficiency, its consequent maternal hypothyroxinemia, and abnormal fetal brain development, Haddow and associates¹⁵¹ conducted a study measuring TSH levels from stored samples from more than 25,000 pregnant women. They located 62 women with high TSH levels and 124 matched women with normal values. Their 7- to 9-year-old children, none of whom had hypothyroidism as newborns, underwent 15 tests to measure intelligence, attention, language, reading ability, school performance, and visual-motor performance. The full-scale IQ for children of hypothyroid women was 4 points lower ($P = .06$); 15% had scores of 85 or less, compared with 5% of controls. The IQ of the children of 48 women whose hypothyroidism was not treated averaged 7 points lower than the 124 controls ($P = .005$), and 19% had scores of 85 or lower. The researchers concluded that undiagnosed hypothyroidism can affect fetuses adversely and recommended screening for hypothyroidism in pregnancy.

In a prospective, population-based cohort study in China, maternal thyroid function in the first 20 weeks of pregnancy and subsequent fetal and infant development were evaluated for 1017 women with singleton pregnancies. Clinical hypothyroidism was associated with increased fetal loss, low birth weight, and circulatory system malformation. Subclinical hypothyroidism was associated with fetal distress, preterm delivery, and neurodevelopmental delay.¹⁵⁵

In a study by Pop and colleagues,¹⁵⁶ even the presence of antithyroid peroxidase antibodies in the maternal circulation was shown to have deleterious effects on child development. In two similar studies, thyroid antibody-positive women had lower free T_4 levels, and lower scores on psychomotor tests were found for children of mothers whose free T_4 value was below the 5th and 10th percentiles as measured at 12 weeks' gestation.¹⁵⁷ In another, first-trimester antibody positivity was a risk factor for perinatal death.¹⁵⁸

OTHER FORMS OF HYPOTHYROIDISM

Subclinical Hypothyroidism and Hypothyroxinemia

Subclinical hypothyroidism is defined as an elevated TSH level when the free T_4 level is in the normal range. More than 90% of hypothyroidism diagnosed in pregnancy is subclinical. Its estimated prevalence in the general population is between 4% and 8.5%. The prevalence in pregnancy was 2.3% in a study of more than 17,000 women enrolled for prenatal care at 20 weeks' gestation or less.¹⁵⁹ In this study, pregnancies in patients with subclinical hypothyroidism were three times more likely to be complicated by placental abruption, and the rate of preterm birth (i.e., delivery at or before 34 weeks) was almost twofold higher.

Hypothyroidism has been associated with impaired neurodevelopment of the fetus.¹⁵¹ However, most of the patients in this study had a TSH level of 10 mU/L or greater, and most had a low free T_4 level, which means that they had overt rather than subclinical hypothyroidism. Nonetheless, this study has prompted rigorous debate on the merits of universal screening of all pregnant women. Controversy surrounding screening of pregnant women for hypothyroidism continues to the present. The American College of Obstetricians and Gynecologists (ACOG) has reaffirmed its previous position, stating that without evidence that identification and treatment of pregnant women with subclinical hypothyroidism improves maternal or fetal outcomes, routine screening is not recommended. The 2011 ATA guidelines³ stated

that there was insufficient evidence to recommend for or against universal TSH screening at the first-trimester visit. Similarly, no agreement was reached regarding universal screening in the Endocrine Society guidelines, with unanimous agreement on targeted screening.² In addition to monitoring those with a prior history of thyroid disease, TSH testing of women in early pregnancy was recommended by both the Endocrine Society and the ATA for several reasons: age older than 30 years, symptoms of thyroid dysfunction, presence of a goiter, thyroid antibody positivity, type 1 diabetes or other autoimmune disease, history of head and neck irradiation, family history of thyroid dysfunction, morbid obesity, infertility, use of amiodarone or lithium, exposure to iodinated radiographic contrast, and residence in an area of moderate or severe iodine deficiency.

ACOG had previously endorsed a case-finding approach.¹⁶⁰ However, targeting high-risk cases may miss significant numbers with hypothyroidism, as was shown by Vaidya and coworkers.¹⁶¹ These investigators evaluated more than 1500 consecutive pregnancies and found increased TSH levels in 40 women (2.6%). Although the prevalence of high TSH levels was higher for the high-risk group (6.8% versus 1% for low-risk patients), 30% of women with high TSH levels were in the low-risk group. A similar conclusion was reached by Wang and coworkers.¹⁶² Although a significantly higher prevalence of hypothyroidism was found for the high risk group, such a strategy would miss about 81.6% of pregnant women with hypothyroidism. The controversy surrounding screening was readdressed by Stagnaro-Green, who suggested there be one set of guidelines.¹⁶³ He discussed the paradox that ACOG does not endorse either guideline and suggested we should perhaps focus on whether detecting and treating overt (as opposed to subclinical) hypothyroidism provides sufficient rationale for universal screening, arguing in favor of such screening. ATA guidelines³ recommend treatment of subclinical hypothyroidism when the test for thyroid peroxidase antibody is positive, but they state that there is insufficient evidence to recommend for or against universal levothyroxine treatment of women with subclinical hypothyroidism for whom the thyroid peroxidase antibody test is negative. In contrast, the Endocrine Society recommends treatment of subclinical hypothyroidism regardless of the antibody status, although the evidence was only fair to poor for those who were antibody negative.²

Isolated maternal hypothyroxinemia (i.e., low free T_4 and normal TSH levels) during early pregnancy has been associated with impaired neurodevelopment of the fetus.^{157,164} The issue of detecting and treating isolated maternal hypothyroxinemia is an area of equal uncertainty. Unfortunately, assays of true free T_4 levels (e.g., equilibrium dialysis, ultrafiltration, gel filtration) are expensive and labor intensive. Clinical laboratories use a variety of tests that estimate the free hormone concentrations in the presence of protein-bound hormone, and they are binding protein dependent to some extent. This negatively affects the accuracy of free hormone assays. Free T_4 assays usually result in lower values in late pregnancy.¹⁶⁵ Nonetheless, in an article in the *Journal of Clinical Endocrinology and Metabolism*, Morreale de Escobar and colleagues¹⁶⁶ made a compelling case for screening pregnant women for hypothyroxinemia, pointing out that maternal T_4 (as opposed to T_3) is the required substrate for the ontogenetically regulated production of T_3 in the amounts needed for optimal temporal and spatial development in different brain structures. This issue is important for women with relative iodine deficiency, because T_3 is preferentially synthesized. The ATA guidelines³ state that because no studies have

demonstrated a benefit from treatment of isolated maternal hypothyroxinemia, universal free T₄ screening of pregnant women is not recommended; they also stated that isolated hypothyroxinemia should not be treated in pregnancy.

To address these dilemmas, the National Institute of Child Health and Human Development Maternal-Fetal Medicine Units Network initiated a randomized trial of T₄ treatment for subclinical hypothyroidism or hypothyroxinemia diagnosed during pregnancy. The primary end point is the intellectual function of the children, and secondary end points include determination of the frequency of pregnancy complications, including preterm delivery, preeclampsia, abruptio, and stillbirth. The results of this study should be available in 2014 or 2015.

What do we do in the meantime? In an editorial accompanying the paper on low-risk versus high-risk case finding, Brent⁶⁸ said that until the results of large, randomized trials are known, the available evidence supports the benefits of T₄ therapy to reduce pregnancy loss and preterm delivery, although the effect on neurologic development is less clear.⁶⁹ This view was previously stated by Larsen.¹⁶⁷ Screening at least high-risk women (as defined by ACOG, the ATA, and the Endocrine Society) for TSH and free T₄ levels is appropriate. Given the lack of harm and possibly improved obstetric outcome, until the trial results are available, it is reasonable to treat subclinical hypothyroidism with thyroxine, although this position is currently not supported by ACOG. Negro and associates recommended that adequate iodine intake should be ensured in those with isolated hypothyroxinemia.¹⁶⁸ I recommend also screening patients who have delivered or had a miscarriage within 1 year of the index pregnancy, because postpartum or post-miscarriage thyroid disease is commonly found in the general population.

Fetal and Neonatal Hypothyroidism

The relationship between iodine deficiency and fetal development was previously discussed. Severe neurologic deficits occur in children with congenital deficiency of thyroid hormone unrelated to iodine deficiency. Neurologic development is impaired if infants are untreated before they are 3 months old. Screening of neonates for thyroid hormone deficiency is mandatory in some states, and with early therapy, their development is reasonably normal.²⁹ Causes include thyroid agenesis and inborn errors of metabolism, such as peroxidase deficiency. Congenital pituitary and hypothalamic hypothyroidism also occur but are rare. Thyroid hormone deficiency can result from maternal blocking antibodies that are transferred to the fetus and that block TSH action or thyroid growth and development.¹⁶⁹

Gruner and associates¹⁷⁰ reported a case of fetal goitrous hypothyroidism in which fetal TSH levels were determined on three occasions by cordocentesis to monitor weekly intra-amniotic administration of T₄. This therapy was initiated to reduce the fetal goiter and polyhydramnios (which it did) and to aid in fetal neurologic development. They also reviewed other reported cases of such therapy and concluded that the optimal dose of T₄ necessary to correct hypothyroidism could more accurately be determined by cordocentesis than by measurement of amniotic fluid hormone concentrations. In 12 cases, intra-amniotic levothyroxine treatment was given for nonimmune fetal goitrous hypothyroidism, and thyroid size and amniotic fluid TSH levels decreased (to normal levels in 4 cases). However, at birth, all infants had hypothyroidism, indicating that amniotic fluid TSH levels did not reliably reflect fetal thyroid function.¹⁷¹

Thyroid Nodules, Malignant Tumors, and Nontoxic Goiter in Pregnancy

Thyroid tumors are the most common endocrine neoplasms. Most are benign hyperplastic (or colloid) nodules, but between 5% and 20% are true neoplasms, which are benign follicular adenomas or carcinomas of follicular or parafollicular (C) cell origin. Nodular thyroid disease is common, especially in women. A prospective study found that the incidence of incipient thyroid nodules increased from 15% in the first trimester to 24% after delivery, with a concomitant increase in the growth of existing nodules.¹⁷² Although the data about the effects of estrogen on thyroid cancer are conflicting, the effects tend to be small, and there is no evidence that thyroid cancer arises more frequently in pregnancy.

When a solitary or a dominant nodule is found within the thyroid, biopsy is commonly performed. Cytopathologic diagnosis of the fine-needle aspiration biopsy (FNAB) for women between the ages of 15 and 40 years seen at the Mayo Clinic revealed benign findings for 64% and suspicious findings for 12%; the FNAB was positive for cancer in 7% and nondiagnostic for 17%.¹⁷³ The topic of nodular thyroid disease in pregnancy was also reviewed. During a 10-year period, 40 pregnant women were evaluated at the Mayo Clinic, and 39 had FNABs, 95% of which were diagnostic.¹⁷⁴ Most (64%) were benign. Three (8%) were positive for papillary thyroid cancer, and nine (23%) were suspicious for papillary cancer or a follicular (Hurthle cell) neoplasm.

The principles of nodular thyroid disease diagnosis in pregnancy resemble those for nonpregnant women. Serum TSH and free T₄ levels should be obtained. Radionuclide scanning is contraindicated, but ultrasound can demonstrate nodules and lymphadenopathy and may delineate the characteristics of the nodule. FNAB is safe and may be performed at any stage of pregnancy. The ATA guidelines³ and recommendations pertain to nodules detected in pregnancy and to patients with previously diagnosed thyroid cancer:

1. Nodules up to 1.5 cm can be followed postpartum.
2. If benign ultrasound characteristics are found in nodules greater than 1.5 cm, FNAB can be deferred till after delivery; otherwise, FNAB can be performed in pregnancy.
3. For nodules pathologically suspicious for papillary cancer, second-trimester surgery or deferring thyroid surgery until after delivery is an acceptable choice.
4. For FNABs showing well-differentiated papillary cancer, second-trimester surgery is recommended for women with lymph node metastases. If there are no demonstrable lymph node metastases, it is acceptable to follow by ultrasound and measure thyroglobulin each trimester. If substantial growth or lymph node metastases are shown, second-trimester surgery is recommended.
5. Thyroid hormone therapy, with the goal of achieving a TSH level between 0.1 and 1.5 IU/L, may be considered for women who have deferred surgery for a well-differentiated cancer until after delivery.
6. Ultrasound monitoring should be performed each trimester in patients with previously treated differentiated thyroid cancer who had high levels of thyroglobulin or evidence of persistent structural disease before pregnancy.
7. Pregnancy should be deferred for 6 months after radioactive iodine treatment, and dosing of levothyroxine should be stabilized before pregnancy.

If the nodule is suspicious for a follicular or Hurthle cell neoplasm, it usually represents a 10% to 15% risk of malignancy. It is recommended that surgery be performed after delivery.¹⁷⁴ The Endocrine Society guidelines are fairly similar.²

The approach to the pregnant patient with thyroid cancer was reviewed in 2011 by Mazzaferri,¹⁷⁵ who found that there was almost always a conflict between optimal therapy for the mother and fetal well-being. He reviewed the scope of the problem (14 in 100,000 pregnancies), the potential role of estrogen (small), and the effect of pregnancy on the growth or progression of thyroid cancer, for which there was some conflict in the data, with one study showing no effect¹⁷⁶ and another showing a poorer prognosis.¹⁷⁷ The spontaneous abortion rates are higher when thyroid surgery is performed in the first trimester, as are the rates of general and endocrine complications.

The role of thyroglobulin measurements and ultrasound was reviewed by Mazzaferri.¹⁷⁵ Whereas thyroglobulin concentrations may increase in pregnancy and do not provide sufficient information for relevant clinical decision making, neck ultrasound is by far a more sensitive and specific measure for follow-up during pregnancy. His opinion was that the safest treatment for most women and fetuses was to perform the initial thyroid surgery after delivery, provided that regular pre-delivery ultrasound studies were obtained. If the patient experiences rapid tumor growth of 50% or more or has evidence of lymph node metastases or extracapsular invasion, surgery should be considered in the second trimester. Figure 60-7 outlines these decision-making steps.

Postpartum Thyroid Disease

Autoimmune thyroid disease, which is suppressed during pregnancy, is exacerbated in the postpartum period. New-onset autoimmune thyroid disease occurs in up to 10% of all postpartum women.³⁹ Up to 60% of Graves disease patients in the reproductive years give a history of postpartum onset.¹⁷⁸ Most of the immune changes of pregnancy gradually return to normal in the 12-month postpartum period. Unlike pregnancy, the major immune changes in T and B cells in the postpartum period are overall T-cell deactivation, enhanced T_H1 cell function, loss of tolerance for fetal alloantigens, enhanced immunoglobulin G (IgG) secretion, and autoantibody secretion. Possible mechanisms explaining postpartum autoimmune exacerbation suggested by Davies³⁹ include a reduced number of fetal cells leading to the loss of maternal tolerance to remaining microchimeric cells and a loss of placental major histocompatibility complex-peptide complexes, which induced T-cell anergy during pregnancy.

POSTPARTUM GRAVES DISEASE

The onset of Graves disease after delivery correlates with the development of TSIs. Peak antibody production is observed 3 to 6 months after delivery. Almost all patients with persistent TSIs at the end of pregnancy have a recurrence of Graves disease if antithyroid drugs are withdrawn. The estimated prevalence of postpartum Graves disease, which can be transient or persistent, is 11% of those with postpartum thyroid dysfunction.¹⁷⁹

POSTPARTUM THYROIDITIS

Depression and postpartum thyroiditis (PPT) are common events, and four large-scale studies have been performed to

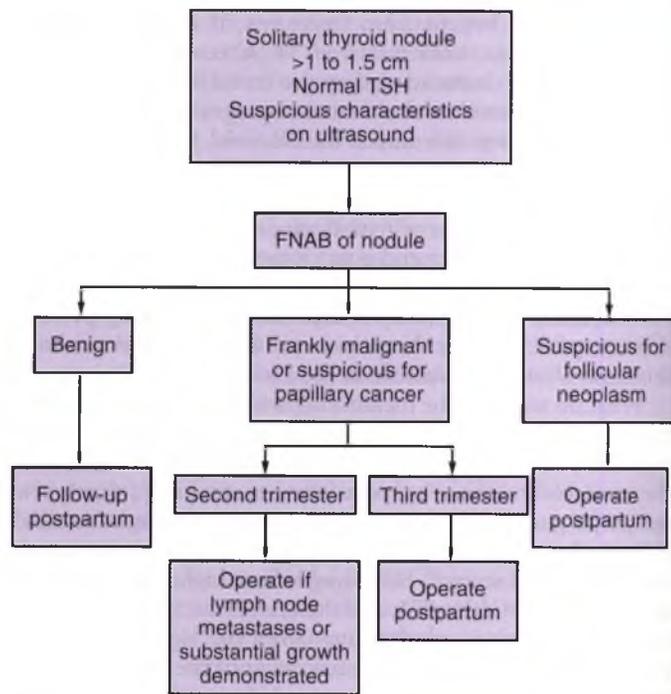

Figure 60-7 Evaluation of thyroid nodules. The decision-making process is outlined for management of a solitary thyroid nodule in pregnancy. FNAB, fine-needle aspiration biopsy; TSH, thyroid-stimulating hormone.

evaluate their association.^{39,179-183} For the diagnosis of PPT, there must be a documented abnormal TSH level (suppressed or elevated) during the first postpartum year in the absence of a positive result for TSIs (excluding Graves disease) or a toxic nodule.

Classically, PPT manifests with a transient hyperthyroid phase at 6 weeks to 6 months after delivery (median time of onset, 13 weeks). A hypothyroid phase follows (median time of onset, 19 weeks) and can last up to 1 year after delivery.¹⁸³ Figure 60-8 schematically demonstrates this and the accompanying changes in serum thyroid antibody concentrations. A review of 11 studies of PPT¹⁸⁴ revealed that only 26% of patients presented in this classic manner. Most patients present with hyperthyroidism alone (38%) or hypothyroidism alone (36%).

The incidence of PPT is 4% to 9%. It is an autoimmune disorder, and patients with type 1 diabetes have an increased incidence of PPT, which was found to be approximately 25% in two North American studies.^{185,186} Women with a history of PPT in a prior pregnancy had a 69% recurrence rate during the subsequent pregnancy. It occurs in up to 50% of women found to be thyroid peroxidase antibody positive at the end of the first trimester.¹⁸²

Symptoms of the hyperthyroid phase of PPT include fatigue, palpitations, heat intolerance, and nervousness. This destructive hyperthyroid phase always has a limited duration (i.e., few weeks to a few months). Although β -blockers may reduce symptoms, antithyroid medications have no role to play.

The hypothyroid phase can be marked by fatigue, hair loss, depression, impairment of concentration, and dry skin. The hypothyroid phase frequently requires treatment, but it is reasonable to wean the patient off therapy 6 months after initiation. Some authorities recommend maintaining T₄ therapy in

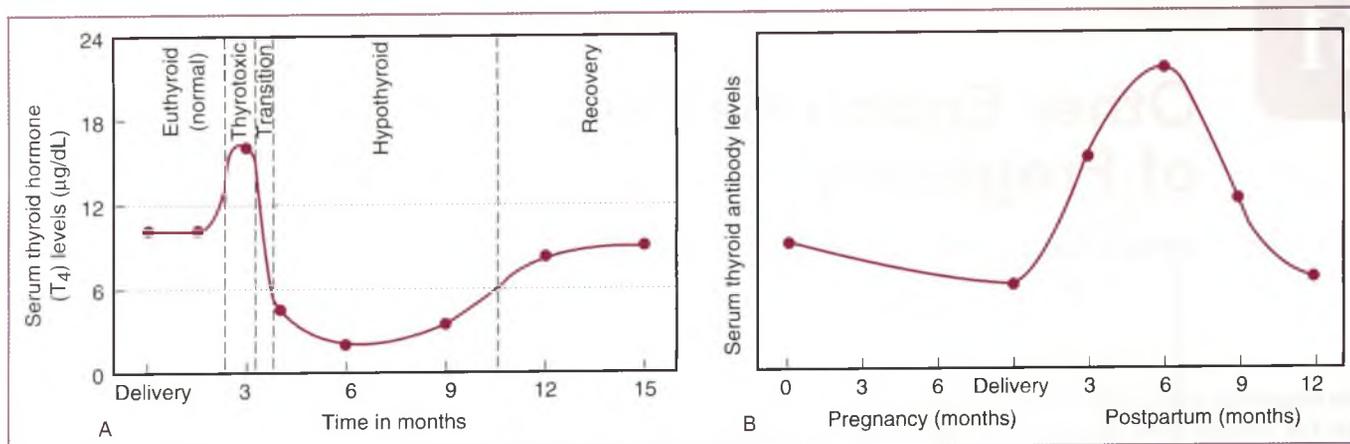

Figure 60-8 Postpartum thyroiditis and changes in thyroid antibody concentrations. A, Postpartum thyroiditis manifests with a transient hyperthyroid phase, during which serum levels of thyroxine (T₄) are elevated. A hypothyroid phase follows. B, Serum thyroid antibody levels fluctuate during and after pregnancy. (From Smallridge RC, Fein HC, Hayship CC: Postpartum thyroiditis, *Bridge Newslett Thyroid Found Am* 3:3, 1988.)

these patients until the childbearing years are over and then attempting to wean them off the therapy a year after the last delivery. In one study,¹⁸³ 54% had persistent hypothyroidism at the end of the first year, although this is higher than found in other studies. Even if normal, they should be checked annually for thyroid dysfunction (see Hypothyroidism and Postpartum Thyroiditis, later).¹⁸²

The thyroid gland is enlarged in PPT, and thyroid hypoechoogenicity appears to be the characteristic ultrasonographic finding.¹⁸⁷ PPT is an autoimmune disorder, and there is an association between it and human leukocyte antigen (HLA)-DR3, HLA-DR4, and HLA-DR5 status. The lymphocytic infiltration is similar to that seen in Hashimoto thyroiditis.

The laboratory hallmarks of PPT, which is a destructive process, are positive test results for antithyroid antibodies (i.e., antithyroglobulin and antithyroid peroxidase), suppressed TSH levels, and high T₄ levels (released from destroyed thyroid cells) in the hyperthyroid phase, along with a profoundly suppressed radioactive iodine uptake (contraindicated in a breastfeeding woman). The absence of TSIs usually rules out Graves disease, which can also be distinguished by high radioactive iodine uptake.

Depression and Postpartum Thyroiditis

Depression and PPT are common postpartum events, and four large-scale studies have been performed to evaluate their association.¹⁸⁸⁻¹⁹³ In summary, the data suggest some association for PPT, thyroid antibodies, and depression. Two of the clinical trials demonstrated an association between PPT and depression, and two demonstrated an association between thyroid antibodies and depression. The role of potential interventions such as T₄ therapy has not been evaluated systematically. The ATA and Endocrine Society guidelines recommend testing for thyroid dysfunction in women with postpartum depression.^{2,3}

Hypothyroidism and Postpartum Thyroiditis

Recovery of thyroid function in women with PPT is not universal, and some women remain permanently hypothyroid. In a study of 44 women with PPT with a mean follow-up of 8.7 years after delivery, Tachi and associates¹⁹⁴ found that 77% of the women recovered during the first postpartum year and

remained euthyroid. Permanent hypothyroidism developed in the other 23%; one half of these women never recovered euthyroid function after the initial postpartum insult, and the other half developed hypothyroidism during the years of follow-up. A 23% incidence of permanent hypothyroidism at long-term follow-up (mean, 3.5 years) was also reported by Othman and coworkers.¹⁹⁵ Women with a history of PPT should be evaluated annually for the possible development of hypothyroidism.

Thyroiditis after Abortion

Several studies have described cases of thyroiditis occurring after an abortion.^{196,197} Neither the incidence nor clinical sequelae are known. In the case report of Stagnaro-Green,¹⁹⁶ the patient developed transient hypothyroidism after a spontaneous miscarriage. After a subsequent term delivery, the patient became severely hypothyroid, and this condition remained permanent.

Prevention and Screening of Postpartum Thyroiditis

Levothyroxine (0.1 mg daily) or iodide (0.15 mg daily) was administered for 40 weeks after delivery to women who were thyroid antibody positive during pregnancy. A control group of antibody-negative women received no treatment. The incidence of PPT was similar in all three groups, and the degree of postpartum elevation of thyroid peroxidase antibodies was indistinguishable in the three groups.¹⁹⁸

Whether screening for PPT is worthwhile is a contentious issue. An article in the *Journal of Clinical Endocrinology and Metabolism* presented arguments for and against screening.¹⁹⁹ It was suggested that screening and treatment of symptomatic hypothyroidism would improve the quality of life of the mother, and the importance of recognizing postpartum depression was stressed. Contradicting arguments posited that the optimal screening strategy was undefined and that no cost-benefit analysis has been performed. It is agreed that women who present with symptoms should have a TSH assay performed. High-risk women (i.e., with a history of PPT or with type 1 diabetes) should be screened.^{186,199}

Other Endocrine Disorders of Pregnancy

SHAHLA NADER, MD

The staggering advancements made in endocrinology over the past few decades have involved both normal physiology and pathophysiology. When pregnancy is superimposed on abnormal endocrine function in the mother, the consequences for the mother and the fetus can be adverse and sometimes disastrous. Awareness of the danger, combined with the knowledge that accurate diagnostic and therapeutic measures are often available, places a substantial burden on the obstetrician caring for the pregnant patient. This chapter summarizes the normal maternal endocrine adaptation to pregnancy (see also Chapters 8, 9, 59, and 60) and outlines maternal disorders, some of which are almost specific to pregnancy.

Hypothalamus and Pituitary

The sella turcica of the sphenoid bone, which is lined by dura mater, is occupied by the pituitary gland. The dura covering the roof, called the sellar diaphragm, is perforated centrally by the pituitary stalk. Directly above this diaphragm and anterior to the stalk lies the optic chiasm. The pituitary gland consists of an anterior lobe (the adenohypophysis) and a posterior lobe (the neurohypophysis); the former accounts for more than 80% of the gland's volume. The pituitary stalk contains the direct neural connections between the hypothalamic nuclei and the posterior lobe, and it is the vascular link between the hypothalamus and the anterior lobe, enabling hypothalamic neurohumoral secretions to influence the activity of the anterior lobe cells. Paired superior hypophyseal arteries arising from the internal carotids anastomose around the upper part of the stalk and terminate in elongated coiled capillary loops into which the hypothalamic hormones are discharged. The capillary bed drains into portal veins that empty into sinusoids of the anterior lobe (e-Fig. 61-1). Paired inferior hypophyseal arteries supply the posterior lobe. The venous drainage of both lobes flows into the cavernous sinuses.

Figure 61-2 is a diagram of the interrelationships and feedback mechanisms of the higher brain centers, hypothalamus, pituitary, and target endocrine glands in normal, nonpregnant women. The adenohypophysis produces gonadotropins (e.g., luteinizing hormone [LH], follicle-stimulating hormone [FSH]), growth hormone (GH), thyrotropin (or thyroid-stimulating hormone [TSH]), prolactin, and adrenocorticotropin (or adrenocorticotrophic hormone [ACTH]) and its related peptide β -lipotropin, from which beta-melanocyte-stimulating hormone (β -MSH) is derived.

Since the 1940s, when the concept that control of the anterior pituitary is exerted through a neurohumoral mechanism was formulated, several peptides have been isolated from the hypothalamus that function in this capacity.

Thyrotropin-releasing hormone (TRH) causes release of TSH (and prolactin); growth hormone-releasing hormone (GHRH) releases GH; gonadotropin-releasing hormone (GnRH) allows release of LH and FSH; and corticotropin-releasing hormone (CRH) releases ACTH. Substances with an inhibitory rather than a stimulatory influence have been identified. Somatostatin inhibits the release of GH (and many other hormones), and dopamine inhibits the release of prolactin. This inhibition of the lactotroph is clinically important; disturbances of the stalk or vascular dissociation of the hypothalamus from the anterior pituitary results in deficiency of all anterior pituitary hormones with the exception of prolactin. The lactotroph is normally under predominantly inhibitory control.

PHYSIOLOGIC CHANGES DURING PREGNANCY

During pregnancy and in the immediate postpartum period, the anterior lobe of the pituitary can double or triple in size because of hyperplasia and hypertrophy of lactotrophs. This is evident at 1 month and continues throughout gestation. At delivery, involution of pregnancy cells occurs for a period of several months but seems to be retarded by lactation.¹ Magnetic resonance imaging (MRI) studies of normal primigravid patients have confirmed progressively increasing pituitary volumes during gestation²; at the end of pregnancy, there is an overall increase in pituitary gland size of 136% compared with control nulliparous subjects. Similar results have been obtained by Dinc and colleagues,³ who found changes in pituitary gland volume of 40%, 75%, and a maximum of 120% in the second, third, and immediate postpartum periods, respectively. The major accompanying physiologic change is a progressive increase in serum prolactin concentrations,⁴ with an approximately 10-fold increase during gestation (e-Fig. 61-3).

Placental estrogens stimulate lactotroph DNA synthesis, mitotic activity, and prolactin secretion. Prolactin prepares the breasts for initiation and maintenance of lactation (see Chapter 9). Despite this dramatic increase in activity, the lactotroph retains its ability to respond to TRH, its releasing hormone (unlike in the case of a prolactinoma, in which this response is usually blunted or absent).

Other physiologic changes during pregnancy include the following⁵:

- Gonadotropin concentrations decline, with a progressively diminishing response to GnRH.
- Pituitary GH levels decline, with an increase of a placental variant of GH. This variant has similar somatogenic but less lactogenic bioactivity than pituitary GH, with increases in insulin-like growth factor 1 (IGF-1, or somatomedin-C) commensurate with elevated levels of the GH variant.

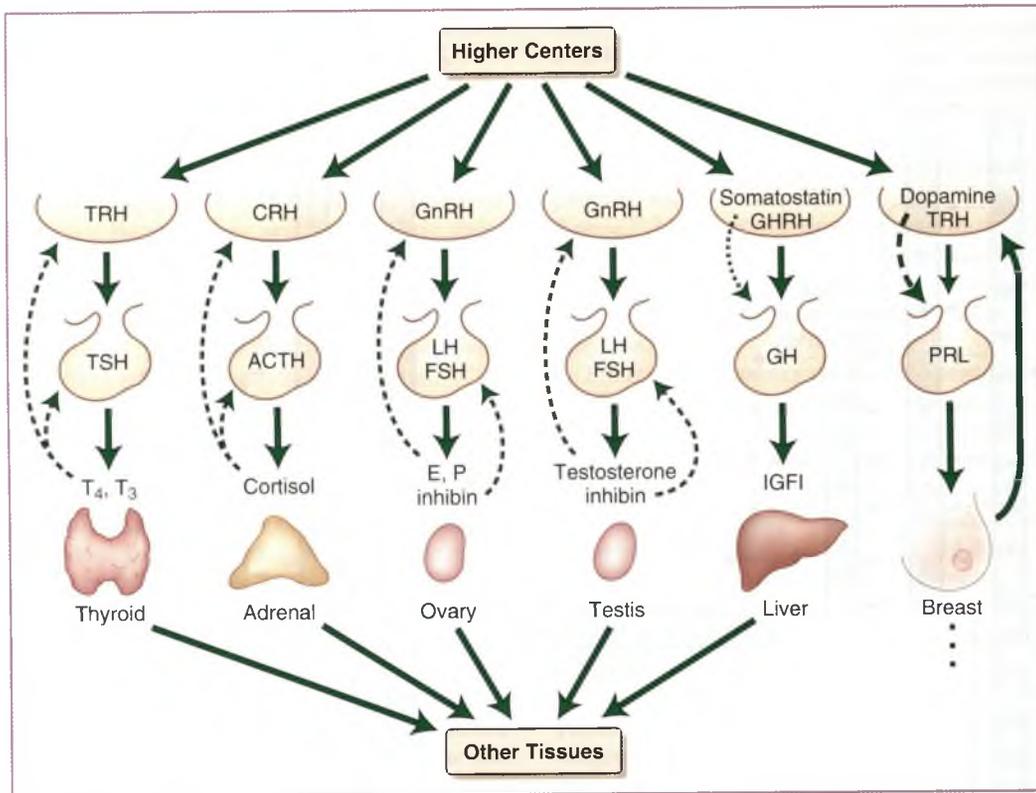

Figure 61-2 Relationships and feedback mechanisms of the neuroendocrine and endocrine systems. The components shown in the schematic drawing include the central nervous system, hypothalamus, anterior pituitary gland, and target glands and tissues. *Solid lines* indicate hormone secretion through stimulatory pathways; *dotted lines* indicate an inhibitory effect. ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; E, estradiol; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; IGF1, insulin-like growth factor 1; LH, luteinizing hormone; P, progesterone; PRL, prolactin; TRH, thyrotropin-releasing factor; TSH, thyroid-stimulating hormone; T₃, triiodothyronine; T₄, thyroxine.

Pituitary GH is the only detectable form during the first trimester. Thereafter, the amount of placental GH increases progressively.

- The levels of CRH of placental origin increase during the second and third trimesters.
- A two- to fourfold increase in ACTH concentration occurs, despite elevations of bound and free plasma cortisol. The placenta provides an alternative source of ACTH.

The diurnal variation of cortisol, although blunted, is preserved during pregnancy (see Adrenal Glands, later). Thyrotropin, decreasing slightly in the first trimester, is otherwise essentially unchanged.

The posterior pituitary is a storage terminal for the neurohypophyseal hormones oxytocin and vasopressin. Produced by the supraoptic and paraventricular hypothalamic nuclei along with their respective binding proteins or neurophysins, these hormones are transported as neurosecretory granules along the supraopticohypophysial tract to the pituitary, and from there they find their way into the circulation. Vasopressin plays a central role in osmolarity and volume regulation. Osmoreceptors are located in the anterior hypothalamus, and vasopressin release increases when plasma osmolality rises (Fig. 61-4).

Early in pregnancy, plasma osmolality decreases to values that are 5 to 10 mOsm/kg below the normal mean of 285 mOsm/kg in nonpregnant women.⁶ Plasma levels of vasopressin and its response to water loading and dehydration, however, are

normal in pregnancy, indicating a resetting of the threshold—that is, vasopressin is secreted at a lower plasma osmolality (see Fig. 61-4). Similarly, the plasma osmolality at which thirst is experienced is lower in the pregnant state. Along with these changes, the metabolic clearance of vasopressin increases markedly between gestational week 10 and mid pregnancy. This is paralleled by the appearance and increase of circulating vasopressinase.⁷

Oxytocin is involved in the process of parturition and in suckling. Although the role of oxytocin in the initiation of labor is unclear, there is significant preterm increase in plasma concentrations of oxytocin.⁸ During nursing, nipple stimulation initiates a neurogenic reflex that is transmitted to the hypothalamus, triggering oxytocin release from the posterior pituitary. Oxytocin then induces contraction of the myoepithelial cells and mammary duct smooth muscle, resulting in milk ejection.

FETAL HYPOTHALAMIC AND PITUITARY DEVELOPMENT

The development of the structural and functional aspects of the neuroendocrine system in the fetus occurs as follows.⁹ By 10 to 13 weeks' gestation, fetal pituitary and hypothalamic tissues can respond *in vitro* to stimulatory or inhibitory stimuli. By mid-gestation, the fetal hypothalamic-pituitary axis is a functional

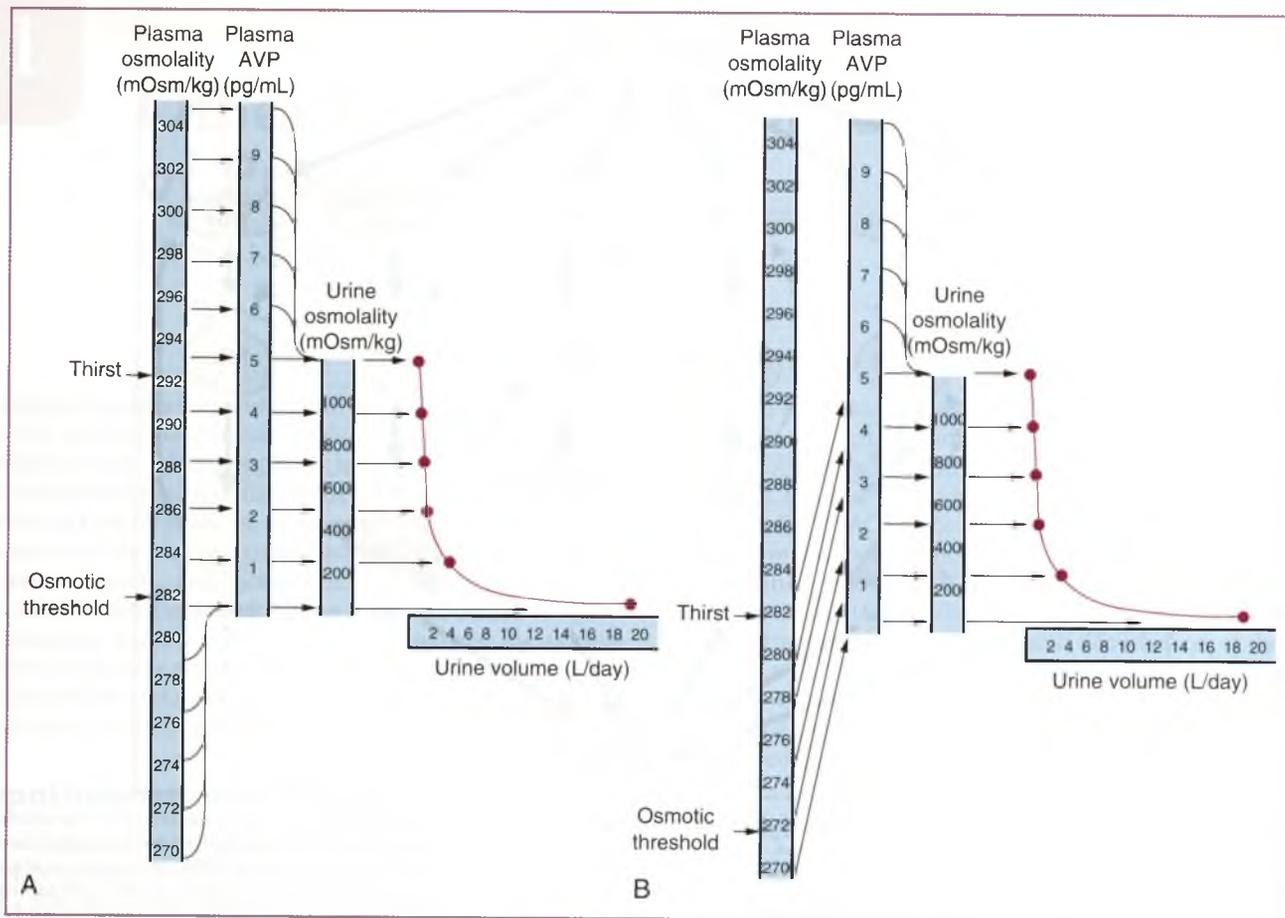

Figure 61-4 Osmolarity and volume regulation. A, Idealized schematic diagram of normal physiologic relationships shows the direct associations between plasma osmolality and plasma vasopressin and between plasma vasopressin and urine osmolality. The osmotic threshold is illustrated as a floor for plasma osmolality below which the plasma osmolality does not normally fall because of excretion of a high volume of dilute urine. Thirst is illustrated as a physiologic ceiling for plasma osmolality, because, above this level, thirst is sensed and water imbibed to avoid further elevation of plasma osmolality. B, Idealized schematic diagram shows the reset osmostat, as occurs in pregnancy. For the patient to function normally with a lower osmolality, thirst and the osmotic threshold must be lowered and maintain their relative relationships with one another. Urine osmolality and urine volume follow appropriately for the level of vasopressin in plasma. Subjects experience extreme thirst if the osmolality is raised into the normal range. AVP, arginine vasopressin. (From Robinson AG: *Disorders of antidiuretic hormone secretion*, Clin Endocrinol Metab 14:55-88, 1985.)

and autonomous unit subject to feedback control mechanisms. The posterior lobe of the fetal pituitary serves as a storage depot for neuropeptides.

DISORDERS OF THE HYPOTHALAMUS

Disorders of the hypothalamus can be congenital (e.g., Laurence-Moon-Bardet-Biedl syndrome) or acquired inflammatory (e.g., meningitis, encephalitis), space occupying (e.g., tumors, cysts), vascular, or degenerative. For many women with these conditions, reproduction is impossible or undesirable. Among female patients with the autosomal recessive Laurence-Moon-Bardet-Biedl syndrome of polydactyly, obesity, retinitis pigmentosa, and mental retardation, 45% to 53% are hypogonadal, but several pregnancies have been reported in such patients.¹⁰ Craniopharyngiomas are derived from vestigial remnants of the Rathke pouch or craniopharyngeal anlage. Manifestations can include headaches, visual disturbances, and hypothalamic dysfunction, including diabetes insipidus. Seven craniopharyngiomas have been reported during pregnancy. In two, the tumor recurred, and its enlargement resulted in loss of

vision in a subsequent pregnancy.¹¹ Two of the case reports of craniopharyngiomas, previously undiagnosed, said that patients presented with diabetes insipidus in pregnancy.¹² One of these patients also had visual field disturbances and symptoms of raised intracranial pressure. Surgery was performed 3 days after delivery at 34 weeks' gestation because of deteriorating visual acuity. Craniopharyngiomas may require surgery during pregnancy. It has even been suggested that the hormonal stimulation of pregnancy may potentiate growth of this congenital tumor. Craniopharyngioma was diagnosed in a pregnant woman who had had a normal MRI result 4 years earlier.¹³

DISORDERS OF THE PITUITARY

Anterior Lobe Disorders

Most commonly, tumors and, less commonly, vascular mishaps and inflammatory changes affect the anterior lobe.

Pituitary Tumors. The topic of pituitary tumors in pregnancy has been reviewed by Molitch⁵ and Gillam and colleagues.¹⁴ Pituitary tumors can be classified as hormonally functioning

or functionless lesions. Examples of the former include GH-producing tumors resulting in acromegaly, ACTH-producing tumors giving rise to Cushing disease, and prolactinomas. Prolactinoma is by far the most common pituitary tumor encountered in pregnancy. Hormonally functionless pituitary tumors are less common (which are clinically hormonally functionless, although some of them produce subunits of pituitary hormones). Because they are functionless, these pituitary tumors are relatively asymptomatic in their early stages and tend to be larger at the time of diagnosis. If they have been identified, the patient should undergo appropriate surgical treatment before becoming pregnant. Tumor expansion with visual field defects during pregnancy has been reported.^{15,16} In the case reported by Masding and coworkers,¹⁶ there was prompt response to bromocriptine, and this response was presumably related to shrinkage of lactotroph hyperplasia.

Prolactinoma. The advent of prolactin radioimmunoassay in the early 1970s permitted the correct diagnosis of prolactinomas in many patients previously thought to have functionless pituitary tumors. Because of the negative effect of excess prolactin on the hypothalamic-pituitary-gonadal axis, most of these women, who were in their childbearing years, presented with amenorrhea and, consequently, with infertility. Parallel with the development of the prolactin assay and improved radiologic techniques for diagnosing these tumors came the development and refinement of transsphenoidal microsurgical techniques and a powerful new drug, bromocriptine mesylate, which can suppress elevated prolactin concentrations to normal levels. Numerous pregnancies resulted from restoring normal gonadal function in these women, and in the 1980s, information about these pregnancies was consolidated. Because of the physiologic changes that occur in the pituitary in a normal pregnancy—enlargement of the gland and hyperplasia of the lactotrophs with a 10-fold increase in serum prolactin—concerns about women with prolactinomas becoming pregnant were reasonable.

Effects of Prolactinoma and Bromocriptine Treatment on Pregnancy and the Fetus. Bromocriptine mesylate is an ergot derivative with potent dopamine receptor agonist activity. Administered orally, it is a potent inhibitor of prolactin secretion, with effects usually lasting only for the duration of treatment. Numerous accounts of the use and safety of bromocriptine in pregnancy are available, but they are best summarized by Krupp and Monka¹⁷ (from the Drug Monitoring Centre, Clinical Research, Sandoz, in Basel, Switzerland). They collected data from 2587 pregnancies in 2437 women treated with bromocriptine during some stage of gestation. The results showed that its use was not associated with an increased risk for spontaneous abortion, multiple pregnancy, or congenital malformation in their progeny.

These investigators followed 546 children postnatally up to the age of 9 years and found no adverse effect on postnatal development. In most women treated, bromocriptine was discontinued on confirmation of pregnancy. These results are important insofar as bromocriptine crosses the placental barrier and can be found in dosage-related concentrations in fetal blood and in the amniotic fluid.¹⁸ The use of bromocriptine throughout pregnancy was limited to approximately 100 patients; one infant had an undescended testicle, and another a talipes deformity.⁵ The newer synthetic dopamine agonist, cabergoline, is also approved for treatment of prolactinomas. As

with bromocriptine, the drug should be discontinued after pregnancy is established. Its twice-weekly administration and reduced side-effect profile makes it more palatable for patients.¹⁹ The experience with cabergoline use in pregnancy, albeit in fewer patients, appears to be similar to that with bromocriptine.^{20,21} There have been reports of cardiac valvular defects in patients using cabergoline in large dosages for Parkinson disease.²² However, the dosages used in patients with prolactinoma are much smaller, and the relevance of these studies to its use in such patients is unknown. As indicated later, it is currently recommended as first-line treatment in patients desiring pregnancy.

Effects of Pregnancy on Prolactinomas. Prolactinomas are subclassified according to size as microadenomas (<10 mm in diameter) (e-Fig. 61-5) and macroadenomas (≥10 mm in diameter). In a review of the subject with data collected and combined from many studies, Albrecht and Betz²³ found that of 352 pregnant patients with untreated microadenomas, 8 (2.3%) experienced visual disturbances, 17 (4.8%) experienced headaches, and 2 (0.6%) had diabetes insipidus. The corresponding figures for 144 pregnant women with macroadenomas were visual disturbances in 22 (15.3%), headaches in 22 (15.3%), and diabetes insipidus in 2 (1.4%).

In the same review, the outcomes of 318 pregnancies in patients with microadenomas and macroadenomas treated (i.e., surgery, radiation therapy, or both) before pregnancy were analyzed. There were visual disturbances in 10 (3.1%), headaches in 12 (3.8%), and diabetes insipidus in 1 (0.3%). In a further compilation of series published in the world literature,¹⁴ of 457 patients with microadenomas, 12 (2.6%) had symptomatic tumor enlargement, but none required surgery. Of 140 macroadenomas previously treated by surgery or radiation, 7 (5%) had symptomatic enlargement, and none required surgery. In contrast, of 142 macroadenomas not previously treated by surgery or radiation, 45 (31%) had symptomatic enlargement, and 12 (8.5%) had surgical treatment. Symptoms related to a pregnancy-induced increase in the size of a pituitary tumor can begin as early as the first trimester, with a mean time for the onset of visual symptoms at 14 weeks' gestation.²⁴ Headaches usually precede visual changes.

The data previously given can be used to counsel patients with prolactinomas who are planning pregnancy.^{14,25} Patients with microadenomas can safely be given dopamine agonists. Visual field testing and MRI should be performed in patients with visual changes or symptoms suggestive of tumor expansion. For patients with small intrasellar or inferiorly expanding macroadenomas, dopamine agonists may also be given as primary therapy. If tumor reduction is demonstrated, pregnancy should be allowed and the drug stopped when pregnancy is identified. The rate of clinically serious complications is unlikely to be high in such cases. In patients with large macroadenomas with suprasellar extension, the risk of tumor expansion is significant when using dopamine agonists to establish pregnancy. Pre-pregnancy tumor debulking can significantly reduce the risk of tumor expansion in pregnancy. Alternatively, bromocriptine, or, if the patient is intolerant, cabergoline, may be administered throughout pregnancy as discussed previously (and see Management of Prolactinoma Complications during Pregnancy, later). For patients with macroadenomas treated with dopamine agonists or surgically, follow-up at 1- to 3-month intervals is recommended, along with visual field testing. Repeat MRI is performed for patients

with symptoms or signs of tumor expansion. Recommendations for management of patients with prolactinomas are outlined in Tables 61-1 and 61-2.

Despite prior surgical intervention, complications can occur during pregnancy.²⁶ Monthly measurement of serum prolactin is not necessary. Prolactin concentrations measured in a group of patients with surgically untreated microadenomas were found to be elevated early in gestation but did not increase further with advancing gestation,²⁷ in contrast with normal pregnant controls (e-Fig. 61-6). A small subset of women appear to experience decrease or normalization of prolactin levels after delivery. Tumor necrosis might have occurred in some, and use of bromocriptine has been associated with tumor fibrosis.

Management of Prolactinoma Complications during Pregnancy. Bromocriptine and cabergoline have tumor-shrinking properties and have been used successfully in the treatment of such complications in pregnancy.⁵ Bromocriptine should be administered with food and the dosage adjusted according to symptoms (e.g., 2.5 to 5 mg given two or three times daily). Cabergoline is given at a dosage of 0.25 to 0.5 mg twice a week. Glucocorticoids may also be given to expedite recovery of visual defects. Surgery is recommended only if there is no response to bromocriptine or cabergoline. In a report of a pregnancy in a woman with dopamine-agonist-resistant macroprolactinoma, treatment with bromocriptine during pregnancy resulted in improvement of symptoms of tumor expansion, presumed to relate to decrease in the pituitary hyperplasia of pregnancy.²⁸

Most patients with microadenomas have uncomplicated pregnancies, whereas a disturbing number of patients with

untreated macroadenomas have symptomatic tumor enlargement. Given the tumor-shrinking properties of bromocriptine, it is not surprising that the continuous use of bromocriptine in pregnancy has been advocated and effected in patients with macroadenomas. Experience with its use throughout gestation is limited to approximately 100 patients.⁵ Although the rates of abortion and perinatal mortality do not differ between women with pituitary tumors that are *untreated* and those whose tumors *are* treated before or during pregnancy, there is a significant increase in prematurity among those treated (i.e., by surgery, radiotherapy, or both) during pregnancy, compared with those not requiring such treatment or with those treated before pregnancy.²⁴

An Endocrine Society Clinical Guideline concerning diagnosis and treatment of hyperprolactinemia gave the following additional recommendations²⁹:

- Cabergoline is to be used as a primary treatment for symptomatic prolactinomas because of its higher efficacy and its higher frequency of tumor shrinkage. It is to be discontinued with identification of pregnancy.
- In selected patients with macroadenomas who become pregnant on dopaminergic therapy and who have not had prior surgery or radiation therapy, it may be prudent to continue dopaminergic therapy throughout the pregnancy, especially if the tumor is invasive or is abutting the optic chiasm.
- Women with macroprolactinomas who have had no tumor shrinkage during dopaminergic therapy or who cannot tolerate such therapy should be counseled regarding the potential benefits of surgical resection before attempting pregnancy. Pituitary apoplexy, which is a rare event, has been reported in a patient with a macroadenoma in early pregnancy.³⁰

Breastfeeding and Postpartum Care. There is no reason to avoid breastfeeding when a patient with prolactinoma wishes to nurse her child. In a small study of 14 women with microadenomas who breastfed for 6 to 14 months, the level of serum prolactin was not significantly higher than it was before pregnancy.³¹ In another study, the increase in prolactin associated with suckling was absent in women with pathologic hyperprolactinemia. For those wishing to inhibit lactation, bromocriptine at a dosage of approximately 2.5 mg given three times daily

TABLE 61-1 Treating Prolactinomas in Patients Who Desire Pregnancy

Treatment	Microadenomas and Intranasal Macroadenomas	Suprasellar Macroadenomas
Primary	Bromocriptine or cabergoline (dopamine agonists)	Transsphenoidal surgery followed by dopamine agonist
Alternative	Transsphenoidal surgery followed by dopamine agonist (if necessary)	Radiotherapy plus dopamine agonist

TABLE 61-2 Management of Prolactinomas Harbored by Patients during Gestation

Status of Patient	Microadenomas	Macroadenomas
Asymptomatic	Stop dopamine agonist. Provide routine obstetric care with evaluation for symptoms of tumor expansion.	Stop dopamine agonist. Monthly evaluation for symptoms of tumor expansion. Check visual fields every 1 to 3 months. Continuous bromocriptine (or cabergoline) if suprasellar and/or abutting chiasm.
Symptomatic	Check visual fields. Measure the serum prolactin concentration. Magnetic resonance imaging of pituitary without contrast. Initiate bromocriptine with or without dexamethasone for visual complications. Perform transsphenoidal surgery if unresponsive to bromocriptine.	Check visual fields. Measure the serum prolactin concentration. Magnetic resonance imaging of pituitary without contrast. Initiate bromocriptine with or without dexamethasone for visual complications. Perform transsphenoidal surgery if unresponsive to bromocriptine.

with food, or cabergoline (0.25 to 0.5 mg twice a week) may be given.

Although occasional case reports have described seizures or strokes in women who used bromocriptine to inhibit postpartum lactation—and it should be kept in mind that suppression of lactation is no longer an approved indication for the use of this agent—a recent case-control study failed to link these events to the use of bromocriptine.³² Estrogen should not be used to inhibit lactation, because the tumor can expand. Ophthalmologic and radiologic evaluation and determination of serum prolactin concentrations should be performed 6 to 8 weeks after delivery. In most instances, the sella returns to its original size and prolactin decreases to previous levels. Further pregnancies are not contraindicated in patients with prolactinomas. Decreases in prolactin and tumor size have been reported in patients with multiple bromocriptine-induced pregnancies.³³

Excessive Growth Hormone Secretion: Acromegaly. Acromegaly is the result of excessive GH secretion in adults, and it is associated with acidophilic or chromophobic pituitary adenomas. About 60% of patients have macroadenomas. Women with acromegaly slowly develop coarse facial features, prognathism, and spadelike hands and feet. When clinical evidence exists, a glucose tolerance test is performed; lack of suppression of GH below 2 ng/mL during this test is in keeping with a diagnosis of acromegaly in nonpregnant patients. Because the biologic effect of GH is mediated through IGF-1, elevation of serum concentration of this growth factor is considered a useful confirmatory test and has been used to monitor the progression of the disease. In the context of pregnancy, however, IGF-1 concentrations should be interpreted with caution because they can be elevated.³⁴ Because of the production of a placental variant of GH, special assays using antibodies that recognize specific epitopes on the two hormones are necessary to differentiate normal from placental GH.³⁵ The placental variant is undetectable within 24 hours after delivery. TRH testing may also distinguish pituitary from placental GH; 70% of patients with acromegaly experience a GH response to TRH, whereas the placental variant does not respond to it.³⁶ Pituitary GH secretion is pulsatile, with 13 to 19 pulses daily, as opposed to the placental variant, which is nonpulsatile.

Menstrual irregularity or amenorrhea is an extremely common finding in acromegalic women. In a study of 55 patients, only 31% were eumenorrheic.³⁷ Nonetheless, pregnancy can occur in women with acromegaly and has been reported in many patients.³⁸ It can be accompanied by tumor expansion in approximately 10%, necessitating hypophysectomy. Despite other soft tissue changes, no major changes occur in the genital tract that would complicate delivery. Definitive treatment before conception is the treatment of choice in acromegalic women desiring children. Carbohydrate intolerance occurs in up to 50% and overt diabetes in up to 20% of acromegalic women, and the insulin resistance of pregnancy is additive. Hypertension occurs in 25% to 35% of acromegalic women, and cardiac disease is common. In a retrospective multicenter study of 46 women with acromegaly, there were 59 pregnancies resulting in 64 healthy babies. Gestational diabetes and pregnancy hypertension occurred in 6.8% and 13.8%, respectively; four of the women had visual field defects, and in three of those four, acromegaly was diagnosed in pregnancy. Four women, all of whom had received somatostatin analogues, had

small-for-gestational-age infants. The majority of those tested had stable tumors after the delivery.³⁹

An algorithm for the management of acromegaly in pregnancy has been presented by Herman-Bonert and colleagues.³⁸ Management was also reviewed by Molitch.⁵ The observation that levodopa (L-dopa) causes a paradoxical decrease in GH in acromegaly led to the use of dopaminergic agonists in the treatment of acromegaly. Tumor expansion resulting in visual field defects has been reported in one of two patients with acromegaly and macroadenomas during pregnancy.¹⁵

If acromegaly is diagnosed in a pregnant patient, management depends on the activity of the disease, the tumor size, and the stage of pregnancy. Active disease during pregnancy may respond to bromocriptine or cabergoline until fetal lung maturation is documented. If signs and symptoms related to suprasellar extension do not abate with dopamine agonists, transsphenoidal surgery could be necessary.

In a case reported by Yap and associates,⁴⁰ acromegaly was diagnosed in the second trimester. Bromocriptine corrected visual field defects and suppressed prolactin secretion but did not reduce fasting GH levels. It was suggested that suppression of physiologic lactotroph hyperplasia by bromocriptine might permit noninvasive management of the pituitary adenoma in pregnancy. The somatostatin analogues octreotide and lanreotide have been used in at least 10 patients.^{41,42} In three patients, the drug was continued throughout pregnancy without reported ill effects on the fetus, despite documented transplacental passage.⁴³ Somatostatin analogues should be discontinued in acromegalic patients contemplating pregnancy, but they may be considered an alternative to transsphenoidal surgery in pregnancy for an expanding tumor if the patient does not respond to dopaminergic agonists. The maternal-fetal transfer of GH is thought to be negligible, and apart from the effect of glucose intolerance, the fetus is not thought to be affected by acromegaly.

Thyrotropin-Secreting Tumors. Three cases of TSH-secreting tumors and pregnancy have been reported. One patient was treated with octreotide before pregnancy, stopped the medication when the pregnancy was identified, but developed symptomatic growth at 6 months. The second, whose pregnancy was uncomplicated, received octreotide throughout gestation. The third had tumor enlargement and visual loss despite bromocriptine, necessitating transsphenoidal surgery.⁴⁴

Cushing Syndrome. The hypothalamic-pituitary-adrenal axis in pregnancy was the subject of a review by Lindsay and Nieman,⁴⁵ and Cushing syndrome in pregnancy the subject of a specific review by Lindsay and associates.⁴⁶ Cortisol secretion is controlled by the hypothalamic-pituitary axis. Cushing syndrome is a state of hypercortisolism that can arise from excess ACTH produced by the pituitary or by an ectopic ACTH source such as a tumor, both of which can lead to bilateral adrenal hyperplasia. An adrenal lesion (i.e., adenoma or carcinoma) may be the direct source of excess cortisol.

Pregnancy is uncommon in patients with Cushing syndrome because of the syndrome's association with a high incidence of menstrual disturbances and anovulation. Pituitary-dependent Cushing syndrome, also called Cushing disease, gives rise to bilateral adrenal hyperplasia and a state of hypercortisolism. Although pituitary-dependent Cushing syndrome is the more common cause in nonpregnant patients, it is less commonly

associated with pregnancy because hyperfunctioning adrenal tumors are more common in pregnant patients with this syndrome. A possible explanation for this discrepancy is the greater degree of ovulatory disturbance in patients with pituitary-dependent Cushing syndrome.⁴⁷

In 136 pregnancies in 122 women,⁴⁵ the mean gestational age at diagnosis was 18 weeks. Adrenal adenomas accounted for almost half of the cases (compared with 15% in nonpregnant women), with adrenal carcinomas occurring in 10%. Pituitary-dependent Cushing syndrome (i.e., Cushing disease) was less common, occurring in a third of the 122 women, compared with 70% in the general population. Ectopic ACTH occurred in four patients. Exacerbation of Cushing syndrome in pregnancy with amelioration or remission after pregnancy has been reported.⁴⁸

Diagnosis. The diagnosis of Cushing syndrome in pregnancy can be rendered more difficult because weight gain, hypertension, striae, edema, and pigmentation may occur in normal pregnancy. More specific signs, such as thinning of the skin, spontaneous bruising, and muscle weakness, should be sought. The laboratory diagnosis is complicated by the changes in adrenal function that occur during normal pregnancy. These include an increase in bound and free serum cortisol levels, increased levels of urinary free cortisol, and a lack of adequate suppression of cortisol after low-dosage dexamethasone treatment.

Urinary free-cortisol excretion is less than 50 µg/24 hours in nonpregnant women with the use of mass spectroscopy assays. The mean 24-hour urinary free-cortisol level is increased at least 180% during normal gestation. Levels of total and free plasma cortisol increase twofold to threefold, with a wide range of normal variation in morning cortisol ranging from 16.3 to 55 µg/dL.⁴⁵ In another longitudinal study, a progressive rise in total plasma cortisol, corticosteroid-binding globulin, and 24-hour urinary free cortisol was demonstrated, peaking in the third trimester with a mean threefold rise compared with controls.⁴⁹ The diurnal variation is blunted. The suppressibility of cortisol was shown to be 40% after 1 mg of dexamethasone in second- and third-trimester normal pregnancies, compared with 80% in nongravid controls; loss of suppression increased with increasing gestation. In a collected series and review of the literature comprising 136 cases of Cushing syndrome in pregnancy in 122 women, the following features were identified⁴⁵:

- There was a mean eightfold elevation in urinary free cortisol (range, 2- to 22-fold).
- Diurnal variation of cortisol was absent.
- Midnight cortisol level was elevated (mean, 30.9 µg/dL).
- Using 1-mg overnight or 2-day low-dosage (2 mg daily) dexamethasone suppression testing, the median suppressibility of cortisol was approximately 30% in women with Cushing disease and 10% in those with adrenal Cushing syndrome; dexamethasone suppressibility was not considered a sensitive test for Cushing syndrome in pregnancy.
- In the differential diagnosis of Cushing syndrome, 8 of 16 with the adrenal form, or ACTH-independent hyperplasia, had ACTH assay results below the detection limit of 10 pg/mL. Conversely, of 18 patients with Cushing disease, two had ACTH values below 10 pg/mL (i.e., inappropriately low).
- Using high-dosage dexamethasone (8 mg daily) and a criterion of 80% suppression as indicative of pituitary-dependent Cushing syndrome, all patients with

ACTH-independent Cushing syndrome failed to suppress. However, three of seven patients with pituitary-dependent Cushing syndrome did not have suppression.

- MRI of the pituitary identified an adenoma in five of eight subjects.
- Adrenal imaging correctly identified the lesion in 11 of 15 by ultrasound; MRI and computed tomography were uniformly successful in identifying the lesion. Bearing these changes in mind, urinary free-cortisol excretion of more than three times the upper limit of normal in the second or third trimesters may suggest Cushing syndrome.

To distinguish pituitary-dependent Cushing disease from hyperfunctioning adrenal tumors, a high-dosage dexamethasone suppression test is recommended (8 mg/day for at least 2 days). Significant (≥50%) suppression of plasma cortisol is the rule in pituitary-dependent Cushing syndrome, and failure of suppression with high-dosage dexamethasone, along with low or undetectable ACTH concentrations, strongly suggests an adrenal source. Because the placenta also produces ACTH, this test may not always be reliable. Ectopic ACTH syndrome also causes failure to suppress. In determining the differential diagnosis, high-dosage dexamethasone suppression testing and plasma ACTH should be performed. The pituitary can be evaluated during pregnancy by means of MRI.^{2,49} CRH testing in pregnancy can also aid in the differential diagnosis. Although the ACTH response to CRH is blunted in the third trimester, a substantial rise in cortisol after CRH stimulation in patients with Cushing syndrome is consistent with pituitary-dependent disease. One microgram of ovine CRH was given per kilogram of body weight (U.S. Food and Drug Administration [FDA] pregnancy category C drug), and a rise in cortisol (44% to 130%) was seen in those with pituitary disease confirmed surgically.⁴⁵ Pituitary disease can also be distinguished from ectopic ACTH by inferior petrosal sinus sampling combined with CRH stimulation. There is one report of such testing in pregnancy.⁵⁰

Maternal-Fetal Complications. Although congenital malformations are not more common in gravidas with Cushing syndrome than in those with a normal pregnancy,⁴⁸ maternal and fetal complications can occur. In the 136 pregnancies reported by Lindsay and Nieman,⁴⁵ maternal morbidity and mortality included hypertension (68%), diabetes or impaired glucose tolerance (25%), preeclampsia (14%), osteoporosis and fracture (5%), heart failure (3%), psychiatric disturbances (4%), wound infections (2%), and maternal deaths (2%). Fetal morbidity was also significant, with a prematurity rate of 43%, stillbirth rate of 6%, and spontaneous abortion rate of 5%, and there were two infant deaths. Intrauterine growth restriction is prevalent, occurring in approximately one half of reported cases.⁴⁷ Possible causes include hypertension and an excess of cortisol itself. Neonatal adrenal insufficiency has been reported and is presumably caused by suppression of the fetal hypothalamic-pituitary-adrenal axis from transplacental transport of excess maternal cortisol. However, placental 11β-hydroxysteroid dehydrogenase type 2 converts maternal cortisol into biologically inactive cortisone and protects the fetus from maternal hypercortisolemia.

Therapy. Because of the poor fetal outcome, therapy aimed at controlling the hypercortisolism is recommended. In the 136 pregnancies discussed previously that had available outcomes, when no active treatment was given, there was a 76% rate of live births, compared with 89% among women treated at a

mean gestational age of 20 weeks. The following recommendations for treatment have been suggested.⁴⁶

In the first trimester, pituitary surgery for pituitary-dependent Cushing syndrome and adrenal surgery for tumors of adrenal origin (especially to rule out carcinoma) should be performed. In the third trimester, early delivery of the fetus—preferably vaginal—may be attempted. Metyrapone therapy (to block cortisol secretion) may reduce hypercortisolism until fetal maturity is attained.⁵¹ In the second trimester, treatment should be individualized; the alternatives are definitive surgery or medical therapy aimed at ameliorating hypercortisolism. Successful transphenoidal surgery has been reported in the second trimester.⁵² The risks of treatment with metyrapone, ketoconazole, and aminoglutethimide, all of which block cortisol secretion, are uncertain because transplacental passage occurs and fetal adrenal steroid synthesis may be affected. The risk for teratogenicity, virilization of female fetuses (with aminoglutethimide), or inadequate masculinization of a male fetus (with ketoconazole) discourages the use of these two agents. Metyrapone is the drug of choice, although there is a potential for exacerbation of hypertension. Mitotane is teratogenic and should not be used.

Nelson Syndrome. When a patient with pituitary-dependent Cushing syndrome undergoes bilateral adrenalectomy as definitive treatment for hypercortisolism and the pituitary lesion is not adequately addressed, a syndrome of hyperpigmentation along with an expanding intrasellar ACTH-producing tumor can result. This is called Nelson syndrome. The association of this syndrome and pregnancy is rare. In a series involving 10 cases, five required postpartum treatment of their pituitary tumors, five were only observed, and one required surgical treatment during the pregnancy, with successful outcomes for the mother and child.⁵³ In a reported series of 20 pregnancies in 11 patients with Cushing disease who had been treated by bilateral adrenalectomy (without pituitary irradiation), corticotroph tumor progression occurred in 8 of 17, and ACTH increased in 8 of 10. However, these rates were not faster than those observed before pregnancy. It was concluded that pregnancy does not accelerate corticotroph tumor progression.⁵⁴

Hypopituitarism. Diminished or decreased production of anterior pituitary hormones results in inadequate activity of target organs, such as the thyroid, adrenals, and gonads. The deficiency can be partial—affecting trophic hormones in various degrees—or it can be complete, resulting in panhypopituitarism. The role of the obstetrician-gynecologist in this context is twofold: to be alert to and aware of the possibility of two disease processes that can affect the pregnant patient—Sheehan syndrome and lymphocytic hypophysitis—and to recognize and treat hypopituitarism in a pregnant patient.

Sheehan Syndrome. In 1937, Sheehan⁵⁵ drew attention to the relationship between postpartum hemorrhage and anterior pituitary necrosis. Because the syndrome is distinctly uncommon, with other conditions associated with shock and vascular collapse, it is assumed that the hyperplastic gland in pregnancy is more vulnerable to an inadequate blood supply. In a retrospective survey by Hall,⁵⁶ pregnant patients admitted for hemorrhagic collapse were subsequently traced and evaluated for hypopituitarism; the incidence was approximately 3.6%. There is said to be no direct correlation between the severity of the hemorrhage and the occurrence of Sheehan syndrome, but the major part of the pituitary must be destroyed before symptoms

become evident.⁵⁶ In one review, small sella size was suggested as a risk.⁵⁷

In a series of 25 cases,⁵⁸ 50% of patients had permanent amenorrhea, and the remainder had rare and scanty menses. Only one patient menstruated normally, and in most, lactation was poor or absent. There was a surprisingly long interval between the obstetric event and diagnosis (>10 years) for more than half of the patients. In a later series of 20 cases, the mean time between diagnosis and date of last delivery was 26.8 years. Amenorrhea and absent lactation occurred in 70%. Some degree of hypogonadism, GH deficiency, and low prolactin levels occurred in all; 90% were hypothyroid, and 55% had adrenal failure.⁵⁹ In a study of 60 patients with Sheehan syndrome from Costa Rica, the most common symptoms were asthenia (85%), amenorrhea (73%), loss of pubic and axillary hair (67%), and agalactia (67%). On testing, 100% had GH deficiency, 97% had adrenal insufficiency, 80% hypothyroidism, 67% hypogonadism, and 69% prolactin deficiency. The average time from event to diagnosis was 13 years.⁶⁰

Although pregnancy in hypopituitary patients is rare, it can occur, and the inability to establish the diagnosis and institute proper therapy can have lethal consequences for the mother and fetus. Grimes and Brooks⁶¹ reviewed the pregnancies of their patients with Sheehan syndrome. There was an 87% rate of live births, 13% rate of abortions, and no stillbirth or maternal death in 15 pregnancies among patients receiving hormonal therapy. In sharp contrast, in 24 pregnancies among 11 women in whom hormone replacement was not provided, there was a 58% rate of live births, 42% rate of abortions, one stillbirth, and three maternal deaths.

In nonpregnant patients thought to have Sheehan syndrome, the diagnosis and the extent of pituitary damage can be determined by tests of target organ function (e.g., thyroid function tests, cortisol concentration) and tests of pituitary reserve. An ongoing pregnancy does not constitute evidence against the diagnosis of Sheehan syndrome, and it should be considered for all patients with a history of postpartum hemorrhage, especially if the patient is currently symptomatic. The finding of a low serum thyroxine level and a low TSH level is in keeping with secondary hypothyroidism; low cortisol concentrations (compared with those of normal pregnant women) and failure of cortisol and ACTH to increase during times of stress are in keeping with diminished ACTH reserves. Imaging studies are likely to reveal an empty sella turcica.⁶²

Treatment of pituitary insufficiency during pregnancy does not present special problems. Oral L-thyroxine (0.1 to 0.2 mg/day) and cortisol (20 mg in the morning and 10 mg in the evening) or prednisone (5 mg in the morning and 2.5 mg in the evening) are administered. There is no need for mineralocorticoids. The dosage of L-thyroxine required in pregnancy is likely to be higher, and free thyroxine concentrations should be kept in the mid-normal range. TSH is not useful for monitoring treatment. As in the nonpregnant state, glucocorticoid requirements may increase during episodes of intercurrent illness. During labor, a good state of hydration should be maintained and parenteral glucocorticoids administered. This is most easily achieved by the intravenous infusion of hydrocortisone (cortisol). The dosage can be adjusted as appropriate for the patient's state, ranging from 25 to 75 mg every 6 hours. After delivery, parenteral glucocorticoids should be continued in smaller dosages for a few days along with intravenous fluids. In an analysis of 31 pregnancies in 27 women, hypopituitary women

were at increased risk for postpartum hemorrhage, transverse lie, and small-for-gestational-age newborns. In one case, third-trimester oxytocin supplementation was implemented to prevent uterine inertia, but it did not prevent postpartum hemorrhage.⁶³

Pituitary Necrosis. Spontaneous pituitary necrosis and hypopituitarism can occur in pregnant diabetic patients, possibly related to diabetic vascular changes and the general susceptibility of the anterior pituitary to ischemia in pregnancy. It is manifested by severe, midline headaches and vomiting during the third trimester, followed by a decrease in insulin requirements. In three of eight patients reported, the condition was associated with fetal death followed by maternal death.⁶⁴ Early recognition and prompt management are essential. Pituitary apoplexy in a nondiabetic patient presenting during pregnancy with headaches and circulatory collapse has also been reported.⁶⁵

Lymphocytic Adenohypophysitis. In 1962, Goudie and Pinkerton⁶⁶ described the case of a 22-year-old woman who died of circulatory collapse 8 hours after an appendectomy. This occurred 14 months after a normal pregnancy and delivery, but she had developed secondary amenorrhea after delivery. Autopsy revealed lymphocytic infiltration of the pituitary and of the thyroid; the investigators postulated an autoimmune mechanism to explain both.

Lymphocytic adenohypophysitis (LAH), the subject of a review,⁶⁷ demonstrates a striking temporal association with pregnancy. Of a total of 245 cases of LAH reported, 210 occurred in women, and of these women, 120 (57%) presented during pregnancy or after delivery, most in the last month of pregnancy or within the 2 months after delivery. There were no fetal complications, but one patient died in labor. Sixteen women had subsequent pregnancies. Release of pituitary antigens during pregnancy-related changes and alterations in pituitary blood supply have been suggested as links to altered immunity. Antipituitary antibodies have been demonstrated in a significant number of cases.^{67,68} Exacerbation of the disease after delivery, even when it initially manifests in pregnancy, has been described.⁶⁹

Table 61-3 inventories the characteristics of patients with LAH. Hypocortisolism is the most important hormone deficiency, followed by TSH, gonadotropin, and prolactin. Hyperprolactinemia may also occur, manifesting as amenorrhea or galactorrhea. Stalk compression, an inflammatory process in the lactotroph that induces release of prolactin, and antibodies stimulating prolactin synthesis are potential mechanisms leading to hyperprolactinemia.

The association of this disease with pregnancy was highlighted in an immunohistochemical study performed on pituitary material obtained at autopsy from 69 women who were pregnant or who had undergone delivery; among these were five cases of mild LAH.¹ In four of the five cases, the patients died at 38 to 41 weeks' gestation.

This disease affecting young women during or after pregnancy is potentially life threatening, but it is treatable. The diagnosis should be considered in women of reproductive age who present with signs and symptoms of anterior pituitary hormone deficiencies (isolated or combined) before or after delivery, especially in the absence of significant bleeding during labor. The diagnosis should also be considered in pregnant or postpartum women with visual symptoms and changes. In the absence of a threat to vision, such patients should be treated medically with hormone replacement and their progress

TABLE 61-3 Characteristics of 245 Patients with Lymphocytic Adenohypophysitis

Characteristic	Quantity or Percent
Mean age of women (n = 210)	35 yr
Mean age of men (n = 35)	45 yr
History of onset in pregnant or postpartum women (120 women)	57%
Hypocortisolism	42%
Hypothyroidism	18%
Hypogonadism	12%
Inability to lactate	11%
Hyperprolactinemia	23%
Polyuria or polydipsia	1%
Headaches	53%
Visual disturbances	43%
Association with other autoimmune disease*	18%
Median duration of symptoms with diagnosis outside pregnancy	12 mo
Median duration of symptoms with diagnosis associated with pregnancy	4 mo
Required long-term hormonal treatment	56%
Deaths	8.6%
Disease resolved spontaneously	4.5%

*Includes 131 patients with infundibulo-neurohypophysitis and panhypophysitis, and 245 patients with lymphocytic adenohypophysitis.

Adapted from Caturegli P, Newschaffer C, Olivi A, et al: Autoimmune hypophysitis, *Endocr Rev* 26:599-614, 2005.

observed. MRI should be used to delineate and follow the anatomic defects. It typically shows a symmetrically enlarged gland and a thickened stalk, and in contrast to what is seen with macroadenomas, MRI shows strong and homogeneous enhancement after gadolinium contrast.

The use of steroids has been associated with amelioration of visual symptoms,^{70,71} and the sellar mass has been shown to regress spontaneously. In another reported case,⁷¹ partial hypopituitarism resolved after delivery in a biopsy-diagnosed case of LAH. Glucocorticoids should be the first line of treatment for the pituitary mass. Other immunosuppressive drugs, such as azathioprine and methotrexate, have also been used. Decompressive surgery is indicated only for progressive visual deficit. Although considered a disease of the anterior pituitary, LAH can manifest as diabetes insipidus with thickening and prominence of the pituitary stalk.⁷² LAH has recurred in a subsequent pregnancy in a case of histologically documented hypophysitis.⁷³ One woman with hypopituitarism subsequently developed type 1 diabetes mellitus; this was followed by recovery of pituitary function over 3 years, and she had two other pregnancies.⁷⁴

Posterior Lobe Disorders

Diabetes Insipidus. Vasopressin and oxytocin, produced in the supraoptic and paraventricular nuclei of the hypothalamus, are released into the posterior lobe and then into the circulation. No disease process with oxytocin deficiency or excess has been described. Lack of vasopressin results in diabetes insipidus, however, and this can occur as a primary or idiopathic disorder (~30% of cases), or it can be acquired secondary to a variety of pathologic lesions, including cranial injuries (16%), infections, sellar and suprasellar tumors (25%), and vascular

lesions. The main symptoms are polyuria, polydipsia, and low urinary specific gravity. The diagnosis is confirmed by water deprivation. During this test, increasing serum osmolality in the face of low urine osmolality is diagnostic of diabetes insipidus; a return toward normal after vasopressin administration confirms vasopressin deficiency.

Effect of Diabetes Insipidus on Pregnancy. In a comprehensive review, Hendricks⁷⁵ concluded that the prior existence of diabetes insipidus in a woman did not appear to alter her fertility, the course of pregnancy, the effectiveness of labor, or lactation. Because oxytocin is also produced in the same hypothalamic nuclei, diabetes insipidus is of particular interest in managing the pregnant woman because of the possible relationship of decreased oxytocin with decreased uterine contractions during labor. Despite one report of uterine atony,⁷⁶ it appears that labor is normal in most patients with diabetes insipidus.

Effect of Pregnancy on Diabetes Insipidus. The effect of pregnancy on diabetes insipidus has been reviewed by Durr and Lindheimer.⁷⁷ The disorder can occur in pregnant women in five distinct forms.

First, the diabetes insipidus can antedate gestation. In a review of the subject, Hime and Richardson⁷⁸ found that 58% of patients deteriorated, 20% improved, and 15% remained the same. The metabolic clearance of vasopressin markedly increased between gestational week 10 and mid pregnancy, and this was associated with parallel increases in circulating vasopressinase. Placental inactivation of vasopressin, with the production of large quantities of vasopressinase by the placenta, may contribute to this increase in clearance rate.⁷ In the few patients in whom preeclampsia developed, the diabetes insipidus improved. The decreased contribution of the placenta to destruction of vasopressin is thought to explain this improvement.⁷⁹

Second, transient arginine-vasopressin (AVP)-resistant but 1-deamino-8-D-arginine vasopressin (DDAVP)-responsive diabetes insipidus is attributable to excessively high quantities of circulating vasopressinase.⁸⁰ It is often associated with liver abnormalities in the mother, such as acute fatty liver or HELLP syndrome (*hemolysis, elevated liver enzymes, low platelets*). Vasopressinase isoenzymes are cleared by the liver, and under these circumstances, excessive amounts are made available. Two cases were reported by Brewster and Hayslett⁸¹ that were unassociated with liver disease. An accompanying commentary stated that a sodium level of 140 mEq/L should be considered hypernatremia in most pregnant women, and early recognition and treatment were advised.⁸² A case of transient diabetes insipidus in pregnancy showed absence of the hyperintensity of the posterior pituitary lobe on MRI during pregnancy with restoration after delivery, presumably reflecting depletion and restoration of neurosecretory granules.⁸³

Third, transient diabetes insipidus during pregnancy can occur in patients with acquired or hereditary latent diabetes insipidus. Patients with limited vasopressin-secreting capacity (latent-central defect) may be unable to sustain the increased production rates necessary during gestation. Clinically, transient diabetes insipidus manifests in the latter part of gestation, coinciding with peak vasopressinase levels, and subsequent pregnancies may involve many recurrences. History of prior insult to the area, such as histiocytosis X or Sheehan syndrome, may be obtained. Classic hereditary nephrogenic diabetes insipidus is caused by an X-linked recessive mutation of the renal vasopressin receptor gene, and symptomatic diabetes insipidus

in female carriers is rare. Some carriers, however, do have defects in renal concentrating ability, and it has been hypothesized that nonrandom X-chromosome inactivation in the kidneys could be responsible for the variable expression. Unmasking of a mild defect in vasopressin action (e.g., nephrogenic diabetes insipidus) may occur. The increased disposal of vasopressin could lead to decompensation. Lowering of the osmotic threshold for thirst, which occurs normally in pregnancy (see Fig. 61-4), causes polydipsia and unacceptable polyuria in a patient with previously compensated nephrogenic diabetes insipidus.⁸⁴

Fourth, diabetes insipidus can occur after a complicated delivery. This is often associated with severe blood loss leading to some degree of pituitary apoplexy or Sheehan syndrome.

Finally, transient *de novo* nephrogenic diabetes insipidus may be resistant to AVP and DDAVP. During pregnancy, the concentration of prostaglandin E₂ in the kidney physiologically increases. Ford and Lumpkin⁸⁵ found high prostaglandin E₂ concentrations. Reduced renal sensitivity to vasopressin has been proposed⁸⁶ to explain this.

Treatment. The treatment of choice for central diabetes insipidus is DDAVP or desmopressin acetate, a synthetic analogue of vasopressin, administered intranasally or orally. Clinical experience with DDAVP, in a study involving many infants exposed during gestation, has confirmed its safety.^{87,88} Dosages range from 10 to 20 µg, given once or twice daily intranasally, or 0.05 to 0.1 mg administered twice daily orally, titrating up if needed. In a study by Burrow and coauthors,⁸⁹ the drug was administered and DDAVP concentrations were measured as vasopressin by radioimmunoassay in maternal serum and breast milk. Whereas maternal serum concentrations rose about sevenfold, breast milk concentrations showed little change. This suggests that, given the low levels of DDAVP in milk, these mothers may breastfeed. DDAVP has little pressor or uterotonic action, and it is not affected by vasopressinase.

Primary Polydipsia during Gestation. Primary polydipsia has rarely been reported during gestation.⁹⁰ Pregnancy was merely incidental and had no role in the polydipsia.

Adrenal Glands

The adrenal cortex plays an important and essential metabolic role in humans. Adrenal steroidogenesis leads to the production of three types of steroids. Mineralocorticoids are produced by the zona glomerulosa, glucocorticoids are produced primarily in the zona fasciculata, and sex steroids are produced in the zona reticularis. Figure 61-7 depicts the biosynthetic pathways.

CONTROL OF ADRENOCORTICAL HORMONES

Aldosterone is primarily under the control of the renin-angiotensin system, although ACTH and hyperkalemia also have a stimulatory role. Renin, which is secreted by the juxtaglomerular apparatus of the kidney, converts angiotensinogen (an α₂-globulin produced by the liver) to angiotensin I, which is converted to angiotensin II. Angiotensin II, in addition to having pressor action, stimulates aldosterone secretion. Although an increase in angiotensin II suppresses renin production, volume and sodium depletion stimulate its release.

Cortisol secretion is controlled by the hypothalamic-pituitary axis. CRH, which is secreted by the paraventricular nucleus of

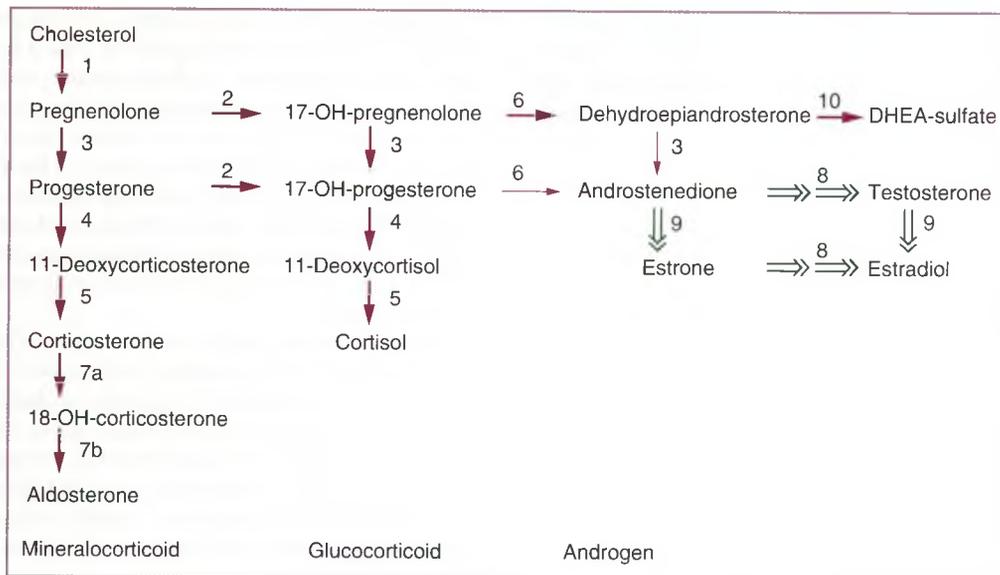

Figure 61-7 Adrenal steroidogenic pathways of mineralocorticoid, glucocorticoid, and androgen synthesis. Major pathways are indicated by thick arrows and minor ones by thin arrows. Extra-adrenal conversion of sex steroids is denoted by double arrows. Numbers indicate enzymatic steps as follows: 1, 20α -hydroxylase; 2, 17α -hydroxylase; 3, 3β -hydroxysteroid dehydrogenase, Δ^4 -isomerase; 4, 21 -hydroxylase; 5, 11β -hydroxylase; 6, $C_{17,20}$ -lyase; 7a, 18 -hydroxylase; 7b, 18 -dehydrogenase; 8, 17β -hydroxysteroid dehydrogenase; 9, aromatase; 10, sulfatase.

the hypothalamus, is a 41-amino-acid peptide that binds to the corticotroph membrane, activating the adenylate cyclase system. ACTH is a 39-amino-acid peptide derived from a much larger precursor, pro-opiomelanocortin (which is processed mainly into ACTH). Cortisol secretion has a diurnal rhythm: The main secretory phase occurs during the late hours of sleep and early morning. There are long- and short-loop negative-feedback mechanisms. In the long loop, the adrenals inhibit the anterior pituitary through plasma cortisol by inhibiting ACTH release and by inhibition of the genome responsible for pro-opiomelanocortin synthesis. In the short loop, ACTH regulates its own secretion by inhibiting CRH release.

ACTH has a stimulatory effect on adrenal androgen synthesis, and production declines with age. The major androgens are androstenedione, dehydroepiandrosterone, and dehydroepiandrosterone sulfate. Androstenedione is converted peripherally to testosterone and to estrone and estradiol.

PHYSIOLOGIC CHANGES DURING PREGNANCY

The plasma level of CRH increases progressively during the second and third trimesters, peaking at delivery. It has been isolated from the placenta, which is its likely source.^{91,92} ACTH concentrations increase threefold from the first to third trimester, and its production by the placenta has been demonstrated.⁹³ The diurnal variation of cortisol and ACTH, although blunted, is retained. Corticosteroid-binding globulin concentrations triple during pregnancy, resulting in an increase in the total plasma cortisol and a decrease in its metabolic clearance. The unbound fraction also increases (free cortisol elevations of twofold to fourfold have been shown), and this is reflected by a rise in urinary free cortisol. These changes are depicted in e-Figure 61-8. In the third trimester, the 9 AM plasma cortisol level ranges between 25 and 46 $\mu\text{g}/\text{dL}$, and the mean urinary

free cortisol excretion is elevated at least 180% during gestation. Neither placental ACTH nor CRH is suppressible in vitro with exogenous glucocorticoids. In the future, salivary assays of free cortisol may become more widely available. The normal response to ACTH has been evaluated.⁹⁴

Renin activity increases early, peaking at 12 weeks' gestation, with a decline in the third trimester.⁹⁵ The decline is probably related to the rise in angiotensin II that occurs at this time. Plasma aldosterone concentrations reach values up to 20 times that of the nonpregnant state by the third trimester. The activation of the renin-angiotensin-aldosterone axis may result from the fall in blood pressure, which in itself results from decreased vascular responsiveness to angiotensin II and decreased vascular resistance. High levels of serum progesterone block aldosterone action, preventing kaliuresis.

Total testosterone increases in pregnancy because of an increase in sex hormone-binding globulin with a reduction in the percentage unbound; although the amount of free testosterone is low to normal in the first 28 weeks, it increases thereafter, with values often exceeding the normal range for nonpregnant women.⁹⁶ Mean levels of androstenedione also increase in the latter part of pregnancy, whereas dehydroepiandrosterone sulfate concentrations decrease because of a major increase in the metabolic clearance rate.

FETAL ADRENAL DEVELOPMENT

Fetal adrenal development has been reviewed by Ishimoto and Jaffe.⁹⁷ The fetal adrenal can synthesize cortisol in vitro by 8 weeks' gestation. In vivo, placental 5-pregnenolone and 4-progesterone are used to synthesize steroids.⁹⁸ Two adrenal cortical zones can be identified in the fetus. The inner, or fetal, zone, which accounts for about 80% of the cortex in utero, involutes in the first few months of extrauterine life. The outer

zone becomes the adult adrenal cortex. The fetal zone lacks 3β -hydroxysteroid dehydrogenase and is therefore unable to synthesize glucocorticoids or mineralocorticoids. The most abundant product is dehydroepiandrosterone, which forms the substrate for placental estrogen synthesis. During most of gestation, most cortisol in the fetal circulation is supplied by the mother through transplacental passage, although fetal cortisol concentrations are lower than maternal because of placental cortisol metabolism.

DISORDERS OF THE ADRENAL CORTEX DURING PREGNANCY

Disorders of the adrenal cortex during pregnancy have been reviewed by Lindsay and Nieman.⁹⁹ Disrupted reproductive function commonly accompanies significant genetic or acquired abnormalities of adrenal cortical function. These abnormalities are usually diagnosed before conception. In patients with previously recognized adrenal disorders, replacement hormone therapy is continued throughout gestation, and the patient is monitored. The pregnancy-associated changes in normal values must be borne in mind.

Primary Adrenocortical Insufficiency: Addison Disease

Atrophy of the adrenals on an autoimmune basis is the most common cause of adrenal failure, accounting for 83% of cases.¹⁰⁰ Other causes include hemorrhage (usually associated with sepsis and burns), infections (viral, fungal, or tuberculous), and infiltrative disorders, including metastases, lymphoma, and amyloidosis. With the availability of hormone replacement, pregnancy is no longer contraindicated.

Diagnosis during Pregnancy. In a review of 40 cases of Addison disease in pregnancy about 5 decades ago, 18 died during pregnancy; 12 of 22 who delivered had a crisis in the puerperium, and seven of these died.¹⁰¹ The diagnosis of Addison disease in pregnancy is uncommon and may be related to the fetal contribution to maternal steroids. The symptoms include weakness, lassitude, nausea with or without vomiting, pigmentation, weight loss, anorexia, and abdominal pain. Some of these symptoms are also common in normal pregnant women. Suspicion should be heightened when a thin pregnant woman complains of prolonged nausea and vomiting, weakness, postural hypotension, and personality changes. A history of polyendocrine autoimmune disorders, type 1 diabetes, adrenogenital syndrome, tuberculosis, or acquired immunodeficiency syndrome (AIDS) places the pregnant woman at increased risk for adrenocortical insufficiency.

The signs, symptoms, and laboratory findings for primary adrenal insufficiency during pregnancy are outlined in Box 61-1. In acutely ill patients, replacement therapy must be initiated immediately and the diagnosis of primary adrenocortical insufficiency during pregnancy confirmed retrospectively by a pretreatment serum or plasma sample for measuring electrolytes, cortisol, and ACTH. In patients whose illness is less severe, a rapid ACTH stimulation test using synthetic ACTH may be performed; 250 μ g is administered intravenously and blood samples are obtained at baseline, 30 minutes, and 60 minutes. Although a cortisol level exceeding 18 μ g/dL and an increment exceeding 7 μ g/dL are considered normal in the nonpregnant state, the mean increments have been reported as 18, 23, and 26 μ g/dL in the first, second, and third trimester of pregnancy,

BOX 61-1 DIAGNOSIS OF PRIMARY ADRENAL INSUFFICIENCY DURING PREGNANCY

SIGNS AND SYMPTOMS

- Nausea with or without vomiting, anorexia
- Systolic blood pressure <100 mm Hg with postural decrease
- Increased pigmentation
- Abdominal pain
- Personality changes
- Weakness, fatigue
- Muscle and joint pain
- Salt craving

LABORATORY FINDINGS

- Decreased sodium concentration
- Increased potassium, blood urea nitrogen (BUN), and creatinine levels
- Hypoglycemia
- Plasma cortisol level below normal pregnancy level
- Urinary free cortisol: 24-hour excretion below normal pregnancy level
- Increased plasma level of adrenocorticotrophic hormone (ACTH)
- Abnormal cortisol response to rapid ACTH stimulation test

respectively.¹⁰² Responses to 1 μ g of ACTH have shown mean peak cortisol levels of 44 μ g/dL in unaffected pregnant women.¹⁰³ It has been suggested that adrenal insufficiency may be excluded if the basal or ACTH-stimulated (250 μ g) cortisol exceeds 30 μ g/dL in the third trimester.

Treatment. Replacement regimens are similar to those used in nonpregnant women. This is usually accomplished by hydrocortisone (cortisol) at a dosage of 20 mg in the morning and 10 mg in the evening, along with 0.05 to 0.1 mg of fludrocortisone administered daily. The dosage of fludrocortisone is increased if postural hypotension or hyperkalemia persists, and it is decreased if hypertension or hypokalemia occurs. The dosage of cortisol should be doubled or tripled in any situation associated with stress, including systemic illness or trauma. Breastfeeding has been discouraged because of the potential hazard of corticosteroids passing into the maternal milk, but some investigators disagree.¹⁰⁴ Less than 0.5% of the absorbed dosage is excreted per liter of breast milk. Labor should be managed with stress dosages of 300 mg of hydrocortisone over 24 hours, with subsequent tapering.

Acute Adrenal Insufficiency during Pregnancy, Labor, Delivery, or the Puerperium. Addisonian crisis is a rare but life-threatening event in pregnant women.¹⁰⁵ The onset can be confused with an abdominal surgical emergency because of the prominence of abdominal pain, nausea, vomiting, and shock. After necessary blood samples are obtained for electrolytes, cortisol, and ACTH determinations, intravenous therapy should be started immediately with 100 mg of hydrocortisone sodium succinate, along with an infusion of normal saline and 5% glucose. During the first 24 hours, 300 to 400 mg of intravenous hydrocortisone sodium succinate should be given continuously, and this can be conveniently added to the replacement fluids administered.

Recovery occurs quickly, and by 24 hours, the patient may be able to return to oral feedings and replacement dosages of oral hydrocortisone and fludrocortisone. If recovery does not

occur, hydrocortisone may be continued intravenously, usually at a diminished dosage. An effort should be made to determine the cause of the adrenal crisis, and the patient should receive careful postpregnancy supervision. Patients with mild deficiency are especially at risk during labor, delivery, and the immediate postpartum period.¹⁰⁴

Effect of Maternal Addison Disease on the Newborn. Addison disease in women is a risk factor for adverse pregnancy outcome. In 1188 women with Addison disease who delivered infants, the odds ratios for preterm birth, low birth weight, and cesarean section were 2.40, 3.5, and 1.74, respectively, compared with age-matched controls.¹⁰⁶ Maternal antibodies to the adrenal cortex cross the placenta but do not significantly affect neonatal adrenal function.

Cushing Syndrome

Cushing syndrome results from an excess of glucocorticoids and is rare during pregnancy. Hypothalamic and pituitary disorders were discussed previously and have been reviewed by Lindsay and colleagues.⁴⁶ Adrenocortical carcinoma is a rare disorder. In a retrospective cohort study of 110 patients with this disease, 12 were pregnant or were within the first 6 months after delivery. Those diagnosed in pregnancy or postpartum were more likely to have cortisol-secreting tumors and to be in a more advanced stage, but the differences were not significant. Fetal outcome was poor, and the overall survival of the mother was worse than matched controls.¹⁰⁷

Primary Hyperaldosteronism

Primary hyperaldosteronism has been reviewed by Lindsay and Nieman.⁹⁹ The autonomous secretion of aldosterone in this disorder may result from an adrenal adenoma, bilateral hyperplasia, or, rarely, an adrenocortical carcinoma. In pregnancy, the clinical picture of hyperaldosteronism is similar to that of the nonpregnant patient, with hypertension, hypokalemia, and, often, kaliuresis and elevated serum bicarbonate.¹⁰⁸ The electrolyte disturbances and hypertension may first be apparent in the peripartum period, coinciding with the removal of the protective antialdosterone effect of progesterone. Of 31 patients reported, most have harbored adenomas.¹⁰⁹

Diagnosis. After standardizing the patient for dietary sodium (100 to 150 mEq daily) and posture (i.e., recumbent) and after replacing plasma potassium, the physician measures renin activity and aldosterone concentrations. The renin activity is lower and the aldosterone concentration higher than those found in normal pregnancy.¹⁰⁸ Suppression of the aldosterone axis can also be attempted with salt loading (200 to 300 mEq/day for 3 to 5 days); the hallmark of primary hyperaldosteronism is a lack of suppression of serum aldosterone concentration. If surgery is contemplated, MRI may be used to localize the adenoma. The course of the pregnancy entails difficult-to-treat hypertension. Neonatal morbidity and mortality are related to placental insufficiency.

Treatment. Medical treatment with standard antihypertensive drugs should be provided, along with potassium supplements. Surgery in the second trimester may be required if medical treatment fails; surgery has gained wider acceptance since the advent of laparoscopic adrenalectomy. Spironolactone is contraindicated in pregnancy, especially in the first trimester,

because of its possible feminizing effects. In the first case report of a pregnant patient with hyperaldosteronism associated with bilateral hyperplasia, documented by Neerhof and colleagues,¹¹⁰ enalapril maleate, an angiotensin-converting enzyme inhibitor, successfully lowered blood pressures in a patient unresponsive to other medications. However, later reports of adverse effects preclude the use of angiotensin-converting enzyme inhibitors in pregnancy.¹¹¹

Congenital Adrenal Hyperplasia

The congenital adrenal hyperplasias (CAHs) involve inherited enzymatic defects of adrenal steroidogenesis. The most severe and life-threatening disorders occur early in the biosynthetic cascade and are usually fatal or incompatible with successful reproduction. Deficiency of 21-hydroxylase is the most common defect (see Fig. 61-7), accounting for 90% to 95% of cases, with an incidence of about 1 in 14,000, although in some areas, such as Alaska, it is more common.¹¹² The second most common form is 11-hydroxylase deficiency. CAH in pregnancy and its prenatal treatment was reviewed in 2001 by New.¹¹³

Genetics. All CAHs are autosomal recessive disorders. The parents of an affected child have at least one haplotype for the defect, giving each subsequent offspring a 25% chance of having the condition and a 50% chance of being a carrier. An affected individual produces 100% carriers if her partner is not affected; if her partner is a carrier, 50% of the offspring are affected, and the other 50% are carriers. Siblings or spouses who want to know whether they are heterozygotes for 21-hydroxylase deficiency can be tested by undergoing measurements of adrenal steroids (notably 17-hydroxyprogesterone) before and after ACTH stimulation.¹¹⁴

21-Hydroxylase Deficiency. Deficiency of 21-hydroxylase arises because of genetic mutations of the 21-hydroxylase gene located at a site linked to the human leukocyte antigen (HLA) histocompatibility complex on the short arm of the sixth chromosome. The variation in severity of the deficiency can be accounted for by allelic variation at the gene locus.¹¹⁵ The enzyme block results in inadequate synthesis of 11-deoxycortisol and cortisol; the resulting excess ACTH stimulates adrenal precursors, notably 17-hydroxyprogesterone. Shunting of these excess precursors results in excess androgens, leading to masculinization of genitalia of the female fetus and excess masculinization of the male infant.

If the defect is severe, mineralocorticoid deficiency occurs with salt wasting. The diagnosis is confirmed by the finding of excess basal 17-hydroxyprogesterone concentrations; in milder forms, ACTH stimulation is necessary and shows an excessive increase in 17-hydroxyprogesterone. Physiologic replacement dosages of glucocorticoids (usually cortisol) are used as therapy, and the dosage is based on surface area. Concentrations of 4-androstenedione, testosterone, and 17-hydroxyprogesterone are used to monitor adequacy of suppression. Fludrocortisone is indicated in salt-losing forms and in non-salt-losing forms with increased plasma renin activity. Virilized females may require surgical reconstruction of the genitalia to provide a normal appearance, intercourse, and pregnancy.

Maternal and Fetal Considerations. Although poor control of CAH results in irregular or absent menses, patients in whom the condition is well controlled may achieve pregnancy, although

less often than expected, possibly because of postnatal intervals of excess androgen exposure. Usually, the same dosage of cortisol can be continued through gestation, with additional amounts given during labor, delivery, and the immediate postpartum period. Cesarean section rates may be higher because of abnormal maternal external genitalia or a small bony pelvis from premature closure of the epiphyses.¹¹⁶ Most children of mothers with CAH are normal, although women receiving suboptimal dosages of replacement therapy have elevated circulating androgens, which may cross the placenta and virilize the fetus.

Free testosterone levels do not change significantly during gestation and can be used as a marker for monitoring therapy. Conversely, excessive glucocorticoid therapy of the mother with CAH may result in suppression of fetal adrenals, with resulting transient adrenocortical insufficiency of the neonate.

Prenatal Diagnosis and Treatment. Prenatal diagnosis of 21-hydroxylase deficiency for offspring of known heterozygotes first became possible with the finding of elevated levels of 17-hydroxyprogesterone in amniotic fluid obtained by amniocentesis.¹¹⁷ By the time amniocentesis is performed in the second trimester, it is too late to prevent virilization. Dexamethasone can be administered in a pregnancy at risk before the end of the 7th week from conception (9 weeks' gestation). This treatment results in suppression of 17-hydroxyprogesterone and renders it unreliable for diagnosis. After HLA profiles were found to be linked to CAH, diagnoses were made with HLA linkage marker analysis using amniotic cells. To avoid errors resulting from recombination or haplotype sharing, however, direct DNA analysis of the 21-hydroxylase gene (*CYP21*) with molecular genetic techniques is recommended. Chorionic villus sampling should preferably be used to obtain fetal tissue sooner (9 to 11 weeks' gestation) for diagnosis by molecular genetic analysis.¹¹⁸

Prenatal treatment of the mother with high-dosage glucocorticoids has been effective in preventing virilization of the affected female fetus; the glucocorticoid crosses the placenta and suppresses ACTH secretion from the fetal pituitary.¹¹⁷ Dexamethasone (20 µg/kg of pre-pregnancy weight) is given orally in divided daily doses after pregnancy has been confirmed. This treatment must be given before the end of the 7th week from conception. Chorionic villus sampling is then performed. If the fetus is male, maternal treatment is discontinued; if female, the treatment is continued until the results of DNA analysis of the 21-hydroxylase gene are available. The glucocorticoids are discontinued only if the female fetus is deemed unaffected.

A review of 532 pregnancies prenatally diagnosed using amniocentesis or chorionic villus sampling between 1978 and 2001 was reported by New and associates.¹¹⁸ Of these 532 pregnancies, 281 were treated prenatally for congenital adrenal hyperplasia because of the risk for 21-hydroxylase deficiency. Of 116 babies affected with CAH, 61 were female, and 49 of those were treated prenatally with dexamethasone. If given in proper dosage, dexamethasone administered at or before week 9 of gestation was effective in reducing virilization. With the exception of striae, weight gain, and edema, there were no other differences in the symptoms of treated and untreated mothers. Prenatally treated newborns had weights that matched untreated and unaffected newborns, and no enduring side effects were observed. Prenatal diagnosis and treatment of 21-hydroxylase

deficiency is possible and effective. An algorithm showing prenatal management of pregnancies in families at risk for a fetus affected by 21-hydroxylase deficiency is provided in e-Figure 61-9. An updated review has been provided by Nimkarn and New.¹¹⁹ However, there are few data on long-term risks. A study based on a maternal survey showed that 174 children (48 had CAH) who received dexamethasone did not differ in cognitive or motor development from 313 unexposed children.¹²⁰ However, a later study showed impaired cognitive function in at-risk children who were treated prenatally.¹²¹ A consensus conference recommended that only an experienced team direct this therapy, preferably under a research protocol, with consent and with prospective and long-term follow-up of the children.¹²² Controversy concerning prenatal treatment of CAH continues. A systematic review and meta-analysis concluded that the observational nature of the available evidence and the overall small sample size significantly weaken inferences about the benefits and harms of dexamethasone in this setting.¹²³ It also concluded that the decision to initiate treatment should be based on the patient's values and preferences and requires fully informed and consenting parents.

11-Hydroxylase Deficiency. An enzyme defect that is not HLA linked, 11-hydroxylase deficiency results in blocked production of cortisol and aldosterone, with a resultant excess of the precursors 11-deoxycortisol and deoxycorticosterone.¹¹⁷ A shunt toward excess androgens occurs, and the presentation is that of androgen excess and hypertension. Diagnosis is based on elevated 11-deoxycortisol and deoxycorticosterone concentrations determined basally or after ACTH stimulation. Heterozygotes have no demonstrable biochemical abnormality, even with ACTH stimulation. Treatment is with glucocorticoid replacement. Prenatal diagnosis is confirmed by measuring 11-deoxycortisol concentrations in amniotic fluid.¹²³ Prenatal treatment of the mother with dexamethasone, as in 21-hydroxylase deficiency, has been reported, resulting in a female without virilization or ambiguous genitalia who was genetically affected.¹²⁴ A successful pregnancy has been reported for a female with 11β-hydroxylase deficiency.¹²⁵

Other Congenital Adrenal Hyperplasia Enzyme Deficiencies. There are a few other rare forms of CAH (see Fig. 61-7). In 17-hydroxylase deficiency, the sex steroid pathway is blocked in the adrenal cortex and gonad, resulting in a hypogonadal state and primary amenorrhea. Deficiency of 3β-hydroxysteroid dehydrogenase, if severe, manifests as lack of pubertal development. Milder forms manifest pubertally with hyperandrogenism.¹²⁶

Long-Term Therapy with Pharmacologic Dosages of Steroids

The occurrence of congenital anomalies in animal experiments—cleft palate in particular—raised concerns about pregnant women receiving glucocorticoids during pregnancy. In a review involving 260 pregnancies in which glucocorticoids had been administered to women in pharmacologic dosages, only two infants had cleft palate.¹²⁷ The mothers of both of these infants had received steroids in large dosages early in pregnancy. Because closure of the palatal process occurs by the 12th week of gestation, it is possible that the anomaly was related to the medication. Although other, smaller studies have not supported this association, a prospective cohort study and meta-analysis of epidemiologic studies concluded that prednisone increases

the risk for oral clefts by 3.4-fold.¹²⁸ The regulation of their transplacental passage, their biologic effects on gestational environment, their possible programming, and their teratogenic action were recently reviewed.¹²⁹

The hypothalamic-pituitary-adrenal axis is suppressed with long-term suprathreshold dosages of glucocorticoids, and abrupt withdrawal should be avoided because it can precipitate maternal adrenocortical insufficiency. Glucocorticoids are excreted in breast milk and have the potential to cause growth restriction in the neonate. Neonatal adrenal insufficiency, although rare, can occur in infants born to mothers being treated with exogenous glucocorticoids.¹²⁷

DISORDERS OF THE ADRENAL MEDULLA DURING PREGNANCY

Pheochromocytoma

Pheochromocytomas have been reviewed by Sarathi and associates,¹³⁰ and several additional cases have also been reported.¹³¹ Pheochromocytomas are tumors of chromaffin cells, and 90% of them cluster in the adrenal medulla. Sites of extra-adrenal tumors range from the carotid body to the pelvic floor. They occur sporadically or as part of the familial multiple endocrine neoplasia type 2 syndrome. Approximately 12% are malignant, but the percentage is higher in pheochromocytomas occurring in extra-adrenal sites.

Symptoms. Pheochromocytoma is a rare but potentially lethal cause of hypertension in pregnancy. Its possibility should be considered in women with intermittent, labile hypertension or paroxysmal symptoms such as anxiety, diaphoresis, headache, and palpitations. Other leads are worsening of blood pressure after β -adrenergic blockade, positive family history, presence of café au lait macules, and diabetes. Symptoms can also include chest or abdominal pain, unusual reactions to drugs affecting catecholamine release and actions, visual disturbances, convulsions, and collapse. Symptoms tend to be similar in pregnant and nonpregnant women. The occurrence of symptoms during pregnancy only, with recurrence in subsequent pregnancies, has also been described. Increased vascularity of the tumor in pregnancy and the mechanical effect of an enlarging uterus may explain this phenomenon. In many cases, severe symptoms develop in the peripartum and postpartum periods. At least 200 cases have been diagnosed in pregnancy, with an estimated prevalence of 1 in 54,000 at term.

Laboratory Diagnosis. Laboratory diagnosis involves biochemical demonstration of elevated levels of vanillylmandelic acid, catecholamines, and fractionated metanephrines in the 24-hour urine specimen, with urinary metanephrines the most sensitive test. Plasma catecholamine and metanephrine levels

can also be determined. Values in pregnant women are similar to those in nonpregnant subjects, but they are elevated for 24 hours after eclamptic seizures. Because methyldopa interferes with catecholamine measurements, it should be discontinued before testing. If necessary, the tumor may be localized during pregnancy by means of MRI, preferably, or ultrasonography. Abdominal MRIs will detect all adrenal tumors but can miss extra-adrenal ones.¹³⁰

Treatment. Treatment of pheochromocytoma in pregnancy is somewhat controversial. Most physicians agree that when the diagnosis is confirmed in the second half of pregnancy, α -adrenergic blockade with phenoxybenzamine is the treatment of choice. This drug is given orally, starting with 10 mg twice daily and gradually increasing by 10 to 20 mg daily until hypertension is controlled. When fetal maturity is achieved, cesarean section should be performed, with simultaneous or subsequent excision of the tumor^{132,133} during adrenergic blockade. Phentolamine (1 to 5 mg) can be used for a hypertensive crisis.

In tumors detected before 24 weeks' gestation, surgery during pregnancy has been advocated¹³³ to avoid fetal wasting. Laparoscopic adrenalectomy can be performed,¹³⁴ and in the review of Sarathi and coworkers,¹³⁰ 45% of antenatal surgeries were laparoscopic with zero maternal mortality. However, a number of such cases have been managed successfully during pregnancy with α - and β -blockade with good fetal outcomes.^{135,136} The arguments against medical therapy are the unknown effects of α - and β -blockade on the fetus in the long term, the teratogenic potential of phenoxybenzamine, and the risk for a malignant lesion. β -Blockade alone should not be used without prior α -blockade because unopposed α -adrenergic activity can lead to generalized vasoconstriction and a steep rise in blood pressure. Anesthetic management of pheochromocytoma resection during pregnancy requires special consideration.¹³⁷ Vaginal delivery carries a higher mortality rate than cesarean section,¹³¹ and general anesthesia is recommended.

Prognosis. Pheochromocytoma is a life-threatening disease for the mother and the fetus, although with better management and the availability of α - and β -adrenergic blockade, the prospects for both have improved. Table 61-4 shows the changes in maternal and fetal mortality rates over the past few decades and indicates that, generally, the prognosis is better when the diagnosis is made during pregnancy.^{130,133,138} However, a 36-year-old woman died at 27 weeks' gestation from a pheochromocytoma (diagnosed at autopsy).¹³⁹ Fetal growth restriction can result from reduced uteroplacental perfusion, and fetal death may occur during acute hypertensive crises.

Four cases of malignant pheochromocytomas in pregnancy were reviewed by Ellison and associates.¹⁴⁰ Another patient was

TABLE 61-4 Changes over Time in Maternal and Fetal Mortalities for More Than 200 Pregnancies Complicated by Pheochromocytoma

Time of Diagnosis	Maternal Mortality (%)					Fetal Mortality (%)				
	Pre-1969	1969-79	1980-87	1988-97	1998-2008	Pre-1969	1969-79	1980-87	1988-97	1998-2008
During pregnancy	18	4	0	2	5	50	42	11	11	12
After delivery	58	50	35	14	28	57	56	39	0	28

reported on by Devoe and coworkers,¹⁴¹ who used α -methyl paratyrosine, a dopamine synthesis inhibitor. Several cases of pregnancy with pheochromocytoma as part of type 2 multiple endocrine neoplasia have been reported.^{133,142,143} Germ-line mutations in predisposing genes have been reported in up to 25% of apparently sporadic tumors, and all patients should be assessed for associated syndromes.¹³⁰

Hirsutism and Virilization in Pregnancy

Hirsutism and virilization in pregnancy have been reviewed by McClamrock and Adashi.¹⁴⁴ Women and their female fetuses are protected from the increased concentrations of androgens by the enhanced binding to sex hormone-binding globulin, competition by progestins for binding to the androgen receptor or for disposition of androgens to more biologically potent compounds, and placental aromatization of androgens. Nevertheless, maternal hirsutism and virilization can occur in pregnancy and usually results from ovarian disease or iatrogenic insult. The female fetus can be affected by elevated circulating maternal androgens. Differentiation of the female external genitalia occurs between 7 and 12 weeks' gestation, and exposure to excess androgens can result in partial or complete labial fusion and clitoromegaly. Clitoromegaly may still occur after 12 weeks' gestation. The approach to maternal hirsutism and virilization in pregnancy is outlined in Table 61-5.

The two major causes of gestational hyperandrogenism are luteomas and hyperreactio luteinalis (i.e., gestational ovarian theca-lutein cysts). Luteomas are benign, solid tumors of the ovary; they are often multinodular and bilateral, and they are usually yellow to tan. Regardless of their virilizing effect, luteomas have been associated with elevated levels of circulating maternal androgens.

Not all luteomas cause maternal virilization (overall incidence is 35%); it depends on the amount of androgen secreted,

the end-organ sensitivity, and the degree of aromatization by the placenta to nonandrogenic steroids. Approximately 80% of female infants born to mothers with virilizing luteomas are virilized and usually exhibit clitoromegaly. Conservative management is generally appropriate, as luteomas usually regress after the delivery, although they may (but rarely) recur in a subsequent pregnancy.¹⁴⁵ Compared with hyperreactio luteinalis, luteomas occur more frequently in black multiparas and are not associated with toxemia, erythroblastosis, or multiple gestation.

Hyperreactio luteinalis is characterized by ovarian enlargement with many large-follicle cysts or corpora lutea, or both, and with marked edema of the stroma. It is usually bilateral, it usually affects white primigravidas, and it is often associated with conditions resulting in increased human chorionic gonadotropin (hCG), such as molar pregnancies and multiple gestations. Maternal hirsutism or virilization has been documented in approximately 30% of reported cases. There are no reported cases of fetal masculinization, even if the mother is virilized. The condition may represent an excessive ovarian sensitivity to hCG. The lack of fetal virilization in this condition is intriguing and has been attributed to androgen aromatization in the placenta. As with luteomas, recurrence of hyperreactio luteinalis in consecutive pregnancies has been reported.¹⁴⁶ Recurrent, severe hyperandrogenism during pregnancy has also been reported without the presence of luteomas or hyperreactio luteinalis.¹⁴⁷

Placental aromatase deficiency is a rare cause of maternal and fetal virilization, and it may be suspected if maternal hyperandrogenism is associated with low maternal estrogen levels.¹⁴⁸ Only 1% enzyme activity appears necessary to prevent virilization.

Another rare cause of maternal and fetal virilization is cytochrome P450 oxidoreductase deficiency, an autosomal recessive disorder caused by mutations in the gene encoding an electron donor of all P450 enzymes.^{149,150} This enzyme is an essential redox partner for CYP17 and CYP21 hydroxylases. Abnormal function of these enzymes can lead to maternal virilization and virilization of the female fetus, together with low estradiol secretion in pregnancy. Variable clinical manifestations include skeletal malformations, referred to as the Antley-Bixler syndrome, with insufficient glucocorticoids and increased 17-hydroxyprogesterone in both sexes.

In a few cases,^{151,152} insulin-resistant patients with polycystic ovary syndrome who achieve pregnancy may become extremely androgenized during pregnancy. Metformin was used in one of these cases.¹⁵¹ Other ovarian lesions that can cause maternal virilization include Sertoli-Leydig cell tumors (i.e., arrhenoblastomas), Krukenberg tumors, Brenner tumors, lipoid cell tumors, dermoid cysts, fibrothecomas, and mucinous and serous cystadenocarcinomas. Most Sertoli-Leydig cell tumors coexisting with pregnancy are associated with maternal virilization, and virilization of the female fetus can occur. The malignancy rate for these tumors is high (44%), with substantial maternal (31%) and perinatal (50%) mortality rates. Krukenberg tumors, which are gastrointestinal tumors metastatic to the ovary, are often bilateral and have caused maternal and fetal virilization in all reported cases.

Adrenal tumors, including adrenocortical carcinoma, can cause maternal and fetal virilization.¹⁵³ Masculinization of the female fetus has been associated with the gestational administration of progestins and androgens and can be unaccompanied by maternal virilization.

TABLE 61-5 Approach to Maternal Hirsutism and Virilization in Pregnancy

Findings	Indicated Action	Possible Virilization of Female Fetus?
HISTORY		
Acute onset in pregnancy	Investigate with studies as indicated below.	—
Androgenic drug exposure	Stop the drug.	Yes
PHYSICAL EXAMINATION OR OVARIAN ULTRASOUND		
Bilateral cystic: theca lutein cysts	Exclude high levels of human chorionic gonadotropin.	No
Bilateral solid: luteoma very likely	—	Yes
Unilateral solid	Perform surgery to exclude malignancy.	Yes
No ovarian mass	Investigate adrenal glands. Consider insulin resistance.	Yes

Parathyroid Glands and Calcium Metabolism

MATERNAL AND FETAL PHYSIOLOGY AND LACTATION

The serum calcium level is tightly regulated and maintained within normal limits by parathyroid hormone (PTH) and vitamin D. Vitamin D can be synthesized in the skin under the influence of ultraviolet irradiation, or it can be absorbed from dietary sources through the gastrointestinal tract. The 25(OH)D form of vitamin D (i.e., 25-hydroxycholecalciferol, or vitamin D₃) is 25-hydroxylated in the liver and then 1-hydroxylated in the kidney. The physiologically active form of vitamin D is 1,25(OH)₂D (i.e., 1,25-dihydroxycholecalciferol, calcitriol, or vitamin D₂), which is responsible for increasing intestinal absorption of calcium and for bone resorption. The Endocrine Society Clinical Guidelines for the evaluation, treatment, and prevention of vitamin D deficiency recommend serum 25-hydroxy vitamin D as the appropriate test. A level of 30 ng/mL or higher is considered normal, less than 20 ng/mL is deficient, and 21 to 29 ng/mL is insufficient. The guidelines recommend that pregnant and lactating women take at least 600 IU/day of vitamin D, and they emphasize that for some women, intake of 1500 to 2000 IU/day may be required to maintain a blood level of greater than 30 ng/mL.¹⁵⁴ The parathyroid glands, which produce PTH, are stimulated by hypocalcemia and suppressed by high concentrations of calcium, magnesium, and 1,25(OH)₂D, and by hypomagnesemia. PTH influences calcium metabolism by directly resorbing bone and by stimulating 1,25(OH)₂D formation. The three major forms of circulating calcium are ionized, protein-bound, and chelated fractions. The ionized fraction is physiologically active and homeostatically regulated.

Calcium homeostasis in pregnancy was reviewed by Kovacs and Fuleihan.¹⁵⁵ Large amounts of calcium and phosphorus are transferred against a concentration gradient from the mother to the fetus,¹⁵⁶ with the net accumulation of calcium being 25 to 30 g by term (mostly in the third trimester). Maternal calcium absorption doubles during pregnancy to meet these demands. Doubling of 1,25(OH)₂D synthesis of placental and maternal renal origin (from increased 1 α -hydroxylase, itself resulting from increased prolactin, estrogen, human placental lactogen, and parathyroid hormone-related peptide [PTHrP]) leads to the opening of voltage-gated calcium channels in the enterocyte membrane, increasing calcium absorption.¹⁵⁷ In the maternal circulation, there is little change in ionized calcium, whereas total serum calcium concentrations fall during gestation, paralleling a decline in serum albumin.

In addition to placental calcium transfer, an expanding extracellular volume and increased urinary calcium losses place further stress on maternal calcium homeostasis. Newer immunoradiometric assays for intact PTH have shown a decline in PTH during pregnancy to 10% to 30% of pre-pregnancy values, increasing toward term. This decline appears to be offset by increased PTHrP concentrations, of placental and fetal parathyroid origin.¹⁵⁸ This peptide shares considerable homology with PTH and a common receptor, and it is the predominant regulator of active placental calcium transport. Transferrin-mediated calcium transfer also depends on an increase in calcium-binding protein, which reaches maximal concentrations in the third trimester when fetal growth is most rapid. As the level of PTHrP,

produced by fetal and maternal tissues, increases during pregnancy, it probably contributes to increased 1,25(OH)₂D and decreased PTH concentrations. Serum calcitonin concentrations have been variously reported as showing a rise or no consistent change during pregnancy.¹⁵⁹ Urinary calcium excretion is also increased.¹⁵⁵

Fetal parathyroid tissue has been identified by 6 weeks' gestation, and skeletal mineralization is apparent by the 8th week. Total and ionized calcium concentrations are elevated in the fetus at term and decrease to normal in the newborn period. PTH levels are low in the fetus and increase after birth.¹⁵⁶ PTHrP is produced by fetal parathyroid glands and is the main regulator of fetal serum calcium. The calcitonin level is elevated in the fetus. These events are summarized in Table 61-6. During lactation, the average daily loss of calcium in human milk is 220 to 340 mg. The ionized calcium concentration increases a little, remaining within the normal range; the serum phosphorus level increases. Intact PTH is reduced 50%, rising to normal with weaning. In contrast to the high levels in pregnancy, serum 1,25(OH)₂D concentrations fall to normal within days of parturition. PTHrP levels (of mammary origin) are significantly higher in lactating women, and the protein plays a key role during lactation in regulating demineralization of the skeleton, stimulating resorption of bone, and in renal tubular reabsorption of calcium and suppression of PTH. Higher PTHrP levels correlate with greater bone loss.¹⁵⁵ Calcitonin levels are high in the first 6 weeks of lactation and may modulate the rate of skeletal resorption. Figure 61-10 shows maternal calcium homeostasis during pregnancy and lactation, contrasting the mechanisms at work in these two situations. In contrast to the other states of rapid bone loss, a small study showed that lactational bone loss occurred in a state of apparent osteoclast-osteoblast coupling.¹⁶⁰

DISORDERS OF THE PARATHYROID GLANDS

Primary Hyperparathyroidism and Hypercalcemia

Hyperparathyroidism is rare in pregnancy. Of 750 cases of parathyroid surgery performed over a 21-year period,¹⁶¹ only six

TABLE 61-6 Levels of Minerals and Hormones Involved in Calcium Homeostasis

Mineral or Hormone	Mother	Fetus	Newborn
Total calcium*	Low	High	Decreases [†]

PTHrP, parathyroid hormone-related protein; 1,25(OH)₂D, 1 α ,25-dihydroxycholecalciferol, calcitriol, or vitamin D₂, the physiologically active form of vitamin D; 25(OH)D, 25-hydroxycholecalciferol, calcidiol, or vitamin D₃.

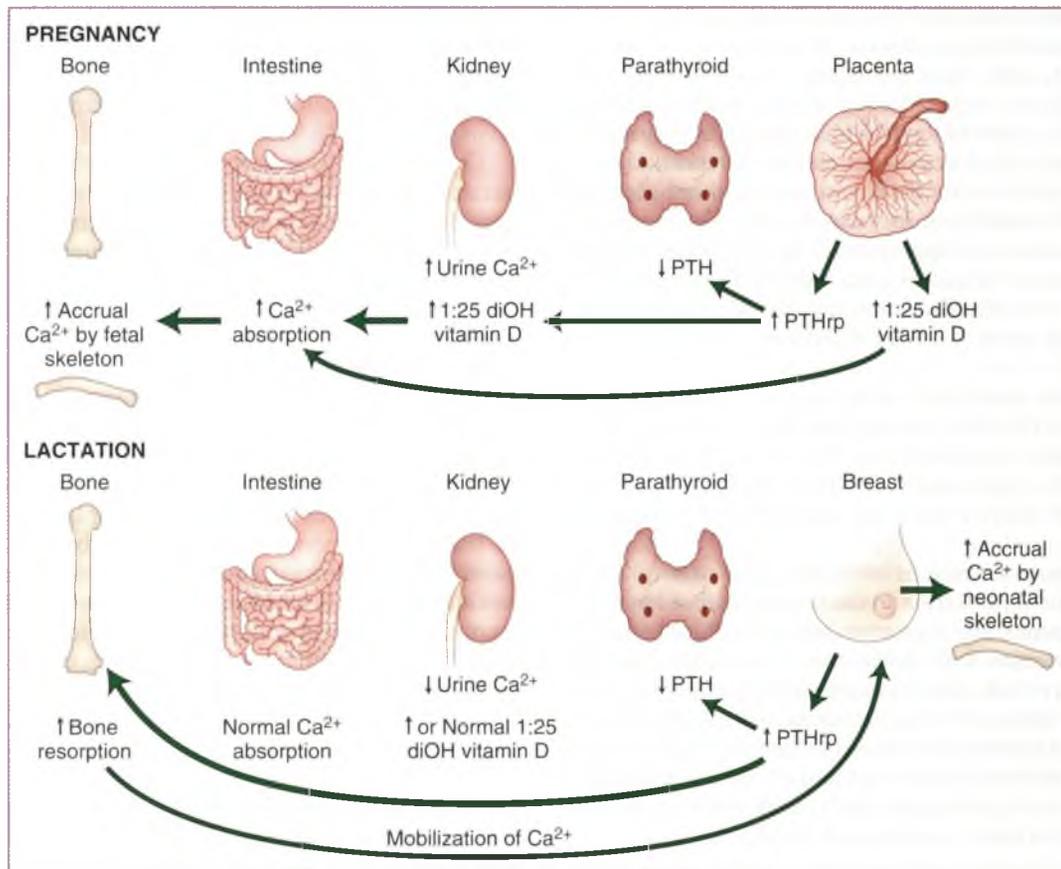

Figure 61-10 Factors regulating maternal calcium metabolism during pregnancy and lactation. Calcium (Ca^{2+}) accrual by the fetus and neonate is achieved during pregnancy and during lactation, but the mechanisms differ. In pregnancy 1,25-dihydroxycholecalciferol (1:25 diOH vitamin D)-mediated increased calcium absorption plays the dominant role, whereas in lactation, parathyroid hormone-related peptide (PTHrp)-mediated bone resorption makes calcium available to the neonate. (Adapted from Kovacs CK, Fuleihan GH: Calcium and bone disorders during pregnancy and lactation, *Endocrinol Metab Clin North Am* 35:21–51, 2006.)

occurred in pregnant women (0.8%). As in nonpregnant women, the histopathology of hyperparathyroidism involves a single adenoma in most reported cases in pregnant women, although hyperplasia and carcinoma have also been reported.^{162,163} Although many patients are asymptomatic, clinical features of the associated hypercalcemia are summarized in Table 61-7.

In the 102 pregnancies (in 73 women) reported by Kristoferson and coauthors,¹⁶² the clinical history was known in 45. Abdominal symptoms, including nausea, vomiting, pain, and renal colic, were the most common, followed by muscular weakness, mental symptoms, and polyuria; 20% were asymptomatic. The diagnosis of hyperparathyroidism during pregnancy is suggested by hypercalcemia. The decline in total serum calcium during pregnancy may mask the diagnosis or be associated with a postpartum flare-up, and ionized serum calcium should be measured in patients suspected of having primary hyperparathyroidism. The physician then confirms the diagnosis by finding inappropriately elevated PTH concentrations and an increase in levels of urinary nephrogenic cyclic adenosine monophosphate (cAMP). Of note, a prior diagnosis of parathyroid adenoma was also significantly associated with preeclampsia.¹⁶⁴

TABLE 61-7 Maternal Features of Hypercalcemia

Affected System	Clinical Features
Urinary	Nephrolithiasis Nephrocalcinosis Polyuria
Neuromuscular Gastrointestinal	Weakness Peptic ulcer disease Constipation Anorexia Nausea and vomiting
Cardiovascular	Hypertension Arrhythmias
Skeletal	Osteitis fibrosa cystica Osteopenia and fractures
Neuropsychiatric	Depression Psychosis Obtundation
Miscellaneous	Coma Thirst Pruritus

The differential diagnosis of hypercalcemia includes malignant disease, granulomatous disease, thyrotoxicosis, hypervitaminosis D or A, milk-alkali syndrome, immobilization, and familial hypocalciuric hypercalcemia (FHH), which is an autosomal dominant, inherited form of mild, benign hyperparathyroidism associated with low urinary calcium excretion. Affected neonates of mothers with FHH can manifest symptomatic hypercalcemia; if unaffected, they can develop severe neonatal hypocalcemia because of suppression of fetal parathyroid function. Severe neonatal hypercalcemia may be the homozygous variant of FHH. An altered calcium ion-sensing receptor gene, changing the set point for PTH secretion, is the underlying defect in FHH.

Hypercalcemia associated with increased production of PTHrP has been described during pregnancy and after delivery.¹⁶⁵ In one case, production of PTHrP by hypertrophied breast tissue led to hypercalcemia.¹⁶⁶ In another, hypercalcemia developed after delivery in a hypoparathyroid woman on vitamin D.¹⁶⁷

During pregnancy, calcium transport across the placenta provides a degree of protection in the mother against hypercalcemia, and this protection is greatest during the third trimester. Loss of this protection with delivery can cause acute postpartum maternal hypercalcemia. In many patients, the diagnosis is confirmed after delivery by the occurrence of neonatal tetany. Ten of 15 cases of hyperparathyroidism reported by Gelister and colleagues¹⁶³ manifested in this way, and the others manifested with hyperemesis, hypertension, and a jaw fracture in a patient who turned out to have a parathyroid carcinoma.

Complications. Complications of hyperparathyroidism affect the mother and infant. Maternal complications include hyperemesis, renal calculi (36%), pancreatitis (13%), hypertension (10%), bone disease (19%), hypercalcemic crises (8%), and psychiatric problems. The overall maternal mortality rate remains low (1 of 73 in the collected series of Kristofferson and colleagues¹⁶²).

Fetal morbidity and mortality rates are significant. A 30% rate of spontaneous abortion or stillbirth, a 50% rate of tetany, and a 25% rate of neonatal death have been reported.¹⁶⁸ Although neonatal hypocalcemia with tetany is usually a transient phenomenon related to suppression of fetal parathyroid glands resulting from maternal-fetal hypercalcemia, it can be more prolonged in less mature infants or in infants with birth asphyxia.

Hypercalcemic crisis also can occur during pregnancy or after delivery with high serum calcium level (>14 mg/dL), generalized weakness, vomiting, and altered mental status. Aggravation of hypercalcemia can occur because of an increase in placental production of 1,25(OH)₂D by the end of gestation and the removal of the placenta, with the loss of the shunt that transfers calcium from mother to fetus.

Treatment. For hyperparathyroidism presenting during pregnancy, standard practice favors surgical treatment. In the collected series of Kristofferson and colleagues,¹⁶² there were 79 pregnancies among 50 women who did not undergo surgery; there were complications in 41 of the pregnancies (52%), and neonatal tetany occurred in 21 (26.6%). This contrasts with the more favorable outcome in 23 pregnancies involving 23 women who underwent surgical treatment during pregnancy; five (22%) had complications, and there were three cases of

neonatal tetany (13%). Ideally, surgery should be performed in the second trimester, when fetal organs are developed and the uterus is less likely to undergo labor.¹⁶⁹ Two pregnant patients requiring reoperation were given technetium-99 sestamibi scans to assist in localizing the abnormal gland.¹⁷⁰

Conservative treatment of mildly affected, asymptomatic patients has also been suggested. In a case reported by Haenel and Mayfield,¹⁷¹ oral phosphate and parenteral saline were used to sustain the patient during the third trimester. However, even mild forms have adverse fetal effects and risk.¹⁷²

The treatment of life-threatening hypercalcemia can be problematic and may require hydration, furosemide, phosphates, and even hemodialysis (Table 61-8).^{173,174} Calcitonin inhibits bone resorption; its effects are generally short lived, and it does not cross the placenta. It has been used briefly in pregnancy in the third trimester in one case.¹⁷⁵ In life-threatening situations, mithramycin (plicamycin) lowers calcium by inhibiting bone resorption. It is an antineoplastic agent and toxic to the fetus. In nonpregnant patients, bisphosphonates (e.g., pamidronate) given intravenously are also effective in lowering calcium levels. Transplacental passage has been shown in animal studies. For a patient with milk-alkali syndrome who presented with severe hypercalcemia related to excessive use of calcium carbonate, a single dose of the bisphosphonate etidronate was given, with prompt reduction of serum calcium and subsequent hypocalcemia.¹⁷⁶

Parathyroid Carcinoma in Pregnancy. Four cases of parathyroid carcinoma during pregnancy were reviewed by Montoro and associates.¹⁷⁷ Severe hypercalcemia, hypertension, and a palpable neck mass were consistent features, whereas palpable

TABLE 61-8 Treatment of Hypercalcemia

Treatment	Adverse Effects
GENERAL APPROACH	
Hydration	—
Discontinue offending drugs	—
Restrict calcium	—
INCREASE RENAL CALCIUM EXCRETION	
0.9% Saline, 200-500 mL/hr	Volume overload
Furosemide, 20-60 mg IV every 2-4 hr	Volume depletion, hypokalemia
Dialysis	—
CALCIUM CHELATION WITH PHOSPHATES	
Oral: Neutra-phos, 500-750 mg every 6-8 hr	Extraskeletal calcification
Rectal: Phospho-soda, 5 mL every 6-8 hr	—
IV: 50 mM phosphate over 8-12 hr	—
DECREASE BONE RESORPTION	
Calcitonin, 4-8 IU/kg IM or SC every 6-12 hr*	Allergic reaction, nausea
Pamidronate (bisphosphonate), 30-60 mg IV as a single infusion over 24 hr	Renal toxicity
Mithramycin, 25 µg/kg IV† every 48-72 hr	Low platelet count, renal toxicity, hepatotoxicity

*No reports of congenital defects; does not cross placenta.

†No reports on use in pregnancy; antineoplastic.

IM, intramuscularly; IV, intravenously; SC, subcutaneously.

TABLE 61-9 Classification of Hypoparathyroid Disorders

Defect	Cause
Absence of PTH or insufficiency	Previous thyroid or parathyroid surgery Idiopathic hypoparathyroidism (familial or sporadic) DiGeorge syndrome Iron overload (rare) Previous irradiation with ¹³¹ I (rare)
Absence of and resistance to PTH	Magnesium depletion
PTH resistance	Pseudohypoparathyroidism
Activating mutation of calcium-sensing receptor	Genetic

PTH, parathyroid hormone.

masses were found in only 5% and hypertension in 10% of pregnant patients with parathyroid adenomas. Because survival depends on complete initial resection, early surgical intervention is important.

Hypoparathyroidism

Hypoparathyroidism in pregnancy usually occurs in patients who have previously undergone neck surgery, but it can occur in less common circumstances (Table 61-9). The diagnosis is confirmed by the combination of hypocalcemia with low PTH, 1,25(OH)₂D, and nephrogenous cAMP concentrations. Other hypocalcemic states that need to be differentiated from hypoparathyroidism include vitamin D deficiency (with a finding of a high PTH level), excessive chelation (after blood transfusion), pancreatitis, and septic states. Rarely, activating mutations of the calcium-sensing receptor may occur, and in one such case calcium and calcitriol requirements decreased in pregnancy and during lactation. The patient briefly experienced hypocalcemia again in the immediate postpartum period and before lactation, presumably during the transition from placental to mammary PTHrP.¹⁷⁸

Clinical features include tetany, which may be elicited in latent form by the Chvostek test (i.e., tapping of the facial nerve) and the Trousseau test (i.e., occurrence of tetany within 3 minutes of the induction of ischemia in the upper extremity). Other symptoms include paresthesia, stridor, muscle cramps, and mental changes, including frank psychosis. The electrocardiogram may reveal prolongation of the QT interval.

Complications. Neonatal hyperparathyroidism may result from maternal hypocalcemia. It can cause fetal bone demineralization and growth restriction.¹⁷⁹ Although this condition is transient, death from the complications of skeletal fractures can occur. Loughhead and colleagues¹⁸⁰ reviewed 16 cases of congenital hyperparathyroidism resulting from maternal hypocalcemia; bone features of hyperparathyroidism were documented in 13 cases. Six of the neonates died within the first 3 months of life. The investigators concluded that the presentation varied greatly, ranging from clinically and radiologically silent cases to neonates with severe skeletal disease and bone demineralization.

Treatment. The maternal serum calcium level should be maintained within normal limits. Calcium salts (1.0 or 1.5 g of

elemental calcium per day) may be given to maintain normocalcemia. In addition, the active form of vitamin D, calcitriol (1,25[OH]₂D), which has a rapid onset of action, can be used. The usual dosage is 0.5 to 1.0 µg/day.¹⁸¹

The normal replacement dosage of vitamin D in a hypoparathyroid woman may need to be increased, possibly because of increased binding of vitamin D to vitamin D-binding protein. In a patient treated with calcitriol, the dosage had to be doubled during pregnancy to maintain normocalcemia, similar to the physiologic twofold rise in 1,25(OH)₂D during pregnancy.¹⁸² The aim should be serum calcium concentrations in the range of 8 to 9 mg/dL, with avoidance of hypercalciuria (>250 mg/24 hr), which can lead to nephrolithiasis. In late pregnancy, the dosage of calcitriol may need to be reduced, and this is likely to be related to the increased PTHrP levels in late pregnancy. In limited reports of pseudohypoparathyroidism (i.e., resistance to PTH), pregnancy has normalized serum calcium, decreased PTH, and increased 1,25(OH)₂D levels. The presence of PTHrP cannot explain these changes, because they are resistant to PTH and PTHrP. The mechanism is unclear but may include increased placental secretion of 1,25(OH)₂D.¹⁸³ In the hypoparathyroid patient whose dosage was increased in pregnancy, a prompt decrease to pre-pregnancy dosages of vitamin D is necessary after delivery so that hypercalcemia can be avoided.¹⁸⁴ Although lactating women usually require continuation of pregnancy dosages of vitamin D, hypercalcemia has been reported,¹⁸⁴ and close monitoring is prudent. This finding may be related to the production of PTHrP by the breasts^{167,185} or to induction of 1α-hydroxylase by prolactin.

Acute symptomatic hypocalcemia is a medical emergency. It should be treated with intravenous calcium (e.g., 10 mL of 10% calcium gluconate over 10 minutes, followed by an infusion of 0.5 to 2.0 mg/kg/hr of elemental calcium, diluted with dextrose to avoid irritation to veins).

Infants receiving breast milk from mothers consuming large dosages of vitamin D should undergo periodic calcium determinations, because the breast milk will have higher than normal levels of vitamin D.¹⁸⁶ The elevated levels of vitamin D can cause hypercalcemia and impaired linear growth in the infant.

Pregnancy-Related Osteoporosis

Osteoporosis is a disorder characterized by loss of bone mass and microarchitectural deterioration, resulting in an increased risk for fracture. Normally, bone formation and resorption are coupled. Bone loss because of reduced formation or increased resorption may occur in estrogen-deficiency states, glucocorticoid-excess syndromes, thyrotoxicosis, and other circumstances.

The effect of pregnancy on bone turnover was evaluated by Black and colleagues,¹⁸⁷ Oliveri and coworkers,¹⁸⁸ and Karlsson and associates.¹⁸⁹ In a detailed study using biochemical markers of bone formation and resorption and dual-energy x-ray absorptiometry (DEXA) before, during (in the forearm), and after pregnancy (in the hip, spine, and forearm), Black and colleagues¹⁸⁷ reported increased markers of bone resorption by 14 weeks' gestation and further by 28 weeks, whereas markers of bone formation did not increase significantly until 28 weeks. Lumbar spine and hip bone mineral density (BMD) decreased significantly during pregnancy. It appeared that bone remodeling became uncoupled, with an increase in resorption during the first two trimesters, and the increase in formation became evident only in the third trimester. In a study of 34 women

during pregnancy, peripheral computed tomography measurements showed no change in cortical bone but tremendous variability in loss of trabecular bone. Fast losers had high serum levels of osteocalcin (a marker of bone formation), and it was suggested that this could be used as a marker of the change.¹⁹⁰ In a study of almost 2500 women who had BMD measurements immediately after the delivery, 210 were followed for 5 to 10 years and had repeat BMD performed. Of the 38 osteoporotic or osteopenic women identified in the puerperal scan, 71% were still osteopenic in the second scan. The author stated that identification of this at-risk group might lead to interventions to reduce fracture risk.¹⁹¹

Pregnancy-related osteoporosis and vertebral fractures were reported in the 1950s. Since that time, sporadic cases and small series of patients with osteoporosis in relationship to pregnancy and lactation have been reported.^{192,193} It has been suggested that failure of calcium accretion by the maternal skeleton, normally facilitated by increased calcium absorption in response to higher 1,25(OH)₂D concentrations, might explain this occurrence in patients with low vitamin D concentrations. Failure of the calcitonin response to pregnancy is another mechanism; calcitonin has antiresorptive properties, and levels may increase during pregnancy.

In a study of 29 women with idiopathic osteoporosis associated with pregnancy,¹⁹⁴ it was observed that pain occurring late in the first full-term pregnancy was the most common presentation and that the natural history was improvement over time. Adult-related fractures occurring at an earlier age were more prevalent in the mothers of these women, suggesting that genetic factors may be involved in osteoporosis.

During lactation, a substantial part of the calcium demand is mobilized from the maternal skeleton because of low estrogen and high PTHrP levels from the breasts.¹⁹⁵ In a study of 18 exclusively breastfeeding women, compared with 18 women in whom lactation was inhibited by bromocriptine, there was a significant decrease in the bone density of the lumbar spine and distal radius, and there was biochemical evidence of increased bone turnover during breastfeeding, with an incomplete recovery 6 months after breastfeeding cessation.¹⁹⁶ In the bromocriptine-treated women, BMD did not change. Overall, it appears that healthy young women have significant early losses of BMD at the axial spine and hip during 6 months of

lactation.¹⁹⁷ Loss, however, does not continue beyond 6 months despite continuing lactation, and BMD loss usually is restored with the return of normal menses. In a study of 60 women, 47% of breastfeeders lost more than 5% of bone at the lumbar spine, and the bottle-feeders maintained BMD. At 1 year after delivery, all but seven had returned to within 5% of preconception values at the spine, but recovery of the total hip loss was less complete. Several women became transiently osteoporotic.¹⁹⁸

The calcium demands of late pregnancy and lactation are about 0.3 g per day. There are limited long-term data on the effects of extended and repeated lactation. Whereas some studies have shown an adverse effect,¹⁹⁹ parity and lactation have not been associated with low BMD or osteoporotic fracture risk in epidemiologic or case-control cohort studies.²⁰⁰ In a study of 11 women with pregnancy and lactation-associated osteoporosis, 10 of whom had vertebral fractures and one a nonvertebral fracture, at least one recognized risk factor (e.g., low body weight, smoking, family history, vitamin D deficiency) was present in nine patients. Nine patients received bisphosphonates for a median of 24 months, with an increase in BMD of 23% after 2 years. Of five women who had subsequent pregnancies, one sustained a fracture after delivery, and two patients followed for more than 10 years sustained fractures outside pregnancy.²⁰¹ The study authors concluded that bisphosphonate therapy administered soon after presentation substantially increased spine bone density. However, because bisphosphonates can have an extremely long half-life and stay in bone for a long period, caution should be exercised if the patient wishes to conceive again, because the effects of bisphosphonates on the developing fetal skeleton have not been well studied, and the long-term safety as far as the fetus is concerned is unknown. Reassuringly, when 21 women exposed to bisphosphonates during pregnancy or within 3 months before were matched with a nonexposed comparison group, no substantial fetal risk was identified.²⁰² In another report, teriparatide, which is recombinant PTH, an anabolic bone agent, was successfully used to increase bone mass in a young woman with spinal fractures and acute back pain right after delivery.²⁰³ In cases of severe osteoporosis, it is reasonable to discourage lactation.

Gastrointestinal Disease in Pregnancy

THOMAS F. KELLY, MD | THOMAS J. SAVIDES, MD

Anatomic and physiologic alterations of the gastrointestinal tract result in significant maternal symptoms that are experienced even in uncomplicated gestations. Difficulty arises in differentiating normal pregnancy complaints from those associated with pathology. The workup of suspected gastrointestinal disease is hampered by the potential risks of radiation or endoscopy to the fetus. Similarly, management may be altered because of the adverse or unknown effects of medical or surgical treatment. In this chapter, we review the common gastrointestinal disorders occurring in pregnancy and describe how pregnancy affects the presentation, diagnosis, and treatment of these disorders.

Alterations in Normal Gastrointestinal Function in Pregnancy

ESOPHAGUS

The esophagus normally maintains an alkaline pH, mainly by peristalsis of orally produced saliva and by the lower esophageal sphincter's preventing reflux of gastric contents.¹ Van Thiel and colleagues found decreased tone of the gastroesophageal sphincter during pregnancy and with the use of progesterone-containing oral contraceptives.^{2,3} However, Fisher and associates found no change in lower esophageal pressure in early pregnancy, but the sphincter's responses to hormonal and physiologic stimuli were reduced.⁴ These investigators observed in opossums decreased responses of the lower esophageal sphincter circular muscle to gastrin and acetylcholine.⁵ Whether arising from reduced sphincter tone or response to stimuli during pregnancy, the potential for gastrointestinal reflux appears to increase compared with that of nonpregnant individuals.

STOMACH

The stomach receives, mixes, and propels food. It has mechanical and secretory properties. Peristaltic contractions are triggered by the gastric pacemaker located between the fundus and the corpus on the greater curvature with a normal frequency of three cycles per minute. Gastric emptying is difficult to measure in pregnancy studies, as it involves the use of radioisotopes in test meals. Measuring serial blood levels of acetaminophen, an agent that is poorly absorbed from the stomach but quickly absorbed from the small intestine, Macfie and coworkers found that gastric emptying was not delayed in pregnancy.⁶ Another study found no differences in pregnant compared with nonpregnant individuals, with the exception of delayed emptying 2 hours after delivery.⁷ Using hydrogen breath testing, there were no delays in gastric emptying, but there were increases in orocecal transit time as pregnancy advanced.⁸ These indirect

observations suggest that gastric motility is not altered in pregnancy. Studies of gastric acid secretory function during pregnancy have produced conflicting results, showing that acid production is decreased, unchanged, or increased.⁹⁻¹¹

SMALL INTESTINE

Small intestinal transit time is prolonged during pregnancy and during the luteal phase in nonpregnant women.¹² It may be caused by elevated progesterone levels during pregnancy and their relaxing effect on smooth muscle.¹³ The teleologic advantage is presumed to be increased nutrient absorption. Vitamin B₁₂ absorption and transluminal transport of some amino acids in animals are increased during pregnancy.^{14,15} The weight of the small intestine is increased during pregnancy in animals and is probably accounted for by the larger mucosal surface, supporting the theory of increased absorptive surface.

COLON

The functional changes of the colon in human pregnancy are inadequately studied. In pregnant animals, colonic transit time is increased, and the smooth muscle is less responsive to stimulation.^{16,17} Because progesterone is known to inhibit colonic smooth muscle activity,¹⁸ it appears plausible that colonic motor activity is diminished during human pregnancy.

Nausea and Vomiting

EPIDEMIOLOGY

Between 50% and 80% of pregnant women experience nausea and vomiting during pregnancy.^{19,20} Annually, 4 million women in the United States and 350,000 in Canada are affected.¹ Symptoms usually begin between 4 and 10 weeks' gestation and resolve by week 20. A minority (3%) of patients experience significant nausea and vomiting only in the third trimester. One half of pregnant women experience nausea in the morning, whereas nausea peaks in the evening in 7% of patients, and 36% experience symptoms constantly.²¹

The term *morning sickness* is misleading. A prospective study suggested that nausea occurring only during the morning affected 2% of patients, whereas 80% of symptomatic patients had nausea or vomiting throughout the day.²² Demographic factors associated with vomiting include first pregnancy, younger age, fewer than 12 years of education, nonsmoking status, and obesity.²³ Nausea and vomiting are more common in the Western countries and Japan and are rare in Africa, Asia, and Alaska (among Native Americans), indicating that factors other than pregnancy contribute to the pathogenesis.²⁴

PATHOGENESIS

The etiology is unknown. Genetic influences have been suggested by the concordance of frequency in monozygotic twins²⁵ and the fact that family members are more likely to be affected.^{26,27}

Human chorionic gonadotropin has been implicated in causing nausea and vomiting. The close temporal association of peak human chorionic gonadotropin levels and nausea and vomiting symptoms and the fact that conditions associated with elevated levels (e.g., female fetal sex, twins, hydatidiform moles) have higher rates of hyperemesis suggest a causal relationship.²⁷⁻³⁴ Fifteen prospective comparative studies have been published since 1990, and 11 have shown a significantly higher level of human chorionic gonadotropin in women with hyperemesis.³⁵ Estrogens also can cause nausea and vomiting. Women who experience nausea with oral contraceptive use have a higher incidence of nausea and vomiting during pregnancy.²¹ There have been 17 studies of the relationship between nonthyroid hormones and nausea and vomiting, and only human chorionic gonadotropin and estrogen have shown a consistent association.³⁶

Prostaglandin E₂ may contribute to this disorder, in that levels are elevated during symptomatic episodes.³⁷ *Helicobacter pylori* has been implicated as an etiologic agent for hyperemesis gravidarum; although a recent review demonstrated an association, there was considerable heterogeneity among the pooled studies.³⁸

Physiologic causes of nausea and vomiting of pregnancy have historically been underemphasized compared with the psychosocial factors, although these issues do have an association.³⁹ Some have proposed that nausea and vomiting of pregnancy is an evolutionary adaptation, protecting the woman and fetus from potentially harmful foods, and is therefore a healthy adaptive response.⁴⁰

Physiologic studies suggest that gastric dysrhythmias may have a role. Electrogastrographic recordings during pregnancy

indicate that women with nausea and vomiting of pregnancy have alterations of the typical nonpregnant frequency of three cycles per minute and that these altered peristaltic contractions correlate temporally with the symptoms.⁴¹ Altered gastric motility and gastroesophageal reflux appear to contribute to the mechanisms of nausea and vomiting in pregnancy.

DIAGNOSIS

Evaluation of the patient is based mainly on history. The nausea usually lasts all day. Pain is usually absent unless recurrent retching leads to abdominal and rib muscle strain. Similarly, the physical examination is unremarkable unless the patient is severely dehydrated, a picture more consistent with hyperemesis gravidarum. Laboratory studies are usually not indicated or helpful. However, they are important in evaluating other potential causes that may mimic the condition, including hepatitis, pancreatitis, pyelonephritis, and uncontrolled diabetes.

MANAGEMENT

Therapy can be instituted before the development of symptoms. Two studies have suggested that multivitamins at the time of conception may reduce the incidence of nausea and vomiting.^{42,43} Nonpharmacologic treatment may include ginger (500 to 1500 mg in divided doses daily).^{44,45} Six randomized controlled trials of vitamin B₆ have suggested superior or equivalent efficacy in improving symptoms over placebo, with no reports of adverse events. Acupressure or electrical stimulation on the P6 point of the wrist has shown conflicting results. The bulk of the literature suggests a benefit, but many of the studies have methodologic flaws or reveal no improvement over sham stimulation.⁴⁶⁻⁴⁹

Pharmacologic therapy may be effective (Table 62-1). Vitamin B₆ in dosages of 10 to 25 mg taken three times daily is probably the best initial treatment and has a low potential of side effects.^{46,50,51} Doxylamine (10 mg) and vitamin B₆ were used

TABLE 62-1 Pharmacologic Treatment of Nausea and Vomiting in Pregnancy

Agent	Oral Dose	FDA Category	Comments
Vitamin B ₆	10-25 mg every 6 hr	A	Recommended first-line treatment
Antihistamines:			Sedation
Doxylamine	12.5-25 mg every 8 hr	A	May add to vitamin B ₆ as adjunctive therapy
Diphenhydramine	25-50 mg every 8 hr	B	
Meclizine	25 mg every 6 hr	B	
Hydroxyzine	50 mg every 4-6 hr	C	
Dimenhydrinate	50-100 mg every 4-6 hr	B	
Phenothiazines:			Extrapyramidal symptoms, sedation
Promethazine	25 mg every 4-6 hr	C	Oral, rectal, or intramuscular routes recommended. Tissue injuries associated with intravenous or subcutaneous use (black box warning)
Prochlorperazine	5-10 mg every 6 hr	C	
Dopamine antagonists:			Sedation, anticholinergic effects
Trimethobenzamide	300 mg every 6-8 hr	C	
Metoclopramide	10 mg every 6 hr	B	Risk of tardive dyskinesia increases with prolonged use
Droperidol	1.25-2.5 mg intramuscularly or intravenously only	C	Black box warning regarding torsades de pointes
5-Hydroxytryptamine type 3 receptor antagonist:			Constipation, diarrhea, headache, fatigue
Ondansetron	4-6 mg every 6 hr	B	
Glucocorticoid:			
Methylprednisolone	16 mg every 8 hr, then taper over 2 wk	C	Avoid use before 10 weeks' gestation. Maximal duration, <6 wk
Ginger	125-250 mg every 6 hr	C	

Adapted from Niebyl JR: Nausea and vomiting in pregnancy, *N Engl J Med* 363:1544-1550, 2010.

until the early 1980s with apparently good effect. The compound Bendectin was removed from the market in 1983, and there was a subsequent increase in hospital admissions for nausea and vomiting.⁵² For other pharmacologic treatments, including antihistamines and phenothiazines, there are no well-controlled trials.¹ Promethazine, prochlorperazine, chlorpromazine, and trimethobenzamide have shown some clinical efficacy, but their safety in pregnancy has not been proven.¹ Metoclopramide improves gastric emptying and corrects gastric dysrhythmias, and it has been safe and effective in small series.⁵³⁻⁵⁵ Droperidol and ondansetron have been used for postoperative nausea and vomiting, but their use in pregnancy has been limited to case reports.¹

Hyperemesis Gravidarum

EPIDEMIOLOGY

A more severe form of nausea and vomiting in pregnancy is hyperemesis gravidarum, which occurs in approximately 0.5% of live births.^{35,56} It is responsible for increased hospitalization and disability, and it can result in weight loss, electrolyte imbalances, and nutritional deficiencies.^{57,58} Maternal factors shown to increase the rate of hospitalization because of hyperemesis gravidarum include hyperthyroidism, psychiatric disorders, diabetes, gastrointestinal disorders, and asthma. Similar to the situation for nausea and vomiting, multiple gestations and singleton female fetuses were associated with a higher risk.⁵⁹ Hyperemesis gravidarum is more likely in gestational trophoblastic disease, hydrops fetalis, and fetal karyotypic abnormalities, including triploidy and trisomy 21.¹

Symptoms typically begin during the first trimester. About 10% of patients are affected throughout pregnancy.¹⁹ This disorder leads to elective pregnancy termination in approximately 2% of affected pregnancies.²¹ Severe rare complications of hyperemesis include Wernicke encephalopathy, pneumomediastinum, and esophageal rupture.^{35,60} Infants born to women with poor weight gain resulting from hyperemesis frequently have low birth weights.^{58,61}

DIAGNOSIS

Symptoms of hyperemesis gravidarum include dry mouth, sialorrhea, hyperolfaction, and altered taste. Physical examination usually reveals dry mucous membranes, poor skin turgor, and hypotension.¹ Unlike in patients with standard nausea and vomiting of pregnancy, electrolyte abnormalities and ketonuria are identified in patients with hyperemesis gravidarum. Severely affected individuals may have elevated levels of hepatic transaminases and abnormalities in renal function.

MANAGEMENT

Intravenous fluid resuscitation is the initial treatment for hyperemesis gravidarum. Up to 2 L of lactated Ringer solution should be infused over 3 to 5 hours, and continuing infusion is subsequently adjusted to maintain urine output greater than 100 mL/hr. Thiamine (100 mg) should be given intravenously before the infusion of dextrose to avoid Wernicke encephalopathy. Electrolyte levels, including magnesium and ionized calcium, should be monitored regularly. Hyponatremia should be corrected with infusion of sodium containing fluids, but not

too rapidly because of concerns of central pontine myelinolysis. Furthermore, potassium should be added until hypokalemia is corrected.⁶²

Pharmacologic treatment includes the various antiemetics previously discussed. In refractory cases, methylprednisolone and hydrocortisone have been used with conflicting results. A randomized trial of oral methylprednisolone (initial dosages of 16 mg three times daily followed by a 2-week taper) resulted in a reduction in readmission to the hospital when compared with oral promethazine.⁶³ Intravenous hydrocortisone 300 mg daily for 3 days followed by a taper over a week reduced vomiting episodes and subsequent readmission when compared with a regimen of metoclopramide.⁶⁴ Another study compared the use of intravenous methylprednisolone followed by an oral prednisone taper plus promethazine and metoclopramide with the use of only the latter drugs and found no difference in the rates of rehospitalization (35%).⁶⁵ Another randomized trial using oral prednisolone that was converted to intravenous hydrocortisone for no response was inconclusive, with a trend toward reduced vomiting, but patients had an improved sense of well-being and weight gain.⁶⁶

The mechanism by which steroids affect nausea is not clear. The nuclei of the solitary tract and raphe and the area postrema, have glucocorticoid receptors and are known to participate in the regulation of nausea and vomiting responses.⁶⁷ Corticosteroid exposure in the first trimester may be weakly associated with an increased rate of facial clefting, potentially accounting for one or two cases per 1000 treated women.⁶⁸⁻⁷⁰ Steroids therefore should be used with caution and should be avoided if possible during the period of fetal organogenesis.⁴⁶

Total parenteral nutrition has been used for hyperemesis gravidarum with reportedly improved outcomes.⁷¹ Significant complications of lipid emulsions have been reported, primarily with the use of cottonseed oil, and they have included placental infarction, ketonemia, and increased uterine activity. Subsequent case reports using soybean- or soybean and safflower oil-based emulsions have not shown the same adverse events.⁷² There is an increased risk for complications directly related to therapy, including infusion catheter sepsis (25%) and venous thrombosis (3%).^{73,74} Centrally placed venous catheters have higher morbidity rates (50%) compared with peripherally inserted lines (9%).⁷⁵ One series of 52 patients receiving peripherally inserted central catheters had a complication rate of 50%.⁷⁶ The use of total parenteral nutrition should be considered a last resort.

Adverse outcomes for women with hyperemesis and low maternal weight gain compared with those for patients without hyperemesis include higher rates of small-for-gestational-age fetuses, low birth weight, prematurity, and 5-minute Apgar scores less than 7.⁵⁸ Among women who experienced hyperemesis gravidarum in their first gestation, 15% to 19% will be affected in the second pregnancy, compared with 0.7% who had unaffected first pregnancies.^{58,77}

Gastroesophageal Reflux Disease

EPIDEMIOLOGY

Heartburn is the most common gastrointestinal complaint in Western populations, with up to 20% of individuals having symptoms on a weekly basis. During pregnancy, up to 80% of women experience heartburn at some point, and 25% are

affected daily.^{78,79} The prevalence and severity progressively increase during pregnancy and resolve after delivery.^{80,81} The prevalence of heartburn symptoms is 22% for patients in the first trimester, 39% for those in the second trimester, and 72% for patients in the third trimester.⁸¹ Factors associated with increased risk for heartburn symptoms were increasing gestational age, pre-pregnancy heartburn, and parity.⁸¹

PATHOGENESIS

The exact cause of gastroesophageal reflux disease (GERD) during pregnancy is unknown. The resting lower esophageal sphincter (LES) pressure is decreased during pregnancy, and progesterone mediates LES relaxation in the setting of elevated estrogen levels.⁸² Other factors may include increased intra-abdominal pressure and decreased gastric emptying (causing gastric fluid reflux), as well as ineffective esophageal motility to clear the esophageal acid.

DIAGNOSIS

The symptoms of gastroesophageal reflux in pregnancy are the same as in the general adult population. They can include substernal burning, epigastric discomfort, dyspepsia, mild dysphagia, and regurgitation. Patients may have extraesophageal manifestations, such as hoarseness, chronic cough, chronic laryngitis, and asthma. Complications of GERD, such as gastrointestinal bleeding and esophageal strictures, are rare during pregnancy.

The diagnosis is usually made by clinical symptoms only. There is rarely reason to do invasive diagnostic tests such as barium radiographs, esophageal pH studies, or esophageal manometry studies. Upper gastrointestinal endoscopy is rarely needed, except in exceptional cases of symptoms refractory to medical management. The endoscopic appearance of GERD ranges from no mucosal breaks to severe ulceration of the distal esophagus (Fig. 62-1).

MANAGEMENT

Lifestyle and dietary changes should be initiated for mild symptoms. Patients should avoid eating within a few hours of bedtime, elevate the head of the bed 6 inches, sleep on the left shoulder, and avoid alcohol, cigarette smoking, caffeine, chocolate, and peppermint.

Medication is commonly used as first-line therapy for GERD in the general adult population. However, in pregnancy, the use of some medications is complicated by the theoretical risk for teratogenicity. Most medications for GERD are not routinely or rigorously tested in pregnant women, and recommendations come from small case series. The risks and benefits of medications for GERD, as well as the limited knowledge of the effects of these medications on the fetus, must be discussed with the patient. Because of concerns of teratogenicity, efforts should be made to avoid all unnecessary medications during the first 10 weeks of gestation. Table 62-2 shows the U.S. Food and Drug Administration (FDA) classification of drug therapy for GERD and peptic ulcer disease during pregnancy. Most drugs are FDA class B.

Antacids are considered safe and can be expected to relieve symptoms in 30% to 50% of pregnant women.⁸³ Sucralfate is a mucosal protectant that can help relieve GERD symptoms.

Figure 62-1 Endoscopic image of severe erosive esophagitis.

Metoclopramide can also be used to help gastric emptying and increase LES pressure, although the duration of use should be short because of concerns about tardive dyskinesia.

Histamine type 2 (H_2)-receptor antagonists appear to be safe and effective in pregnancy.^{84,85} Proton pump inhibitors are more effective than H_2 blockers for healing esophagitis and treating GERD, but they are less well studied in pregnancy than H_2 blockers. Omeprazole is categorized as a class C drug by the FDA because of embryotoxicity and fetotoxicity in animals and because of a few case reports of fetal birth defects in humans.⁸² However, a meta-analysis of the risk for fetal malformations during the first trimester found no increase with the use of proton pump inhibitors in general and with omeprazole specifically by pregnant women.⁸⁶ A large study from Europe comparing several proton pump inhibitors, including omeprazole, also found no increase in major fetal anomalies compared with patients not exposed to proton pump inhibitors.⁸⁷ A Danish cohort study specifically assessing proton pump inhibitor usage during pregnancy did not suggest an increased risk for malformations. However when a group exposed 4 weeks before pregnancy was included, there was a small but statistical increase in risk (OR = 1.39; 95% confidence interval [CI], 1.10 to 1.76).⁸⁸ A review of studies has suggested that proton pump inhibitor therapy predisposes the fetus to minimal risk.⁸⁹

A recommended algorithm for treating GERD in pregnancy is shown in Figure 62-2. Patients should be instructed on lifestyle modifications. The clinician should assess for medication use, including anticholinergics, calcium channel antagonists, antidepressants, and antipsychotics, that could aggravate her symptoms.⁹⁰ If these are unsatisfactory, use of antacids or

Metronidazole	B	

*U.S. Food and Drug Administration (FDA) classification of teratogenic drug risk:

- A: Well-controlled studies in pregnant women have failed to demonstrate an increased risk for fetal abnormalities.
 B: Animal studies show no fetal risk, and no human data are available, or animal studies show a risk, but well-controlled studies in pregnant women have failed to show a risk to the fetus.
 C: Risk cannot be ruled out because animal studies have shown an adverse effect, and there are no adequate, well-controlled studies in pregnant women, or no animal studies have been conducted, and there are no adequate, well-controlled studies in pregnant women.
 D: Well-controlled or observational studies in pregnant women have demonstrated a risk to the fetus, but the benefits of therapy may outweigh potential risk.
 X: Well-controlled or observational studies in animals or pregnant women have demonstrated positive evidence of fetal abnormalities, and the product is contraindicated in women who are or may become pregnant.

sucralfate should be considered. Persistent symptoms, especially after the first trimester, can be treated with H₂ blockers. If symptoms persist despite H₂ blockers, consideration can be given to using proton pump inhibitors or undergoing upper endoscopy to assess the cause of GERD.

Peptic Ulcer Disease

EPIDEMIOLOGY

The incidence of peptic ulcer disease (PUD) during pregnancy is estimated from case reports and retrospective studies.⁹¹ Epidemiologic studies suggest a decreased incidence, and in those affected, there appears to be an improvement during pregnancy. Clark found that in 313 pregnancies occurring after a diagnosis of PUD, 45% of patients had no symptoms, 44% improved, and 12% experienced no improvement.⁹² Hypotheses for this improvement include physiologic changes, including increased

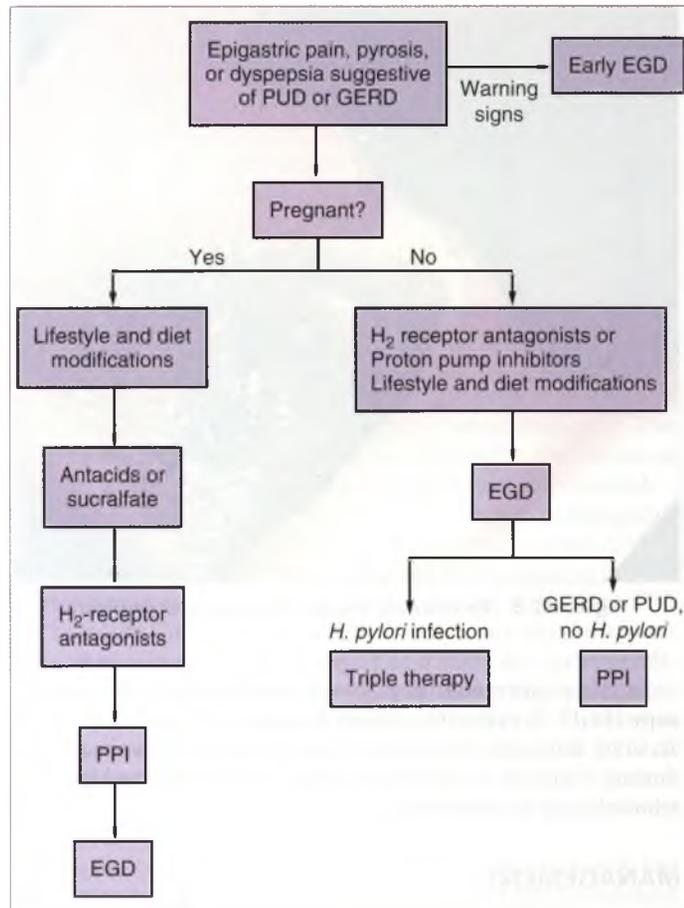

Figure 62-2 Stepwise management of gastroesophageal reflux disease (GERD) or peptic ulcer disease (PUD). EGD, esophagogastroduodenoscopy; PPI, proton pump inhibitor. (Modified from Cappell MS: *Gastric and duodenal ulcers during pregnancy*, *Gastroenterol Clin North Am* 32:263–308, 2003.)

plasma histaminase or estrogen levels leading to reduced gastric acid; increased gastric mucosal protection induced by progesterone; immunologic tolerance allowing *H. pylori* colonization without injury; and elevated epidermal growth factor levels stimulating mucosal growth. Maternal alterations such as avoidance of alcohol, smoking, and nonsteroidal anti-inflammatory drugs (NSAIDs); increased rest; and improved nutrition have also been postulated.⁹¹

DIAGNOSIS

Symptoms of PUD are similar to those in the nonpregnant population and include epigastric pain, anorexia, postprandial nausea, and vomiting. Duodenal ulcer pain can occur several hours after a meal or at nighttime, and usually improves with eating.⁹³ Gastric ulcers may not follow the classic pattern of symptoms (Fig. 62-3), and older patients who use antiulcer medication and NSAIDs may be asymptomatic.⁹⁴ GERD symptoms differ in that there may be a sense of substernal chest burning and fluid reflux, and these symptoms are often worse after meals. Results of the physical examination are nonspecific, but they are helpful in ruling out complicated ulcer disease or other causes of abdominal pain, including pancreatitis, cholecystitis, and appendicitis.

Figure 62-3 Endoscopic image of a deep gastric ulcer.

In the nonpregnant population, esophagogastroduodenoscopy (EGD) is preferable mainly because of its ability to allow accurate diagnosis of ulcers and to provide histologic specimens that are tested for *H. pylori* infection.⁸⁷ EGD (discussed later) is relatively safe in pregnancy.⁹⁵

MANAGEMENT

Management begins with empiric treatment (see Fig. 62-2). Because PUD and GERD therapies are similar, a stepwise scheme should be followed before considering EGD. Dietary and lifestyle alterations include avoidance of fat-laden foods, acidic drinks, caffeine, chocolate, NSAIDs, and alcohol. Smoking, stress, anxiety, and nighttime snacks should also be avoided.⁹¹

Antacids should be used as first-line medical therapy because they have been effective in approximately 75% of duodenal ulcers. Dosages range from 15 to 30 mL, taken 1 hour after meals and at bedtime. Extra doses may be taken 3 hours after meals.⁹¹ Aluminum- and magnesium-containing antacids have little systemic absorption and appear to be safe in pregnancy. Sucralfate, an aluminum-based polysaccharide complex, attaches to the surface of an ulcer, protecting the mucosa from further injury, and it may suppress *H. pylori* infection.^{96,97} Seventy-five percent of duodenal ulcers heal with 4 weeks of sucralfate therapy.⁹⁷ Because of its minimal systemic absorption, it is a preferred drug for treating PUD in pregnancy.⁹⁸

H₂-receptor antagonists are an effective treatment for PUD; about 80% of duodenal ulcers heal with this therapy in the general population.⁹⁹ Before the discovery of *H. pylori* and the introduction of proton pump inhibitors, H₂ blockers were the mainstay of treatment. Their safety profile in pregnancy has not been adequately demonstrated. H₂-receptor antagonists cross the placenta, but their use is justifiable if significant clinical conditions warrant.¹⁰⁰ Cimetidine and ranitidine have had considerable use over the past 20 years. In animal studies, cimetidine has caused a reduction in the size of fetal testes, prostate, and seminal vesicles, presumably by means of a weak antiandrogenic effect.¹⁰¹ Ranitidine has no such effects in

animals, and neither drug has had reports of genital malformations in humans.^{82,102} More than 2000 pregnancies in database studies with exposure to cimetidine or ranitidine have been assessed, and there has not been an associated risk for congenital malformations. There is less information reported for famotidine and nizatidine. Because of conflicting animal data for nizatidine, it is preferable to use the more extensively studied H₂-receptor antagonists as first-line agents.⁸²

Proton pump inhibitors suppress gastric acid secretion at the level of the H⁺,K⁺-ATPase on the parietal cell surface.⁹¹ These agents are highly effective in the treatment of esophagitis and gastroduodenal ulcers, and they are often used in combination therapy for eradication of *H. pylori* infection. In the nonpregnant population, proton pump inhibitors are usually the initial treatment for suspected or documented reflux esophagitis and PUD. H₂-receptor antagonists, sucralfate, and antacids are used as secondary medications and for symptomatic relief.⁹¹ During pregnancy, therapy should be modified to avoid fetal harm and also because PUD usually improves during gestation. EGD is usually avoided unless the patient is failing empiric therapy with H₂-receptor antagonists. There appears to be little benefit in diagnosing *H. pylori* infection during pregnancy, because treatment involves triple-drug therapy, including antibiotics, and it is usually deferred until after delivery.⁹¹

Appendicitis

EPIDEMIOLOGY

Acute appendicitis is one of the most common causes of an acute abdomen in pregnancy, occurring in 1 in 1500 pregnancies,¹⁰³ and it has an approximate incidence of 0.15 to 2.10 per 1000 gestations.¹⁰⁴ Previous studies suggested similar incidences for nonpregnant adults, but a large case-control study indicated a lower incidence than among nonpregnant individuals, particularly in the third trimester.¹⁰⁵ Incidence rates in the first trimester range between 19% and 36%, and the rates increase in the second trimester to between 27% and 60%.¹⁰⁵⁻¹⁰⁷ The incidence decreases in the third trimester, with rates ranging from 15% to 30%. Appendiceal perforation rates in pregnancy are higher when compared with those for nonpregnant populations (55% versus 4% to 19%).¹⁰⁷⁻¹⁰⁹ This is probably explained by confounding variables leading to the delay of diagnosis and therapy. In contrast, the negative appendectomy rate in pregnancy is substantially higher (23% to 36%) than that noted in nonpregnant adults.^{110,111} However, this rate should be reduced with more consistent use of appropriate preoperative imaging.

Fetal and maternal morbidity and mortality rates increase when appendicitis occurs during pregnancy, particularly if perforation occurs.^{112,113} The fetal loss rate associated with appendectomy is higher (2.6%) than for other surgical procedures (1.2%) during pregnancy, and the rate approximates 10% if peritonitis is present.¹¹⁴ There is a high rate of appendicitis-induced delivery (4.6%), and if preterm labor occurs, it is usually within 5 days of the surgery.^{112,114} The fetal loss rate of a negative appendectomy ranges between 2% and 4% and is similar to or mildly greater than that of a procedure done for an inflamed appendix (2% to 3%).^{110,111} The advancing pregnancy appears to impair the ability of making an accurate diagnosis. Cunningham and McCubbin¹¹³ identified delays in diagnosis of 18% and 75% in the second and third trimester, respectively, which corresponded to the higher rates of

complications, including perforation and peritonitis, found in other series.¹⁰⁷ Hee and Viktrup found the ratio of perforated appendicitis to nonperforated appendicitis to be 1.0, 2.1, and 1.6 in the first, second, and third trimesters, respectively, and they found the overall rate of appendicitis confirmed by pathologic analysis to be 50%.¹⁰⁶

DIAGNOSIS

Right lower quadrant pain is the most common symptom of appendicitis, regardless of gestational age, and it occurs in about 80% of patients.^{103,106,112} Right upper quadrant pain varies and is seen in about 10% to 55% of patients.^{103,107} Nausea and vomiting may be absent in approximately 20% of patients, and anorexia is not a reliable marker. Objective findings are similarly confusing. Fever, tachycardia, a dry tongue, and localized abdominal tenderness are common in nonpregnant individuals, but they are less reliable findings during pregnancy.¹¹⁵ The Rovsing and psoas signs have not been shown to have clinical significance.¹¹²

Laboratory evaluation of patients with appendicitis is important for excluding alternative diagnoses (Table 62-3). Urinalysis and chest radiography should be considered because urinary

tract infection and right lower lobe pneumonia may manifest with lower abdominal pain. However, pyuria may occur in 40% of pregnant patients with appendicitis.¹¹⁶ White blood cell counts are not predictive, mainly because of the physiologic leukocytosis of pregnancy. Mean white cell counts in acute appendicitis are in the range of 16,000 cells/mm³.¹⁰³

Imaging modalities help to make the diagnosis of acute appendicitis (Table 62-4). Abdominal plain film radiography should be avoided, unless there is suspicion of bowel obstruction or visceral perforation. Ultrasound with a graded compression technique, available in most hospitals, avoids ionizing radiation. However, ultrasound detection of appendicitis is operator dependent. Studies assessing the accuracy of ultrasound for the diagnosis of appendicitis have been of insufficient quality or fraught by small numbers or selection bias.¹¹⁷ The usefulness of the graded compression technique diminishes as the uterus enlarges, and often the appendix is not visualized.

Helical computed tomography (CT) in the nonpregnant population is highly sensitive and specific (approximately 98% each) for appendicitis.¹¹⁸ Its use has reduced the negative appendectomy rate from 24% to 3% over a period of 10 years.^{119,120} CT scans are considered abnormal if there is an enlarged appendix (>6 mm in maximal diameter) or if there are periappendiceal inflammatory changes, such as fat stranding, phlegmon, fluid collection, and extraluminal gas.¹¹⁸ Radiation exposure is 300 mrad with a limited helical CT scan, which is one third of the amount of the average abdominopelvic CT scan.¹²¹ Unfortunately, published experience with this technique in pregnancy is limited.

Magnetic resonance imaging (MRI) during pregnancy has no known adverse fetal effects, and its use has been advocated in patients for whom the diagnosis has not been confirmed by other techniques.^{122,123} The American College of Radiology 2007 white paper for safe MRI practices reaffirmed its use in pregnancy if considered necessary irrespective of gestational age.¹²⁴ Intravenous gadolinium contrast agents have been associated with growth restriction and congenital anomalies in animals in dosages two to seven times higher than those used in humans. There have been no known adverse effects in humans, but its use should be based on whether the potential benefits to the patient exceeds the theoretical risks to the fetus.^{122,124} A recent meta-analysis of six studies suggested a high specificity (98% to 100%) and high negative predictive value (94% to 100%), suggesting that a normal appendix on MRI has a high accuracy in excluding acute appendicitis.¹²⁵ A normal appendix was suggested by a diameter of 6 mm or less, or by its being filled with

TABLE 62-3 Differential Diagnosis of Acute Appendicitis

Evaluation	Alternative Diagnoses
Surgical	Acute cholecystitis Pancreatitis Mesenteric adenitis Diverticulitis Intestinal obstruction Meckel diverticulum
Medical	Gastroenteritis Pneumonia Inflammatory bowel disease Lupus serositis Diabetic ketoacidosis Porphyria

air or oral contrast. On the other hand, a fluid-filled appendix greater than 6 or 7 mm in diameter or the presence of periappendiceal inflammatory changes (or both) was considered abnormal.^{125,126} Current evidence-based guidelines from the American College of Radiology suggest ultrasound and MRI to be more appropriate imaging techniques than CT for the evaluation of right lower quadrant pain in pregnant women.¹²⁷

MANAGEMENT

Prompt surgical intervention is the standard treatment. Appendectomy may be delayed during active labor, but it should be performed immediately after delivery or if labor is abnormally prolonged or perforation is suspected.¹²⁸ If an open procedure is chosen, a muscle-splitting incision is made over the point of maximal tenderness. If diffuse peritonitis is present, a midline incision is usually performed. A periappendiceal abscess can be treated with percutaneous drainage followed by an interval appendectomy 2 to 3 months later.¹²⁸ Perioperative antibiotics should be administered, usually a second-generation cephalosporin, expanded-spectrum penicillin, or even triple-agent therapy.

Laparoscopic appendectomy was first performed in 1980, and it spawned controversy about its use in pregnancy that continues to the present.¹²⁹ Its use in pregnancy has been documented with a good safety record,^{130,131} and it has a complication rate similar to that for nonpregnant laparoscopy.¹³² It may have advantages over open appendectomy, such as less abdominal wall trauma, less pain and narcotic use, and faster return to normal activity.^{129,133} However, the presence of the enlarged

uterus does increase the risk for inadvertent puncture with a trocar or Veress needle.¹³⁴ In the second half of pregnancy, open laparoscopy may be preferred to avoid such complications. Unlike nonpregnant laparoscopy, no instrument should be applied to the cervix. The primary trocar is inserted after determining the height of the uterus, and the secondary trocars are inserted under direct visualization. Consideration of supraumbilical, subxiphoid insertions may be necessary. Limiting intraabdominal pressure to less than 12 mm Hg and reducing operative time can reduce concerns about maternal hypercarbia and subsequent fetal acidosis.^{133,135} Guidelines regarding the use of laparoscopy for surgical problems during pregnancy have been developed by the Society of American Gastrointestinal and Endoscopic Surgeons (Table 62-5).¹³⁶

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) refers to ulcerative colitis and Crohn disease. Their similarities and differences are outlined in Table 62-6. These entities are similar in that both are inflammatory conditions of the luminal gastrointestinal tract. They differ in terms of the layer of involvement of the intestinal wall, the anatomic location of involvement in the gastrointestinal tract, and the response to surgical resection. Both are treated with similar medications, and their causes are unknown. There seems to be a genetic component in some patients, but there is also the possibility of an environmental trigger such as an infection. The final common pathology is an increased inflammatory response against the tissues of the gastrointestinal tract.

TABLE 62-5 SAGES Recommendations for Laparoscopy during Pregnancy: Guidelines Relevant to Appendicitis

PATIENT SELECTION

Preoperative decision making	Laparoscopic treatment of acute abdominal processes has the same indications in pregnant and nonpregnant patients (level II, grade B)
Laparoscopy and trimester of pregnancy	Laparoscopy can be safely performed in any trimester of pregnancy (level II, grade B)

TREATMENT

Patient positioning	Gravid patients should be placed in the left lateral recumbent position to minimize compression of the vena cava and the aorta (level II, grade B).
Initial port placement	Initial access can be safely accomplished with open (Hassan), Verres needle, or optical trocar technique if the location is adjusted according to fundal height, previous incisions, and experience of the surgeon (level III, grade B).
Insufflation pressure	CO ₂ insufflation of 10-15 mm Hg can be safely used for laparoscopy in the pregnant patient. Intraabdominal pressure should be sufficient to allow for adequate visualization (level III, grade C).
Intraoperative CO ₂ monitoring	Intraoperative CO ₂ monitoring by capnography should be used during laparoscopy in the pregnant patient (level III, grade C).
Venous thromboembolism prophylaxis	Intraoperative and postoperative pneumatic compression devices and early postoperative ambulation are recommended prophylaxis for deep venous thrombosis in the gravid patient (level III, grade C).
Laparoscopic appendectomy	Laparoscopic appendectomy may be performed safely in pregnant patients with suspicion of appendicitis (level II, grade B).

PERIOPERATIVE CARE

Fetal heart monitoring	Fetal heart monitoring should occur preoperatively and postoperatively in the setting of urgent abdominal surgery during pregnancy (level III, grade B).
Obstetric consultation	Obstetric consultation can be obtained preoperatively and/or postoperatively depending on the acuteness of the patient's disease, gestational age, and availability of the consultant (level III, grade C).
Tocolytics	Tocolytics should not be used prophylactically but should be considered when signs of preterm labor are present in coordination with obstetric consultation (level I, grade A).

SAGES, Society of American Gastrointestinal and Endoscopic Surgeons.

From Yumi H: *Guidelines for diagnosis, treatment, and use of laparoscopy for surgical problems during pregnancy: this statement was reviewed and approved by the Board of Governors of the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES), September 2007. It was prepared by the SAGES Guidelines Committee, Surg Endosc 22:849-861, 2008.*

TABLE 62-6 Comparison of Ulcerative Colitis and Crohn Disease

Feature	Ulcerative Colitis	Crohn Disease
Extent of inflammation	Limited to mucosa	Involves all layers (transmural)
Intestine involved	Colon only	Throughout the gastrointestinal tract, especially the terminal ileum
Rectal involvement	Always	Sometimes
Pattern of spread	Contiguous	Skip lesions
Granulomas	No	Yes (sometimes)
Fistula	No	Yes
Strictures	No	Yes
Abscess	No	Yes
Perianal disease	No	Yes
Bloody diarrhea	Yes	Maybe
Ileal disease on computed tomography	No	Yes
Increased colon cancer risk	Yes	Maybe (if colonic involvement)
Cure with surgery	Yes	No
Percentage of patients who will require surgery	20%	70%

**Figure 62-4** Endoscopic image of severe ulcerative colitis.

Ulcerative colitis is characterized by inflammation limited to the mucosal surface of the colon (Fig. 62-4). It always starts at the dentate line of the rectum and extends proximally but involves only the colon. Patients, who usually present with bloody diarrhea, are usually managed with medical therapy consisting of 5-aminosalicylates, prednisone, 6-mercaptopurine or azathioprine, and occasionally biologic agents such as infliximab. Surgery, which is rarely required for refractory disease, results in complete cure of the ulcerative colitis.

Crohn disease is characterized by inflammation that can be transmural, involving all layers of the gastrointestinal wall. It often involves the terminal ileum, but it can involve any part of the luminal gastrointestinal tract. Transmural inflammation

may result in intestinal strictures or intestinal fistulas or abscesses. Patients are usually managed medically with 5-aminosalicylates, prednisone, 6-mercaptopurine or azathioprine, and biologic agents such as infliximab. They also may benefit from antibiotics such as metronidazole and ciprofloxacin.

EFFECT OF INFLAMMATORY BOWEL DISEASE ON PREGNANCY

In general, there is an increased risk for preterm birth, low birth weight, and being small for gestational age among infants of mothers with IBD, but no increased risk for congenital anomalies.¹³⁷⁻¹⁴⁴ However, it is unclear from these studies whether the degree of disease activity correlated with the differences in outcomes. If a woman has quiescent IBD, the pregnancy can be expected to proceed without increased complications.^{145,146}

EFFECT OF PREGNANCY ON INFLAMMATORY BOWEL DISEASE

Approximately one third of pregnant patients with active ulcerative colitis or Crohn disease will experience a flare during pregnancy, which is identical to the annual risk for flaring in nonpregnant women.¹⁴⁴ Active ulcerative colitis or Crohn disease at the time of conception tends to remain active, and inactive disease tends to remain inactive.^{141,147,148}

MODE OF DELIVERY IN INFLAMMATORY BOWEL DISEASE

Cesarean section is performed in up to 44% of patients with IBD, which is higher than the general population.¹⁴⁴ Current recommendations are for delivery by cesarean section for women with active perineal disease, as well as possibly for others with IBD, depending on the patient's unique circumstances.

DIAGNOSTIC TESTING FOR INFLAMMATORY BOWEL DISEASE DURING PREGNANCY

Patients with known IBD can be managed on the basis of their history, physical examination findings, and blood test results. It is important to determine whether a patient with IBD who is having a flare of diarrhea during pregnancy has an intestinal infection, especially with *Clostridium difficile*, before starting any new immunosuppressive therapy (Fig. 62-5). In selected pregnant patients with IBD, stool studies for infectious causes are needed. Flexible sigmoidoscopy appears to be safe during pregnancy, and it is usually the only endoscopic procedure needed in selected IBD patients. Abdominal CT or MRI may be used in carefully selected cases if the benefits outweigh potential risks.

SAFETY OF INFLAMMATORY BOWEL DISEASE MEDICATIONS DURING PREGNANCY

Pregnant patients with IBD should stay on the medications that are maintaining them in remission. Stopping the medications can induce a relapse or flare of disease. Table 62-7 shows the safety of various IBD medications during pregnancy.

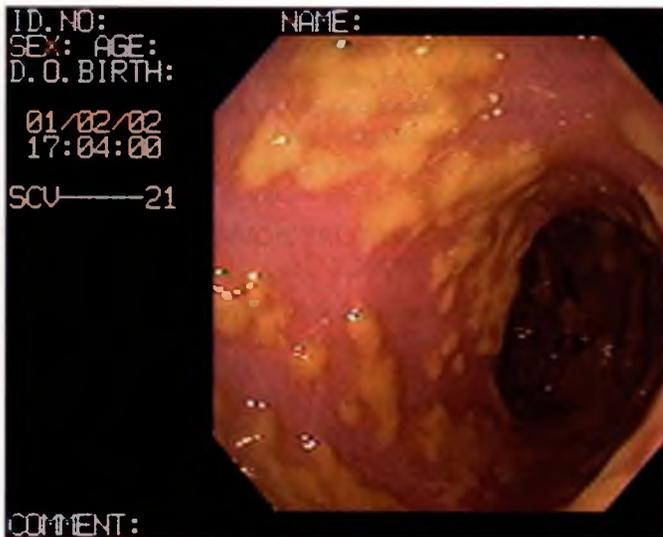

Figure 62-5 *Clostridium difficile* colitis.

TABLE 62-7 Safety of Inflammatory Bowel Disease Medications during Pregnancy

Safe to Use	Probably Safe but Limited Data	Contraindicated
Sulfasalazine	Azathioprine	Methotrexate
5-Aminosalicylates	6-Mercaptopurine	Diphenoxylate
Corticosteroids	Cyclosporine	
	Metronidazole	
	Ciprofloxacin	
	Infliximab	
	Loperamide	

Antidiarrheal Medications

Loperamide (Imodium) appears to be safe during pregnancy because it has not been associated with increased rates of fetal malformations, spontaneous abortions, low birth weight, or prematurity.¹⁴⁹ In contrast, there have been reports of fetal malformations in patients exposed to diphenoxylate with atropine (Lomotil) during the first trimester, and it should be avoided.¹⁵⁰ It is probably best to avoid antidiarrheal drugs, if possible, during pregnancy and instead rely on supplemental fiber or psyllium seed husks.

Antibiotics

Metronidazole and ciprofloxacin are occasionally used in the management of patients with Crohn disease. Several studies have shown that short-term use of metronidazole is safe during pregnancy.^{151,152} Some animal studies suggested that musculoskeletal abnormalities resulted from ciprofloxacin, but small clinical series have not reported any fetal malformations or arthropathies.^{153,154} In 2009, the FDA added a black box warning to the labels of fluoroquinolone medications, directing physicians to observe for signs of tendonitis (especially Achilles tendon) and if present to stop the medication immediately.

Sulfasalazine and 5-Aminosalicylate Drugs

Sulfasalazine and 5-aminosalicylate drugs are often used for long-term maintenance of mild or moderately active IBD. These drugs appear to be safe to use in pregnancy.^{87,155-158}

Corticosteroids

Oral corticosteroids such as prednisone are commonly used to manage active ulcerative colitis and Crohn disease. They are typically used for short periods to induce remission but are not used for maintenance of remission. The use of prednisone for IBD appears to be relatively safe in pregnancy, although an increased incidence of low-birth-weight neonates has been reported.^{157,159}

Immunomodulators

Azathioprine and 6-mercaptopurine are increasingly used to maintain remission in patients with ulcerative colitis or Crohn disease. Azathioprine and 6-mercaptopurine cross the placenta. The largest experience with azathioprine in pregnancy comes from the renal transplant literature, which suggests it is safe to use.¹⁶⁰ There is less information on 6-mercaptopurine in pregnancy, but it also appears safe to use in pregnant patients with IBD to keep them in remission.^{161,162}

Methotrexate is occasionally used in challenging cases of IBD. Methotrexate is associated with fetal malformations and fetal demise, and it should not be used during pregnancy, and ideally for not at least 3 months before conception.

Biologic Agents

Anti-tumor necrosis factor medications, such as infliximab, adalimumab, and certolizumab, are increasingly being used for induction and maintenance of remission of Crohn disease and occasionally for ulcerative colitis. There are only small case series of infliximab being continued intentionally for Crohn disease during pregnancy, but the limited data show no obvious adverse effects.¹⁶³ Because patients who are taking maintenance infliximab usually have been refractory to other treatments, it is likely that their Crohn disease will flare during pregnancy if infliximab is stopped. The unknown risks and benefits must be discussed with the patient. A 2011 position statement of the World Congress of Gastroenterology and the European Crohn and Colitis Organization concluded that anti-tumor necrosis factor therapy in pregnancy is considered to present a low risk and be compatible with use in men and women during conception, and during pregnancy in at least the first two trimesters.¹⁶⁴

SURGERY FOR INFLAMMATORY BOWEL DISEASE DURING PREGNANCY

Surgery for IBD during pregnancy is done for emergencies such as intestinal obstruction, perforation, abscess, or fulminant colitis. In these cases, the surgery is required for the mother's health.

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is characterized by chronic abdominal pain and altered bowel habits without obvious organic cause. It is the most commonly diagnosed gastrointestinal pathology. The estimated prevalence of IBS in the United States is between 10% and 15%.¹⁶⁵ IBS tends to affect younger women more than other demographic groups, which means many pregnant women also have IBS. It accounts for 25% to 50% of clinic referrals to gastroenterologists and approximately 10% of referrals to primary care physicians.¹⁶⁵

It is unclear whether pregnancy worsens IBS symptoms, because many pregnant women develop constipation or loose stools during pregnancy. Because IBS usually poses no threat to maternal or fetal health, it can be treated symptomatically during pregnancy.

SYMPTOMS

IBS is a heterogeneous collection of symptoms. The most common include chronic abdominal pain and altered bowel habits. Upper abdominal symptoms can also occur. The abdominal pain is often described as crampy, lower abdominal discomfort (often in left side), which can become worse with stress and better after bowel movements. Patients with IBS often complain of altered bowel movements, with constipation, diarrhea, or alternating constipation and diarrhea. When describing constipation, they often mention stools resembling rabbit pellets. They often describe needing to have bowel movements several consecutive times in the morning to completely empty the rectum. They may have mucus in their stools. The diarrhea never wakes them from sleep. Upper gastrointestinal symptoms such as GERD, dyspepsia, and nausea are common, as are symptoms of gas and bloating. Extraintestinal symptoms include dyspareunia, increased urinary frequency and urgency, and fibromyalgia.¹⁶⁶

Symptoms that are not consistent with IBS include blood in the bowel movements, weight loss, and being awakened from sleep for abdominal pain or bowel movements. These symptoms should prompt additional evaluation.

DIAGNOSTIC CRITERIA

The most common diagnostic criteria for standardizing the diagnosis of IBS are the Manning criteria and the Rome III criteria (Box 62-1). The Manning criteria include abdominal pain relieved with bowel movements, looser and more frequent stools with onset of pain, passage of mucus, and sense of incomplete evacuation.¹⁶⁷ The Rome III diagnostic criteria for IBS are recurrent abdominal discomfort with two or more of the following: improvement with defecation, onset associated with a

change in stool frequency, and onset associated with a change in stool appearance or form.¹⁶⁸ The Rome III criteria also describes four subtypes of IBS: IBS with constipation, IBS with diarrhea, mixed diarrhea and constipation IBS, and unsubtyped IBS.

PATHOPHYSIOLOGY

The pathogenesis of IBS is unknown but probably multifactorial. The most common possibilities include altered motility of the gastrointestinal tract and visceral hypersensitivity. There may also be a central nervous system component because IBS patients have an increased frequency of psychiatric abnormalities such as depression, somatization disorders, and generalized anxiety disorders. There also is a subgroup of patients with postinfectious IBS.

DIAGNOSIS

IBS should be suspected with the appropriate clinical symptoms and lack of symptoms that raise an alarm for more serious pathology (i.e., blood in stool, weight loss, waking from sleep because of pain or bowel movements). The diagnostic evaluation is often geared to symptoms and may include blood work and endoscopic evaluations. IBS often is a diagnosis of exclusion in the correct clinical setting.

MANAGEMENT

There is no specific treatment for IBS, and it tends to be a chronic condition. Reassurance of the patient by an understanding physician is important. Dietary changes may identify foods that worsen symptoms (e.g., dairy products, fatty foods). Supplemental fiber can help a subset of patients, although the mechanism is uncertain. Medications are needed only by a minority of patients with IBS. These drugs can include antispasmodic medicines such as hyoscyamine. Low-dosage antidepressants can be used to modify chronic abdominal pain. Probiotics have been reported to help some symptoms. Diarrhea can be controlled with antidiarrheal medications, and constipation can be controlled by laxatives or lubiprostone. Antibiotics may help the gas and bloating symptoms of IBS in selected patients.¹⁶⁹

Celiac Disease

EPIDEMIOLOGY

Celiac disease is also known as celiac sprue or gluten-sensitive enteropathy.¹⁷⁰ Gliadin and related proteins activate the immune system, resulting in the inflammation of the small intestinal mucosa and malabsorption.¹⁷⁰ Celiac sprue is caused by an abnormal T-cell response against gluten in genetically predisposed people.¹⁷¹

Celiac disease is often underdiagnosed. The prevalence of this disorder ranges from 1 in 80 to 1 in 300 individuals.^{172,173} The highest reported prevalence is in Western Europe and places to which Europeans immigrate.¹⁷³⁻¹⁷⁵ Genetic predisposition for celiac disease is confirmed by a high rate of concordance in monozygotic twins.¹⁷⁶ The diagnosis may be associated with other conditions such as diabetes, lymphocytic colitis, irritable bowel syndrome, diarrhea, and unexplained anemia. Survival of these patients has improved with appropriate therapy.¹⁷⁷

BOX 62-1 DIAGNOSTIC CRITERIA FOR IRRITABLE BOWEL SYNDROME

Manning Criteria	Rome III Criteria
Pain relieved with defecation	Recurrent abdominal discomfort at least 3 days per month in the past 3 months associated with two or more of the following: 1. Improvement with defecation 2. Onset associated with change in stool frequency 3. Onset associated with change in form of stool
More frequent stools at the onset of pain	
Looser stools at the onset of pain	
Visible abdominal distention	Supporting features: abnormal stool frequency (<3 bowel movements per week or >3 bowel movements per day), abnormal stool form, defecation straining, urgency, sense of incomplete bowel movement, mucus passage, bloating
Mucus in stool	
Sense of incomplete evacuation	

DIAGNOSIS

Although celiac disease often begins in childhood, clinical symptoms of the disease may begin at any age.¹⁷⁸ One fourth of individuals are diagnosed after the age of 15 years.¹⁷⁹

Celiac sprue may manifest in pregnancy or after delivery, and the diagnosis should be entertained when encountering severe anemia in a gravid patient.^{170,180} Adults usually present with episodic diarrhea, flatulence, and weight loss. They also may have lactose intolerance and steatorrhea. Patients have abdominal discomfort, bloating, malaise, and recurrent aphthous stomatitis ulcers.¹⁷⁰

Laboratory abnormalities include iron deficiency, macrocytic anemia, and vitamin D and K deficiencies. The most widely available screening test for celiac disease is the antiendomysial IgA test. The test has excellent specificity (approaching 100%), but its sensitivity as a stand-alone screen is less because of an increased prevalence of selective IgA deficiency in patients with celiac disease.¹⁷⁷ IgA and IgG antigliadin antibodies have moderate sensitivity but are less specific than antiendomysial antibodies; normal individuals and those with gastrointestinal inflammation from other causes test positive.¹⁸¹ IgA antigliadin antibody levels are useful for monitoring dietary compliance, because they become detectable within 6 months of maintaining a gluten-free diet.¹⁷⁰ A rapid bedside screening test has been developed that detects IgA and IgG tissue transglutaminase. The sensitivity of this test is higher than that for IgA endomysial antibodies, and it is increasingly being used as the initial screening test for celiac disease.¹⁸² The gold standard of diagnosis remains biopsy of the small intestine during an upper gastrointestinal biopsy from the distal duodenum.¹⁷⁰

MANAGEMENT

Management consists of eliminating gluten, including wheat, rye, and barley gluten, from the diet. Seventy percent of patients improve symptomatically within 2 weeks.¹⁸³ During the initial phase of treatment, oats and lactose-containing products should also be eliminated.¹⁷⁰ Because of problems of malabsorption, multivitamin therapy and specific replacement of vitamin D and calcium may be necessary.

The importance of recognizing celiac disease may be reflected in the studies that suggest that uncontrolled disease may be associated with adverse pregnancy outcome.^{184,188} Studies of untreated and treated celiac patients revealed an increased rate of spontaneous miscarriages in the untreated cases.^{184,185} The rate of intrauterine growth restriction is higher among untreated patients.¹⁸⁸⁻¹⁹⁰ Whether these outcomes imply causation or merely association is debatable. An epidemiologic study involving 1521 women with celiac disease suggested that fertility in these patients is similar to that for the general female population.¹⁹¹ Although the researchers found somewhat higher miscarriage and cesarean section rates in the affected population, there was also a trend toward delayed childbearing, which may influence the statistics. It appears that the negative effects of celiac disease, including miscarriage, are reduced by institution of a gluten-free diet.¹⁷⁷

Pregnancy may unmask or reactivate celiac disease and should lead the obstetrician to evaluate signs such as anemia refractory to iron, hypokalemia, and hypocalcemia in the

absence of clinical symptoms. The reason for worsening symptoms is unknown, but it is speculated to be the loss of borderline tolerance to gluten resulting from hormonal or endocrine mechanisms.¹⁹²

Bariatric Surgery

Obesity has become an epidemic in the United States. Pregnancy outcomes for these women are worse than those with a normal body mass index.¹⁹³ Complications include gestational diabetes, hypertension, preeclampsia, macrosomia, and an increased rate of cesarean section.

The 1991 National Institutes of Health Consensus Developmental Conference concluded that bariatric surgery is the most effective treatment for morbidly obese patients.¹⁹⁴ A consequence of the increased rate of obesity is the increased numbers of gastrointestinal operations performed for weight loss. The number of operations increased from 16,000 in the early 1990s to 103,000 in 2003.¹⁹⁵

Two types of procedures dominate the practice of bariatric surgery. One is diversionary bypass, which constructs a proximal gastric pouch to an outlet of a Y-shaped limb of small bowel (i.e., Roux-en-Y procedure). Variants include biliopancreatic diversion and long-limb gastric bypass, which are usually reserved for heavier patients.¹⁹⁶ The second type is restrictive and involves reducing the volume of the stomach and includes gastric banding and sleeve gastrectomy. Gastric bypass surgery results in more weight loss, but it can be associated with nutritional deficiencies and the dumping syndrome. Because of the lack of functional proximal small bowel, patients can have iron, vitamin B₁₂, vitamin D, and folic acid deficiencies (see Table 62-8). Parenteral replacement (especially iron) may be necessary if oral supplementation is not successful. After bariatric surgery, patients can have acute postgastric reduction surgery neuropathy. Prominent features include progressive vomiting, weakness, and hyporeflexia. This disorder overlaps with other syndromes caused by deficiencies of many nutrients.¹⁹⁷ Gastric banding and sleeve gastrectomy result in somewhat less weight loss and do not change the metabolic consequences of obesity, but they maintain the normal intestinal continuity with fewer problems from dumping or vitamin malabsorption.

Pregnancy outcomes in patients with prior bariatric surgery appear to be relatively good. Early case reports described complications, including gastrointestinal bleeding,¹⁹⁸ intrauterine growth restriction,¹⁹⁹ and fetal anomalies.²⁰⁰ However, population-based studies suggest very acceptable outcomes. Sheiner and associates identified 298 deliveries complicated by an open or laparoscopic bariatric procedure.²⁰¹ They found no differences between procedures, but compared with no prior bariatric surgery, there was a higher rate of labor induction, fetal macrosomia, cesarean section, and premature membrane rupture.²⁰¹ Specifically addressing gastric bypass, Dao and colleagues evaluated 2423 patients who underwent a Roux-en-Y procedure.²⁰² Of these, 34 became pregnant, and 21 became pregnant within a year of the surgery. There were no significant differences with respect to outcome compared with those who became pregnant more than a year after surgery.²⁰² A larger series of 104 patients who conceived during the first postoperative year revealed no differences in hypertensive disorders, diabetes, congenital malformations or bariatric

complications when compared with 385 patients who were pregnant after the first postoperative year.²⁰³ A recent systematic review of 75 articles suggested that the rates of many adverse maternal and neonatal outcomes are lower in those pregnant after bariatric surgery than in obese pregnant women.²⁰⁴

As the frequency of bariatric operations has increased, so has awareness of the complications of these procedures. Case reports of internal hernias causing acute surgical emergencies, including intestinal infarction, have been published in the obstetric literature.^{205,206} Furthermore, it appears that internal hernias and small bowel obstruction occur more frequently with laparoscopic Roux-en-Y gastric bypass (0.6% to 7.3%) than with open procedures (1% to 4.7%).²⁰⁷ The increased incidence is thought to result from the fewer postoperative adhesions with the laparoscopic approach. Most occur with the first postoperative pregnancy.²⁰⁷ Diagnostic imaging for evaluation may be problematic, and evaluation should be performed by a radiologist experienced in bariatric patients or a bariatric surgeon. Gastric ulcer perforation and gastrointestinal hemorrhage have also been reported.^{198,208} More common problems are the nutritional deficiencies that are associated primarily with gastric bypass. They include iron, vitamin B₁₂, folate, and calcium deficiencies (Table 62-8).²⁰⁹ Screening and supplementation for micronutrient deficiencies is important to reduce the risk for maternal (anemia, pernicious anemia, osteopenia, and vitamin K-dependent clotting diathesis) and fetal (neural tube defects, rickets, and intracranial hemorrhage) complications.^{210,211}

Constipation

EPIDEMIOLOGY

Constipation is defined as difficult defecation and infrequent bowel movements that do not result from an underlying cause.²¹² The estimated incidence during pregnancy is between 10% and 40%, as derived from studies done 2 decades ago.^{213,214}

PATHOGENESIS

Factors contributing to constipation during pregnancy include iron supplementation, decreased activity, uterine enlargement, hemorrhoids, and hormonal factors, including increased progesterone and estrogen and decreased motilin levels.²¹⁴ In animal studies, progesterone decreases smooth muscle contractility and slows gastrointestinal transit.²¹⁵ Pregnant and ovariectomized rats given estrogen and progesterone had longer colonic transit than nonpregnant or ovariectomy control animals.¹⁶ Human studies of sex hormone effects have relied on orocecal transit times. In nonpregnant women, the transit time was significantly longer during the luteal phase, when progesterone levels are usually higher.¹³ A study involving seven women with intractable constipation and documented slow transit times who required colectomy were compared with six women requiring colectomy for adenocarcinoma. Progesterone receptors were overexpressed in the patients with constipation. This overexpression was reproduced in normal colonic cells treated with progesterone.²¹⁶ Plasma motilin levels are depressed

TABLE 62-8 Vitamin and Mineral Deficiencies after Bariatric Surgery

Deficiency or Complication	Risk Level	Results of Laboratory Tests	Routine Pregnancy Supplement	Treatment in Refractory Cases
Vomiting	AGB ++ VGB ++ GBS ±	—	—	Deflate adjustable gastric band
Iron	AGB + GBS ++ SG +	Microcytosis ↓ Ferritin	Ferrous sulfate, 300 mg 2-3 times/day, with vitamin C	Parenteral iron
Vitamin B ₁₂	AGB + GBP ++ SG +	Macrocytosis Anemia ↓ Vitamin B ₁₂ Neuropathy	4 µg/day	Oral B ₁₂ , 350 µg/day or 1000-2000 µg IM every 2-3 mo
Calcium, vitamin D	AGB ± GBP ++ SG ?	↓ 1,25(OH) ₂ D ₃ ↑ Parathyroid hormone	Calcitriol: oral vitamin D contained in prenatal vitamins	1200 mg/day calcium citrate in addition to prenatal vitamins Calcitriol: oral vitamin D, 1000 IU/day Oral folate, 1000 µg/day
Vitamin B ₉	AGB ± GBP ± SG ±	↓ Folate Macrocytosis	400 µg/day folic acid contained in prenatal vitamins	Supplement should not exceed 10,000 IU/day
Vitamin A	AGB – GBP ± SG ±	↓ Vitamin A level Night blindness	Vitamin A, 4000 IU/day contained in prenatal vitamins	Thiamine, 100 mg intravenously, particularly if glucose infusions are administered
Vitamin B ₁	AGB ± GBP ± SG ±	↓ Thiamine Neuropathy Wernicke encephalopathy	—	—
Zinc, selenium	AGB + GBP + SG ?	↓ Zinc ↓ Selenium Hair loss	—	—

AGB, adjustable gastric banding; GBP, gastric bypass procedure; SG, sleeve gastrectomy; VGB, vertical banded gastroplasty.

Adapted from Ziegler O, Sirveaux MA, Brunaud L, et al: Medical follow up after bariatric surgery: nutritional and drug issues. *General recommendations for the prevention and treatment of nutritional deficiencies*, Diabetes Metab 35:544–557, 2009; and Kominariak MA: Preparing for and managing a pregnancy after bariatric surgery, *Semin Perinatol* 35:356–361, 2011.

during pregnancy but return to normal within 1 week after delivery.²¹⁷ Although colonic transit times during pregnancy have not been studied, diaries of patients' symptoms have suggested increased problems with bowel movements in all three trimesters.²¹³ The causes and treatment of constipation appear to be similar to those for the general population.²¹⁴

DIAGNOSIS

The diagnosis of constipation is based on the patient's history, and the physician can use the Rome III criteria—12 weeks (not necessarily consecutive) in the prior 12 months when two of the following have occurred: straining, lumpy or hard stools, sensation of incomplete evacuation or anorectal obstruction or manual maneuvers to assist in more than 25% of defecations, and less than three bowel movements per week.²¹⁸ Problems with adherence to the Rome criteria were highlighted in a study in which 40% to 50% of patients who fulfilled the criteria did not feel constipated.²¹⁹ Constipation can arise de novo during gestation or be a chronic condition that is exacerbated by pregnancy.

MANAGEMENT

Education should be the first-line treatment.²²⁰ Patients should be instructed to increase fluid and fiber intake, exercise, and attempt defecation in the morning or after meals, when colonic activity is the highest. Dietary habits should be explored. If needed, 2 to 6 tablespoons of bran should be added to each meal, followed by a glass of water. However, the laxative effect

may take 3 to 5 days.²¹⁴ Psyllium, polycarbophil, and methylcellulose act by increasing fecal water content and decreasing stool transit time. Hyperosmolar laxatives such as polyethylene glycol, sorbitol, and lactulose are poorly absorbed and increase fecal water content. Because prolonged use may lead to electrolyte imbalances, they should be used with caution. Stimulant laxatives have a fast onset of action and may be considered in patients who fail to respond to bulk or osmotic agents.²¹⁴ Their short-term use is generally safe, but long-term use is not recommended. Tolerance, although uncommon in most users, can occur in patients with severe forms of slow colonic transit.²²¹ A list of these agents is provided in Table 62-9.

Hemorrhoids

EPIDEMIOLOGY

Hemorrhoids are common in adults.²²² One third of pregnant women are symptomatic, and approximately 10% require treatment for hemorrhoids.²²³

PATHOGENESIS

Etiologic factors include constipation and straining at defecation, vascular engorgement from increased intraabdominal pressure and blood volume, and the absence of valves in hemorrhoidal veins.²¹⁴ Internal hemorrhoids originate above the dentate line, and they are supplied by the superior hemorrhoidal plexus and covered with columnar epithelium. External hemorrhoids are below the dentate line, and they are supplied

TABLE 62-9 Preferred Laxatives in Pregnancy

Laxative	Usual Dosage	Advantages	Disadvantages
BULK FORMING			
		Long-term use in patients with normal gut motility	Slow onset of action (48-72 hr). Risk of mechanical obstruction. Excessive gas formation. Potential for iron and calcium malabsorption
Psyllium	1 tsp up to 3 times daily	—	Potential for anaphylaxis
Methylcellulose	1 tsp up to 3 times daily	Less bloating	—
HYPEROSMOLAR			
		Fast onset of action	Long-term use may be associated with electrolyte abnormalities in certain populations.
Polyethylene glycol (PEG)	8-32 oz daily	Long-term efficacy and safety. Consensus is PEG is superior to lactulose. Preferred treatment for chronic constipation in pregnancy	Incontinence due to potency. More expensive than sorbitol and lactulose
Lactulose	15-30 mL once or twice daily	—	—
Sorbitol	15-30 mL once or twice daily	Sweet taste	Transient abdominal cramps
STOOL SOFTENER			
Docusate	100 mg twice daily	—	—
STIMULANTS			
		Fast onset of action	Long-term use limited to 3 days/wk. Caution advised in pregnancy.
Bisacodyl	10 mg per rectum, 30 mg PO	—	Incontinence, hyperkalemia, abdominal cramping
Senna	17-34 mg	Less colic than with bisacodyl	—
SALINE OSMOTIC LAXATIVES			
		Fast onset of action	Unsuitable in long term. Dehydration can result from diarrhea. Magnesium toxicity
Milk of magnesia	15-30 mL daily	—	Caution advised in pregnancy.

PO, by mouth.

by the inferior hemorrhoidal plexus and covered with squamous epithelium.

MANAGEMENT

External hemorrhoids infrequently require treatment unless complicated by thrombosis. For mild discomfort, conservative treatment includes stool softeners, sitz baths, and mild analgesics. If the pain is severe, surgical excision under local anesthesia can be performed during pregnancy.^{214,223} Clot incision with removal is less efficacious, mainly because of recurrent thrombosis.²²⁴ Internal hemorrhoids usually manifest as painless bleeding, although they can manifest with discomfort caused by prolapse or incarceration. Diagnosis may require anoscopy. Treatment is usually conservative and includes increased fiber and stool softeners. Local measures, including skin protectants and topical anesthetics, can improve symptoms. Patients with refractory symptoms may require band ligation, injection, sclerotherapy, or coagulation.²¹⁴ Rubber band ligation is effective for internal hemorrhoids that are reducibly prolapsed. Sclerotherapy using 5% phenol is safe in pregnancy, and infrared photocoagulation and laser coagulation for first- and second-degree hemorrhoids are theoretically safe.²²³ Surgical hemorrhoidectomy is reserved for internal hemorrhoids that prolapse and incarcerate or that have failed conservative in-office measures, but postoperative bleeding and subsequent risks for hypotension may be more of a risk to both mother and fetus.^{214,225}

Gastrointestinal Endoscopy in Pregnancy

UPPER GASTROINTESTINAL ENDOSCOPY AND COLONOSCOPY

Upper gastrointestinal endoscopy (i.e., esophagogastroduodenoscopy) and colonoscopy play vital roles in the diagnosis and treatment of a variety of gastrointestinal disorders. Few pregnant patients with gastrointestinal disorders need gastrointestinal endoscopy, but if they do, the main risks are related to the endoscopy itself (e.g., perforation, bleeding, infection) and complications of sedation (e.g., cardiovascular events, pulmonary aspiration, teratogenic risks of medications). Results from several small studies suggest that careful upper endoscopy and colonoscopy are safe during pregnancy.^{95,226-230}

The American Society for Gastrointestinal Endoscopy, with input from the American College of Obstetricians and Gynecologists Committee on Obstetric Practice, published guidelines related to endoscopy in pregnant women.²³¹ They have developed general indications for endoscopy in pregnancy (Box 62-2).

Sedation for the procedure poses the greatest risk to the fetus, and consideration should be given in these cases to having supervision by an anesthesiologist. Gastroenterologists usually perform upper endoscopy and colonoscopy on adults using moderate sedation or monitored anesthesia care. The drugs commonly used for gastrointestinal endoscopy sedation, and their FDA category regarding safety during pregnancy, are as follows: meperidine (B), fentanyl (C), naloxone (B), benzodiazepines (D), flumazenil (C), propofol (B), simethicone (C), glucagon (B), and polyethylene glycol (C).

BOX 62-2 INDICATIONS FOR ENDOSCOPY IN PREGNANCY

- Significant or ongoing gastrointestinal bleeding
- Severe or refractory nausea and vomiting or abdominal pain
- Dysphagia or odynophagia
- Strong suspicion of a mass in the upper gastrointestinal tract or colon
- Severe diarrhea with negative result for noninvasive evaluation
- Choledocholithiasis or cholangitis
- Biliary or pancreatic duct injury

Adapted from Qureshi WA, Rajan E, Adler DG, et al: ASGE guidelines for endoscopy in pregnant and lactating women, *Gastrointest Endosc* 61:357-362, 2005.

Regarding patient positioning, it is recommended that the patient not lie on her back in the second and third trimesters because the pregnant uterus compresses the aorta and inferior vena cava, causing maternal hypotension and decreasing placental perfusion. Because most procedures are done with the patient in the left lateral position, this is usually not an issue.

ENDOSCOPIC ULTRASOUND

The endoscopic ultrasound (EUS) technique uses an ultrasound probe that is incorporated into the tip of the endoscope. This allows ultrasound imaging from within the luminal gastrointestinal tract. This technique is commonly used to stage gastrointestinal malignancy and to evaluate pancreatic lesions. EUS is used during pregnancy only to look for stones in the common bile duct because it is more sensitive than MRI, CT, or ultrasound; it is also much safer than endoscopic retrograde cholangiopancreatography because it does not involve radiation and presents no risk for pancreatitis.

SMALL BOWEL WIRELESS CAPSULE ENDOSCOPY

The small intestine had been unreachable with the standard endoscopic techniques of EGD and colonoscopy. Wireless capsule endoscopy can visualize the entire small intestine. The procedure involves swallowing a miniaturized camera that has been placed in a large pill. Images are sent back to an external recording device for a total of 8 hours of video as the pill camera moves by peristalsis through the small intestine. It would be unusual to have a pregnant woman swallow a pill camera, unless there was unexplained severe or recurrent gastrointestinal bleeding.²³² The safety and efficacy of wireless capsule endoscopy of the small bowel has not been tested in humans, and pregnancy therefore is considered a relative contraindication to capsule endoscopy.²³³

DOUBLE-BALLOON ENTEROSCOPY

A technique using a scope with a balloon on the tip and an overtube with a balloon on the distal end is used to advance a thin endoscope from the mouth into the mid ileum. Double-balloon enteroscopy allows the endoscopist for the first time to gain access to the middle of the small intestine to obtain biopsies or to perform therapeutic maneuvers. Because this is a time-intensive procedure with a large amount of pushing and

stretching in the abdomen, it would rarely be considered for use during pregnancy.

Summary and Recommendations

Corticosteroids should be considered only in cases refractory to conventional therapies for hyperemesis and is preferably avoided in the early first trimester.

Treatments of GERD and PUD involve similar pathways entailing lifestyle changes followed by stepwise medication management. Histamine receptor blockers and proton pump inhibitors appear to be safe for the fetus, but the latter should be avoided in the periconception time period. EGD should be considered in cases refractory to medical management.

A stepwise imaging strategy for the evaluation of suspected appendicitis should be undertaken to reduce the rate of negative appendectomy. Graded compression ultrasound is the recommended first modality. If those results are equivocal, MRI, if readily available, should be considered. If MRI is unavailable, helical CT is an appropriate alternative.

Laparoscopy for acute appendicitis appears safe, and its complication rate is similar to that noted for laparotomy.

Patients with a history of bariatric surgery have a potential for micronutrient deficiencies, which should be screened for and then supplemented if needed. Furthermore, they are at increased risk for surgical complications, including internal hernia formation and bowel obstruction. Evaluation of these patients is challenging, so involving surgeons and radiologists who are experienced in bariatric procedures is important.

Patients with IBD have an increased risk for adverse pregnancy outcomes and should be followed as high-risk obstetric patients.

Celiac disease is underrecognized and may be associated with disorders not commonly associated with gastrointestinal disease. If untreated, it may be associated with adverse pregnancy outcomes, but the current literature has not yet defined causality.

Constipation is a common complaint in pregnancy. Lifestyle changes followed by the use of either bulk-forming or hyperosmolar agents are the optimal management strategies.

Diseases of the Liver, Biliary System, and Pancreas

CATHERINE WILLIAMSON, MD | LUCY MACKILLOP, BM, BCh, MA |
MICHAEL A. HENEGHAN, MD, MMedSc

Liver disorders may be unique to or commonly associated with pregnancy. Liver disease may precede or develop *de novo* during pregnancy. Some of these disorders are so uncommon that even an experienced maternal-fetal medicine specialist may rarely encounter them. In this chapter, we review the effect of preexisting liver conditions in pregnancy in conjunction with those that are primarily associated with pregnancy.

Liver Function in Normal Pregnancy

There is no evidence that enlargement of the liver occurs during human gestation. In that context, hepatomegaly should be considered a potential pathologic finding, signifying the need to determine whether underlying liver disease exists. The liver is frequently elevated superiorly, especially in the third trimester as a result of the expanding uterus. There is little evidence that the liver undergoes any major histologic changes during pregnancy. Hepatic blood flow remains constant in pregnancy (i.e., 25% to 33% of cardiac output).

Major changes occur in the serum concentration of plasma proteins during gestation, and these alterations may persist for a few months after delivery. Total serum protein concentration decreases largely because of a 20% to 40% reduction in serum albumin concentration. Some of this decline may be explained by hemodilution due to the increase in total plasma volume associated with pregnancy. Maher and colleagues¹ suggested a reciprocal relationship between rising levels of α -fetoprotein and the decline in serum albumin concentration.

Fibrinogen biosynthesis and manufacture of other coagulation factors, such as factors VII, VIII, IX, and X, increase during pregnancy and with estrogen administration. Estrogens increase hepatic rough endoplasmic reticulum and accelerate synthesis of proteins. Increased amounts of progesterone lead to proliferation of smooth endoplasmic reticulum and an increase in cytochrome P450 isoenzyme levels. The serum levels of other proteins, such as ceruloplasmin and transferrin, also increase with gestation. The concentrations of specific binding proteins, such as thyroxine-binding globulin (TBG) and corticosteroid-binding globulin (CBG), increase in normal pregnancy, which affects the concentration of the bound portion of these hormones.

A prospective, cross-sectional study of 430 women at a single center was carried out to determine the reference ranges for liver function tests and liver enzymes in uncomplicated pregnancies.² The study found a decrease in the upper limit of aspartate aminotransferase (AST), alanine aminotransferase (ALT), and γ -glutamyl transpeptidase (GGT) in normal

pregnancy (Table 63-1). The investigators² also demonstrated a decrease in bilirubin concentration, but this finding has not been demonstrated in other studies.³

Total serum alkaline phosphatase (ALP) activity increases dramatically during pregnancy, largely related to placental production. It may reach two to four times its baseline level by the third trimester, returning to normal levels within a few weeks after delivery. Occasionally, the ALP concentration may increase to more than 1000 U/L, and although this is invariably of placental origin, isoenzyme testing may be requested to exclude ALP from liver or bone. Most articles concerning plasma lipids in pregnancy agree that total cholesterol and triglyceride levels are increased during pregnancy.

Liver function test results change significantly in the puerperium (Table 63-2) and are affected by common obstetric events, such as cesarean section.⁴ This can be a confounding factor in clinical interpretation of women recovering from liver-related illnesses after delivery.

Clinical Diagnosis of Liver Disease

Hepatomegaly is an abnormal finding. It may signify an infiltrative process such as acute fatty liver of pregnancy (AFLP), an inflammatory condition (e.g., viral hepatitis), passive congestion in the context of right-sided heart failure, venous occlusion in Budd-Chiari syndrome, or a malignant process (e.g., lymphoma, secondary malignancy).

Skin findings typically associated with chronic liver disease, such as palmar erythema and spider nevi, are often found in normal pregnancy. Jaundice and scleral icterus are abnormal findings and always warrant further evaluation.

Imaging of the liver may be required during pregnancy. Ultrasound remains the primary imaging tool because of its safety record in pregnancy, but it may have limited value in assessing liver architecture. Computed tomography (CT) and endoscopic retrograde cholangiopancreatography (ERCP) can also be used during pregnancy. However, precautions should be taken to shield the fetus from radiation or to provide dosimetry estimates if significant exposure is likely. Magnetic resonance imaging (MRI) has the advantage of no radiation exposure, and it has an established safety profile in pregnancy.

Rarely, histologic diagnosis may be essential to management of a pregnant woman, particularly when AFLP is being considered in the differential diagnosis or when infiltration is suspected. In that context, the biopsy is likely to influence the decision to proceed with delivery. Liver biopsy remains safe in expert hands if coagulation parameters are within normal limits.

TABLE 63-1 Liver Function Test Results in Normal Pregnancy

Test	Not Pregnant	1st Trimester	2nd Trimester	3rd Trimester
AST (IU/L)	7-40	10-28	11-29	11-30
ALT (IU/L)	0-40	6-32	6-32	6-32
Bili ($\mu\text{mol/L}$)	0-17	4-16	3-13	3-14
GGT (IU/L)	11-50	5-37	5-43	5-41
Alk phos (IU/L)	30-130	32-100	43-135	130-418

Alk phos, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; Bili, bilirubin; GGT, γ -glutamyl transpeptidase.

Liver Disorders Unique to Pregnancy

INTRAHEPATIC CHOLESTASIS OF PREGNANCY

Epidemiology

Intrahepatic cholestasis of pregnancy (ICP) affects 0.7% of white, pregnant women,⁵ approximately twice as many South Asian women,⁵ and up to 5% of Chilean women.⁶ The geographic variation in prevalence of the condition can be explained by genetic and environmental influences, particularly because ICP is seen less frequently in Chile and Scandinavia than it was in the past.^{6,7} ICP occurs more frequently in winter months.^{7,8} The reasons for these epidemiologic fluctuations is not clear, but they indicate that environmental factors must play a role in the cause of ICP. ICP has occurred more commonly in women with multiple gestations⁹ and in women older than 35 years.¹⁰ The recurrence rate of ICP varies from 60% to 90% in different populations.⁶

Pathogenesis

The cause of ICP is complex, with genetic, endocrine, and environmental factors playing roles. Evidence for a genetic origin includes the demonstration that parous sisters of affected women have a 20-fold increased risk of developing ICP.¹¹ This idea is further supported by pedigree studies^{12,13} and the demonstration of genetic variation in biliary bile acid receptors and transporters. A few women with ICP have relatively highly penetrant heterozygous mutations in biliary transporters that result in abnormal biliary transport and accumulation of bile acids, which produces a clinical picture of cholestasis.

Mutations have been reported in the *ABCB4* and *ATP8B1* genes that encode phospholipid transporters,¹⁴⁻¹⁶ the *ABCB11*

gene that encodes the principal bile salt transporter, and the main bile acid receptor.¹⁷ Heterozygosity for the common *ABCB11* mutations accounts for 1% of European ICP cases, and these two mutants are probably responsible for the reduction in the folding efficiency of the bile salt export pump protein.¹⁸ Women who carry these mutations do not usually have symptoms when they are not pregnant, but they develop cholestasis in pregnancy.

Evidence that elevated levels of reproductive hormones cause susceptible women to develop cholestasis includes the increased prevalence of ICP in multiple pregnancy⁹ and the recurrence of cholestatic symptoms when women who previously had ICP are given exogenous estrogens or oral contraceptive (OC) pills.^{13,19} Progestogens may also play a role; 34 (68%) of 50 women in a French prospective series of OC-related ICP cases had been treated with oral micronized natural progesterone for risk of premature delivery.²⁰

Other environmental factors may influence susceptibility to ICP. Women with hepatitis C infection develop cholestasis more commonly than other pregnant women.²¹ Plasma selenium levels were significantly reduced in pregnant women on OCs compared with controls in Finnish²² and Chilean studies,²³ and it has been proposed that selenium deficiency in women on OCs may contribute to estrogen-induced oxidation damage to hepatocytes.²³ The Chilean study demonstrated that plasma selenium levels have increased in nonpregnant individuals since the 1980s, and the investigators suggested that this may partly explain the reduction in the prevalence of ICP among women on OCs in Chile since then.²³

The pathogenesis of the symptom of pruritus in ICP is not fully understood. Treatments that have some efficacy in treating cholestasis-related pruritus in nonpregnant patients include anion exchange resins, rifampicin, opiate antagonists, ondansetron, and phototherapy.²⁴

Fetal complications that occur more commonly in ICP pregnancies include preterm labor, fetal asphyxial events, meconium staining of amniotic fluid, and intrauterine death. Three studies have demonstrated that ICP patients with higher maternal serum bile acid levels ($>40 \mu\text{mol/L}$ in two studies) more commonly have pregnancies complicated by meconium-stained liquor and fetal asphyxial events,²⁵⁻²⁷ and the largest study demonstrated that patients with higher levels of bile acids had higher rates of spontaneous preterm labor.²⁷

The likely pathogenesis of the fetal complications of ICP is related to increased levels of fetal serum bile acids, but the precise mechanisms are not understood. Most stillborn infants are of appropriate weight and have no evidence of uteroplacental insufficiency.^{28,29} The evidence suggests that the intrauterine death is a sudden event. Studies have shown an abnormal fetal heart rate^{26,30} or arrhythmia³¹ in pregnancies complicated by ICP, and in vitro studies of neonatal heart cells indicate that they are susceptible to bile acid-induced arrhythmia.³² The increased frequency of preterm labor may be a consequence of bile acid-induced release of prostaglandins, which may initiate labor.³³ The increased rates of meconium-stained liquor^{27,28,30,34} may be related to the toxic effects of bile acids or may be a consequence of bile acids stimulating gut motility.³⁵

Diagnosis

ICP should be suspected in pregnant women with pruritus but without a rash. The pruritus is commonly generalized or affects the palms and soles, but it can occur on any part of the body.

There is no consensus about the most reliable biochemical test for diagnosing ICP. We recommend measuring AST and ALT levels in conjunction with serum levels of bile acids. This is a useful screening test because some patients have elevated aminotransferase levels several weeks before the levels of bile acids are increased. Because there are also cases of ICP with elevated concentrations of serum bile acids and normal levels of AST and ALT, it is advisable to test both.

Cholestasis may occur in conjunction with other liver diseases. It is advisable to perform a liver ultrasound examination to exclude biliary obstruction. Affected women commonly have gallstones, which may have a genetic cause. Some of the genes implicated in ICP are also mutated in pedigrees with familial gallstones.³⁶ However, the gallstones are unlikely to be the cause of the cholestasis unless the woman has symptoms of biliary obstruction. Other conditions that can be associated with ICP are hepatitis C virus infection, autoimmune hepatitis (AIH), and primary biliary cirrhosis. These conditions have important implications for the subsequent health of the mother, and it is therefore advisable to screen for them.

Management

Maternal Disease. Ursodeoxycholic acid (UDCA) is the only drug that has consistently been shown to improve the maternal symptoms and biochemical features of ICP. There have been several reports about the efficacy of UDCA in ICP.^{37,38} One of the larger trials showed that UDCA reduced levels of pruritus, AST, ALT, and bilirubin compared with dexamethasone or placebo and that it was particularly effective in women with serum levels of bile acids higher than 40 $\mu\text{mol/L}$.³⁸ UDCA is usually started at a dose of 500 mg twice daily, and the dose may be increased further. In one trial, 111 women were randomized to UDCA (500 mg twice daily) or placebo, and the drug dose was increased as necessary (to a maximum of 2 g/day) for symptomatic or biochemical improvement until delivery.³⁹ The same study evaluated 62 women who were randomized to early-term delivery (i.e., induction or delivery started between 37+0 and 37+6) or expectant management (i.e., spontaneous labor waited until 40 weeks' gestation or cesarean section undertaken by normal obstetric guidelines, usually after 39 weeks' gestation). UDCA reduced itching, albeit not to the extent specified a priori as clinically meaningful. Early-term delivery did not increase the rate of cesarean section compared with the expectant management group.³⁹

Other drugs have been proposed as treatments for ICP, including dexamethasone, S-adenosyl methionine, cholestyramine, and guar gum, but there is less evidence for their efficacy than there is for UDCA.³⁷ Aqueous cream with menthol may improve the symptoms of ICP, although it does not affect the disease process.

Fetal Concerns. No treatments have been shown to reduce fetal risks associated with ICP. However, it is likely that treatments that reduce levels of maternal bile acids also reduce fetal risk because of the data that implicate bile acids in pregnancies complicated by spontaneous preterm delivery, fetal asphyxial events, and meconium-stained amniotic fluid.²⁵⁻²⁷ None of the UDCA trials has been powered to investigate whether the drug protects the fetus, but it is known that UDCA treatment improves the serum bile acid levels measured in cord blood and amniotic fluid at the time of delivery.⁴⁰ In vitro studies have shown that maternal cholestasis causes impairment of placental

bile acid transfer and that this is restored to normal in the placentas of women treated with UDCA.⁴¹ Studies of neonatal rat cardiomyocytes have also shown that incubation of cells in culture medium containing UDCA or dexamethasone later protects networks of contracting cells from the arrhythmogenic effect of bile acids.⁴²

The only forms of fetal surveillance that have predicted which fetuses may be at risk are amniocentesis²⁸ and amniocopy⁴³ for meconium. However, these approaches are considered too intrusive to be used routinely by most obstetricians. Many obstetric units review women with ICP several times per week for fetal assessment by electronic fetal monitoring or biophysical profile, or both. Although there is no evidence that this approach can prevent subsequent fetal complications, there are a few reports of abnormal electronic fetal monitoring traces having been identified and emergency cesarean section performed as a consequence. Many women with ICP find this strategy reassuring.

Prevention

The rate of ICP recurrence varies from 40% to 90%.⁶ It is not possible to prevent the condition in predisposed women, although it is possible to screen for biochemical abnormalities before symptoms occur. If a woman with a history of ICP requires antibiotics, it is advisable to avoid drugs that more commonly cause cholestasis in susceptible individuals, such as erythromycin, flucloxacillin, and amoxicillin with clavulanic acid. Women with a history of ICP should be advised to use hormonal contraception with care, because there is a 10% chance of developing pruritus or hepatic impairment, or both.¹⁹

OVERLAP SYNDROMES WITH LIVER DYSFUNCTION

Preeclampsia, HELLP syndrome (*hemolysis, elevated liver enzymes, and low platelets*), AFLP, and liver rupture are separate but similar conditions that usually occur during the third trimester and after delivery. They are often characterized by hypertension, elevated levels of liver enzymes, and thrombocytopenia, and resolution usually follows delivery (see Chapter 48). In some cases, there may be progressive disease with multisystem organ failure and possibly maternal death. HELLP syndrome is most often a variant of severe preeclampsia because hypertension and proteinuria typically are accompanying features. There is also overlap between AFLP and preeclampsia, which occurs in approximately 50% of patients of AFLP.^{44,45}

It is essential for the clinician to differentiate the overlap syndromes from unrelated conditions, which do not improve after delivery. A multidisciplinary team approach consisting of maternal-fetal medicine and liver specialists is recommended to guide therapy.

FATTY ACID OXIDATION PATHWAYS

Disorders of fatty acid β -oxidation play a role in the cause of AFLP, HELLP syndrome, and preeclampsia. Fatty acids are a major metabolic fuel for humans. In the presence of oxygen, fatty acids are catabolized to carbon dioxide and water, and approximately 40% of the free energy produced in this process is conserved as adenosine triphosphate (ATP). The remainder of the energy is released as heat, a process that occurs in the mitochondria by β -oxidation. This enzymatic process is particularly important for the provision of energy when glycogen

stores are depleted. It consists of many transport processes and four enzymatic reactions that cause two-carbon fragments to be successively removed from the carboxyl end of the fatty acid, which has been described in detail by Ibdah.⁴⁶

An enzyme that plays a central role in this pathway is long-chain 3-hydroxyacyl-coenzyme A dehydrogenase (LCHAD). It is part of an enzyme complex, the mitochondrial trifunctional protein (MTP), which is located on the inner mitochondrial membrane. In LCHAD deficiency, there is accumulation of long-chain hydroxyl-acylcarnitines, free plasma hydroxyl-long-chain fatty acids, and dicarboxylic acids, which results in cell toxicity. MTP defects are autosomal recessive conditions that cause nonketotic hypoglycemia and hepatic encephalopathy in early infancy and that may progress to coma and death if untreated. The defects also can cause cardiomyopathy, peripheral neuropathy, myopathy, and sudden death, although the latter clinical features are not characteristically seen in isolated LCHAD deficiency. It is important to diagnose MTP disorders because the clinical complications can be avoided with dietary manipulation.

Several case series have demonstrated an increased prevalence of AFLP and, to a lesser extent, HELLP syndrome and severe preeclampsia among heterozygous mothers of children that are homozygous for LCHAD deficiency.⁴⁶⁻⁴⁸ A subsequent study of 27 pregnancies complicated by AFLP demonstrated that 5 had fetuses with MTP mutations and that at least one copy of the common glutamic acid 474 to glutamine (E474Q) mutation was present in each case.⁴⁹ The study authors recommended that the neonates of women whose pregnancies are complicated by AFLP should be screened for MTP disorders or for the E474Q mutation. Several studies of pregnancies complicated by HELLP syndrome have not demonstrated that MTP disorders are common in the fetuses,⁴⁹⁻⁵¹ and screening of these offspring therefore is not recommended.

Maternal liver disease occurs in pregnancies in which the fetus is affected by a spectrum of fatty acid oxidation disorders, including short-chain and medium-chain defects.⁵² In a case-control series of 50 infants from pregnancies complicated by severe maternal liver disease, including AFLP and HELLP syndrome, long-chain defects were 50 times more common in cases than controls, and short-chain and medium-chain defects were 12 times more likely to occur.⁵²

ACUTE FATTY LIVER OF PREGNANCY

Epidemiology

AFLP is a rare, potentially life-threatening, pregnancy-related disease that affects 1 in 7000 to 16,000 pregnancies.⁵³ The condition occurs more commonly in primigravidas, multiple pregnancy, and pregnancies carrying a male fetus.^{45,53} In two case series of 32 and 16 affected women admitted to tertiary centers, the maternal mortality rate was 12.5%.^{44,45} However, there were no maternal deaths in a series of 12 pregnancies among 11 women.⁵³ Perinatal mortality rates are reported as approximately 10% in the latest series,^{44,45,54} although they were higher in another series,⁵³ and the investigators proposed that this was principally a consequence of premature delivery.

Pathogenesis

The pathogenesis of AFLP is not well understood. The previously described studies found that fatty acid oxidation disorders contributed to approximately 20% of cases.⁴⁹ In these cases, it

is likely that the heterozygous mother has a reduced hepatic capacity to metabolize long-chain fatty acids. Although there is sufficient capacity in the nonpregnant state, when a heterozygous woman becomes pregnant, her liver is required to metabolize fatty acids from the fetoplacental unit in addition to her own. This increased metabolite load likely results in hepatotoxicity, which may be further compounded by the fluctuations in lipid metabolism that occur in normal pregnancy.

Diagnosis

AFLP typically manifests in the third trimester with symptoms of nausea, malaise, and anorexia. Later symptoms include vomiting and abdominal pain. Polydipsia and polyuria may also occur.^{7,55} Liver function tests should be requested for any pregnant woman reporting these symptoms, because quick diagnosis of an acute fatty liver allows stabilization of the patient and rapid delivery.

It is often difficult to differentiate AFLP from HELLP syndrome. Patients with AFLP more commonly have high levels of bilirubin, creatinine, uric acid, and neutrophils; a prolonged prothrombin time; acidosis; and hypoglycemia. Patients with more severe disease may have disseminated intravascular coagulation. Although levels of liver transaminases can be markedly increased, they also may be barely higher than normal. The level of ALT or AST should not be taken as a marker of severity of disease, because hepatocytes cannot release transaminases if they have been destroyed by severe injury. Diagnostic criteria for AFLP have been created and are summarized in Box 63-1.

Imaging modalities that have been used to diagnose AFLP include liver ultrasound, MRI, and CT. A study that compared the three techniques found that CT was the best modality for demonstrating fat in the liver.⁵⁶ However, CT was successful in only 50% of cases. Liver biopsy may be used to obtain a definitive diagnosis using an oil red O stain or electron microscopy. However, this is not always practical, particularly if there is a coagulopathy and rapid delivery is required.

Some women who present with apparent AFLP have a different diagnosis. In a series of 32 patients seen in a tertiary

BOX 63-1 SWANSEA DIAGNOSTIC CRITERIA FOR ACUTE FATTY LIVER OF PREGNANCY

Six or more criteria are required in the absence of another cause:

- Vomiting
- Abdominal pain
- Polydipsia or polyuria
- Encephalopathy
- Elevated bilirubin level (>14 μmol/L)
- Hypoglycemia (<4 mmol/L)
- Elevated urea level (>340 μmol/L)
- Leukocytosis (>11 × 10⁹/L)
- Ascites or bright liver on ultrasound scan
- Elevated transaminase levels (AST or ALT >42 IU/L)
- Elevated ammonia level (>47 μmol/L)
- Renal impairment (creatinine >150 μmol/L)
- Coagulopathy (PT >14 sec or aPTT >34 sec)
- Microvesicular steatosis on liver biopsy

ALT, alanine aminotransferase; aPTT, activated partial thromboplastin time; AST, aspartate aminotransferase; PT, prothrombin time. Adapted from Ch'ng CL, Morgan M, Hainsworth I, et al: *Prospective study of liver dysfunction in pregnancy in Southwest Wales*, Gut 51:876-880, 2002.

TABLE 63-3 Biochemical Features of Acute Fatty Liver of Pregnancy

Biochemical Feature*	Average at Diagnosis	Range at Diagnosis	Peak or Nadir
AST (<32 IU/L)	523	120-2317	692
ALT (<32 IU/L)	423	43-1504	493
BR (3-22 μ mol/L)	99.18	15-203	180
LDH (<250 IU/L)	1483	244-3992	1709
Glu (3.9-5.8 mmol/L)	4.5	0.6-8.7	3.1
Creatinine (μ mol/L)	212.2	44-389	4950
Platelets ($\times 10^3$)	88	33-303	88

*Parenthetical values are average normal values in pregnancy.

ALT, alanine transaminase; AST, aspartate transaminase; BR, bilirubin; Glu; glucose; LDH, lactate dehydrogenase.

referral unit in London, 6 had other diagnoses. Two patients had malignancy, one had alcohol-induced fatty liver, one had veno-occlusive disease with antiphospholipid syndrome, and another had acute viral hepatitis A infection.⁴⁴ Poisoning with acetaminophen can cause a clinical presentation that is hard to distinguish from AFLP. Table 63-3 summarizes some of the typical biochemical parameters seen in this context.

Management

Women with more severe degrees of AFLP should be managed by a multidisciplinary team that includes obstetricians, hepatologists, anesthesiologists, obstetric physicians, neonatologists, and intensivists. The mother should be cared for in an intensive care setting. Blood should be taken every 6 hours to ensure that biochemical and hematologic abnormalities are diagnosed and corrected. It is essential to monitor the prothrombin time and other markers of coagulopathy, plasma glucose, platelets, creatinine, liver function test results, and arterial blood gases. Fresh-frozen plasma should be given as required. Women may require large amounts of glucose intravenously to correct hypoglycemia. If multisystem failure develops, it may be necessary to use dialysis and ventilation. *N*-Acetylcysteine is often used by liver care units to treat AFLP, and we advocate its use.

Women with AFLP should be assessed regularly for encephalopathy. Mild encephalopathy manifests with confusion, fetor hepaticus (i.e., unpleasant breath), and asterixis (i.e., liver flap). A more objective assessment can be performed by asking women to draw a five-pointed star or a clock face. It is advisable to discuss patients who have AFLP with a liver unit specialist at the time of presentation for advice on the detailed management of fulminant liver failure and because assessment of suitability for orthotopic liver transplantation may be necessary. In a study of 56 admissions to a liver failure unit in the United Kingdom, encephalopathy in conjunction with an elevated blood lactate level was highly associated with a poor prognosis and a need for liver transplantation.⁵⁴ Standard poor prognostic criteria associated with a need for liver transplant were not fulfilled.

The most important management strategy is delivery of the infant. The decision about the mode of delivery is often complex because the mother is likely to have a coagulopathy. Although vaginal delivery reduces the risk of hemorrhage, induction of labor often takes longer, and prompt delivery can improve the maternal outcome. Regional anesthesia should be avoided or

used with caution and in conjunction with close monitoring. Blood tests should be performed frequently to ensure that coagulopathy is rapidly corrected in the days after delivery.

Prevention

AFLP does not commonly recur in subsequent pregnancies, although recurrent cases are reported in the literature. In women who are heterozygous for disorders of fatty acid oxidation, it may be possible to establish whether the fetus is affected, and this can indicate the magnitude of the mother's risk. If she is carrying a fetus that is homozygous for the disease, she will have a greater chance of recurrence. For heterozygous mothers who do not have affected fetuses and for others who do not have a fatty acid oxidation disorder, the recurrence risk is lower. However, the disease has potentially disastrous consequences, and women who have had one affected pregnancy should be managed in an obstetric clinic specializing in high-risk pregnancies.

PREECLAMPSIA AND HELLP SYNDROME

Liver involvement often signifies the development of severe preeclampsia. Elevation of liver enzyme levels may also occur as an isolated laboratory abnormality or as a component of the HELLP syndrome. Although severe hypertension may be absent in women with HELLP syndrome, in most instances, there is some degree of accompanying hypertension that helps to differentiate this disorder from other diseases. Although there may be overlap between HELLP syndrome and AFLP, isolated serum transaminase elevations in severe preeclampsia rarely exceed 500 U/L. Elevated serum bilirubin levels occur in women with the HELLP syndrome, partly as a consequence of liver damage and partly in response to hemolysis, but bilirubin levels usually are higher in AFLP. Hepatic failure with encephalopathy and coagulopathy are uncommon in preeclampsia and should prompt consideration of a different diagnosis, including fatty liver and other causes of hepatic dysfunction.

Hepatic involvement occurs in approximately 10% of women with severe preeclampsia.⁵⁷ Most of these women have only liver enzyme elevations and no epigastric pain. The development of right upper quadrant pain usually signifies liver involvement, and liver function tests should be promptly obtained in this setting. The pain likely results from hepatic ischemia, and the increased transaminase levels may occur several hours after the onset of pain in a manner similar to cardiac enzymes after a myocardial infarction. Histologic descriptions of hepatic involvement in preeclampsia include periportal hemorrhage, sinusoidal fibrin deposition, and cellular necrosis.⁵⁸ The pathophysiologic basis of these findings likely includes ischemia, although hepatic blood flow primarily depends on the portal venous system.

Women with preeclampsia and liver involvement usually should undergo delivery, although administration of steroids first to promote fetal lung maturity can be undertaken in preterm cases when the maternal condition is otherwise stable. Laboratory abnormalities usually improve within 5 days after delivery, although they may become worse before they resolve. Because HELLP syndrome may develop during the postpartum period in 20% of cases, liver function testing and imaging should be undertaken if abdominal pain, thrombocytopenia, or other clinical features suggesting preeclampsia occur after delivery.

LIVER RUPTURE AND INFARCTION

Epidemiology

Rupture of the liver during pregnancy is a rare but often catastrophic event, with substantial risk of fetal and maternal death.^{54,59} More than 95% of cases during pregnancy involve severe preeclampsia and HELLP syndrome.^{44,60} However, liver rupture occurs only in a small proportion of women with preeclampsia. For example, in one series, subcapsular liver hematoma was reported in approximately 1% (4 of 442) of women with HELLP syndrome.⁶¹ Hepatic hematoma and rupture may also occur after uncomplicated pregnancy^{62,63} or in association with biliary disease, infection, aneurysm, and hepatic neoplasm.⁶⁴

Pathogenesis

Although the pathogenesis of hepatic rupture remains unclear, subcapsular hemorrhage is a common finding at autopsy in cases of maternal preeclampsia. The right lobe of the liver is affected more commonly than the left. Because major hemorrhage might have occurred by the time the patient is seen, there may be minimal or no hypertension. Subcapsular hemorrhage produces stretching of the liver capsule, and significant right upper quadrant pain can result from the distention. If stretching is expanded, rupture will occur. The resultant hemoperitoneum produces peritoneal signs and probable hypovolemic shock.

Diagnosis

Hepatic rupture most often occurs in the setting of HELLP syndrome, and the most common presentation includes right upper quadrant pain, hypertension, and shock. Hypertension may not be present at the time of diagnosis because of hypovolemia, and it may become obvious only after fluid resuscitation. Symptoms include nausea, vomiting, shoulder pain, and headache.⁶⁰ Diagnostic imaging is required to establish a diagnosis.⁶⁵ Bedside ultrasonography often demonstrates hemoperitoneum, but CT or MRI is the preferred technique for visualizing liver hematomas. Imaging is critical before consideration of liver biopsy if the diagnosis is unclear, because liver biopsy is contraindicated for patients with suspected subcapsular hemorrhage. To confirm the presence of intraperitoneal bleeding, paracentesis may occasionally be helpful.

Laboratory evaluation of women with subcapsular hematoma or rupture reveals thrombocytopenia, hypofibrinogenemia, or prolonged prothrombin and partial thromboplastin times. Patients have anemia and hemolysis, and levels of bilirubin, lactate dehydrogenase, and liver transaminases are elevated. The differential diagnosis for unruptured liver hematoma includes AFLP, placental abruption with coagulopathy, thrombotic thrombocytopenic purpura, and cholangitis with sepsis.

Management

Conservative management is recommended for an intact hematoma without rupture, particularly if the patient is hemodynamically stable.⁶⁵ It is necessary to closely follow these patients in an intensive care setting with serial imaging studies to define the extent and progression of the subcapsular hemorrhage and whether leaking has occurred. Sudden increases in intra-abdominal pressure from coughing or emesis should be avoided, and palpation of the liver should be kept to a minimum.

Management options for hepatic rupture include hepatic resection, hepatic artery ligation, embolization of the hepatic artery and exploration with digital compression of the hepatic artery and portal vein to temporarily arrest the hemorrhage (i.e., Pringle maneuver), and evacuation of hematoma and temporary packing with gauze swabs. A woman with hepatic rupture likely requires surgical exploration by a team skilled in the management of liver trauma to make the diagnosis and for treatment. Fluid replacement, multiple transfusions, and correction of coagulopathy are necessary components in conjunction with an attempt to control the hepatic bleeding. In a patient who is relatively stable, angiography may be attempted while making preparations for potential laparotomy.

Maternal and fetal mortality rates may approach 50% in cases of liver rupture. In a series of seven cases, the four survivors were managed with packing and drainage.⁵⁹ The three women undergoing hepatic lobectomy did not survive. In another series of 10 patients, 9 were treated surgically with a combination of stitching of the lesion, omental patching, hepatic artery embolization, and ligation. The 10th patient was dead on arrival at the hospital. Five patients were treated with hepatic artery ligation, and all survived.⁶⁶ An analysis of all cases in the English language literature from 1960 to 1997 showed improvement in maternal mortality rates over time.⁶⁰ This study compared management strategies for 141 cases.⁶⁰ However, because of the retrospective nature of the study, it was not possible to conclude which treatment modality was most effective. In many cases, the diagnosis was made at laparotomy, and this group of patients had a high survival rate that might have been related to the aggressive surgical approach. However, the group that received arterial embolization, whether it was performed with or without a laparotomy, also had a better prognosis than other groups.

Death is often caused by massive blood loss and coagulopathy. Patients who survive commonly experience respiratory insufficiency from adult respiratory distress syndrome or pulmonary edema and acute liver failure. Fluid and respiratory status monitoring (see Chapter 71) is essential, as is ongoing hepatic imaging to be certain that stabilization has occurred.

LIVER INFARCTION

Infarction involving many areas of liver parenchyma may be a feature of severe preeclampsia or HELLP syndrome.⁶⁷ Presenting signs usually include abdominal pain and frequently include fever. Thrombocytopenia is common, and transaminase levels often are very high. CT demonstrates clearly demarcated areas of poor vascularization involving many liver segments. Biopsy demonstrates hemorrhage and leukocyte infiltration in areas adjacent to hemorrhage. In the setting of HELLP syndrome, many adjacent areas of periportal hemorrhage most likely form these infarcted segments. Improvement after delivery can be expected, even in the face of laboratory evidence of severe liver inflammation.

Maternal Disorders Coincidental to Pregnancy

VIRAL HEPATITIS

Viral hepatitis is the most common cause of jaundice during pregnancy.⁶⁸ There are six primary subtypes of hepatitis virus:

TABLE 63-4 Comparison of Hepatitis Viruses

Feature	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
Viral type	RNA	DNA	RNA	RNA	RNA
Incubation period	14-50 days	30-180 days	30-160 days	30-180 days	14-63 days
Transmission	Fecal-oral	Parenteral	Parenteral	Parenteral	Fecal-oral
Diagnosis	IgM anti-HAV Ab	HBsAg	anti-HCV Ab	Delta Ag	IgM anti-HEV Ab
Chronic infection	0	10%-15%	50%-85%	With HBV	0
Vertical transmission	No	Yes	Yes	Yes	Yes
Vaccination available	Yes	Yes	No	No	No

Ab, antibody; anti-HAV Ab, IgM-specific antibody to hepatitis A; anti-HBc, antibody to hepatitis B core antigen; anti-HBs, antibody to hepatitis B surface antigen; anti-HEV Ab, IgM-specific antibody to hepatitis E; anti-HEV, antibody to hepatitis E virus; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen.

TABLE 63-5 Interpretations of Serologic Testing for Patients with Hepatitis B Virus Infection

HBsAg	HBsAb	HBcAb	HBeAg	HBeAb	Possible Interpretation
-	-	-	-	-	Never infected
+	-	-	-	-	1. Early acute infection 2. Transient (≤ 18 days) after vaccination
+	-	IgM	+	-	Acute HBV infection, highly infectious
+	-	IgG	+	-	Chronic HBV infection, highly infectious
+	-	IgG	-	+	Late acute or chronic HBV infection, low infectivity
-	-	IgM	\pm	\pm	Acute HBV infection
-	-	IgG	-	\pm	1. Low-level HBsAg carrier or remote past infection 2. Passive transfer to infant of HBsAg-positive mother
-	+	IgG	-	\pm	Recovery from HBV infection and immune
-	+	-	-	-	1. Immune if concentration ≥ 10 mIU/mL 2. Passive transfer after hepatitis B immune globulin

A, B, C, D, E, and G (Table 63-4). The incubation periods vary, and clinical features of acute infection may overlap. The diagnosis ultimately requires specific serologic markers for acute and chronic infection (Table 63-5 and Box 63-2; see Table 63-4). The clinical implications of each virus for maternal and fetal or neonatal health vary considerably.

The maternal management of viral hepatitis is not altered greatly by pregnancy. Supportive therapy is usually sufficient, although some cases of certain viral subtypes may lead to progressive liver failure. Hepatitis A and B remain the most common viruses responsible for acute hepatitis in pregnancy in North America and Europe. Infection during the third trimester is most common. There is evidence that infection with hepatitis E during pregnancy, which is rare in the United States, can lead to acute liver failure, which is associated with high mortality rates.⁶⁹ The severity of infection with viruses A through D is not influenced by gestation. Prematurity and perinatal death are uncommon, but their rates are slightly increased over background rates for the general population. In contrast, miscarriage, fetal intrauterine growth restriction, and congenital malformation rates are not increased.

Hepatitis A

Hepatitis A virus (HAV) is a major cause of acute hepatitis in the United States. The virus is a ubiquitous RNA picornavirus, which is primarily transmitted from person to person through fecal-oral contamination and facilitated by poor hygiene and

BOX 63-2 HEPATITIS B VACCINATION RECOMMENDATIONS

MATERNAL HBsAg TESTING

All pregnant women should be tested routinely for HBsAg.

VACCINATION OF INFANTS

At Birth

Infants born to HBsAg-positive mothers should receive hepatitis B vaccine and HBIG within 12 hours of birth.

Infants who are born to mothers whose HBsAg status is unknown should receive hepatitis B vaccine within 12 hours of birth.

Term infants who weigh 2000 g or more at birth, are medically stable, and are born to HBsAg-negative mothers should receive hepatitis B vaccine before hospital discharge.

Preterm infants who weigh 2000 g or less at birth and are born to HBsAg-negative mothers should receive the first dose of hepatitis B vaccine 1 month after birth.

After the Birth

All infants should complete the hepatitis B vaccine series.

Infants born to HBsAg-positive mothers should be tested for HBsAg and HBsAb after completion of the hepatitis B vaccine series at 9 to 18 months of age.

HBIG, hepatitis B immune globulin; HBsAb, hepatitis B surface antibody; HBsAg, hepatitis B surface antigen.

Adapted from Centers for Disease Control and Prevention: A comprehensive immunization strategy to eliminate transmission of hepatitis B virus infection in the United States, MMWR Morb Mortal Wkly Rep 54:1-23, 2005.

poor sanitation, resulting in contaminated food and water. The disease is more common among immigrants, drug users, and men who have sex with men.⁷⁰

The incubation period of HAV ranges from 14 to 50 days and is followed by the nonspecific symptoms of malaise, headache, fatigue, anorexia, nausea, vomiting, and diarrhea. Cholestasis shortly follows with jaundice, acholic stools, and dark urine. Some patients, especially children, may be asymptomatic and therefore represent a key group who has a role in transmission of infection.

The diagnostic test most commonly used is an immunoglobulin M (IgM)-specific antibody to HAV. The presence of IgG antibody to HAV indicates postinfection status and immunity. In developing countries with poor sanitation, childhood infection is common, and acute HAV infection is therefore uncommon in adult populations. In the United States, seasonal variation and an increasing frequency of HAV infection in adults have been observed. IgM antibody is detectable 1 month after exposure and may persist for as long as 6 months. Immunoglobulin G (IgG) antibody to HAV appears within 35 to 40 days of exposure and provides lifelong immunity.

Acute HAV infection rarely requires more than general supportive care. Hepatitis A is a self-limited disease without the chronic process that complicates other viral hepatitis infections, and recovery follows typically within 4 to 6 weeks. HAV infection has been associated with an increased risk of pregnancy complications such as threatened preterm labor and preterm rupture of membranes.⁷¹ Only 1 in 10,000 patients has a severe or aggressive course.⁷² These individuals may require intensive care for treatment of coagulopathy and encephalopathy.

HAV is excreted in large amounts in stool before the onset of symptoms of jaundice. Affected patients should be advised of their potential risk for transmission. For short-term protection, immune globulin is used prophylactically and after exposure. Pregnant women embarking on travel to endemic areas should be screened for immunity to HAV, and if IgG negative, they should receive vaccination because it appears to be safe for use in pregnancy.⁷²

Perinatal transmission of HAV is rare. In such cases, fecal contamination occurs when maternal incubation coincides with delivery. Children of mothers manifesting acute hepatitis A should receive immune globulin to prevent horizontal transmission. Although not licensed for children younger than 2 years, vaccination appears to be efficacious in small studies of this age group.⁷³ Breastfeeding is not contraindicated, and the HAV vaccine is safe for lactating mothers.

Hepatitis B

Hepatitis B virus (HBV) infection is a worldwide health problem, and it is most prevalent in Asia, Southern Europe, and Latin America. Prevalence of hepatitis B surface antigen (HBsAg) among carriers in the general population is 2% to 20%. HBV accounts for 40% to 45% of all cases of hepatitis in the United States.^{73,74} Acute HBV infection occurs in 1 or 2 per 1000 pregnancies.⁷⁵ In the United States each year, approximately 20,000 infants are delivered of HBsAg-positive women.⁷⁶ Infection with HBV in infancy or early childhood may lead to a high rate of chronic infection. In most endemic areas, infection occurs mainly during infancy and early childhood, and mother-to-infant transmission accounts for approximately 50% of the chronic infection cases. The high risk of vertical

transmission from carrier pregnant women to their offspring and its potential prevention by screening and immunization are areas of special interest to the practicing obstetrician and maternal-fetal specialist.

Acute Hepatitis B. HBV is a DNA virus with three major structural antigens: HBsAg, core antigen (HBcAg), and e antigen (HBeAg) (see Table 63-5). The core antigen is present only in the hepatocytes and does not circulate in the serum. The intact virus is known as the *Dane particle*. Transmission occurs principally through parenteral drug use, during sexual intercourse, and vertically after perinatal exposure. The peak prevalence of disease occurs in the reproductive age group, and for females, heterosexual contact represents the most common method of infection. Population groups at increased risk include drug addicts, transfusion recipients, dialysis patients, and non-Hispanic blacks.⁷⁴

Onset of the acute disease is usually insidious, and infants and young children typically remain asymptomatic. When present, clinical symptoms and signs include anorexia, malaise, nausea, vomiting, abdominal pain, and jaundice. Patients also may have rashes, arthralgias, and arthritis.

HBsAg is found in blood 2 to 8 weeks before the development of symptoms or laboratory abnormalities. Serum HBsAg usually remains detectable until the convalescent phase. HBeAg becomes detectable after HBsAg and indicates a high serum level of HBV DNA and active viral replication. The diagnosis of acute hepatitis B requires the detection of surface antigen and IgM antibody to the core antigen (IgM HBcAb). Identification of IgM HBcAb is important because certain individuals with fulminant acute hepatitis B may experience a period when HBsAg is not easily detectable. Clinical recovery is accompanied by clearance of HBV DNA followed by HBeAg and HBsAg antigenemia within 1 to 3 months, along with the presence of IgG HBcAb and antibody to HBeAg (HBeAb). The presence of HBsAb indicates recovery, clearance of the virus, and immunity.

Chronic Carrier State. Chronic infection occurs in approximately 90% of infected infants, 30% of infected children younger than 5 years, and less than 5% of infected persons older than 5 years.⁷⁷ Of these chronically infected people, 15% to 30% develop acute hepatitis or cirrhosis, and a small but significant group eventually develops hepatocellular carcinoma. Chronic infection is more likely in those who remain HBeAg positive or become superinfected with hepatitis D.⁷³ Other factors associated with the chronic carrier state include infection early in life, symptomless infection, immunosuppression, Asian background, and Down syndrome.

Liver damage is related primarily to immunologic events. Cytotoxic T-cell destruction of infected hepatocytes manifesting core antigen results in massive liver injury over time. Exacerbations of inflammatory activity follow viral replication and mirror the load of HBV DNA detectable in serum.

Perinatal Aspects of Hepatitis B. Pregnancy does not increase maternal morbidity or mortality from HBV or the risk of fetal complications such as fetal death or congenital abnormalities. However, spontaneous abortions in the first trimester and preterm labor in the third trimester have increased among mothers with acute HBV infection, although the rates may be no higher than those for other febrile illnesses.⁷⁸

Women with chronic HBV infection who become pregnant while on therapy can continue treatment, but the stage of the mother's liver disease and the potential benefit of treatment must be weighed against the small risk to the fetus. Lamivudine has been classified as a category C drug by the U.S. Food and Drug Administration (FDA), and it is not recommended in the first trimester. Lamivudine crosses the placenta freely and can be found in breast milk in equivalent concentrations to those of the mother's serum. Interferon- α (IFN- α) does not cross the placenta, but it is a FDA category C drug, and its use must be carefully considered in pregnancy. Widely used in the past, lamivudine is no longer the drug of choice in the treatment of HBV infection, primarily because of its potential for development of viral resistance and development of cross-resistance to other antiviral agents.

In most cases, the principal concern is potential transmission of the virus to contacts and the fetus during pregnancy and delivery. The age at which HBV infection occurs affects outcome. Without neonatal immunoprophylaxis, perinatal transmission occurs in 70% to 90% of individuals positive for HBsAg and HBeAg, but this high rate is reduced to less than 10% of infants born to HBsAg-positive, HBeAg-negative women.⁷⁹ This rate compares with 5% to 10% of individuals infected in adulthood. High viral loads and coinfection with human immunodeficiency virus (HIV) are additional risk factors for vertical transmission. The presence of HBeAg beyond the second month of life denotes likely chronic carriage. The risk of becoming a chronic carrier is independent of gestational age, birth weight, and viral subtype.

In patients with acute HBV infection, the frequency of transmission depends on gestation; 10% of neonates become infected if infection occurs in the first trimester, with the rate increasing to 80% to 90% if infected in the third trimester.⁷⁷ Transmission during labor and birth likely results from fetal exposure to virus in maternal blood and contact with infected cervicovaginal secretions and amniotic fluid. Transplacental transmission may occur and explains some failures of immunoprophylaxis.⁸⁰ Delivery by cesarean and avoidance of breastfeeding do not prevent infection of the newborn.

Women who present in labor with unknown HBsAg status should be considered potentially infectious until serologic testing confirms otherwise. In the absence of known maternal serologic status, some institutions have used neonatal combined immunoprophylaxis as a cautionary approach.

Prevention and Treatment. The American College of Obstetricians and Gynecologists (ACOG) and the Centers for Disease Control and Prevention (CDC)⁷⁶ continue to endorse universal prenatal screening for hepatitis B. This strategy has been deemed cost-saving in identifying 20,000 HBsAg-positive women and preventing 3000 chronically infected neonates per year in the United States. High-risk status, including admitted intravenous drug use and prostitution, may identify no more than 50% of infected women. Screening is performed at the first prenatal visit, and testing should be repeated later in pregnancy and after delivery for seronegative mothers at high risk.⁸¹

A combination of passive and active immunization can effectively prevent most cases of horizontal and vertical transmission of hepatitis B. Individuals who have had household or sexual contact with infected individuals should undergo serologic testing to determine their immune status. If they are found to be seronegative, hepatitis B immune globulin (HBIG) in

addition to hepatitis B vaccination may be given. HBIG is also recommended for the neonate immediately after birth, and the hepatitis B vaccination series is instituted within 12 hours of birth (see Box 63-2). This vaccine is composed of inactivated portions of the surface antigen manufactured by recombinant DNA technology. Neonatal immunoprophylaxis is 85% to 95% effective in preventing neonatal hepatitis B infection.⁸²

Other strategies in the management of HBV infection have included the incorporation of more potent antiviral agents into management paradigms. Often introduced in the third trimester in an attempt to reduce viral load at the time of birth, agents such as entecavir and tenofovir (both with a better long-term viral resistance profile than lamivudine) are increasingly used in preference to lamivudine. Entecavir, a nucleoside analogue, has been designated as a category C drug in pregnancy by the FDA and shows promise. Tenofovir has been widely used in HIV-positive patients and seems to have an excellent safety profile. It is regarded as a category B drug by the FDA, and an analysis of 13,711 cases from the U.S. Antiretroviral Pregnancy Registry identified comparable overall birth defect prevalences for lamivudine and tenofovir (2.8%; 95% confidence interval [CI], 2.6% to 3.1%). This finding was comparable to CDC population-based data (2.72%; CI, 2.68% to 2.76%; $P = .87$) and data from two prospective, antiretroviral-exposed newborn cohorts (2.8%; CI, 2.5% to 3.2%; $P = .90$ and 1.5%; CI, 1.1% to 2.0%; $P < .001$). The prevalence of birth defects between first-versus second- or third-trimester exposure was similar for the two drugs (3.0% versus 2.7%), and no specific pattern of major birth defects was observed for individual antivirals or overall.⁸³

Despite recommendations for maternal screening and newborn immunoprophylaxis, approximately 10% of neonates of infected mothers fail to receive HBIG and vaccination after birth.⁷⁶ Each institution should provide a systematic review of maternal hepatitis B status. Postimmunization testing is important for high-risk groups likely to have carriers within a household. The CDC has recommended universal hepatitis B vaccination for all infants.⁸¹ Testing is recommended at 12 months to ensure presence of antibodies to HBsAg. The detection of IgM anti-HBc suggests recent infection, whereas maternal IgG anti-HBc may persist beyond 12 months. Immunization failures are thought to result from a genetically predetermined response, in utero infection, immunosuppression (e.g., intercurrent HIV infection), other diseases, or the emergence of antibody-escape variants of HBV.

Medical Personnel Concerns. Health care workers may acquire hepatitis B infection from patients. Approximately 380,000 American hospital-based workers sustain percutaneous injury each year.⁸⁴ Transmission of HBV, HCV, and HIV is well described, and it is estimated that percutaneous injuries account for up to 37% of HBV infections among health care workers.⁸⁵ Prevention of these infections is promoted by vaccination of health care workers, vaccination of individuals at high risk for contracting hepatitis B, and following universal precautions about sharp objects and handling of body fluids. Testing for antibodies to HBsAg (HBsAb) approximately 1 month after the third vaccine dose is advisable, because poor responders account for 20% of vaccinated individuals. Levels of HBsAb decline greatly over time; however, immunocompetence is demonstrated in most individuals by an appropriate increase in antibody to an antigen challenge (i.e., immune memory). The minimum level of protective anti-HBs is unknown. Individuals

who are poor responders to vaccination should receive HBIG after an exposure.

Infected health care workers may pose a risk to patients by transmitting HBV during invasive procedures. If a patient does not have immunity to hepatitis B, an infected health care worker is obligated to inform the patient about the possibility of transmission of the virus if blood-to-blood exposure occurs. After consent is obtained, great care and caution should be used to prevent any sharp injury.

Hepatitis C

Hepatitis C virus (HCV) infection affects more than 1% of the world's population and approximately 4 million individuals in the United States, where it is the leading cause of chronic liver disease. The prevalence of HCV infection among pregnant women varies from 1% to 5%, with the highest rates of infection found in urban populations.⁸⁶

Because HCV is blood-borne, it is more common among intravenous drug users and individuals who have received many transfusions. Sexual and vertical transmission may be alternative modes of transmission. Blood transfusion donors have been routinely tested for HCV since 1990, and the risk of HCV infection is less than 1 case per 1 million screened units of blood. The disease has a peak incidence among people between the ages of 30 and 49 years; however, a large percentage of those affected report no risk factors. Only 24% of infected pregnant women gave a history of receiving blood products, and a similar percentage (27%) denied transfusion or intravenous drug use.^{87,88}

Acute HCV infection has an incubation period of 14 to 180 days. Seventy-five percent of acute cases are asymptomatic, which means that only 25% to 30% of infected individuals are diagnosed.⁸⁹ However, the data suggest that 80% of infected patients will develop chronic liver disease with biochemical evidence of liver dysfunction and that 20% to 35% will develop cirrhosis, of whom 5% to 10% will be at risk for hepatocellular carcinoma.^{90,91} HCV infection follows an indolent course in most patients, and the average time is 10 years to significant hepatitis, 20 years to cirrhosis, and 30 years to hepatocellular carcinoma. This course may be altered and accelerated by coinfection with HIV.

The diagnosis of HCV infection relies on the identification of anti-hepatitis C antibody. Initial screening consists of an enzyme immunoassay. Confirmation is often obtained through a recombinant immunoblot assay against four specific viral antigens. Antibody may not be detected until 4 to 5 months after acute infection. The presence of antibody does not differentiate acute from chronic disease or determine the extent of viremia. Branched-chain DNA and reverse transcription-polymerase chain reaction assays may be used to quantify HCV RNA and viral loads (Table 63-6).

TABLE 63-6 Definitions of Hepatitis C Virus Infections

Type of Infection	Status of Patient
HCV	HCV Ab positive
Chronic HCV	HCV Ab positive and HCV RNA positive for 6 mo
Chronic active HCV	HCV Ab positive and HCV RNA positive for 6 mo and abnormal liver function test results

Ab, antibody; HCV, hepatitis C virus.

Pregnancy Concerns. There is no evidence that HCV infection affects fertility. The indolent nature of the disease, with the peak incidence occurring in the childbearing-age group, makes potential HCV infection a primary concern for the obstetrician. Pregnancy does not appear to affect the clinical course of acute or chronic hepatitis C, and there appears to be no increased risk for adverse pregnancy outcomes among HCV-infected women; specifically, there is no increased risk of miscarriage, preterm delivery, or need for obstetric intervention.⁹² Vertical transmission of HCV may occur, although less frequently than HBV infection. However, the diagnosis of vertical transmission is not straightforward. Many infants born to HCV-infected mothers are found to have passively acquired transplacental IgG antibodies for up to 18 months of life, making antibody testing of the newborn of little value. Diagnosis can be reliably established by positive HCV RNA identification on two occasions 3 to 4 months apart after the infant is at least 2 months old and by detection of anti-HCV antibodies after the infant is 18 months old.⁹³

Overall, the risk of perinatal transmission is approximately 5%.^{94,95} HIV coinfection, drug abuse, and high HCV viral loads are associated with an increased risk of perinatal transmission.^{96,97} In a review of 383 cases of vertical transmission,⁹⁸ weighted transmission rates were calculated to adjust for sample size and variance. For a mother who was HCV antibody positive but RNA negative, the vertical transmission rate was 1.7%, compared with 4.3% for an RNA-positive mother, and this rate increased to 36% in another study if titers were more than 10⁶ copies/mL.⁹⁹ Vertical transmission rates were higher (19.4%) for RNA-positive mothers coinfecting with HIV. There is some evidence that treatment of HIV infection with highly active antiretroviral therapy (HAART) during pregnancy reduces the risk of HCV vertical transmission.

Pregnancy Management. There is no contraindication to pregnancy in HCV-infected women. The risk of perinatal infection must be discussed and the extent of maternal disease considered before making recommendations. IFN- α and pegylated interferon in combination with oral ribavirin may ameliorate disease, and they are being used as first-line therapy for chronically infected individuals. IFN- α does not cross the placenta, but it is a category C drug, and its use must be carefully considered in pregnancy. Ribavirin is a category X drug and should not be used in pregnant women, women attempting to become pregnant, or their male partners because of its risk of teratogenicity.

There is no association between mother-to-infant transmission and gestational age,¹⁰⁰ but prolonged rupture of membranes (>6 hours) may increase the risk of transmission.⁹³ Because there is conflicting evidence about whether the practice of using fetal scalp electrodes increases the risk of transmission, this practice is discouraged.⁷⁸

There appears to be no benefit in cesarean delivery to prevent vertical transmission in HIV-negative, HCV positive women. Although Gibb and colleagues¹⁰¹ reported an overall transmission rate of 6.7% with no cases of perinatal transmission in 31 elective cesarean sections, a large study of 275 HCV-positive women⁹⁴ found no significant difference in vertical transmission rates (4% vaginal versus 6% cesarean). Breastfeeding is not considered a risk factor for vertical transmission.

There is no vaccine available for HCV. Whereas passive immunization with immunoglobulin is recommended after

percutaneous exposure, immunoprophylaxis of the newborn has not been beneficial in clinical trials.

Hepatitis D

Hepatitis D is an RNA virus that depends on the hepatitis B virus for replication and expression. HDV infection is found only as a simultaneous acute infection (coinfection) acquired with HBV or as a superinfection in an individual who is a chronic HBV carrier. Epidemiologic features of hepatitis D are similar to those for hepatitis B.

Coinfection with HBV usually is self-limited and carries a similar risk of progression to chronic liver disease as isolated acute hepatitis B infection. However, superinfection with hepatitis D is associated with an 80% progression to chronic hepatitis. Superinfection ultimately occurs in 25% of chronic HBV carriers. Those who develop chronic hepatitis have a 75% to 80% risk of cirrhosis with potential for liver failure. HDV is transmitted by blood and blood products, and the risk factors for infection are similar to those for HBV.

The diagnosis of acute coinfection is confirmed by the presence of delta antigen or IgM-specific antibody in sera of an individual demonstrating HBsAg and core antigen IgM. Superinfection is marked by delta antigen or IgM to HDV and positive hepatitis B core antigen IgG, indicating chronic hepatitis B infection.

Women with acute hepatitis D are managed supportively, as is done for acute hepatitis of other causes. Those with chronic infection require monitoring of liver function, including coagulation parameters. Perinatal transmission of HDV has been reported,¹⁰² but active measures to prevent transmission of HBV to the neonate can prevent HDV transmission.

Hepatitis E

The hepatitis E virus (HEV) is an RNA virus found most frequently in Asia, Africa, and South America. It is similar to hepatitis A in that it is transmitted by the fecal-oral route and does not progress to chronic infection. The incubation period is 2 to 9 weeks, with an average of 45 days.¹⁰³ In the nonpregnant person, HEV infection is usually self-limited and mild. However, pregnancy seems to be associated with an increased risk of contracting the virus, which leads to a particularly poor outcome. Acute liver failure has been reported for approximately 20% of pregnant women with acute HEV infection, and mortality rates in these cases are 10% to 20%.^{104,105} The incidence of acute liver failure due to HEV infection increases with advancing gestation and is most common during the third trimester. HEV-associated acute liver failure is associated with significant obstetric complications such as antepartum hemorrhage, intrauterine death, poor fetal outcome, and preterm delivery.⁶⁹

Diagnosis of hepatitis E relies on identification of IgM antibody to HEV in the sera of infected individuals. Women with HEV infection may require intensive care if liver failure develops. Although perinatal transmission is uncommon, it has been reported and may be associated with biochemical evidence of liver injury, hypoglycemia, and neonatal death.¹⁰⁶ Precautions should be taken when caring for infected women to minimize contact with infected feces and contaminated clothing.

Hepatitis G

Hepatitis G virus (HGV) is a single-stranded RNA flavivirus that was first described in the 1960s. Although it is found in approximately 1% of blood donors in the United States and

persistent viremia is common, clinical disease and chronic hepatitis rarely occur. There are scarce data about this disease in pregnancy, but a few case reports have documented vertical transmission.

OTHER HEPATIC VIRUSES

Primary herpes simplex virus (HSV) infection is a rare cause of hepatitis in pregnancy, but it may lead to severe maternal illness and may be associated with transplacental virus transmission with consequences such as abortion, stillbirth, and congenital malformations.¹⁰⁷ Maternal and perinatal mortality rates of 39% have been reported for HSV hepatitis during pregnancy.¹⁰⁸ A high index of suspicion is warranted when disseminated maternal herpes simplex infection is present because typical mucocutaneous lesions and jaundice may be absent in affected patients. Antiviral therapy with acyclovir may be used in affected patients.¹⁰⁶

Primary cytomegalovirus (CMV) infections affect 1% to 4% of seronegative women during pregnancy, and the risk of transmission to the fetus is 30% to 40%.¹⁰⁹ Acute CMV infection in pregnancy is usually asymptomatic. However, it may cause maternal hepatitis, and it is the most common viral cause of congenital infection that is associated with hearing loss and neurodevelopmental disability in the neonate.¹¹⁰ CMV hepatitis is more common in individuals with advanced HIV infection and transplant recipients. Serious CMV infections, including hepatitis, are treated with intravenous ganciclovir. There are few data regarding the use of this medication during pregnancy, and it is unknown whether maternal treatment prevents fetal infection. Similarly, data are sparse regarding the safety of phosphonoformate (foscarnet), another drug used to treat severe CMV infections. No vaccine is available, and prevention includes hygienic measures such as hand washing after contact with saliva or urine.

Hepatitis is a well-described feature of Epstein-Barr virus infection (i.e., mononucleosis). Most cases are self-limited, although liver failure may occasionally follow infection.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Liver disease is common in patients with advanced HIV infection and acquired immunodeficiency syndrome (AIDS). Liver abnormalities may follow drug-induced hepatotoxicity with HIV drugs such as nevirapine and with the concomitant use of the antituberculosis drugs isoniazid and trimethoprim-sulfamethoxazole for the treatment of *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) infection. Acute and chronic hepatitis may be caused by common etiologic agents and by herpesviruses. Opportunistic and fungal infections may lead to inflammation and obstruction of the biliary tract, cholestasis, and right upper quadrant pain. Potential agents include CMV and *Cryptosporidium*, *Toxoplasma*, *Cryptococcus*, *Histoplasma*, and *Mycobacterium* species. Intrahepatic neoplasms most likely associated with HIV infection include non-Hodgkin lymphoma and Kaposi sarcoma.

The clinical manifestations of most liver diseases in women with HIV infection are nonspecific. Fever, hepatomegaly, right upper quadrant pain, and biochemical abnormalities consistent with cholestasis are typical features. Viral loads (i.e., RNA levels) usually are high. Imaging studies are valuable in differentiating HIV-related processes from other causes of cholestatic jaundice.

To avoid irradiation of the fetus, ultrasound or MRI is preferable to CT. Liver biopsy may be valuable in securing tissue for culture and diagnosis.

Chronic Liver Disease in Pregnancy

AUTOIMMUNE HEPATITIS

Most cases of chronic nonviral hepatitis in reproductive-age women result from AIH. AIH is a diagnosis of exclusion, and serologic evidence of antinuclear and anti-smooth muscle antibodies is common. In younger patients with AIH, antibodies that cross-react with liver-kidney microsomes may be detectable.

Amenorrhea and infertility are common in affected women and represent the classic phenotype of disease. Treatment with immunosuppressive regimens commonly stalls progression of disease and results in renewed fertility. The most commonly used immunosuppressive agents are prednisolone and azathioprine, although cyclosporin and tacrolimus may be used in selected circumstances.¹¹¹ If disease activity is well controlled, most women have a good prognosis for pregnancy. However, approximately 33% of patients have an AIH flare after delivery.¹¹²

A large, single-center study of 81 women with AIH found that 33 (41%) pregnancies occurred in the context of cirrhosis. At conception, 61 patients (75%) were on therapy for AIH. The live birth rate was 73% (59 of 81). Prematurity affected 12 (20%) of 59 pregnancies, and 6 infants (11%) required admission to a level 1 neonatal care unit. The overall maternal complication rate was 38% (31 of 81). A flare in disease activity occurred in 26 (33%) of 81 pregnancies. A serious maternal adverse event (i.e., death or need for liver transplantation) during or within 12 months of delivery or hepatic decompensation during or within 3 months of delivery occurred with 9 pregnancies (11%) and was more common among women with cirrhosis ($P = .028$).

Maternal therapy had no significant impact on the live birth rate, termination rate, or gestational period. AIH flares were more likely in patients who were not on therapy or who had a disease flare in the year before conception. Patients who had a flare associated with pregnancy were more likely to decompensate because of liver dysfunction.¹¹² Given the reassuring data about the use of azathioprine¹¹³ during pregnancy and breastfeeding,¹¹⁴ women with AIH should continue treatment, because the risk of a flare outweighs the potential risks of treatment.

PRIMARY BILIARY CIRRHOSIS

Primary biliary cirrhosis is an autoimmune liver disease that is characterized by the presence of antimitochondrial antibodies. It occurs more commonly in women and classically manifests at a later age than AIH, although it may occur as an overlapping syndrome in patients with pruritus and evidence of inflammatory activity. Data about the disease in pregnancy are limited.

Affected women commonly have pruritus with elevated serum levels of bile acids in addition to cholestatic hepatic impairment. It is reasonable to anticipate that the fetal risks related to increased concentrations of bile acids will be the same as in ICP. Primary biliary cirrhosis is treated with UDCA or cholestyramine. Both drugs should be continued in pregnancy if their use is associated with an improvement in maternal

disease. However, cholestyramine binds fat-soluble vitamins, and vitamin K supplementation should be given. If overlap with AIH exists, patients should be treated with corticosteroids. Fetal surveillance strategies should be the same as for ICP.

PRIMARY SCLEROSING CHOLANGITIS

Primary sclerosing cholangitis (PSC) is a chronic cholestatic disease of unknown origin that is characterized by fibrosis and inflammation of the intrahepatic and extrahepatic bile ducts. It is more common in men than women. The disorder can follow a progressive course, leading to biliary cirrhosis, hepatic failure, and death. Affected individuals are also at risk for cholangiocarcinoma. PSC usually occurs in patients with ulcerative colitis and to a lesser extent in those with Crohn disease. In most cases, the onset of inflammatory bowel disease precedes the development of PSC. The cause of PSC remains obscure, but the disorder may have an immunologic basis.

The diagnosis of PSC is based on clinical, laboratory, and histologic findings and includes a characteristic cholangiographic appearance of diffuse irregularity and narrowing of the hepatic bile ducts. Pruritus, jaundice, and abdominal pain are typical clinical features. Itching usually is severe enough to require UDCA or other therapies. Favorable pregnancy outcomes have been reported for women with PSC.^{115,116} In one series of 25 pregnancies in 17 patients, no significant maternal or neonatal morbidity was observed.¹¹⁶ Individual case reports have detailed various courses for PSC during pregnancy. In one report, the cholestatic process paradoxically improved with advancing gestation, followed by a decline in hepatic function after delivery.¹¹⁵ Other reports have described deterioration of liver function¹¹⁷ and the need for transplantation during pregnancy.¹¹⁸ Severe elevations in fetal bile acid levels have been documented, indicating placental transfer.¹¹⁵ Meconium passage is common, and fetal surveillance is recommended for maternal PSC in the same way as for patients with ICP.

WILSON DISEASE

Wilson disease is a rare disorder of copper metabolism characterized by liver failure and neurologic dysfunction. Kayser-Fleischer corneal rings are a hallmark of diagnosis, but they may be absent in patients with liver disease. Levels of ceruloplasmin are depressed in Wilson disease but may increase to normal with advanced liver disease. The diagnosis must be considered in reproductive-age women presenting with advanced liver disease of unknown origin.

Treatment of Wilson disease consists primarily of penicillamine or trientine. Both drugs are well tolerated and should be continued during pregnancy. Hepatic function may deteriorate if these medications are abruptly discontinued.¹¹⁹ Several series have reported successful pregnancies in women with treated Wilson disease.¹²⁰⁻¹²² The drug used to reduce excess copper in the mother crosses the placenta and may result in copper deficiency in the fetus. Most women with Wilson disease are treated with lower doses than those used to treat cystinuria and from which the data on teratogenicity were derived.

BUDD-CHIARI SYNDROME

Budd-Chiari syndrome is a rare disorder that results from hepatic vein occlusion. It primarily affects women and has been

linked to pregnancy and OC use.¹²³ In one series, almost 15% of cases were associated with pregnancy.¹²³ The disease may manifest acutely with obstruction of major hepatic veins or may be chronic and marked by involvement of smaller interlobular veins. The chronic variety is associated with a better prognosis. Both varieties produce congestion and necrosis of centrilobular areas of the liver.¹²⁴ Large-vein obstruction is often associated with pregnancy and preeclampsia.¹²⁵ Some have suggested that Budd-Chiari syndrome complicating pregnancy is associated with thrombophilias, including antiphospholipid antibodies and factor V Leiden mutation.^{126,127}

The disorder manifests with abdominal pain, distention, and ascites. Ascitic fluid has a high protein content. Some patients have fever, nausea, vomiting, and jaundice. Laboratory evaluation shows marked elevation of the alkaline phosphatase level beyond that of normal pregnancy levels. Concentrations of liver enzymes are modestly elevated. The results of histologic examination are nonspecific, demonstrating centrilobular zonal congestion with hemorrhage and necrosis. Diagnosis can be achieved by pulsed-wave Doppler imaging demonstrating the direction and amplitude of flow. Percutaneous hepatic venous catheterization can demonstrate elevated hepatic vein pressures, venous occlusion, and collateral circulation. MRI may aid in the diagnosis.¹²⁵

Women who develop acute major venous obstruction often deteriorate rapidly, with portal hypertension, variceal bleeding, and fulminant hepatic failure. Pregnancy outcome depends on maternal status. Portacaval shunting may improve portal hypertension and ascites, although many pregnant women are not surgically stable enough to undergo this procedure. These procedures have been primarily accomplished in postpartum cases. There are reports of successful pregnancies after mesocaval shunting.¹²⁸ Patients developing Budd-Chiari syndrome should be evaluated for underlying thrombophilias, and particular attention should be given to the underlying, latent or overt myeloproliferative disease. Testing for a *JAK2* mutation is appropriate. Even in the absence of these disorders, treatment with anticoagulation is advised, although therapy does not eliminate the risk of recurrent thrombosis.

CIRRHOSIS

Pregnancy in women with cirrhosis is uncommon because most of them experience oligomenorrhea and infertility. Nonetheless, there have been considerable reports of end-stage liver disease during pregnancy. Many of the series in the literature are at least 25 years old.

Cirrhosis is associated with an increased risk of premature delivery and perinatal mortality. In a series of 95 pregnancies in 78 women with cirrhosis, 10 stillbirths were observed, and no significant change in liver function occurred in two thirds of the women.¹²⁹ Prematurity (20% risk) and the need for early termination (18% risk) have also been reported.¹³⁰ Maternal complications associated with cirrhosis include anemia, preeclampsia, postpartum hemorrhage, and bleeding from esophageal varices.¹³⁰

A review of the outcomes of pregnant patients with cirrhosis identified 62 pregnancies in 29 women.¹³¹ Calculation of hepatic disease severity was performed using several modeling systems. The median model for end-stage liver disease (MELD) score at conception was low (7; range, 6 to 17) for those who managed to conceive. Similarly, the median Child-Pugh score was 5

(range, 5 to 8). For all patients, the live birth rate was 58%, and the median gestational age was 36 weeks. Higher MELD scores and scores associated with advanced liver disease were associated with gestations of less than 37 weeks. Maternal complications (e.g., ascites, encephalopathy, variceal hemorrhage) occurred in 10% of patients and were associated with higher (poorer) prognostic scores. Receiver operator curve analysis demonstrated that a MELD score of 10 or more predicted (with 83% sensitivity and 83% specificity) which patients were likely to have significant, liver-related complications (area under curve = 0.8). In the study, no patient who had a MELD score of 6 or less developed any significant hepatologic complications during pregnancy despite the presence of cirrhosis.

Because most women with cirrhosis have uncomplicated pregnancies, careful monitoring should allow progression to term. Nutritional intervention such as limiting protein intake is advised only in advanced cases and after surgical portal decompression. Maneuvers to reduce straining and thereby portal pressure are advised if varices have been documented. Vaginal delivery is preferred, with an attempt to shorten the second stage by forceps or vacuum extraction to limit excessive pushing and increases in intraabdominal pressure. The pharmacokinetics and metabolism of anesthetic agents must be carefully considered. Postpartum bleeding may be increased, and vitamin K, fresh-frozen plasma, and platelets should be available.

PORTAL HYPERTENSION

Although studies indicate that the pregnant woman with cirrhosis usually has an uncomplicated pregnancy, the substantial risk of hemorrhage from bleeding varices must be emphasized to the patient and her family. The death rate for pregnant women with cirrhosis is 10% to 18%, with most of these cases complicated by massive gastrointestinal bleeding.¹³² Women at highest risk have a history of gastrointestinal bleeding antedating pregnancy. The risk of variceal bleeding is thought to increase as pregnancy advances because of increased circulating blood volume, elevation in portal pressure, and vena cava compression resulting in enhanced flow through the azygos venous system. Most bleeds occur during the second and third trimesters, and some occur in the postpartum period. The likelihood of bleeding may be decreased in individuals who have undergone portacaval decompression procedures before pregnancy. In a study addressing this topic, only one death occurred among 21 women who had undergone previous portosystemic shunting, and it was caused by hepatic coma in the postpartum period.¹³⁰ It follows that the pregnant woman with cirrhosis must be evaluated endoscopically for varices and appropriate treatment undertaken.

Management of bleeding varices may be accomplished with endoscopic band ligation as an alternative to portacaval shunting. Alternatively, endoscopic sclerotherapy has been performed. In a study of 11 women with cirrhosis during pregnancy, 4 of 6 with documented varices experienced gastrointestinal hemorrhage requiring endoscopic sclerotherapy.¹³² Five of these women also had significant coagulation disorders. In the whole series, there were six growth-restricted infants, three preterm deliveries, and one neonatal death. In addition to sclerotherapy, portal pressure may be reduced with β -blocker therapy and vasodilators. Portal decompression surgery has been accomplished during pregnancy, but it is used less often than endoscopic sclerotherapy.

Another feared complication associated with portal hypertension is development of splenic artery aneurysm. Pulsed-wave Doppler and CT imaging may be helpful in establishing the diagnosis. Elective laparoscopic surgery with ligation should be strongly considered before pregnancy because rupture carries with it an enormous risk of maternal and fetal death.

The literature describes the outcome of pregnancy in women with noncirrhotic portal hypertension, which is most commonly caused by noncirrhotic portal fibrosis, Budd-Chiari syndrome, or extrahepatic portal venous obstruction. Affected women are more likely to be of childbearing age than are women with cirrhosis. This group of women rarely has abnormal liver function, and their fertility rates are the same as controls.^{133,134} The fetal risks associated with noncirrhotic portal hypertension vary. An Indian series of 116 pregnancies in 44 patients¹³³ and a U.S. series of 38 cases¹³⁵ reported fetal loss rates between 7% and 8%. Two other series that included only women with extrahepatic portal venous obstruction reported fetal loss rates of 23% to 28%,^{131,132} which may reflect the different causes of portal hypertension in this group.

The frequency of variceal bleeding in pregnant women with noncirrhotic portal hypertension is lower if they have had treatment for esophageal varices before pregnancy by endoscopic sclerotherapy or a decompression operation. In an Indian study of 50 pregnancies in 27 women, the rate of bleeding for 35 women for whom the disease was diagnosed and treated before conception was 8.6%, compared with a rate of 93% for 15 women whose disease was diagnosed during pregnancy.¹³⁴ Treatment with sclerotherapy is safe for women with bleeding varices during pregnancy.¹³³ For prevention of recurrent bleeding, it is advisable to use β -blocker therapy in addition to sclerotherapy. The overall prognosis for women with noncirrhotic portal hypertension in pregnancy is better than for those with cirrhosis, particularly if the disease was diagnosed and treated before conception.

Acute Liver Failure during Pregnancy

Acute liver failure is an uncommon medical emergency during pregnancy that is associated with significant maternal and fetal morbidity and mortality. Acute liver failure is defined as the development of hepatic encephalopathy caused by severe liver dysfunction within 12 weeks of the onset of symptoms in a patient with previously normal liver function.¹³⁶ It may be further categorized as hyperacute, acute, or subacute liver failure, depending on the interval between jaundice and encephalopathy of 0 to 7 days, 8 to 28 days, or 29 days to 12 weeks, respectively.

Clinical features of acute liver failure are not diagnostic. Cutaneous stigmata such as spider nevi and palmar erythema can be seen in patients with acute liver failure, chronic liver disease, and healthy pregnancy. Other symptoms include nausea, vomiting, fatigue, and abdominal pain. Clinical signs may include hepatomegaly, splenomegaly, and ascites. Altered mental state and icterus are the clinical hallmarks of severe liver disease, and early recognition is essential because affected individuals should be promptly transferred to a tertiary facility where transplantation is available.

Laboratory investigations compatible with acute liver failure include abnormal liver function test results for bilirubin, AST, ALT, ALP, and GGT. Levels of transaminases higher than 2000 IU/L suggest liver ischemia, rupture, or infarction.

BOX 63-3 CAUSES OF ACUTE LIVER FAILURE

Viral hepatitis (e.g., CMV, HSV, EBV, hepatitis A, B, C, D, or E virus)
 Acetaminophen toxicity
 Idiosyncratic drug reactions
 Pregnancy-related causes (e.g., AFLP, HELLP syndrome, preeclampsia, severe hyperemesis gravidarum)
 Budd-Chiari syndrome
 Ischemic necrosis
 Wilson disease
 Autoimmune hepatitis
 Toxin exposure (e.g., alcohol)
 Malignancy (e.g., lymphoma, hepatocellular carcinoma)

AFLP, acute fatty liver of pregnancy; CMV, cytomegalovirus; EBV, Epstein-Barr virus; HELLP, hemolysis, elevated liver enzymes, and low platelets; HIV, human immunodeficiency virus; HSV, herpes simplex virus.

However, low or declining levels may indicate extensive hepatocellular necrosis and lack of regenerating hepatocytes, which carries a poor prognosis. Other laboratory indices that carry a poor prognosis include low serum levels of albumin and an elevated prothrombin time, which are markers of poor hepatic synthetic function. Acidosis (pH < 7.35) and renal impairment are associated with acute liver failure, as is profound and sometimes refractory hypoglycemia. These features also indicate a poor prognosis. Hyponatremia and thrombocytopenia (<100 × 10⁹ cells/L) are commonly found in acute and chronic liver disease. The causes of acute liver failure are summarized in Box 63-3.

In the nonpregnant woman, acetaminophen hepatotoxicity and viral hepatitis are the most common causes of acute liver failure in the United States.¹³⁷ There have been no epidemiologic studies of acute liver failure in pregnancy, but viral hepatitis (particularly hepatitis B and E) is probably the most common cause in the developing world, and acetaminophen overdose and pregnancy-related causes are more common in more developed nations.

MANAGEMENT

It is imperative to rule out pregnancy-associated diagnoses such as acute fatty liver, HELLP, or preeclampsia because delivery often leads to improvement or resolution of the maternal condition. There is no evidence that delivery affects the course of liver failure in cases of viral hepatitis. However, delivery of a viable fetus should be considered because the fetal mortality rate is high for these patients.

Patients with acute liver failure should be considered for transfer to a tertiary care center with transplantation facilities. King's College Hospital criteria (Box 63-4) are widely used in Europe and to a lesser extent in the United States to accurately predict poor outcome and indicate those who should be transferred.¹³⁸

Management includes strenuous efforts to confirm the cause of acute liver failure coupled with intensive monitoring and supportive treatment until recovery begins or transplantation is undertaken. *N*-Acetylcysteine has improved the prognosis of women with acetaminophen overdose. Therapy should be commenced as soon as possible, and in practice, it is given to most patients until acetaminophen overdose has been ruled out.

Administration of fresh-frozen plasma without overt bleeding does not alter the outcome and obscures results of the

BOX 63-4 KING'S COLLEGE HOSPITAL CRITERIA FOR PREDICTING POOR OUTCOMES FOR PATIENTS WITH ACUTE LIVER FAILURE

PATIENTS TAKING ACETAMINOPHEN

pH <7.30 (regardless of encephalopathy grade)
or
PT >100 seconds (INR >6.5) and serum creatinine level >300 $\mu\text{mol/L}$ (>3.4 mg/dL) in patients with grade III or IV encephalopathy

PATIENTS NOT TAKING ACETAMINOPHEN

PT >100 seconds (INR >6.5, regardless of encephalopathy grade)
or any three of the following variables (regardless of encephalopathy grade):
Age: <10 or >40 years
Cause: non-A, non-B hepatitis; halothane hepatitis; idiosyncratic drug reactions
Jaundice duration before onset of encephalopathy: >7 days
PT > 50 seconds (INR >3.5)
Serum bilirubin level: >300 $\mu\text{mol/L}$ (>17.5 mg/dL)

INR, international normalized ratio; PT, prothrombin time.

prothrombin time test. Parenteral vitamin K₁ and folic acid should be given routinely. Fresh blood and blood products should be available to support any obstetric or surgical intervention. Gastrointestinal bleeding from gastric erosions is decreased by the prophylactic administration of a proton pump inhibitor. The stomach should be emptied hourly to prevent aspiration of gastric contents. Early enteral feeding reduces translocation of microbes from the intestinal wall into the circulation and reverses the catabolic state. Elective endotracheal intubation may be required to protect the airway (particularly before transfer and surgical procedures, including delivery) before the development of overt cerebral edema. Intubation must be performed by an experienced anesthetist.

Profound hypoglycemia remains a common cause of fetal and maternal death. Blood glucose levels should be closely monitored and immediate provisions made to administer large quantities of glucose by a central venous catheter. The patient should be maintained at 10 to 20 degrees of elevation with minimal turning and stimulation. Early manifestations of cerebral edema include peaks of systolic hypertension and tachycardia and should be treated by body cooling and by early institution of continuous hemofiltration, which also can be used to remove excess fluid. Levels of blood urea may be misleadingly low, and renal function is best monitored by serial levels of blood creatinine and creatinine clearance. Hyperventilation to reduce the partial pressure of carbon dioxide further reduces the limited brain flow and is no longer recommended. Intracranial pressure monitoring should be considered early for the patient likely to progress to grade IV coma and for transplantation candidates. Seizures seem to be more common than previously realized and should be suspected in a deteriorating patient without specific elevations in intracranial pressure. They should be considered for assisted ventilation, especially if they require benzodiazepines and other sedative drugs. Detailed microbiologic cultures and analysis should be performed serially on all body fluids, including blood, urine, and sputum. Infections, including fungal infections, are common in patients with liver failure.

PROGNOSIS

The overall survival rate with medical treatment is 10% to 40%. The prognosis depends on the cause. It is best for patients with acetaminophen overdose or hepatitis A and less favorable for other causes. The time to the onset of encephalopathy also affects the prognosis. Hyperacute failure has a better prognosis than subacute failure. The outcome for transplantation for acute liver failure is improving, and success rates are 75% to 90%.¹³⁹

Liver Transplantation and Pregnancy

Several case reports,¹⁴⁰⁻¹⁴³ registry data,^{144,145} and two retrospective reviews, including a meta-analysis,^{146,147} have cumulatively described pregnancy outcomes for more than 400 women with liver transplants. In contrast to the reduced fertility and menstrual dysfunction associated with end-stage liver failure, restoration of menses occurs, and fertility rates increase within months after liver transplantation. Successful outcomes for pregnancy can be expected by these women, although they are at increased risk for preeclampsia, preterm birth, and low-birth-weight and small-for-gestational-age infants.

Pregnancy should be delayed for at least 1 year after transplantation because pregnancies occurring within that period have an increased incidence of prematurity, low birth weight, and acute cellular rejection compared with those occurring later than 1 year.¹⁴⁷ Liver transplant recipients with biopsy-proven acute rejection during pregnancy are at greater risk for poor outcomes and recurrent rejection episodes.¹⁴⁸ However, pregnancy itself does not seem to impair graft function or accelerate graft rejection if the patient is adequately immunosuppressed.

Immunosuppressive therapy, such as cyclosporin and tacrolimus, that is commonly used in liver transplant recipients does not appear to be teratogenic, and breastfeeding is advocated. Careful monitoring of plasma levels is advised because of the physiologic changes in pregnancy that can alter the pharmacokinetics of immunosuppressive therapy.¹⁴⁹ Malabsorption due to hyperemesis gravidarum may decrease plasma levels of the drug.

Liver transplantation has been described during pregnancy for a number of pregnancy-related and coexistent conditions, including Budd-Chiari syndrome, viral hepatitis, AFLP, and HELLP syndrome with associated hepatic rupture and necrosis. In women who do survive acute liver failure and transplantation operation during pregnancy, increased risks for impaired homeostasis as a result of coagulopathy remain throughout pregnancy and delivery. Infection, renal failure, hypoglycemia, and adult respiratory distress syndrome are common complications.

Gallbladder Disease

EPIDEMIOLOGY

Cholelithiasis is common in the adult population. Cross-sectional studies of nonpregnant women in the United States found that 6.5% of women between 20 and 29 years old and 10.2% of women between 30 and 39 years old have gallstones or have had a cholecystectomy.¹⁵⁰ Pregnancy and the postpartum period appear to predispose women to gallstone formation. This is attributed to the increase in sex steroid hormone

levels in pregnancy, causing biliary stasis, prolonged intestinal transit, and increased cholesterol saturation of bile. Multiparity is a risk factor; one study found that gallstones occurred in 7% of nulliparous women, with the rate rising to 19% of women with two or more pregnancies.¹⁵¹ Pre-pregnancy obesity is associated with an increased risk of gallbladder disease (odds ratio = 4.45; 95% CI, 2.59 to 7.64) for a body mass index greater than 30 kg/m².¹⁵² The risk of gallstones appears to increase during gestation, with sludge (i.e., precursor to stones) or stones being found in 5.1% of 3254 prospectively studied women in the second trimester, 7.9% in the third trimester, and 10.2% by 4 to 6 weeks after delivery.¹⁵² Gallbladder disease is the most common non-obstetric cause of maternal hospitalization in the first year after delivery.¹⁵³

Despite the high prevalence of gallstones, pregnant women are usually asymptomatic. Biliary colic was reported for only 1.2% of pregnant women with known gallbladder disease.¹⁵² However, biliary colic was a common presenting complaint of 43 (55%) of 78 symptomatic pregnant women admitted with biliary tract disease.¹⁵⁴ Acute cholecystitis accounted for 25% (20 of 78) of symptomatic pregnant women in the same study. However, for those who develop symptoms, the frequency of recurrence of symptoms during pregnancy is high.

CLINICAL FEATURES AND DIAGNOSIS

Box 63-5 summarizes the most common gallbladder diseases. The symptoms of gallbladder disease in pregnancy are similar to those in the nonpregnant population. Biliary colic can manifest as intermittent right upper quadrant pain. More serious symptoms include anorexia, nausea, vomiting, and severe right upper quadrant or epigastric pain. Symptoms may be associated with signs of infection, which classically include a mild leukocytosis and elevated temperature.

Laboratory investigations may reveal elevated serum bilirubin and ALP levels, although the level of ALP is commonly increased in normal pregnancy because of placental production. Levels of AST and ALT may also be increased. Jaundice or hyperamylasemia may be signs of complicated gallbladder disease (see Box 63-5). The differential diagnosis includes appendicitis, pancreatitis, peptic ulcer disease, pyelonephritis, AFLP, and HELLP syndrome.

Abdominal ultrasound, which has an accuracy of 97% in diagnosing cholelithiasis, should be performed. If extrahepatic ductal stones are suspected but not demonstrated on ultrasound, MR cholangiography may be performed. ERCP, with its associated radiation exposure, should be limited to cases in which treatment for documented ductal stones is required.

BOX 63-5 GALLBLADDER DISEASES

- Biliary colic*
- Acute cholecystitis
- Common bile duct obstruction
- Ascending cholangitis
- Gallstone ileus
- Pancreatitis

*Gallbladder disease may be complicated by any combination of the disorders listed.

MANAGEMENT

Operative management for complicated gallbladder disease is advocated for pregnant and nonpregnant women. However, the appropriate management for biliary colic and acute cholecystitis during pregnancy is controversial. Traditional conservative measures include withdrawal of oral food and fluids, administering intravenous fluids, nasogastric aspiration, and providing analgesia and antibiotics, with avoidance of surgical intervention when possible. A more aggressive approach has been advocated, leading to more surgical interventions in pregnancy.

A retrospective review of 78 pregnancies in 76 patients showed that nonoperative management of symptomatic cholelithiasis (i.e., biliary colic or acute cholecystitis) led to suboptimal clinical outcomes in 38% of patients, including a 34% relapse rate and significantly higher rates of labor induction, cesarean section for treatment, and preterm delivery compared with the operative group.¹⁵⁴ Of the 10 patients undergoing operative management, 8 underwent surgery in the second trimester and 2 in the early third trimester. Operative management was associated with an increased risk of premature contractions, which were treated successfully with tocolytics. A review of conservative management favored the use of ERCP or laparoscopic cholecystectomy for patients with cholelithiasis. The investigators found that conservative management was associated with increased pain and more frequent visits to the emergency department.¹⁵⁵ Perioperative fetal monitoring and low pneumoperitoneum pressures were recommended.

Pancreatitis

EPIDEMIOLOGY

Acute pancreatitis is a rare and serious complication during pregnancy. The incidence of pancreatitis complicating pregnancy is difficult to ascertain and may range from 1 case in 1000 to more than 10,000 pregnancies.¹⁵⁶ In a series of 500 patients with acute pancreatitis, only 7 women developed the disease while pregnant.¹⁵⁷ Although alcohol is the most common cause in nonpregnant patients, studies have repeatedly shown that gallstones are the most common cause in pregnancy.¹⁵⁸ Other causes, particularly hyperlipidemia and alcohol consumption, have been described in pregnancy, as has an association between AFLP and pancreatitis, which carries a particularly poor prognosis.¹⁵⁹

CLINICAL FEATURES AND DIAGNOSIS

The clinical presentation of pancreatitis is not significantly altered in pregnancy. The disease may occur at any stage in gestation but is more common in the third trimester and the puerperium. Epigastric pain, which may radiate to the flanks or shoulders along with abdominal tenderness, should prompt appropriate laboratory investigations. Occasionally, a patient presents with nausea and vomiting as her only complaints. She may have mild fever and leukocytosis, and radiologic examination of the abdomen may reveal an adynamic ileus. Ultrasound imaging of the pancreas can be difficult. If significant pancreatic necrosis is suspected, CT becomes preferable, but in most cases, this radiologic study is unnecessary.

TABLE 63-7 Side Effects of Immunosuppressants Used in Organ Transplantation

Drug	Side Effects	FDA Category*
Azathioprine	Lymphopenia, hypogammaglobulinemia, thymic hypoplasia	D
Cyclosporin	Premature labor, low birth weight, neonatal hyperkalemia, renal dysfunction	C
Mycophenolate	First-trimester loss, microtia, increased risk of congenital malformations	D
Prednisolone	Cleft palate, intrauterine growth retardation, premature rupture of membranes, fetal adrenal hypoplasia	C
Tacrolimus	Effects similar to those of cyclosporin, neonatal malformation rates of 4%	C

*Pregnancy category C risk: Animal reproduction studies have shown an adverse effect on the fetus, but no adequate and well-controlled studies in human beings exist. Potential benefits may warrant use of the drug in pregnant women despite potential risks. Pregnancy category D risk: Positive evidence of human fetal risk is based on adverse reaction data from investigational or marketing experience or studies in human beings. However, potential benefits may warrant use of the drug in pregnant women despite potential risks.

FDA, U.S. Food and Drug Administration.

Adapted from Joshi D, James A, Quaglia A, et al: *Liver disease in pregnancy*, *Lancet* 375:594–605, 2010.

In evaluating young pregnant patients with suspected pancreatitis, the differential diagnosis includes most causes of abdominal pain, which are principally peptic ulcer diseases, including perforation, acute cholecystitis, biliary colic, and intestinal obstruction. Elevated amylase levels should suggest pancreatitis, although they may occur with other conditions, such as cholecystitis. Serum amylase concentrations greater than three times normal suggest pancreatitis.

MANAGEMENT

Acute pancreatitis usually resolves spontaneously within several days.¹⁵⁶ However, 10% of patients have a more severe course, and they are best managed in an intensive care environment. The general principles of management are the same as for non-pregnant women: bowel rest with or without nasogastric aspiration, intravenous fluids with electrolyte replacement, and parenteral analgesics. Meperidine is the drug of choice for analgesia; unlike morphine, it does not constrict the sphincter of Oddi. Important additional measures for the pregnant patient include fetal monitoring, attention to the choice of medications, consideration of irradiation of the fetus, and positioning of the mother to avoid inferior vena cava constriction. Because associated gallstone disease is likely, ERCP may be beneficial if common duct obstruction has occurred. Early surgical intervention is advocated for gallstone pancreatitis in all trimesters, because 70% of these patients will otherwise relapse before delivery.¹⁶⁰

For cases of mild disease that are responsive to conservative management, the prognosis for mother and fetus is excellent. However, for women with more severe disease, fetal morbidity and mortality rates increase. Of 43 women with acute pancreatitis, perinatal outcomes were available for 39.¹⁵⁶ Thirty-two newborns were delivered at term without complications, and six were delivered before term, including two stillbirths and one early neonatal demise.¹⁵⁶ One patient underwent therapeutic abortion. The mechanisms of demise included placental abruption and profound metabolic disturbance, including acidosis. This highlights the importance of regular fetal monitoring and consideration of delivery if the maternal condition is deteriorating.

PANCREATIC TRANSPLANTATION

The National Transplantation Pregnancy Registry reports outcomes for pregnant patients who are kidney-pancreas transplant recipients.¹⁶¹ Maternal and fetal morbidity rates are high, with maternal hypertension complicating 75% of pregnancies, preeclampsia occurring in 34%, and infection occurring in 55%. Outcomes after transplantation of solid organs are poorer for all other transplanted organs, including liver and pancreas, than for kidney transplantation alone. The mean gestational age at birth was 34 weeks, compared with 36 weeks for kidney-only recipients. The mean birth weight was significantly lower for the kidney-pancreas transplant group, with 68% of infants weighing less than 2500 g at birth. Twenty-six infants had neonatal complications, including one death due to sepsis. There were six graft losses within 2 years.

Pregnancy in transplant recipients should be planned, and multidisciplinary care is imperative. Table 63-7 summarizes potential side effects and risk stratification of immunosuppressant drugs. Women desiring pregnancy should be encouraged to wait until immunosuppression doses are stable. Couples should consider waiting until a minimum of 1 year after transplantation, when the risks for the mother and fetus are lower. After 1 year, medication doses are reduced, and the risk of graft rejection is thought to be lower,¹⁶² although few data are available to confirm this assumption. Attention to the effects of medication on the fetoplacental unit and, if necessary, substitution of immunosuppressants should be undertaken before conception. This is particularly the case for mycophenolate mofetil. Drug concentrations in maternal blood should be monitored throughout pregnancy, because the physiologic changes associated with pregnancy can affect drug bioavailability. Increased surveillance of the mother and fetus should be undertaken to quickly detect any complications.

Pregnancy and Rheumatic Diseases

MICHAEL D. LOCKSHIN, MD | JANE E. SALMON, MD | DORUK ERKAN, MD

Epidemiology

The systemic rheumatic illnesses commonly complicating pregnancy are systemic lupus erythematosus (SLE), antiphospholipid antibody syndrome (APS), rheumatoid arthritis, scleroderma, juvenile arthritis, spondyloarthropathy, and Takayasu arteritis. Both SLE and Takayasu arteritis affect 15- to 45-year-old adults, with a sex ratio of nine women to each affected man. APS has a female-to-male ratio of 7:1, rheumatoid arthritis and scleroderma have a ratio of 3:1, juvenile arthritis is almost sex neutral, and spondyloarthropathy has a ratio of about one woman to three men. Rheumatoid arthritis and scleroderma affect middle-aged more often than young women. SLE has a higher prevalence among African Americans than among whites (4:1). Up to 1% of all women have rheumatoid arthritis. One of 5000 to 10,000 women have SLE, and APS may be as common as SLE, whereas the other diseases are less common.

Because of these demographic patterns, the autoimmune illnesses most frequently encountered in obstetric practices are SLE and APS. Rheumatoid arthritis is a more common illness, but it occurs more often after the childbearing years and is therefore seen less often in pregnant women.

Diagnosis of the systemic rheumatic diseases rests more on clinical than on serologic criteria (discussed later with the individual diseases). Features common to all are arthralgia or arthritis; fever, myalgia, and malaise; and markers of inflammation. Current theories consider the systemic rheumatic diseases to be driven by disordered immune mechanisms, probably resulting from a genetic defect in processing exogenous infectious material, but the mechanisms and possible triggers are different among the different illnesses. Systemic rheumatic illnesses are chronic and relapsing, with temporary remissions. It is more likely that a new pregnancy will be diagnosed in a woman with an established diagnosis of rheumatic illness than that a new diagnosis will be made for a previously healthy pregnant woman. Table 64-1 provides the epidemiologic, clinical, and laboratory characteristics of the rheumatic diseases most often encountered in pregnant women.

Pathogenesis

No single theory of pathogenesis explains all autoimmune diseases. Each has a clear genetic association; most prominent are the spondyloarthropathies, in which human leukocyte antigen (HLA)-B27 is present in more than 80% of patients. This compares with an incidence of HLA-B27 of less than 5% in general European white populations, and an even lower incidence in Asian and African populations, but higher than 5% in some Native American populations.¹ Class II HLA and non-HLA genetic associations occur with SLE and rheumatoid arthritis.^{2,3} Complement protein deficiencies and other immune deficits appear to predispose to SLE.⁴ Smoking increases the risk for rheumatoid arthritis.⁵ Deficits in T-cell regulation or

uncontrolled B-cell upregulation or other abnormalities in the relevant cytokine profiles are common in autoimmune disease, although no dominant abnormality explains the pathogenesis of any rheumatic illness. Rheumatoid arthritis is successfully treated with agents that block the effect of tumor necrosis factor α (TNF- α), suggesting a critical role for that cytokine in pathogenesis.⁶ Upregulation of type 1 interferon characterizes SLE.⁷ Details of how these abnormalities lead to the specific symptoms of arthritis, nephritis, and vasculitis are conjectural.

Serologic abnormalities may precede the clinical onset of illness by decades.⁸ High prevalence and titer of antibodies to Epstein-Barr virus in patients with SLE suggest that this virus may have an etiologic role.⁹

Some immunologic phenomena of pregnancy may be relevant to autoimmune disease. In vitro data show that estrogens upregulate and androgens downregulate T-cell responses, immunoglobulin synthesis, and leukocyte production of interleukin (IL)-1, IL-2, IL-6, and TNF- α , although changes in these cytokines are quantitatively small and remain within physiologic ranges.¹⁰ In pregnancy, cell-mediated immunity is depressed, as reflected by abnormal lymphocyte stimulation, decreased ratios of T cells to B cells, increased ratios of suppressor T cells to helper T cells, and decreased ratios of lymphocytes to monocytes, all of which vary with the stage of pregnancy.^{11,12} The pregnancy-specific proteins α -fetoprotein, β_1 -glycoprotein, and β_2 -macroglobulin suppress in vitro lymphocyte function. IL-1, IL-3, TNF- α , interferon γ , and granulocyte-macrophage colony-stimulating factor are critical in sustaining pregnancy.¹³ IL-3 levels are low in women with repeated pregnancy loss.

In normal pregnancy, total C3, C4, and 50% hemolytic complement (CH₅₀) levels are usually unchanged or raised relative to nonpregnant levels; however, increases in classic pathway complement-activation products suggest that low-grade classic pathway activation is a normal phenomenon in pregnant women. Complement activation products can alter the balance of angiogenic factor production by inflammatory cells and can result in excess soluble vascular endothelial growth factor receptor type 1 (sFlt-1), which has implications for placental development and the risk for preeclampsia.¹⁴ Inherited alterations in complement regulatory proteins may predispose to preeclampsia in patients with SLE or APS, as well as in patients without autoimmune disease.¹⁵ Inhibition of complement activation in the placenta may be essential for fetal survival,¹⁶ and the trophoblast may be a target of autoimmunity.¹⁷ Theoretically, these pregnancy-related changes may alter the course of specific autoimmune diseases, but clear documentation that they do is lacking.

Diagnosis

Establishing a diagnosis of a systemic rheumatic illness requires combining symptoms and physical findings with compatible serologic abnormalities, markers of inflammation, and,

TABLE 64-1 Common Autoimmune Rheumatic Illnesses: Characteristics

Disease	Epidemiology	Common Symptoms	Laboratory Results	Pregnancy Issues
Systemic lupus erythematosus	Age, 15-45 yr Female-to-male ratio, 9:1 Black-to-Asian/Hispanic-to-white ratio, 4:2:1	Arthritis Rash Fever Anemia Thrombocytopenia Nephritis Neurologic disease Alopecia	High positive ANA value Anti-DNA or anti-Smith antibodies (diagnostic) Antiphospholipid, anti-SSA/Ro, anti-SSB/La, anti-RNP antibodies (common) Raised ESR level Anemia, thrombocytopenia Proteinuria Low complement level	Fetal loss Neonatal lupus Organ system flare
Antiphospholipid antibody syndrome	Age, 15-60 yr Prevalence, female > male Prevalence, white > black	Blood clots Fetal loss Livedo reticularis Thrombocytopenia Cardiac valve disease	Anticardiolipin Anti- β_2 -glycoprotein-1 Lupus anticoagulant test Thrombocytopenia Proteinuria	Fetal loss HELLP syndrome
Rheumatoid arthritis	Age, 35-75 yr Female-to-male ratio, 3:1 Prevalence, white = black	Destructive arthritis	Anti-cyclic citrullinated peptide antibody Rheumatoid factor Raised ESR, CRP levels Bone erosions at joints Raised ESR, CRP values	Remission in some cases during pregnancy Positioning for delivery a problem
Spondyloarthropathy	Age, 15-60 yr Prevalence, male > female HLA-B27	Spinal and sacroiliac arthritis	HLA-B27 Radiographic sacroiliitis Spinal fusion Enthesitis	Arthritis management
Takayasu arteritis	Age, 15-60 yr Female-to-male ratio, 9:1	Large-vessel vasculitis Cardiac valve disease	Raised ESR, CRP levels Alternating narrowing and aneurysm formation in aorta and great vessels	Vascular integrity Measurement of blood pressure Cardiac failure
Scleroderma	Female-to-male ratio, 3:1	Raynaud phenomenon Skin disease Pulmonary hypertension Hypertensive renal failure Esophageal reflux Pulmonary fibrosis	Fibrosis on skin biopsy Pulmonary fibrosis Esophageal and intestinal hypomotility Reduced pulmonary diffusion capacity Urinary protein	Complications related to esophagus, lung, heart, kidneys
Juvenile arthritis	Before age 18 yr Prevalence for some types, female > male	Polyarthritis High fever and rash (Still type)	Raised creatinine level Raised ESR, CRP levels Raised ferritin level Erosions of joints	Complications related to joint disease

ANA, antinuclear antibody; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; HELLP, hemolysis, elevated liver enzymes, and low platelets; HLA, human leukocyte antigen; RNP, ribonucleoprotein.

sometimes, imaging abnormalities. Established criteria exist for diagnosis of many of these diseases.¹⁸⁻²⁰ Critical clinical and laboratory findings that can differentiate the various rheumatic diseases are displayed in Table 64-1.

Inflammatory arthritis may be indistinguishable in patients with SLE, rheumatoid arthritis, or juvenile arthritis, but in the latter two, it is more likely to be sustained than transient and is more likely to cause deformity. In patients with these illnesses, arthritis involves peripheral joints; in spondyloarthropathy, axial joint involvement predominates. The rashes of SLE and scleroderma are diagnostic. Livedo reticularis is common in patients with APS but is not specific for this diagnosis. Asymptomatic or minimally symptomatic pulselessness or vascular bruits suggest Takayasu arteritis; arterial occlusion resulting from APS is usually abrupt and symptomatic.

A diagnosis of SLE in an untreated patient requires a strongly positive result for antinuclear antibody and anti-DNA or anti-Smith antibody. However, the concept of a "lupus-like" condition is accepted, and these patients are managed as if they had unequivocal lupus. Similarly, the diagnosis of APS requires, in addition to thrombosis or pregnancy morbidity, the persistent

(at least 12 weeks) presence of one or more of the following blood tests: a moderate to high titer (>40 IU) of anticardiolipin antibody of the IgG or IgM isotype, a moderate to high titer of anti- β_2 -glycoprotein-1 antibody-1 of the IgG or IgM isotype, or lupus anticoagulant defined by the International Society on Thrombosis and Haemostasis standards.²¹ Diagnoses of rheumatoid arthritis, scleroderma, and juvenile arthritis can be made on clinical grounds alone. A diagnosis of Takayasu arteritis requires a biopsy, angiogram, or magnetic resonance or positron emission image that documents involvement of the aorta or its great branches.

Management and Prevention

Knowledge of the pharmacology of drugs specific to systemic rheumatic disease is essential to the management of pregnant patients.²²⁻²⁴ Because these diseases are chronic and likely to become exacerbated, withdrawal of medications before or during pregnancy is usually ill advised. Planning for pregnancy must take into consideration the medications that the patient can take safely when she conceives.

Nonsteroidal anti-inflammatory drugs (NSAIDs) may cause oligohydramnios or, rarely, injure fetal kidneys or induce premature closure of the ductus arteriosus, particularly after 34 weeks. Prednisone and methylprednisolone are largely inactivated by a placental hydroxylase and do not reach the fetus in significant concentrations. Fluorinated corticosteroids (dexamethasone and betamethasone) are not inactivated and should be used only when there is intent to treat the fetus. Whether the commonly used pulse administration of corticosteroid (1000 mg of methylprednisolone by rapid intravenous infusion, usually on 3 consecutive days) is safe in pregnancy is unknown.

Azathioprine, which is widely used in renal transplant recipients and patients with Crohn disease, is relatively safe,²⁵ but fetal malformations have occurred in animal models.²⁶ Cyclophosphamide, methotrexate, and leflunomide are contraindicated in early pregnancy because of their teratogenic and abortifacient properties, although a few infants of women given cyclophosphamide late in pregnancy have been normal.²⁷ The TNF- α inhibitors (etanercept, infliximab, and adalimumab) are rated relatively safe, despite the lack of long-term experience with these drugs.^{22-24,28} Table 64-2 summarizes conclusions of an international group that systematically reviewed the published data.²²

Patients with SLE, APS, or spondyloarthritis have normal fertility, and those with rheumatoid arthritis and scleroderma probably have slightly lower than normal fertility. Oral contraceptives probably do not induce exacerbation of SLE; they have a small or no effect on disease incidence.²⁹ Ovulation induction for purposes of enhancing fertility probably does not induce flares of lupus or induce thrombosis in patients with APS.³⁰ Except for imparting genetic susceptibility, paternal rheumatic illness does not cause infertility or affect the child.

Specific Rheumatic Diseases

SYSTEMIC LUPUS ERYTHEMATOSUS

Although patients with SLE may have intrinsic hormonal abnormalities, they are quantitatively minor and have no discernible effect on pregnancy outcome.³¹⁻³³ Pregnancy probably does not induce serious lupus flare.^{34,35} Diagnosing flare during pregnancy is difficult because pregnancy-induced thrombocytopenia, preeclamptic proteinuria, and palmar and facial erythema resemble the signs of SLE flare. Flare is most confidently diagnosed when a pregnant patient has new or increasing diagnostic rash (not erythema alone), lymphadenopathy, arthritis, fever, or anti-double-stranded DNA (anti-dsDNA) antibody.

Fetal health is threatened because approximately one third of all patients with SLE have anti-Ro/SSA or anti-La/SSB antibodies, or both, as do a few patients with discoid lupus, most with subacute cutaneous lupus, and most with Sjögren syndrome. These antibodies predispose to neonatal lupus. One third to one half of patients with SLE have antiphospholipid antibodies, predisposing to fetal loss.

Maternal Complications

Maternal complications are best addressed when discussing the affected organ system, because global SLE exacerbation is rare, and if patients become pregnant while their disease is inactive, outcomes are likely to be good. Approximately one fourth of all patients with SLE develop thrombocytopenia during pregnancy,

compared with about 7% of normal women.³⁶ Patients with antiphospholipid antibodies often have asymptomatic, low-grade thrombocytopenia ($>50 \times 10^9/L$) that worsens slightly during pregnancy. Abrupt, severe thrombocytopenia of the immune thrombocytopenia (ITP) type, and lupus-related, low-grade chronic thrombocytopenia occur independent of pregnancy. No specific test clearly differentiates types of thrombocytopenia in pregnant patients with SLE. In our experience, in pregnant patients with lupus, thrombocytopenia results equally often from antiphospholipid antibodies, active SLE, and preeclampsia.

In patients with proteinuria, clinical signs of active SLE, rising levels of anti-dsDNA antibody, very low concentrations of complement, and urinary erythrocyte casts favor a diagnosis of lupus nephritis rather than preeclampsia. Rapid worsening over days suggests preeclampsia. Hypertension, thrombocytopenia, hyperuricemia, and hypocomplementemia occur in both; normal complement levels suggest preeclampsia. Two thirds of pregnant lupus patients who entered pregnancy with renal disease develop preeclampsia, compared with less than 20% of those without prior kidney disease.³⁷ In women with preexisting renal disease who develop preeclampsia, renal function may not return to its pre-pregnancy baseline. Because skin blood flow increases in pregnancy, existing rash may become more prominent as pregnancy progresses. Patients who discontinue hydroxychloroquine for pregnancy often have recurrence of rash.

Joints previously damaged by lupus arthritis may develop noninflammatory effusions when ligament loosening occurs in late pregnancy. Neurologic lupus during pregnancy is rare, but case reports document chorea and transverse myelitis induced or exacerbated by pregnancy. In patients with seizures late in pregnancy, accompanied by hypertension and renal failure, it may not be possible to distinguish between cerebral SLE and eclampsia. Treatment for both is usually indicated. Pulmonary hypertension may develop or worsen during pregnancy. Concomitant care with the obstetrician and rheumatologist is advisable.

Fetal Complications

If antiphospholipid antibodies, anti-Ro/SSA and anti-La/SSB antibodies, maternal fever, severe anemia, uremia, hypertension, and preeclampsia are absent, active SLE itself does not compromise the fetus. Infants born of SLE mothers with IgG-induced thrombocytopenia usually have normal platelet counts. Rarely, Coombs antibody causes hemolysis in the fetus; anti-dsDNA antibody has no apparent pathologic effect. Thrombosis resulting from antiphospholipid antibodies rarely occurs in the fetus.

The neonatal lupus syndrome includes photosensitive rash, thrombocytopenia, hepatitis, and hemolytic anemia, all of which are transient, and congenital complete heart block, which is not.³⁸ The syndrome occurs exclusively in neonates of women with high-titer anti-Ro/SSA or anti-La/SSB antibodies, or both, many of whom are clinically well (a small number later develop SLE or Sjögren syndrome). With the exception of neonatal lupus syndrome, there are no congenital abnormalities associated with SLE.

Congenital heart block is first diagnosable in utero by fetal electrocardiography, ultrasound, or cardiac rate monitoring between 18 and 25 weeks' gestation (average, 23 weeks). Among SLE patients with anti-Ro/SSA antibody, the risk that a liveborn

TABLE 64-2 Pregnancy-Relevant Characteristics of Commonly Used Antirheumatic Drugs

Drug	FDA Pregnancy Class ^a	FDA Lactation Class ^b	Safety	Comments
Aspirin [†]	D [§]	S(?)	Variable: depends on dosage and time of use	Low dosage may be partially protective against fetal death in antiphospholipid syndrome May cause maternal and fetal bleeding if administered near term
Naproxen, ibuprofen, ketoprofen, nabumetone, and similar drugs [‡]	B/D [§]	S(*)	Variable, depends on dosage and time of use	High dosage: safety uncertain Experience largely accumulated through treatment of headache or dysmenorrhea No major teratogenicity Use after 34 weeks not advised
Ketorolac [‡]	C	S(*)	Causes dystocia and neonatal death in animals	Insufficient human experience
Celecoxib	C	S(?)	Limited data	Not protective against thromboembolic disease
Indomethacin [‡]	B/D [§]	S(*)	Variable, depends on dosage and time of use	Fetal pulmonary hypertension if used at term or in third trimester Oligohydramnios
Prednisone	B	S	Generally safe	Trivial passage across placenta Safe in lactation but may suppress milk production
Methylprednisolone	B	NS	Probably safe	Similar to prednisone but fewer data available
Dexamethasone, betamethasone	C	NS	Probably safe in late pregnancy	Important transfer across placenta Used to induce fetal lung maturation
Hydroxychloroquine	C	S	Probably safe	Small published experience indicating safety
Azathioprine	D	NS	Safety uncertain	Large experience with renal transplant patients indicates no immediate danger to offspring if maternal dosage is <2 mg/kg/day Rare reports of congenital anomalies, including immunodeficiency
Cyclosporine	C	NS	Probably safe	Little experience, none suggesting high fetal risk
Cyclophosphamide	D	NS	Dangerous	Abortifacient, teratogenic
Methotrexate	X	NS	Dangerous	Abortifacient, teratogenic
Leflunomide	X	NS	Dangerous	Abortifacient, teratogenic
Etanercept	B	S(?)	Appears to be safe	No long-term studies in children
Infliximab	B	S(?)	Appears to be safe	No long-term studies in children
Adalimumab	B	S(?)	Appears to be safe	No long-term studies in children
Heparin	B	S	Appears to be safe	Anticoagulant of choice Causes osteoporosis
Low-molecular-weight heparin	B	S(?)	Similar to heparin	Similar to heparin, fewer data
Warfarin	X	S	Teratogenic and possibly fetotoxic	Fetal warfarin syndrome when given in first trimester May cause central nervous system defects in second and third trimesters Risk for severe neonatal hemorrhage when given near term
Intravenous immunoglobulin	B	—	Appears to be safe	Administered antibodies carried to fetus

*U.S. Food and Drug Administration (FDA) pregnancy risk classification: A, controlled trials show no risk in humans; B, animal studies show no risk but no definitive studies in humans; C, animal studies show risk, or no studies in humans or no information; D, positive evidence of risk but risk-benefit ratio may be acceptable in some circumstances; X, fetal risk and risk-benefit ratio always unacceptable.

[†]Lactation classification: S, safe; S(*), potential for significant effects on nursing infants, give only with caution; S(?), unknown, theoretically safe, insufficient literature; NS, not safe, contraindicated, known danger.

[‡]All inhibitors of prostaglandin synthesis activity may inhibit labor and prolong gestation. There is also a risk for in utero closure of the ductus arteriosus, particularly when used after 34 weeks' gestation.

[§]Risk category D when used in the third trimester.

^{||}Drug use restricted in patients with arterial occlusive disease.

child will have neonatal lupus rash is 25%, and congenital complete heart block is less than 3%. However, the risks for recurrent congenital heart block and neonatal lupus rash are 18% and 25%, respectively. Cardiac injury may be related to expression of the cardiac 52B Ro antigen after apoptosis of cardiomyocytes, and related to induction of profibrotic cytokines around the conducting system.^{39,40} No specific antibody pattern

predicts neonatal lupus rash. Several dizygotic twins and at least one monozygotic twin pair have been discordant for neonatal lupus, suggesting fetal contribution to illness.

Dexamethasone and plasmapheresis for the mother and early delivery have been used, with variable success, to treat fetal incomplete heart block, myocarditis, heart failure, and hydrops fetalis. Complete heart block in a newborn usually requires a

permanent pacemaker. Even with a pacemaker, progressive fibrosis of the conducting system, cardiac failure, and sudden death may occur before age 5.

Preliminary data suggest that boys of mothers with SLE have increased risk for learning disabilities but have normal intelligence, compared with sex- and gestational age-matched controls.⁴¹ Children with complete congenital heart block remain at risk for cardiac death. Although case reports have described survivors of neonatal lupus who developed systemic lupus when they became adults, such events are rare. Other than the inherited tendency to develop rheumatic illness, there are no other known risks to children of mothers with other rheumatic disease.

ANTIPHOSPHOLIPID ANTIBODY SYNDROME

(See Chapter 53 for in-depth discussion of coagulation effects of antiphospholipid antibodies.)

Untreated patients with antiphospholipid antibody syndrome and a history of a fetal loss have a high frequency of mid-pregnancy intrauterine growth restriction or fetal death. Very high levels of antibody worsen the prognosis; most risk is associated with lupus anticoagulant.⁴² Low-level IgM and IgG anticardiolipin antibodies are not associated with poor fetal outcome, nor is an isolated false-positive test result for syphilis in the absence of other markers. Few patients with APS suffer thromboses during pregnancy, possibly because most are prophylactically treated with heparin and low-dosage aspirin. Risks for stroke and thrombophlebitis increase after delivery, especially after discontinuation of anticoagulant therapy. Ischemic cardiomyopathy and myocardial infarction may also occur after delivery. Thrombocytopenia, if a new occurrence during pregnancy, usually remits after delivery.

A pregnancy compromised by antiphospholipid antibodies is often initially uneventful, but the fetal growth rate then slows. Antepartum fetal heart rate monitoring studies show nonreactive fetal heart rate pattern, spontaneous bradycardia, diminished fetal motion, decreased amniotic fluid, reduced placental size, and, if delivery is not accomplished, fetal death. The mother may show no evidence of illness or may develop severe preeclampsia or HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets). Fetal survival rates of more than 80% are now possible, compared with less than 20% in the earliest series of untreated patients. After a patient has had a strongly positive test result for antiphospholipid antibodies during pregnancy, the fetal prognosis does not improve if lupus anticoagulant activity disappears or if anticardiolipin antibody levels decrease.

Placentas of patients with SLE without antiphospholipid antibodies exhibit ischemic-hypoxic change and chronic villitis, whereas those of patients with antiphospholipid antibodies can also have decidual vasculopathy, extensive maternal floor infarction (Fig. 64-1) resulting from uteroplacental or spiral artery thrombosis, endothelial cell proliferation, or other fetoplacental vasculopathy.^{43,44} Antiphospholipid antibody, β_2 -glycoprotein-1, and placenta anticoagulant protein 1 (PAP-1) deposit together in placentas of mothers with antiphospholipid syndrome.⁴⁵ Studies underscore the importance of inflammatory infiltrates and complement deposits in placentas from patients with antiphospholipid antibodies.⁴⁶⁻⁴⁸ The cycling endometrium of patients with APS displays decreased

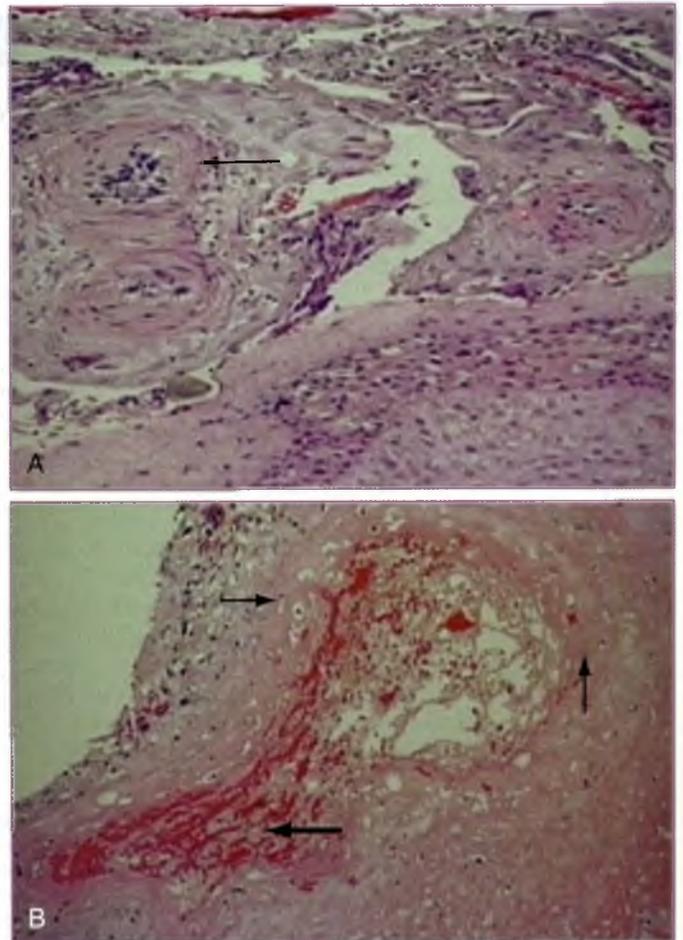

Figure 64-1 Placental biopsy specimens: antiphospholipid antibodies. Patients with antiphospholipid antibodies may have decidual vasculopathy, extensive maternal floor infarction, endothelial cell proliferation, and other fetoplacental vasculopathy. **A**, Placental biopsy specimen demonstrates a lack of physiologic conversion, resulting in decidual vasculopathy. Arrow indicates spiral arterioles with smooth muscular walls and a small lumen. **B**, Placental biopsy specimen demonstrates fibrinoid necrosis in the decidual vessel wall (small arrows) and thrombosis in the decidual vessel (large arrow). (From George D, Vasanth L, Erkan D, et al: Primary antiphospholipid syndrome presenting as HELLP syndrome, *Hosp Special Surg J* 3:216-221, 2007.)

endometrial differentiation and reduced expression of complement inhibitor, decay-accelerating factor, suggesting that decidualization may be compromised and that these patients may be more susceptible to complement-mediated events at the maternal-fetal interface.⁴⁹

Monitoring of APS pregnancies consists of ultrasound evaluation of the fetal growth rate and placental volume and appearance. Weekly antepartum fetal heart rate testing may begin as early as 25 weeks. In the 25- to 32-week period, a reactive nonstress test is defined as two accelerations of at least 10 beats/min during a 20-minute interval. Thereafter, 15 beats/min is used. Nonreassuring fetal testing indicates a need to deliver. Choice of the route of delivery is determined by obstetric criteria, as well as by maternal and fetal platelet counts. Newborns who test positive rarely have pathologic clotting. Short-term follow-up studies of infant survivors of patients with lupus indicate that these children develop normally compared with children of equivalent prematurity, but detailed

information regarding children of non-SLE patients with APS is not available.⁵⁰

The relationship of autoantibodies, particularly antiphospholipid antibodies, to failure of in vitro fertilization (IVF) and embryo transfer is unproved. Murine models of APS show abnormal blastocyst development and impairment of embryo implantation.⁵¹ In animal models, fetal death depends on complement and adhesion molecules, and prevention of complement activation prevents fetal death. Heparin, the standard of care for pregnant patients with APS, inhibits activation of complement and blocks leukocyte adhesion.^{16,52} Further evidence that these antibodies do not appear to be associated with very early pregnancy loss is found in a meta-analysis of seven studies examining the impact of antiphospholipid antibodies on IVF outcomes. Hornstein and associates⁵³ reported no significant association between antiphospholipid antibodies and clinical pregnancy (odds ratio [OR] = 0.99; 95% confidence interval [CI], 0.64 to 1.53) or live birth rates (OR = 1.07; 95% CI, 0.66 to 1.75). The investigators concluded that measurement of antiphospholipid antibodies is not warranted in patients undergoing IVF. Moreover, there is no evidence that treating patients who have antiphospholipid antibodies improves IVF success rates.⁵⁴ Other than placental insufficiency, with its risk for intrauterine growth restriction or fetal death, there are no special risks to the fetus.

Treatment recommendations for APS pregnancy are presented in Table 64-3. Controlled treatment trials of women with two or more pregnancy losses demonstrate that low-dosage aspirin (81 mg/day) plus subcutaneous unfractionated heparin (5000 to 12,000 units twice daily), begun after ultrasonographic confirmation of a viable pregnancy, results in a rate of live births (not necessarily term) of more than 80%.^{55,56} However, clinical trials of the highest-risk pregnant patients, those with lupus anticoagulant or high-titer antiphospholipid antibody as shown on enzyme-linked immunosorbent assay (ELISA) (or both), have not been done. The lower heparin dosage is as effective as higher dosages, but patients who have had prior thromboses

require full anticoagulant dosages. In a small controlled trial, intravenous immunoglobulin did not show benefit in the primary treatment of low-risk patients with APS,⁵⁷ but it is often used in those in whom heparin has failed. Warfarin is contraindicated because it is teratogenic. Osteoporosis remains a major potential side effect of heparin treatment,⁵⁸ but it is less common with low-molecular-weight heparin. There is no information about use of nonheparin anticoagulants in APS pregnancy; in animal models, fondaparinux does not work.¹⁶ Based on empiric data of postpartum thromboses, treated women with no prior thromboses should receive heparin or oral warfarin for 6 to 12 postpartum weeks. Aspirin, if used during pregnancy, should also continue for at least 3 months.

RHEUMATOID ARTHRITIS

Whether women have a high rate of pregnancy loss before developing rheumatoid arthritis is controversial. Patients with established rheumatoid arthritis frequently improve during pregnancy. Proposed reasons include the immunosuppressive effects of endogenous corticosteroid, pregnancy-associated plasma protein A, and disparity between maternal-fetal HLA-DQ and HLA-DR. The latest data favor the latter explanation.⁵⁹ Flare of rheumatoid arthritis often follows delivery, as does new development of rheumatoid arthritis.

A recent prospective case-control study by Guthrie and colleagues suggests that HLA-disparate fetal microchimerism may explain why parous women are 40% less likely to develop rheumatoid arthritis than nulliparous women.⁶⁰ This study further showed that the interval since the previous childbirth correlated with the risk of developing rheumatoid arthritis, suggesting that pregnancy protects against this disease, as would a vaccine. Other studies have also shown that rheumatoid arthritis flare follows delivery, as does development of new rheumatoid arthritis.⁶⁰

Pregnancy is usually uneventful in patients with rheumatoid arthritis. Rheumatoid joints may become unstable in late

TABLE 64-3 Treatment Recommendations for Pregnant Women with Positive Antiphospholipid Antibody Results and No Other Explanation for Pregnancy Loss

Patient Characteristic	Recommendation
HIGH-TITER IgG OR IgM ACA (>40 IU) OR POSITIVE LA TEST*	
Primipara, multipara with most recent pregnancy liveborn, or multipara with most recent pregnancy failure at <10 weeks (one loss)	Consider aspirin, 81 mg/day, or no therapy initially. If modest (>50 × 10 ⁹ /L) thrombocytopenia occurs, add aspirin.*
Multipara with most recent pregnancy failure at <10 weeks (more than one loss), or multipara with most recent pregnancy failure at ≥10 weeks (fetal loss)	Aspirin while trying to conceive
Multipara with prior premature birth due to preeclampsia or IUGR	Add heparin, 5000 units bid, or low-dosage LMWH at confirmation of fetal heartbeat, and continue for duration of pregnancy
	Aspirin beginning after first trimester
	Consider heparin, depending on blood pressure control and renal function
LOW-TITER IgG OR IgM ACA	
Primipara, multipara with most recent pregnancy liveborn, or multipara with most recent pregnancy failure at <10 weeks (one loss)	No therapy
Multipara with most recent pregnancy failure at <10 weeks (more than one loss), or multipara with most recent pregnancy failure at ≥10 weeks (fetal loss)	Aspirin while trying to conceive
Multipara with prior premature birth due to preeclampsia or IUGR	Add heparin, 5000 units bid, or low-dosage LMWH at confirmation of fetal heartbeat, and continue for duration of pregnancy
	Aspirin beginning after first trimester
	Consider heparin, depending on blood pressure control and renal function

*For thrombocytopenia level of <50 × 10⁹/L, consider intravenous immunoglobulin or prednisone, or both.

ACA, anticardiolipin antibody; IUGR, intrauterine growth restriction; LA, lupus anticoagulant; LMWH, low-molecular-weight heparin.

pregnancy as physiologic joint loosening occurs and as the patient's weight distribution changes. Undiagnosed cervical spine subluxation is a particular concern. Bacteremia occurring during labor, although rare, may seed involved joints. Antiphospholipid, anti-Ro/SSA, and anti-La/SSB antibodies are uncommon, and neonatal lupus therefore occurs infrequently. High-risk pregnancy monitoring is usually not necessary. There is a slight increase in risk for fetal growth restriction and maternal hypertension, and hospitalizations are slightly longer than normal for patients with rheumatoid arthritis.⁶¹

Most patients need to continue their pre-pregnancy medications, including NSAIDs, corticosteroids, hydroxychloroquine, azathioprine, and TNF- α inhibitors. Low-dosage prednisone is the safest option. It is advisable that the obstetrician and rheumatologist provide concomitant care.

Before delivery, the team managing the patient must take special care to identify the patient's disabilities to prepare her for labor. Points for special emphasis are hip, knee, and neck arthritis and the potential risks of forcing joint motion beyond disease-imposed constraints, causing fracture or other injury. Elective cesarean delivery may be necessary. If intubation is planned, an anesthesiologist familiar with temporomandibular arthritis and rheumatoid cervical spine disease should be available. There are no special risks to the fetus other than those related to maternal therapy.

SJÖGREN SYNDROME

Sjögren syndrome is characterized by generally less severe arthritis but keratoconjunctivitis sicca. Sjögren syndrome often results from another autoimmune disease, and little is known about the interaction of pregnancy with the primary syndrome. About 80% of Sjögren patients have anti-Ro/SSA and anti-La/SSB antibodies, and their children are therefore at risk for neonatal lupus.⁶² Intrauterine growth restriction is uncommon. Management of patients with Sjögren syndrome is the same as that for rheumatoid arthritis, except for the monitoring necessary for neonatal lupus. Treatment of the eye and mouth manifestations of primary Sjögren syndrome is the same as in the non-pregnant patient, but the effect of pilocarpine or cevimeline (U.S. Food and Drug Administration [FDA] category C drugs) on a fetus is unknown.

SCLERODERMA

Scleroderma often affects women in their late reproductive years, and pregnancy during established disease is uncommon. Patients with scleroderma generally do well but may tolerate pregnancy poorly if they have limited pulmonary, cardiac, or renal function. Occasionally, scleroderma renal crisis occurs during pregnancy; it may be difficult to distinguish from preeclampsia.^{63,64} A recent study suggests that, in contrast to rheumatoid arthritis, in which fetal microchimerism may be protective, gravidity and parity may increase the risk for scleroderma. This concept remains unproved, however, and the literature is contradictory.⁶⁵

Problems in patients with scleroderma derive from nondissectible vascular beds and from preexisting renal, cardiac, and pulmonary insufficiency. Gastroesophageal reflux, which is common during pregnancy even in women with normal esophageal motility, can be disabling. Treatment is standard: small meals, elevating the head of the bed, histamine type-2 blockers

(FDA category B), and proton pump inhibitors (FDA category C), but not the prostaglandin E₁ analogue misoprostol (FDA category X). Maternal preeclampsia, congestive heart failure, pulmonary hypertension, pulmonary insufficiency, and renal insufficiency may occur. Renal scleroderma may be indistinguishable from preeclampsia; it may justify termination of pregnancy.⁶⁶ Angiotensin-converting enzyme inhibitors and receptor antagonists are contraindicated in the periconceptional period because of their teratogenicity (risk ratio [RR] = 2.71; 95% CI, 1.72 to 4.27) and during pregnancy because of their potential for inducing renal failure and fetal deformation as a result of prolonged oligohydramnios, except if renal hypertensive crisis refractory to all other antihypertension medications occurs.⁶⁷ Patients with severe atonic small bowel disease can carry a pregnancy to term with the use of parenteral nutritional support. Prematurity and intrauterine growth restriction are the greatest risks to the infant. A high and persistent degree of transplacental transfer of fetal cells occurs in patients with scleroderma, but the relationship of this finding to disease pathogenesis is unknown. Years after pregnancy is over, fetal cells can still be found in affected maternal skin sites.^{68,69}

SPONDYLOARTHROPATHY

Women with ankylosing spondylitis have normal fertility. Most patients experience no change or modest worsening of complaints during pregnancy; those who worsen return to baseline after delivery.⁷⁰ Patients with psoriatic arthritis may improve during pregnancy. Other than the specific anatomic problems of spondyloarthropathy such as restricted motion of the hips and lower back that may impede vaginal delivery, patients have no unusual problems with pregnancy. Treatment for painful back is problematic because indomethacin and other NSAIDs may cause fetal harm.

VASCULITIS

Patients with Takayasu disease may do well, but renovascular occlusive disease, pulmonary hypertension, and aortic insufficiency remain important potential problems. Preeclampsia is common. Management during pregnancy involves careful monitoring and treatment of hypertension (diagnosis and monitoring of which is difficult when arm arteries are occluded) and aggressive hemodynamic and pharmacologic management in the peripartum period. Sixty percent of infants have intrauterine growth restriction related to maternal aortic involvement, hypertension, and preeclampsia.

MISCELLANEOUS DISORDERS

Hip disease of any kind may interfere with normal vaginal delivery, because abduction may be severely limited. Forcing a patient's joint motion beyond the point at which she feels pain or at which resistance is encountered risks fracture, dislocation, or other permanent harm. Antibiotic coverage (a cephalosporin plus gentamicin, or vancomycin plus gentamicin) may be indicated in women who have artificial joint replacements and are undergoing vaginal delivery. Pelvic and back pain may be caused by laxity of the pubic symphysis and sacroiliac joints, which is associated with increased serum levels of relaxin. Labor and delivery are occasionally complicated after delivery by infectious sacroiliitis or osteitis pubis. For diagnosis of back pain in

TABLE 64-4 Recommended Evaluation of Pregnant Patients with Autoimmune Rheumatic Disease

Recommended Frequency	Monitoring Test
First visit	Complete blood count and urinalysis* Creatinine clearance Antiphospholipid antibodies Anti-Ro and anti-La antibodies Anti-dsDNA antibody (patients with SLE) Complement (C3 and C4, or CH ₅₀) (patients with SLE)
Monthly	Platelet count [†]
Each trimester	Creatinine clearance [†] A 24-hour urine protein assay if screening urinalysis is abnormal [†] Complement [†] and anti-dsDNA antibody [†]
Weekly (last trimester, mothers with antiphospholipid antibodies)	Antenatal fetal heart rate testing (nonstress test), and/or biophysical profile [‡]
Between 18 and 25 weeks (mothers with anti-Ro or anti-La antibodies)	Fetal echocardiogram, fetal electrocardiogram (?)

*The erythrocyte sedimentation rate is often abnormal in uncomplicated pregnancy.

[†]More frequently if abnormal.

[‡]Measurement of fetal size and activity, and of amniotic fluid volume. CH₅₀, 50% hemolytic complement level; dsDNA, double-stranded DNA; SLE, systemic lupus erythematosus.

pregnant patients, magnetic resonance imaging is preferable to computed tomography. Ultrasound, infrared therapy, and warm-water therapeutic pool therapy may injure the fetus.

Pregnancy Management

Monitoring recommendations for patients with rheumatic disease are presented in Table 64-4. Unexplained elevations of maternal α -fetoprotein and human chorionic gonadotropin occur in patients with lupus and with antiphospholipid antibodies. These abnormalities correlate with preterm delivery,

requirements for a higher prednisone dosage, and fetal death.⁷¹ Because intervention with dexamethasone at the earliest sign of cardiac dysfunction may reverse myocarditis and possibly congenital heart block, women with high-titer anti-Ro/SSA and anti-La/SSB antibodies and those who have previously given birth to a child with any form of neonatal lupus should undergo fetal cardiac monitoring weekly during the vulnerable period of 18 to 25 weeks' gestation. In women known to be strongly positive for lupus anticoagulant and anticardiolipin antibody, repeat testing for these antibodies during pregnancy is unnecessary, because spontaneous correction of the lupus anticoagulant level and a decrease in the anticardiolipin antibody level does not improve prognosis. In women with low antibody levels or negative test results, repetition at least once each trimester is useful because overall prognosis is based on the highest level seen during the pregnancy. The platelet count should be repeated monthly. Women significantly positive for antiphospholipid antibodies and who have had a prior fetal loss should be treated with low-dosage aspirin and unfractionated or low-molecular-weight heparin.

Decisions regarding timing and route of delivery are dictated by the status of the fetus but may be influenced by maternal illness and its complications. Approximately one third of patients with SLE undergo operative delivery. The usual indications for cesarean delivery are fetal distress, prior cesarean delivery, prolonged ruptured membranes, failure to progress at labor and other obstetric reasons, thrombocytopenia, and severe maternal illness.

There is little information about the use of tocolytics or stimulators of labor in pregnant women with rheumatic disease. Magnesium sulfate and prostaglandin suppositories have been used without incident. At delivery, stress corticosteroid doses (usually 100 mg of hydrocortisone every 8 hours from the onset of labor until 24 hours after delivery) are administered to patients currently or recently taking corticosteroids. Asymptomatic bacteremia occurs in 3.6% of vaginal deliveries. Because of limited hip joint movement or risk for bacterial seeding, osteonecrosis of the hip may justify a decision for operative rather than vaginal delivery. The mode of delivery for patients with total hip replacements need not be surgical; patients have been delivered vaginally with appropriate attention paid to the positioning of the patient.

The complete reference list is available online at www.expertconsult.com.

Neurologic Disorders

MICHAEL J. AMINOFF, MD, DSc | VANJA C. DOUGLAS, MD

Women are as susceptible to neurologic disorders during gestation as at other times, and certain disorders may be aggravated or influenced by pregnancy. Investigation and management of many neurologic disorders may be complicated by the pregnancy and by concern about the safety of the developing fetus. This chapter describes some of the special problems posed by neurologic disorders during pregnancy, as well as problems posed by pregnancy in patients with neurologic disorders.

Epilepsy

Women with epilepsy should be advised about possible interactions between anticonvulsant drugs and oral contraceptive agents. Certain anticonvulsants, including phenytoin, phenobarbital, primidone, carbamazepine, oxcarbazepine, topiramate, and felbamate may interfere with the effectiveness of oral contraceptives and implanted progestins, leading to unwanted pregnancy.¹ The possibility of contraceptive failure must be discussed with women taking these anticonvulsants and then documented in the records. Regular counseling of women with epilepsy is necessary during the reproductive years, because unplanned pregnancy may occur. Valproic acid and the newer anticonvulsants (e.g., zonisamide, vigabatrin, gabapentin, lamotrigine, levetiracetam, pregabalin, and tiagabine) have not been reported to cause contraceptive failure.^{1,2} When oral contraception is desired for women taking enzyme-inducing anticonvulsants, a formulation that includes at least 50 µg of ethinyl estradiol or mestranol is preferred, but the best way to ensure contraception is to use an alternative method. Combined oral contraceptives may increase the metabolism of lamotrigine, causing lower lamotrigine blood levels, and may increase seizure frequency in patients on this medication.

Between 0.3% and 0.6% of pregnant women have epilepsy. Pregnancy may affect the seizure disorder, and the disorder may affect the course of the pregnancy and the manner in which it is best managed. Moreover, recurrent seizures and drugs given to the mother in an attempt to control them may affect fetal development.

EFFECT OF PREGNANCY ON SEIZURE DISORDERS

Pregnancy has unpredictable and variable influences on epilepsy. When seizure frequency increases, it most commonly does so in the first trimester and usually reverts to the pregestational pattern at the conclusion of the pregnancy, although a few patients experience a permanent deterioration in seizure control. In general, control in patients with frequent seizures (i.e., more than one a month) before pregnancy is likely to deteriorate during the gestational period, whereas only about 25% of patients with infrequent attacks (i.e., less than one every 9 months) experience an exacerbation during pregnancies.

Several case series have examined changes in seizure frequency during pregnancy, using pre-pregnancy or postpartum seizure frequency as the control.³ Seizure frequency remained unchanged in 54% to 80% of patients, with the highest rate of stability in those with documented medication compliance. Seizure frequency increased in 14% to 32% of patients and decreased in 3% to 24%. Seizures are more likely to be exacerbated during pregnancy in women with more frequent seizures before the pregnancy and in those with focal seizure disorders.⁴ For those who have been seizure free for at least 9 months prior to conception, the likelihood of remaining seizure free during pregnancy is 84% to 92%.

It is usually not possible to predict the outcome in individual cases, regardless of the maternal age, the outcome of previous pregnancies, or any apparent relationship between seizures and the menstrual cycle. None of these factors provides a guide to the effect that pregnancy will have on the course of epilepsy. Moreover, attacks may occur during pregnancy in patients who have been free of seizures for several years.

Epilepsy may appear for the first time during or immediately after pregnancy. It is uncommon for patients in the latter group to have seizures only in relationship to pregnancy and at no other time (i.e., gestational epilepsy). Some patients with true gestational epilepsy experience recurrent seizures during pregnancy, and the remainder have only a single convulsion. The occurrence of seizures in one pregnancy is no guide to the course of subsequent pregnancies.

The seizures that occur during pregnancy do not differ clinically from those occurring in other circumstances. Improved compliance with an anticonvulsant drug regimen may sometimes account for the reduction in seizure frequency that occasionally occurs during pregnancy in a woman with epilepsy.

The increase in seizure frequency that occurs in some epileptic patients during pregnancy may relate to the metabolic, hormonal, or hematologic changes of the gestational period, or to fatigue or sleep deprivation. A rapid and excessive gain in weight sometimes occurs before an increase in seizure frequency, providing some support for the belief that fluid retention may occasionally be a factor, perhaps by a dilutional effect on anticonvulsant drug concentration. It is tempting to relate any change in seizure frequency to hormonal factors because estrogens are epileptogenic in animals and progesterone has both convulsant and anticonvulsant properties. Nausea, vomiting, reduced gastric motility, or use of antacids may also lead to reduced absorption of anticonvulsant drugs.

There is sometimes difficulty in maintaining adequate treatment with anticonvulsant drugs during pregnancy. Serum levels of the older antiepileptic drugs and the newer drug lamotrigine generally decline in pregnancy and rise in the postpartum period.⁵ For phenytoin, carbamazepine, and valproate (but not phenobarbital), the decline is less for free levels than for total levels. An increase in dosage is frequently required to maintain

plasma levels at pre-pregnancy values; monitoring of drug levels before planned conception and during pregnancy should be considered, remembering that the free level, rather than the total level, of the drug correlates best with therapeutic efficacy. The levels of several newer antiepileptic drugs, including levetiracetam and oxcarbazepine, may also decline during pregnancy, but the effect of pregnancy on the pharmacokinetics of other newer agents, such as felbamate, gabapentin, pregabalin, zonisamide, topiramate, and lacosamide, is unclear.

The reason for the changes in drug requirements is unknown. One possibility is the dilutional effect of increasing plasma volume and extracellular fluid volume. Poor compliance with the anticonvulsant drug regimen, perhaps because of nausea and vomiting or concerns about the effect of medication on the fetus, may also be an important contributory factor, as may decreased plasma protein binding and changes in the absorption and excretion of drugs. The increased metabolic capacity of the maternal liver in pregnancy and possible fetal or placental metabolism of part of the anticonvulsant dose may influence the changes in anticonvulsant drug requirements that occur in epileptic women during pregnancy.

Folic acid therapy may lower the plasma phenytoin level, sometimes to below the therapeutic range, and other drugs taken concomitantly with an anticonvulsant medication also may lead to reduced plasma levels of the anticonvulsant. Antiacids and antihistamines merit particular mention, because it is not uncommon for them to be taken during pregnancy.

Status epilepticus sometimes complicates pregnancy and may occur without any preceding increase in seizure frequency, occasionally because of the injudicious discontinuation of anticonvulsant drugs. Fortunately, this is a rare occurrence, but it may lead to a fatal outcome for the mother or fetus. The absence of hypertension, proteinuria, and edema helps in distinguishing this condition from eclamptic convulsions. As in the nonpregnant patient, it is essential to obtain control of the seizures as rapidly as possible, but the formerly accepted practice of terminating pregnancy is usually unnecessary.

Status epilepticus is treated with anticonvulsant drug therapy, with the pregnancy being allowed to continue to term. Intravenous diazepam (10 to 30 mg) or lorazepam (4 to 8 mg) usually provides temporary control of the seizures, but other anticonvulsant drugs are needed as well to prevent seizure recurrence. Intravenous phenytoin is usually given but is best administered in the form of fosphenytoin sodium, the dosage of which is expressed in terms of phenytoin equivalents. Fosphenytoin sodium is water soluble, may be infused with dextrose or saline, is better tolerated at the infusion site than phenytoin, and may be infused three times more rapidly than intravenous phenytoin, with the same pharmacologic effects. It is converted in the body to phenytoin, which may be cardiotoxic, and cardiac monitoring is required while the fosphenytoin is given in a loading dose of 20 mg of phenytoin equivalents per kilogram, infused at a rate of up to 150 mg of phenytoin equivalents per kilogram. Other anticonvulsants may also be required, including intravenous phenobarbital or midazolam. It is essential to maintain control of the airway and of glucose and electrolyte balance.

EFFECT OF EPILEPSY ON PREGNANCY AND LACTATION

Only a few studies have attempted to document the effect of epilepsy on pregnancy. The results are often difficult to evaluate

because of the limited number of cases reported; the lack of comparative data on nonepileptic women attending the same institutions; differences in the severity of the epilepsy and how it has been treated; differences in age, medical background, and socioeconomic status of the patients reported; and the lack of information concerning relevant social habits such as cigarette smoking and alcohol ingestion.

The incidences of vaginal hemorrhage and of toxemia during pregnancy among epileptic women were found to be increased in some studies but not others. Whether preterm labor occurs more commonly in epileptic women, as is sometimes reported, is unclear.⁶ Cesarean section is not indicated simply because of maternal epilepsy, except when seizures occur frequently or during labor, when they are precipitated by physical activity, or when patients cannot cooperate during labor because of their neurologic disorder or mental abnormality.⁷ Fetal death can result from maternal seizures, presumably because of the accompanying hypoxia and acidosis, but recent evidence suggests that there are no more stillbirths among epileptic patients than in the general population.^{7,8} The effect of maternal seizures on placental blood flow is not established, but changes in fetal heart rate suggestive of hypoxia have been described⁹; they may relate to reduced placental blood flow or to metabolic changes in the mother.

Anticonvulsant drugs taken by the mother may be present in breast milk, but data as to whether they have any major effect on the infant are limited. There is evidence that primidone, ethosuxamide, gabapentin, lamotrigine, levetiracetam, and topiramate enter breast milk in clinically significant quantities; valproic acid, phenytoin, carbamazepine, and phenobarbital may also do so, but the evidence is less clear.⁵ When an infant develops sedation that is likely to be related to antiepileptic drugs in breast milk, breastfeeding should be discontinued, and the infant should be observed for signs of drug withdrawal. However, breastfeeding does not need to be discouraged for reasons related to the milk's content of anticonvulsant medication, and current guidelines do not recommend changing the treatment regimen to a drug that does not penetrate breast milk.⁵

EFFECT OF MATERNAL EPILEPSY AND ANTICONVULSANT DRUGS ON THE FETUS AND NEONATE

The epileptic woman who becomes pregnant is usually concerned that her unborn child may inherit a similar susceptibility to seizures. The risk of epilepsy in the child depends on the nature of the mother's seizure disorder, and it is higher in idiopathic than acquired maternal epilepsy. Although precise quantification of the risk is not possible, it is probably quite small. The cause of this increased risk to the offspring of epileptic mothers is unknown. It may relate to genetic factors, seizures arising during pregnancy, or the metabolic and toxic consequences of seizures or anticonvulsant drugs. In general, pregnancy in epileptic women does not need to be discouraged on these grounds, but reassurance and support are necessary.

A major problem in management of epileptic patients during pregnancy is the possibility that certain anticonvulsant drugs may induce fetal abnormalities. However, epilepsy has a relatively low prevalence rate, can occur for a multitude of reasons, can vary markedly in severity, can be treated by a variety of drugs singly or in combination, and can itself be associated with

an increased risk of fetal malformations. Some patients may have a common genetic predisposition to seizures and to fetal malformation. Environmental factors may be important in the genesis of congenital abnormalities, and socioeconomic backgrounds must be matched as much as is possible when comparisons are made of the incidence of malformations in different patient populations.

All the commonly used older antiepileptic drugs are probably teratogenic to some extent, and malformation rates are higher for the offspring of mothers taking drug combinations.^{6,10} The absolute risk of major congenital malformations based on a large registry of pregnant women with epilepsy is 2.2% for carbamazepine, 3.2% for lamotrigine, 3.7% for phenytoin, and 6.2% for valproate.¹⁰ Valproic acid has an especially high (1%) rate of neural tube defects including spina bifida; it may also cause cleft lip or palate, polydactyly, hypospadias, craniosynostosis, delayed development, and disorders of the cardiovascular and endocrine systems.^{10,11} Trimethadione, which is now rarely used and should be avoided during pregnancy, seems particularly dangerous, as it causes fetal malformations and mental retardation in more than 50% of exposed infants. It is not clear that the rates of major congenital malformations seen with antiepileptic drugs other than valproate differ from rates for women with epilepsy not taking antiepileptic drugs, although some data suggest that phenytoin and carbamazepine are associated with cleft palate, that phenobarbital may be associated with cardiac malformations, and that a dosage-response effect has been noted with lamotrigine.⁶ Whether newer anticonvulsant drugs, such as felbamate, gabapentin, pregabalin, levetiracetam, lacosamide, tiagabine, topiramate, oxcarbazepine, and vigabatrin, are teratogenic is unknown.

Animal studies lend support to the belief that some anticonvulsants are teratogenic. The mechanism involved is unclear but may include folate deficiency or antagonism. Low blood folate levels before or early in pregnancy are significantly associated with spontaneous abortion and the occurrence of developmental anomalies.¹² It has also been suggested that certain oxidative intermediary metabolites of anticonvulsants may affect cell division and migration.

Although most children born to epileptic mothers are cognitively normal, prenatal antiepileptic drug exposure may be associated with developmental delay, particularly when more than one drug has been taken by the mother.⁶ It appears that exposure to valproic acid, in particular, carries a higher risk of impaired cognitive outcomes; in one study, children exposed to valproic acid in utero scored an average of 6 to 9 points lower on an IQ test at 3 years of age than those exposed to carbamazepine, lamotrigine, or phenytoin.¹³

Maternal use of phenytoin during pregnancy has been associated with the fetal hydantoin syndrome, which is characterized by prenatal and postnatal growth deficiency, microcephaly, dysmorphic facies, distal phalangeal hypoplasia, and mental deficiency. Among infants exposed to phenytoin in utero, 11% have enough clinical features to be classified as having this syndrome, and almost three times as many may show lesser degrees of impairment of performance or morphogenesis. The syndrome is not unlike that ascribed to phenobarbital and carbamazepine, and it resembles fetal alcohol syndrome.¹⁴ A consistent facial phenotype has also been reported in children exposed to valproic acid or sodium valproate in utero.¹⁵

Maternal use of barbiturates (60 to 120 mg daily) in late pregnancy may be associated with neonatal withdrawal

symptoms beginning a week after birth. They include restlessness, constant crying, irritability, tremulousness, difficulty in sleeping, and vasomotor instability but not seizures.

Clinical or subclinical coagulopathy may occur in the neonate whose mother received anticonvulsants during pregnancy. In affected infants, levels of factors II, VII, IX, and X are decreased, and levels of factors V and VIII and fibrinogen are normal. The abnormalities are similar to those produced by vitamin K deficiency. As a result, some experts advocate maternal ingestion of vitamin K₁ (10 mg daily) during the last month of pregnancy. However, it is unclear whether routine prophylaxis in this manner is justifiable, because more recent studies suggest that such hemorrhagic complications are rare, and even call into question whether maternal antiepileptic use raises the risk of hemorrhage in neonates at all.⁵ The routine practice of administering 1 mg of vitamin K to all neonates is likely to be sufficient to mitigate any risk of hemorrhagic complications that could result from maternal antiepileptic use.

GENERAL THERAPEUTIC APPROACHES

It is difficult to make more than general therapeutic recommendations about pregnancy in the epileptic woman. Epilepsy should be treated with the smallest effective dosage of an anticonvulsant drug, and monotherapy is preferable to polytherapy. Drug selection is based on seizure type, clinical status, and the maternal and fetal risks. Valproate should be avoided if possible.⁶ Folate supplementation (4 mg daily) is usually provided. Because many pregnancies are unintended and congenital malformations may have already occurred by the time a woman realizes she is pregnant, consideration can be given to provide folate supplementation for any woman of childbearing age taking antiepileptic medications. Similar reasoning suggests that it may be advisable to avoid valproate in epileptic women of childbearing age.

Prenatal counseling is important. If a nonpregnant epileptic woman asks about pregnancy, it is appropriate to inform her that there is a small risk of having a malformed child because of the seizure disorder or the drugs used in its treatment. This risk is probably about double that for the nonepileptic patient, but there is still a more than 90% chance that she will have a normal child.

Data concerning the relative safety and therapeutic effectiveness of different anticonvulsant drugs in the management of pregnant epileptic patients are insufficient to guide the physician responsible for the care of these patients. It seems clear, however, that trimethadione should not be used, and that valproic acid should be avoided. If valproic acid must be used, prenatal testing for maternal serum α -fetoprotein levels or with ultrasound is advisable to detect neural tube defects, so that therapeutic abortion can be considered if necessary. Substitution of one anticonvulsant drug for another in epileptic women whose first medical visit is after the first trimester should be avoided, because if a major malformation of the fetus is going to occur, it has probably occurred already.

The principles of drug management of a seizure disorder in the pregnant woman are the same as in the nonpregnant woman. Anticonvulsant drugs are as necessary to epileptic patients during pregnancy as at other times. A detailed account of the drugs used in the treatment of epilepsy is unnecessary here, but several points are worthy of comment.

A solitary seizure, unrelated to toxemia, should not lead to a diagnosis of epilepsy because there may be no further attacks. Only time will tell whether an individual who has a single seizure is going to have further attacks, thereby justifying a diagnosis of epilepsy and necessitating prophylactic anticonvulsant drug treatment.

Although some physicians start a patient on anticonvulsant medication after one convulsion, others prefer to withhold medication until the patient has had at least two seizures, at least in the nonpregnant state. During pregnancy, many physicians initiate anticonvulsant therapy after even a single seizure and arrange for neurologic reevaluation after delivery. This approach merits emphasis because many patients with so-called gestational epilepsy have only a single convulsion, and continued treatment in such circumstances may be unnecessary. Simple medical and neurologic investigations are indicated in an adult who has an isolated seizure and is otherwise well with no neurologic signs: hematologic and biochemical screening tests, electroencephalogram, and, particularly in the nonpregnant patient, magnetic resonance imaging (MRI) of the head and a chest radiograph. If the findings of such investigations are unremarkable, discuss the controversial issue of anticonvulsant drug treatment with the patient but generally recommend that treatment be withheld unless a future attack occurs.

Pregnant women experiencing two or more seizures merit prophylactic anticonvulsant drug treatment. In those with a progressive history, abnormal neurologic signs, or a focal electroencephalographic abnormality, it is necessary to exclude an underlying structural lesion by means of MRI of the head. The management of such a lesion is described later in this chapter.

If prophylactic anticonvulsant drug treatment is necessary, it is generally continued until the patient has been seizure free for at least 2 or 3 years. Treatment is started with a small dosage of one of the anticonvulsants, depending on the type of seizure experienced by the patient and the considerations outlined earlier. The dosage is increased until seizures are controlled, blood concentrations reach the upper end of the optimal therapeutic range, or side effects limit further increments. If seizures continue despite optimal blood levels of the anticonvulsant drug selected, a second drug should be substituted for the first. Patients often respond better to one or another of the various drugs that are available. Experience during pregnancy with certain newer antiepileptic agents (e.g., felbamate, gabapentin, topiramate, pregabalin, levetiracetam, zonisamide) is limited, however, and their effect on the developing fetus is uncertain.

Patients must take medication as prescribed, and treatment should be controlled by frequent monitoring of the plasma concentration of the anticonvulsant drug. Monthly follow-up visits during pregnancy usually permit satisfactory supervision of the patient. At the initial visit, trough values of total and free concentrations of each drug should be measured. Total levels should then be measured each month in patients whose seizures are well controlled; free levels should be monitored monthly in those with poor seizure control, seizures during pregnancy, or a marked (>50%) decline in total level. Poor compliance with an anticonvulsant drug regimen can often be improved by encouragement and by explaining the importance of taking medication regularly. Simplifying the dosage schedule so that medication is taken just once or twice daily may be helpful.

As the pregnancy continues, the dosage of the anticonvulsant drug may need to be increased if seizures become more common,

or the free level of the anticonvulsant drug declines by more than about 30%. In some instances, the required dosage may reach a level that would probably cause toxic side effects in a nonpregnant patient. If the anticonvulsant dosage is increased during the pregnancy, reductions will probably be necessary in the puerperium to prevent toxicity, but this change must be based on clinical evaluation and measurement of the plasma concentration of the drug, because the period over which drug requirements decline varies considerably. Because of the poorly defined risks of increased obstetric complications among pregnant epileptic women, close supervision of these patients by the obstetrician is mandatory, and delivery in a hospital is advised.

After delivery, the infant must be inspected for congenital malformations and given an injection of vitamin K₁ (1 mg/kg intramuscularly). Clotting factors may be studied after about 4 hours, and further injections of vitamin K₁ can be given if necessary. If hemorrhage occurs, infusions of fresh-frozen plasma or of factors II, VII, IX, and X may also be necessary. Breastfeeding of a healthy infant by an epileptic mother should not be discouraged. The effect of enzyme-inducing anticonvulsants on oral contraceptives and implantable progestins should be discussed.

Headache

Headache is a common complaint and may have many causes. Among patients attending headache clinics, symptoms are most frequently attributed to migraine or tension-type headaches. Tension-type headaches are commonly chronic, last all day, are worse in the evening, may be described as having a tight quality, may be accompanied by local soreness and concern about lumps or bumps on the head, and are often accompanied by poor concentration and nonspecific symptoms such as dizziness. The pain frequently commences or is most intense in the neck and the back of the head. If treatment with over-the-counter analgesics (e.g., acetaminophen) is unsuccessful, a trial of antimigraine preparations may be worthwhile.

Most patients presenting with headache do not have severe underlying structural disease, but it is important to consider this possibility. About one third of patients with brain tumors present with a primary complaint of headache. The headache in such patients is often an intermittent, dull, nonthrobbing ache that is exacerbated by exercise and may be associated with nausea or vomiting, but these features do not in themselves permit any reliable distinction from migraine. Similarly, the severity of the headache is unhelpful in this regard. Headaches that disturb sleep, however, suggest an underlying structural lesion, as do exertional headaches and late-onset paroxysmal headaches.

The duration and course of a headache provide a guide to the underlying cause. A long history of chronic headache without other accompaniments is unlikely to reflect serious disease unless associated with drowsiness, visual disturbances, limb symptoms, seizures, intellectual changes, or other neurologic symptoms. The sudden development of severe headache in a previously well patient is more ominous and may be caused by acute intracranial abnormality (e.g., subarachnoid hemorrhage), glaucoma, or another condition requiring specific treatment.

The evaluation of patients with headaches demands a full general and neurologic examination together with an assessment of mental status. Headaches accompanied by systemic

symptoms and signs such as fever, stiff neck, or rash, and those in patients with cancer or underlying immunodeficiency may point to a structural lesion or infection. It may be necessary to include examination of the teeth, eyes (including the optic disc), paranasal sinuses, and urine, and various investigative procedures may be indicated, depending on the initial clinical impression. If intracranial disease is suspected on the basis of the history or presence of neurologic signs, the need for computed tomography (CT) or MRI of the head and examination of the cerebrospinal fluid must be decided on an individual basis. Cranial arteritis and cervical spondylosis are important causes of headache but are not expected among patients in the child-bearing age group.

Post-traumatic headaches usually pose no diagnostic problem because of the relationship to previous injury, and they usually respond to simple analgesics or antimigraine preparations. Acute sinusitis typically produces a localized, throbbing headache accompanied by tenderness; the relationship of symptoms to a respiratory tract infection and the radiologic findings permit the diagnosis to be made with confidence, and treatment is directed at the underlying infection.

MIGRAINE

Among women of childbearing age, migraine is an important cause of headache. Women with migraine outnumber men by a factor of two or three.¹⁶ Migraine with aura, in which episodic headache is preceded by visual, sensory, or motor symptoms, affects 20% of migraine sufferers. Typical auras are visual, with photopsias (flashes of light), scintillations (flickering lights), scintillating scotoma (areas of visual loss surrounded by flickering light), or fortification spectra (jagged, bright zigzags of light) most commonly described. Other focal neurologic symptoms preceding or accompanying the headache may include tingling, numbness, weakness, or impairment of consciousness. The remaining 80% of migraineurs do not experience premonitory focal symptoms. Headaches may be lateralized or generalized, usually have a gradual onset, and usually last for less than a day, although they may persist for longer. They may be dull or throbbing; are commonly accompanied by nausea, vomiting, and photophobia; and are often associated with blurring of vision, lightheadedness, and scalp tenderness. Positive visual and sensory phenomena are important diagnostic clues for migraine, but in patients with purely negative symptoms or focal weakness, structural or vascular brain disease should be considered.

Many women with migraine link the periodicity of some of their attacks to the menstrual cycle, with headaches occurring usually just before or during menstruation. Migrainous attacks without aura are most likely to be related to the menstrual cycle.¹⁷ Some patients may have headaches that occur only in relation to the menstrual cycle, although this pattern is much less common. The manner in which hormonal factors provoke migraine remains unclear, although some evidence suggests that the drop in estrogen that precedes menstruation is a trigger.¹⁷

Migraine headaches are commonly exacerbated in women using oral contraceptives, but improvement can occur in some patients. Such exacerbation usually becomes apparent within the first few months of oral contraceptive use. Preparations with a relatively high estrogen content are most likely to influence the headache pattern and are generally not as well tolerated as

low-estrogen preparations. Migraines are more likely to occur during the hormone-free week, and in such cases eliminating the hormone-free interval can be an effective strategy.¹⁸ Because migraine with aura and combined oral contraceptives are both risk factors for stroke, most advocate avoiding combined oral contraceptives in patients with migraine with aura, but progestin-only pills are considered a safe option.¹⁹ However, a large meta-analysis of cohort and case-control studies did not demonstrate that migraine modifies the increase in stroke risk observed with combined oral contraceptives,²⁰ and current American Stroke Association guidelines do not recommend avoiding combined oral contraceptives in women with migraine.²¹ Nevertheless combined oral contraceptives should be avoided in patients with migraine with aura, but they are probably safe in migraine without aura, especially if a preparation containing less than 25 µg of ethinyl estradiol is used.¹⁸

Migraine often improves considerably after the first trimester of pregnancy, regardless of whether the attacks are related to the menstrual cycle. It occasionally worsens or occurs for the first time during pregnancy, most commonly during the first 3 months of gestation.²² The response of migraine to pregnancy does not correlate with sex of the fetus or with differences in plasma levels of hormones.

Management of migraine consists of the avoidance of precipitating factors coupled with prophylactic or abortive drug treatment, if necessary. In general populations, when simple analgesics do not abort the headache, treatment with extracranial vasoconstrictors (e.g., ergotamine, dihydroergotamine), serotonin agonists (e.g., sumatriptan), phenothiazines (e.g., prochlorperazine), or other drugs may be necessary. For migraineurs suffering more than three headaches per month, prophylactic treatment with β -blockers (e.g., propranolol), calcium channel blockers (e.g., verapamil), or tricyclic antidepressants (e.g., amitriptyline) is usually offered. Although menstrual migraine should be treated with the same approach as nonmenstrual migraine, the predictable timing of the headaches allows other strategies, such as a short course of twice-daily triptans or transdermal estradiol perimenstrually.²³

During pregnancy, medication is best avoided if possible. Dietary and other precipitants of headache should be avoided. Biofeedback and relaxation should be attempted and the patient reassured that most women experience a decrease in headache frequency as pregnancy proceeds. When drugs are required, simple analgesics should be used. Acetaminophen is preferred over aspirin and other nonsteroidal anti-inflammatory drugs, because the latter are weakly associated with miscarriage in the first trimester and premature ductus closure in the third. Similarly, caffeine is an effective migraine abortive that is probably safe in pregnancy, although it has also been associated with increased rates of miscarriage in the first trimester. Metoclopramide is an effective migraine abortive that is probably safe in pregnancy.²⁴ Triptans should be avoided during pregnancy because they may be associated with premature labor, although there is increasing evidence they are not teratogenic.²⁵ As a last resort, opiates can be considered, although these are associated with rebound headaches and medication-overuse headache. An effort should be made to avoid ergotamine-containing preparations because of the effect this drug may have on the gravid uterus and its potential teratogenicity. Propranolol is also best avoided during pregnancy because it is associated with intrauterine growth restriction and may lead to β -adrenergic blockade, hypoglycemia, and

hypothermia in the fetus or newborn.²⁴ In patients with frequent headaches, comorbidities such as depression require special consideration.

A study of the possible association of maternal migraine during pregnancy with outcome revealed that women with severe migraine have a higher prevalence of preeclampsia and severe nausea or vomiting but a lower prevalence of threatened abortion and preterm delivery.²⁶ This did not appear to influence delivery outcome.

POSTNATAL HEADACHE

About a third of women experience headaches in the week after delivery, and most of them have a personal or family history of migraine. The headaches, which are usually mild and bifrontal, respond well to simple analgesics and are self-limited.

Tumors

Any type of intracranial tumor can appear during the gestational period, and accurate diagnosis may then be delayed because symptoms are erroneously ascribed to toxemia of pregnancy. Although the relationship between the tumor and pregnancy is usually fortuitous, pituitary adenomas, meningiomas, neurofibromas, hemangioblastomas, and vascular malformations occasionally exhibit relapses in relation to pregnancy, with symptoms developing or rapidly worsening during gestation, remitting to some extent after delivery, and recurring in a subsequent pregnancy. Attention here focuses on the aspects of intracranial tumors that relate to pregnancy, rather than on a more general account of intracranial neoplasms.

Visual field defects sometimes develop during pregnancy in patients with a pituitary adenoma or a craniopharyngioma, which must be excluded in such circumstances. Meningiomas in the suprasellar or parasellar region or on the medial sphenoidal wing may produce symptoms such as diplopia and unilateral scotoma or ptosis, which relapse and remit in relationship to pregnancy over several years. Symptoms tend to develop in the last 4 months of gestation and often lead to a mistaken initial diagnosis of multiple sclerosis. Early surgical intervention may help to preserve vision and prevent other neurologic catastrophes.

Symptoms caused by acoustic neuroma may begin or may be aggravated in the latter stages of pregnancy.^{27,28} The symptoms in different patients include hearing loss, tinnitus, headaches, vertigo, dysequilibrium, facial weakness, and diplopia. Aggravation of symptoms in one pregnancy does not necessarily indicate that exacerbation will occur in subsequent ones. Cerebellar hemangioblastomas,²⁹ medulloblastomas,³⁰ and other tumors may occur during pregnancy. Atypical psychiatric symptoms in the antenatal or postnatal period may result from an intracranial structural lesion that is unrecognized unless the patient is examined neurologically and investigated by neuroimaging studies.

How pregnancy may precipitate or exacerbate symptoms caused by intracranial tumors is unclear. The most likely explanation is that pregnancy leads to a slight increase in the size of the tumor. Tumors with symptoms consistently related to pregnancy are usually located so that only slight enlargement leads to significant involvement of important neural structures. Symptoms of spinal meningiomas may be exacerbated by pregnancy, but convexity meningiomas, which have room for

Figure 65-1 Computed tomography (CT) of a pituitary adenoma. CT shows an enhancing lesion (arrow) in the suprasellar cistern. More inferior axial scans showed this lesion arising from the sella.

expansion, are unlikely to show any particular relationship of symptoms to pregnancy.

Several possibilities have been advanced to account for the manner in which pregnancy might influence tumor size. Suggested mechanisms include accelerated growth rate, vascular engorgement, and increased fluid content, but supportive evidence for these proposals is lacking. Nevertheless, there is accumulating evidence for sex steroid-binding sites in a number of human tumors, especially meningiomas.³¹ The presence of such receptors in tumors suggests that the natural history of these tumors may be modified by these hormones or their antagonists.

Patients with intracranial neoplasms may have nonspecific symptoms of cerebral dysfunction, with evidence of raised intracranial pressure or some characteristic combination of symptoms and signs that reflect the location of the lesion. The history and physical findings guide the manner in which these patients are evaluated further. MRI or CT of the head (Fig. 65-1 and e-Fig. 65-2) can provide an enormous amount of additional information noninvasively. MRI is more sensitive for the diagnosis of an intracranial tumor and is safe in pregnant women because it does not involve exposure to radiation. When CT or other radiologic investigations are necessary, shielding may help to protect the fetus from excessive radiation.

Each patient must be treated on an individual basis, and essential neurosurgical treatment should not be delayed because of the pregnancy. For pituitary adenomas or other benign tumors encountered in the latter half of pregnancy, operations can sometimes be delayed until a more propitious time if the patient is carefully observed. However, signs of increased intracranial pressure, visual deterioration, an increasing neurologic deficit, or the clinical features of an infratentorial lesion mandate early or immediate intervention. For patients with pituitary adenomas, pharmacologic intervention (e.g., corticosteroids,

bromocriptine) may be adequate. In most instances, visual disturbances improve spontaneously after delivery, regardless of any pharmacologic measures. Cranial irradiation during the first trimester for the treatment of malignant brain tumors is associated with an increased risk of fetal loss or malformation; during later pregnancy, it is associated with an increased risk of childhood leukemia.³²

In general, pregnancy can be allowed to proceed—at least until the fetus is viable and often to term—in patients with intracranial neoplasms; however, therapeutic abortion may be justifiable for some patients with malignant brain tumors and if significant symptoms, such as uncontrollable seizures, occur during pregnancy, particularly when the tumor cannot be removed completely. Obstetric management must also be determined on an individual basis. Some investigators have proposed that delivery by cesarean section is safer than spontaneous vaginal delivery in women with cerebral tumors because the vaginal delivery may enhance any increase in intracranial pressure caused by the neoplasm. However, vaginal delivery with adequate regional anesthesia and judicious shortening of the second stage of labor by use of low forceps (to prevent any increase in intracranial pressure associated with the abdominal pushing efforts of this stage) is often satisfactory.

Pregnancy may be followed by the development of chorio-carcinoma, which commonly metastasizes to the brain (see Chapter 56).³³ Neurologic presentation is typically with symptoms of a space-occupying cerebral lesion or with an acute deficit resulting from hemorrhage into the lesion. Treatment of cerebral metastases may involve chemotherapy, radiation therapy, and, for isolated metastases, surgery.

Pseudotumor Cerebri

Benign intracranial hypertension is associated with pregnancy and with the use of oral contraceptive preparations. When symptoms do develop during pregnancy, they usually occur in the first trimester or the month after delivery, but they may occur at any time during the gestational period. Symptoms consist of headache and visual disturbances caused by papilledema and sometimes diplopia resulting from abducens weakness. The patient looks well despite the grossly abnormal appearance of the optic disks, and MRI does not reveal any evidence of a space-occupying lesion. Although lumbar puncture reveals increased pressure of the cerebrospinal fluid, the composition of the fluid is unremarkable. The possibility of intracranial venous sinus thrombosis must be considered when the patient is being evaluated.

Although benign intracranial hypertension is self-limiting, remission may not occur until well after delivery. Subsequent pregnancies are not risk factors for recurrence, although the disorder has been reported to recur in a subsequent pregnancy.³⁴ If the condition is left untreated, there is a risk of secondary optic atrophy and subsequent permanent impairment of vision. Several therapeutic approaches to lowering intracranial pressure have been reported, including use of high-dosage steroids, acetazolamide, furosemide, repeated lumbar punctures or continuous lumbar drainage, and lumboperitoneal or other shunting procedures. Acetazolamide is generally the first-line therapy for nonpregnant patients, and it has been used safely during pregnancy.³⁵ Even though the condition tends to improve after delivery, it can usually be managed with the aforementioned

measures and therapeutic abortion is not necessary.³⁶ There are no specific obstetric complications, and the patient can be expected to give birth to a normal infant.

Occlusive Cerebrovascular Disease

Cerebrovascular disease may develop during an otherwise normal pregnancy as a result of arterial or venous occlusion. Estimates of stroke incidence during pregnancy vary widely, from 4.3 to 210 strokes per 100,000 deliveries, but it seems clear that pregnancy increases the risk of cerebral infarction.³⁷ The risk seems to be greatest in the few days around the time of delivery.³⁸

ARTERIAL OCCLUSIVE DISEASE

Arterial disease is not unusual, even in the absence of diabetes or severe hypertension, in women of childbearing age. Major arterial occlusion accounts for most cases of nonhemorrhagic hemiplegia that develop during pregnancy or the puerperium.³⁹ Numerous cases of occlusion of the middle cerebral artery or one of the other major intracranial arteries have been described during pregnancy, with occlusion usually occurring in the third trimester or the postpartum period. Such a stroke is usually caused by the development of a thrombus on a preexisting atheromatous plaque. Predisposing factors may be age, anemia, hormonal influences, hypertension, diabetes, smoking, migraine headaches, increased platelet aggregation, reduced tissue plasminogen activity, changes in blood coagulation factors (especially factors V, VII, VIII, IX, X, and XII and fibrinogen) during late pregnancy, preeclamptic toxemia with hypertension, and puerperal septicemia.³⁷ Other causes of stroke in young women include protein C, protein S, and antithrombin III deficiencies; hyperhomocysteinemia; arteritis; meningovascular syphilis; sickle cell disease; antiphospholipid antibodies; polycythemia and other hematologic disorders; prosthetic cardiac valvular disease; and cardiomyopathy.

An embolus resulting from rheumatic or ischemic heart disease, subacute bacterial endocarditis, or a cardiac myxoma may occur. Rare instances of arterial occlusion by paradoxical embolization from a pelvic vein through a patent foramen ovale have also been described. Rarely, a fat, air, or amniotic fluid embolism may occur in relation to childbirth and may have a fatal outcome.⁴⁰ Hypotension as a consequence of hemorrhage or related to anesthesia during labor may lead to watershed cerebral infarction.

Transient cerebral ischemic attacks may precede occlusion of one of the major intracranial arteries. The neurologic disorder and the underlying arterial disease must be investigated and treated as in nonpregnant patients. Investigations should include complete blood cell count, blood smear, erythrocyte sedimentation rate, fasting serum cholesterol and triglyceride levels, prothrombin and partial thromboplastin times, electrocardiogram, echocardiography, and radiologic procedures. CT is an important means of excluding intracranial hemorrhage, although MRI may be preferable to avoid radiation exposure to the fetus. Carotid ultrasound is necessary to rule out carotid stenosis in anterior circulation strokes. CT or magnetic resonance angiography and venography are helpful to diagnose arterial occlusion or venous sinus thrombosis. Pregnancy is not an absolute contraindication to thrombolytic agents—tissue

plasminogen activator has been used safely and effectively in pregnant patients—although they may increase the risk of miscarriage.⁴¹

Aspirin is indicated within 48 hours of ischemic stroke or transient ischemic attack.⁴² Anticoagulation is reserved for patients with atrial fibrillation, mechanical heart valves, certain hypercoagulable states, or venous occlusive disease.⁴³ Warfarin is best avoided, if possible, because it crosses the placenta and increases hemorrhagic complications, and because of the risks for teratogenicity and fetal wastage, especially during the first trimester.⁴⁴ Patients requiring anticoagulation during pregnancy are maintained instead on subcutaneously administered heparin, which is usually discontinued when labor begins and resumed about 12 hours after vaginal delivery or 24 hours after cesarean section. Carotid endarterectomy should be performed for severe carotid stenosis (70% to 99%) and can be considered for moderate stenosis (50% to 69%), although the benefit in women with moderate stenosis is not clear.⁴⁵ With regard to subsequent obstetric management, vaginal delivery, unless specifically contraindicated, is preferable to cesarean section. Other diseases that may be associated with arterial occlusive disease in pregnancy (e.g., eclampsia, thrombotic thrombocytopenic purpura) are discussed in Chapters 48 and 55.

A noninflammatory cerebral angiopathy may complicate an otherwise normal pregnancy or the postpartum period (Fig. 65-3). The presentation typically involves a thunderclap headache, and the vasculopathy can be complicated by infarction and intracranial or subarachnoid hemorrhage. It is sometimes associated with hypertension or the use of vasoactive drugs, and, although it may simulate vasculitis, it is typically treated with calcium channel blockers as opposed to immunosuppression.⁴⁵

Figure 65-3 Internal carotid angiogram. The angiogram shows multiple areas of segmental narrowing (arrows) in a patient with a noninflammatory angiopathy known as reversible cerebral vasoconstriction syndrome, which can occur during the postpartum period.

INTRACRANIAL VENOUS OCCLUSIVE DISEASE

Intracranial venous occlusive disease is an uncommon complication of pregnancy and childbirth. When the thrombosis occurs in the first trimester, it usually follows a complication such as spontaneous abortion, therapeutic abortion, or stillbirth, but it may occur in an otherwise normal pregnancy. Intracranial venous thrombosis is more likely in the third trimester or in the puerperium and is sometimes related to preeclampsia.

Intracranial venous thrombosis is characterized clinically by headache, weakness, focal or generalized convulsions, drowsiness, and confusion. Disturbances of speech, sensation, or vision may also occur, and patients may have mild pyrexia. There may be signs of meningeal irritation resulting from subarachnoid bleeding caused by cortical infarction, and fluctuating hypertension is sometimes found. Papilledema may be present, particularly if the superior sagittal sinus is involved. The cerebrospinal fluid pressure may be increased, and the protein or cell content is often elevated; occasionally, the fluid is stained with frank blood. The diagnosis may be confirmed by CT and magnetic resonance angiography, which are also necessary to exclude arterial pathology and vascular malformation (Figs. 65-4 and 65-5). The symptoms and signs of intracranial venous thrombosis are sometimes mistakenly ascribed to

Figure 65-4 Superior sagittal sinus thrombosis. Computed tomography shows curvilinear areas of high density, which represent cortical venous thromboses and adjacent parenchymal venous infarcts.

Figure 65-5 Intracranial venous thrombosis. A 26-year-old woman presented in the middle trimester of pregnancy with headache, and she had bilateral papilledema. The brain appeared normal in imaging studies. This coronal view of her magnetic resonance venogram (obtained using a two-dimensional time-of-flight technique) shows loss of flow-related enhancement in the left transverse sinus (arrows), which is consistent with thrombus formation.

eclampsia, but the absence of previous signs of preeclampsia should help prevent diagnostic confusion.

The prognosis is grave, with a 15% rate of death and dependency, based on the pooled results of multiple cohort studies.⁴⁶ However, in some series, as many as 80% of patients have an excellent recovery, although lasting neuropsychiatric deficits may have been underreported. Intracranial venous thrombosis is not a contraindication to future pregnancy; the risk of recurrence is probably around 1%.⁴⁶ Women with an intracranial venous thrombosis have a higher risk for early spontaneous abortion with subsequent pregnancies.

The etiologic basis of aseptic intracranial venous thrombosis is uncertain; coagulation abnormalities, changes in the constituents of the peripheral blood, and intimal damage to the dural sinuses have been suggested as causes. Inherited prothrombotic states that have been associated with intracranial venous thrombosis include protein C, protein S, and antithrombin III deficiencies, factor V Leiden deficiency, and hyperhomocysteinemia. In addition to pregnancy and oral contraceptive use, other acquired conditions associated with intracranial venous thrombosis are the antiphospholipid antibody syndrome and systemic malignancy. Testing for these conditions in young women with either arterial or venous occlusive disease is reasonable.⁴⁶ On the basis of several small randomized trials and additional observational studies, anticoagulation with unfractionated or low-molecular-weight heparin is recommended, even in the presence of associated intraparenchymal hemorrhage.⁴⁶ Anticonvulsant drugs may be necessary if

seizures have occurred; treatment of raised intracranial pressure with osmotic agents (e.g., mannitol) or neurosurgical intervention may also be required. Labor can usually be allowed to commence spontaneously, with forceps assistance of delivery, if the thrombosis occurred early in pregnancy. If thrombosis occurs shortly before or during labor, however, cesarean section may be necessary. Anticoagulation should be continued after delivery for at least 3 to 6 months.

PITUITARY INFARCTION

Sheehan syndrome is a well-recognized complication of the peripartum period (see Chapter 61).

Intracranial Hemorrhage

Intracerebral hemorrhage and subarachnoid hemorrhage occur with approximately equal frequencies during the peripartum period, with the majority of cases occurring after delivery.^{47,48} Sudden, severe headache, sometimes accompanied by nausea and vomiting, is the main symptom of subarachnoid hemorrhage. Examination reveals signs of meningeal irritation that may be accompanied by depressed consciousness, cranial nerve abnormalities, and a neurologic deficit in the limbs. Patients with intracerebral hemorrhage usually present with focal neurologic deficits that depend on the location of the blood.

In patients in whom subarachnoid hemorrhage complicates otherwise normal pregnancies, the underlying source is less often an aneurysm than in nonpregnant patients with subarachnoid hemorrhage.⁴⁷ Other, less common causes of intracranial hemorrhage include arteriovenous malformations (AVMs), mycotic aneurysms, vasculitides, various hematologic disorders, disseminated intravascular coagulation, eclampsia, and metastatic choriocarcinoma. Treatment focuses on the underlying cause. Although bleeding may occur at any time during the pregnancy, aneurysms are somewhat more likely to bleed in the latter half of the gestational period.

Cerebral AVMs, which are located supratentorially in at least 70% of patients, may appear at any age. Intracerebral or subarachnoid hemorrhage is the most common manifestation, and the peak age for hemorrhage is between 15 and 20 years. The mortality rate for an initial hemorrhage is approximately 10%, but this has varied in different series; survivors are more likely to experience further hemorrhage than patients who have never had one. Other patients with intracranial angiomas may present with focal or generalized seizures, headache, focal neurologic deficits, or nonspecific neurologic symptoms. There is still some controversy as to whether intracranial AVMs are more likely to bleed during pregnancy, but the most recent data suggest that this is not the case, and the presence of a known AVM should not preclude pregnancy.^{49,50}

Intracranial saccular aneurysms arise from a developmental arterial defect, and with increasing age, they become more common sources of hemorrhage than AVMs. They are usually located at sites of vessel branching, commonly occurring in relationship to the anterior or posterior communicating arteries. Although such aneurysms sometimes cause focal symptoms that relate to compression of neighboring structures, patients usually present with hemorrhage that occurs without warning because of aneurysmal rupture. This type of hemorrhage seems to occur more commonly in the late stages of pregnancy or after the birth,⁴⁷ and occurrence during labor and delivery has been

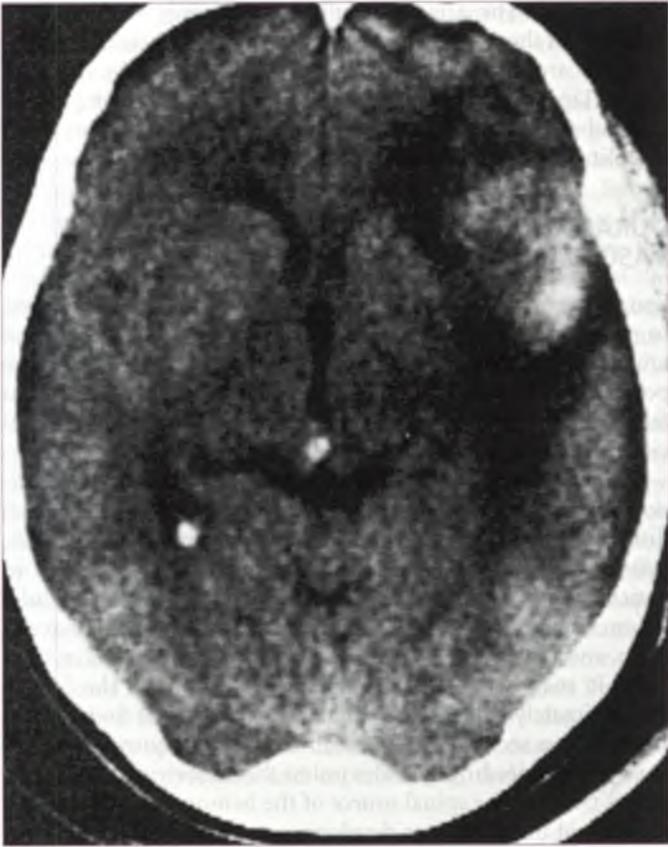

Figure 65-6 Evaluation of intracranial hemorrhage. Computed tomography shows hemorrhage into the sylvian fissure and adjacent parenchyma, with surrounding edema or ischemia. The findings are indicative of subarachnoid and intracerebral hemorrhage and localize the source of bleeding to the middle cerebral artery.

reported only rarely. In addition to the signs of subarachnoid hemorrhage, focal or lateralizing neurologic signs may be present and help to localize the source of bleeding.

In the evaluation of patients presenting with symptoms of intracranial hemorrhage, the first diagnostic study performed is usually a CT of the head, which is a reliable means of detecting recent subarachnoid or intracerebral hemorrhage and may permit the source of bleeding to be identified (Fig. 65-6). In patients with AVMs, nonhomogeneous areas of mixed density with irregular calcifications are typical, and vermiform areas of enhancement are seen after infusion of contrast material. Aneurysms are seen as small, round, dense areas after infusion of contrast material and are sometimes evident even without contrast. If CT findings are normal, the cerebrospinal fluid should be examined and angiography performed if the fluid is blood-stained or xanthochromic.

Angiography enables the identity of the lesion to be established with certainty and provides important additional information concerning its anatomic features (Fig. 65-7). Special shielding during this and other radiologic procedures should be provided for pregnant patients. All the major intracranial vessels should be opacified; feeding vessels to AVMs sometimes arise from the contralateral side, and many aneurysms may be seen. Angiography does not always reveal the malformation in a patient with a suspected AVM, possibly because the lesion was

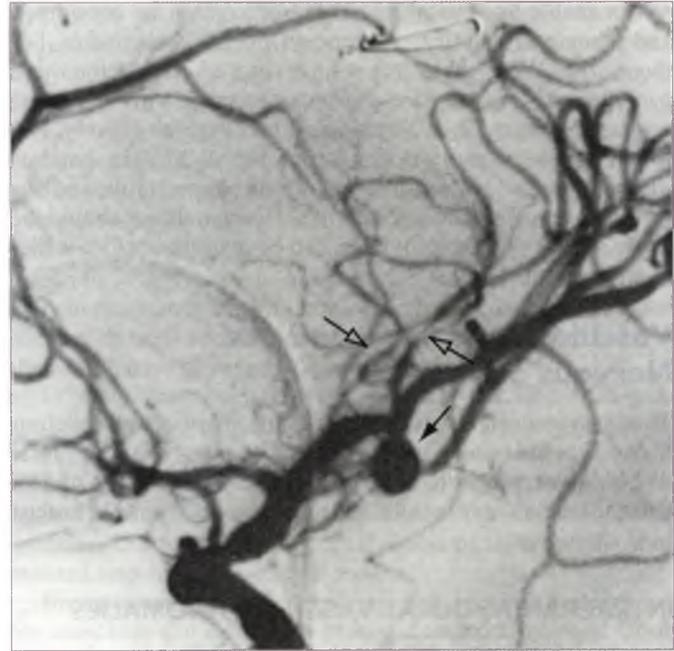

Figure 65-7 Evaluation of aneurysm. In the carotid angiogram of the patient seen in Figure 65-6, an aneurysm (solid arrow) is shown at the trifurcation of the middle cerebral artery. There is some spasm of vessels in the vicinity of the aneurysm (open arrows).

small and destroyed itself when it bled (i.e., cryptic malformation). Nevertheless, if angiography shows neither an AVM nor an aneurysm in a patient presenting with subarachnoid hemorrhage, the study should be repeated after about 14 days, because vascular spasm after a bleed may obscure an aneurysm.

The management of subarachnoid hemorrhage consists of bed rest, with sedation and analgesia as necessary and operative or endovascular treatment of the underlying lesion if feasible. In aneurysmal subarachnoid hemorrhage, the systolic blood pressure is usually lowered below 160 mm Hg until the aneurysm is secured. Surgical treatment is aimed at preventing further hemorrhages, but induction of hypotension during the course of the intracranial surgery should be avoided unless it is essential, because it may be followed by premature labor or fetal death; hypothermia is well tolerated.

If the anomalous vessels constituting an AVM are surgically accessible and do not involve a critical vessel or area of the brain, they can often be excised. Surgery is commonly preceded by embolization of the main vessels feeding the malformation in an attempt to reduce its size. Other oblitative techniques have been developed. The optimal time for treatment of an AVM is uncertain, but therapeutic intervention can sometimes be delayed until after childbirth.⁵¹ In the patient with an aneurysm that has bled, the risk of further bleeding is much greater, and oblitative treatment, if indicated by the angiographic findings and the condition of the patient, should not be delayed because of the pregnancy.⁵¹ An endovascular approach carries lower morbidity and is favored increasingly over surgery, depending on the location and angiographic characteristics of the aneurysm.⁵²

In patients with aneurysms that have been successfully obliterated, pregnancy and delivery can usually proceed normally. In women who present early during pregnancy with AVMs that

are amenable to surgical resection, surgery can be considered and labor and delivery can proceed normally thereafter. For those with AVMs that carry a high surgical risk or for those patients who present late during pregnancy, some advocate cesarean delivery or at least a modified vaginal delivery, followed by postpartum treatment of the AVM.⁵¹ In patients showing a steady deterioration in neurologic status and for whom a fatal outcome seems likely, preparations should be made so that the fetus, if viable, can be delivered before it dies of anoxia.

Vascular Anomalies and the Nervous System

The most important vascular anomalies that occur in relation to the nervous system are intracranial aneurysms and cerebral AVMs (discussed earlier). However, several other types of vascular anomalies may manifest during pregnancy, and they merit brief discussion.

INTRACRANIAL DURAL VASCULAR ANOMALIES

Certain intracranial dural vascular anomalies may become evident for the first time during pregnancy. They consist of abnormal arteriovenous shunts involving meningeal branches of the carotid and vertebral arteries and the dural veins and sinuses. Although some represent a developmental anomaly, others are acquired in adult life, occasionally after trauma, presumably because of the close anatomic relationship of certain meningeal arteries and veins.

Shunts involving the anteroinferior group of dural sinuses (i.e., cavernous, intercavernous, sphenoparietal, superior and inferior petrosal, and basilar plexus) are characterized clinically by unilateral orbital or head pain, diplopia, a red or protruding eye, and tinnitus. The onset of symptoms sometimes follows abortion or occurs in the postpartum period, possibly because of rupture of the thin-walled dural arteries during the straining of labor or because of the circulatory changes that occur in pregnancy.

On examination, there is usually a mild proptosis, distended conjunctival veins, increased intraocular pressure, transient sixth nerve palsy, or a bruit over the eye. Angiography reveals a low-volume shunt supplied from meningeal branches of the internal or external carotid arteries, sometimes from the contralateral side. Drainage may be directly into the cavernous sinus or into a more distant dural sinus or venous structure that communicates with the cavernous sinus. The fistula may close spontaneously, but if it remains patent, embolization of the feeding vessels may help to relieve intolerable symptoms or failing vision.

Arteriovenous shunts to the superoposterior group of dural sinuses (i.e., superior and inferior sagittal, straight, transverse, sigmoid, and occipital) may occur, with a female predominance among the reported cases. Symptoms and signs may relate to the shunt itself, to subarachnoid hemorrhage, to increased intracranial pressure, or to cerebral ischemia.

Tinnitus is the most common complaint, but headache, visual deterioration, subarachnoid hemorrhage, seizures, and various neurologic deficits may also occur. A bruit is often present and may be the sole finding on examination; it is best heard over the mastoid region or behind the ear. Papilledema may be present, and other neurologic signs are sometimes

encountered. The arterial supply is commonly derived from branches of the external carotid artery, tentorial branches of the internal carotid artery, and meningeal branches of the vertebral artery. Ligation or embolization of feeding vessels or a direct surgical approach to the lesion may be helpful in patients with disabling symptoms or a history of hemorrhage.

DURAL AND INTRADURAL SPINAL VASCULAR ANOMALIES

Spinal arteriovenous fistulas are uncommon but are important to recognize because many are readily treated by surgery. Most are dural; if intradural, they are commonly extramedullary, are posterior to the cord, and are fed by one or more arteries that fail to supply the cord or contribute only to the posterior spinal circulation.⁵³

Spinal arteriovenous fistulas may lead to spinal subarachnoid hemorrhage but more commonly give rise to a gradual disturbance in the function of the cord or nerve roots, or both. Spinal subarachnoid hemorrhage is much more common in patients with a cervical malformation than a more caudal lesion, may sometimes occur from an associated (arterial) aneurysm, and is associated with an overall mortality rate of at least 15%. It may be the first symptom produced by the lesion. Approximately half of the patients who survive the first hemorrhage have a second, and one half of the subsequent survivors have further bleeding episodes unless the underlying malformation is treated. The spinal source of the hemorrhage may not be recognized until the later development of symptoms and signs of cord dysfunction, despite the local occurrence of sudden severe pain at the onset of bleeding, accompanied by signs of meningeal irritation.

Myelopathy or radiculopathy, or both, of gradual or sudden onset, is the more common manifestation. By the time of diagnosis, approximately two thirds of patients complain of leg weakness, sensory symptoms, pain, and a sphincter disturbance. In some patients, symptoms, especially pain, are precipitated or aggravated by exercise and relieved by rest, whereas symptoms in other patients may relate to specific postures, such as sitting or bending forward. Symptoms occasionally relate to pregnancy, the menstrual cycle, nonspecific infective illness, a transient increase in body temperature, or trauma. On examination, signs of an upper or lower motor neuron disturbance or a mixed motor deficit are usually found in the legs; sensory deficits are common and are usually extensive, but occasionally they are restricted to a radicular distribution. There may be a coexisting cutaneous angioma that occasionally relates segmentally to the spinal lesion, and a bruit may be audible over the spine on auscultation.

Numerous case reports illustrating the influence of pregnancy on these lesions have been published. In one case that we encountered, symptoms occurred during each of three pregnancies, with complete clearing after delivery. Their basis was not recognized until the patient later experienced leg weakness and urinary retention that necessitated immediate hospitalization. Myelography and spinal angiography then demonstrated an arteriovenous malformation that was treated surgically.

The relationship of symptoms to pregnancy in such cases may be based in part on enhancement of preexisting cord ischemia by hemodilution and anemia. Moreover, pressure on pelvic and abdominal veins by an enlarged uterus may aggravate symptoms of caudally situated malformations by obstructing

venous return to the heart, with a consequent reduction in the intramedullary arteriovenous pressure gradient and in cord blood flow.⁵³

Diagnosis depends on radiologic investigations, which must not be postponed out of concern for the developing fetus, because any delay in establishing the diagnosis may lead to increased, often irreversible, disability in the mother. Spinal MRI is an excellent screening test. If it suggests a vascular malformation, spinal angiography is undertaken to determine the level and extent of the vascular abnormality; the position of the arteriovenous shunt in relationship to the cord; the number, origin, and anatomic location of arteries feeding the malformation; and the main supply to the cord in the region of the malformation.

Treatment is indicated in all patients who have progressive symptoms or functional incapacity or who have had a hemorrhage. Delay in these cases may lead to irreversible disability or death. When the fistula is dural or intradural, but mainly or completely extramedullary, is posterior to the cord, and is fed by vessels that do not contribute to the anterior spinal circulation, surgical treatment or embolization generally poses no specific problem. Feeding vessels are obliterated, and the fistulous portion of the lesion is removed. Fistulas located anterior to or in the cord are more difficult to treat because of their inaccessibility and because they are often supplied by the anterior spinal artery or one of its feeders. These lesions are often regarded as inoperable, and experience in their treatment is limited.

Infections

The central nervous system may be infected by bacterial, viral, fungal, or other organisms through the blood supply, by extension from infected adjacent structures, or by direct inoculation such as may follow trauma. The neural parenchyma may be involved diffusely (e.g., encephalitis) or focally (e.g., cerebral abscess), or infection may involve primarily the meninges and parameningeal structures (e.g., meningitis, subdural empyema). Although the resulting neurologic disorder may complicate pregnancy or delivery or may necessitate antimicrobial therapy that can harm the developing fetus, the clinical features, diagnosis, and management of infections during pregnancy are essentially the same as at other times. Further discussion is limited to certain infections that pose some particular problem when they occur during pregnancy or are especially likely to develop in relationship to pregnancy.

POLIOMYELITIS

The development of an effective vaccine has all but eradicated paralytic poliomyelitis in developed countries. Even pregnant women can be included safely in programs of mass vaccination with live oral poliovirus vaccine.⁵⁴ Nevertheless, the disorder still occurs in unprotected persons and remains common in many parts of the world. Moreover, people with residual disability from previous poliomyelitis are seen fairly regularly in most large medical centers, and obstetric management of such patients may be complicated by their neurologic deficits.

Most patients infected with poliovirus are asymptomatic or have only minor, nonspecific respiratory or gastrointestinal symptoms. Nervous system involvement occurs in only a few instances; its clinical manifestations are described in standard

neurologic textbooks. Patients with neurologic involvement should be hospitalized, with care taken to handle any circulatory or respiratory complications that may develop. Simple analgesics can be provided for relief of pain, and physical therapy may be helpful after muscle weakness has stabilized.

During pregnancy, women are more susceptible to clinical poliomyelitis, but it is unclear whether this is because they are more susceptible to the initial viral infection or to invasion of the nervous system. Pregnancy may also alter the course of the infection. The course is unaffected if poliomyelitis develops early in pregnancy, but an increase in severity or distribution of the muscle weakness may occur if childbirth takes place during the acute phase or shortly thereafter.

In early pregnancy, especially during the first trimester, spontaneous abortion may occur in association with a febrile reaction in the acute phase of poliomyelitis or in relationship to apparently mild nonparalytic attacks of the disease. Abortion or fetal loss may also occur spontaneously in the second or third trimester but often with maternal illness of such severity that assisted respiration may be necessary.

Even patients with severe poliomyelitis necessitating respirator assistance can usually be managed supportively, and labor can be managed as it is in unaffected women unless there are specific obstetric indications for operative delivery or induction of labor. The uterine muscle is not paralyzed.

Fetal poliomyelitis is rare. Unaffected offspring can generally be anticipated, but neonatal cases of poliomyelitis are well recognized. If an infant is affected within the first 5 days of life, the disorder is assumed to result from transplacental transmission of the virus. These neonatal cases are associated with a mortality rate of at least 50%, but subclinical infection with poliovirus may also occur in newborn infants.

TETANUS

A worldwide disease, tetanus is rarely encountered in developed countries where immunizations are freely available. *Clostridium tetani* infection by means of tetanus spores may follow injury, surgical procedures, childbirth, abortion, and injections. If the spores are converted into gram-positive vegetative rods, and if favorable anaerobic conditions exist, tetanospasmin, a toxin that is responsible for the symptoms of tetanus, is produced.

The incubation period varies. In patients with generalized tetanus, the most common presenting symptom is trismus, and the disorder itself is characterized by frequent spasms of various muscles that can be provoked by minor external stimuli and may occur against a background of continuous tonic muscle contractions. Typically, the trunk is hyperextended, the arms are flexed, and the legs are extended; laryngospasm may lead to respiratory obstruction.

Localized tetanus is more benign and is characterized by persistent rigidity of muscles close to the site of inoculation with the organism. A splanchnic form is described after abdominal and pelvic operations or uterine trauma, with prominent involvement of the muscles of deglutition and respiration.

The morbidity and mortality rates vary. Respiratory complications are a leading cause of death, as is the autonomic hyperactivity that sometimes complicates tetanus. Treatment is directed at the following:

- Neutralizing unbound toxin with antitoxin
- Reducing further toxin production by surgical toilet and antibiotic treatment

- Controlling tetanic spasms by drugs such as diazepam, chlorpromazine, and barbiturates
- Assisting respiration mechanically if necessary
- Undertaking general supportive measures

Tetanus may develop as a complication of childbirth or abortion, especially in underdeveloped countries. It leads to abortion in many instances and has a maternal mortality rate that often exceeds 50%. In addition to the measures listed, evacuation of products retained in the uterus may be necessary, and hysterectomy is sometimes required.

Tetanus is a common cause of neonatal death in underdeveloped countries. Infection usually results from a lack of hygiene during delivery, with consequent contamination of the umbilical cord. The clinical manifestations differ from those in older children or adults, in that dysphagia and respiratory problems are often more marked, fever is usually higher, and the disease is generally more severe, often fulminating. Most affected infants are 6 to 9 days old when admitted and have a typical history of continuous crying for up to 48 hours, followed by cessation of sucking and then of crying, accompanied by convulsions and often by fever.

In regions where neonatal tetanus is common, the infant mortality rate is high. Improvement of delivery practices and obstetric services may prevent the disorder, as may the active immunization of pregnant women or of all women of child-bearing potential⁵⁵ and the substitution of disinfectants for traditional cord-care practices.⁵⁶ Unfortunately, in most areas with a high incidence of tetanus neonatorum, there are no widely available maternity services, and any prophylactic approach that depends on the early identification of pregnant women is impractical.

MISCELLANEOUS MATERNAL INFECTIONS

Clinical or subclinical maternal infection may involve the fetus and may affect the developing nervous system and therefore the neonate. The resulting neurologic complications merit brief comment here. Fetal infection may be inconsequential or may result in abortion, stillbirth, growth retardation, congenital disease, or developmental anomalies. Gestational age at the time of infection influences the effects (see Chapter 51).

Infection with *Listeria monocytogenes* is an important cause of habitual abortion, and it may lead to a variety of other manifestations in pregnant women including meningitis. In neonates, infection may take an early-onset, predominantly septicemic form, characterized by prematurity, respiratory distress, heart failure, and increased neonatal mortality, or it may take a late-onset, predominantly meningitic or meningoencephalitic form. Diagnosis depends on the bacteriologic and serologic findings. Treatment consists of appropriate antibiotic therapy, usually with ampicillin.

Maternal rubella, especially when it occurs in the first 2 months of pregnancy, may cause fetal infection and a congenital syndrome characterized by ocular abnormalities, deafness, mental retardation, seizures, focal neurologic deficits, cardiac anomalies, hepatosplenomegaly, and other abnormalities in a variety of combinations. In rare patients with congenital rubella, pyramidal and extrapyramidal signs, seizures, and dementia occur as part of a progressive panencephalitic illness during the second decade of life; high antibody titers to rubella virus occur in blood and cerebrospinal fluid, and the virus may even be isolated from the brain.⁵⁷

In congenital toxoplasmosis, seizures and pyramidal defects may result from meningoencephalitis together with chorioretinitis, obstructive hydrocephalus, and cerebral calcification. There may be respiratory and feeding difficulties. Later, mental development may be retarded. For prophylactic purposes, pregnant women should be advised to avoid contact with cat feces and ingestion of raw or undercooked meat.

Fetal infections with cytomegalovirus may cause hepatosplenomegaly, jaundice, petechiae, ocular defects, cardiac defects, and other abnormalities. Involvement of the nervous system may lead to cerebral malformation, microcephaly, mental retardation, seizures, obstructive hydrocephalus, cerebral calcification, deafness, or chorioretinitis.

Herpes simplex virus infection in the neonate is characterized primarily by visceral involvement, but the brain may be affected. Seizures, irritability, motor deficits, increased intracranial pressure, and depression of consciousness may occur, sometimes in the apparent absence of more widespread disease.

Children born to women infected with the human immunodeficiency virus (HIV) are at risk of infection with the virus. The risk varies in different series for uncertain reasons. The virus may infect the fetus in utero or the neonate during birth or through breast milk. Infected children may develop acquired immunodeficiency syndrome (AIDS) after an interval ranging from several months to several years. This leads typically to developmental delay and regression as a result of progressive encephalopathy. Calcification of the basal ganglia may occur. Systemic features include failure to thrive, pneumonitis, hepatosplenomegaly, and recurrent bacterial infections. Management of pregnant women with HIV infection therefore includes minimizing the risk of transmitting the infection to offspring, recognizing neonatal infection early, reducing the risk of opportunistic infection, and managing psychosocial aspects. Combination antiretroviral therapy for infected women during pregnancy, and zidovudine or nevirapine therapy for neonates for 6 weeks are helpful without an increase in fetal adverse events.^{58,59} Compared with no antiretroviral treatment or monotherapy, combination therapy does not seem to be associated with increased risks of prematurity or other adverse outcomes of pregnancy,⁶⁰ although there are limited data concerning teratogenicity during pregnancy. The use of infant formula to prevent postnatal transmission through breast milk has helped to reduce the incidence of infection in developed countries, although in developing countries the use of formula is associated with an increase in adverse events.⁶¹ Infants may require monitoring for 1 to 2 years with testing for HIV to exclude infection (see Chapter 51). Fetal infection itself may lead to teratogenicity, with nervous system malformations that are associated with vasculitic microinfarcts of the fetal brain.⁶²

The possibility of syphilitic infection must be considered during the evaluation of all pregnant women. Effective treatment of maternal syphilis at an early stage of pregnancy usually prevents fetal involvement, and treatment in later pregnancy affects both mother and fetus. Syphilis may severely affect pregnancy, leading to increased chances of abortion and perinatal mortality and to symptomatic congenital syphilis in many of the surviving infants. Infants may also be infected at birth if they come into contact with an infective lesion. The possibility of congenital infection can be confirmed by various serologic tests. The clinical features of congenital neurosyphilis, which may become apparent after the first few weeks of life or may be delayed for several years, are essentially the same as those of

neurosyphilis in adults. Infants with clinical or laboratory evidence of infection require treatment to prevent its occurrence, and penicillin is the drug of choice.

Metabolic Disorders

Several metabolic disorders are considered elsewhere in this chapter, including Wilson disease, hepatic porphyria, and the Wernicke-Korsakoff syndrome. Here, attention is confined to two other disorders that are important to recognize for therapeutic purposes: vitamin B₁₂ deficiency and phenylketonuria (PKU).

VITAMIN B₁₂ DEFICIENCY

Vitamin B₁₂ deficiency is a well-known cause of neurologic disease (i.e., myelopathy characterized predominantly by pyramidal and posterior column deficits, polyneuropathy, mental changes, optic neuropathy) in adults, in whom it may arise from malabsorption, dietary inadequacy, or other causes. Patients may have accompanying megaloblastic anemia, but this may be obscured if folic acid supplements have been taken. Clinical presentation during pregnancy does not differ from that in the nongestational period. Treatment with parenteral vitamin B₁₂ prevents further progression and may lead to partial improvement of the neurologic disorder.

Maternal vitamin B₁₂ deficiency during pregnancy and the puerperium may lead to a similar deficiency in the fetus and neonate. A reduced content of vitamin B₁₂ in maternal milk may then lead to frank deficiency in breastfed infants. The resulting clinical syndrome in these infants is characterized by megaloblastic anemia, cutaneous pigmentation, apathy, developmental delay or regression, and involuntary movements. The clinical and biochemical abnormalities are rapidly corrected by vitamin supplementation.

PHENYLKETONURIA

An autosomal recessive disorder, PKU is an important cause of mental retardation, which develops in the absence of adequate dietary treatment. Screening programs for neonates with PKU have enabled identification and treatment of affected infants to prevent intellectual deterioration, but the optimal duration of treatment remains unclear. Women with PKU have a high rate of spontaneous abortion, and their nonphenylketonuric (heterozygote) offspring have a high incidence of certain abnormalities. Among the offspring of pregnancies during which the maternal PKU is untreated, there are marked increases in the incidence of mental retardation, microcephaly, and congenital heart disease compared with the normal population, and these increases correlate with maternal blood levels of phenylalanine.

The fetal effects of maternal PKU occur because of the high maternal blood levels of phenylalanine, not because the infant has PKU. Dietary treatment before or during early pregnancy (i.e., within the first 2 months) may prevent or lessen the fetal effects.⁶³⁻⁶⁶ Treatment may need to be in effect at conception for maximal benefit. Even so, a normal child cannot be ensured.

The mother with undiagnosed PKU poses different problems. Antenatal screening for maternal PKU or testing for PKU at the first antenatal visit of a woman with a family history of

the disease, low intelligence of uncertain origin, or a history of microcephalic offspring is appropriate.

The newborn offspring of a mother with PKU are homozygous or heterozygous for the disorder. The homozygotes definitely require a diet low in phenylalanine, but the proper nutritional management of heterozygotes is less clear. The mother should be advised against breastfeeding, because her milk will contain a high concentration of phenylalanine. Elevation of blood phenylalanine levels is only minimal during pregnancy in mothers who are heterozygous for the disorder, and the incidence of congenital anomalies and brain damage does not appear to be increased in their offspring.

Movement Disorders

When dystonia develops during pregnancy, it usually manifests acutely as a consequence of treatment with antiemetic dopamine antagonists (e.g., metoclopramide), neuroleptic drugs, or levodopa. For patients with established dystonia, genetic counseling may be prudent if the disorder has a hereditary basis, and the need to continue on pharmacologic treatment should be evaluated before planned pregnancy. Parkinson disease shows no consistent change during pregnancy, but little information is available concerning the safety of antiparkinsonian agents when taken during the gestational period.

CHOREA GRAVIDARUM

The term *chorea* refers to involuntary rapid muscle jerks that occur unpredictably in different parts of the body. When the disorder is florid, choreic limb movements and facial grimacing are unmistakable and distort any concomitant voluntary activity. In mild cases, there may be no more than a persistent restlessness and clumsiness.

Sydenham chorea is regarded as a complication of infection with group A hemolytic streptococci, and the underlying pathology may be an arteritis. When it occurs during pregnancy, it is referred to as chorea gravidarum. This disease occurs most commonly in primigravidas, with symptoms tending to occur in the early part of pregnancy and remitting after delivery. A history of chorea and rheumatic fever is obtained in about two thirds of patients, and the other third have clinical signs of rheumatic heart disease. Psychological disturbance may occasionally be conspicuous. Chorea gravidarum may recur in later pregnancies. Death, primarily caused by underlying rheumatic heart disease, is rare.

Symptomatic benefit follows bed rest and sedation, and there is no indication for termination of pregnancy. The prognosis is essentially that of any cardiac complication. No specific obstetric complications are associated with chorea gravidarum, and a normal, healthy infant can generally be anticipated.

Although many cases of chorea gravidarum result from preceding streptococcal infection, in other instances, there is no clinical or laboratory evidence of such an association. Instead, clinical impression suggests that pregnancy has in some way merely exacerbated some preexisting disturbance that then becomes clinically evident. Similarly, chorea is occasionally induced by oral contraceptives in women with preexisting basal ganglia abnormalities resulting from various causes. The dyskinesia in such cases usually begins within about 3 months of the introduction of contraceptive therapy, evolves subacutely, is often asymmetrical or unilateral, and resolves

with discontinuation of the offending substance. The pathophysiological basis of hormonal contraceptive-induced chorea is uncertain, but a vascular or immunologic mechanism or a hormone-dependent alteration in central dopaminergic activity has tentatively been advanced as the underlying cause.

Chorea developing for the first time during pregnancy must not automatically be regarded as a variant of Sydenham chorea, because it may arise for other reasons. The choreic movements of Huntington disease occasionally occur for the first time during pregnancy, but the subsequent course of events and the family history will point to the correct diagnosis. Systemic lupus erythematosus may also cause chorea that sometimes commences during pregnancy, and a thorough search for evidence of this disorder should be made in all patients without clear evidence of a rheumatic basis for chorea. Finally, as in nonpregnant patients, chorea may result from polycythemia vera rubra, thyrotoxicosis, hypocalcemia, Wilson disease, and treatment with phenytoin or a major tranquilizing drug.

RESTLESS LEGS SYNDROME

Between 10% and 20% of pregnant patients experience unpleasant creeping sensations deep in the legs and occasionally in the arms.⁶⁷ Symptoms generally occur when patients are relaxed, especially at night, and prompt a need to move about. These symptoms usually develop in the latter half of pregnancy, subsiding soon after delivery. Similar symptoms may also occur without any relation to pregnancy.

No abnormalities are found on neurologic examination. The cause of the disorder is unknown, but symptoms sometimes resolve after correction of any coexisting anemia or iron deficiency. Persistent or intolerable symptoms may respond to treatment with drugs such as diazepam or clonazepam. Other drugs that are sometimes helpful include levodopa, dopamine agonists, clonazepam, and opiates, but these drugs are better avoided during pregnancy if possible. Reassurance is important, as symptoms usually resolve spontaneously within a few weeks of the end of pregnancy.

WILSON DISEASE

An autosomal recessive disorder caused by a gene defect on the long arm of chromosome 13, Wilson disease is characterized by the accumulation of copper in the brain, liver, and other organs. Neurologic and mental symptoms such as intellectual disturbances, abnormal movements of all sorts, dysarthria, dysphagia, and rigidity are common presenting complaints. After neurologic signs are identified, careful examination of the eyes invariably shows the presence of Kayser-Fleischer rings, which are brown deposits of copper along the edge of the cornea in Descemet membrane. Clinical evidence of hepatic involvement may be present but is variable.

The diagnosis is suggested by the family history, low serum copper and ceruloplasmin concentrations, and increased 24-hour urinary excretion of copper. Treatment with a low-copper diet and with penicillamine, a chelating agent that promotes copper excretion, may lead to marked improvement of neurologic and hepatic status.

Patients with untreated Wilson disease have a high miscarriage rate. Pregnancy generally proceeds normally in patients who have received adequate chelation therapy and carries no particular hazard for the mother or fetus.^{68,69} Although

penicillamine therapy has been associated with mesenchymal birth defects, several reports document normal pregnancies and infants in mothers on treatment with it. An alternative approach is treatment with trientine and zinc, but experience with oral zinc salts taken during pregnancy is limited, and trientine is teratogenic in rats.⁷⁰ Labor and delivery may be complicated in patients with portal hypertension. Hemorrhage from esophageal varices may occur, especially during the second or third trimesters. Extradural analgesia helps to avoid straining during vaginal delivery; cesarean section is best reserved for obstetric indications.

Multiple Sclerosis

Multiple sclerosis is a disorder in which plaques of demyelination develop at different times and in different sites throughout the central nervous system. Its cause remains uncertain; clinical onset usually occurs in early adult life. There is considerable variability in the tempo and character of neurologic symptoms and signs. The disorder is classically associated with unpredictable exacerbations during which neurologic deficits develop, followed by remissions during which symptoms and signs may partially or completely resolve. With time, patients become increasingly disabled, although perhaps not for many years after the appearance of the initial symptoms. In other patients, the disorder follows a progressive course from its onset.

Several epidemiologic studies have suggested a tendency for remissions during pregnancy and an increased frequency of multiple sclerosis exacerbations in the first 3 to 6 months after childbirth.^{71,72} Breastfeeding does not have an impact on the relapse rate after pregnancy.⁷³ Pregnancy itself or the number of pregnancies has no effect on subsequent neurologic disability.⁷⁴⁻⁷⁶ The remission of multiple sclerosis during pregnancy is consistent with observations in other autoimmune diseases and probably relates to a gestational immunosuppressive state. Similarly, multiple sclerosis does not influence the natural course of pregnancy or childbirth, although some investigators have reported an increased incidence of small infants for age.⁷⁷ Disease-modifying therapies such as β -interferon, glatiramer acetate, or natalizumab are not recommended during pregnancy.

The possibility of a familial incidence of multiple sclerosis is widely recognized, but this pattern is uncommon and tends to involve siblings rather than different generations. It may merely reflect common exposure to some unrecognized etiologic agent rather than genetic predisposition to the disorder. With these points in mind, inquiries by a pregnant woman with multiple sclerosis who is worried that her child may later become affected should be met with firm reassurance. A patient with multiple sclerosis does not need to be discouraged from pregnancy unless she is already so disabled by the disorder that she will clearly be incapable of coping with the responsibilities and physical demands of parenthood. Patients with minimal incapacity who are anxious to have a child will usually do so anyway and do not need to be discouraged as long as they have some understanding of the nature of their disorder and its unpredictable course. In discussions between such patients and physicians, it seems reasonable to provide optimistic assurance that multiple sclerosis does not shorten life and that significant disability may not occur for many years, if at all.

The management of multiple sclerosis during pregnancy is supportive. The treatment of acute exacerbations consists of

bed rest and prescription of a brief course of steroids, which may hasten recovery without necessarily influencing its extent. Patients with sphincter disturbances or who are paraplegic may experience increased difficulties during pregnancy. The method of delivery should depend solely on obstetric factors.

Optic Neuritis

Any type of optic neuropathy may develop fortuitously during gestation. Optic neuritis may develop during pregnancy or lactation in patients with established multiple sclerosis or in patients who will later develop other manifestations of that disorder. Optic nerve involvement by tumors or vascular malformations may also appear for the first time in the gestational period, as may the optic neuropathy that sometimes complicates vitamin deficiency. Optic nerve involvement may complicate hyperemesis gravidarum, with rapid onset of marked, usually bilateral, visual loss; the entity is rare, but if vomiting is unresponsive to treatment, it may be necessary to terminate the pregnancy.

Leber optic atrophy is a hereditary disorder that usually occurs in early adult life. It commonly has a sex-linked recessive mode of inheritance, so that the male offspring of women carriers of the disorder may be affected. Other modes of inheritance have also been described. The clinical deficit begins abruptly with visual loss and leads ultimately to bilateral central scotoma with optic atrophy. No abnormalities are found in the neonate. Other forms of hereditary optic atrophy have been described in which the disorder is congenital or develops in infancy or early childhood and may have a dominant or a recessive mode of transmission. The family pedigree is important for diagnostic and counseling purposes in all such instances.

Traumatic Paraplegia

When spinal cord injury resulting in paraplegia occurs during the course of an established pregnancy, it may be followed by spontaneous abortion or stillbirth. If the pregnancy continues, the detailed radiologic investigations that are needed to determine the nature and extent of the spinal injury may be hazardous to the developing fetus, especially if it is still very immature (see Chapter 31). In such circumstances, the interests of the mother are of paramount importance.

Many patients with established paraplegia are eager to experience motherhood, and because they are capable of sexual intercourse, they inquire about the possibility and potential hazards of childbirth. Urinary tract infection, a common complication of paraplegia, can be exacerbated by pregnancy but is not a contraindication to pregnancy if there is no gross impairment of renal function. In the management of paraplegics, it is important to reeducate the paralyzed bladder so that only a minimal amount of residual urine remains after micturition. If this is achieved, difficulty with micturition can usually be postponed to the last stages of pregnancy, when catheterization is often necessary.

Pregnancy may increase the likelihood of development of pressure sores in paraplegic women. Patients and their families should be informed about the cause of these sores and the manner in which prolonged pressure can be avoided. Because anemia lowers the resistance of paraplegic patients to infection and pressure, particular care must be taken to prevent its development during pregnancy.

The uterus itself contracts normally in labor despite interruption of its nerve supply. However, patients with complete spinal cord lesions above the tenth thoracic segment cannot appreciate the onset of labor or feel any pain during it because afferent fibers from the uterus enter the cord more caudally. Medical attendants need to examine the state of the cervix to identify the onset of labor with certainty. Because labor often commences before term in such circumstances, the cervix is examined at each antenatal visit after 24 to 26 weeks' gestation; the patient should be hospitalized if the cervix is dilated.

The occurrence of symptoms such as leg spasms in association with uterine contractions may be helpful in signaling the onset of labor, as may uterine palpation by the patient's spouse. Routine hospitalization after the 32nd week should be considered. In patients with cord lesions below the 10th or 11th thoracic segment, uterine contractions produce normal pain sensations. A patient with spasticity resulting from the cord lesion may develop painful flexor spasms and ankle clonus during uterine contractions.

Pregnant women with complete cord lesions above the fifth or sixth thoracic segment (i.e., above the splanchnic outflow) may develop the syndrome of autonomic hyperreflexia with excessive activity of a viscus. This is characterized by throbbing headache, hypertension, reflex bradycardia, sweating, nasal congestion, and cutaneous vasodilation and piloerection above the level of the lesion. During labor, these symptoms are most conspicuous with uterine contractions and become especially prominent just before delivery. Electrocardiographic monitoring may facilitate recognition of any changes in cardiac rate or rhythm that occur during uterine contractions. Symptoms are caused by the sudden release of catecholamines.

Treatment in the past has relied on reserpine (which depletes catecholamines from sympathetic nerve terminals but also can cause potentially dangerous nasal congestion in the nasal-breathing neonate), atropine, clonidine, glyceryl trinitrate, or hexamethonium (a ganglion blocker). The syndrome can be prevented or treated by spinal or epidural anesthesia extending to the level of the 10th thoracic segment, and early consultation with an anesthesiologist may therefore be helpful.

Cesarean section is not indicated by paraplegia per se, but it may be required because of bony deformity of the spine or pelvis. If the patient has a permanent suprapubic cystostomy, a vertical incision rather than a lower segment transverse incision must be used. Forceps delivery or vacuum extraction is often required because the muscles responsible for the expulsive efforts of the second stage are paralyzed and because severe hypertension sometimes necessitates shortening the second stage.

Absorbable sutures, such as catgut, are poorly absorbed in paraplegics, and sterile abscesses commonly form around buried catgut. Nonabsorbable sutures, such as nylon, are preferred for repairing an episiotomy. Paraplegic and quadriplegic patients can successfully breastfeed their infants, and they have a normal letdown (i.e., milk ejection) reflex during suckling.

Root Lesions

PROLAPSED INTERVERTEBRAL DISK AND PREGNANCY

The symptoms and signs of lumbar disk protrusion during pregnancy are similar to those occurring in nonparous women.

Radicular pain and low back pain are usually conspicuous features, and there may be a segmental motor and sensory disturbance in the limbs. When the disk prolapses centrally rather than laterally, symptoms and signs in the legs may be bilateral, and sphincter disturbances occur more commonly.

Lumbar disk protrusion must be distinguished from other causes of leg weakness developing during or soon after pregnancy. Lumbosacral palsy may arise during labor from compressive injury of the plexus, but tenderness and rigidity of the lumbar spine, sciatica, and signs of root tension favor the diagnosis of protruded disk. The distribution of muscle weakness may also be helpful: Depending on their location, plexus lesions cause weakness and sensory symptoms in a polyradicular or peripheral nerve distribution in the legs. Because only the anterior primary rami contribute to the plexus, a proximal radiculopathy can be distinguished from a plexus lesion by electromyographic examination of muscles supplied by the posterior primary rami (i.e., paraspinal muscles), involvement of which therefore favors a root lesion.

Management is the same as for nonpregnant women. MRI has no known effects on the fetus, but contrast agents are probably best avoided. In patients with lateral protrusion of a lumbar disk, simple analgesics provide symptomatic relief. Surgery can usually be deferred until after childbirth. However, laminectomy and excision of the protruded disk may be necessary during pregnancy, especially if symptoms are bilateral or if there is any disturbance of sphincter function.

OTHER LUMBOSACRAL ROOT LESIONS

Most disk lesions involve the L5 or S1 roots. Although a disk lesion may occasionally affect the L4 root, involvement of an upper lumbar nerve root suggests other compressive disease. In a patient presenting with an L5 or S1 radiculopathy, there may be a more rostrally situated lesion if no abnormality, such as a protruded disk, is seen in the L4-5 or L5-S1 region, because the spinal cord ends at the lower border of L1 and the roots then descend intradurally before exiting through their respective intervertebral foramina. In such circumstances, the possibility of other compressive lesions must be considered. As with nonpregnant patients, each case is best managed on an individual basis.

Plexus Lesions and Peripheral Mononeuropathies

Certain peripheral entrapment neuropathies are particularly liable to develop in pregnancy and may lead to troublesome symptoms. Recognition of the basis of such symptoms is important because, with reassurance about their benign nature, most patients can tolerate them until they give birth, when the symptoms usually subside spontaneously. Other peripheral nerve or plexus lesions may develop during labor or obstetric surgical procedures as a result of compression or stretch of nerves, especially in anesthetized patients.

Disorders of peripheral nerves may be characterized by slowing or blocking of conduction along intact axons or by axonal degeneration. The former carries a much more favorable prognosis for recovery than the latter, because after axonal degeneration has occurred, recovery can take place only by regeneration, a process that may take many months and may never be complete.

ELECTROPHYSIOLOGIC EVALUATION

In the evaluation of patients with suspected nerve lesions, electrophysiologic techniques have been helpful in several ways.⁷⁸ Electromyography can aid in determining whether weakness is neurogenic; if so, the electromyographically demonstrated pattern of affected muscles may indicate the location of the lesion (i.e., whether root, plexus, or an individual peripheral nerve has been affected). The findings may also indicate whether neurogenic weakness is a consequence of impaired conduction along otherwise intact axons or a consequence of axonal degeneration, a distinction that has prognostic importance.

The motor responses to nerve stimulation provide complementary information. If axonal degeneration results from a focal lesion in a peripheral nerve, the motor responses to electrical stimulation proximal or distal to the lesion become small or absent about a week after injury, depending on the completeness of the lesion. In contrast, in patients with a conductive disturbance caused by an acute focal lesion, the motor responses to stimulation beyond (distal to) the lesion are generally normal, whereas those elicited by more proximal stimulation may be small.

Motor and sensory conduction velocity can be measured in various accessible segments of peripheral nerves, and focal slowing may provide confirmatory evidence of an underlying entrapment or focal neuropathy. In patients presenting with a mononeuropathy, nerve conduction studies can be used to exclude the real possibility of an underlying subclinical polyneuropathy.

LUMBOSACRAL PLEXUS LESION

The roots of the sciatic nerve may be compressed in the pelvis by the fetal head or obstetric forceps, and the brunt of the resulting motor deficit is then borne by muscles supplied by the common peroneal fibers because of their relationship to the bony pelvis. This type of injury to the maternal lumbosacral plexus is more likely when a short patient with a small pelvis carries a rather large infant, so that labor is complicated by minor disproportion, or when a mid-forceps delivery is used because of malpresentation. The features of the pelvis that predispose to this complication include a straight sacrum, a flat wide posterior pelvis, posterior displacement of the transverse diameter of the inlet, wide sacroiliac notches, and prominent ischial spines.

Symptoms are usually unilateral and develop immediately after delivery, but they may not be noticed until the patient is allowed out of bed. When the common peroneal fibers are involved, the main complaint is of leg weakness, which is sometimes erroneously attributed to a painful episiotomy. In more severe cases, there is footdrop. Numbness and paresthesias may occur over the dorsum of the foot and lateral aspect of the leg, and cutaneous sensation may be impaired in this distribution.

Unless the injury has been severe, the predominant pathologic change is demyelination of the affected fibers, and this is reflected in the electrophysiologic findings. With mild injuries, the prognosis for recovery is excellent; if wallerian degeneration has occurred, recovery may take many months and may never be complete. Physical therapy is all that is needed for treatment of mild cases, but calipers and night casts may be required in more severe instances to prevent contracture.

Subsequent pregnancies can be allowed to proceed normally if an easy vaginal delivery is anticipated. A low forceps delivery can be used with caution if necessary, but a mid-forceps delivery may be hazardous. It seems sensible to advise cesarean section if the infant is very large or if premonitory symptoms suggesting nerve compression occur with attempted engagement of the fetal head in the pelvic brim during the last 4 weeks of pregnancy in a patient with a history of obstetric lumbosacral plexus palsy.

ACUTE FAMILIAL BRACHIAL NEURITIS

Several reports document the rare occurrence of brachial plexus neuropathy on a familial basis. One of the earliest reports described 24 of 119 members of a family covering five generations experiencing single or multiple attacks of acute brachial neuropathy.⁷⁹ This disorder was characterized by pain, weakness, atrophy, and sensory loss that was usually unilateral but occasionally bilateral, and from which gradual recovery generally occurred. Male and female family members were affected, but among the women, there was a striking association of attacks with pregnancy or the puerperium, in contrast to the more common idiopathic disorder, which is rarely associated with pregnancy. In some instances of the familial disease, the lower cranial nerves were involved, and isolated mononeuropathies of the other extremities were present. Other cases have been described. Treatment with oral steroids may be helpful in relieving pain but does not seem to affect the rate of recovery.

CARPAL TUNNEL SYNDROME

Compression of the median nerve may occur in the carpal tunnel at the wrist, especially when the normal size of the carpal tunnel is reduced, as by degenerative arthritis, or when the volume of its contents is increased, as in inflammatory disorders involving the tendons and connective tissues at the wrist. Carpal tunnel syndrome is common during pregnancy,⁸⁰ perhaps because of excessive fluid retention. Pain and paresthesias are early symptoms and frequently occur at night, awakening the patient from sleep. The symptoms usually involve the first three digits and the lateral border of the ring finger, but some patients report that all digits are affected. Pain may occur in the forearm, and it occasionally occurs in the upper arm. With time, weakness of the thenar muscles may develop. On examination, it is often possible to elicit the Tinel sign (percussion of the nerve at the wrist causing paresthesias in its distal distribution), and the Phalen maneuver (flexion at the wrist for more than a minute) sometimes reproduces or enhances symptoms. There may be mild weakness and wasting of the abductor pollicis brevis and opponens pollicis muscles, impaired cutaneous sensation in a median nerve distribution in the hand, or both motor and sensory signs.

Electrophysiologic testing usually suggests or confirms the diagnosis (e-Fig. 65-8). In the evaluation of patients, it is important to remember that the carpal tunnel syndrome is commonly bilateral, even though it may be unilaterally symptomatic, and an entrapment neuropathy may be the first manifestation of a subclinical polyneuropathy. These possibilities can be excluded by appropriate electrophysiologic studies.

Symptoms developing or worsening during pregnancy usually respond to the nocturnal use of a wrist splint and clear within about 3 months of delivery, often settling within 1 or 2

weeks.⁸¹ They may recur in subsequent pregnancies. The splint is placed on the dorsal surface so that the wrist can be maintained in a neutral or slightly flexed position. Some patients are helped by injection of steroids into the carpal tunnel and others by treatment with diuretics. The physician must explain to the patient that her symptoms are benign and will generally subside spontaneously after the pregnancy. With such reassurance, most patients accept their symptoms without difficulty.

Surgical division of the anterior carpal ligament may be necessary if symptoms are intolerable or do not clear in the weeks after delivery. Surgical treatment may also be necessary in a patient with clinical or electrophysiologic evidence of increasing nerve dysfunction despite conservative measures, but it can usually be avoided during the pregnancy.

MERALGIA PARESTHETICA

The lateral femoral cutaneous nerve, a purely sensory nerve derived from the L2 and L3 roots, is particularly susceptible to compression or stretch injury during pregnancy, especially during the third trimester. Obesity and diabetes mellitus are other predisposing factors. The nerve usually runs under the outer portion of the inguinal ligament to reach the thigh, but the ligament sometimes splits to enclose the nerve. In the latter circumstance, hyperextension of the hip or an increased lumbar lordosis, such as occurs during pregnancy, leads to compression of the nerve by the posterior fascicle of the ligament. Entrapment of the nerve at any point along its course may lead to similar symptoms, and several anatomic variations may predispose the nerve to damage when it is stretched. Pain, paresthesias, and numbness may occur about the outer aspect of the thigh and are sometimes relieved by sitting. Symptoms are unilateral in approximately 80% of cases.

Little may be found on physical examination, but in severe cases cutaneous sensation is disturbed in the affected area. Symptoms, which are usually mild, subside spontaneously in the puerperium or within a few weeks of delivery. Patients should be reassured about the benign nature of the disorder. In a few instances, however, pain has been so severe that labor had to be induced early. Hydrocortisone injections in the region where the nerve lies medial to the anterior superior iliac spine may relieve persistent symptoms for a time, and low-dosage tricyclic antidepressant drugs may also be helpful. Anticonvulsant agents, which are sometimes helpful for neuropathic pain, are best avoided during pregnancy. Nerve decompression by transposition may provide more lasting relief but is rarely required.

TRAUMATIC MONONEUROPATHIES

Certain causes and clinical features of traumatic mononeuropathies are likely to develop in relation to obstetric procedures.

The obturator nerve originates in the psoas muscle from the L2, L3, and L4 nerves; it emerges from the medial border of the psoas and enters the pelvis immediately in front of the sacroiliac joint. It sweeps around the lateral pelvic wall and then passes through the obturator foramen, dividing into branches that supply the adductor, gracilis, and external obturator muscles; the skin over part of the medial thigh; and the hip joint. The nerve may be injured during genitourinary operations involving the lithotomy position because of angulation as it leaves the obturator foramen or compression between the fetal head (or

a pelvic mass) and the bony pelvic wall.⁸² An obturator nerve palsy leads to impaired gait, because of weakness of the adductor muscles, and to a sensory disturbance involving particularly the medial part of the middle thigh and lower thigh. Pain may also occur and tends to radiate from the groin down the inner side of the thigh.

The femoral nerve originates in the psoas muscle from the L2, L3, and L4 nerves and passes beneath the inguinal ligament to enter the thigh. It innervates the iliacus, sartorius, pectineus, and quadriceps femoris muscles, and its cutaneous branches supply anterior and medial portions of the thigh and, through the saphenous nerve, the medial portions of the lower leg. Clinical features of a femoral nerve palsy are weakness and, in severe cases, wasting of the quadriceps muscle, sensory impairment over the anteromedial aspect of the thigh and occasionally of the leg to the medial malleolus, and depression or absence of the knee jerk. This type of palsy can occur as an isolated phenomenon in the patient with diabetes mellitus, a bleeding tendency, or a retroperitoneal neoplasm, and it may sometimes arise by angulation and pressure from the inguinal ligament when the thighs are markedly flexed and abducted, as in the lithotomy position in anesthetized patients.

The saphenous nerve, the branch of the femoral nerve that supplies sensation to the medial aspect of the leg below the knee, may be damaged by pressure from leg braces when the patient is improperly suspended in the lithotomy position. The compressive injury leads to numbness and paresthesias that are usually fairly short-lived.

Sciatic or common peroneal nerve palsies are easy to confuse with a plexus palsy because their constituent fibers are susceptible to compressive injury in the sacral plexus during labor. Misplaced deep intramuscular injections are probably still the most common cause of sciatic nerve palsy. The sciatic nerve may also be injured by stretching when a patient is positioned in stirrups on the obstetric table. To avoid this injury, the knee and hip joints should be well flexed, and extreme external rotation of the hip should be avoided.

In patients with sciatic nerve palsy, the resulting weakness and sensory disturbance depend on whether the entire nerve has been affected or certain fibers are selectively involved. In general, the peroneal fibers of the sciatic nerve are much more likely to be damaged than fibers destined for the tibial nerve. The clinical features of a sciatic nerve lesion may simulate those of a peroneal neuropathy, although electromyographic evidence of involvement of the short head of the biceps femoris muscle favors the former. The common peroneal nerve is vulnerable to compression or direct trauma in the region of the head and neck of the fibula, and it may be injured at this site by pressure from the leg braces of the obstetric table, especially in anesthetized patients.⁸³ Weakness of dorsiflexion and eversion of the foot are accompanied by numbness or blunted sensation of the anterolateral aspect of the calf and the dorsum of the foot.

BELL PALSY

Sir Charles Bell first established the motor function of the seventh cranial nerve in the early 19th century. His name soon came to be associated with all forms of facial paralysis, but the designation of Bell palsy is now used for facial paresis of lower motor neuron type when no specific etiologic agent can be found. Some cases are probably caused by viral infection or an

inflammatory reaction involving the facial nerve near the stylomastoid foramen or in the bony facial canal.

The incidence of Bell palsy is increased during pregnancy. The idea of a relationship with hypertension or preeclampsia is supported by one study.⁸⁴

The clinical features of Bell palsy are well known. The facial paresis usually is abrupt in onset, although it may worsen over the following day. Pain around the ear may precede or accompany the weakness in about half the cases but usually lasts for only a few days. The face itself feels stiff and pulled to one side. It may be difficult to close the eye on the affected side, and ipsilateral epiphora may occur. The patient may have difficulty with eating and with fine facial movements (e.g., when applying cosmetics). A disturbance of taste, caused by involvement of chorda tympani fibers, is common, and hyperacusis, caused by involvement of fibers to the stapedius, is occasionally troublesome.

Treatment is somewhat controversial. Most patients recover without treatment, and only about 10% of all patients are seriously dissatisfied with the final outcome because of permanent disfigurement or other long-term sequelae. Treatment is best reserved for patients in whom an unsatisfactory outcome can be predicted soon after onset. To be effective, treatment should commence within the first 3 to 5 days.

The best clinical guide to prognosis at an early stage is the severity of the palsy. Patients who have clinically complete palsy when they are first seen are less likely to recover fully than those with an incomplete palsy. Other clinical indicators for a poor prognosis for recovery include advancing age, hyperacusis, and severe initial pain.

The only medical treatment that may influence the outcome of Bell palsy is steroid therapy, based on several randomized controlled trials.⁸⁵ Antiviral therapies (e.g., acyclovir and valacyclovir) are not effective.⁸⁶ Most physicians routinely prescribe steroids to patients who are seen within 3 to 5 days of onset. Surgical procedures to decompress the facial nerve have not been beneficial.

Polyneuropathies

Although several early reports noted the occasional occurrence of a polyneuropathy during pregnancy, there does not appear to be any specific polyneuritis of pregnancy. Any type of polyneuropathy, such as that caused by diabetes mellitus, may develop during the gestational period. Discussion here is limited to those most likely to manifest clinically or to pose a management problem during pregnancy.

NUTRITIONAL NEUROPATHIES

Nutritional deficiency may be the most probable cause of peripheral nerve involvement in patients who come from underdeveloped countries or have hyperemesis. Signs of peripheral nerve involvement may be found in patients with hyperemesis gravidarum who have Wernicke encephalopathy. In the limbs, numbness, paresthesias, and dysesthesias are accompanied by cutaneous sensory loss, depressed tendon reflexes, and distal weakness. Retrobulbar neuropathy may also occur, and tachycardia, postural hypotension, exertional dyspnea, and sphincter disturbances are sometimes conspicuous. The polyneuropathy is accompanied by ophthalmoplegia (e.g., horizontal and vertical nystagmus, impaired lateral gaze, conjugate gaze

palsies), ataxia of gait, and a confusional state. The features of Korsakoff psychosis, which consists of impaired memory and an inability to acquire new information, sometimes accompanied by confabulation, may also be conjoined.

The diagnosis of Wernicke encephalopathy is confirmed by the finding of a marked reduction in blood transketolase activity and a marked thiamine pyrophosphate effect. Treatment consists of thiamine (500 mg), which is given intravenously three times daily and then once daily intravenously or intramuscularly for several days, followed by 100 mg orally until a satisfactory dietary intake is ensured.

In other instances, a severe polyneuropathy may develop without an accompanying encephalopathy, presumably in relation to a nutritional deficiency, although the specific factors responsible for the peripheral nerve involvement are not known. Patients may complain about pain, paresthesias, and dysesthesias in the extremities; limb weakness; or ataxia. There may be accompanying cardiac involvement, with tachycardia, exertional dyspnea, and heart failure. Treatment consists of a balanced diet and supplements of vitamins, especially B vitamins. Vitamin B₁₂ deficiency may lead to maternal polyneuropathy and other neurologic abnormalities and can affect the fetus and neonate.

ACUTE IDIOPATHIC POLYNEUROPATHY: GUILLAIN-BARRÉ SYNDROME

An acute or subacute polyneuropathy that sometimes follows infective illnesses, inoculations, or surgical procedures but often occurs without any obvious preceding event characterizes acute idiopathic polyneuropathy. In many such instances, the neuropathy follows clinical or subclinical infection with *Campylobacter jejuni*. The disorder may have an immunologic basis, but the precise mechanism is unclear. It can pose an especially difficult management problem when it occurs during pregnancy.

The main complaint is of weakness that varies widely in severity in different patients, is often more marked proximally than distally, and is often symmetric in distribution. It usually begins in the legs, frequently comes to involve the arms, and often affects one side or both sides of the face. Weakness may progress to total paralysis and may be life-threatening if the muscles of respiration or deglutition are involved. Sensory symptoms are common but are usually less conspicuous than motor symptoms. Autonomic dysfunction may manifest with tachycardia, cardiac irregularities, hypotension or hypertension, facial flushing, disturbances of sweating, disturbed pulmonary function, and other signs and symptoms.

Examination of the cerebrospinal fluid reveals characteristic changes: The protein content is significantly increased, but the cell content is normal. Measurement of motor and sensory conduction velocity in the peripheral nerves may reveal marked slowing, but the chronology of this reduction does not necessarily parallel that of the clinical disorder. In some patients, the conduction velocity remains normal, presumably because disease is restricted to the nerve roots or proximal segments of the nerves. Most patients eventually make a good recovery, but it may take many months, and some patients have persistent disability.

The Guillain-Barré syndrome does not occur more commonly during gestation than at other times, and the course of the disorder does not seem to be influenced by pregnancy.

Improvement in neurologic status may occur before delivery and is not necessarily delayed until the infant is born.

In addition to supportive care, with attention directed at the prevention of complications such as respiratory failure and vascular collapse, plasmapheresis or treatment with intravenous immunoglobulins hastens and improves the ultimate degree of recovery in severely affected patients. Although experience with such approaches during pregnancy is limited, both have been used safely in pregnant patients and treatment should probably not be withheld.⁸⁷ Severely affected patients are best managed in intensive care units, where respiratory and circulatory function can be monitored, and assisted respiration can be started as soon as is necessary. Ultrasonographic fetal monitoring generally reveals normal fetal movements even when the mother is severely paralyzed.⁸⁸

Approximately 3% of patients with acute idiopathic polyneuropathy have one or more relapses, sometimes several years after the initial illness. Such relapses, which are clinically similar to the original illness, occasionally occur during pregnancy.

PORPHYRIC NEUROPATHY

In the hepatic forms of porphyria, the central and peripheral nervous systems may be affected. Acute intermittent porphyria, inherited as an autosomal recessive trait, is characterized by increased production and urinary excretion of porphobilinogen and δ -aminolevulinic acid. Colicky abdominal pain is often the most conspicuous symptom, but the usual neurologic manifestation is a polyneuropathy that is predominantly motor but sometimes occurs with pronounced autonomic involvement, which may take weeks or months to regress, depending on its severity. Cerebral manifestations may also occur, often preceding the development of a severe polyneuropathy and similarly clearing after a variable time. Clinical indicators of disease activity include tachycardia, fever, and a peripheral leukocytosis. In variegate porphyria, cutaneous sensitivity to sunlight is an additional clinical feature.

Attacks may be precipitated by pharmacologic agents such as barbiturates, sulfonamides, and estrogens. Some women have found that relapses are most likely to occur premenstrually; long-term combination oral contraceptives may prevent attacks in these patients.⁸⁹ In other patients, oral contraceptives may precipitate exacerbations, and this form of contraception is probably best avoided in women with a blood relative who has a hepatic type of porphyria.⁹⁰

Pregnancy may lead to an acute exacerbation that may even have a fatal outcome, but many patients tolerate attacks without apparent ill effect. When relapses occur, they usually do so in early pregnancy and may lead to spontaneous abortion. However, exacerbations may occur at any time during pregnancy or after delivery. The implications and uncertain outcome must be explained to patients who are contemplating pregnancy, and close supervision should be provided during the gestational period. Latent cases may be exacerbated by medication used during or after labor, and particular care must be exercised in this regard. In general, if the pregnancy proceeds satisfactorily, a healthy infant can be anticipated.

Myasthenia Gravis

Variable weakness and fatigability of skeletal muscles, resulting from defective neuromuscular transmission, are the clinical

hallmarks of myasthenia gravis. The disorder has an autoimmune basis. It is characterized by a reduced number of available acetylcholine receptors at the neuromuscular junctions. Myasthenia gravis is more common in females. In some patients, the external ocular muscles or levator palpebrae are especially affected; in others, the facial and bulbar muscles are selectively involved; and in other patients, the limb muscles, especially the proximal ones, are predominantly affected. Weakness may remain localized to a few muscle groups or may become generalized, and it can be a life-threatening disorder if the muscles of respiration or deglutition are involved.

Repetitive supramaximal electrical stimulation of motor nerves may lead to an abnormal decline in the size of the evoked muscle action potentials. This finding is sometimes of diagnostic help, as is the finding of elevated levels of circulating acetylcholine receptor antibodies or antibodies to muscle-specific kinase and the clinical response to edrophonium or neostigmine. Patients are particularly sensitive to even small dosages of neuromuscular-blocking agents, such as tubocurarine, but improvement results from treatment with acetylcholinesterase inhibitors. Thymectomy often leads to a remission of symptoms, and myasthenia gravis may be associated with thymoma. In addition to thymectomy in appropriate cases, treatment may involve the use of anticholinesterases, steroids, intravenous immunoglobulins, and plasmapheresis.

Exacerbations of myasthenia gravis sometimes occur shortly before the onset of the menstrual period and tend to improve after menstruation has begun. This association may disappear after thymectomy.

Myasthenia gravis may first appear during or shortly after pregnancy, but it is difficult to predict the influence of pregnancy on a patient with the disorder. Moreover, the effect of pregnancy may vary on different occasions, so that the outcome in individual cases cannot be predicted on this basis. Relapses can occur in early pregnancy, with partial or complete remission often occurring at a later stage. In one prospective study of 47 women, it was found during pregnancy that myasthenia relapsed in 17% of asymptomatic patients who were not on treatment before conception; among patients on therapy, symptoms improved in 39% of pregnancies, were unchanged in 42%, and worsened in 19%.⁹¹ Furthermore, myasthenic symptoms worsened after delivery in 28% of pregnancies. It may be tempting to terminate a pregnancy because of the severity of myasthenic symptoms—death has been reported in pregnancy complicated by myasthenia gravis—and because of the difficulties in their treatment, but termination does not necessarily lead to clinical benefit. Myasthenia gravis should be managed in pregnant patients as it is in nonpregnant patients.

Myasthenia gravis has little effect on the pregnancy itself. Moreover, there may be a marked contrast during labor between the strength of uterine contractions in the second stage and the skeletal muscle weakness exhibited by the patient. If the expulsive phase of labor is prolonged, instrumental assistance may help to avoid maternal exhaustion. Cesarean section should be reserved for patients in whom it is indicated on obstetric grounds. Regional analgesia is preferable to general anesthesia, and the use of muscle-relaxant drugs is avoided if possible. Similarly, the use of magnesium sulfate for eclampsia should be avoided, because it may precipitate myasthenic crisis. No differences were found in perinatal mortality, gestational age, or birth weight between the offspring of myasthenic and nonmyasthenic women in a population-based cohort study.⁹²

Infants born to myasthenic patients should be carefully watched during the week after delivery for signs of neonatal myasthenia. Such signs include a poor cry, respiratory difficulties, weakness in suckling, a weak Moro reflex, and feeble limb movements, usually becoming apparent within the first 72 hours of birth. Symptoms are usually not evident immediately after birth, and this delay has been attributed to protection of the infant by placental transfer of maternal anticholinesterase drugs.

Neonatal myasthenia is a transient disorder that results from placental transfer of maternal antibody against acetylcholine receptors. It occurs in 10% to 15% of infants born to myasthenic mothers and does not seem to be related to the duration or severity of maternal illness, although disease in mothers of myasthenic newborns is usually generalized rather than localized. It can be treated with anticholinesterase drugs and usually subsides within 6 weeks of delivery, but it may result in death caused by aspiration or respiratory failure. Facilities should be available for the immediate resuscitation of affected infants or those at risk of being affected. Immunosuppressive therapy is sometimes required. Maternal myasthenia has also been incriminated as a rare cause of congenital arthrogryposis.⁹³

The birth of a child with neonatal myasthenia does not necessarily imply that future children will also have the disorder, although they often do. The transient neonatal disorder that may occur in the offspring of a myasthenic mother must not be confused with congenital myasthenia gravis. The latter is rare, occurs in children born of healthy mothers, and is usually permanent.

Disorders of Muscle

MYOTONIC DYSTROPHY

Myotonic dystrophy type 1 is a slowly progressive, dominantly inherited disorder that usually appears in early adult life but may manifest in childhood. It has been related to an expanded trinucleotide repeat in a gene localized to 19cen-q13.2. Increasing numbers of triplet repeat expansions govern clinical expression of disease; prenatal detection of the disorder is possible.^{94,95} Myotonia is accompanied by weakness of the facial, sternomastoid, and distal limb muscles. Associated features may include cataracts, frontal baldness, cardiac and endocrine disturbances, and intellectual changes. During pregnancy, the weakness and myotonia may be aggravated, and the course of the disorder is sometimes accelerated. When deterioration does occur, it often begins at about the 6th or 7th month of pregnancy.

In the antepartum period, the major reported obstetric complications of myotonic dystrophy include threatened, spontaneous, and habitual abortion. Hydramnios is well described. Ectopic pregnancy and placenta previa may occur, and perinatal loss is increased.⁹⁶ Premature onset of labor in patients with myotonic dystrophy has been attributed in some instances to abnormalities of uterine muscle. Labor may be abnormal because of failure of the uterus to contract normally. The first stage may be prolonged, and retention of the placenta and postpartum hemorrhage may occur. Manual removal of the placenta is sometimes necessary. Skeletal muscle weakness may also lead to poor voluntary assistance in the second stage.

Type 2 myotonic dystrophy (CCTG expansion involving the *ZNF9* gene) may first manifest during pregnancy, with worsening occurring in subsequent pregnancies for uncertain reasons; improvement often follows delivery.⁹⁶ Preterm labor is more likely in women who developed initial manifestations or a deterioration of the disorder during pregnancy than in those whose pregnancy did not appear to influence the disease course, but obstetric risk is not increased.⁹⁶

Myotonic dystrophy type 1 may manifest in infancy, occurring congenitally among the offspring of mothers who have the disorder, sometimes only mildly. In such cases, it is often possible to obtain a history of hydramnios or reduced fetal movements during the latter part of the pregnancy. Some affected infants die within hours or a few days of birth. The clinical features in affected infants include facial diplegia, hypotonia, neonatal respiratory distress, feeding difficulties, delayed motor development, and mental retardation. Myotonia, a cardinal feature of the adult disease, is absent in the congenital form. The neonatal respiratory distress may result from involvement of the respiratory muscles, pulmonary immaturity, aspiration pneumonia, and impaired neural control of respiration. Talipes is present at birth in about half of all cases and may require surgical correction. Myotonic dystrophy type 2 has not been described in congenital form.

Familial studies have indicated that in almost every case of congenital myotonic dystrophy, transmission occurred from the mother. This type of transmission does not fit with an autosomal dominant pattern of inheritance. Genetic data suggest that the congenital form results from the combination of the gene responsible for the disorder in adults and some maternally transmitted factor, the nature of which is unclear. Others have suggested that the maternal transmission of the congenital form is associated with relative male infertility.

The management of patients requiring anesthesia for obstetric or other reasons merits comment. Depolarizing muscle relaxant drugs should be avoided because they may cause myotonic spasm, and nondepolarizing agents, such as tubocurarine, can be used but should be given in reduced dosage to patients receiving quinine for myotonia. Thiopental sodium (Pentothal) may lead to marked respiratory depression and is best avoided, as are other respiratory-depressant drugs, especially if the patient already has impaired respiratory function. Electrocardiographic monitoring permits the early recognition of any cardiac arrhythmias, to which patients with myotonic dystrophy are prone. For these reasons, regional analgesia is the preferred method of management.

MYOTONIA CONGENITA

The dominant form of myotonia congenita, Thomsen disease, is usually present from birth, although symptoms may not appear until early childhood. Patients complain of muscle stiffness (i.e., myotonia) that is enhanced by cold or inactivity and is relieved by exercise; power is full, but the muscles may be diffusely hypertrophied. Pregnancy may aggravate the myotonia, especially in the latter half of the gestational period, and improvement occurs after delivery.

POLYMYOSITIS

In polymyositis or dermatomyositis, which can occur at any age, there is weakness and wasting, especially of the proximal musculature, as a result of inflammatory infiltration of muscles and destruction of muscle fibers. The muscles are often painful and tender. There may be an association with malignancy or one of the collagen diseases. The erythrocyte sedimentation rate and serum creatine kinase levels are elevated. Histologic examination of a muscle biopsy specimen usually permits the diagnosis to be made with confidence so that treatment with steroids can be instituted. Pregnancy has a variable effect on the muscle weakness, but a high perinatal mortality rate has been reported.⁹⁷

Psychiatric Disorders

Pregnancy may occur during the course of established psychiatric illness, and psychiatric disorders may first develop during or shortly after pregnancy, although no specific disorders are associated with this period. In the evaluation of patients with psychiatric disorders, physicians must consider that pregnancy can have a number of different psychopathologic implications, depending on the patient's social, cultural, educational, emotional, and medical background. The attitude of a patient to pregnancy, especially with regard to whether it was desired, influences her psychological response, and her capacity to cope with pregnancy depends on her acceptance of it. If the pregnancy was planned, the factors that motivated it are of some relevance because the aim might have been to overcome marital disharmony or to keep up with peers. These aspects clearly govern the response of an individual patient to pregnancy. Chapter 66 discusses psychiatric disorders.

Management of Depression and Psychoses in Pregnancy and in the Puerperium

KIMBERLY A. YONKERS, MD

Epidemiology

Approximately one in five women experiences an episode of major depressive disorder (MDD) over the course of her lifetime. Chronic psychotic disorders are less common, affecting about 1% of women. The risk for developing any type of depressive, bipolar, or chronic psychotic disorder such as schizoaffective disorder or schizophrenia peaks when women are in their early 20s.¹

MOOD DISORDERS IN PREGNANT AND POSTPARTUM WOMEN

Mood disorders are common in pregnant and postpartum women, although prevalence rates vary among studies. The Agency for Health Care Research and Quality found a best estimate for risk for MDD at any point in pregnancy to be 12.7% (95% confidence interval [CI], 7.1 to 20.4); the best estimate for risk for an episode during the 3 months after delivery was 7.1% (95% CI, 4.1 to 11.7).² Because of the overlap between confidence intervals, these data do not necessarily support a difference between pregnant and postpartum women in their risks for unipolar MDD. The course of illness can vary: some women become depressed in pregnancy and continue to be symptomatic into the postpartum period. Others improve shortly after delivery. In probably half of the women who are depressed in the postpartum period, the onset of illness was after the delivery.³

The typical age of onset for bipolar disorder is in the late teens to early 20s. Bipolar disorder is far less common than unipolar MDD, and although we lack data for its prevalence among pregnant women, it is not likely to differ from the rate of 1% identified in nonpregnant women.¹ The risk of a mood episode for a woman with bipolar disorder is clearly increased during the postpartum period in comparison to the risk for nonpregnant^{4,5} and pregnant women^{6,7} with unipolar MDD.

MAJOR PSYCHOTIC DISORDERS IN PREGNANT AND POSTPARTUM WOMEN

Women with schizophrenia and schizoaffective disorder have chronic conditions with symptoms that, ideally, are kept under control because they are taking antipsychotic medication and mood-stabilizing drugs. Vulnerability to either schizophrenia or schizoaffective disorder is not affected by being pregnant or in the postpartum period, although symptoms may be under slightly better control in pregnancy. However, women who

become pregnant are vulnerable to exacerbation of symptoms if medications are stopped. The stress associated with either pregnancy or being in the postpartum period can also exacerbate symptoms and feed psychotic delusions.

Pathogenesis of Mood Disorders and Psychotic Disorders, and the Effects of Pregnancy and Delivery

MAJOR DEPRESSIVE DISORDER

As with many psychiatric disorders, biologic (e.g., genetic) vulnerability and stress and trauma are some of the factors that underlie the risk for MDD. There are multiple theories of depression, and they are not necessarily exclusive. For example, the presence and activity of neurotrophic and growth factors are enhanced by antidepressant treatment.⁸ People with depression show dysregulation and volume reduction in critical brain areas such as the anterior cingulate cortex, the amygdala, and the hippocampus,⁹ regions that are affected by elevations in glucocorticoids.¹⁰ A wealth of literature associates mood symptoms with elevated levels of cortisol¹¹ and corticotrophin-releasing hormone,¹² and serotonin is involved in the regulation of the hypothalamic-pituitary-adrenal (HPA) axis.¹³

Specific triggers or biologic deficits that increase the risk for mood symptoms and mood disorders in pregnancy or the postpartum period are not well delineated. Some work suggests dysregulation in the HPA axis.^{14,15} Women who experience postpartum mood symptoms, as compared with postpartum women who do not, may be more likely to have elevations in corticotrophin-releasing hormone levels in pregnancy,¹⁶ although not all studies have found this.¹⁵

The elevations of placental corticotrophin-releasing hormone in pregnancy lead to a refractory period of HPA reactivity after delivery, although women who are postpartum and depressed have an extended, blunted response.¹⁷ It is also notable that the elevation in adrenocorticotropin hormone (ACTH) that occurs after delivery coincides with the development of mood symptoms.¹⁸ Uncoupling between ACTH and the cortisol response has been found among women depressed after delivery.¹⁹

Other studies have found that women who are depressed in pregnancy have mild elevations of thyroid-stimulating hormone and lower thyroxine levels,²⁰ indicative of mild hypothyroidism. Lower levels of triiodothyronine and thyroxine in pregnancy have been associated with postpartum depressive symptoms.²¹

Psychosocial and familial factors and medical history are related to the risk for depression after delivery.²² In particular, a personal history of depression, a family history of depression, and the lack of partner support increase the risk for postpartum depression.

BIPOLAR DISORDER

The biologic underpinnings of bipolar disorder are being actively explored, particularly through the use of brain imaging and genetics. Although not definitive, differences in the amygdala, paralimbic structures, and frontal cortices, as well as in the connections between these structures, have been found between individuals with and without bipolar disorder.^{23,24} The amygdala appears to be hyperactive in patients with mania, whereas top-down control from the prefrontal cortex is reduced.²³ Dysfunction in the prefrontal cortex may be a trait deficit, as it has also been found in depressed and euthymic mood states of people with bipolar disorder.²³ Genetics probably plays a role, as selective nerve growth factors have been associated with amygdala size.^{24,25} Treatment with agents such as lithium may promote cellular growth in certain regions, perhaps explaining the long-term therapeutic effects of these agents.²³

The state of pregnancy, per se, does not increase the risk for relapse among women with bipolar disorder.^{7,26} Rather, discontinuation of a number of medications used to treat bipolar disorder, many of which are teratogenic,²⁷ is a powerful cause for illness relapse in pregnancy.²⁸ On the other hand, numerous studies have found that women who suffer from bipolar disorder are at high risk for relapse during the postpartum period whether compared with nonpregnant or pregnant women with bipolar disorder.^{4,26,29} Some hypothesize that dysregulation of sleep patterns contributes to postpartum relapse,³⁰ but this has not been empirically proven.³¹ It could also be that the high dosages of gonadal steroids expressed by the placenta contribute to mood stabilization in pregnancy and deterioration in mood after postpartum withdrawal. Of course, mania and depression are characterized by sleep difficulties, so there is some circularity in this hypothesis, and careful longitudinal studies are needed.

SCHIZOPHRENIA AND SCHIZOAFFECTIVE DISORDER

As with the disorders already discussed, definitive causes of schizophrenia and schizoaffective disorder, which are major psychotic disorders, are not known, although genetic vulnerability, epigenetic factors, and, to a lesser extent, environmental stressors contribute to illness expression. For decades, the "dopamine hypothesis" dominated explanations for psychotic disorders such as schizophrenia and schizoaffective disorder. This model assumed that hyperactivity of the dopaminergic system was at the root of psychosis. The model was largely based on the antidopaminergic properties of first-generation antipsychotic agents, but it was also a result of the observation that psychotic patients are sensitive to dopamine agonists when administered in provocation studies. Over the years, the dopamine hypothesis has been modified to consider that a hyper-responsive dopamine system may be at fault. In this regard, the roles of glutamate and γ -aminobutyric acid (GABA) and their receptors and circuits are implicated. For example, GABA is a major inhibitory neurotransmitter and inhibits release of

dopamine. Loss of GABAergic inhibition, either because of hypoactivity of glutaminergic receptors or neurons in critical brain regions³² or because of destruction of GABAergic neurons³³ as a result of environmental insult or infection,³⁴ releases the tonic inhibition of dopamine and hence increases dopamine activity.³⁵

A frequently cited clinical finding among women who suffer from schizophrenia or schizoaffective disorder is that their illness improves during pregnancy and then worsens after delivery.³⁶ Some also claim that women with psychotic disorders, particularly when pregnant, require lower dosages of antipsychotic medications.³⁷ These findings have been attributed to the antidopaminergic effects of estrogen, which leads to the damping of dopamine activity. The situation is reversed after delivery, when estrogen levels diminish and higher dopamine activity ensues.

Diagnosis of Mood or Psychotic Disorders

Features of mood and psychotic disorders overlap, but there are central elements that differentiate the various conditions. These elements relate directly to the clinical management of mood and psychotic disorders, as follows and in Tables 66-1 and 66-2.

MAJOR DEPRESSIVE DISORDER

A major depressive episode includes symptoms of low mood and diminished capacity to experience pleasure (see Table 66-1). There are nine candidate symptoms for MDD, although a minimum of five, including either low mood or diminished pleasure, are required. Symptoms should be present for most of the day, and for most days during a 2-week interval. Women who are depressed frequently cite problems with energy, they may either oversleep or sleep too little, and they overeat or have a poor appetite. Women who are pregnant and not depressed also experience changes in energy, sleep, and appetite. Thus, a diagnosis of MDD in pregnancy requires that a clinician ask specifically about mood and other nonbehavioral symptoms. Knowledge about mood symptoms in conjunction with behavioral symptoms will allow the clinician to render an accurate diagnosis of MDD.³⁸

Depression screening scales can be helpful in identifying women who are symptomatic. However, the benefits of screening are realized only if practitioners have the skills and resources to deliver adequate interventions or to provide appropriate referrals. Well-validated screening instruments measure general distress and dysphoria and are often less specific for MDD. Appropriate tools for assessment of depressive symptoms in pregnant women include the Edinburgh Postnatal Depression Scale (EPDS),³⁹ the Inventory of Depressive Symptomatology (IDS),⁴⁰ or the Primary Care Evaluation of Mental Disorders (PRIME-MD) depression module.⁴¹ The EPDS is designed specifically for use with perinatal women, although it is less comprehensive than the IDS and does not include all of the criteria for MDD. The EPDS has 10 items and a mood and anxiety subscale. The IDS measures severity of cognitive features of depression and anxiety and atypical depressive symptoms, such as overeating and oversleeping (rather than undersleeping and undereating); it has self-report and clinician-administered versions, as well as a brief version. The PRIME-MD records

TABLE 66-1 Symptoms of Depression, Mania, and Psychosis

Criteria*	Depressive Episode	Manic Episode	Psychosis
Sad, blue, depressed mood	X		
Persistently elevated, expansive, or irritable mood		X	
Decreased interest in pleasurable activities	X		
Increased interest in pleasurable activities that are likely to lead to painful consequences (shopping sprees, sexual indiscretions)		X	
Decreased or increased appetite or weight	X		
Undersleeping	X	X	
Oversleeping	X		
Physical or mental slowing (includes catatonia)	X		X
Agitation	X (Fidgety, cannot relax)	X (Increase in goal-related activities)	X (Purposeless movements)
More talkative than usual (e.g., excessive, pressured speech)		X	
Racing thoughts		X	
Decreased energy	X		
Increased energy		X	
Worthlessness, guilt	X		
Grandiose, inflated self-esteem		X	
Poor concentration, indecision, distractibility	X (Unfocused, difficulty concentrating, difficulty making decisions)	X (Key feature: extremely distractible by irrelevant external stimuli)	X (Includes incoherence, disorganized speech)
Suicidal ideation/intent/plan	X	X	
Delusions			X
Hallucinations			X
Disorganized behavior			X
Flat affect, "no emotion"			X

*These items are the criteria for diagnosis. Patients with any of the three diagnoses may have one or more of these symptoms even if the item is not part of the diagnosis. A depressive episode requires at least five symptoms, including either low mood or diminished pleasure, lasting for 2 weeks. Mania requires at least three symptoms for at least 1 week. Schizophrenia requires two symptoms for 4 weeks.

TABLE 66-2 Depressive and Psychotic Disorders

Psychiatric Disorder	Depressive* Episodes?	Manic† Episodes?	Psychotic‡ Symptoms?	Lifetime Prevalence	Type of Treatment Usually Needed
Major depressive disorder	Yes. Central feature of the condition	No	Can have a psychotic variant	21%	Antidepressant or psychotherapy. Antipsychotic is needed for psychotic features.
Minor depressive disorder	Yes. Central feature of the condition	No	Does not typically have a psychotic variant	—	Psychotherapy is often sufficient in pregnancy, but antidepressant may be useful after delivery.
Dysthymic disorder	Yes. Chronic	No	Does not typically have a psychotic variant	—	Psychotherapy is often sufficient in pregnancy, but antidepressant may be useful after delivery.
Bipolar disorder	Yes. May have depressive episodes, or episodes with mixed depressive and manic symptoms	Yes. May have manic or hypomanic episodes. Depressive and manic symptoms can co-occur	Psychotic symptoms commonly occur but only when the patient is in an episode of mania or depression.	0.5%-1%	A mood stabilizer or antipsychotic agent is (or both are) typically needed to maintain stability.
Schizoaffective disorder	Yes. May have depressive episodes, or episodes with mixed depressive and manic symptoms	Yes. May have manic or hypomanic episodes. Depressive and manic symptoms can co-occur	Psychotic symptoms commonly occur, even when the patient is not in an episode of mania or depression.	0.5%-1%	An antipsychotic agent is typically needed to maintain stability.
Schizophrenia	Yes, but mood symptoms are neither necessary nor a central feature	No	Yes. Central feature of the condition	1%	An antipsychotic agent is typically needed to maintain stability.

*Depressive symptoms include low mood; decreased interest; alterations in sleep, energy and appetite; guilt; poor concentrations; psychomotor retardation; and suicidal ideation.

†Manic symptoms include diminished need for sleep, decreased appetite, increased energy, racing thoughts, pressured speech, and grandiosity.

‡Psychotic symptoms include auditory hallucinations, visual hallucinations, paranoia, and other delusions.

diagnoses of MDD and minor depressive disorder and has been used in obstetric-gynecologic settings; it takes 5 to 20 minutes to complete.

BIPOLAR DISORDER

A depressive episode is also experienced by individuals with bipolar disorder. However, for a diagnosis of bipolar disorder, a woman must have experienced an episode of mania or hypomania (see Table 66-1) at some point in her life. Thus, the defining feature for bipolar disorder is at least one episode of mania or hypomania, with or without a history or a current episode of MDD. It is not unusual for a person to present initially in an episode of MDD and then experience an episode of mania later in the course of her illness. This occurs more often in women than in men and reflects the fact that women with bipolar disorder are more likely to have episodes of MDD and depressive symptoms along with manic episodes during the course of their illness.⁴² Psychotic symptoms such as auditory hallucinations or delusions can also occur in women who have unipolar MDD or bipolar disorder, schizoaffective disorder, or schizophrenia. However, psychotic symptoms are not the central feature in either MDD or bipolar disorder, as they are among individuals with schizophrenia or schizoaffective disorder.

Many women with bipolar disorder were diagnosed before presenting in pregnancy and are usually able to provide this information and their lifetime treatment history to their obstetric provider. However, the first onset of bipolar disorder may occur after delivery or even during late pregnancy. In fact, women who develop psychiatric symptoms rapidly, even if the symptoms are those of depression, are highly likely to manifest bipolar disorder in the upcoming months and years.²⁹ Whereas a postpartum woman may be exhausted, a woman with mania has excessive energy and is unable to sleep even if she is given the opportunity to rest. Other symptoms of mania are listed in Table 66-1.

Screening for bipolar disorder is complicated, because an individual may present either in a manic or in a depressed state. Only two screening questionnaires have been tested in pregnant and postpartum women, and the evaluation has been limited to mania. The Highs⁴³ screens for an elevated mood that, depending on severity, may be indicative of mania. It was specifically developed for use in postpartum women.⁴⁴ The Mood Disorder Questionnaire⁴⁵ was developed for use in primary care and was evaluated in one perinatal study. Both instruments are short and easy to administer.⁴⁴ A woman who screens positive or develops the symptoms in Table 66-1 should be immediately evaluated by a psychiatrist.

SCHIZOPHRENIA AND SCHIZOAFFECTIVE DISORDER

Women who experience psychosis and are not in an episode of mania or depression may have a chronic psychotic condition such as schizophrenia or schizoaffective disorder. Schizoaffective disorder is differentiated from schizophrenia in that the former condition requires mood symptoms, including episodes of mania or major depression, that are prominent, although psychosis may also occur without mood symptoms. Mood symptoms can occur in women with schizophrenia, but they are not a cardinal feature of that disorder and are not

as prominent. Psychosis is chronic and central to both of these diagnoses.

The peak period for the onset of schizophrenia or schizoaffective disorder is the late teens and early 20s. Thus, many women who are pregnant and suffer from schizophrenia or schizoaffective disorder can provide diagnostic and treatment history. Although there are no screening scales for schizophrenia in pregnant or postpartum women, the development of delusions or hallucinations should trigger a psychiatric evaluation. Because many individuals and their doctors are uncomfortable with the use of psychotropic medication in pregnancy, they may stop pharmacologic treatment, which can precipitate an illness relapse. Postpartum women with schizophrenia or schizoaffective disorder may be at greater risk for relapse during the puerperium because of biologic factors, such as the withdrawal of reproductive hormones at delivery.

Management

Developing a treatment plan for a pregnant or postpartum woman requires consideration of the relative risks of the underlying illness and various treatment options. Women with an untreated mood or psychotic disorder face a number of potential complications. Psychiatric illness can lead to poor self-care, partial or total disability that can impair the care of others, and, in the worst scenario, suicide or homicide as a result of psychotic thoughts. Compared with women who are free of a mood or psychotic disorder, women with such conditions are more likely to smoke, use hazardous substances (e.g., alcohol, illicit drugs), and have a concurrent medical condition, and they are less likely to receive adequate prenatal care.⁴⁶⁻⁴⁹ The review that follows addresses the risk for standard obstetric outcomes, including spontaneous abortion, preterm delivery, growth restriction, congenital malformations, and perinatal complications. It does not address the maternal morbidity occurring in the context of a psychiatric illness, for which systematic data are insufficient.

UNIPOLAR MAJOR DEPRESSIVE DISORDER

Limited research suggests that high levels of stress are associated with spontaneous pregnancy loss in chromosomally normal offspring.⁵⁰ Because MDD is a stress-related illness, similar results may be expected for depressives. Unfortunately, studies looking specifically at depression are small, and the results are mixed, making it difficult to draw definitive conclusions.⁵¹⁻⁵³

Most research addressing the relationship between depression and pregnancy outcomes has assessed women with depressive symptoms rather than a diagnosed depressive disorder. This distinction is important, because people with other psychiatric conditions have elevated scores on depression screening measures. There is now a substantial literature that has assessed the possible impact of depressive symptoms on adverse birth outcomes. A meta-analytic review of 18 cohort studies found that depressive symptoms were only marginally related to preterm birth (relative risk [RR] = 1.10; 95% CI, 1.04 to 1.17). A subset of 11 studies found depression was related to low birth weight (RR = 1.18; 95% CI, 1.07 to 1.30), but the condition was not associated with delivery of small-for-gestational-age (SGA) fetuses in the 12 studies that included this outcome.⁵⁴ The small increased risk of 10% to 18% for these outcomes may be attributable to residual confounding that resulted from

a lack of information about other deleterious health habits. More recent larger studies that included a depression diagnosis, rather than depressive symptoms, have not observed that MDD is an independent and robust risk factor for an adverse birth outcome.^{55,56} Thus, current evidence does not support the conclusion that MDD in pregnancy is a significant risk factor for preterm birth, or for delivery of a low-birth-weight infant or an SGA fetus.

BIPOLAR DISORDER

Most research on birth outcomes and other postnatal complications derive largely from linked administrative databases^{57,58} that allow investigators to obtain sufficient sample sizes for relatively uncommon disorders (~1% for bipolar) and birth outcomes. Such studies have important limitations. For example, most are not able to control adequately for smoking and illicit drug use. The possible role of medication treatment in poor birth outcomes has been inadequately addressed because of heterogeneity in medication use and limited cohort sizes.

An Australian study compared outcomes for women with bipolar disorder ($n = 1301$), schizophrenia ($n = 618$), unipolar psychotic depression ($n = 1255$), and controls ($n = 3129$).⁵⁷ Placenta previa and antepartum hemorrhage were more common in women with bipolar disorder (4.2 versus 2.4%; odds ratio [OR] = 1.66; 95% CI, 1.15 to 2.39). There were no differences in birth weight, duration of pregnancy, or fetal malformations in this study.⁵⁷ Another report that included pregnant women with schizophrenia or bipolar illness found an increased risk for stillbirth (OR = 4.03; 95% CI, 1.14 to 4.25) in mothers with psychotic disorders.⁵⁸

SCHIZOPHRENIA AND SCHIZOAFFECTIVE DISORDER

The same caveats for studies of bipolar disorder in pregnancy are relevant for studies in pregnant and postpartum women who suffer from schizophrenia. Available literature suggests that women with schizophrenia have worse birth outcomes than women without the disorder.^{57,59-64} In a linked Danish database,⁶⁵ women with schizophrenia had a 46% higher relative risk for preterm birth (95% CI, 1.19 to 1.79), a 57% higher likelihood of delivering a low-birth-weight infant (95% CI, 1.36 to 1.82), and a 35% higher risk for an SGA fetus (95% CI, 1.17 to 1.53) compared with the overall population of women, findings consistent with previous reports.^{57,60} In a study that compared pregnancy outcomes in women with schizophrenia who were or were not treated with antipsychotic agents⁶⁴ to an unaffected comparison group, women with schizophrenia, regardless of treatment, had higher rates of low-birth-weight and SGA deliveries than the comparison group. Additional complications reported for women with schizophrenia include placental abruption⁵⁷ and fetal malformations,⁶⁰ including cardiac defects.⁵⁷

Some^{58,61} but not all⁶⁰ studies show an increased risk for stillbirth and neonatal death for women with psychotic disorders (including women with schizophrenia and bipolar disorder⁵⁸), and specifically for women with schizophrenia.⁶¹ The literature also notes differences in the rates of post-neonatal deaths for infants born to women with schizophrenia (0.73%) compared with mortality rates for the general population (0.26%) (RR = 2.76; 95% CI, 1.67 to 4.56).⁶⁰ Most of the deaths

were attributable to sudden infant death syndrome (SIDS), which occurred at a rate of 0.46% for children born to women with schizophrenia and 0.1% for the general population (RR = 5.23; 95% CI, 2.82 to 9.69).

Risks of Psychopharmacologic Treatment during Pregnancy

ANTIPSYCHOTIC AGENTS

Antipsychotic agents include older, typical antipsychotic medications and newer, atypical antipsychotic agents. The older ones are further divided into the low-potency medications, such as the phenothiazines, and high-potency agents, such as the butyrophenones.

Malformations

A comprehensive meta-analysis showed a small increase (of four cases for every 1000 women) in the overall malformation rate among women who took low-potency agents, but there was no specific pattern to the reported anomalies.⁶⁶ This finding was echoed by a Swedish registry, which failed to find a specific pattern of malformations associated with antipsychotic medication use.⁶⁷ The lack of a pattern in these studies leaves open the possibility that factors other than the drugs contributed to this association. A prospective study of butyrophenones in pregnancy found no differences in the rates of malformations for this exposure compared with controls, but it was underpowered for that endpoint.⁶⁸

Information regarding risks associated with atypical antipsychotics is sparse but increasing. Postmarketing data about prenatal exposure to risperidone showed a rate of malformations that was consistent with the rate (3.8%) in the general population.⁶⁹ However, the report included prospective outcomes for only 68 women. Rates of malformations in retrospectively reported cases subject to ascertainment bias were higher.

Gestational Age and Size

A registry study compared women with schizophrenia who were not treated, and women treated with typical antipsychotics or atypical antipsychotics, and an unaffected, untreated group. The risk for preterm birth was more than twice as high among women who suffered from schizophrenia and took a typical antipsychotic agent as among women in other groups.⁶⁴ Another registry study found significantly higher rates of preterm birth and low-birth-weight delivery in mothers who took antipsychotic agents in pregnancy than in nonexposed maternal controls.⁶⁷

The largest prospective cohort study ($n = 206$ first-trimester exposures versus 631 controls) of birth outcomes and the high-potency butyrophenones such as haloperidol found that preterm birth (13.9%, versus 6.9% for controls) was more common for women who used this class of antipsychotic agent.⁶⁸ Birth weight was significantly lower in infants born to mothers taking a butyrophenone.

Other Pregnancy Complications

There is an increased risk for gestational diabetes in antipsychotic-treated women.^{70,71} Insulin resistance and weight gain⁷² have been linked to use of these agents in nonpregnant populations.⁷³

Postnatal Effects

Postnatal effects related to in utero exposure to antipsychotic agents were studied by comparing neurodevelopmental scores in 6-month-old infants who were exposed to an antipsychotic agent or an antidepressant agent, with the scores of infants unexposed to psychotropic agents in utero. Normal neuromotor function was observed in 50% of unexposed infants and 32% of those exposed to antidepressants, compared with 19% of infants exposed to an antipsychotic agent in utero.⁷⁴

In sum, no specific pattern of fetal anomalies has been associated with older antipsychotic agents. Perinatal complications such as preterm birth have been found among women who were treated with antipsychotic agents, particularly older, high-potency agents. Newer agents may increase the risk for insulin resistance and weight gain in pregnancy. Findings with regard to differences in neuromotor function after the neonatal period require replication and assessment of longer-term consequences.

MOOD STABILIZERS

Lithium

The use of lithium during pregnancy has been comprehensively reviewed by the Institute for Evaluating Health Risks.⁷⁵ Early reports from the International Registry of Lithium Babies,⁷⁶ a voluntary physician-reporting database, described a 400-fold increased rate for cardiovascular malformations, most notably Ebstein anomaly, in offspring who were exposed in utero. This high rate was probably an overestimate resulting from ascertainment bias, because the risk for Ebstein anomaly among lithium users in subsequent prospective studies ranged from 2 per 1000 (0.05%) and 1 per 1000 (0.1%), or 20 to 40 times higher than the rates for the general population.^{77,79} A population-based study⁸⁰ found that the odds ratio for any cardiac malformation was 7.7 (95% CI, 1.9 to 7.7), although none of these anomalies was an Ebstein type. The odds ratio for any malformation was 3.3 (95% CI, 1.2 to 9.2) in this study.

Other complications found among women who used lithium in pregnancy include growth reduction,^{75,78} acute lithium toxicity in neonates,^{75,81} and possibly neonatal mortality.^{75,82} There is little evidence for long-term neurodevelopmental complications from in utero exposure to lithium.^{83,84}

Valproic Acid

Valproic acid use during pregnancy is associated with neural tube defects in 5% to 9% of exposed offspring.^{85,86} Neural tube-related teratogenicity occurs between 17 and 30 days after conception and is dosage related.^{85,87} Valproic acid is more commonly associated with lumbosacral than with anencephalic lesions.⁸⁷ There is now evidence to suggest that first-trimester exposure to monotherapy with valproic acid is more likely to lead to spina bifida than are exposures to other common antiepileptic drugs,⁸⁸ and the relationship is increased by higher dosages.⁸⁹ Aside from spina bifida, valproic acid is associated with heart valve defects,⁸⁸ cleft palate,⁸⁸ hypospadias,⁸⁸ and polydactyly.⁸⁸

Valproic acid use in pregnancy has been linked to growth restriction,⁸⁷ withdrawal symptoms of irritability and jitteriness, feeding difficulties, abnormal tone,^{86,90} hypoglycemia,⁹¹ and reduced neonatal fibrinogen levels.⁹² Mental retardation has also been described.⁹³

In women who use antiepileptic medication such as valproic acid, limited data suggest that folic acid supplementation before conception reduces the risk for major congenital malformations.^{89,94,95} The risk for major congenital malformations is not eliminated but is reduced among those who used folic acid supplementation in the first trimester.⁸⁹ There is no clear benefit for higher dosages.⁹⁴

Carbamazepine

Like valproic acid, carbamazepine is considered a human teratogen. Neural tube defects are prominent, occurring in 0.5% and 1% (in two studies) of offspring exposed in utero.^{96,97} Other anomalies include craniofacial defects (11%), fingernail hypoplasia (26%), and developmental delay (20%) in liveborn offspring.⁹⁶

The teratogenic potential of carbamazepine is frequently attributed to the toxic epoxide metabolites.⁹⁸ Oxcarbazepine, which does not produce the epoxide metabolite, may be less teratogenic, although this has not been confirmed by empirical data.

Other complications associated with carbamazepine use include reduction in birth weight (about 250 g),⁹⁹ head circumference (standardized for gestational age and sex),¹⁰⁰ and hepatic dysfunction.¹⁰¹

Lamotrigine

Outcomes of pregnancy in women treated with lamotrigine were published by the Lamotrigine Pregnancy Registry maintained by GlaxoSmithKline.¹⁰² Rates of defects among 785 exposed infants followed prospectively were similar to the base rate in nonexposed populations. However, a twofold increased risk in the overall malformation rate was observed in offspring born to women whose dosage of lamotrigine exceeded 300 mg/day.⁸⁹ A follow-up study of 23 infants exposed demonstrated no alterations in development at 12 months of age.¹⁰³

ANTIDEPRESSANTS

Increasing numbers of women are undergoing antidepressant treatment during pregnancy.¹⁰⁴ According to one estimate,¹⁰⁴ 13% of women took an antidepressant at some point during pregnancy, so information about exposure to antidepressants and birth outcomes is important.

There are several classes of antidepressants, including monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), and others (e.g., bupropion) (Table 66-3). SSRIs are the most frequently prescribed antidepressants during pregnancy, whereas MAOIs are rarely used.^{104,105} Information about antidepressant use in pregnancy is greatest for the SSRIs and TCAs.¹⁰⁴

Miscarriage

An earlier meta-analytic study found that antidepressant use in early pregnancy was associated with a 45% higher risk (95% CI, 1.19 to 1.77) for miscarriage.¹⁰⁶ The absolute risks in this analysis ($n = 3567$) were 12.4% and 8.7% for exposed and nonexposed mothers, respectively, raising the question of ascertainment bias in some of the studies included. Information about other maternal illnesses or confounding health habits was not available in most of the studies constituting the meta-analysis. A registry study also found elevations in the rate of

TABLE 66-3 Antidepressants

Class	Name: Generic (Trade)	Daily Dosage (mg)
Selective serotonin reuptake inhibitors (SSRIs)	Citalopram (Celexa)	20-40
	Escitalopram (Lexapro)	10-20
	Paroxetine (Paxil)	20-50
	Paroxetine controlled release (Paxil-CR)	25-62.5
	Fluoxetine (Prozac)	20-80, or 90 mg on a weekly basis
	Sertraline (Zoloft)	50-200
	Fluvoxamine (Luvox)	50-300
Monoamine oxidase inhibitors (MAOIs)	Isocarboxazid (Marplan)	10-60
	Phenelzine (Nardil)	60-90
	Tranylcypromine (Parnate)	30-60
Tricyclic antidepressants (TCAs)	Amitriptyline (Elavil)	50-200
	Clomipramine (Anafranil)	25-250
	Desipramine (Norpramin)	100-300
	Doxepin (Sinequan)	25-150
	Imipramine (Tofranil)	75-200
	Maprotiline (Ludiomil)	75-225
	Nortriptyline (Pamelor)	25-150
	Protriptyline (Vivactil)	15-60
	Trimipramine (Surmontil)	75-200
	Serotonin-norepinephrine reuptake inhibitors (SNRIs)	Duloxetine (Cymbalta)
Desvenlafaxine (Pristiq)		50
Venlafaxine (Effexor)		25-375
Venlafaxine (Effexor XR)		37.5-225
Other	Bupropion (Wellbutrin)	200-450
	Bupropion sustained release (Wellbutrin S)	150-400
	Bupropion extended release (Wellbutrin XL)	150-450
	Trazodone (Desyrel)	150-400

late miscarriage among women who took an antidepressant, particularly an SSRI or an SNRI (e.g., venlafaxine) during pregnancy.¹⁰⁷ Analyses indicate that the highest risk was associated with multiple antidepressant use; when the type of antidepressant was analyzed, only paroxetine and venlafaxine showed significant effects.

Fetal Growth and Prematurity

Several studies have reported that antidepressant use during pregnancy is associated with shorter gestations,^{56,108-113} particularly for exposures occurring during the third trimester.^{108,109,112} Overall, the effect on length of gestation is modest, with differences of 1 week or less between exposed and nonexposed offspring, but very large sample sizes would be necessary to see the less common, earlier preterm deliveries.^{110,113-118} Several reports attempted to control for a depressive illness. The effects of antidepressant exposure endured in two investigations^{55,56} was limited to fetal head growth in a third study¹¹⁹ but not related to antidepressant use in the other investigation.¹¹³

Reductions in birth weight, including low-birth-weight and SGA infants, have been associated with SSRI use during pregnancy.^{55,112,113,119} Study findings regarding the risk for delivering an SGA infant after maternal TCA use in pregnancy are mixed.^{112,120} The differences between exposed and nonexposed infants are small (e.g., increases from 7.4% to 8.5% for rates of SGA infants in one study after exposure to an SSRI⁵⁵). Statistical attempts to control for maternal illness did not account for the possible effects of SSRIs on birth weight.^{55,113}

Structural Malformations

Available information does not suggest that TCAs increase the risk for structural malformations.^{66,113,121} Older studies did not find an association between SSRIs and structural

malformations,^{122,123} but later reports suggest a modestly increased risk for malformations for infants born to mothers exposed to SSRIs in early pregnancy.¹²⁴ Findings of the National Birth Defects Prevention Study¹²⁵ show an association between SSRI use (during the month before and the first 3 months of pregnancy) and anencephaly (OR = 2.4; 95% CI, 1.1 to 5.1), craniosynostosis (OR = 2.5; 95% CI, 1.5 to 4.0), and omphalocele (OR = 2.8; 95% CI, 1.3 to 5.7). Somewhat different findings were reported by a similar case-control study,¹²⁶ in which the overall malformation rate among SSRI users was not increased, but the rate of omphalocele and septal defects was higher among offspring specifically exposed to sertraline (OR = 5.7; 95% CI, 1.6 to 20.7 for omphalocele, and OR = 2.0; 95% CI, 1.2 to 4.0 for septal defects). Right ventricular outflow tract obstruction defects occurred at a significantly higher rate among paroxetine-exposed infants (OR = 3.3, 95% CI, 1.3 to 8.8). Other studies found an increased risk for cardiac malformations among offspring specifically exposed to paroxetine, compared with those exposed to drugs deemed nonteratogenic¹²⁷ or population-based controls.^{116,128} Most defects were atrial or ventricular septum defects, and one report suggested that an elevated risk occurred only for infants whose mothers took 25 mg per day or more of paroxetine.¹²⁹ A meta-analytic review of first-trimester paroxetine exposure found an increased risk for any cardiac malformation (OR = 1.46; 95% CI, 1.17 to 1.82), netting an additional one case for every 200 additional exposures.¹³⁰

As noted earlier, if defects associated with the class of SSRIs or individual SSRI agents are causal, the absolute risk remains small. A twofold to fivefold increased risk is small in absolute numbers for the rates of omphalocele (background rate, 1 in 5000), craniosynostosis (background rate, 1 in 1800), and anencephaly (background rate, 1 in 1000). The most common

anomalies are cardiac, for which the incidence is 1.8% to 2% for the exposed population compared with about 1% for an unexposed population. It is precisely because these events remain so rare that there are inconsistencies among studies. An editorial acknowledged a possibly increased risk for malformations for infants born to mothers who used SSRIs in the first trimester, but it argued that these data also show that SSRIs are not major teratogens.¹³¹ Given the sources for most reports (e.g., linked databases, surveillance database) and the lack of information about maternal illness or concurrent hazardous substance use, confounding effects remain possible.

The newer, non-SSRI antidepressants include bupropion, venlafaxine, duloxetine, reboxetine, nefazodone, and mirtazapine (see Table 66-3). These agents vary in chemical structure, and there is far less information regarding their possible teratogenic effects. The largest analysis of their associated risks found no statistically significant difference in the rate of congenital anomalies for offspring exposed to any one of them compared with the offspring exposed to antidepressants in aggregate or to nonteratogens.^{110,115-117}

Other Perinatal Complications

Compared with unexposed infants, newborns exposed to TCAs and SSRIs in utero are more likely to experience jitteriness, irritability, and, rarely, convulsions.^{109,112,132,133} The underlying mechanisms related to prenatal antidepressant exposure and short-term sequelae are not known but may be a sort of pharmacologic toxicity.¹³⁴ These symptoms are transient and usually resolve by 2 weeks of age.¹³⁵

As noted earlier, 6-month-old infants who were exposed to antidepressants in utero were numerically less likely to score on the normal range of a neurodevelopmental battery than nonexposed infants, but the difference did not achieve statistical significance.⁷⁴

Persistent pulmonary hypertension was initially reported in infants exposed to SSRIs after 20 weeks' gestation,¹³⁶ for whom the likelihood was sixfold higher than for controls. This translated into an absolute risk of 6 to 12 cases per 1000 exposed, compared with 1 or 2 cases per 1000 nonexposed infants. Neither exposure to SSRI medications before 20 weeks' gestation nor exposure to non-SSRI antidepressants affects the risk for persistent pulmonary hypertension. Since publication of this report, the finding has been replicated by several^{137,138} but not all groups.¹³⁹ The replications have suggested absolute risks that are lower, at about 3 cases per 1000 exposed infants.

A single case-control study that used medical record information from mothers enrolled in the Kaiser-Permanente group found an association between SSRI use in pregnancy and autism spectrum disorders.¹⁴⁰ It is not yet clear whether the association was causal, and this finding has not yet been replicated.

Clinical Approach to Treatment of Depression and Psychoses in Pregnancy

Clinical guidelines for treatment of pregnant women with unipolar MDD are available from the American Psychiatric Association (APA)¹⁴¹ and experts in the field.¹⁴² There are also guidelines available from the American College of Obstetricians and Gynecologists in conjunction with the APA.¹⁴³ Guidelines for treating women with bipolar illness are available from the APA.²⁷ There are no APA guidelines for treatment of women

TABLE 66-4 Antipsychotics and Mood Stabilizers

Name: Generic (Trade)	Daily Dosage (mg)
FIRST-GENERATION ANTIPSYCHOTICS	
Chlorpromazine (Thorazine)*	75-400
Fluphenazine (Prolixin)	1-20
Haloperidol (Haldol)	3-15
Loxapine (Loxitane)	60-100
Perphenazine (Trilafon)	8-64
Pimozide (Orap)	1-10
Thioridazine (Mellaril)	50-800
Thiothixene (Navane)	6-60
Trifluoperazine (Stelazine)	10-40
SECOND-GENERATION ANTIPSYCHOTIC AGENTS	
Aripiprazole (Abilify)*	10-15
Asenapine (Saphris)*	10-20
Clozapine (Clozaril)	12.5-900
lloperidone (Fanapt)	12-24
Lurasidone (Latuda)	40-60
Olanzapine* (Zyprexa)*	2.5-20
Paliperidone (Invega)	3-12
Quetiapine* (Seroquel)*	150-800
Risperidone* (Risperdal)*	1-8
Ziprasidone* (Geodon)*	20-160
MOOD STABILIZERS	
Valproic acid (Depakote)	750
Lamotrigine (Lamictil)	25-200
Cabamazepine (Tegretol and Tegretol-XR)	200-400

*These antipsychotic medications are also approved for the treatment of mania.

with schizophrenia who are pregnant, but Trixler and colleagues¹⁴⁴ contributed a thorough review in 2005.

A treatment plan for a pregnant or postpartum woman with depression should begin with a determination of whether the patient has had recent or past symptoms of mania or psychosis, because this can help to determine the optimal treatment approach. In general, individuals with severe or recurrent unipolar MDD may need antidepressant treatment (see Table 66-2). If they have psychotic symptoms, treatment with an antipsychotic agent is also required. Because antidepressants can trigger or promote mania, antidepressant treatment must be used judiciously in women with a history of mania. Instead, mood stabilizers or antipsychotic agents with mood-stabilizing properties (e.g., atypical antipsychotics) are necessary (Table 66-4). Women with schizophrenia or schizoaffective disorder require treatment with an antipsychotic agent and, in the latter case, a mood stabilizer.

Unipolar Depression

Factors that need to be considered to determine optimal therapy for a woman with mood disorders include her treatment preferences, her clinical history, her current illness status, her resources, and the risks associated with the various medications that she may consider as treatments in pregnancy. An evaluation before conception allows a discussion of all treatment options and may allow a change in therapy, if so desired. Some women prefer not to take any medication, whereas others want to continue medication, especially if they have a history of severe, recurrent illness and relapse after medication discontinuation. A discussion about therapeutic options and the patient's preferences should be documented in the medical chart. Discussion

of the risks associated with medication treatment and underlying illness should occur with the patient, and her family if she desires, and documented in the medical record. If appropriate, women may be encouraged to engage in psychotherapy, which may allow them to be medication free during pregnancy or may improve the response to pharmacologic treatment. A healthy mother is the goal. Her well-being promotes the health of her fetus.

Women who do not have a history of severe recurrences after medication has been discontinued may be candidates for watchful waiting or behavioral therapy.¹⁴⁵ Empirically validated psychotherapies, including interpersonal psychotherapy¹⁴⁶ and cognitive-behavioral therapy,¹⁴⁷ may help women stay well after they discontinue medication. Women who do not have severe or recurrent depression may stay euthymic in pregnancy, even after medication discontinuation.¹⁴⁵ Women often have a sense of whether they can or cannot safely discontinue medication during pregnancy. Perhaps they tried to stop pharmacotherapy in the past to prepare for pregnancy and had a relapse. Clinicians should query women about attempts to discontinue pharmacotherapy in the past to help guide clinical decision making in pregnancy. A woman who discontinues pharmacotherapy should be monitored closely for relapse. Risks are probably elevated for women who have had an episode of illness in the 6 months before pregnancy¹⁴⁵ or have had multiple prior episodes of illness.^{145,148} For women whose history precludes medication discontinuation, treatment with the lowest effective dosage of an agent that has been helpful to them is indicated. Because of the data discussed previously regarding paroxetine use in pregnancy, some clinicians and experts prefer other medications as a first-line agent.

Women who are already pregnant and develop a depressive disorder may be referred for psychotherapy as a first-line intervention or to augment pharmacotherapy. If the woman relapsed in the setting of discontinuing an antidepressant to which she had responded, she might need to have the medication restarted.

Bipolar Disorder

Because of the seriousness of bipolar disorder and the need for pharmacotherapy, pregnant women with bipolar disorder should be co-managed by a psychiatrist. Women who have a history of mania, whether they are in an episode of depression or not, should be treated with pharmacotherapy. Psychotherapy may be a helpful adjunct for these women, but it is not likely to supplant the efficacy of pharmacotherapy. Unfortunately, many of the medications used to treat bipolar disorder, including selected anticonvulsants such as valproate and carbamazepine, have teratogenic effects (described previously and in Chapter 31). Teratogenic effects have also been found after first-trimester exposure to lithium. As an alternative to these agents, some experts rely on the use of older antipsychotic agents, at least during the first trimester or longer.¹⁴² Lithium or an anticonvulsant may be reinstated after the first trimester. Lamotrigine is a possible treatment during pregnancy. However, it needs to be titrated slowly from about 25 mg daily to about 200 to 300 mg daily, so it is not an option for women who need to discontinue one mood stabilizer (e.g., valproic acid, lithium) and rapidly start another one.

Women with bipolar disorder need careful monitoring throughout pregnancy. Changes in renal and hepatic function and volume of distribution in pregnancy mean that dosage requirements may increase. This is particularly true with

lithium⁷⁵ and lamotrigine.¹⁴⁹ Not all pregnant women with bipolar disorder can remain euthymic without a mood stabilizer. The beginning signs of relapse should prompt clinicians to restart these treatments. Difficulty sleeping during pregnancy and after delivery may trigger mania or signify incipient relapse. Women who report this symptom should be prescribed adjunctive antipsychotics with soporific effects to aid in sleep and mood stabilization.

Schizophrenia and Schizoaffective Disorder

Women who suffer from schizophrenia and schizoaffective disorder typically require pharmacologic treatment to control symptoms. A mood stabilizer may also be indicated, although first-trimester use of valproate, carbamazepine, and lithium should be avoided if possible. There are substantial data about the use of older, typical antipsychotic agents in pregnancy, and clinicians may elect to rely on these agents. Women with these conditions are at high risk for developing a mood disorder after delivery and are liable to experience worsening of their psychosis.²²

PERIPARTUM COMPLICATIONS

Women treated with lithium or lamotrigine during pregnancy require adjustment in dosage after delivery. Some experts recommend withholding lithium for about 24 hours before parturition because of the risk for maternal toxicity when the patient's volume contracts.¹⁵⁰

Neonates exposed to lithium in utero are at risk for neuromuscular complications, respiratory difficulties, cardiac arrhythmias, and renal and hepatic dysfunction.^{73,150} Because neonatal complication rates increase with maternal dosage, maintaining the lowest effective dosage is optimal for the infant.¹⁵⁰ In utero exposure to antipsychotic agents may lead to neonatal complications, including hypertonicity, motor restlessness, tremor, and difficulty with feeding.¹⁴⁴ Similarly, in utero exposures to TCAs and SSRIs are associated with increased perinatal complications, including jitteriness, irritability, and convulsions in as many as 20% to 30% of infants.^{66,109,112,151} Acute signs of the anticholinergic effects of TCAs, such as functional bowel obstruction and urinary retention, have also been described. These problems resolve within a few days to a week.

Studies examining the long-term developmental outcomes of children exposed to TCAs, SSRIs, and lithium in utero have failed to demonstrate that exposure to these agents affects global IQ, language development, or behavioral development, but these investigations were relatively small.^{84,121,152-154} One study found short-term effects on neurodevelopment in neonates exposed to antipsychotic agents, but long-term outcomes have not yet been reported.⁷⁴

PHARMACOTHERAPY DURING LACTATION

Psychotropic medications are usually alkaline and lipid soluble. They diffuse into breast milk. Infants have immature renal and hepatic systems, their blood-brain barrier is more permeable, and they may be more vulnerable to side effects. The use of psychotropic medications in lactating women has been extensively reviewed¹⁵⁵ (see Chapter 9).

Several factors should be considered before prescribing psychotropic medications to nursing mothers, including the

benefits of breastfeeding for the infant, the severity of the mother's symptoms if left untreated, mothers' preferences, and the potential risk to the infant if psychotropic drugs are ingested through breast milk. With the exception of lithium, which equilibrates well in breast milk,¹⁵⁶ the amount of psychotropic drugs excreted in the mother's breast milk is modest.¹⁵⁵ Infants younger than 2 months old¹⁵⁵ and those exposed to medication in utero achieve higher psychotropic drug levels and are at greater risk for side effects.¹⁵⁷ Fortunately, data suggest that exposure to these drugs in breast milk does not seem to have any deleterious effects on growth or development.¹⁵⁵ Because of the narrow therapeutic index of lithium and the immature renal status of neonates, some experts recommend avoiding this agent during lactation,¹⁵⁵ although the American Academy of Pediatrics does not absolutely contraindicate breastfeeding for women receiving lithium therapy.¹⁵⁸

Another drug to be avoided is the atypical antipsychotic clozapine (Clozaril), because agranulocytosis may occur in the infant or the mother.

If a mother decides to breastfeed while taking an antidepressant, antipsychotic, or mood-stabilizing agent, she should monitor her infant carefully for irritability, poor feeding, difficulty with arousal, muscle rigidity, tremors, fever, and difficulty gaining weight. Such symptoms should prompt reevaluation and consideration of a trial off breast milk.

Prevention

The psychiatric illnesses described tend to be chronic conditions. Even though MDD is often episodic, the norm is for an individual to have recurrent illness. Similarly, bipolar disorder is characterized by episodes that may be interspersed with euthymia. Individuals with schizophrenia tend to have ongoing symptoms although pharmacologic treatment may damp symptom expression. Thus, prevention should be thought of as secondary or tertiary prevention. In essence, it typically means avoiding recurrences of episodes or worsening of episodes. Because many women attain a degree of stability in pregnancy,^{4,7,26} the goal in many instances is to avoid episode recurrence around the time of delivery.

MAJOR DEPRESSIVE DISORDER

Both pharmacologic and behavioral treatments have been studied as possible prophylactic strategies for recurrence of postpartum depression. The few studies of pharmacotherapy have not shown clear benefit of prophylactic initiation of antidepressant medication after delivery as compared with clinical monitoring.¹⁵⁹ One small study suggested that an SSRI would have prophylactic benefit,¹⁶⁰ but a follow-up study failed to show that this class of agents is superior to TCAs, which previously failed to show prophylactic benefit in postpartum women.¹⁶¹

Behavioral interventions have also failed to show definitive benefit.¹⁶² A recent study showed peer support for postpartum women with depressive symptoms was superior to a no-support condition.¹⁶³ However, peer support did not lead to higher

treatment success rates for women with more severe depression.

BIPOLAR DISORDER

As noted earlier, many women with postpartum psychosis go on to evidence a clinical course consistent with bipolar disorder. Therefore, bipolar disorder and postpartum psychosis are considered jointly. Older work found that initiation of lithium in late pregnancy decreased the likelihood of relapse into an episode postpartum psychosis,¹⁶⁴ and that lithium discontinuation in postpartum women is a particularly robust trigger of relapse.⁴ However, a randomized controlled trial did not support postpartum prophylactic treatment with other mood-stabilizing agents.¹⁶⁵

A large cohort of women with a history of postpartum psychosis or bipolar disorder was followed. Medication treatment in pregnancy appeared to only partially mitigate the risk for relapse in pregnancy for women with bipolar disorder; the rate of relapse was higher after the birth than during the pregnancy despite ongoing pharmacotherapy.¹⁶⁶ On the other hand, women with a history of postpartum psychosis who did not carry a diagnosis of bipolar disorder were likely to remain stable in pregnancy and benefit from postpartum prophylaxis with lithium.

Summary

Pregnancy does not protect women from developing or continuing to experience a mood or psychotic disorder, although rates of mood disorders and symptom expression for psychotic disorders tend to be lower in pregnancy than in other times of a woman's life. Schizophrenia and bipolar disorder have been associated with severe complications, including stillbirth, neonatal and post-neonatal deaths, and low-birth-weight and preterm deliveries. Women with these psychiatric illnesses should be considered to have high-risk pregnancies. Some women with severe recurrent MDD may be at risk for preterm delivery or delivery of a low-birth-weight infant, although milder instances of a depressive illness do not appear to incur high risks.^{54,56,167} The psychotropic agents most frequently associated with malformations are the antiepileptic mood stabilizers, valproic acid and carbamazepine, and the standard bipolar therapy, lithium. Paroxetine may also be associated with a higher risk for malformations, particularly cardiac malformations, than other antidepressant agents.¹³⁰ First-trimester use of these agents should be avoided if possible. Women of reproductive potential who are taking these agents may consider taking folate prophylactically in case of unintended pregnancy, but it is not clear that this substantially diminishes risks. Collaboration between obstetric and psychiatric providers in managing pregnant women with mood and psychotic disorders can enhance maternal and infant health and well-being.

Substance Abuse in Pregnancy

MONA R. PRASAD, DO, MPH | HENDRÉE E. JONES, PhD

Substance abuse and dependence disorders are among the most complex clinical health challenges that affect individuals, families, and society. Only rarely do pregnant women initiate drug use during pregnancy. It is most common for women to enter pregnancy already abusing or dependent on drugs. This chapter reviews the prevalence of drug abuse and dependence among individuals in the United States and discusses the uses and limitations of screening in women of reproductive age. Exposure to six different classes of drugs during pregnancy is then reviewed: tobacco, alcohol, marijuana, opioids, stimulants, and benzodiazepines. For each class of agent, the prevalence, pharmacology, screening, effects on maternal physiology and lactation, and effects on the fetus, neonate, and child are discussed, followed by treatment recommendations. The chapter concludes with a review of the current gaps in the research literature as they relate to clinical practice, and suggestions for future research.

Extent of Drug Abuse and Dependence in the United States

DRUG USE AMONG THE GENERAL POPULATION

Estimates suggest that the number of new initiates to cocaine and methamphetamine is significantly less in 2013 than in 2002. In the United States, there are an estimated 810,000 to 1 million chronic opioid (heroin) users and 6.4 million abusers of prescription narcotics. Remarkably, 12% of 12- to 17-year-olds and 22% of 18- to 25-year-olds report prescription opioid abuse. The number of new initiates to opioid abuse has been steady over the past 7 years. Tracking these trends and their regional and local variations offers opportunities to understand and potentially reduce the problem of substance abuse and dependence in pregnancy.

In addition to the alarming numbers of new and young drug initiates, the prevalence of substance use disorders is a concern. In 2010, 22.1 million Americans 12 years of age or older (8.9% of that population) met criteria for substance abuse or dependence.^{1,2} The prevalence of substance abuse among males in this age group was twice that of females (11.2% versus 6.8%). However, the prevalence data for adolescents suggest that the gender gap may be closing, primarily due to an increase among females (10.4% for males, 9.8% for females) that has the potential to complicate pregnancy.

DRUG USE AMONG WOMEN

An estimated 4.5 million U.S. women abuse alcohol, 3.5 million women abuse prescription drugs, and 3 million women regularly use illicit drugs (Fig. 67-1).³ Substance abuse has unique

effects in women that lead to more severe sequelae from addiction than in men.⁴ The transition of illicit drug *use* to *abuse* is more rapid for women than for men.⁵ In addition to unintended pregnancy, women are more likely to have a dual diagnosis, most commonly depression. They are also at greater risk than men for past and current physical and sexual victimization and post-traumatic stress disorder.^{2,3,6-8} Women are more susceptible to liver disease and hepatitis than men who consume the same amount of alcohol, and their alcohol-related mortality rate is 50 to 100 times that of men (Table 67-1).^{9,10}

DRUG USE AMONG PREGNANT WOMEN

During pregnancy, 16.3% of women report continued tobacco use, 10.8% report continued alcohol use, and 4.4 % report illicit drug abuse.¹ The financial impact of substance abuse has been quantified with regard to the care of neonates prenatally exposed to substances. For example, \$5.4 billion was spent in 2008 caring for alcohol-exposed neonates.¹¹ Costs for delivery and immediate postnatal care of infants exposed to tobacco were estimated at \$122 million nationally.¹² For neonates prenatally exposed to opiates, the latest national data show that average hospital charges for those discharged with a diagnosis of neonatal abstinence syndrome (NAS) were \$53,400 (95% confidence interval [CI], \$49,000 to \$57,700), yielding \$720 million (CI, \$640 to \$800 million) as a total estimate of hospital charges for infants with NAS.¹³

All forms of substance abuse contribute to poor maternal, fetal, and neonatal outcomes, but attention devoted to prenatal exposure to alcohol, stimulants, and sedatives by social, clinical, and scientific researchers has varied substantially over past decades. These disorders are best understood and treated in a context that acknowledges the myriad life challenges faced by drug-abusing or -dependent pregnant women.¹⁴

Screening of Pregnant Patients

Because pregnancy is one of the few opportunities for many substance-using women to encounter the health system, prenatal care providers are well positioned to screen for substance abuse and dependence and to initiate interventions. Accurate assessment of substance abuse during pregnancy is difficult because of the sensitive nature of the problem and the reliance on self-report for ascertainment. Substance-abusing patients come from all socioeconomic strata, races, ethnicities, and ages. Screening methods that target high-risk patients typically underestimate the magnitude of the population in need and fail to identify women who require services.^{15,16} There is considerable stigma associated with drug and alcohol use during pregnancy, further deterring patients from providing this information.

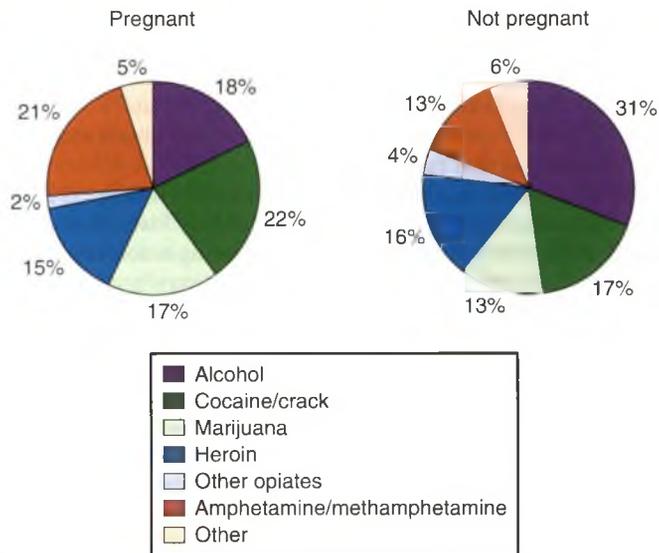

Figure 67-1 Primary substance of abuse by pregnant and nonpregnant women between 15 and 44 years of age who were admitted to treatment in 2002. (From *Substance Abuse and Mental Health Services Administration: Treatment episode data set (TEDS). 1999-2009. National Admissions to Substance Abuse Treatment Services, DASIS Series: S-56, HHS Publication No. (SMA) 11-4646. Rockville, MD, 2011, Substance Abuse and Mental Health Services Administration. <http://www.dasis.samhsa.gov/teds09/teds2k9nweb.pdf>. Accessed June 28, 2013.*)

TABLE 67-1 Rates of Co-occurring Mood and Anxiety Disorders among Women in the General Population with a Drug Use Disorder

Type of Mental Health Disorder	Rate of Concurrent Mental Health and Substance Use Disorders (%)
Major depression	30.1-48.5
Dysthymia	10.1-20.9
Bipolar disorders	3.8-6.8
Panic disorder	7.3-12
Social phobia	24.1-30.3
Simple or specific phobia	28.2-30.7
Generalized anxiety disorder	8.4-15.7

Adapted from American College of Obstetricians and Gynecologists (ACOG): Clinical updates in women's health care: addiction and substance abuse, vol XI, 2012. <http://www.clinicalupdates.org/topTitles.cfm>. Accessed January 23, 2013.

Despite the adverse outcomes associated with exposure, only about 41% and 20% of obstetric providers effectively screen patients for use of alcohol and illicit drugs, respectively.³ Barriers to screening include physician discomfort with posing the appropriate questions, fear that patients will change practitioners if they are offended by these questions, and uncertainty about the appropriate response to a positive screening result. The resources available to address substance abuse, especially while pregnant, are often minimal, and many practitioners are reluctant to screen for a problem they cannot satisfactorily treat. This attitude must be counterbalanced by identification of community agencies and resources that can provide compassionate and effective services to substance-abusing pregnant women.

An additional barrier is patient denial, which can exist even when the patient is directly questioned. Denial is often rooted in

guilt about the impact of substance use on the pregnancy, legal implications, and fear of losing custody of one's children.¹⁷

Many instruments exist for screening for substance abuse. The 4P's Plus screen, which has been validated for use in identifying substance abuse in the pregnant population, has a sensitivity of 87% and a specificity of 76%. The instrument includes the questions such as the following:

- Did your parents have trouble with drugs?
- Does your partner have a problem with drugs or alcohol?
- Did you ever drink beer, wine, or liquor in the month before you knew you were pregnant?
- How many cigarettes did you smoke in the month before you knew you were pregnant?
- How many beers, how much wine, and how much liquor did you drink in the month before you knew you were pregnant?¹⁸

The CAGE questionnaire (discussed in the Alcohol section) has been used for drug abuse screening as the CAGE-AID (Adapted to Include Drugs). The same screening questions are employed but with reference to drugs included. A single "yes" response renders 79% sensitivity and 77% specificity for identifying drug abuse.¹⁹ Because any identified drug abuse is considered to be clinically important, consideration can be given to single-item screening, although this has not been validated in pregnancy specifically. The principal question is, "How many times in the past year have you used an illegal drug or used a prescription medication for nonmedical reasons?" In the primary care setting, a positive response is considered to be 100% sensitive and 74% specific for a drug use disorder.

Biochemical screening can be useful as an adjunct to self-report screening tools. Various biologic samples can be tested, including urine, blood, hair, saliva, and sweat. Urine is the most accessible and easiest to obtain. However, biochemical screening alone has limitations. Negative test results do not rule out substance abuse, and positive results do not identify how much drug has been used. Alcohol is hardest to detect because of its short half-life. A woman who knows she will be tested may delay access to prenatal care because of possible repercussions. False-positive results can be devastating for drug-free women. Women may avoid detection by abstaining for 1 to 3 days before testing, by substituting urine samples, or by increasing oral beverage intake just before testing to dilute the urine.²⁰ The American College of Obstetricians and Gynecologists (ACOG) does not endorse biochemical screening as a sole method of detecting substance abuse during pregnancy.¹¹ If it is performed, it is recommended that the woman's full consent be obtained.

The neonate can also be screened for in utero drug exposure by testing meconium and urine. Urine can be tested to determine drug exposure in the days before delivery, and meconium may reflect exposure that occurred in recent weeks. Neonatal screening is not an effective method to determine first- or second-trimester drug use.²¹⁻²³ Like maternal screening, the ethical issues surrounding which patients are tested (i.e., universal or targeted testing) and disclosure of results must be carefully evaluated before this method is adopted.

The most effective approach to screening for substance abuse during pregnancy may be through a series of nonjudgmental, assumptive questions. ACOG recommends that all pregnant women be questioned thoroughly regarding substance abuse. A universal, structured, self-reported screening approach for substance abuse can make providers more comfortable with this discussion, reduce interviewer bias, and reduce the stigma

associated with substance use and abuse. It also allows the opportunity for brief intervention, which may have an important influence on pregnancies exposed to substance abuse.

Tobacco

PREVALENCE

It is difficult to assess the prevalence of smoking associated with pregnancy, because many women fail to report that they began or continued smoking while pregnant. In 2010, 69.6 million Americans 12 years of age or older were current users of a tobacco product, representing 27% of the population in that age range. Although this report demonstrates decreased prevalence (30% prevalence in 2002 and decreasing rates among youth aged 12 to 17 years),¹ smoking continues to be the most important modifiable risk factor associated with adverse pregnancy outcomes. According to the Pregnancy Risk Assessment Monitoring System (PRAMS), the prevalence of smoking during pregnancy in 2005 was 14%, and there was a 9% decrease between 2000 and 2005.²⁴ Based on PRAMS data, certain demographic groups were more likely to engage in smoking while pregnant: women younger than 25 years of age, single women, low-income women, women with less than a high school education, American Indian or Alaskan Native women, and non-Hispanic white women. Smoking among opioid-dependent women is common, approaching 90%.²⁵ Comparisons of self-report with detection using biochemical markers indicate that underreporting of smoking status and extent of smoking is common; 24% to 50% of pregnant women fail to disclose smoking status when queried by health care providers.²⁶⁻²⁹

PHARMACOLOGY

Tobacco use is most prevalent in cigarette form. Adverse pregnancy outcomes related to cigarette smoking may be the result of exposure to nicotine or to one of the 4000 other substances found in cigarettes, including tar, carbon monoxide, acetaldehyde nitrosamines, ammonia, polycyclic aromatic hydrocarbons, and hydrogen cyanide. It is well established that dependence on cigarette smoking is driven by nicotine.³⁰ The average smoker inhales 1 to 2 mg of nicotine per cigarette. Nicotine rapidly reaches peak levels in the bloodstream and enters the brain, where peak levels are reached within 10 seconds after inhalation. Immediately after nicotine exposure, the adrenal glands are stimulated and epinephrine is released, causing an increase in blood pressure, respiration, and heart rate.³⁰ The addictive properties of nicotine arise from dopaminergic effects on the brain.

Cotinine is the metabolite of nicotine that is measured in a urine drug screen. Cotinine levels consistent with smoking can be seen in women exposed to second-hand smoke as well as in primary smokers.^{31,32}

SCREENING

Several screening measures for smoking have been described in the literature. The Tobacco Screening Measure, developed by Maryland MDs Making a Difference,³³ has four staged questions:

1. "Have you ever smoked cigarettes or used other tobacco products?"

2. If "yes" to question 1: "Have you smoked or used any in the past 30 days?"
3. If "yes" to question 2: "On average, how many cigarettes do you smoke (or times do you use) per day?"
4. If "yes" to question 3: "How long have you been smoking (using) at that rate?"

More detailed smoking information can be obtained from the Fagerstrom Test of Nicotine Dependence,³⁴ which is composed of six multiple-choice queries regarding smoking behavior (e.g., "Do you smoke in bed?"). This is a very brief measure that is used in both research and clinical practice. Although this screening tool has not been well validated, it has been found to be reliable with regard to consistent outcomes in patients tested and retested.³⁵ Despite low sensitivity and specificity, it is the standard against which other tools are compared.

MATERNAL EFFECTS

The risks of smoking on pregnancy are well described and well accepted. They include spontaneous pregnancy loss, placental abruption, preterm premature rupture of the membranes (pPROM), placenta previa, preterm delivery, low birth weight (LBW), and ectopic pregnancy, in addition to postnatal associations with neonatal death and sudden infant death syndrome.

Women who smoke during pregnancy have higher risks of deep venous thrombosis, stroke, pulmonary embolus, myocardial infarction, and pulmonary complications such as influenza, pneumonia, and bronchitis.³⁶ Smokers have a *reduced* risk of preeclampsia, a phenomenon discussed in Chapter 48. Examining the potential mechanisms by which maternal smoking affects these outcomes is an important step in reducing smoking-related morbidity and mortality.

BREASTFEEDING

The American Academy of Pediatrics (AAP) has historically opposed breastfeeding by women who smoke because nicotine is found in breast milk in concentrations 1.5 to 3 times greater than in maternal blood plasma. However, research indicating that such concentrations constitute a health risk to the infant is lacking. Moreover, there is research to suggest that smoking and bottle-feeding is more deleterious to an infant than smoking and breastfeeding.³⁷ Therefore, AAP now suggests that smoking is not an absolute contraindication to breastfeeding.

FETAL EFFECTS

Maternal smoking can result in impaired fetal oxygen delivery, as demonstrated by structural changes in the placentas of smoking women. A reduction in fraction of capillary volume and increased thickness of the villous membrane have been demonstrated and contribute to impaired gas exchange.³⁸⁻⁴⁰ Cigarette smoke acutely decreases intervillous perfusion, a possible effect of vasospasm.⁴¹

Direct toxicity from the substances found in cigarettes may influence pregnancy outcomes. Carbon monoxide contributes to formation of carboxyhemoglobin, which is cleared slowly from the fetal circulation and causes a left shift of the oxyhemoglobin dissociation curve. Direct toxic effects from ammonia, polycyclic aromatic hydrocarbons, hydrogen cyanide, vinyl chloride, and nitrogen oxide have been described.⁴²⁻⁴⁴

Smoking may also result in direct genotoxicity, leading to chromosomal instability, which is seen more commonly in smokers than in nonsmokers. De la Chica and colleagues published a study of 25 smokers and 25 nonsmokers undergoing amniocentesis.⁴⁵ Amniocytes were evaluated for structural abnormalities. Twelve percent of smokers and 3.5% of nonsmokers demonstrated genetic instability ($P < .002$). The most common location of deletion or translocation was in the 11q23 region, which is implicated in hematologic malignancies.⁴⁵ An association of prenatal smoking with childhood cancers has been suggested but not definitively determined.⁴⁶⁻⁴⁸

A teratogenic risk associated with tobacco has been suggested, although no malformation syndrome has been identified. The suggested malformations linked to smoking include talipes, craniosynostoses, cleft lip or palate, urinary tract malformations, cardiac malformations, and limb reduction defects. The data on malformations vary (Table 67-2).⁴⁹⁻⁶³

Animal studies suggest that nicotine may directly impair lung development, which may explain why some children have measurable defects on pulmonary function testing, independent of environmental exposure to tobacco smoke at birth.^{64,65} Nicotine may interact with nicotinic acetylcholine receptors (nAChR), which in primate models appear to be abundant in fetal lung tissue.⁶⁶ The same investigators demonstrated that continuous nicotine infusion into pregnant rhesus monkeys resulted in significantly decreased lung weight and volume and increased airway resistance.⁶⁷

NEONATAL EFFECTS

Maternal genotype appears to have an impact on the risk of LBW and on pulmonary function in the offspring of cigarette smokers. The *CYP1A1*, *GSTM1*, and *GSTT1* genes were studied because they encode genes that participate in the elimination of toxic substances contained in cigarette smoke.

In a study of 741 mothers, decreased birth weight and decreased length of gestation were confirmed for 174 smokers

compared with 567 nonsmokers.⁶⁹ Smokers with *CYP1A1* heterozygous and homozygous variants (Aa/aa) and absence of *GSTT1* (deletion) had significantly greater reductions in infant birth weight than those homozygous for the wild-type *CYP1A1* (AA) or with an extant *GSTT1* genotype.⁶⁸ Another study found the *GSTT1* deletion to be associated with a significant reduction in gestational age-adjusted birth weight among the offspring of smoking mothers.⁶⁹ When spirometry was performed on the offspring of 370 mothers who smoked, maternal smoking was found to be associated with decreased lung function, particularly in those children 6 to 10 years old whose mothers had the *CYP1A1* Aa/aa and *GSTM1*-absent genotype.⁷⁰ These studies suggest a unique interplay between genetics and environment and shed light on the outcomes previously identified as being associated with smoking.

TREATMENT RECOMMENDATIONS

Effective treatments are available to arrest cigarette smoking. Pregnancy is a uniquely motivating time, especially when coupled with frequent interaction with a physician to reinforce smoking abstinence and lend support. Some studies have shown that 45% of pregnant smokers completely stop by the end of pregnancy.²⁴ Women who are most likely to quit completely have already done so by the time of their first prenatal visit, but women still smoking at their first prenatal visit are likely to continue to smoke throughout their pregnancy without an effective intervention. In one study, a voucher-based contingency management program (in which patients who abstained from smoking earned vouchers exchangeable for retail items) was effective in promoting abstinence (34.1%, compared with 7.4% among those who received a voucher regardless of smoking status) and also improved mean birth weight and decreased the percentage of LBW babies.⁷¹ A Cochrane review suggested that interventions geared toward smoking cessation, even late in pregnancy, have the potential to decrease LBW and preterm births.⁷² Therefore, any opportunity to intervene should be seized.

TABLE 67-2 Suspected Teratogenic Effects of Nicotine

Malformation	Study	Findings
Craniosynostoses	Kallen, 1999 ⁴⁹	First-trimester maternal smoking related to isolated craniosynostoses
	Honein and Rasmussen, 2000 ⁵⁰	Possible dose-response relationship between maternal smoking and craniosynostoses
Cleft lip or palate	Kallen and Robert-Gnansia, 2005 ⁵¹	No significant association between outcome and smoking
	Carmichael et al, 2008 ²¹³	No significant association between outcome and smoking
	Hwang et al, 1995 ⁵²	Dose dependence of maternal smoking and transforming growth factor- α (TGF- α) polymorphism associated with outcome
	Shaw et al, 1996 ⁵³	Dose dependence of maternal smoking and TGF- α polymorphism associated with outcome
Urinary tract abnormalities Congenital heart disease Limb reduction abnormalities	Chung et al, 2000 ²¹⁴	Association of smoking and facial clefting without evaluation of genetic polymorphisms
	Kallen, 1997 ⁵⁴	Association of smoking and facial clefting without evaluation of genetic polymorphisms

	Van den Eeden et al, 1990 ²¹⁵	No association between limb reduction defects and smoking

The clinical practice guidelines released by the U.S. Department of Health and Human Services made three recommendations for treatment of tobacco use during pregnancy⁷³: (1) Offer psychosocial intervention that exceeds minimal advice to quit; (2) Offer intervention throughout pregnancy; and (3) Offer pharmacotherapy. Randomized, controlled trials in nonpregnant patients have demonstrated that pharmacotherapy substantially increases quit rates. Although pharmacotherapy is advocated for all smokers by the Agency for Health Care Policy and Research and the American Psychiatric Association, the U.S. Preventive Services Task Force could not substantiate the safety or efficacy of pharmacotherapy during pregnancy.⁷⁴

There are essentially two forms of pharmacotherapy: nicotine replacement and bupropion. Concerns about nicotine replacement are related to the sympathetic response initiated by the drug. However, proponents argue that nicotine replacement results in lower drug levels and less exposure to other toxins associated with cigarette smoke. If nicotine replacement results in smoking cessation, the benefit may outweigh the risk. ACOG recommends smoking cessation and advocates the use of nicotine replacement therapy.⁷⁵ However, a randomized controlled trial of 1050 pregnant women assigned to brief intervention and nicotine patches versus placebo identified no significant difference in abstinence from the quit date until delivery (9.4% versus 7.6%). This intervention was met with exceedingly low compliance; only 7% of the nicotine replacement group and 3% of the placebo group remained compliant with their patches for longer than 1 month.⁷⁶ Results of this study imply that the theoretical benefit of nicotine replacement may not be practically achieved in a pregnant population.

Although there is a possible risk of malformations associated with bupropion,⁷⁷ it is apparently effective for use during pregnancy as an aid to smoking cessation. A small randomized, placebo-controlled trial reported that 45% of those receiving bupropion successfully quit smoking, compared with 14% of control subjects ($P < .047$).⁷⁸ The safety of bupropion in pregnancy should be discussed in the same context as any medication exposure, weighing the risks and benefits. In this setting, it appears that bupropion may be effective at promoting smoking cessation during pregnancy, but further investigation is warranted.

Alcohol

PREVALENCE

“Not a Single Drop” is the public health campaign addressing alcohol use in pregnancy in Ohio, and this message is echoed nationwide. Despite public health campaigns, however, current patterns of use demonstrate limited adherence to that recommendation. Among pregnant women aged 15 to 44 years, 10.8% reported current alcohol use, 3.7% reported binge drinking, and 1% reported heavy drinking. Binge drinking in the first trimester of pregnancy was reported by 10.1% of pregnant women aged 15 to 44.^{1,79} In some states, the highest prevalence of alcohol use in pregnancy was reported among women older than 35 years of age, non-Hispanic women, women with more than a high school education, and women with higher incomes.⁷⁹ These findings show that a subset of women who may not otherwise be classified as being at risk for adverse pregnancy outcomes is actually participating in a significant high-risk behavior.

PHARMACOLOGY

Alcohol acts as an antagonist at *N*-methyl-D-aspartate (NMDA) receptors and as a facilitator at γ -aminobutyric acid (GABA) receptors. It also interacts with endogenous opioids and with serotonin and dopamine systems, which are involved in substance abuse. Alcohol stimulates dopamine release specifically from the nucleus accumbens, and this stimulation is thought to be involved in the initiation of alcohol reinforcement.⁸⁰ Different responses in blood alcohol levels among individuals ingesting the same amount of alcohol may be explained by polymorphisms in the alcohol dehydrogenase gene. Maternal polymorphisms in the *ADH1B* gene are hypothesized to affect peak blood alcohol levels by altering alcohol metabolism.⁸¹⁻⁸⁵ Similarly, expression of another cytochrome P450 gene, *CYP2E1*, may affect alcohol metabolism. These polymorphisms may correlate with the risk of adverse fetal effects.

SCREENING

Screening for alcohol use can be difficult. Barriers include lack of practitioner time, inadequate practitioner assessment and intervention skills, pessimistic health provider attitudes about their contribution to or facilitation of change, and practitioner fear that women may view questions about drinking as offensive, prompting a change in provider.³

Current screening tools most effectively identify *alcohol abuse* rather than *unhealthy alcohol use* (i.e., amounts that have pregnancy-related consequences); the latter is more difficult to evaluate. Questions that pose alcohol drinking (or use of tobacco or other drugs) as a normative behavior may be more sensitive in providing accurate results, rather than asking a woman to endorse or deny any use, because the latter approach bias the woman's response toward denying use. Because any use during pregnancy is considered to be significant, a clinician's screening may feasibly be accomplished with a single question: “How much beer, wine, or other alcoholic beverages do you consume in an average week?”

The simplest and easiest tool for alcohol screening in the general population is the CAGE questionnaire. The acronym is derived from the following four questions:

1. Have you ever tried to *Cut down* on your drinking?
2. Have people *Annoyed* you by criticizing your drinking?
3. Have you ever felt *Guilty* or bad about your drinking?
4. Have you ever taken a drink first thing in the morning (*Eye-opener*) to steady your nerves or get rid of a hangover?

Two affirmative responses to CAGE questions have 77% sensitivity and 79% specificity for identifying alcohol abuse and dependence, but are only 53% sensitive and 70% specific for determining unhealthy alcohol use.⁸⁶ Sokol and colleagues used T-ACE, their variation of the CAGE questionnaire for pregnant women, and found it useful for identifying at-risk drinking.⁸⁷ The T-ACE questions address *Tolerance*, *Annoyance*, the need to *Cut down*, and the use of *Eye-openers*.

Biochemical screening for alcohol use without the patient's consent is not endorsed except in the case of obvious intoxication.^{11,88} There is no agreement concerning the best method for assessing this exposure in pregnant women.⁸⁹ Serum can be examined for blood alcohol level, which can also be assessed by breathalyzer, recognizing that this test reveals only recent use. Signs of chronic alcohol use may be demonstrated by

abnormalities in liver function test results, macrocytosis, or anemia, and this information can be used as an adjunct to substantiate concerns.

MATERNAL EFFECTS

Women are uniquely affected by alcohol use. Because of their differing alcohol-processing abilities, women demonstrate a higher blood alcohol level than men when exposed to the same dose, and they suffer alcohol-related illness at lower levels of alcohol exposure than men. Some studies suggest that women are more likely to demonstrate cognitive and motor impairment, and they may be more likely than men to suffer physical harm and sexual assault when using alcohol. Alcohol has effects on all aspects of reproduction, including fertility, fetal anomalies, and lactation.⁹⁰

BREASTFEEDING

The AAP advises pregnant and lactating women to abstain from alcohol, because it is concentrated in breast milk and can decrease milk production. Breastfeeding women should be advised that pumping and dumping milk does not remove alcohol from breast milk, because alcohol is not stored in breast milk. Women who do drink while breastfeeding should be advised to have no more than one drink and to wait at least 2 hours after this drink before breastfeeding. Having more than a single drink necessitates waiting 4 to 8 hours for the alcohol to pass from the body, to ensure that the milk is free of alcohol.

FETAL EFFECTS

There is no known lower limit of safety for alcohol exposure in pregnancy to avoid the common and most severe associated outcomes: fetal alcohol spectrum disorder (FASD) and stillbirth. Data on miscarriage vary and are not definitive.

The term *FASD* describes the broad range of adverse sequelae in the offspring of alcohol-using women, including alcohol-related birth defects (ARBDs), alcohol-related neurodevelopmental disorder (ARND), and fetal alcohol syndrome (FAS). ARBDs and ARND fall short of meeting all the criteria for the diagnosis of FAS, but they are terms that refer to offspring with structural or neurodevelopmental abnormalities in the setting of alcohol use. FAS is defined by maternal drinking during pregnancy, fetal growth problems at any point in time, facial dysmorphism (i.e., smooth philtrum, thin vermilion border, and small palpebral fissures), and central nervous system (CNS) abnormalities (i.e., structural abnormalities, neurologic problems, and low functional performance).⁹¹ Among offspring of heavy drinkers, the prevalence of FAS is 10% to 50%.⁸⁸ Fetal alcohol exposure can result in specific impairments of verbal learning, visual-spatial learning, attention, reaction time, and executive functions,⁹² which may be related to developmental abnormalities in the CNS. Functional magnetic resonance imaging (fMRI) identifies reduced overall brain size in persons with FAS.⁹³ Specific size reductions in the basal ganglia and cerebellum and an impaired or absent corpus callosum due to irreversible prenatal brain damage are suggested.⁹²

FASDs are considered to be completely preventable birth defects and neurodevelopmental abnormalities, and they are arguably the most common nongenetic cause of developmental delay.⁹⁴ Women who are older, of high parity, or of

African-American or Native-American heritage are at increased risk for having offspring affected by FAS.

STILLBIRTH

Kesmodel and colleagues correlated the risk of stillbirth with maternal consumption of alcohol in a Danish cohort of 24,768 mothers.⁹⁵ The rate of stillbirth was increased across all categories of maternal alcohol use, even after adjusting for potentially confounding variables that included smoking, caffeine intake, pre-pregnancy weight, and parity. The rate of death from otherwise unexplained stillbirth ranged from 1.37 cases per 1000 women consuming less than one drink per week to 8.83 cases per 1000 women consuming five or more drinks per week (relative risk = 2.96; CI, 1.37 to 6.41).

NEONATAL EFFECTS

A meta-analysis found no significant relationships between the frequency of LBW or small-for-gestational-age (SGA) infants and alcohol intake up to approximately one drink per day nor for preterm birth and alcohol intake up to 1.5 drinks per day.⁹⁶ However, these outcomes increased with greater alcohol consumption, ultimately reaching statistical significance. This study did not report outcomes related to alcohol-induced fetal damage.

Maternal alcohol consumption can have negative effects at any time during pregnancy. A prospective study of 992 subjects between 1978 and 2005 correlated the timing and pattern of alcohol exposure with the incidence of dysmorphia associated with FAS.⁹⁷ Dysmorphia and growth disturbance were increased in women with first-trimester alcohol use. The risk was dose related without evidence of a threshold. Decreased birth length correlated with exposure in any trimester, and birth weight was more significantly affected by second-trimester exposure.

CHILD EFFECTS

Prenatal exposure to alcohol can increase the likelihood of problems detected in childhood or adult life, including psychiatric illnesses, substance use disorders, poor social relations, inferior school performance, and legal issues.⁹⁸

TREATMENT RECOMMENDATIONS

Treatment for alcoholism is largely psychosocial, with an emphasis on brief interventions. The influence of a nonjudgmental physician cannot be overemphasized. In a randomized controlled trial of 250 women with a positive alcohol screen result, participants decreased their drinking by one third to two thirds when given an alcohol assessment tool with or without brief intervention by the care provider.⁹⁹ Reduction in alcohol use by heavy drinkers (defined as those having a positive screen on the T-ACE) was greater when a partner chosen by the patient was included in a brief intervention.¹⁰⁰

WITHDRAWAL

The severity of withdrawal increases with each withdrawal episode. Severe withdrawal (e.g., seizures, delirium tremens) occurs in 2% to 5% of chronic alcoholics fewer than 3 days after stopping alcohol, and it may last for 3 to 7 days. With treatment,

the mortality rate is 1%. Benzodiazepines can greatly reduce the risk of seizure and symptoms of withdrawal, and the need for pharmacotherapy can be easily assessed by a Clinical Institute for Withdrawal Assessment for Alcohol, Revised (CIWA-Ar) protocol. The need for appropriate vitamin supplementation in this population must be recognized.

For prolonged treatment of alcoholism, disulfiram is an aversive agent that is intended to block alcohol dehydrogenase. Ingestion of alcohol while taking disulfiram results in the unpleasant effects of accumulated acetaldehyde in the blood: sweating, headache, nausea, and vomiting. In practice, this medication has not been particularly effective, largely due to noncompliance, as suggested by a study of U.S. veterans in which the results for disulfiram were similar to those for placebo.¹⁰¹

Naltrexone, a μ -opioid receptor antagonist, has been employed as an anticraving drug in nonpregnant populations. A dose of 50 mg/day produces a significant decrease in alcohol consumption. When used with psychosocial support, naltrexone can effect a significant decrease in relapse.¹⁰² Naltrexone has received limited study in pregnancy. If a woman is already established on this medication, it is not expected to increase the risk of fetal malformation, but postnatal behavioral effects have not been established.¹⁰³

Acamprosate is similarly used in nonpregnant populations to prevent alcohol craving by modulation of glutamate neurotransmission at the metabotropic glutamate receptor 5,¹⁰⁴ but literature suggesting that it may interfere with embryologic development limits its use in pregnancy.¹⁰⁵

Data support the "Not a Single Drop" policy for pregnant women. It is unclear whether moderate drinking is worse than binge drinking. Does consumption of four drinks in 1 week pose the same risk as consuming four drinks in one sitting? The protective effect on development of FAS in mothers with polymorphisms of the alcohol dehydrogenase gene (*ADH*) that result in rapid metabolism of alcohol suggests that dose does matter.¹⁰⁶ These questions must be addressed before a lower limit of safety for alcohol consumption in pregnancy can be proposed.

Marijuana

PREVALENCE

Marijuana (i.e., cannabis) is the most common illicit drug of abuse. In 2010, there were 17.4 million past-month users. Between 2007 and 2010, the rate of use increased from 5.8% to 6.9%, and the number of users increased from 14.4 million to 17.4 million.¹ As with many substances of abuse, exposure to marijuana is commonly coupled with other exposures. In a German study of marijuana use the prevalence was 90% for comorbid alcohol use, 68% for nicotine, 12% for cocaine, 9% for stimulants, 6% for hallucinogens, 3% for opioids, and 1% for sedatives.¹⁰⁷ Transition from marijuana use to dependence is not as common as for other drugs. Among the 46% of the U.S. population who have ever used marijuana, only 9% have a lifetime history of dependence.¹⁰⁸

PHARMACOLOGY

Marijuana is derived from the hemp plant (*Cannabis* species). The psychoactive substance is Δ -9-tetrahydrocannabinol

(THC). On the street, it is known as pot, reefer, Mary Jane, hash, weed, hemp, blunt, and many other nicknames. The dried leaves are most commonly smoked, and in the process, 20% to 50% of the THC content is absorbed in the lungs. If THC is ingested, its bioavailability is lessened by the first-pass effect of the drug, because THC is metabolized by many hepatic isoenzymes. Marijuana is considered to be purer now than in the 1960s, when THC content was 1% to 5%; current THC content is 10% to 15%. Metabolites of THC are detected in the urine for 1 to 3 days after a single use and for up to 30 days if preceded by chronic use.¹⁰⁹

THC readily crosses the blood-brain barrier and binds to neuronal type 1 cannabinoid receptors (CB₁), which are also expressed in the lungs, liver, and kidneys.¹¹⁰ Activation of the CB₁ receptors stimulates the mesolimbic dopamine system, which is thought to mediate the rewarding and reinforcing effect of the drug. Although marijuana is less addictive than other substances of abuse, it can precipitate a withdrawal syndrome, and tolerance resulting from downregulation and desensitization of the CB₁ receptor has been described.¹¹¹

MATERNAL EFFECTS

Because of the debate shaped by the drug's proponents and opponents, determining the risks associated with marijuana use is extremely difficult.¹¹² The research literature is also conflicting. Nonetheless, a summary of the available literature suggests that marijuana smoke is most likely carcinogenic and that it is mutagenic in vivo and in vitro. Long-term chronic smoking of marijuana is associated with chronic bronchitis and decreased lung function, and there is an increased risk of various oral cancers. Subtle forms of cognitive impairment with long-term use have been described. Certain individuals have the potential for development of dependence. These issues have not been addressed in pregnant women who use marijuana.

BREASTFEEDING

Breastfeeding while using marijuana should be avoided. THC, the active metabolite of marijuana, is concentrated in breast milk compared with maternal blood plasma levels.

FETAL EFFECTS

Marijuana extract and THC have been studied in many animal models, and no pattern of malformation has emerged as uniquely associated with marijuana exposure.¹¹³ Torfs and colleagues reported a case-control study of mothers of 110 infants with gastroschisis who were enrolled in the California Birth Defects Monitoring Program, compared with 220 age-matched mothers of unaffected infants.¹¹⁴ The association of gastroschisis with maternal marijuana exposure was strong (odds ratio [OR] = 3.0; CI, 1.3 to 6.8), but only 10% of subjects in this cohort had marijuana as their sole exposure, making the association uncertain.¹¹⁴ In 2006, Forrester and colleagues reported a case-control study from the Hawaii Birth Defects program that identified 109 cases of gastroschisis¹¹⁵; only three of the affected infants had been exposed to marijuana in utero. It was determined that marijuana did not play a significant role in this congenital defect when maternal age was taken into account.¹¹⁵

NEONATAL EFFECTS

Smoking marijuana increases the carboxyhemoglobin level, impairs oxygen transfer in the lung, reduces the oxygen-carrying capacity of blood, and releases oxygen from hemoglobin.^{116,117} Despite these consequences, the effect of marijuana on birth weight is not clear. Prenatal exposure to marijuana was not related to any growth measures at birth in the Ottawa Prenatal Prospective Study (OPPS), which compared 140 infants born to women who drank alcohol, used marijuana, or smoked cigarettes during pregnancy with 50 infants born to unexposed women.¹¹⁸ The Avon Longitudinal Study of Pregnancy and Childbirth surveyed 12,000 pregnant women; 2% to 3% reported using THC during pregnancy. Rates of preterm birth, neonatal intensive care unit (NICU) admission, and perinatal mortality were not increased among users, but sustained weekly use was linked to a trend toward decreased birth weight.¹¹⁹

CHILD EFFECTS

There was some suggestion of neurobehavioral effects of prenatal marijuana exposure in the OPPS among predominantly low-risk, white, middle-class families and in the Maternal Health Practices and Child Development (MHPCD) study, which enrolled a higher-risk cohort with lower socioeconomic status. Both studies found that infants born after prenatal exposure to marijuana had increased tremors, exaggerated and prolonged startle responses, or altered sleep patterns.¹²⁰⁻¹²² The Maternal Lifestyle Study found more withdrawal- and stress-related behaviors in neonates at 1 month of age.¹²² At 6 years of age, impulsivity and hyperactivity were identified. At 10 years of age, increased hyperactivity, inattention, delinquency, and impulsivity were described. Findings for both cohorts emphasize the effects of heavy marijuana exposure.

Infants monitored in the OPPS had no delay in cognition or motor development at 1 year of age.¹²³ In the higher-risk MHPCD cohort, an association was observed between smoking one or more joints per day in the third trimester of pregnancy and decreased Bayley scores at 9 months of age, but this effect was not evident at 18 months.¹²⁴ At 4 years of age, the OPPS cohort scored lower on verbal and memory testing. Similar findings in impairment of short-term memory and in verbal and abstract or visual reasoning were found in the MHPCD cohort at age 3 years.^{125,126} As the cohorts were followed over the next 9 to 12 years, executive function and difficulty organizing and integrating specific cognitive and output processes were observed.¹²⁷⁻¹³⁰

Acute nonlymphocytic leukemia was reported among persons exposed prenatally and postnatally to marijuana, but subsequent case-control examinations failed to confirm this finding.¹³¹ Neuroblastoma has also been linked to first-trimester marijuana use, although this association requires further investigation.

TREATMENT RECOMMENDATIONS

No effective pharmacologic agent is available for the treatment of marijuana dependence. Moreover, few research studies have focused on behavioral treatments for marijuana abuse and dependence.¹³² Clinical trials and prospective studies suggest that marijuana dependence is responsive to cognitive-behavioral

therapy and contingency management interventions, but many patients remain unresponsive to treatment.

Opioids

PREVALENCE

Chronic heroin abuse is estimated to affect 810,000 to 1 million Americans. When these figures are coupled with 6.4 million prescription narcotic abusers, an epidemic of opiate abuse becomes evident. In 2010, an estimated 140,000 people became new heroin users.¹ Pregnant women are uniquely vulnerable to opiate abuse for many reasons. Opiates are exceedingly addictive and are often obtained by trading sex for drugs. Compared with men, women are more likely to initiate use earlier in life and to become dependent more rapidly. Heroin use in particular is strongly associated with the behaviors of a male partner.

PHARMACOLOGY

The category of opiates encompasses heroin, methadone, oxycodone, and other forms. Abuse of any of these agents carries the risk of adverse pregnancy outcomes. Opiates can be inhaled, injected, snorted, swallowed, or used subcutaneously (i.e., skin popping). When opiates are combined with cocaine, the term *speedballing* may be applied. Oxycodone derivatives intended for sustained release contain 20 times the normal amount of active ingredient. When the tablets are crushed, the slow-release polymer is destroyed, and the product can then be swallowed, snorted, or injected, and results are similar to a heroin high.¹³³ Urine toxicology can identify opiate metabolites (e.g., morphine, codeine, methadone) for 1 to 3 days after use. Screening should occur with maternal consent and education.¹⁰⁹

Opiates exert their effect by binding to the μ - and κ -receptors in the limbic and limbic-related areas of the brain. Binding of the opiate receptors sends a signal to dopamine terminals to release dopamine. Dopamine then binds dopamine receptors, stimulates the postsynaptic cell, and creates a positive emotional response. Opiate pathways play a role in reward and reinforcement, modulation of responses to pain and stress, and homeostatic regulation. Activation of the μ -receptors produces analgesia, euphoria, miosis, and reinforcement of the reward behavior. Activated κ -receptors produce the subjective sensation of dysphoria, spinal analgesia, sedation, and miosis.¹³³ Opiates are highly addictive, and once used, the transition to abuse is likely. After dependence is established, the success rates for recovery are not encouraging; 70% of abusers relapse within 6 weeks of nonmedication rehabilitation efforts.¹³⁴

SCREENING

Although several instruments have been developed to assess the potential risk of opioid misuse or dependence, there are no well-validated screening measures for opioid dependence. The Structured Clinical Interview for the *Diagnostic and Statistical Manual for Mental Disorders*, fourth edition (DSM-IV) is a reliable and valid assessment, but it requires extensive training and time to administer.¹³⁵ In women with suspected opioid dependence, a brief interview may uncover opioid abuse or dependence. Biologic testing, with the patient's consent, may be warranted in such cases.

MATERNAL EFFECTS

The financial impact of opiate abuse in pregnancy is significant, especially because of the need for extended neonatal care. Resources available to pregnant opiate addicts are scant. A more intensive focus on this population would offer the possibility of primary prevention of neonatal complications encountered as a result of maternal opiate abuse.

BREASTFEEDING

Advice about breastfeeding and opioid intake must begin by determining whether the mother is abusing an opioid but is not receiving opioid-agonist pharmacotherapy treatment or is receiving opioid-agonist treatment with methadone or buprenorphine. Women who are currently abusing heroin or prescription opioids and choose to breastfeed may expose their infants to levels of opioids that are sufficient to cause tremors, restlessness, vomiting, poor feeding, or addiction. Breastfeeding is not recommended for mothers who are abusing opioids. In contrast, women who are in opioid-agonist treatment with methadone or buprenorphine should be encouraged to breastfeed, because methadone and buprenorphine concentrations in breast milk are low. For doses of methadone between 50 and 105 mg/day, the neonatal dose is less than 0.2 mg/day, a level unlikely to have clinical effects.¹³⁶ Breastfeeding is therefore recommended for agonist-maintained women unless contraindicated by other medical conditions (e.g., human immunodeficiency virus [HIV] infection). For women who are concerned that the cessation of breastfeeding may precipitate narcotic withdrawal in the infant, a period of weaning is appropriate to avoid that outcome.

FETAL EFFECTS

Mouse models suggest an increased risk of neural tube defects in heroin-exposed fetuses,¹³⁷ an effect countered by pretreatment with the opiate antagonist naloxone. Human studies have not shown the same risk.¹³⁸ An association between major congenital malformations and methadone exposure was observed in a study¹³⁹ that did not control for adequacy of opioid-dependence treatment or aspects of care that affect fetal well-being.

NEONATAL EFFECTS

From 2000 to 2009, the number of newborns with NAS increased from 1.20 to 3.39 per 1000 hospital births per year.¹³ Common adverse outcomes include preterm delivery, LBW, and perinatal mortality. Other adverse outcomes are attributed to drug-seeking behaviors, concomitant smoking, and inadequate nutrition, all of which are common in this population.

CHILD EFFECTS

Research on the longer-term development effects of in utero exposure to heroin and methadone is far from definitive, and current approaches to such research may be too simplistic.¹⁴⁰ Research suggests that school-age children who were exposed to heroin in utero experience developmental delay¹⁴¹ and may exhibit behaviors such as aggressiveness, hyperactivity, and disinhibition.¹⁴² However, the family and social environment in

which these children mature is likely to be disadvantaged, with attendant poor parenting, and this may contribute to developmental delay and behavioral problems.^{143,144} Neurodevelopmental studies of children prenatally exposed to drugs have applied statistical controls for postnatal environment, but variations in parental care may modify the expression of the effects of in utero drug exposure.¹⁴⁵

TREATMENT EFFECTS

Although abstinence from drugs and medications is an ideal goal, detoxification has a minimal role during pregnancy. There do not appear to be adverse consequences to tapered opiate withdrawal in pregnancy,¹⁴⁶ although miscarriage, preterm birth, meconium passage, stillbirth, and elevated epinephrine and norepinephrine levels have been reported.^{147,148} However, detoxification in pregnancy usually is unsuccessful, with relapse rates exceeding 50%.¹⁴⁹ Because limited data suggest that the risk of miscarriage may increase with detoxification in the first trimester, it is probably best to defer attempted withdrawal until 12 to 14 weeks' gestation.¹⁴⁹ Antenatal surveillance should be performed if detoxification is attempted in the third trimester.

One study compared various detoxification regimens in pregnant, opioid-dependent patients with methadone maintenance. There were five participant groups: those receiving 3-day methadone-assisted withdrawal (MAW) alone ($n = 67$), 3-day MAW followed by methadone maintenance (MM) ($n = 8$), 7-day MAW alone ($n = 28$), 7-day MAW followed by MM ($n = 20$), and a continuous MM sample ($n = 52$). Women in the three MM groups remained in treatment longer, attended more obstetric visits, and more often delivered at the program hospital than patients in the two MAW-alone groups. Because of the poor maternal outcomes for the MAW groups, the investigators concluded that methadone maintenance should be considered as the primary treatment approach for opioid-dependent pregnant women.¹⁵⁰

Fortunately, treatment is available for opiate maintenance to decrease the impact of high-risk activities and improve neonatal outcomes. The classic opiate maintenance drug is methadone, a full μ -agonist and weak NMDA receptor antagonist that is metabolized by the cytochrome P450 system. It has many favorable qualities: high bioavailability, long half-life, low cost, convenient (daily) dosing, and slow onset of withdrawal syndrome. It has been used for more than 40 years for the treatment of opiate addiction¹⁵¹ and has demonstrated benefits of deterring high-risk behaviors, reducing incarceration, and diminishing the spread of infectious disease.

Methadone maintenance therapy for addiction is available in the United States through federally funded opiate maintenance programs. In this setting, patients are dosed daily and participate in counseling and drug screening according to the regulations of the facility. Methadone maintenance programs are not widely available, and transportation issues and the need for daily compliance are often obstacles to participation.

Despite these challenges, the benefits of methadone maintenance have been demonstrated in pregnant women. Methadone maintenance has been associated with earlier and more compliant prenatal care, improved nutrition and weight gain, fewer children in foster care, and improved enrollment in substance abuse treatment and recovery programs. Pregnant women remain opiate dependent, but they become more functional.¹⁵² The goal of treatment is to provide sufficient dosing to prevent drug

cravings, eliminate illicit use, and to provide adequate dosing so that use of additional opiates does not create euphoria.

The model of opiate maintenance in pregnancy is one of harm reduction rather than abstinence. There is no ceiling of benefit to dosing methadone. Because it is a full μ -agonist, increasing doses offer increasing benefit. The average methadone maintenance dose is between 80 and 120 mg/day.¹⁵³ A maintenance dose of less than 60 mg/day is thought to be insufficient to prevent drug-seeking behavior. Because of physiologic adaptations to pregnancy, split dosing is sometimes recommended.

Buprenorphine, a synthetic opioid and partial μ -agonist with a very high affinity for the μ -opioid receptor, has been increasingly used for opioid addiction during pregnancy. Buprenorphine disassociates slowly from the receptor, can displace circulating opiates, and is unlikely to be displaced by other competing opiates. A ceiling effect for the benefit of buprenorphine is thought to exist, and additional dosing beyond 24 to 32 mg/day may not achieve any additional benefits. The autonomic withdrawal associated with buprenorphine is less significant than with other opiates. Buprenorphine shares favorable qualities with methadone, such as decreased drug craving with daily dosing, and it has the additional benefit of being prescribed by specifically certified physicians rather than federally funded clinics. This promotes improved patient autonomy and broader availability of opiate maintenance.

In pregnancy, buprenorphine alone is favored over the buprenorphine-naloxone combination product because data about the combination product are lacking in pregnancy and because of concerns about the possibility that naloxone may produce maternal and fetal hormonal changes.^{154,155} The naloxone component was added to limit the abuse potential of the drug, because when the combination is taken sublingually, naloxone is not bioavailable. However, if the combination of buprenorphine and naloxone is injected or snorted, it will precipitate withdrawal in opioid-dependent individuals. We routinely use the combination drug in our clinics, and recent preliminary findings indicate no significant adverse maternal or neonatal outcomes related to the use of the combination product.^{155a} Until more research is available, it is considered standard practice to use buprenorphine alone, but the high abuse potential is a significant concern.

There have been numerous comparisons of methadone and buprenorphine for the treatment of opioid dependence in pregnant women.¹⁵⁶ Because withdrawal symptoms associated with buprenorphine are reportedly less intense than with methadone, Jones and colleagues compared the occurrence of NAS among infants born to women treated with methadone with those treated with buprenorphine in a double-dummy, double-blind, randomized controlled trial, the MOTHER study.¹⁵⁷ Compared with prenatal methadone exposure, significantly lower doses of morphine for treatment of NAS, shorter duration of treatment, and shorter hospital stays were observed with prenatal buprenorphine exposure. This study has led to increased use of buprenorphine to treat opiate dependence in pregnancy.

A review of the literature comparing methadone and buprenorphine supported several conclusions. First, buprenorphine produces a less severe NAS than does methadone. Second, buprenorphine's efficacy to treat opioid dependence during pregnancy does not negate methadone's utility in this regard, because no single treatment is likely to be maximally effective for all patients. Third, the long-term effects of buprenorphine and methadone require further study.¹⁵⁸

NAS is a risk for all opiate-exposed infants. It occurs in 60% to 90% of methadone-exposed infants and is characterized by CNS irritability, respiratory distress, gastrointestinal dysfunction, and autonomic instability. NAS is treated most commonly with opiates (e.g., morphine, methadone), but phenobarbital plays a therapeutic role in some centers.¹⁵⁹ The decision to treat an infant is standardized by adherence to measurement instruments such as the Finnegan scale for NAS. The usual onset of NAS is in days 2 to 3 of life, and the duration of therapy (days to weeks) depends on the neonatal response. Treatment ceases when the neonate has been free of signs of withdrawal for 24 to 48 hours.

The role of methadone dosing in the development of NAS is controversial. Groups led by Berghella,¹⁶⁰ Kuschel,¹⁶¹ McCarthy,¹⁶² and Seligman¹⁶³ found that higher doses of methadone were unrelated to the severity of NAS, but studies led by Lim,¹⁶⁴ Dashe,¹⁶⁵ and Cleary¹⁶⁶ reached the opposite conclusion. A comprehensive review concluded that the severity of NAS was not related to the dose of methadone maintenance therapy,¹⁶⁷ and it recommended that providers should treat the pregnant patient with a methadone dose that effectively prevents her use of other opiates.

Because *effective* implies that the mother is free of illicit drugs, elimination of drug craving is a key component of therapy. The difficulty of dosing methadone during pregnancy is that pregnancy-associated somatic complaints (e.g., musculoskeletal pains, nausea, sleeplessness, anxiety, irritability) can also imply suboptimal dosing. The physiology of pregnancy leads to decreased absorption, increased volume of distribution, rapid elimination, and higher clearance of the drug, all of which may mandate higher doses as gestational age advances.

Cocaine

PREVALENCE

Cocaine is a potent stimulant that has been linked to many adverse pregnancy outcomes. The 2010 National Survey on Drug Use and Health found that 1.5 million Americans were current cocaine abusers, with 5.3 million having ever used cocaine in previous surveys.¹ Although the number of new initiates to cocaine is decreasing, perinatal cocaine abuse remains a significant problem.

Cocaine in powder or salt form is highly water soluble, making it easy to dissolve for injection and facilitating transport across mucous membranes when it is inhaled. The salt form is not efficiently smoked because it has a melting point of 195°C. The free-base form is not water soluble and has a much lower melting point; smoking is the preferred mode of use for this form.

PHARMACOLOGY

Cocaine is used pharmacologically as a local anesthetic for neuronal fast sodium channel blockade. This same mechanism of action causes cardiac arrhythmia. Blockade of myocardial fast sodium channels results in prolongation of the QRS complex and dysrhythmia.¹⁶⁸ Cocaine also blocks catecholamine reuptake in the central and peripheral nervous systems. Blockade of norepinephrine reuptake creates an intense sympathetic response. Blockade of dopamine reuptake centrally produces a profound euphoria that is responsible for the high abuse

potential. The norepinephrine release related to euphoria augments the norepinephrine reuptake mechanism and contributes further to vasoconstriction.¹⁶⁹

SCREENING

As with opioids, there are no well-validated, brief measures that detect stimulant use accurately. Detection of misuse largely depends on accurate self-report from the patient. Biologic testing for cocaine measures its metabolite benzoylecgonine, which is present in urine for 2 to 4 days after exposure.¹⁰⁹

MATERNAL EFFECTS

The vasoconstrictive properties of cocaine may cause hypertensive emergencies and placental abruption. A cocaine-induced hypertensive emergency can mimic preeclampsia. Physicians practicing in the 1980s have anecdotal experience with women who presented with hypertension, abdominal pain, and non-reassuring fetal status, prompting delivery due to cocaine-induced abruption. This pathophysiology has been demonstrated in animal models, in which cocaine administration induces a hypertensive response and reduction in uterine blood flow lasting 15 minutes.¹⁷⁰⁻¹⁷²

The adrenergic effects of acute cocaine ingestion increase heart rate, blood pressure, and systemic vascular resistance, leading to increased myocardial oxygen demand.^{173,174} In association with vasospasm of coronary arteries, this can cause myocardial ischemia and infarction and arrhythmia. The risk of cardiovascular toxicity is increased in pregnancy.¹⁷⁵ Chronic use of cocaine can be associated with left ventricular hypertrophy, cardiomyopathies, myocardial fibrosis, and myocarditis. Women who are determined to be cocaine users during pregnancy warrant a comprehensive cardiac workup, including electrocardiography and echocardiography, and an anesthesia consultation before delivery.

β -Blockade treatment of hypertension and cardiovascular complications caused by cocaine is *contraindicated* because it can lead to unopposed α -adrenergic stimulation that results in end-organ ischemia and coronary vasospasm. This effect has particular significance in obstetrics, because β -blockade with labetalol is commonly used for hypertension. Labor and delivery personnel should know that hydralazine, not labetalol, is the drug of choice for treatment of hypertension in pregnant women exposed to cocaine.

BREASTFEEDING

Breastfeeding is contraindicated during cocaine use.¹⁷⁶ Maternal cocaine appears in breast milk, and the cocaine in breast milk is easily absorbed through the infant's intestinal tract. Metabolism of cocaine may take several days before an infant's urine does not test positive for cocaine ingestion through breast milk. Infants exposed to cocaine through breast milk ingestion may have increased heart rate and blood pressure, choking, and vomiting; they often show increased irritability and agitation.

FETAL EFFECTS

Cocaine readily crosses the placenta and enters the fetal brain. The vasoconstrictive properties of cocaine can have a wide range of fetal effects. There have been numerous reports of congenital

malformations attributed to prenatal cocaine exposure, but the current literature suggests that these outcomes were overreported during the early years of the crack and cocaine epidemic because of publication bias for positive findings.

In rodent studies of cocaine exposure during pregnancy that employed intraperitoneal injection, cocaine did not increase the incidence of congenital malformations, but it did decrease maternal and fetal weight. Subcutaneously administered cocaine was associated with ophthalmologic, skeletal, and urogenital tract abnormalities.^{177,178} Rat fetuses exposed to cocaine near term demonstrated possible vasoconstrictive sequelae of cocaine, including hemorrhage and edema of the distal limbs and tail, leading to necrosis of those structures.¹⁷⁹

Human reports have described an increased incidence of cranial defects, limb reduction defects, urogenital abnormalities, and intestinal perforation, obstruction, and atresia. Urogenital abnormalities were the most commonly confirmed anomalies in the population-based Atlanta Birth Defects Case-Control Study by the Centers for Disease Control and Prevention. Maternal cocaine use was defined as reported use at any time from 1 month before pregnancy through the first 3 months of pregnancy. In this study of birth certificate data from Atlanta residents between 1968 and 1980, cocaine users had an increased risk of urinary tract defects (OR = 4.39; CI, 1.12 to 17.24), but there was no increase in genital tract anomalies.¹⁸⁰ When the Atlanta Congenital Defects Program examined the incidence of vascular disruption defects between 1968 and 1989, they did not identify a significant increase, suggesting that this pathway of teratogenesis was not evident in the exposed population.¹⁸¹

A prospective, multicenter trial (the Maternal Lifestyle Study) sought to determine the relation of fetal cocaine exposure in pregnancy to acute maternal and infant medical outcomes and to long-term neurodevelopmental infant outcomes.¹⁸² This study screened 19,079 mother-infant dyads to identify 717 pregnancies uniquely exposed to cocaine, which were compared with 7442 infants who were not exposed in utero. Exposure was documented by self-report or identification of cocaine metabolites in the meconium of the neonate. The incidence of congenital malformations was not increased in the cocaine-exposed group. Several malformations were cited: clubfoot (OR = 0.9; CI, 0.06 to 13.32), cleft lip or palate (OR = 1.24; CI, 0.08 to 19.10), genitourinary malformations (OR = 1.81; CI, 0.45 to 7.33), and abdominal wall defects (OR = 2.26; CI, 0.63 to 8.11).

NEONATAL EFFECTS

Data linking cocaine to adverse pregnancy outcomes are fraught with methodologic flaws. Many such studies did not control for confounding variables such as maternal age, parity, socioeconomic status, and concomitant alcohol and cigarette exposure, suggesting that the risk attributed to cocaine was perhaps inappropriately estimated. The Knowledge Synthesis Group on Determinants of Low Birth Weight and Preterm Births examined the effect of cocaine use during pregnancy by meta-analysis. They combined the data from 31 well-controlled studies and determined that cocaine was associated with preterm birth (OR = 3.38; CI, 2.72 to 4.21), LBW (OR = 3.66; CI, 2.90 to 4.63), SGA infants (OR = 3.23; CI, 2.43 to 4.30), younger gestational age at delivery (OR = -1.47; CI, -1.97 to -0.98), and reduced birth weight (-492 g; CI, -562 to -421 g).¹⁸³

The postnatal impact of cocaine-exposed pregnancies is the cause of much debate. The initial 1985 report¹⁸⁴ described 23

cocaine-exposed infants who demonstrated depression of interactive behavior and poor organizational response to environmental stimuli on the Brazelton Neonatal Behavioral Assessment Scale. This small study, heavily promoted by lay media, raised concerns about a “generation of crack babies.” Subsequent prospective research has determined a more reliable profile of the postnatal effects of cocaine exposure in pregnancy.

In a longitudinal study that compared 154 pregnant crack or cocaine users and 154 controls matched for race, parity, socioeconomic status, and type of prenatal care, infants who were exposed to tobacco and cocaine or marijuana had fewer alert periods and less alert responsiveness.^{185,186} The amount of cocaine used in the third trimester was negatively related to the regulation of state, which is described as a precursor to alertness and the infant’s ability to orient to the environment.

CHILD EFFECTS

The impact of prenatal cocaine exposure and quality of the caregiving environment on 4-year cognitive outcomes was reported from a longitudinal, prospective, masked-comparison cohort study from birth to 4 years.¹⁸⁷ Cocaine-exposed ($n = 190$) and nonexposed ($n = 186$) children were compared. Prenatal cocaine exposure was not associated with lower full-scale, verbal, or performance IQ scores, but it was associated with an increased risk of specific cognitive impairments (i.e., visual-spatial skills, general knowledge, and arithmetic skills) and lower likelihood of IQ above the normative mean at 4 years. A better home environment was associated with IQ scores that were similar in cocaine-exposed and nonexposed children.¹⁸⁷ The home environment was the most important independent predictor of outcome, suggesting the potential to compensate for in utero drug exposure.

TREATMENT RECOMMENDATIONS

There is no pharmacologic treatment or replacement for cocaine abuse. The backbone of therapy is psychosocial treatment. In the acute withdrawal phase, no medication has proved effective in treating cocaine withdrawal, and hospitalization is rarely indicated on medical grounds.

Fetal surveillance in this population is not warranted for cocaine abuse alone. However, if obstetric complications arise that warrant assessment (e.g., chronic abruption, growth restriction, oligohydramnios), antenatal testing is appropriate.

Methamphetamine

PREVALENCE

Methamphetamine has been increasingly available as a drug of abuse since the 1980s. It can be made from legally obtained substances—common chemicals combined with over-the-counter cold remedies—to create illicit methamphetamine in small “meth labs.” Methamphetamine, known as meth, speed, ice, crystal, crank, and glass, can be abused in many ways; it can be smoked, snorted, injected, or ingested orally or anally. Each method provides variations in onset and duration of euphoria.

Methamphetamine exposure as reported by the National Survey on Drug Abuse is declining, falling in a survey of past-month users from 731,000 in 2006 to 353,000 in 2010. The rate of overall use has decreased from 0.6% in 2002 to 0.2% in 2010.¹

Despite this national trend, methamphetamine abuse remains a significant problem in some areas.

PHARMACOLOGY

Methamphetamine is more potent than its parent compound, amphetamine. In smaller doses than recreational use, it is recommended for the treatment of refractory narcolepsy and attention deficit disorder.¹⁸⁸ It has stimulant effects on the central and peripheral nervous systems. Similar to cocaine, it blocks the reuptake of adrenergic neurotransmitters. It has a unique mechanism as an indirect neurotransmitter that is incorporated into cytoplasmic vesicles, where it displaces epinephrine, norepinephrine, dopamine, and serotonin into the cytosol. This prompts diffusion out of the neuron and into the synapse, where postsynaptic receptors are activated.¹⁸⁹ Methamphetamine is the metabolite identified in urine drug screens, and it remains detectable for up to 3 days.¹⁰⁹

SCREENING

There are no well-validated, brief measures that accurately detect stimulant use. Detection of misuse largely depends on accurate self-report from the patient and biologic testing.

MATERNAL EFFECTS

The literature on methamphetamine complicating pregnancy is more limited than for cocaine and other illicit drugs. Animal studies of teratogenicity have produced unclear results. Studies have identified cleft palate, exencephaly, and eye defects in mice; head defects in rabbits; and eye defects in rats.¹⁹⁰ Significant amounts of methamphetamine can reach the fetal compartment, and the effects may be compounded by the longer elimination half-life in the fetus.¹⁹¹⁻¹⁹³ The human literature includes case reports of abnormalities in the cardiovascular, gastrointestinal, and central nervous systems; facial clefts; and limb reduction defects.¹⁹⁴⁻¹⁹⁶ Case-control studies, however, do not confirm an association of methamphetamine with an increased risk of malformation.¹⁹⁷ Methamphetamine exposure is unlikely to result in fetal malformation.¹⁸⁸

BREASTFEEDING

Due to enhanced concentration of methamphetamine in the breast milk (2.8 to 7.5 times that of maternal plasma)¹⁹⁸ and neonatal observations of adverse effects in infants breastfed by users, breastfeeding is not recommended for women with ongoing methamphetamine use.

FETAL EFFECTS

As expected for a drug with vasoconstrictive properties, methamphetamine exposure during pregnancy increases the risk of preterm birth, LBW, and SGA infants. These results have been demonstrated in small and large studies, although most studies have not adjusted for confounding factors.¹⁹⁹ The Infant Development and Lifestyle (IDEAL) study demonstrated an increased frequency of SGA infants among the offspring of methamphetamine-exposed mothers.²⁰⁰ Adjusted for covariates, the methamphetamine-exposed group was 3.5 (CI, 1.65 to 7.33) times as likely to be SGA as the unexposed group.²⁰⁰

NEONATAL EFFECTS

Neonatal effects of methamphetamine, especially immediately after birth, mirror those of cocaine. The IDEAL study screened 13,808 mother-infant dyads to identify a cohort of 166 infants, 74 of whom were exposed to methamphetamine and 92 of whom were nonexposed.²⁰⁰ Both groups were similarly exposed to alcohol, tobacco, and marijuana. The NICU Network Neurobehavioral scale, which was administered within 5 days of birth, suggested that prenatal methamphetamine exposure was associated with decreased arousal, increased stress, and poor quality of movement in an apparent dose-response fashion. Higher levels of methamphetamine metabolites in meconium were related to markers of increased CNS stress.²⁰¹

CHILD EFFECTS

A small study of described neurodevelopmental outcomes of 13 methamphetamine-exposed children and 15 unexposed children between 3 and 16 years of age. Impairment of tests of attention, visual motor integration, verbal memory, and long-term spatial memory were observed,²⁰² but there were no differences in motor skills, short-delay spatial memory, and nonverbal intelligence. Another MRI study found differences in the volumes of the putamen, globus pallidus, and hippocampus that were related to poorer performance on attention and memory tasks.²⁰² Studies using functional MRI (fMRI) found more diffuse activation during verbal memory tasks, suggesting activation of compensatory pathways in the methamphetamine-exposed children.²⁰³ Infants in the IDEAL study were tested with Peabody Developmental Motor Scales and Bayley Scales of Infant Development at 1, 2, and 3 years of age. There were no differences in cognition as assessed by Bayley scores. A subtle methamphetamine exposure effect on fine motor skills was observed at 1 year, with the poorest performance observed in the most heavily exposed children. At 3 years, there were no differences in fine motor performance.²⁰⁴

TREATMENT RECOMMENDATIONS

There is no pharmacologic treatment or replacement for methamphetamine use. As with cocaine, management consists of psychosocial therapy. If the patient is acutely intoxicated, hypertension should be treated, avoiding drugs that act through β -blockade. All pregnant women who report methamphetamine use should be encouraged to seek treatment. Implementation of a harm-reduction model that encompassed perinatal care, transportation, child care, social services, family planning, motivational incentives, and addiction medicine resulted in improved birth outcomes, including reduced frequency of positive urine toxicology results at delivery, diversion of children from foster care, and increased use of postpartum contraception to promote pregnancy spacing.²⁰⁵

Benzodiazepines

PREVALENCE

Benzodiazepines are among the most frequently prescribed medications for pregnant women. Diazepam (Valium), alprazolam (Xanax), lorazepam (Ativan), clonazepam (Klonopin), and chlordiazepoxide (Librium) are the most common drugs.

Because diazepam is the only benzodiazepine for which there is sufficient research among pregnant women,²⁰⁶ the discussion that follows regarding the effects of benzodiazepines focuses on diazepam.

PHARMACOLOGY

Benzodiazepines affect the inhibitory neurotransmitter GABA and appear to act on the limbic, thalamic, and hypothalamic levels of the CNS to produce sedative and hypnotic effects, reduction of anxiety, anticonvulsant effects, and skeletal muscle relaxation.

SCREENING

There are no well-validated, brief measures that accurately detect the use of benzodiazepines. Detection of misuse largely depends on accurate self-report from the patient or biologic testing.

MATERNAL EFFECTS

Benzodiazepine pharmacotherapy during pregnancy may be necessary for the treatment of specific medical problems. However, benzodiazepines used in combination with other depressants such as alcohol or opioids pose a high potential for abuse. Benzodiazepine dependence is one of the major challenges faced by clinicians providing methadone maintenance for opioid dependence, and it is especially problematic in pregnant women. The abuse of benzodiazepines in methadone-maintained patients has the potential to increase the CNS-depressant effects of methadone and is therefore a risk factor for fatal overdose.

BREASTFEEDING

Given the paucity of research, it is difficult to provide firm guidance about breastfeeding by mothers currently using benzodiazepines, other than to suggest caution. Diazepam and its active metabolite (*N*-desmethyldiazepam) have been found in breast milk and infant blood. Little is known about the excretion of benzodiazepines into breast milk or the relative concentrations of their active metabolites in breast milk and infant blood plasma. Virtually no research had described medication or behavioral effects in exposed infants, including sedation, lethargy, and weight loss.

FETAL EFFECTS

Diazepam is readily transferred across the placenta and accumulates in the fetal circulation at about one to three times the level in maternal blood.²⁰⁷ The fetal effects of in utero exposure to benzodiazepines do not suggest that exposure is teratogenic. After initial reports of an increased incidence of facial clefts associated with in utero exposure to diazepam, later prospective studies failed to support this finding. Subsequent reviews have concluded that diazepam is not teratogenic.²⁰⁶

NEONATAL EFFECTS

Infants with extended in utero exposure to diazepam have exhibited an NAS resembling that shown with opioid

withdrawal.²⁰⁸ NAS symptoms include hypertonia, irritability, abnormal sleep patterns, inconsolable crying, tremors, bradycardia, cyanosis, poor sucking, apnea, diarrhea, vomiting, and risk of aspiration of feeds.²⁰⁶ If treatment is indicated, phenobarbital is the recommended medication.²⁰⁹

Neonates exposed in utero to methadone may also experience extended exposure to benzodiazepines, and they then require treatment for a longer period than neonates exposed in utero to methadone alone.¹⁶³ The onset of benzodiazepine-associated NAS may be delayed for 2 to 3 weeks after birth, complicating diagnosis and treatment of the problem. Opioid treatment of NAS has no effect on non-opioid NAS. Phenobarbital is the pharmacotherapy of choice for non-opioid-related withdrawal, but a treatment protocol for infants with concomitant opioid and benzodiazepine withdrawal has not been developed.¹⁶³

CHILD EFFECTS

The effects of in utero exposure to benzodiazepines are similar to those of opioids. Developmental delay has been suggested, but a study of 550 children followed up to 4 years of age found no negative effects of benzodiazepine exposure on neurocognitive development or intelligence.²¹⁰ Infants with evidence of developmental delay also had family or social problems. As with in utero exposure to opioids, it has been difficult to differentiate the relative contributions of the drug from those of the child's social environment.

TREATMENT RECOMMENDATIONS

Treatment of benzodiazepine abuse is difficult because the drug is associated with poor psychological functioning and a reduced effect of other interventions for illicit drug use.²¹¹ Treatment may be complicated by the potential for seizures during rapid withdrawal and by patient resistance to a benzodiazepine taper due to a fear of seizures. Successful withdrawal from benzodiazepines is likely to occur only when the taper from benzodiazepine dose is slow and gradual and in the context of extensive psychological counseling and support.

Conclusions

FUTURE RESEARCH DIRECTIONS

Much is unknown about substance abuse and its treatment in pregnant women. Research on tobacco use, alcohol and stimulant abuse, and substances that affect breastfeeding is needed to improve maternal-fetal clinical care.

Highly effective interventions are needed for smoking reduction or cessation during pregnancy. Research in substance abuse has focused on illicit substances that pose high risks for the mother and on treatments that parallel those for nonpregnant women and men. However, given the teratogenic effects of smoking and the long list of related fetal and neonatal complications,

development of effective smoking-cessation programs should be the first priority. Because pregnant women who abuse other substances are often heavy smokers, it is particularly important to create smoking-cessation programs that are tailored to women engaging in concomitant substance abuse.

Effective pharmacotherapeutic agents and psychosocial treatments for alcohol and stimulant abuse are urgently needed. The high prevalence of alcohol and stimulant abuse and the increased risks of fetal and neonatal defects associated with alcohol or stimulant exposure make more effective treatments a priority.

Excretion of illicit substances into breast milk, their relative concentrations in the blood plasma of infants, and the short- and longer-term threats of these exposures must be studied. Because of the many benefits of breastfeeding, it is important to identify the medication and substance exposures that do or do not affect or contraindicate breastfeeding.

CLINICAL PRACTICE

Substance abuse during pregnancy is underestimated, especially among women of higher social status, despite the impact it can have on pregnancy. This chapter highlights the major substances of abuse and the effects on pregnancy, the mother, and her child. The highest hurdle in the successful treatment of pregnant women for substance abuse or dependence is the failure to understand that substance abuse does not occur in isolation. Adverse pregnancy outcomes associated with substance abuse are not always linked to direct toxicity of the substance but instead reflect the constellation of behaviors associated with substance abuse or dependence. Factors such as maternal and fetal malnutrition, dehydration, lack of adequate prenatal care, exposure to sexually transmitted diseases and other infectious diseases, polysubstance abuse, impoverished housing, psychiatric comorbidity, and exposure to violence and physical abuse significantly contribute to the development and maintenance of substance abuse among pregnant women.¹³⁰ These factors independently and collaboratively place the fetus, infant, and child at risk for poor developmental outcomes.

Pharmacotherapeutic treatment alone is unlikely to be successful for most pregnant women who seek treatment of their substance abuse. Pharmacotherapy is unlikely to lead to remission even during the period of pregnancy unless it is provided in the context of a program of comprehensive care that includes a multidisciplinary, woman-centered, trauma-informed approach that includes obstetricians, pediatricians, psychiatrists, psychologists, and social workers, all focusing on maximizing maternal resources and empowering the woman to accomplish significant and enduring life changes.²¹² The next generation of care for pregnant women with substance use disorders must recognize and actively address the underlying roots of the drug abuse and dependence.

The Skin and Pregnancy

RONALD P. RAPINI, MD

The physical and hormonal alterations induced by pregnancy, childbirth, and the puerperium are associated with numerous cutaneous changes. Some occur so frequently that they are not considered abnormal and vary only in degree. This chapter discusses these physiologic changes, the pathologic rashes of pregnancy, and the effects of pregnancy on preexisting dermatologic diseases.

Common Skin Changes Induced by Pregnancy

PIGMENTARY CHANGES

Hyperpigmentation occurs in at least 91% of pregnant women.¹ Much of it is presumed to result from the effects of increased levels of melanocyte-stimulating hormone (MSH)² or estrogen and progesterone on the melanocytes in the epidermis (see Chapter 8). Other bioactive molecules, such as placental lipids, can stimulate tyrosinase activity, which increases pigmentation. Pigmentation is typically most accentuated in the areolar and genital skin. The neck and axillae can become hyperpigmented, but if those areas become velvety or papillomatous, the physician should consider acanthosis nigricans associated with diabetes mellitus and other endocrinopathies. Hyperpigmentation of the linea alba, the longitudinal demarcation line on the midline of the abdomen, is called *linea nigra*. Pigmentary demarcation lines (i.e., Voigt or Fitcher lines) may also appear on the legs and other locations.³ All of these pigmentary changes typically regress after delivery.

Melasma is diffuse macular hyperpigmentation of the face, usually involving the forehead, cheeks, and bridge of the nose. Although the antiquated term *chloasma* has often been used as a synonym, it was typically restricted to cases occurring during pregnancy (i.e., mask of pregnancy). Melasma occurs in about 70% of pregnant women but can occur in women who are not pregnant, especially those using oral contraceptives, hormonal creams, and other hormones. Increased expression of α -MSH has been found in lesional skin.⁴ The hyperpigmentation is usually blotchy and poorly demarcated, and it is bilaterally symmetric. It usually resolves after delivery, although it persists for months or years in about 30% of patients.

Avoidance of exposure to sun during pregnancy helps to prevent or minimize the formation of melasma. Topical sun-screen lotions with sun protective factor (SPF) ratings of 15 or greater should be used. For troublesome hyperpigmentation that persists after delivery, topical hydroquinone bleaching creams and solutions (U.S. Food and Drug Administration [FDA] pregnancy category C drugs), such as Lustra, Alustra, Melanex, or Solaquin, are sometimes useful.⁵ In the United States, 4% hydroquinone cream is available as a generic

prescription medication, and more than 200 brand names of lower concentrations are available over the counter, but the FDA has been considering removing them from the market. Hydroquinone is banned in many countries because it is carcinogenic in rodents. Treatment is frequently prolonged for months. Cosmetics are useful for covering irregular pigmentation. Additional therapeutic options for melasma persisting after pregnancy include daily topical retinoic acid (tretinoin [Retin-A, Avita]), salicylic acid (SalAc cleanser), or azelaic acid (Azelex, Finacea). A combination of topical fluocinolone, hydroquinone, and tretinoin (Tri-Luma cream) has been FDA approved, but its future status is uncertain. Chemical peels with trichloroacetic acid, phenol, glycolic acid, Jessner solution (i.e., lactic acid, resorcinol, and salicylic acid in ethanol), or kojic acid may be effective. All of these treatments are more effective if the pigmentation is epidermal rather than dermal. Although the Q-switched lasers (i.e., yttrium-aluminum-garnet, ruby, or alexandrite) have been useful for many other pigmentary problems, they provide little help for melasma. Intense pulsed light (IPL) and the fractionated photolysis laser (Fraxel) have produced good results in some patients.

Pregnancy can produce new melanocytic nevi or enlarge pre-existing nevi, but the incidence of changes in nevi and the formation of melanoma seems to be no greater than for nonpregnant women.⁶ Most melanomas exhibit asymmetry, an irregular border, variegated colors (i.e., red or white in addition to black or blue), and a diameter greater than 6 mm. Suspicious lesions should be excised immediately.⁷ Local anesthetic agents, such as lidocaine, are regarded as safe. The use of epinephrine in low doses along with lidocaine can expedite surgery. The subject of melanoma during pregnancy is addressed in Chapter 56.

VASCULAR CHANGES

Pregnancy induces dilation and proliferation of blood vessels. Although this is thought to result largely from estrogen, the mechanism is not completely understood. Telangiectasias (i.e., persistently dilated blood vessels) that resemble those seen with chronic sunlight or radiation exposure can occur during pregnancy. Spider angioma (i.e., nevus araneus) is characterized by a central arteriole with radiating vascular "legs" resembling those of a spider and is most prevalent in sun-exposed areas. Multiple spider angiomas also can occur in persons with liver disease (resulting from decreased hepatic estrogen catabolism), with estrogen therapy, and in normal, nonpregnant women. These lesions can regress spontaneously. Persistent lesions are best treated with low-energy electrocoagulation or laser ablation.

Palmar erythema occurs in many normal pregnant women and can be associated with liver disease, estrogen therapy, and

collagen vascular diseases. These vascular changes require no therapy and usually resolve after delivery.

Pyogenic granuloma is a misnomer for a red, nodular, often pedunculated, exuberant proliferation of blood vessels and inflammatory cells. This granulation tissue is not a granuloma, which is a nodular aggregate in which macrophages predominate. The surface is often ulcerated, with yellowish purulence (i.e., pyogenic appearance). These lesions can be found anywhere on the skin but most commonly occur on the scalp, upper trunk, fingers, and toes. They are especially common on the gums, often resulting from gingivitis or trauma, and have been called *epulis gravidarum*. The terms *lobular capillary hemangioma*, *pregnancy tumor*, and *granuloma gravidarum* are other synonyms for pyogenic granuloma.⁸

Therapy consists of surgical excision or electrosurgical destruction,⁹ but it can often be delayed until after delivery because some lesions regress spontaneously. Regression is associated with apoptosis of endothelial cells and a dramatic decrease in expression of vascular endothelial growth factor (VEGF),¹⁰ mediated by a decline in estrogen and progesterone levels.¹¹ Immediate biopsy should be performed if there is problematic bleeding or if the clinical diagnosis is in doubt because some neoplasms, such as amelanotic melanomas, can resemble pyogenic granulomas.

Venous congestion and increased vascular permeability during pregnancy commonly cause gingivitis and edema of the skin and subcutaneous tissue, particularly of the vulva and lower legs.¹² Severe labial edema has occasionally been reported during pregnancy, and a search for other causes is sometimes warranted. Varicosities are common on the legs and around the anus (i.e., hemorrhoids). They may regress after delivery but usually not completely.

CONNECTIVE TISSUE CHANGES

The mechanisms by which collagen and other connective tissue elements are influenced during pregnancy are poorly understood. Striae (i.e., stretch marks) represent linear tears in dermal connective tissue and appear as red or purple, atrophic bands over the abdomen, breasts, thighs, buttocks, groin, and axillae. They usually begin in the second or third trimester, but they sometimes occur in the first. Some lesions may be pruritic. At least a few striae occur in 50% to 80% of pregnancies, and they are severe in about 10%, especially in teenagers.^{13,14} Risk factors for more severe striae include maternal family history of striae, young maternal age, nonwhite race, larger baseline and delivery body mass index (weight gain >15 kg), increased abdominal and hip girths, increased newborn weight, and larger fetal height and head circumference.^{15,16} Women with striae have an increased incidence of subsequent pelvic relaxation (i.e., prolapse).¹⁷

Despite numerous anecdotal claims of therapeutic efficacy, no topical therapy prevents or affects the course of striae, which ordinarily become less apparent as the red or purple color fades after delivery. There are numerous testimonials regarding the value of olive oil, cocoa butter, vitamin E, tretinoin, and nutritional therapy, but none of these has proved valuable in controlled studies.¹⁸ The pulsed dye laser has been helpful, particularly in obliterating the red color of early lesions, but it is difficult to determine whether the short-term improvement is better than that after long-term observation.

Skin tags (i.e., acrochordons, soft fibromas, fibroepithelial polyps, or molluscum fibrosum gravidarum) are soft, papular

or pedunculated growths of fibrous and epithelial tissue that are common in obesity and in pregnancy. They are usually skin colored to dark brown and usually appear on the neck, axillae, or groin. Skin tags often persist after delivery and can easily be electrocoagulated or snipped off with scissors.

HAIR AND NAIL CHANGES

The hair growth cycle is divided into three phases: anagen, catagen, and telogen. The duration of the growing phase (i.e., anagen) of each scalp hair follicle persists 3 to 4 years, with an average daily growth rate of approximately 0.34 mm. Growth activity is followed by a transitional (i.e., catagen) phase that lasts about 2 weeks, followed by a resting phase (i.e., telogen) that lasts several weeks. When the next hair cycle starts, newly forming hair causes shedding of the older telogen hairs.

Activity of each of the approximately 100,000 follicles on the human scalp cycles randomly and independently from the activity of neighboring follicles. At any given time, approximately 10% to 15% of hair follicles are in the telogen phase. If the average duration of growth of each follicle is approximately 1000 days (3 years), it can be calculated that about 100 hairs are shed normally each day.

In late pregnancy, hormones appear to increase the number of anagen hairs and decrease those in telogen. Estrogen receptors found in hair follicles may play a role in this. After hormone withdrawal in the postpartum period, telogen hairs can increase to 35% or more of scalp hairs, resulting in a transient hair loss peaking about 3 to 4 months after parturition. This diffuse hair loss has been called *telogen effluvium*, whether it occurs after delivery, surgery, illness, crash dieting, or some other stressful event.¹⁹ The severity varies greatly, and it takes a total hair loss of 40% to 50% to become noticeable. Telogen effluvium usually is easy to distinguish from other causes of hair loss, and patients should be reassured that regrowth is likely to occur by 9 months after delivery without any treatment.

Hirsutism of the lower facial or sexual skin areas is uncommon, but it occasionally occurs in the second half of pregnancy and can be accompanied by acne. It is presumed to result from the effects of ovarian and placental androgens on the pilosebaceous unit. The possibility of underlying androgen secretion by a tumor of the ovary, a luteoma, or a lutein cyst should be considered, although polycystic ovary disease appears to be the most frequent cause. Options for hair removal include waxing, electrolysis, and laser ablation. Shaving does not increase the coarseness or growth of hair, but many women are not inclined to want to treat increased hair by this method.

Several types of nail changes have been reported during pregnancy but do not occur regularly. These changes include transverse or longitudinal grooving, increased brittleness, softening, and distal onycholysis.

Skin Conditions Specific to Pregnancy

Table 68-1 lists the rashes specific to pregnancy. Because of a lack of understanding of the pathogenesis of most of these conditions and the lack of specific diagnostic criteria, the terminology has been confusing.²⁰ Many of the same conditions have been described by different investigators using different names.²¹

All tend to be pruritic and usually resolve within a few weeks after delivery. They all can recur in subsequent pregnancies,

TABLE 68-1 Rashes of Pregnancy

Rash	Frequency (%)	Lesion Morphology	Typical Locations	Important Laboratory Features	Usual Trimester of Onset	Increased Fetal Mortality
Pruritus gravidarum	1.5-2.0	Pruritus, no rash	Anywhere, abdomen	Sometimes increased bile salt levels and liver function test values (intrahepatic cholestasis of pregnancy)	3	Yes (?)
PUPPP, PEP	0.6	Papules, plaques, urticaria	Abdomen, thighs, especially in striae	None	3	No
Atopic eruption of pregnancy (prurigo gestationis)	0.3	Excoriated papules	Extremities	None	2	No
Pemphigoid gestationis (herpes gestationis)	0.002	Papules, vesicles	Anywhere, periumbilical	Direct immunofluorescence skin biopsy	2 or 3	Yes (?)
Impetigo herpetiformis (pustular psoriasis)	Rare	Pustules	Intertriginous areas, trunk	Biopsy of subcorneal pustule	1, 2, or 3	Yes
Autoimmune progesterone dermatitis	Rare	Acneiform, urticarial	Buttocks, extremities	Progesterone intradermal skin test	1	Unknown

PEP, polymorphic eruption of pregnancy; PUPPP, pruritic urticarial papules and plaques of pregnancy.

except the polymorphic eruption of pregnancy and prurigo gestationis. Three of the diseases may be associated with increased fetal mortality. Pregnant women also can experience dermatoses other than those specific to pregnancy. Contact dermatitis, eczema, superficial fungal infections, folliculitis, erythema multiforme, urticaria, vasculitis, viral exanthems, scabies, secondary syphilis, and drug eruptions can occur, and it can be difficult to distinguish these from some of the pregnancy-specific rashes.

GENERAL TREATMENT

The same treatment principles apply to all of the specific dermatoses of pregnancy. Few drugs have been proved safe during pregnancy, and the risk-benefit ratio must be considered. Milder disease is treated with topical emollients, calamine lotion, cool compresses or baths, and topical corticosteroids. Topical corticosteroids (e.g., hydrocortisone, triamcinolone) are classified as FDA pregnancy risk category C drugs, but they are still widely used during pregnancy when the possible benefits outweigh the risks of minimal percutaneous absorption. Some of the very-high-potency topical corticosteroids, such as clobetasol, have potential for significant absorption on large body surface areas.

Many oral antihistamines, including the nonsedating fexofenadine (Allegra) and desloratadine (Clarinex), are labeled as FDA pregnancy risk category C drugs because available data are insufficient. Hydroxyzine (Atarax) is not recommended in the first trimester because it has been associated with a slightly increased rate (5.8%) of congenital malformations, but otherwise, it is in risk category C.²² Oral antihistamines classified as category B drugs (e.g., cetirizine [Zyrtec], chlorpheniramine, cyproheptadine [Periactin], diphenhydramine [Benadryl], loratadine [Claritin]) may be worth trying in patients with bothersome pruritus. Cetirizine and loratadine are relatively non-sedating agents. The favorite antihistamine in pregnancy appears

to be diphenhydramine, even though it produces annoying drowsiness. One study associated diphenhydramine with cleft palate, but this finding has been disputed in other studies.²² An increased rate of retrolental fibroplasia has been reported for premature infants whose mothers took antihistamines within 2 weeks of delivery. No antihistamines are recommended during lactation by the manufacturers, but diphenhydramine is probably safe because levels in breast milk are low.

Use of systemic corticosteroids (e.g., prednisone, prednisolone), which are category C drugs, appears to be relatively safe in humans when their use is warranted due to severe disease, but a modest increase in birth defects was reported in the Michigan Medicaid Birth Defects Study of 229,101 pregnancies. Cleft palates have occurred in offspring of pregnant rabbits undergoing such therapy, with a moderate increased risk of oral clefts in the first trimester of human pregnancy.²³ Infants of mothers treated with systemic corticosteroids should be monitored for evidence of adrenal insufficiency. Ultraviolet phototherapy can be offered to pregnant women with severe pruritus if the benefits outweigh the risks of burning and excessive heat.²⁴

PRURITUS GRAVIDARUM

Pruritus gravidarum is generalized itching during pregnancy without the presence of a rash, although excoriations can occur. Up to 14% of pregnant women complain of itching, but pruritus associated with cholestasis (i.e., intrahepatic cholestasis of pregnancy [see Chapter 63]) occurs in only about 1.5% to 2% of pregnant women, with onset usually occurring in the third trimester. Some authorities seem to confuse definitions by reserving the term *pruritus gravidarum* for patients with cholestasis of pregnancy. Frank clinical jaundice occurs in only 0.02% of pregnancies. Pruritus limited to the anterior abdominal wall is common and is usually caused by skin distention and development of striae rather than cholestasis. Pruritus usually

disappears shortly after delivery but recurs in approximately 50% of subsequent pregnancies.

Cholestatic itching correlates better with elevated serum bile acid levels than with the results of other biochemical liver function tests such as alkaline phosphatase, aspartate aminotransferase (AST), alanine aminotransferase (ALT), and bilirubin. An elevated level of glutathione S-transferase- α , a specific marker of hepatocellular integrity, identifies women with intrahepatic cholestasis and distinguishes them from those with benign pruritus gravidarum.²⁵ Abnormal plasma lipid profiles are common in those with cholestasis. Biliary obstruction in pregnancy is discussed in more detail in Chapter 63. Because some patients with skin lesions indicative of one of the other pregnancy rashes described in this chapter have coexisting cholestasis of pregnancy, screening with liver function tests may be reasonable for patients with pregnancy-related rashes and for those experiencing pruritus without rash. Pruritus can precede abnormal findings of liver function tests or total serum bile acids, and follow-up testing for obstetric cholestasis may be needed for itchy pregnant patients with initially normal findings.²⁶

Pruritus gravidarum is associated with twin pregnancies, fertility treatments, diabetes mellitus, and nulliparity, but it is not associated with adverse perinatal outcomes for patients without cholestasis.²⁷ Reported increases in rates of premature delivery and perinatal mortality appear to be restricted to those in whom frank clinical jaundice develops and in cases of intrahepatic cholestasis of pregnancy.

Treatment is symptomatic, and mild cases usually respond to adequate skin lubrication and topical antipruritics. Oral antihistamines can be of some benefit. Ultraviolet light treatment or judicious sun exposure can decrease pruritus. In more severe cases of cholestasis, phenobarbital or bile-sequestering agents such as cholestyramine (Questran) that are supplemented with fat-soluble vitamins can be beneficial, although there is no agreement about efficacy.²⁰ A review of published studies concluded that there is insufficient evidence to recommend corticosteroids, guar gum, activated charcoal, S-adenosylmethionine, and ursodeoxycholic acid.²⁸ Other authorities are convinced that ursodeoxycholic acid reduces premature labor, fetal distress, and fetal deaths,²⁰ and it has been shown to improve serum bile acid levels in amniotic fluid and cord blood at delivery.²⁹ It is not clear whether early delivery by 38 weeks' gestation reduces perinatal complications for patients with cholestasis.³⁰

PRURITIC URTICARIAL PAPULES AND PLAQUES OF PREGNANCY

Pruritic urticarial papules and plaques of pregnancy (PUPPP)³¹ is a designation for a rash characterized by erythematous papules, plaques, and urticarial lesions that usually begins in the third trimester. It is the most common pregnancy rash. The rash was named polymorphic eruption of pregnancy (PEP) by Holmes and Black in 1982,²⁰ and this term is preferred in Europe. PUPPP is the most popular term in the United States. The eruption was called toxic rash of pregnancy³² and late-onset prurigo of pregnancy in the older literature.

PUPPP is almost always pruritic, and itching is severe in 80% of patients. The lesions begin on the abdomen in 80% to 90% of patients, often sparing the umbilicus (Fig. 68-1). The striae become involved in 67% of women, suggesting that abdominal distention may contribute to the inflammation occurring with this rash (Figs. 68-2 and 68-3). In many cases, the eruption

Figure 68-1 Pruritic urticarial papules and plaques of pregnancy. Lesions commonly begin in the abdominal striae. Confluent, erythematous, urticarial papules and plaques are seen on the thighs in this patient.

Figure 68-2 Pruritic urticarial papules and plaques of pregnancy. Urticarial involvement of abdominal striae occurs, with the papular eruption spreading to the arms.

Figure 68-3 Pruritic urticarial papules and plaques of pregnancy. The eruption often begins in itchy, red striae. Notice the linea nigra.

spreads to the proximal thighs, buttocks, and proximal arms. The face is usually spared. Sometimes, erythema multiforme-like target lesions are present.

The rash usually resolves before or within several weeks after delivery, but it rarely persists or even begins after delivery.³³

Some patients have had significant reductions in serum cortisol levels.³⁴ The disease is most prevalent among primigravidas. PUPPP is associated with increased maternal weight gain, increased twin pregnancy rate, hypertension, and induction of labor.³⁵ Unlike most of the other rashes of pregnancy, PUPPP does not tend to recur with subsequent pregnancies. There is no increase in the fetal morbidity or mortality rate.

Routine skin biopsies show nonspecific changes, including variable parakeratosis, spongiosis, acanthosis, dermal edema, and perivascular lymphocytes and eosinophils. Vesicles occur in a minority of cases and can cause confusion with pemphigoid gestationis, but the results of direct immunofluorescence of skin biopsy specimens are usually negative. Treatment depends on the severity of the condition. Topical corticosteroids are adequate for most patients with PUPPP.³⁶

ATOPIC ERUPTION OF PREGNANCY

Atopic eruption of pregnancy is a term proposed to encompass what was formerly called *prurigo gestationis* and *folliculitis of pregnancy*.^{37,38} The general term *prurigo* designates an intensely pruritic skin eruption in which excoriation predominates, suggesting a prominent emotional component. Many of these patients have a genetic predisposition for atopic dermatitis (i.e., atopic eczema), and many examples of this disorder may instead be eczema or dermatitis.³⁴ Atopic dermatitis in pregnancy is considered later in this chapter.

Prurigo gestationis was first described by Besnier in 1904 and is similar to the early prurigo of pregnancy described by Nurse in 1968.³⁴ The lesions consist of excoriated papules or nodules that occur mostly over the extremities, usually beginning in the middle of pregnancy, whereas most of the other specific pregnancy rashes start later in pregnancy (Figs. 68-4 to 68-6). Elevated liver function test results have been reported for some patients, but this probably represents an overlap of findings for patients with pruritus gravidarum. The eruption usually clears by 3 months after delivery, and the recurrence rate in subsequent pregnancies is low. Treatment depends on the severity of the condition.

Papular dermatitis of pregnancy was designated a distinct entity by Spangler and coauthors³⁷ on the basis of markedly elevated levels of 24-hour urinary human chorionic gonadotropin (hCG) levels for that stage of pregnancy and decreased

levels of plasma and urinary estriol and plasma cortisol levels. The lesions were more widespread than lesions of the other pregnancy rashes. Whether these criteria are sufficient to determine a separate disease is questionable.

There have been few case reports, and some of the reported cases of papular dermatitis have been questionable because of the lack of appropriate laboratory studies to exclude the other pregnancy rashes discussed in this chapter. Vaughan Jones and coworkers³⁴ concluded that the papular dermatitis described by Spangler and colleagues was not a separate entity because they were unable to identify any patients with decreased estradiol levels in a large series of patients with pregnancy rashes.

PEMPHIGOID GESTATIONIS

Pemphigoid gestationis is a rare, autoimmune, blistering dermatosis of pregnancy and the immediate postpartum period.³⁹ It is not related to infection by herpesvirus; the unfortunately common synonym *herpes gestationis* refers to the grouped (herpetiform) nature of the blisters, which often are not herpetiform.²⁰ It is best to avoid the term *herpes gestationis* because of the risk of misleading patients and misinformed health care workers; not using the term avoids potentially inappropriate treatments for herpesvirus.

Figure 68-5 Prurigo gestationis. Close-up view of excoriated papules on the same patient as in Figure 68-4.

Figure 68-4 Prurigo gestationis. The predominant lesions are excoriated papules.

Figure 68-6 Prurigo gestationis. Although papules are more common, lesions occasionally coalesce into crusty plaques.

Onset of pemphigoid gestationis usually occurs during the second or third trimester, but cases beginning in the first trimester or the immediate postpartum period have been well documented. A high frequency of human leukocyte antigen (HLA) haplotypes B8 and DR3/DR4 has been reported.⁴⁰

Lesions often begin around the umbilicus (Fig. 68-7). Other commonly involved areas include the trunk, buttocks, and extremities. The face and mucous membranes are usually not affected. Vesicles and bullae are the most important clinical lesions (Figs. 68-8 and 68-9). Erythematous plaques, often annular or urticaria-like, are common, and they can resemble PUPPP. The extent of the disease process and the degree of accompanying pruritus can be mild to severe.

The estimated mortality rate for infants born to affected mothers may be as high as 30%,⁴¹ although this figure is probably inflated. Increased likelihood of prematurity and small-for-gestational-age infants has been reported.^{41,42} With systemic corticosteroid treatment for severe cases, fetal risk appears to be minimal. Transient inconsequential urticarial and vesicular lesions thought to be caused by transplacental immunoglobulin G4 (IgG4) antibody transfer have been observed in 5% to 50% of infants born of affected mothers (Figs. 68-10 and 68-11).

Figure 68-9 Pemphigoid gestationis. Close-up view of crusts and blisters on the mother seen in Figure 68-8.

Figure 68-7 Pemphigoid gestationis. The patient has a characteristic periumbilical urticarial plaque. Blisters may or may not be present.

Figure 68-10 Pemphigoid gestationis. Newborn child of the mother seen in Figure 68-8 has urticarial, erythematous patches with rare blisters.

Figure 68-8 Pemphigoid gestationis. Crusts and blisters on the mother of the child seen in Figure 68-10.

Figure 68-11 Pemphigoid gestationis. Close-up view of the erythematous patches seen in Figure 68-10.

Postpartum flares occur in 50% to 75% of patients with pemphigoid gestationis. Exacerbation typically begins within 24 to 48 hours after delivery and can last for several weeks or months. Skin lesions may persist for more than a year in women who do not breastfeed compared with those who do, for whom the average postpartum duration of lesions is 1 to 6 months.⁴³ Flares also can occur with subsequent pregnancies, subsequent menses, ovulation, or treatment with estrogen or progesterone. About 20% to 50% of patients who have had pemphigoid gestationis experience recurrent skin lesions when treated with oral contraceptives.

The routine histopathologic location of the blisters is usually subepidermal, but blisters sometimes are intraepidermal as a result of spongiosis. Focal necrosis of basal keratinocytes can occur. The dermis contains perivascular lymphocytes and a significant number of eosinophils, and nonspecific dermal changes are found if nonblistering sites are sampled for biopsies. A biopsy for direct immunofluorescence from red macules or perilesional blisters is recommended, because the routine biopsy changes are often not specific.

Immunopathologically, pemphigoid gestationis and bullous pemphigoid (an autoimmune disease most prevalent among the elderly and those with HLA-DQ3) are strikingly similar. Heavy linear deposits of C3 are present in the epidermal basement membrane zone (BMZ) of pemphigoid gestationis perilesional skin (Fig. 68-12), with only 25% to 50% of patients also having IgG deposits when direct immunofluorescence staining methods are used. BMZ C3 deposits have been described in some infants born to mothers with pemphigoid gestationis. In contrast, direct immunofluorescence of bullous pemphigoid shows C3 and IgG. In both diseases, the staining is found on the epidermal side of the subepidermal blister.

Unlike cases of bullous pemphigoid, circulating anti-BMZ IgG autoantibodies are measurable in the serum by indirect immunofluorescence in only 10% to 20% of cases of pemphigoid gestationis. When antibodies are present, titers are usually low, in contrast to bullous pemphigoid. Circulating autoantibodies (i.e., herpes gestationis factor [pemphigoid gestationis factor]) avidly fix complement to the BMZ in pemphigoid gestationis. They are present in such low levels, however, that they often escape detection by routine methods. IgG4 and IgE pemphigoid gestationis autoantibodies usually react with the NC16a domain of a 180-kDa protein associated with hemidesmosomes of basal keratinocytes,^{41,44} whereas bullous pemphigoid autoantibodies potentially react with two protein bands—almost always with a 230-kDa protein (i.e., dystonin [DST], formerly designated BPAG1) and sometimes with the same NC16a domain of the 180-kDa protein that is the main target in pemphigoid gestationis (i.e., collagen type XVII- α 1 [COL17A1], formerly designated BPAG2). Only a small number of patients with pemphigoid gestationis have autoantibodies directed against the DST protein. Studies have found that immunoblotting and enzyme-linked immunosorbent assay (ELISA) are sensitive methods for detecting the COL17A1 in the sera of patients with pemphigoid gestationis, in contrast to the often negative results obtained with indirect immunofluorescence of sera.⁴⁵ Serologic testing for antibodies often designated as BPAG2 or BP180 is readily available commercially, but the testing is often not performed by the more sensitive ELISA or immunoblotting methods.

There is an increased incidence of antithyroid antibodies in pemphigoid gestationis, but clinically apparent thyroid

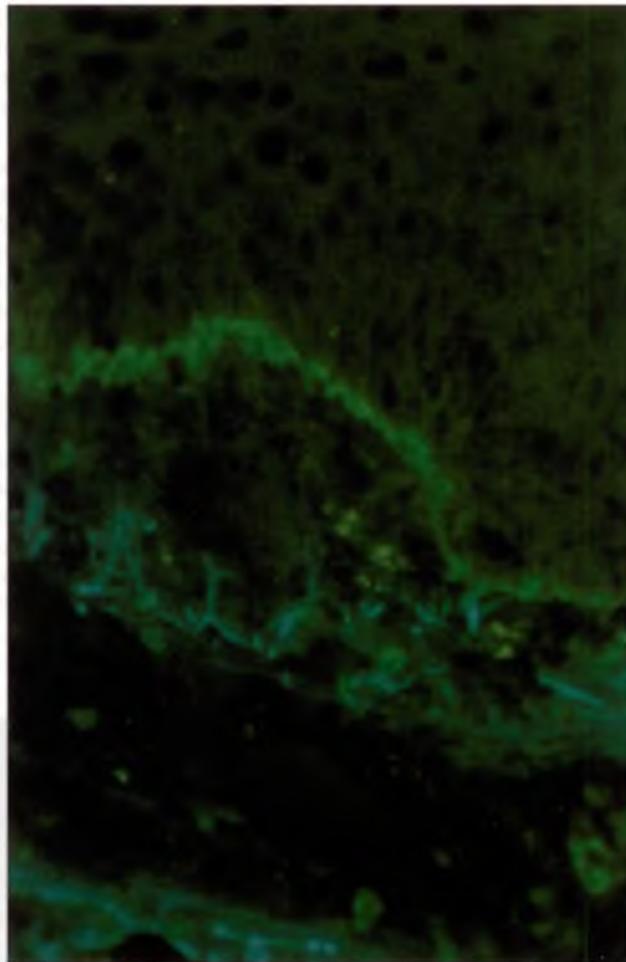

Figure 68-12 Pemphigoid gestationis. The skin biopsy specimen taken for direct immunofluorescence assay demonstrates a linear band of C3 at the basement membrane zone.

dysfunction is rare.⁴⁶ Patients are at an increased risk for Graves disease, but this usually does not occur simultaneously with pemphigoid gestationis.

Placental antibody deposition may result in placental insufficiency. It has been suggested (based on the study of one patient) that pregnant women with pemphigoid gestationis undergo frequent umbilical artery Doppler studies to document end-diastolic velocity even without the ultrasound finding of intrauterine growth restriction.⁴⁷

Treatment of pemphigoid gestationis should not be designed to suppress the disease process entirely, because the higher doses of therapy needed to suppress disease activity completely can have serious side effects. Instead, therapy should be directed toward suppressing the appearance of new lesions and relieving the intense pruritus. Potent topical corticosteroids can be attempted in mild to moderate cases. In moderate to severe cases, prednisone (20 to 40 mg/day) is often adequate to suppress new blister formation and relieve symptoms. After new blister formation has been suppressed, the prednisone dose can be tapered to lower doses or to just enough to maintain control and relieve symptoms. Eventually, alternate-day therapy may become more appropriate and should be attempted.

If the disease flares in the immediate postpartum period, treatment with prednisone (20 to 40 mg/day) should be

reinstated. Higher doses may be instituted at this time if necessary. Infants of mothers treated with prednisone should be monitored for evidence of adrenal insufficiency. Minocycline and nicotinamide have been used anecdotally as alternatives to prednisone in pregnancy.⁴⁸ Plasmapheresis or intravenous immunoglobulin is used for severe cases.⁴⁹ Dapsone is often used for other autoimmune blistering disorders, but it is contraindicated during pregnancy because it can cause hemolytic disease of the newborn. Other treatment modalities useful for all pregnancy rashes have been discussed previously.

IMPETIGO HERPETIFORMIS

First described in 1872 by von Hebra, impetigo herpetiformis is a severe, generalized pustular dermatosis associated with pregnancy.⁵⁰ The name is unfortunate because it is unrelated to bacterial infection (i.e., impetigo) or herpesvirus infection. It probably represents pustular psoriasis in pregnancy, mostly occurring in patients who have never had psoriasis before pregnancy. It is closely related to acute generalized exanthematous pustulosis (AGEP), which is typically drug induced.

Onset of the disease usually occurs in the third trimester, but well-documented cases have occurred as early as the first trimester. The disease usually subsides between pregnancies but can recur with subsequent pregnancies and usually occurs earlier in a subsequent pregnancy. Patients may have hypoparathyroidism, hypocalcemia, hypophosphatemia, decreased vitamin D levels, elevated erythrocyte sedimentation rate, and leukocytosis.⁵¹ The cause remains unknown, but it may be a reaction to drugs or occult infection in a genetically predisposed patient.

Clinically, impetigo herpetiformis is characterized by hundreds of translucent, white, sterile pustules (Figs. 68-13 and 68-14) that arise on irregular erythematous bases or plaques. These lesions extend peripherally while central pustules rupture because of their superficial locations, leaving denuded surfaces with crusts, as occur in some forms of pemphigus. Common areas of involvement include the axillae, inframammary areas, umbilicus, groin, and gluteal crease. Pustular lesions can also occur on the hands and involve the nails with subsequent nail loss or onycholysis.

Figure 68-13 Impetigo herpetiformis (i.e., pustular psoriasis). The patient has extensive sterile pustules.

Constitutional symptoms are common and include fever, chills, nausea, vomiting, and diarrhea with severe dehydration. Delirium, tetany, and convulsions are rare complications that are usually associated with hypocalcemia. Death may result from these complications and septicemia. Histopathologically, impetigo herpetiformis is characterized by subcorneal pustules containing neutrophils and degenerated keratinocytes. Cultures of pustular lesions are usually negative for pathogens unless they are secondarily infected.

Differential diagnosis includes AGEP, which is a severe pustular drug reaction, and it is more likely to have eosinophils in the biopsy specimen. Scabies, bacterial impetigo, fungal infections, folliculitis, and acne can be pustular, but they usually look different to an experienced clinician. Cultures, potassium hydroxide preparations, and biopsies can be done when necessary.

Systemic corticosteroid therapy is the treatment of choice for impetigo herpetiformis. Usually, 20 to 40 mg of prednisone per day is sufficient to control new lesion formation. Systemic antibiotics may help when secondary infection is present. Topical measures, such as wet compresses with or without topical corticosteroid preparations, provide relief for itchy pregnancy rashes. Intravenous fluids and electrolytes are important for patients with diarrhea, vomiting, high fever, and extensive skin pustulation. Cyclosporin has been used successfully in pregnancy for severe cases.⁵² Acitretin (i.e., synthetic vitamin A derivative given orally) and methotrexate, both of which are commonly used for generalized pustular psoriasis, are contraindicated during pregnancy.

AUTOIMMUNE PROGESTERONE DERMATITIS

Autoimmune progesterone dermatitis is a rare, poorly defined, urticarial, papular, vesicular, eczematous or pustular eruption thought to be caused by hypersensitivity to progesterone in ovulating women.⁵³ It usually appears as a recurrent, cyclic eruption during the luteal phase of each menstrual cycle. It often resembles erythema multiforme. Very few cases have involved onset or worsening of this condition with pregnancy. At least two of three cases were associated with spontaneous abortion.⁵³ In other cases of autoimmune progesterone dermatitis, the rash improved or cleared during pregnancy.

Figure 68-14 Impetigo herpetiformis (i.e., pustular psoriasis). Close-up view of superficial pustules occurring just beneath the stratum corneum shows the characteristic coalescence into so-called lakes of pus.

Estrogen dermatitis has been described in seven patients, all of whom had severe premenstrual exacerbations of a variety of skin eruptions.⁵⁴ Skin test results were positive for estrogen, such as ethinyl estradiol, in all seven cases.

Autoimmune progesterone dermatitis has been documented by the use of intradermal or intramuscular test injections of progesterone.⁵⁵ Intradermal tests usually produce an immediate local urticarial reaction or a delayed reaction, but a delayed positive test result is considered more diagnostic. For example, a solution made from progesterone powder diluted with a 60% ethanol-saline mixture to concentrations of 0.01% to 1% can be injected intradermally on the volar forearm, using normal saline and the 60% ethanol-saline mixture as controls.²⁰ The area is evaluated every 10 minutes for the first 30 minutes, then every 30 minutes for the first 4 hours, and again at 24 and 48 hours. A positive reaction is declared if a reaction persists for 24 to 48 hours at the progesterone test site. Intramuscular challenges have caused exacerbations of the rash or even angioedema. Progesterone antibodies have been demonstrated in four cases by indirect immunofluorescence. An indirect basophil degranulation test has also been used; in it, the patient's serum is mixed with synthetic progesterone and rabbit basophils.

Specific therapy for autoimmune progesterone dermatitis during pregnancy is unclear. Prednisone may help patients with severe eruptions. Nonpregnant patients have responded to estrogens (if the allergen was progesterone), birth control pills (e.g., Loestrin, which contains ethinyl estradiol plus norethindrone), the antiestrogen tamoxifen, the anabolic androgen danazol, thalidomide, or oophorectomy.⁵⁶ Spontaneous remission can occur after successful treatment.²⁰ Regional anesthesia may be preferred over general anesthesia for patients with progesterone dermatitis who are also prone to angioedema and need to undergo obstetric procedures.⁵⁷

Skin Disorders Affected by Pregnancy

The effect of pregnancy on preexisting skin diseases varies.⁵⁸ Box 68-1 lists some skin diseases that improve or become aggravated by pregnancy, although the course of a disease in a given patient is not always predictable.^{29,59} Most skin diseases do not affect fetal outcome.⁶⁰ Cutaneous infections are discussed in Chapter 51, and connective tissue diseases involving the skin are discussed in Chapter 64. Some infectious, autoimmune, or rheumatic diseases tend to worsen during pregnancy.

ACNE

Acne is a disease of the pilosebaceous unit. It is partially influenced by androgens such as testosterone and dehydroepiandrosterone sulfate (DHEAS), which increase sebaceous gland activity. Estrogen reduces sebaceous gland size and activity, but this is probably a function of negative feedback on androgen production by the ovary. Sebaceous gland activity is increased during pregnancy. Montgomery tubercles are small sebaceous glands on the areolae of the breasts, and their papular enlargement is one of the first signs of pregnancy.

Acne consists of erythematous papules, pustules, comedones, and cysts on the face, back, and chest. Some cases reported as "pruritic folliculitis of pregnancy" of widespread locations may represent hormonally induced acne.⁶¹ Pregnancy has various effects on acne, probably because many other factors

BOX 68-1 EFFECT OF PREGNANCY ON SKIN DISEASES

USUALLY IMPROVED BY PREGNANCY

- Fox-Fordyce disease
- Hidradenitis suppurativa

USUALLY AGGRAVATED BY PREGNANCY

- Condylomata acuminata
- Ehlers-Danlos syndrome
- Erythema multiforme
- Erythema nodosum
- Herpes simplex
- Lupus erythematosus
- Neurofibromatosis
- Pemphigus
- Pityriasis rosea
- Porphyrias
- Pseudoxanthoma elasticum
- Scleroderma (increased renal disease)
- Tuberous sclerosis (increased seizures)

UNPREDICTABLE RESPONSE TO PREGNANCY

- Acne
- Acquired immunodeficiency syndrome
- Atopic dermatitis
- Dermatomyositis
- Melanoma
- Psoriasis

are involved in its pathogenesis besides the hormonal influences discussed.

Acne can be controlled during pregnancy or lactation with topical benzoyl peroxide (category C), salicylic acid, azelaic acid (category B), or topical antibiotics such as erythromycin (category B) or clindamycin (Cleocin T [category B]).⁶² Topical and oral sulfonamides should be avoided near term. Forms of topical metronidazole such as MetroLotion, MetroGel, Metro-Cream, and Noritate cream (all category B) typically are used if other alternatives have failed.

More severe acne can be treated with the apparent oral antibiotic of choice, erythromycin (category B), starting with 1 g daily. However, the efficacy of erythromycin has been dwindling because of the increasing resistance of bacterial flora. It appears to be safe during lactation. Erythromycin estolate has been implicated as a cause of hepatotoxicity in pregnancy after prolonged use and should be avoided.

Tetracycline should be avoided because of its potential risk of fatty liver of pregnancy and adverse effects on fetal dentition. Vitamin A derivatives (i.e., retinoids) such as oral isotretinoin are contraindicated because of teratogenic effects. Topical retinoids such as tretinoin (Retin-A or Avita [category C drugs]) or topical adapalene (Differin [category C drug]) are not contraindicated, but different topical drugs are probably better during pregnancy. Topical tazarotene is a category X drug, but healthy infants have been born to six women using it.

ATOPIC DERMATITIS

Atopic dermatitis is an allergic skin disease characterized by intensely pruritic, eczematous lesions that become lichenified when patients are caught in a scratch-itch cycle.⁶³ There appears to be an inherited irritability of the skin (the "itch that rashes"

instead of the rash that itches), and many patients have a personal or family history of eczema, asthma, hay fever, food allergies, or allergic rhinitis beginning in childhood. This disease can worsen (52%) or improve (24%) during pregnancy.⁶⁴ Exacerbation of atopic dermatitis changes in pregnancy has been called *atopic eruption of pregnancy* (previously discussed).

Some studies show that breastfeeding reduces the incidence of atopy in infants because cow's milk has been implicated as a significant aggravating factor. Soya milk is often substituted, but it also can be allergenic.⁶⁵ The mother's diet has not been shown to make a significant difference during pregnancy and breastfeeding.⁶⁶ An increased incidence of atopy in children has been associated with a wide variety of confusing factors in various studies, such as increased fetal growth and a larger head circumference,⁶⁷ increased gestational age,⁶⁸ low parity, febrile infections in pregnancy, the use of contraceptives before pregnancy,⁶⁹ and maternal smoking.⁷⁰

Treatment with topical emollients, topical corticosteroids, and oral antihistamines is usually effective. If the skin is extremely dry and scaly, greasy ointments may be more effective than creams. Patients should be instructed to use soap sparingly and should always apply topical emollient lotions or creams after bathing. The newer immunomodulators, topical pimecrolimus (Elidel cream) and tacrolimus (Protopic ointment), are FDA pregnancy risk category C drugs. Exceptional patients may require systemic corticosteroids.

ERYTHEMA NODOSUM

Erythema nodosum is characterized by tender nodules on the anterior lower legs and is usually considered to be a reaction to a drug or an infection somewhere else, such as streptococcal pharyngitis or coccidioidomycosis.⁷¹ Sarcoidosis and inflammatory bowel disease are also common causes.⁷² Women account for 90% of patients. Erythema nodosum is known to be precipitated by pregnancy and by oral contraceptives,⁷³ which suggests an estrogen influence on this disease.⁷⁴

Treatment begins with specific therapy for the underlying inciting cause. Nonsteroidal anti-inflammatory agents other than acetaminophen are usually not recommended because they can constrict the ductus arteriosus or cause prolonged labor by inhibiting prostaglandin synthesis. Systemic corticosteroids may be used in more severe noninfectious cases.

FOX-FORDYCE DISEASE

Fox-Fordyce disease is a rare entity, often called apocrine miliaria because it can be similar to the prickly heat or heat rash involving eccrine glands. Fox-Fordyce disease occurs mainly in women and usually begins shortly after puberty.⁷⁵ Many pruritic, dome-shaped, follicular papules develop in the axillae and anogenital region, areas that are rich in apocrine glands.

The disease usually improves during pregnancy or with oral contraceptive therapy, probably because of an estrogen effect. Apocrine activity, unlike eccrine activity, appears to be decreased during pregnancy. Response to topical corticosteroids or pimecrolimus varies.

GENODERMATOSES

A long list of inherited, severe cutaneous diseases involving the mother or other family members can affect fetal mortality or

morbidity. In this rapidly changing field, newer techniques are making it possible to study the molecular, enzymatic, and ultrastructural basis of these conditions.

Modalities useful for detecting severe fetal skin diseases include chorionic villus sampling, amniocentesis, fetal skin biopsy,⁷⁶ and preimplantation genetic diagnosis. DNA-based tests involve screening by nucleotide sequencing, restriction enzyme digests, or linkage analysis.⁷⁷ Although ichthyosis and epidermolysis bullosa are the two most important groups of disorders, prenatal diagnosis has been successful in many other skin diseases.⁷⁸ More details about prenatal diagnosis are given in Chapter 30.

There are many types of ichthyosis, all of which cause extensively thickened, scaly skin resembling the scales of a fish. A variety of ichthyotic syndromes have been described that involve abnormalities other than the skin. Ichthyosiform erythroderma is subdivided into dominant and recessive forms, and generalized involvement is usually present at birth. The collodion and harlequin fetuses are severe examples of ichthyosis in which an infant with grotesque deformities, often resulting in death, is born encased in a horny sheet. Genetic defects have been discovered in many forms of ichthyosis.⁷⁹⁻⁸¹

The many forms of epidermolysis bullosa are characterized by extensive blistering that can contribute to excessive fluid loss or predispose to scarring, deformities, and fatal neonatal infection. The dystrophic and letalis forms of the disease can be distinguished from the less severe simplex form by using electron microscopy or immunofluorescent staining of BMZ antigens to determine the level of blistering in the skin.⁸² DNA-based prenatal diagnosis also has been used.⁸³

PSORIASIS

Psoriasis is a papulosquamous skin condition found in 1% to 3% of the population.⁸⁴ It is usually mild but sometimes can become severe, generalized, or associated with psoriatic arthritis. The pustular form of psoriasis was discussed earlier in the section on impetigo herpetiformis. In one study, psoriasis remained unchanged during pregnancy in 43% of patients, improved in 41%, and worsened in 14%. In the postpartum period, it remained unchanged in 37%, improved in 11%, and worsened in 49%.⁸⁵

Psoriasis in pregnancy is commonly treated with topical corticosteroids (mostly category C agents). Low-potency hydrocortisone is used commonly on delicate skin areas such as the face and intertriginous areas, and medium-potency triamcinolone is used on most other areas. The topical vitamin D derivative calcipotriene (Dovonex [category C drug]) has not been evaluated during pregnancy or lactation, and use of large quantities can result in hypercalcemia. The topical retinoid tazarotene is a category X agent. For severe disease, oral cyclosporin (category C drug) has been used without an apparent increase in problems. Ultraviolet B light therapy is safe in pregnancy. Oral psoralen combined with ultraviolet A light (PUVA) has a category C designation. The oral retinoid acitretin and the antimetabolite methotrexate are category X drugs and should not be used during pregnancy. Etanercept (Enbrel), adalimumab (Humira), and ustekinumab (Stelara) are all pregnancy risk category B drugs, and they are indicated only for very severe disease.

The complete reference list is available online at www.expertconsult.com.

Benign Gynecologic Conditions in Pregnancy

ALESSANDRO GHIDINI, MD | PATRIZIA VERGANI, MD

Pathologies involving the genital organs are often detected for the first time during pregnancy because of the closer clinical and ultrasonographic surveillance that is usually instituted during gestation. Diagnosis of uterine or ovarian pathology before conception must prompt careful consideration of the risks and benefits of interventions (e.g., surgical removal of myomas). During pregnancy, knowledge of risks for adverse outcomes may lead to the implementation of preventative measures.

Uterine Leiomyomas

EPIDEMIOLOGY

Leiomyomas are the most common uterine solid masses. Their prevalence is between 1.6% and 4%, according to series that used routine ultrasound screening in cohorts of women who presented for prenatal care.^{1,2} Epidemiologic studies suggest that the prevalence of leiomyomas correlates primarily to maternal age, African-American ethnicity, age at menarche, length of menstrual cycles, age at first and last birth, and breastfeeding.^{3,5} Reported associations between leiomyomas and other risk factors, such as tobacco use, parity, history of diabetes mellitus, or chronic hypertension, are possibly mediated by the confounding effects of race and age.

PATHOGENESIS

Effect of Pregnancy on Myomas

Several changes in the myometrium associated with pregnancy can affect the size of myomas, including hypertrophy, edema, and the stretching of the myometrium caused by progressive expansion of the amniotic cavity. Degenerative changes can also occur and may be related to ischemia, which is thought to occur when the growth of the myoma, stimulated by the hormonal changes of pregnancy, outpaces its blood supply. In support of this hypothesis is the ultrasonographic evidence that the degenerative changes observed in symptomatic myomas during pregnancy mimic those seen after myoma embolization. Whereas approximately 40% (range, 25% to 60%) of myomas remain stable in size during pregnancy, the others either increase or decrease by more than 10% of the original size. One third of myomas larger than 5 cm grow during pregnancy, but less than 10% of myomas smaller than 5 cm grow.¹ An increase in size occurs most commonly in the first trimester.⁶⁻⁸ This may be related to the effect of rising levels of human chorionic gonadotropin (hCG), receptors for which have been found in leiomyoma cells.⁹ Rapid growth of the myoma does not suggest an

underlying sarcoma, because most leiomyosarcomas occur in women beyond reproductive years and originate from myometrial cells outside of myomas.¹⁰

Effects of Myomas on Pregnancy

Conflicting evidence has associated the presence of myomas with increased rates of infertility and obstetric complications, including spontaneous abortion, preterm delivery, placental abruption, fetal growth restriction, and malpresentation. The most reliable conclusions are derived from prospective cohort studies of women in whom myomas were detected at routine ultrasound screening early in their pregnancy, allowing inclusion of asymptomatic women and of myomas of any size. Not surprisingly, the frequency of myoma-related obstetric complications is generally lower among cohorts of women identified with myomas at ultrasonographic screening than from series derived from referral radiology centers or registries of hospital admissions during pregnancy, with the inherent potential biases associated with the latter reports.

Several mechanisms have been suggested to explain the association between uterine fibroids and pregnancy complications:

- A large submucous fibroid projecting into the uterine cavity may lead to spontaneous pregnancy loss by disturbing perfusion of the endometrium at the site of blastocyst implantation, or it may interfere with normal placentation and development of the uteroplacental circulation.¹¹
- Rapid fibroid growth may lead to increased uterine contractility or decreased placental oxytocinase activity,¹¹ both of which may result in a localized increase in oxytocin levels and preterm contractions.
- As blood flow has been shown to be reduced in fibroids and the adjacent myometrium, it has been hypothesized that myomas may cause placental ischemia and decidual necrosis, which may lead to placental abruption.¹²
- Large myomas distorting the shape of the uterine cavity may cause fetal malpresentation and placenta previa.
- By decreasing the force and coordination of uterine contractions, fibroids may predispose to postpartum hemorrhage and uterine atony.¹³

Infertility. There are no randomized, controlled trials testing the benefit of pre-conceptual removal of myomas to fertility. A meta-analysis¹⁴ of the limited available data suggests that in infertile women with no identifiable infertility factors, submucous myomas are associated with lower pregnancy rates compared with infertile women without myomas (relative risk [RR] = 0.32; 95% confidence interval [CI], 0.13 to 0.70). Similar conclusions were reached by a recent review of controlled studies from populations of patients undergoing assisted

reproductive techniques.¹⁵ Indirect support for a causal role of submucous myomas on infertility comes from reports that after hysteroscopic myomectomy, women achieve pregnancy rates comparable to those of women without myomas and significantly higher than those of women who declined myomectomy.¹⁵

Less consistent is the evidence for an effect of asymptomatic intramural myomas on fertility. Some series have suggested that leiomyomas distorting the uterine cavity lower pregnancy rates in women attempting assisted reproductive techniques.¹⁴ A recent review concluded that although there is cumulative evidence that intramural myomas may be associated with lower implantation rates than controls (18% versus 22%), the presence of biases in the published studies should lead to caution before such results are translated into a recommendation for myomectomy to optimize reproduction.¹⁵

Spontaneous Abortion. Most of the evidence of an effect of myomas on rates of spontaneous abortion comes from studies of infertile women with asymptomatic myomas undergoing assisted reproductive techniques. A meta-analysis of controlled studies found increased rates of spontaneous abortion in women with intramural myomas compared with controls without myomas (20% versus 13%; odds ratio [OR] = 1.82; CI, 1.43 to 2.30).¹⁵ The largest study on the subject did not find an effect from myoma size, but rather from the number of myomas, with no increased risk for miscarriage in women with single intramural myoma.¹⁶ Less conclusive, mainly because of the small number of cases reported, is the evidence for an effect of submucous myomas on risk for miscarriage.¹⁵

Fetal Death. In one small study with design limitations, the rate of second-trimester losses was significantly higher before versus after myomectomy (7 of 14 versus 0 of 6; $P = .04$).¹⁷ Another study found increased rates of second-trimester fetal losses between 18 and 23 weeks' gestation in two groups of 128 women with myomas undergoing (group 1) or not undergoing (group 2) genetic amniocentesis, compared with controls without myomas (group 3) undergoing amniocentesis, that were matched for maternal age, nulliparity, prior abortion or preterm birth, and gestational age at amniocentesis or sonogram (6%, 7%, and 1%, respectively; $P = .02$).¹⁸ Although the investigators concluded that the presence of myomas increased the risk for second-trimester fetal losses, the strength of the

conclusions was weakened by several biases, such as lack of information on criteria used for choosing controls and on the indications for sonogram or amniocentesis. A third, more recent study found an increased risk for fetal death in the presence of fetal growth restriction in women with myomas compared with those without myomas after controlling for advanced maternal age, African-American race, diabetes mellitus, and chronic hypertension, and excluding major fetal anomalies (OR = 2.1; 95% CI, 1.2 to 3.6), but the risk did not hold when the fetus was of appropriate size.¹⁹ The risk was greatest for women with more than three myomas (OR = 2.2; 95% CI, 1.1 to 4.6) and myomas larger than 5 cm (OR = 2.6; 95% CI, 1.5 to 4.5).¹⁹ Performing serial ultrasonographic assessment of fetal growth with antenatal testing in the presence of fetal growth restriction may thus be clinically useful.

Preterm Delivery. Women with myomas seem to have higher rates of hospital admissions for preterm labor,^{2,12,20} and the risk for preterm uterine activity has been correlated with the size of the myoma.²¹ Several studies have dealt with the risk for preterm delivery for women with myomas (Table 69-1). Despite the biases present in several such studies, including use of hospital discharge codes for diagnosis of myoma to identify cases, a design that is prone to ascertainment biases,^{4,22} as well as lack of correlation between the number of myomas or myoma size and the risk for preterm delivery,³ there seems to be a modest increase in risk for prematurity at less than 37 weeks. A systematic review calculated an OR of 1.5 (95% CI, 1.3 to 1.7) for preterm delivery in the presence of myomas.¹⁵

Placental Abruption. An increased rate of placental abruption has been described among women with myomas admitted for antepartum hospital care compared with those without myomas (10 [11%] of 93 versus 48 [0.7%] of 6613).¹² The study authors found that the risk for abruption was associated with myomas larger than 3 cm in diameter and in a retroplacental location. Similarly, studies using International Classification of Diseases, Ninth Revision (ICD-9) hospital codes, and multivariate analysis to control for confounders, found that a diagnosis of abruption was significantly associated with a code for myomas compared with the absence of such a code (OR = 3.8; 95% CI, 1.6 to 9.2⁴; and OR = 2.6; 95% CI, 1.6 to 4.2²²). A retrospective ultrasonographic cohort study confirmed an association between abruption and myomas.² However, these studies did

not consistently find an association between risk for abruption and myoma number, size, or location.

At variance with these findings were two large cohort studies of myomas detected prospectively at ultrasonography,^{3,23} which found no significant association between the presence of myomas and the occurrence of abruption (1.2% versus 0.4%,²³ and 2.2% versus 1.8%³). Moreover, a case-control study of myomas larger than 5 cm detected prospectively at routine sonographic screening found no significant association between myomas and abruption.²⁴ Another case-control study found no association between abruption and myomas.²⁰ In summary, the evidence about a possible association between myomas and abruption is conflicting.

Placenta Previa. The presence of uterine myomas may facilitate an abnormally low placental implantation. A large sonographic series of almost 15,000 women found significantly higher rates of placenta previa among patients with myomas (3.5% versus 1.8%), and a trend was identified between myoma size (≥ 10 cm) and risk for placenta previa.³ In line with these findings, two large cohorts of women undergoing sonographic screening reported significantly higher rates of placenta previa among women with myomas larger than 5 cm in diameter (2.4% versus 0.6%, OR = 2.1; 95% CI, 1.4 to 3.1,²⁴ and 2.7% versus 0.5%, OR = 2.4; 95% CI, 2.6 to 7.5).¹⁹ Furthermore, the finding of any leiomyoma in the lower uterine segment seemed to confer an increased risk for abruption.¹⁹ Unlike size and location, the number of myomas does not seem to correlate with occurrence of placenta previa.³

Fetal Malpresentation. A significant association (OR = 1.6 to 4.0) between myomas and fetal malpresentation has been reported in several large, prospective series in which multivariate analysis was used to control for confounders, including gestational age and parity.^{3,4,19,24} A meta-analysis reported an OR of 2.9 (95% CI, 2.6 to 3.2) for malpresentation in association with myomas.¹⁵ The size of the myoma plays an important role. One series reported significantly higher rates of malpresentation at term in women with myomas larger than 5 cm than in controls without myomas (12% versus 5%).²⁴ Other investigators found a progressive increase in rates of malpresentation with myoma size: 8% in women without myomas, 10% in those with myomas smaller than 10 cm, and up to 23% in those with myomas at least 10 cm in diameter.³ Similarly, a large series reported an association between myoma volume and rates of breech presentation after adjusting for confounders.¹⁹ Unlike myoma size, the number of myomas does not seem to affect the risk for fetal malpresentation.³

Labor Complications. A large series using ICD-9 codes found increased rates of labor complications (OR = 1.9; 95% CI, 1.6 to 2.2) in women with leiomyomas after controlling for maternal age, parity, and previous cesarean delivery.⁴ Labor complications were mainly limited to those with an ICD-9 code of dysfunctional labor (OR = 1.8; 95% CI, 1.3 to 2.7), because rates for those with an ICD-9 code of prolonged labor did not significantly differ between the two groups.⁴ However, a large cohort study of cases in which myomas were diagnosed prospectively at a second-trimester sonographic screening did not find an association between the presence of myomas and the duration of the first or second stage of labor.³ That leiomyomas do not disrupt uterine contractility is further supported by the

observation that women with large tumors (≥ 10 cm) and those with small myomas have similar durations of first and second stages of labor and similar rates of cesarean delivery among labor-eligible women.³ Similar rates of cesarean delivery for dystocia (OR = 1.1; 95% CI, 0.4 to 2.3) and fetal distress (OR = 0.9; 95% CI, 0.3 to 1.9) have been reported for women with myomas larger than 5 cm compared with those without myomas.²⁴ In summary, women with leiomyomas of any size can be reassured that if they are eligible for vaginal delivery and they initiate labor, their likelihood of successful vaginal delivery can be expected to be similar to that in the general obstetric population.

Cesarean Section. An increased rate of cesarean delivery before labor is the obstetric complication most frequently observed for women with leiomyomas.^{2,12,19,23,25} A recent systematic review calculated an OR of 3.7 (95% CI, 3.5 to 3.9) for cesarean delivery in the presence of myomas.¹⁵ Consistent and cumulative evidence suggests that malpresentation,^{3,4,22} placenta previa,^{3,4,22} and location of the tumors in the lower uterine segment below the presenting fetal part²² are the most common indications for cesarean delivery in women with leiomyomas. However, the presence of leiomyomas remains significantly associated with increased risk for cesarean delivery before labor, even after correcting for these indications.²⁴ Size and volume of the myomas do not independently explain the increased risk for cesarean section.¹⁹

Postpartum Hemorrhage. Although one report⁴ using ICD-9 discharge codes found no relationship between myomas and postpartum hemorrhage, more robust studies have reported an increased risk.^{3,24,26} A cumulative OR of 1.8 (95% CI, 1.4 to 2.2) has been reported in a systematic review.¹⁵ Size of myomas does not seem to play a role in the risk, because women with myomas 10 cm or larger have rates of postpartum hemorrhage similar to rates for those with smaller myomas.³

Perinatal Outcome. Women with myomas can be reassured that most adverse perinatal outcomes (e.g., neonatal death, small size for gestational age, low Apgar scores, malformations) are not affected by the presence of uterine myomas.^{2,4,12,15,23,24,27} However some adverse outcomes seem to be increased in the presence of myomas, including prematurity at less than 37 weeks (see Preterm Delivery, earlier) and stillbirth in the presence of fetal growth restriction or large or multiple myomas.²⁰ The purported fetal compression syndrome, caused by the pressure effects of large myomas on fetal parts, is limited to isolated case reports.

DIAGNOSIS

The ultrasonographic diagnosis of leiomyoma rests on visualization of persistent, hypochoic, spherical masses distorting the myometrial contour. When located in the myometrium, they should be differentiated from focal myometrial contractions, which tend to disappear during the examination or on follow-up scans. The hypochoic sonographic appearance of leiomyomas may change when the masses undergo degeneration, which may lead to the appearance of cystic spaces or a coarse heterogeneous pattern consisting of hyperechogenic clusters in the myomas (Fig. 69-1). In such cases, myomas may have a worrisome appearance, and they can be mistaken for

Figure 69-1 Degenerated myoma. Degenerated myomas have a heterogeneous echogenic pattern, with hypoechoic and hyperechoic areas seen in the myoma.

Figure 69-2 Pedunculated myoma. The arterial blood supply from the uterus can be demonstrated using color flow mapping.

ovarian neoplasms or other intraabdominal masses. When in doubt, magnetic resonance imaging (MRI) can confirm the diagnosis of a large, degenerating leiomyoma.²⁸ Pedunculated myomas can be differentiated from other pelvic masses by visualization of the blood supply by using color flow mapping (Fig. 69-2).

Myomas are often classified on the basis of their location in relationship to the uterine cavity (i.e., submucosal if they distort the uterine cavity, intramural if they are predominantly located in the myometrial layer, and subserosal if they predominantly protrude out of the serosal surface of the uterus); in relationship to their anatomic location in the uterus (i.e., fundal, corporal, isthmic, or cervical); and in relationship to the placental insertion site (i.e., retroplacental or not). Such classifications are often difficult to apply in pregnancy because of uterine

enlargement. Moreover, the location of a myoma can change during pregnancy because of changes in uterine size, so-called placental migration, and development of the lower uterine segment. Despite these difficulties, several series have attempted to correlate the location of myomas with the subsequent occurrence of pregnancy complications. The evidence for such associations will be discussed.

MANAGEMENT

Fertility

A meta-analysis has shown that among infertile women with no identifiable infertility factors except submucous myomas, resection of myomas is followed by increased fertility rates (RR = 1.72; 95% CI, 1.13 to 2.58),¹⁴ suggesting that resection of submucous myomas may be a treatment for infertility in selected cases.¹⁵ Moreover, women with infertility resulting from submucous myomas who conceive spontaneously after myoma resection have higher pregnancy rates than those who conceive with assisted reproductive techniques.¹⁴ There is controversial evidence whether subserosal or intramural myomas without intracavitary involvement may affect fertility.¹⁵ The risk for myomectomy must be weighed against the surgical risks to the woman, increased risks for future pregnancies because of the presence of the uterine scar, and risks for recurrence of myomas. In asymptomatic patients selected for in vitro fertilization, fibroids smaller than 5 cm not encroaching on the endometrial cavity do not affect the rate of clinical pregnancies compared with women without myomas.²⁹ Until randomized clinical trials demonstrate benefits from myoma resection in infertile women with intramural or subserosal myomas, the procedure should not be recommended.^{15,30} A recent meta-analysis of available cohort studies³¹ demonstrated no evidence that myomectomy had a significant effect on the clinical pregnancy rate (OR = 1.88; 95% CI, 0.57 to 6.14) if the myoma did not involve the uterine cavity.

Miscarriage

A recent study evaluated the effect of myomectomy on mid-trimester fetal losses in women with myomas distorting the uterine cavity. Compared with rates before myomectomy, mid-trimester fetal losses were significantly lower after myomectomy among those who remained pregnant (21.7% versus 0%).³² In contrast, a recent meta-analysis of available cohort studies³¹ demonstrated no evidence of a significant benefit from myomectomy on miscarriage rate (OR = 0.89; 95% CI, 0.14 to 5.48) for myomas not involving the uterine cavity. Because of the known risks of myomectomy, the procedure should not be offered to women with myomas and a history of miscarriages until prospective, observational studies with appropriate controls demonstrate an independent association between myomas and miscarriages, and until randomized, controlled trials document a beneficial effect of myoma resection on the risk for recurrent miscarriages.

Painful Myomas

Changes caused by large myomas during pregnancy may lead to the syndrome of painful myomas (i.e., red degeneration, carneous degeneration, hemorrhagic infarction, and aseptic necrobiosis) in less than 5% of patients.^{1,33} The pathogenesis of the pain is unclear, although it has been attributed to ischemia

and necrosis caused when the rapid growth of the myoma outpaces its blood supply, or when acute disruption of the blood supply leads to hemorrhagic necrosis. The exquisite response of the myoma pain to cyclooxygenase inhibitors (i.e., indomethacin or ibuprofen) suggests that release of prostaglandins plays an important role in the genesis of the pain.

Clinically, the diagnosis should be considered if there is localized tenderness over the myoma; in rare cases, the syndrome may be associated with low-grade pyrexia, mild leukocytosis, nausea, and vomiting. The differential diagnosis is extensive because of the lack of specificity of the symptoms, and it includes appendicitis, ureteral stones and pyelonephritis, adnexal torsion, and preterm labor. Ultrasonography plays a critical role in establishing a correct diagnosis by demonstrating the topographic association between the site of pain and the myoma, as well as the presence of cystic areas related to myoma degeneration in 70% of cases. If the diagnosis is uncertain, MRI may be indicated.³⁴

Expert opinions and case series suggest that nonselective cyclooxygenase inhibitors are more effective in the treatment of myoma-related pain than standard analgesics or narcotics.^{25,35} Use of indomethacin (25 to 50 mg every 6 hours) or ibuprofen (600 to 800 mg every 6 hours) usually leads to resolution of the symptoms within 48 hours. Intravenous therapy with ketoprofen (100 mg every 6 hours) is also useful, particularly in patients with gastrointestinal symptoms in response to indomethacin or ibuprofen. An infected myoma (i.e., a pyomyoma) is a rare cause of a painful myoma. It can be suspected in the presence of fever, moderate leukocytosis, and lack of response to appropriate medical therapy.³⁶⁻³⁸ Most cases are associated with termination of pregnancy, or they occur in the puerperium. Intravenous antibiotics together with myomectomy^{36,39} or hysterectomy³⁷ are the mainstays of therapy in such cases.

Prevention of Adverse Obstetric Outcomes. Although myomas seem to be associated with an increased risk for prematurity, it is not known whether such prematurity is spontaneous or predictable, and therefore what measures could be implemented to predict them and improve the outcome. Although myomas do not affect fetal growth, fetal death is more common in the presence of fetal growth restriction. Therefore, sonographic monitoring of fetal growth seems indicated, particularly with multiple myomas or those larger than 5 cm in diameter. Myomectomy of large asymptomatic myomas does not improve future obstetric and delivery outcomes, indicating that most asymptomatic myomas should be managed conservatively in women still considering childbearing.⁴⁰

Myomectomy during Pregnancy. Myomas in pregnancy are best treated conservatively because of the risks of performing a myomectomy in a pregnant uterus (chiefly, bleeding and preterm delivery). Surgery may be reserved for cases of painful myomas refractory to medical therapy, and for cases of rapid myoma growth leading to constipation or urinary retention. A total of 67 instances of myomas removed at laparotomy and six removed laparoscopically have been reported in the literature (and have been summarized^{41,42}). Because such cases are frequently related to torsion of pedunculated subserosal myomas, surgery is relatively safe and facilitated by clamping of the myoma pedicle.⁴³ Most series have reported a good pregnancy outcome. However, the small sample size and possible selection bias of successful reports does not allow firm conclusions to be drawn.

Cesarean Myomectomy. Occasionally, myomas need to be removed at the time of cesarean delivery to facilitate closure of the uterine incision or, rarely, to facilitate access to the fetus. With the exception of pedunculated myomas, which can be safely removed at the time of cesarean delivery, cesarean myomectomy carries significant risks of hemorrhagic complications. Bleeding significant enough to require transfusion, uterine artery ligation, embolization, or hysterectomy has been reported for an average of 11% of cases of myomectomy at cesarean section (range, 0% to 33%), with published series reporting on small numbers of cases (from 5 to 25).^{2,43-47}

In light of the risk for severe bleeding, appropriate planning is desirable for women with large uterine myomas located in the anterior uterine wall or lower uterine segment. Planning should include careful ultrasound mapping of the myoma in relationship to placental insertion and fetal position before surgery, as well as making sure that blood products and appropriate support personnel are available in case of complications. Extensive cesarean myomectomies with removal of multiple myomas should be discouraged as an elective procedure because of the risk for bleeding and the natural history of myomas, which tend to undergo involution after delivery.

Pregnancy after Myomectomy. The main concern for pregnancies after any type of myomectomy is the risk for uterine rupture before or during labor. The risk seems to depend on the location of the myoma and the type of surgery. A history of myomectomy after laparotomy carries an increased risk for uterine rupture (about 1.7%).⁴⁸ Most obstetricians consider myomas that enter the uterine cavity to present a particular risk for uterine rupture, so spontaneous or induced labor is contraindicated.⁴⁹ After laparoscopic myomectomy, the risk for uterine rupture seems to be increased (about 0.5%), and to be related to the location of the myoma, the use of electrocautery, and inadequate suturing.^{48,50} It has been suggested that, if there is a history of laparoscopic myomectomy, the pregnancy be managed as it would if there had been a prior low transverse cesarean delivery.⁴⁸ Uterine rupture in pregnancies after hysteroscopic myomectomy is a rare event, having been reported only in cases of uterine perforation at the time of the procedure.

Particular risks may affect pregnancies after uterine artery embolization for myomas. A total of 144 pregnancies reported in women after uterine artery embolization resulted in 83 deliveries.⁵¹⁻⁵³ The preterm delivery rate was 20% (17 of 83), and the average cesarean delivery rate was in excess of 50%. Rates of fetal growth restriction and low birth weight were not consistently reported, but they did not seem to be significantly affected.⁵² Several series have reported occurrences of abnormal placentation (including accreta and previa) as high as 12% in pregnancies after uterine artery embolization.⁵⁴ Although these complications should be kept in the context of additional risk factors, including advanced maternal age, previous uterine surgeries, and presence of residual myomas, they raise serious concerns that uterine artery embolization may permanently alter myometrial function and induce changes in the uterine vasculature. In summary, given that the risks for obstetric complications, including prematurity and placental abnormalities, may be higher than expected for the general population, uterine artery embolization for myomas seems most appropriate for patients with symptomatic myomas who have completed childbearing.⁵⁵

Adnexal Masses

The detection of ovarian cysts in pregnancy is not uncommon. Small cysts discovered in early pregnancy are often functional, and expectant management is recommended because most of them resolve spontaneously and do not pose a risk to the pregnancy. Larger or complex cysts pose more of a clinical dilemma. Although some clinicians often remove them in the second trimester because of the risk for complications, even large and complex masses may be followed expectantly if they appear to be benign.^{56,57}

EPIDEMIOLOGY

Because of spontaneous resolution with advancing gestation, the prevalence of adnexal masses depends on gestational age. During the first 5 weeks of pregnancy, adnexal masses have been reported in 8.8% of women undergoing ultrasonographic examination. Similarly, Condous and associates⁵⁸ identified ovarian cysts in 6.1% of pregnant women examined with ultrasonography before 14 weeks.

Spontaneous resolution during pregnancy occurs for most adnexal masses. Resolution is common even in large masses. In a series of 123 asymptomatic ovarian cysts detected at prenatal ultrasound examinations and followed conservatively, complete resolution was observed in 89% of cases, including 82% of the cysts larger than 6 cm in diameter.⁵⁹ Similarly, spontaneous resolution was reported for 72% (119 of 166) of ovarian cysts followed with ultrasonography,⁵⁸ and for 69% (70 of 102) of simple or complex adnexal masses larger than 5 cm in diameter.⁵⁶ The high rate of resolution reflects the physiologic nature of most ovarian masses detected early in pregnancy; expectant management is thus a reasonable option.^{56,60}

PATHOGENESIS

The frequency and classification of persistent ovarian masses is limited to masses removed during or immediately after pregnancy, generating an inevitable bias because most ovarian masses with a benign appearance are not surgically removed. A review of the largest series reveals that three types of benign ovarian pathology account for most ovarian masses in pregnancy: corpus luteum cysts, mature teratomas, and cystadenomas (Table 69-2).⁶⁰⁻⁶³

DIAGNOSIS

Diagnosis relies on ultrasonography. In a series of ovarian cysts detected during the course of ultrasonographic examination in the first trimester, the rate of complications was 4% (7/166).⁵⁸ The most common complications of adnexal masses in pregnancy are malignancy; torsion, rupture, or hemorrhage; and dystocia at delivery. The ultimate goal of the imaging evaluation of adnexal masses is to aid the physician in distinguishing cases in which conservative management with observation is possible from those requiring surgical intervention. Because ultrasonography is so accurate at determining the source of the adnexal mass and characterizing its morphology, this procedure is usually sufficient to make decisions regarding management of an adnexal mass.

Ruling out Malignancy

The potential for malignancy is the paramount concern for the managing clinicians. Among women of reproductive years,

TABLE 69-2 Histologic Prevalence of Ovarian Cysts in Pregnancy

Behavior	Type of Pathology	Frequency (%)
Benign	Corpus luteum	15-20
	Mature teratoma	7-42
	Luteoma or functional cyst	11-19
	Endometrioma	1-5
	Leiomyomas or adenofibromas	4-5
Borderline	Serous and mucinous cystoadenomas	9-16
	Borderline (serous, mucinous, other)	1-2
Malignant	Epithelial ovarian cancer, germ cell tumor, sex-cord stromal tumors	2-7

Data from Bromley et al, 1997⁶⁰; Whitecar et al, 1999⁶¹; Schmeler et al, 2005⁶²; Soriano et al, 1999.⁶³

TABLE 69-3 Ultrasonographic Classification of Ovarian Masses in Pregnancy

Category	Sonographic Features
Simple cyst	Anechoic cyst without septa or vegetations
Endometriosis-like or corpus luteum-like	Hypochoic content, homogeneous or trabecular, no papillae
Dermoid-like	Combination of hyperechogenic and hypochoic content, shadows
Complex benign	Septa, thick content but no papillae
Borderline	Smooth capsule, presence of intracystic papillae, absence of gross solid parts
Suspect	Solid parts, irregular capsule or border, ascites, irregular vascularization

Modified from Zanetta G, Mariani E, Lissoni A, et al: A prospective study of the role of ultrasound in the management of adnexal masses in pregnancy, *BJOG* 110:578-583, 2003.

germ cell tumors are common in younger women, whereas epithelial ovarian cancers occur more frequently in older patients. The rate of malignancy for adnexal masses identified during pregnancy is commonly reported as 1% to 3% of surgically removed ovarian masses. The largest series on the subject, involving 9375 patients with a hospital discharge diagnosis of an ovarian mass, found a 2.1% incidence of malignancy, including 87 (0.9%) ovarian cancers of various histologic types, and 115 (1.2%) ovarian tumors of low malignant potential.⁶⁴ In a series of 470 women who underwent surgery for adnexal masses during pregnancy, malignancy was confirmed in 20 (4.3%).⁶⁵ Several algorithms have been proposed to differentiate benign from malignant ovarian tumors and to stratify the risk for malignancy using ultrasonographic characteristics.

Ultrasound Characteristics

Although malignant masses tend to be larger than benign ones, the size of an ovarian mass in pregnancy cannot be used to predict malignancy. In a case-control series, the average size of nonmalignant tumors was 7.6 cm and that of malignant neoplasms was 11.5 cm.⁶⁶ All masses smaller than 6 cm were benign. Zanetta and colleagues⁵⁷ proposed a triage system to identify those who were candidates for expectant management (Table 69-3 and Fig. 69-3). The system was applied to 79 pregnant women with adnexal masses followed prospectively. Only

Figure 69-3 Ovarian cyst. Ultrasonographic appearance of ovarian cysts classified according to the system of Zanetta and colleagues.⁵⁷ **A**, On the left is a simple cyst. The uterus is visible on the right side of the image. **B**, This cyst has endometriosis-like or corpus luteum-like characteristics. **C**, This ovarian mass has borderline characteristics (see Table 69-3).

pregnant patients with suspect masses were triaged to surgical intervention at diagnosis, and women with masses of all the other categories were considered candidates for expectant management. There were no malignant tumors among the 23 women who underwent surgery because of persistent masses, torsion, rupture, or nonreassuring ultrasonographic findings, and all three borderline tumors were correctly suspected prenatally. Similarly, in a series of 131 tumors, ultrasonography accurately identified 95% of dermoid cysts, 80% of endometriomas, and 71% of simple cysts during pregnancy, and, more importantly, it correctly suspected the only case of malignancy.⁶⁰ In a case-control study of 40 patients (Table 69-4), three of whom had malignant neoplasms and five of whom had tumors of low malignant potential, a uniform cystic appearance of the tumors had high specificity, whereas the presence of internal papillary excrescences had high sensitivity for diagnosis of malignancy.⁶⁶

Wheeler and Fleischer⁶⁷ prospectively investigated 34 ovarian masses with ultrasonography and color Doppler, and compared their results with histologic diagnoses (Fig. 69-4). The mean

TABLE 69-4 Risk of Ovarian Malignancies Based on Sonographic Criteria

Characteristic	Benign, n = 32	Malignant, n = 8

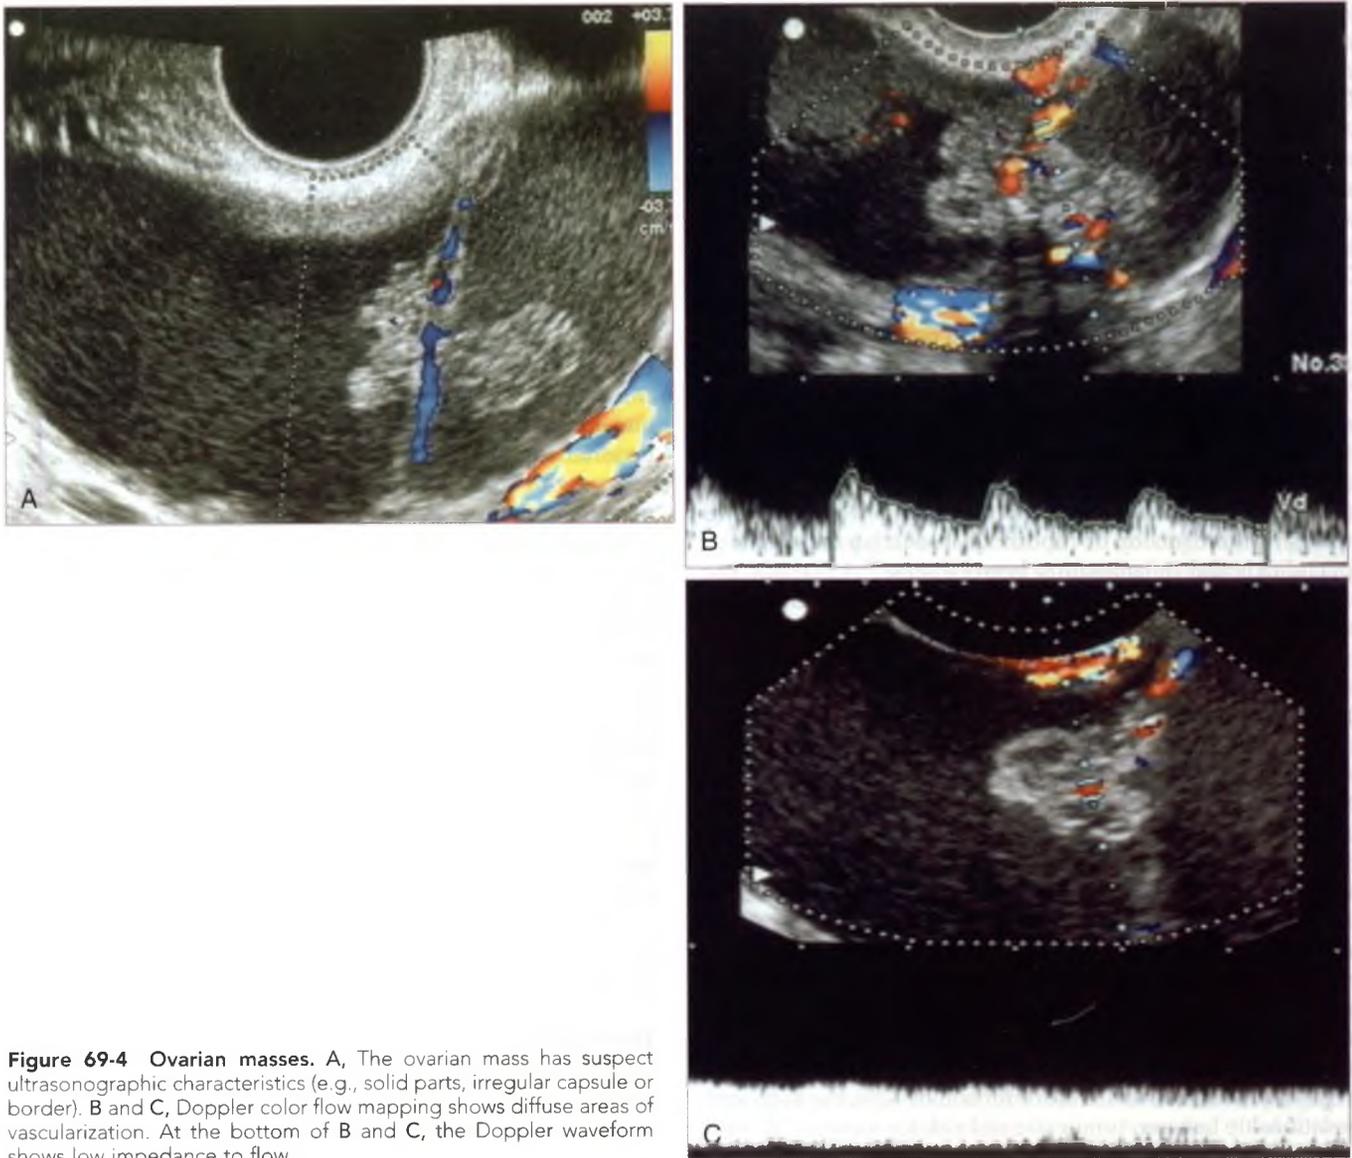

Figure 69-4 Ovarian masses. A, The ovarian mass has suspect ultrasonographic characteristics (e.g., solid parts, irregular capsule or border). B and C, Doppler color flow mapping shows diffuse areas of vascularization. At the bottom of B and C, the Doppler waveform shows low impedance to flow.

pulsatility index in morphologically suspect areas in the tumor was significantly lower for malignant than for benign masses (0.7 [range, 0.4 to 1.3] versus 1.2 [range, 0.4 to 2.8]; $P = .03$), suggesting low impedance to flow in malignant masses. A pulsatility index less than 1.0 correctly identified three malignant ovarian lesions and five tumors of low malignant potential, with a sensitivity of 89%, a positive predictive value of 42%, and a negative predictive value of 93%. However, the overlap in blood flow patterns between benign and malignant tumors was such that the false-positive rate was almost 48%, causing incorrect assignment of malignant potential to some benign lesions and offering no advantage over the use of sonographic morphology alone. A review on the subject⁶⁸ concluded that Doppler did not further aid diagnosis compared with ultrasonography alone.

Serologic Markers

Serum tumor markers are used primarily for surveillance of known, treated ovarian malignancies, but they are of limited benefit in the initial assessment of ovarian masses in pregnancy.

The level of cancer antigen 125 (CA 125) is elevated in 80% of nonpregnant women with epithelial ovarian malignancies, with mucinous adenocarcinomas being a notable exception. CA 125 has inadequate diagnostic accuracy in premenopausal women because many benign gynecologic conditions, such as uterine fibroids, and especially pregnancy, are associated with elevated values. When elevated, the CA 125 level can provide a baseline value before treatment of ovarian cancer, but it does not help to differentiate benign from malignant masses during pregnancy.

Various other tumor markers are used to monitor germ cell tumors: α -fetoprotein (AFP) for endodermal sinus tumor, hCG for choriocarcinoma, and lactate dehydrogenase (LDH) for dysgerminoma. Although germ cell tumors are among the most common ovarian malignancies seen in pregnancy, hCG and AFP have very limited use as tumor markers during pregnancy. Levels of tumor markers should be obtained before any surgical intervention when there is a suspicion of ovarian malignancy, to provide a baseline value in case a malignancy is diagnosed. Any elevation in the levels of tumor markers should be

considered in conjunction with the results of the imaging tests to avoid unnecessary intervention when possible.

Magnetic Resonance Imaging

Magnetic resonance imaging can be safely used during pregnancy to evaluate adnexal masses even without the use of gadolinium-based contrast. The primary advantages of MRI are its capacity to develop three-dimensional planar images, to delineate tissue planes, and to characterize tissue composition. Kier and colleagues⁶⁹ reported that MRI is a useful complement to ultrasonography for patients with adnexal masses in pregnancy. In their series of 17 patients, MRI correctly identified the cause in 100%, whereas ultrasonography was accurate in 71%.⁶⁹ Three patients with ultrasonographic findings of suspect ovarian masses were found to have pedunculated uterine leiomyomas on MRI, and unnecessary surgery was avoided. MRI may also be better than ultrasonography at distinguishing parovarian cystic lesions, as well as in the diagnosis of conditions that may mimic torsion or rupture of an ovarian mass, such as appendicitis and inflammatory bowel disease.⁷⁰ Currently, use of MRI in pregnancy is reserved for cases in which the ultrasound diagnosis is uncertain.

COMPLICATIONS

Torsion and Rupture

During pregnancy, the progressive enlargement of the uterus displaces the ovaries and fallopian tubes out of the pelvis. This phenomenon and the rapid return of these structures to their normal anatomic location after parturition increases the risk for torsion of adnexal masses in pregnancy, particularly at the beginning of the second trimester and during postpartum involution. The rate of torsion in published series varies from 1% to 12%.^{56,58,60} Rupture, bleeding, and infection appear to be less common, with rates of less than 1%.^{60,61} A recent series of 470 women who underwent surgery for adnexal masses during pregnancy, with an overall rate of torsion of 12%, has suggested a relationship between tumor size and risk for torsion.⁶⁵ A mass size of 6 to 10 cm had a nearly threefold greater risk for torsion than a mass less than 6 cm or greater than 10 cm.⁶⁵

Risk for Dystocia at Delivery

Obstruction of labor is a complication that can occur when large adnexal masses are lodged between the presenting fetal part and the birth canal. Obstruction of labor occurs in 2% to 17% of patients with large adnexal masses.^{71,72}

MANAGEMENT

Optimal management of adnexal masses should be based on an accurate assessment of the risks for the complications just outlined. Ultrasonographic criteria can successfully stratify the risk by identifying the few masses with suspect complex features that warrant surgical management. Most masses have a benign ultrasonographic appearance, and they are suitable for conservative (expectant) management.

Surgery

Surgical management of adnexal masses during the first trimester should be limited to lesions with complications (e.g., torsion, rupture). Persistence of adnexal pathology during the second

and third trimester may warrant intervention if there is a strong suspicion of malignancy or large size (>6 cm), or if there are symptomatic complaints. A large size may signal increased risk for torsion, rupture, or obstruction during labor. Before undergoing surgical removal, patients should be appropriately counseled about the possibility of an underlying malignancy and be prepared for possible ovarian cancer staging and related evaluation of tumor serum markers. Although the risks to mother and fetus have been substantially reduced with the improvement of anesthesia, intraoperative and postoperative care, and prenatal care, surgery during pregnancy requires a trained team of surgeons and anesthesiologists and close monitoring postoperatively.

Laparoscopy offers clear advantages to exploratory laparotomy for surgical management of adnexal masses, including less invasive surgical management and a shorter postoperative course with fewer complications.⁷² Patients with an ovarian mass that is not suspected to be malignant in the first or second trimester of pregnancy may benefit from laparoscopic surgery. Sound clinical judgment is critical for patient selection, and caution is strongly advised when considering laparoscopic management of possible ovarian cancer. Although many case series proposed aspiration of simple unilocular cysts to avoid the need for major surgery, to provide symptomatic relief, or to allow these masses to fit into endoscopic bags, aspiration of a complex ovarian cyst runs the potential risk for malignant fluid spillage, which is associated with decreased survival.⁷³ Ovarian masses, especially those suspected to be cancerous, should be removed intact when possible, and surgical intervention for large, complex ovarian masses should be performed by laparotomy.

Whether by laparoscopy or laparotomy, consideration can be given to ovarian cystectomy if the imaging criteria for a benign mass are met. Otherwise, oophorectomy is appropriate.

Timing of Surgery. Delaying surgery because of fear about the risks of the operation may lead to increased fetal and maternal complications. Adverse fetal outcomes associated with abdominal surgery are most commonly the result of an abdominal catastrophe, such as ovarian torsion or rupture as indications for the surgery. In elective surgical cases, there seems to be no association between surgery and adverse perinatal outcome. Hess and colleagues⁷¹ reported that patients who underwent emergency surgery because of adnexal torsion or hemorrhage had a greater incidence of abortion and preterm delivery than patients who underwent elective laparotomy. Elective surgical intervention is preferably timed for the second trimester, when the risk for fetal loss is minimal. Whitecar and colleagues⁶¹ found that adverse pregnancy outcomes, including preterm deliveries and fetal loss, were significantly less common if laparotomy occurred before rather than after 23 weeks' gestation (OR = 0.15; $P = .005$). Laparotomy in the third trimester was associated with a 50% risk for preterm delivery.

Other Management Considerations

If there is a risk for disrupting a corpus luteum cyst at up to 12 weeks' gestation, progesterone supplementation is indicated. The effectiveness of tocolytics for suppression of preterm delivery associated with adnexal surgery is similar to that of tocolysis administered for preterm labor. Whitecar and coworkers⁶¹ reported that tocolytics were administered to 13 patients who had operations in the second and third trimesters; 6 of 13 had

preterm deliveries, although only two delivered within 2 weeks of laparotomy. Given the potential for preterm delivery unresponsive to tocolysis and the negligible risks of steroids, consideration may be given to a prophylactic course of steroids for fetal maturity enhancement if the surgery is performed between 24 and 34 weeks' gestation.

Congenital Uterine Anomalies

EPIDEMIOLOGY

The mean overall prevalence of uterine malformations in the general population of fertile women is 4.3%, which is similar to the mean incidence of müllerian defects in infertile patients (3.4%).⁷⁴ This is an indirect indication that most müllerian defects have no impact on women's fertility. Congenital uterine malformations complicate 1 in 594 pregnancies.⁷⁵

PATHOGENESIS

Uterine malformations consist of a group of congenital anomalies of the female genital system that result from disturbances in the development, formation, or fusion of the müllerian or paramesonephric ducts during fetal life. They are usually classified as six major anatomic types:

Type I: hypoplasia or agenesis (usually with infertility)

Type II: unicornuate uterus (i.e., normal differentiation of only one müllerian duct, often with a contralateral communicating or noncommunicating rudimentary horn)

Type III: didelphic uterus (i.e., complete failure of the müllerian ducts to fuse in the midline)

Type IV: bicornuate uterus (i.e., two normally differentiated ducts partially fused in the region of the fundus)

Type V: septate uterus (i.e., failure of resorption of medial segment of the müllerian ducts)

Type VI: arcuate uterus (i.e., minor change in the uterine cavity shape with no external dimpling)

Table 69-5 shows the prevalences of uterine anomalies. Uterine malformations result in an abnormal uterine cavity, which is thought to impair reproductive performance, increasing the incidence of early and late abortions, preterm deliveries, and obstetric complications. Other factors may be associated with the anatomic anomalies and may have the potential to affect pregnancy outcomes. For example, anomalies in uterine arterial circulation may result in uterine hypoperfusion, abnormalities in thickness of uterine walls may affect blastocyst implantation and result in poor decidualization and placenta-tion, and associated cervical structural or functional anomalies

may result in cervical incompetence. Such factors may explain why even a minor uterine anomaly, such as arcuate uterus, has been found by some investigators to result in an excess of spontaneous abortions, second-trimester losses, and preterm deliveries.^{74,76} One study⁷⁷ reported significantly higher blood pressure values and higher rates of fetal growth restriction among 16 primigravidas with congenital uterine malformations compared with controls matched for parity, age, and gestation, suggesting altered uteroplacental circulation in pregnancies with uterine anomalies.

DIAGNOSIS

Diagnosis of uterine anomalies is usually made after a workup for recurrent pregnancy losses.⁷⁸ The rates of uterine malformations in patients with recurrent pregnancy losses range from 1.8% to 37.6%,^{75,76} with a mean overall rate of 12.6%.⁷⁴ Less commonly, a diagnosis of uterine anomaly is made during the course of sonographic evaluation of an ongoing pregnancy, serendipitously during the course of imaging testing, or at laparoscopy or laparotomy.

Accurate identification of the type of uterine malformation is important because each type is associated with different rates of obstetric complications.^{74,76,79-81} Visualization of the uterine cavity and the fundal uterine contour is essential to differentiate between uterine anomalies (e.g., between septate and bicornuate uteri). Traditionally, diagnosis rested on hysteroscopy, hysterosalpingography, or sonohysterography for visualization of the uterine cavity, and on laparoscopy or laparotomy for intraabdominal views. Three-dimensional ultrasound and saline contrast sonohysterography appear promising for reliable diagnosis and classification of congenital uterine anomalies in a noninvasive way. Although MRI is often helpful, incorrect diagnoses have been reported with the use of MRI alone; for example, a unicornuate uterus that has an associated contralateral rudimentary horn is frequently mistaken for a bicornuate or didelphic uterus. When a recent study compared the accuracy of three-dimensional ultrasound with hysterosalpingography for diagnosing congenital uterine anomalies, 30 of 30 were correctly identified by three-dimensional sonography, but only 10 of 30 by hysterosalpingography.⁸² Because urinary tract anomalies occur in about 60% of congenital uterine anomalies, imaging of the urinary tract is indicated.

MANAGEMENT

Several series have documented an increased risk for obstetric complications and adverse obstetric outcome in the presence of uterine anomalies. The evidence in support of preventative measures is scant.

OUTCOME

Certain obstetric complications seem to be more common to, or even unique to, certain types of malformations (Table 69-6). Septate uterus has been associated with the poorest reproductive outcome, mainly because of an association with a high rate of spontaneous abortion.^{80,83-85} Uterus didelphys, bicornuate uterus, and septate uterus are associated with rates of preterm delivery that are two to three times higher than expected in the general pregnant population.^{74,76,81} A recent study using logistic regression analysis, and controlling for preeclampsia, race,

history of preterm delivery or stillbirth, and history of maternal medical conditions, found that the presence of any uterine anomaly is associated with a sevenfold risk for preterm delivery at less than 34 weeks (95% CI, 4.9 to 11.4) and a sixfold risk for preterm delivery at less than 37 weeks (95% CI, 4.3 to 8.1).⁸⁶ Other complications independently associated with congenital uterine anomalies include fetal growth restriction (OR = 2.0; 95% CI, 1.3 to 3.1) and placental abruption (OR = 3.1; 95% CI, 1.1 to 8.3).⁸⁶ Approaching delivery, women with uterine anomalies are at increased risk for fetal malpresentation: an adjusted OR of 8.6 (95% CI, 6.2 to 12) for breech presentation has been recently reported.⁸⁶

A large case-control study in which patients with congenital abnormalities were matched with unaffected controls has found that the presence of unicornuate or bicornuate uterus is associated with an increased risk for postural deformities in the offspring, in particular clubfoot (OR = 2.1; 95% CI, 1.1 to 3.8).⁸⁷

Uterine rupture is a rare but dramatic complication of major uterine anomalies.⁸⁸ In the presence of rudimentary horns, uterine rupture complicates about 50% of cases, in 80% of which it occurs before the third trimester of pregnancy.⁸⁹ A rare complication specific to uterus didelphys is hemiuterus torsion.⁹⁰

PREVENTION

Pre-conceptional interventions to improve pregnancy outcome include hysteroscopic metroplasty, mainly in cases of septate,

arcuate, and bicornuate uterus, which results in significantly lower abortion and preterm delivery rates,^{91–93} and removal of the rudimentary or minor horn in asymmetric uterine malformation to prevent uterine rupture.⁹⁰

During pregnancy, several interventions have been proposed, but their efficacy has not been adequately tested. The risk for uterine rupture should be considered in the presence of asymmetric uterine malformations or uterine anomalies of unclear types. Therefore, induction or augmentation of labor is contraindicated.⁸⁸ Monitoring of uterine wall thickness has been suggested to identify cases that may benefit from elective preterm delivery at documented fetal lung maturity.⁹³ One study evaluated cervical length in 64 women with uterine anomalies and found it predictive of spontaneous preterm birth at less than 35 weeks (positive likelihood ratio = 8.14; 95% CI, 3.12 to 21.25).⁹⁴ It is not known whether mid-trimester sonographic assessment of cervical length and cerclage placement or progesterone administration in the presence of a short cervix might improve outcome by reducing risk for preterm delivery. Identification of fetal growth restriction and of postural deformities can be achieved by serial sonographic assessments during pregnancy. Fetal presentation during labor should be verified with ultrasonography in doubtful cases.

Anesthesia Considerations for Complicated Pregnancies

JOY L. HAWKINS, MD

An estimated 1% to 3% (40,000 to 120,000) of pregnant women require critical care services in the United States each year.¹ Most are admitted because of hemorrhage, preeclampsia, or cardiac disease.^{1,2} When the diagnosis requires any of the following procedures, the patient should be admitted to an intensive care unit (ICU): respiratory support such as endotracheal intubation, treatment of pneumothorax, cardiovascular support with pressors or inotropic agents, placement and interpretation of pulmonary artery (PA) catheterization, and abnormal electrocardiographic findings requiring interpretation or cardioversion.¹ The management of high-risk pregnancies requires a team approach with communication between obstetricians, perinatologists, anesthesiologists, nursing personnel, and appropriate consultant physicians. Necessary medications and procedures should not be withheld from a pregnant woman because of fetal concerns.¹

This chapter focuses on the anesthesia considerations for the management of selected conditions complicating pregnancies during the intrapartum and immediate postpartum periods. More extensive discussions of each disease occur elsewhere in this textbook.

The physiologic changes of pregnancy affect disease processes and their treatments, often altering care that might have been given to a nonpregnant patient (Table 70-1). Drug effects and serum levels may be altered during pregnancy and normal values for laboratory testing may change over the three trimesters of pregnancy so that normal values for a nonpregnant patient may be significantly abnormal during pregnancy.³ Examples include serum creatinine, hematocrit, and arterial oxygen values. Care of these women always involves vaginal or cesarean delivery at some point in the course, and delivery may need to be performed emergently due to concerns about the mother or fetus. The well-being of both patients is always part of the risk-benefit analysis when developing a treatment plan. Because anesthesiologists receive training in the care of parturients in labor and delivery units and gain extensive critical care experience during their residency and fellowship training, they are uniquely able to collaborate on critically ill pregnant patients.

Maternal Morbidity and Mortality

The Centers for Disease Control and Prevention published their maternal mortality statistics with data from 1998 through 2005.⁴ Deaths from hemorrhage and hypertensive disorders declined, but the proportion arising from coexisting medical conditions, especially cardiovascular conditions, increased. For

deaths occurring after a live birth (compared with stillbirth, ectopic pregnancy, or abortion), the most common causes were hypertensive disorders (15%), cardiomyopathy (13.3%), cardiovascular conditions (12.5%), and noncardiovascular medical conditions (11.3%). Hemorrhage (9.7%), pulmonary embolism (9.7%), and infection (9.2%) completed the seven leading causes of death (Table 70-2).

The Centre for Maternal and Child Enquiries (CMACE) in Great Britain published its own audit of maternal mortality for 2006 through 2008.⁵ Sepsis was the leading direct cause of death in this period and cardiac disease the leading indirect cause. Their overall maternal mortality rate fell due to improvement in death rates for thrombosis, thromboembolism, and hemorrhage. The report emphasizes that management of systemic sepsis requires early recognition, immediate treatment, and multidisciplinary management that includes “anaesthetists and critical care specialists.”⁶ The indirect deaths were often complicated by failure to recognize how seriously ill the patient was, whether the diagnosis was sepsis, preeclampsia, or hemorrhage. Worldwide, the number of women who die during pregnancy or childbirth has dropped by 34% since 1990, but the leading global cause of death responsible for 35% of deaths is still hemorrhage.⁷

Mothers in the United States are becoming older and perhaps sicker. Rates of severe obstetric morbidity increased in a review of more than 32 million deliveries between 1998 and 2006.⁸ These authors found that rates of mechanical ventilation, adult respiratory distress syndrome, renal failure, shock, pulmonary embolism, and blood transfusion all increased over the time period studied, but cesarean delivery rates also increased from 21% to 30%. Much of the morbidity was related to performance of more cesarean deliveries. Near-miss morbidity, defined as end-organ injury associated with length of stay greater than the 99th percentile or discharge to a second medical facility, was reviewed from 2003 through 2006 in the Nationwide Inpatient Sample to determine what maternal characteristics predict which parturients are at risk.⁹ The highest rates of morbidity or death were found among women with pulmonary hypertension, malignancy, and lupus, but many other preexisting conditions and antenatal obstetric complications such as placenta accreta put women at risk. The investigators suggest that a multidisciplinary care conference for these patients before delivery may reduce bad outcomes. Several studies have shown that 35% to 40% of maternal deaths in developed countries are avoidable, and that is where attention and resources should be focused to provide a target for improvement.¹⁰

TABLE 70-1 Physiologic Changes of Pregnancy and Their Clinical Implications

Physiologic Variables	Change	Clinical Implications
CARDIOVASCULAR		
Blood volume	↑40%	Hypervolemic
Plasma volume	↑50%	Dilutional anemia
Heart rate	↑15 beats/min	Mild tachycardia
Cardiac output	↑40%	Increased cardiac work to handle increased volume
Systemic resistance	↓20%	Maintains normal blood pressure with increased cardiac output and volume
Aortocaval compression	Varies	Loss of cardiac preload when supine
RESPIRATORY		
Alveolar ventilation	↑70%	Elevated arterial PO ₂
Minute ventilation	↑50% (↑15% respiratory rate)	PCO ₂ reduced about 10 mm Hg, mild tachypnea
Functional residual capacity	↓20%	Rapid desaturation with apnea
Metabolic rate	↑20%	Rapid desaturation with apnea
Mucosal edema, friability	Varies	Difficult intubation increases 10-fold
HEMATOLOGIC		
Coagulation status	Thrombophilic	Risk of deep venous thrombosis and embolism
Hemoglobin, hematocrit	Anemic	Dilutional rather than iron or blood loss
GASTROINTESTINAL AND RENAL		
Lower esophageal sphincter tone	Reduced	Reflux symptoms, potential aspiration risk, but normal gastric emptying
Renal blood flow and glomerular filtration rate	↑60%	Serum creatinine decreased by 50%
Aldosterone levels	Increased	Sodium and water retention
Albumin levels	Decreased	Decreased oncotic pressure leads to increased risk of pulmonary edema with increased volume or endothelial leak
NEUROLOGIC		
Minimum alveolar concentration	↓30%-40%	Lower requirement for volatile anesthetics during general anesthesia
Local anesthetic requirement	↓30%	Use lower spinal and epidural doses

TABLE 70-2 Maternal Mortality in the United States after Live Birth by Cause of Death

Causes of Death after Live Birth*	Percent (%) of Total Deaths
Preeclampsia or eclampsia	15.0
Cardiomyopathy	13.3
Cardiovascular conditions	12.5
Noncardiovascular medical conditions	11.3
Hemorrhage	9.7
Thrombotic pulmonary embolism	9.7
Infection	9.2
Amniotic fluid embolism	9.0
Cerebrovascular accident	7.0
Anesthesia complications	1.2

Obstetric Patient Safety Programs and Cardiac Arrest

Studies from several institutions have shown that implementing comprehensive obstetric patient safety programs can lead to significant improvements in multiple metrics, including improved workforce perceptions of safety and an improved

patient safety climate, while also decreasing sentinel events and reducing compensation payments, a significant savings for the institution.^{11,12} These safety programs focus on crew resource management training and often involve multidisciplinary simulations of rare events. One such event is maternal cardiac arrest. A review of the Nationwide Inpatient Sample of the Healthcare Cost and Utilization Project data on the frequency and causes of maternal cardiac arrest found it complicated 1 of 12,300 admissions for delivery, a rate higher than previously reported.¹³ Approximately one half of cardiac arrests were associated with maternal hemorrhage, and only 55% of women who arrested survived to hospital discharge.

A randomized controlled trial compared perimortem cesarean delivery in the labor room with moving to the operating room during simulated maternal cardiac arrest.¹⁴ The authors found that labor room delivery was significantly faster: 4 minutes 25 seconds for labor room delivery versus 7 minutes 53 seconds to move to the operating room. Fifty-seven percent of labor room teams met the Advanced Cardiovascular Life Support (ACLS) guidelines of delivering within 5 minutes, compared with only 14% of the operating room teams.

In another study, an experienced simulation group reviewed videotaped simulations of maternal amniotic fluid embolus and resultant cardiac arrest.¹⁵ Despite the fact that all participants had current ACLS certification, multiple deficits were found in the provision of cardiopulmonary resuscitation (CPR) to parturients. For example, left uterine displacement occurred in only 44%, placing a firm back support before compressions in

BOX 70-1 RECOMMENDED MANAGEMENT OF CARDIAC ARREST IN THE PARTURIENT

- Maintain left uterine displacement in the supine position.
- Use cricoid pressure until the airway is secured by endotracheal intubation.
- Perform bag-mask ventilation only until intubation can be performed.
- Perform chest compressions midsternum.
- Do not modify the position of paddles during cardioversion for ventricular fibrillation.
- Perform cardioversion for ventricular fibrillation before the baby is delivered.
- Use full normal doses of medications according to Advanced Cardiac Life Support (ACLS) guidelines.
- There are no limitations on choice of medications used to increase blood pressure.
- For parturients at more than 20 weeks' gestation, deliver the baby by cesarean after 4 to 5 minutes of unsuccessful resuscitation for cardiac arrest.

22%, proper compressions in 56%, and proper ventilations in 50%. The neonatal team was not called until 1 minute 42 seconds had passed. The study recommended revisions to ACLS certification and training for obstetric staff.

A group in The Netherlands reported actual outcomes of maternal cardiac arrests before and after initiation of their Managing Obstetric Emergencies and Trauma (MOET) course.¹⁶ Perimortem cesarean delivery was performed more often after its introduction, but the outcome was still poor, with an 83% fatality rate for mothers and 58% for neonates. Frequent simulations of cardiac arrest events, involving all teams working on labor and delivery units, and education about adaptations of ACLS to the parturient, are keys to achieving better outcomes.

Two other surveys from the United States and Israel found providers on labor and delivery units had inadequate awareness of basic CPR concepts for the parturient (Box 70-1). Obstetricians, anesthesiologists, and emergency medicine physicians were given a 12-question survey about resuscitation of parturients.¹⁷ Anesthesiologists scored highest overall, but emergency medicine physicians scored highest in the ACLS category. Scores were similar for questions on left uterine displacement and the need for cesarean within 5 minutes of cardiac arrest, but 25% to 40% of those questions were answered incorrectly. Overall, 15% of participants received a passing score (i.e., 85% correct).

The second survey questioned obstetricians, midwives, and anesthesiologists about their management of a case vignette.¹⁸ Despite the existence of current guidelines from the International Liaison Committee on Resuscitation/American Heart Association that address each question, participants were divided in their answers to every choice of action. The investigators concluded that deficiencies should be addressed by regular training that teaches the guidelines as they relate to pregnancy and stated, "even if a pregnant woman were to suffer cardiac arrest in front of a trained clinician, this might not improve her likelihood of survival, despite the existence of guidelines specifically for resuscitation in this population."

Amniotic Fluid Embolism

Amniotic fluid embolism (AFE) is difficult to study because of the rare, sporadic, and unpredictable nature of its occurrence.

As a spectrum disorder, the manifestation can range from subclinical to fatal, making its incidence difficult to ascertain. It can be neither predicted nor prevented. Registries have been set up in the United States and United Kingdom. A prospective, population-based, cohort study in the United Kingdom identified 60 cases matched with a control group.¹⁹ They found an incidence of 2.0 per 100,000 deliveries, with an increased risk among older, ethnic-minority women (adjusted odds ratio [aOR] = 9.9), those with a multiple pregnancy (aOR = 10.9), and those undergoing an induction of labor (aOR = 3.9). Cesarean delivery was significantly associated with postnatal AFE (aOR = 8.84). All affected women had at least one diagnostic feature of AFE, including shortness of breath, hypotension, hemorrhage, coagulopathy, and premonitory symptoms (e.g., agitation). The case-fatality rate was 20% for affected mothers and 13.5% for their newborns.

Early recognition and aggressive resuscitation are critical to management.²⁰ Early intubation and ventilation with 100% oxygen and positive end-expiratory pressure are needed to correct cyanosis and hypoxia. Large-bore intravenous access and arterial line placement are needed to treat and monitor hemorrhage and coagulopathy. If AFE occurs before delivery, cesarean delivery should be performed to improve resuscitation of the mother and survival of the fetus. After intubation, transesophageal echocardiography (TEE) is helpful to evaluate and follow cardiac function and maternal volume status. Epinephrine and steroids may be used because of the similarity to anaphylaxis. Pressors such as phenylephrine and vasopressin and inotropes such as norepinephrine usually are needed to maintain a viable maternal hemodynamic status.²¹

Blood products, including packed red blood cells, fresh-frozen plasma (FFP), platelets, and cryoprecipitate, are needed to resuscitate the patient and treat coagulopathy. In addition to providing a concentrated form of fibrinogen, cryoprecipitate is thought to provide fibronectin, which aids the reticulo-endothelial system in the filtration of antigenic and particulate matter.²² This situation is similar to that of severely ill patients with trauma, burns, or sepsis, in which there may be impaired clearance of circulating microaggregates and immune complexes, leading to hemodynamic instability and coagulopathy.

In addition to supportive therapy, novel treatments that have shown benefit in case reports include exchange transfusion or plasma exchange, nitric oxide or inhaled prostacyclin, cardiopulmonary bypass or assist devices, and recombinant factor VIIa.^{20,21} The latter therapy is controversial, because a systematic review of case reports found that the use of recombinant factor VIIa during coagulopathy and hemorrhage associated with AFE led to worse outcomes due to major organ thrombosis and death.²³

Cardiac Disease in Pregnancy

Cardiac disease is a leading indirect cause of maternal death in the United States and United Kingdom.^{4,5} The many causes of cardiac disease in pregnancy include congenital lesions, stenotic valvular lesions, regurgitant valvular lesions, myocardial infarction, peripartum cardiomyopathy, and primary pulmonary hypertension. Cardiac conditions usually require consultation and collaboration with a cardiologist who is knowledgeable about the physiologic changes caused by pregnancy and the impact of vaginal versus cesarean delivery.

A review of chronic heart disease in the United States from 1995 through 2006 found that 1.4% of obstetric hospitalizations for delivery were complicated by chronic heart disease, with a decrease in the rate of nonrheumatic valve disease over time and an increase in the rate of postpartum hospitalizations for patients with chronic heart disease.²⁴ One institution's report of their maternal ICU admissions and near-miss maternal morbidities from 2005 through 2011 found the largest number of admissions were for known, severe cardiac disease with complications or for acute cardiac events during pregnancy.² The diagnoses included cardiomyopathy, pulmonary hypertension, congenital heart disease, valvular disease, and Marfan syndrome with dilated aortic root. Advances in neonatology and pediatric cardiology have allowed increasing numbers of women with congenital cardiac lesions to reach their childbearing years. The physiology after palliative or corrective procedures can be quite complex, and consultation with a cardiologist who has experience with adult congenital cardiac disease patients is strongly recommended.

Initial assessment of the patient with cardiac disease is based on her functional status, often using the New York Heart Association (NYHA) classification. NYHA classes I and II have minimal or no symptoms, except with greater than normal activity, and their management should be straightforward and have little change from usual care. In contrast, NYHA classes III (i.e., symptomatic with normal activity) or IV (i.e., symptoms at rest) are considered high risk and usually require antepartum optimization with the cardiologist, invasive monitoring during labor and delivery, and postpartum care in a cardiac ICU. Functional status may deteriorate during pregnancy, especially when blood volume increases and cardiac output is maximal at about 28 to 30 weeks' gestation and immediately after delivery. Increased thrombotic tendencies during pregnancy may also lead to cardiac complications and make anticoagulation difficult to maintain for patients with mechanical heart valves.

Discussion of individual lesions is beyond the scope of this chapter, but in general, stenotic valvular lesions and pulmonary hypertension do not respond well to the physiologic changes of pregnancy, which include increased intravascular volume, increased cardiac output, and increased heart rate (see Table 70-1). The highest-risk lesions are mitral and aortic stenosis, right-to-left intracardiac shunting, primary pulmonary hypertension or Eisenmenger syndrome,²⁵ Marfan syndrome, and peripartum myocardial infarction. These lesions require high-level involvement of a cardiologist familiar with her physiology and ongoing medical management. Decisions about timing and mode of delivery should be made in a setting that involves a multidisciplinary team of nurses, maternal-fetal medicine specialists or obstetricians, anesthesiologists, and cardiologists. There are risks and benefits to induction of labor and vaginal delivery and to scheduled elective cesarean delivery (Table 70-3). The precise anesthesia management depends on the mode of delivery (Fig. 70-1).

Infective endocarditis prophylaxis is no longer recommended for vaginal or cesarean delivery in the absence of infection, except possibly for the small subset of patients at highest risk for adverse cardiac outcomes, including patients with prosthetic cardiac valves, previous infective endocarditis, unrepaired cyanotic congenital heart disease (CHD), completely repaired CHD with prosthetic material during the first 6 months after repair, and repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or device. Obstetric

TABLE 70-3 Vaginal versus Cesarean Delivery for the Parturient with Cardiac Disease

Effects	Vaginal Delivery	Elective Cesarean Delivery
Advantages	Less blood loss Avoids surgical stress Hemodynamic stability Early ambulation	Able to time the delivery and have consultants available Avoids the need for emergency cesarean
Disadvantages	Labor can be prolonged, unpredictable	Major abdominal surgery Major anesthesia Increased risk of hemorrhage Increased risk of postoperative infection Increased risk of postoperative pulmonary complications

TABLE 70-4 Hemodynamic Effects of Medications Used in Labor and Delivery

Hemodynamic Effect	Medication
↑Heart rate	β-Agonist tocolytic agents (e.g., terbutaline) Meperidine (Demerol)
↓Heart rate	Opioids (e.g., fentanyl) Phenylephrine or other α-agonist pressor agents
↑Pulmonary resistance	Prostaglandin F _{2α} (e.g., Hemabate) Systemic narcotics if hypoventilation occurs and PCO ₂ increases Butorphanol (Stadol) Methylergonovine (Methergine)
↓Systemic resistance	Neuraxial anesthetics (e.g., spinal, epidural) Morphine Prostaglandin E ₂ β-Agonist tocolytic agents (e.g., terbutaline) Oxytocin as a bolus or in high concentrations Magnesium sulfate as a bolus Nifedipine

medications, including tocolytic drugs, uterotonic agents, and analgesics, have hemodynamic side effects that may be harmful in the setting of certain cardiac lesions (Table 70-4). For example, β-agonist tocolytic agents can lead to tachycardia. Hemabate (carboprost tromethamine), a synthetic prostaglandin analogue (prostaglandin F_{2α}), can increase pulmonary and systemic vascular resistance, as can methylergonovine (Methergine). Nifedipine, β-agonists, magnesium boluses, and oxytocin boluses can reduce systemic vascular resistance, as can spinal and epidural techniques. All parenteral narcotics used for analgesia lead to hypercarbia, which can increase pulmonary vascular resistance. Depending on the cardiac physiology, these side effects can be beneficial or detrimental.

Neuraxial analgesia and anesthesia are preferred unless the patient is extremely preload dependent or cannot tolerate a drop in systemic vascular resistance associated with local anesthetic sympathectomy. Lesions for which a high neuraxial block should be used cautiously, if at all, for cesarean delivery include severe pulmonary hypertension or Eisenmenger syndrome,

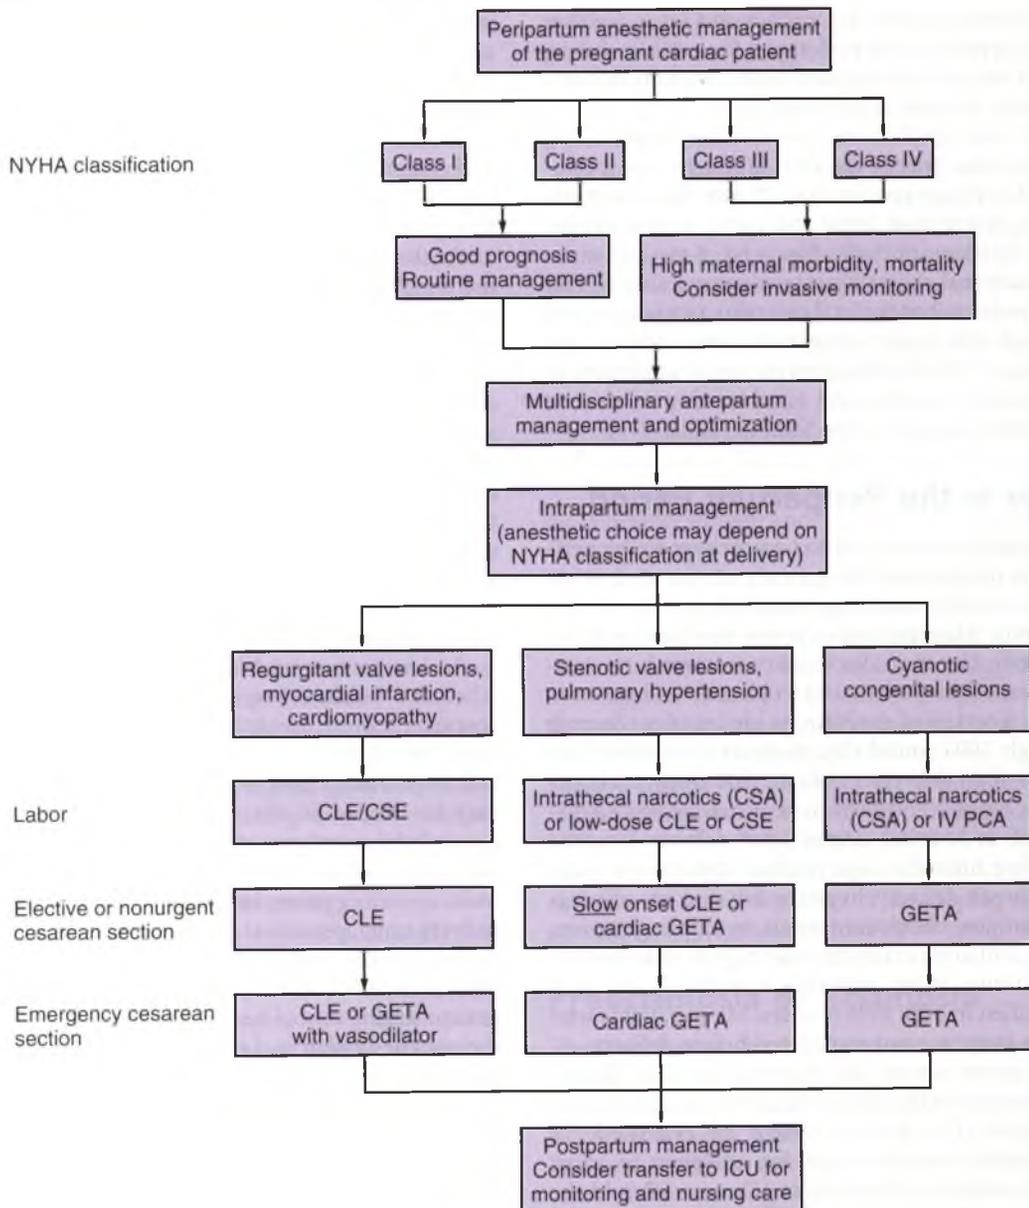

Figure 70-1 Peripartum anesthetic management of the pregnant cardiac patient. CLE, continuous lumbar epidural; CSA, continuous spinal anesthesia; CSE, combined spinal-epidural; GETA, general endotracheal anesthesia; ICU, intensive care unit; IV PCA, intravenous patient-controlled opioid analgesia; NYHA, New York Heart Association.

critical mitral or aortic stenosis,²⁶ and congenital lesions with a right-to-left cardiac shunt.²⁷ These patients may benefit from invasive monitoring, use of intrathecal (spinal) narcotics for labor analgesia, and a modified cardiac general anesthetic for cesarean delivery. Lesions that may benefit from the preload and afterload reduction associated with neuraxial blocks are regurgitant valvular lesions, cardiomyopathies,²⁸ and myocardial infarction.²⁹ The anesthesiologist must have a complete understanding of a parturient's underlying cardiac physiology and how it will be affected by additional fluids or hypovolemia, drops or elevation in preload and afterload, dysrhythmias during delivery, and changes in heart rate. Cardiac anatomy and physiology of parturients with palliated congenital lesions can be difficult to understand, and careful review of the woman's

predominant remaining physiology is critical to making an anesthesia plan for delivery.^{30,31} Often the delivery management plan must be based on information from small case series, because no institution will have a large number of patients with each type of cardiac lesion.

Occasionally, cardiac surgery may become necessary during pregnancy because medical management has failed. For example, mitral stenosis may lend itself to catheter balloon commissurotomy.³² A comprehensive, 20-year review of the literature with recommendations jointly written by perinatologists and cardiologists advises that the procedure be done in the cardiac catheterization laboratory during the second or third trimester with abdominal and pelvic shielding. TEE guidance may be helpful. The report describes good procedural outcomes

and low complication rates for the mother and fetus. Cardiac surgery requiring bypass can be performed successfully during pregnancy, sometimes in conjunction with cesarean delivery when the pregnancy is in the third trimester.

Reviews from two institutions recommend maintaining bypass pump flow rates greater than 2.5 L/min/m² and perfusion pressure on the pump greater than 70 mm Hg, maintaining a hematocrit greater than 28%, and using normothermic perfusion (when feasible), pulsatile flow, and α -stat pH management.³³ The maternal mortality rate is comparable to that for nonpregnant patients, but the fetal mortality rate is increased by urgent and high-risk surgery, maternal comorbidities, and early gestational age.³⁴ The investigators recommend surgery in the second trimester if possible and consideration of elective delivery before cardiac surgery if the fetus is viable.

Hemorrhage in the Peripartum Period

Although many conditions can lead to hemorrhage in the peripartum period, the most commonly seen are uterine atony after delivery and placental abnormalities, including previa, accreta, percreta, and increta. Management of severe postpartum hemorrhage requires effective multidisciplinary teamwork to coordinate resuscitation of the patient and to identify and treat the cause of bleeding. A review of the Nationwide Inpatient Sample from 1995 through 2004 found that postpartum hemorrhage complicated 2.9% of all deliveries with uterine atony, accounting for 79% of the cases.³⁵ Postpartum hemorrhage was associated with 19% of in-hospital deaths after delivery. Logistic regression modeling identified age younger than 20 or older than 40 years, cesarean delivery, hypertensive diseases of pregnancy, polyhydramnios, chorioamnionitis, multiple gestation, retained placenta, and antepartum hemorrhage as independent risk factors for uterine atony requiring transfusion, but risk factors were identified in only 39% of cases. Many patients who hemorrhage from atony are not recognized before delivery.

When uterine atony occurs, the obstetric provider should mobilize other members of the labor and delivery teams, including anesthesiologists. The patient should be evaluated for hemodynamic stability and the need for analgesia to allow cooperation with obstetric maneuvers. Oxygen should be applied and monitors placed for blood pressure and heart rate. If blood loss is ongoing, additional intravenous access should be obtained for volume replacement. If the patient does not have regional anesthesia in place and requires analgesia for

obstetric maneuvers, intravenous fentanyl or ketamine may be given. If the patient is still in a labor room delivery setting, consider moving to the operating room in case general anesthesia is needed or more aggressive obstetric management is indicated. The anesthesiologist should be aware of the dose, route, and major side effects of the oxytocic drugs that can be used (Table 70-5). Oxytocin, methylergonovine, Hemabate, and misoprostol (Cytotec) should be available in the room.

As the incidence of primary and repeat cesarean deliveries increases, so does the rate of placental abnormalities such as accreta, increta, and percreta. A woman with placenta previa and one or more previous cesarean deliveries should be evaluated for placenta accreta and delivered in a tertiary care medical center. Because of the need for many tertiary care services, maternal morbidity is reduced when delivery occurs in a hospital with blood bank capabilities, anesthesiology services available regardless of time or day, and ready access to surgical specialists.³⁶ Ultrasound diagnosis can be made in the antepartum period in most cases. When the diagnosis of placenta accreta is made before rather than at delivery, blood loss and the need for transfusion are lower, and there is a higher rate of administration of steroids for fetal lung maturity.³⁷

An antepartum multidisciplinary care conference should be scheduled before 34 weeks' gestation to plan for a scheduled cesarean delivery. Invited attendees should include representatives from anesthesiology, nursing, maternal-fetal medicine, and neonatology and representatives from other services that may be needed in the operating room, such as gynecology, gynecologic oncology, urology, general surgery, vascular surgery, and interventional radiology. The date, time, location (e.g., main operating room, interventional radiology suite, labor and delivery unit), personnel required, other patient-related medical issues, and the blood bank orders should be discussed. If possible, a member of the anesthesiology team should meet the patient during one of her antepartum obstetric visits to discuss the anesthesia plan and answer her questions about the perioperative management. Even if neuraxial anesthesia is planned for the case, she should be counseled about the need to convert to general anesthesia if major hemorrhage occurs. When placenta accreta is diagnosed, one approach to obstetric management is to leave the placenta in situ partially or totally. A review of 167 women treated conservatively had a 78% success rate of uterine preservation, and the remaining patients had an immediate or delayed hysterectomy.³⁸ Spontaneous placental resorption occurred in 75% of cases, with a median time of 13.5 weeks.

TABLE 70-5 Oxytocic Medications Used to Manage Uterine Atony

Medication	Dosage	Effects	Cautions
Oxytocin (Pitocin)	20-50 U/L as an IV infusion	Vasodilation, hypotension (mainly with boluses), hyponatremia	Avoid IV boluses in favor of infusions
Methylergonovine (Methergine)	0.2 mg IM	Diffuse vasoconstriction, HTN, increased PA pressures, coronary artery vasospasm, nausea	Possible vascular disease, severe hypertension or preeclampsia, pulmonary HTN, ischemic heart disease
Prostaglandin F _{2α} or carboprost (Hemabate)	0.25 mg or 250 μg IM	Bronchospasm, increased PA pressures, V/Q mismatch and hypoxia, nausea, diarrhea	Possible severe asthma, pulmonary HTN
Misoprostol (Cytotec)	200-800 μg rectal, vaginal, buccal	Minimal	None

HTN, hypertension; IM, intramuscular; IV, intravenous; PA, pulmonary artery; V/Q, ventilation/perfusion.

However, morbidity was common, and severe maternal morbidity occurred in 6% (10 cases) and included the death of one patient.

Anesthesia management of placenta previa or accreta or percreta involves preparation for major blood loss associated with potential cesarean hysterectomy.³⁹ Large-bore intravenous access and a pressure and warming system for giving intravenous fluids and blood are essential, as is rapid availability of cross-matched blood. Emergency (unplanned) hysterectomy involves more blood loss than elective (planned) surgery, but there is no evidence that regional anesthesia should be avoided. A review of 350 consecutive cases of placenta previa found regional anesthesia was associated with reduced blood loss and reduced need for transfusion compared with general anesthesia.⁴⁰ Conversion from regional to general anesthesia was required only for inadequate duration of two spinal anesthetics during hysterectomy for placenta accreta. If regional anesthesia is planned, it should be an epidural or combined spinal-epidural technique to allow for adequate duration. If major hemorrhage occurs, conversion to general anesthesia should be done early, before airway swelling from massive fluid administration makes the airway difficult to manage. Vasoactive drugs should be immediately available along with a skilled assistant and ultrasound to help place invasive monitoring if needed.

Concern about development of AFE syndrome has previously limited the use of red blood cell salvage during cesarean delivery. However, a review of cell salvage in obstetrics found no serious maternal complication leading to poor outcome associated with its use.⁴¹ If banked blood cannot be cross-matched or the patient refuses transfusion for religious or other reasons, the use of cell salvage can be lifesaving.

Another therapeutic technique for real or potentially uncontrolled hemorrhage involves interventional radiology techniques, with catheters placed preoperatively or after life-threatening hemorrhage that is unresponsive to other treatments. Arterial embolization of the iliac or uterine vessels can be used to treat hemorrhage after vaginal or cesarean deliveries when other measures have not been successful. Fertility is preserved, and success rates are high in some series.⁴² Catheters can be placed prophylactically before cesarean delivery if placenta accreta or percreta are diagnosed in the antepartum period.

The use of preoperatively placed internal iliac balloon catheters to tamponade uterine blood flow has gained popularity. However, a case-control, retrospective review of cesarean hysterectomy with ($n = 19$) and without ($n = 50$) prophylactic placement of intravascular balloon catheters for placenta accreta did not show any improvement in outcomes.⁴³ Complications related to the catheters, primarily vascular injury and vascular compromise of the leg, can occur.⁴⁴

Case series have reported use of recombinant factor VIIa for postpartum hemorrhage. A European registry of recombinant activated factor VII use in postpartum hemorrhage found that 80% of women improved after a single dose, but 14% failed treatment.⁴⁵ Adverse events were rare, with four cases of thromboembolism, one myocardial infarction, and one rash. The Australian and New Zealand Haemostasis Registry published results from 110 cases treated for severe postpartum hemorrhage.⁴⁶ The median dose given was 92 $\mu\text{g}/\text{kg}$, with a positive response rate of 76% overall, including 64% of patients who responded to the first dose. There were two postpartum thromboembolic events. Factor VIIa is not a first-line treatment for hemorrhage. The keys to effective use of this expensive

medication are that surgical bleeding must be controlled; the patient must not be hypothermic, acidemic, or hypocalcemic; and coagulation factors must be replaced.⁴⁷ Many providers recommend starting with a lower dose of 40 $\mu\text{g}/\text{kg}$ and repeating if necessary.

A large series of 66 patients with placenta accreta found that 95% required red blood cell transfusion and 39% required massive transfusion, including 10% who required more than 20 units of packed red blood cells.⁴⁸ Every labor and delivery unit should have a recently updated massive transfusion protocol that gathers needed personnel, engages the laboratory and blood bank, and guides early use of component therapy (Fig. 70-2). Avoid massive crystalloid resuscitation to prevent increases in hydrostatic pressure and decreases in colloid oncotic pressure that can dislodge clots at the sites of endothelial injury and cause fluid leak from the intravascular compartment. Permissive hypotension to 80 to 100 mm Hg is preferable in these young, previously healthy women until surgical bleeding has been controlled. Obstetric hemorrhage seems to be associated with increased fibrinolytic activity that can be diagnosed by thromboelastography (TEG).⁴⁹ The thromboelastogram gives a global picture of real-time clotting activity and can guide component therapy. Evidence from the military experience suggests that earlier and more aggressive use of FFP improves outcomes, although these data come primarily from the trauma literature, and there are no randomized controlled trials for any patient population. Massive transfusion protocols are recommending early use of FFP and transfusion ratios of 1:1:1 for packed red blood cells, FFP, and platelets.⁵⁰ A low fibrinogen level appears to correlate with the volume of hemorrhage, can predict severe hemorrhage, and may be a useful marker of developing coagulopathy, supporting early transfusion with FFP or cryoprecipitate.⁵¹

Preeclampsia or Eclampsia

The risk factors for development of preeclampsia are well known, even though the cause is not. Severe hypertension is associated with stroke and intracranial bleeding that can result in maternal death. The 2006-2008 CMACE report from Great Britain found that intracerebral hemorrhage was the leading cause of death among women with preeclampsia and eclampsia, and care was assessed as substandard in 91% of cases.⁵ At least 32% of maternal deaths due to hypertensive disorders in the United States had a cerebrovascular or central nervous system cause of death.⁴

The goal of antihypertensive therapy is to prevent maternal morbidity from pulmonary edema or cerebral hemorrhage by decreasing systolic blood pressure to less than 160 mm Hg and diastolic pressure to less than 110 mm Hg. At the same time, treatment should not impair uteroplacental perfusion or cause fetal compromise. A review of stroke associated with severe preeclampsia suggests that systolic hypertension may be more important than diastolic for preventing stroke related to severe preeclampsia.⁵² They found that 93% of the strokes they reviewed were hemorrhagic, 54% of women died, and almost all who lived had severe, permanent disability. All had a systolic pressure greater than 155 mm Hg, and only 12% had a diastolic pressure greater than 110 mm Hg.

In 2011, the American College of Obstetricians and Gynecologists (ACOG) issued a committee opinion called "Emergent Therapy for Acute-Onset, Severe Hypertension with Preeclampsia or Eclampsia."⁵³ They define a hypertensive emergency as

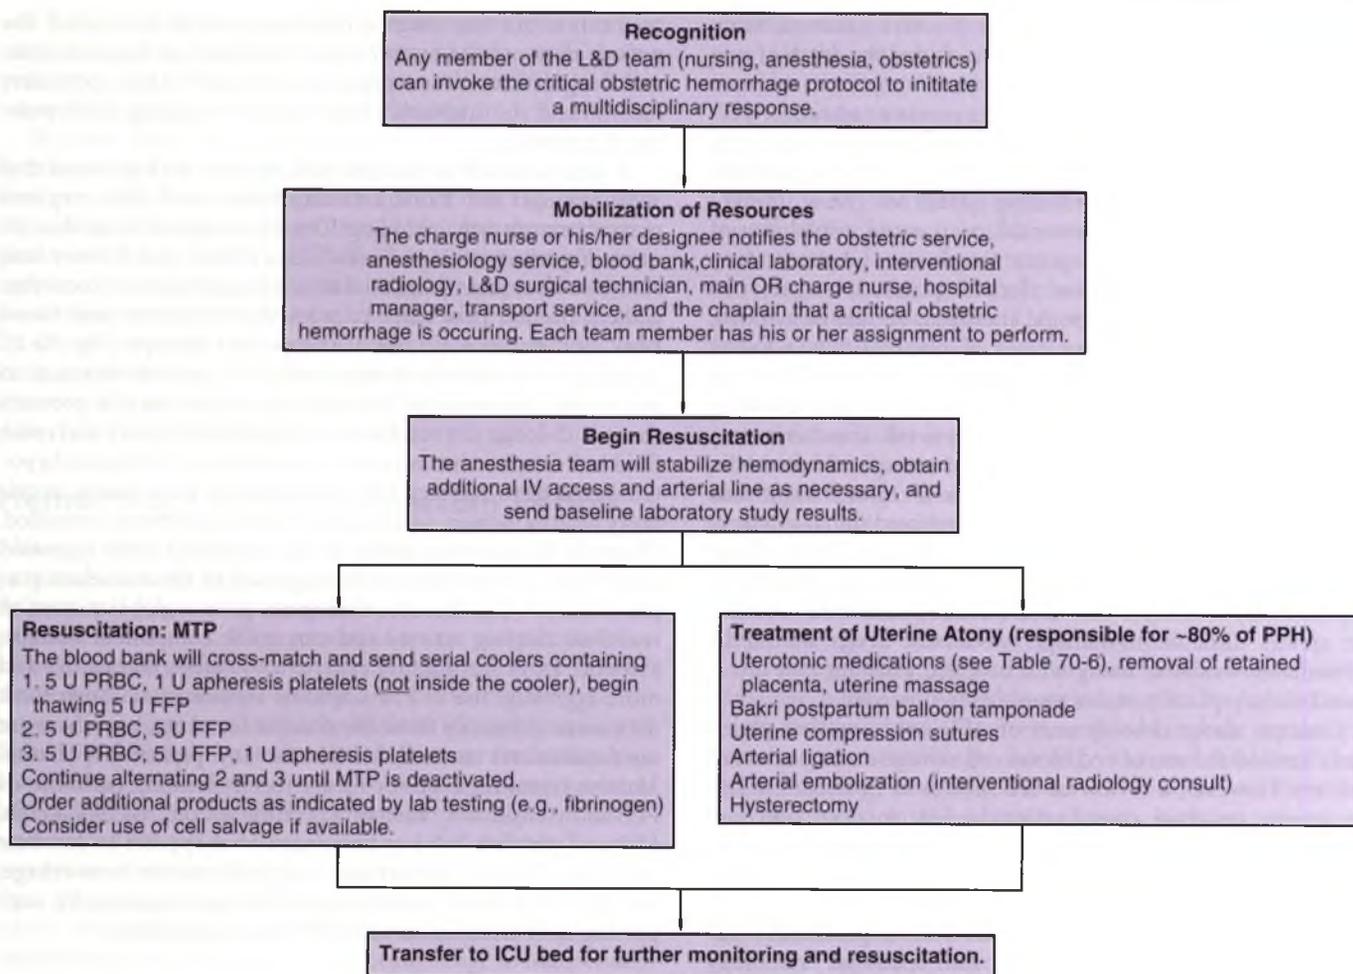

Figure 70-2 Example of a postpartum hemorrhage algorithm and massive transfusion protocol. FFP, fresh-frozen plasma; ICU, intensive care unit; IV, intravenous; L&D, labor and delivery; MTP, massive transfusion protocol; OR, operating room; PPH, postpartum hemorrhage; PRBC, packed red blood cells; U, units.

lasting 15 minutes or longer with a systolic pressure greater than 160 mm Hg or diastolic pressure greater than 110 mm Hg. Intravenous labetalol or hydralazine are considered first-line treatments, and the document includes order sets for both. If these two medications fail to control her blood pressure, ACOG recommends “emergent consultation with an anesthesiologist, maternal-fetal medicine subspecialist, or critical-care specialist to discuss second-line intervention.” Recommendations may include additional intravenous antihypertensive medications and placement of an arterial line to more accurately track blood pressure changes.

Use of invasive monitoring is rarely necessary in obstetric patients. They are usually young, previously healthy women with few or no comorbidities. However, arterial lines are low risk and can be useful in patients whose blood pressures are consistently above 160/110 mm Hg and when vasodilator infusions are deemed necessary. They may also be helpful for patients with coagulopathy who need frequent blood draws, and when the patient is obese or has marked edema that makes venipuncture difficult. If pulmonary edema develops, the arterial line can be used to monitor arterial blood gases. In contrast, central venous monitoring entails higher risk and has not been shown to affect outcome. A central venous pressure (CVP) or

PA catheter may be useful if there is cardiac failure or pulmonary edema, a large alveolar-arterial oxygen gradient, or oliguria despite fluid administration and afterload reduction. Consider the nursing resources available before initiating invasive monitoring. Can the nursing staff manage a CVP or PA catheter in the labor and delivery unit, or is ICU admission necessary?

Several agents are effective and safe to use as antihypertensives in preeclampsia in an acute setting (Table 70-6). Magnesium sulfate has no substantial long-term effect on blood pressure, but has other benefits. In addition to preventing eclamptic seizures, it attenuates the vascular response to pressor substances (endogenous or exogenous) and dilates vascular beds, in part by increasing prostacyclin release from endothelial cells, decreasing plasma renin activity, and decreasing angiotensin-converting enzyme levels. Hydralazine (5 to 20 mg) is recommended by ACOG because it is an arteriolar vasodilator that increases uterine and renal blood flow. However, it has an unpredictable onset and duration, causes reflex tachycardia, and occasional ventricular arrhythmias when given without β -blockade to control heart rate. Labetalol decreases systemic vascular resistance without maternal tachycardia and preserves placental blood flow. It does not cause sympathetic blockade in the neonate. It can be transitioned to an oral form after delivery.

TABLE 70-6 Intravenous Antihypertensive Medications for Acute Treatment of Severe Hypertension in Pregnancy

Medication	Benefits	Potential Risks
Hydralazine	Arteriolar vasodilator Increases uterine and renal blood flow Endorsed by ACOG ⁵²	Unpredictable onset, effect, and duration Reflex tachycardia, ventricular arrhythmias Theoretical neonatal hypotension
Labetalol	Decreases heart rate, systemic vascular resistance Preserves placental flow Preserves maternal cardiac output No significant sympathetic blockade in the neonate Endorsed by ACOG ⁵²	Variable dosing requirements Variable duration
Nitroprusside	Fast onset Short duration Preserves uterine blood flow if no hypotension	Reflex tachycardia Cerebral vasodilator Potential hypoxia from decreased hypoxic pulmonary vasoconstriction Inconvenient to use (e.g., arterial line, pharmacy preparation) Cyanide toxicity in high or prolonged doses Headache (a concerning symptom) Uterine relaxation leads to slow induction and postpartum atony Possible adverse interaction with magnesium sulfate ⁵³
Calcium channel blockers	Increased renal perfusion and urine output Rapid, smooth fall in blood pressure	

ACOG, American College of Obstetricians and Gynecologists.

However, its dosing and duration may be quite variable. Nitroprusside has a fast onset and short duration, and it preserves uterine blood flow. However, there is reflex tachycardia and the potential for cyanide toxicity. It causes cerebral vasodilation and potential hypoxia from decreased hypoxic pulmonary vasoconstriction. It is inconvenient to use and requires an arterial line, as does nitroglycerin, another effective vasodilator. Nitroglycerin also has uterine relaxant properties. It can be given as intravenous boluses or as an infusion.

Calcium channel blockers such as nifedipine and nimodipine cause a rapid, smooth fall in blood pressure while increasing renal perfusion and urine output. Although there has been concern about combining magnesium and nifedipine therapies, a study found that in women receiving magnesium sulfate therapy, there was no increase in muscle weakness due to magnesium alone, and there was less hypotension with nifedipine than with other antihypertensives.⁵⁴ Nimodipine reverses cerebral vasospasm measured by transcranial Doppler and is well tolerated by mother and fetus. However, calcium channel blockers cause uterine relaxation, making induction of labor more difficult and potentially causing atony after delivery.

A model attempting to predict which patients with pre-eclampsia will progress to life-threatening complications within 48 hours found the strongest predictors were early gestational age, chest pain or dyspnea, low oxygen saturation, low platelet count, and elevated levels of creatinine or liver transaminases.⁵⁵ Multiorgan system involvement occurs in women with pre-eclampsia, and laboratory evaluations and a thorough physical examination must be done to accurately define the extent of disease.

Eclampsia is rare and life-threatening for the mother and fetus. A Canadian review found eclampsia was associated with increased risk of maternal death (OR = 26.8), assisted ventilation, respiratory distress syndrome, acute renal failure, obstetric embolism, neonatal death (OR = 2.9), newborn respiratory distress syndrome, and small-for-gestational-age neonates.⁵⁶ A population-based study of risk factors for eclampsia found that being nulliparous, young (<20 years), or older (>35 years) increased the risk.⁵⁷ Other risk factors included longer birth

interval, low socioeconomic status, gestational diabetes, pre-pregnancy obesity, and too much or too little weight gain during pregnancy. Prodromal symptoms usually occur before the seizure. A prospective, observational study of women in Africa admitted with eclampsia characterized their prodromal symptoms as headache in 80% and visual disturbances in 45%.⁵⁸ Only 20% had no warning symptoms before their seizure. Eclamptic seizures occur after delivery in about 30% of patients. A retrospective cohort study of patients who experienced postpartum eclampsia found that 90% presented within 7 days after delivery, 69% had headache, and compared with the control group, they were younger and had lower readmission hemoglobin levels.⁵⁹

When an eclamptic seizure occurs, the following steps should be taken:

- Administer high-flow supplemental oxygen by mask, and place a pulse oximeter.
- Turn her full left or right lateral decubitus, and have suction immediately available.
- Give a small dose of propofol or midazolam to terminate the seizure. Avoid polypharmacy and long-lasting medications so that a neurologic examination can be done as soon as possible.
- Administer an additional 2-g magnesium sulfate bolus to ensure a therapeutic magnesium level and prevention of further seizures.
- Monitor the fetus if possible, but recognize that heart rate abnormalities are common during a seizure and usually resolve soon after the seizure is terminated. Do not intervene to deliver immediately unless abruption or cord prolapse has occurred.
- Consider computed tomography (CT) or magnetic resonance imaging (MRI) to rule out a cerebral hemorrhage if seizures are recurrent or focal, if seizures occur despite therapeutic and repeated magnesium dosing, or if there is a decreasing level of consciousness when not in a postictal state.
- Although eclampsia is an indication for delivery, it is not an indication for cesarean delivery. Consider whether induction is feasible or labor is already progressing.

When the decision has been made to proceed to delivery, the anesthesiologist must have plans for three potential scenarios in mind: labor followed by a spontaneous or instrumented vaginal delivery, trial of labor followed by an urgent or emergent cesarean for fetal or maternal reasons, and planned cesarean for the patient who is not a candidate for labor. All plans must take into account whether the use of neuraxial analgesia is appropriate based on platelet count or other measures of coagulopathy.

The advantages of neuraxial analgesia for labor are numerous. It provides the best quality of pain relief, attenuates hypertensive responses to pain, reduces circulating catecholamines, and does not require fluid preload when dilute local anesthetic or opioid solutions are used. Two studies have compared the use of intravenous patient-controlled opioid analgesia (IV PCA) with epidural analgesia for women with severe preeclampsia. In the first, 738 women were randomized to IV PCA or epidural, and cesarean delivery rates were similar.⁶⁰ Neonates in the IV PCA group required more naloxone (12% versus 1%), but women in the epidural group had a longer second stage of labor, had more forceps deliveries, and required ephedrine more often (11% versus 0%). Not surprisingly, epidural pain relief was superior. Results were similar in the second study.⁶¹ There was no difference in cesarean delivery rates, neonates were more likely to receive naloxone in the opioid group (54% versus 9%), and epidural patients had significantly better pain relief but required more ephedrine (9% versus 0%). Perhaps most importantly, there were no differences in preeclampsia-related complications. The ACOG practice bulletin called "Diagnosis and Management of Preeclampsia and Eclampsia" states, "With improved techniques over the past 2 decades, regional anesthesia has become the preferred technique for women with severe preeclampsia and eclampsia—both for labor and delivery. A secondary analysis of women with severe preeclampsia in the National Institute of Child Health and Human Development (NICHD) trial of low-dose aspirin reported that epidural anesthesia was not associated with an increased rate of cesarean delivery, pulmonary edema or renal failure."⁶²

Fluid management has been a controversial topic. The maternal vasculature in preeclampsia or eclampsia has been described as contracted and porous due to endothelial damage but not underfilled. In addition to endothelial damage, the colloid osmotic pressure is low in pregnancy and even lower in preeclamptic patients with proteinuria. Crystalloids and colloids readily leak out, increasing the risk of postpartum pulmonary edema. Obstetric management limits fluids to 80 to 100 mL/hr of total fluid intake, including magnesium and oxytocin infusions. Anesthesia management should also limit fluids using conservative preload for surgical regional anesthesia and no preload for labor analgesia. Several studies and a systematic review have shown little or no benefit for crystalloid or colloid preloading in preventing hypotension during obstetric regional anesthesia.⁶³

Despite years of concern and study, there is no test of platelet function and no specific platelet count that predicts bleeding into the neuraxis after regional anesthesia techniques. For patients with preeclampsia, many anesthesiologists are comfortable placing neuraxial blocks with platelet counts as low as 75,000/mm³, provided the count is stable and not falling and that there are no signs of clinical bleeding at venipuncture sites, gums, or other locations. Thromboelastography can add information if the test is available, but there is still no cutoff value of any variable that predicts complications.

Because pregnancy is a prothrombotic state, parturients have significant hemostatic reserves before becoming coagulopathic. A review of 1.7 million spinal or epidural blocks found that complications were more common after administration of epidural than spinal anesthetics and that obstetric patients were less likely than surgical patients to have an injury (1 of 25,000 obstetric patients versus 1 of 3600 women after surgical epidurals).⁶⁴ Two obstetric patients in their series developed a neuraxial hematoma, for an incidence of 1 case per 200,000. One occurred after a spinal and the other after epidural catheter removal, and both patients had HELLP syndrome (*hemolysis, elevated liver enzymes, and low platelets*). Such a low incidence is reassuring, but it remains important to balance the risk-benefit ratio for each patient.

Factors supporting regional anesthesia, even with borderline coagulation studies, include a worrisome airway examination, the prospect of a lengthy induction of labor, and the rarity of an epidural hematoma. Factors that support use of intravenous opioids for labor or general anesthesia for cesarean delivery are clinical signs of bleeding, a rapidly worsening platelet count, the need for an urgent cesarean, and a reassuring airway examination. If a neuraxial anesthetic is not appropriate, an intravenous opioid regimen can be used for the patient's labor analgesia. For example, fentanyl can be used in an IV PCA. An intravenous bolus loading dose of 2 to 3 µg/kg is administered to make the patient comfortable. The PCA pump is set with a 50-µg incremental bolus, 10-minute lockout interval, and no basal rate. As labor progresses and titration is needed, the lockout is decreased from 10 to 5 minutes, and the bolus dose is then increased from 50 to 75 µg.⁶⁵

The choices for cesarean birth for patients with preeclampsia or eclampsia are epidural, spinal (or combined spinal-epidural), and general anesthesia. In the past, spinal anesthesia was avoided because of concerns that hypotension would be more severe and less treatable than that seen after sympathectomy from an epidural anesthetic. However, a comparison of women with severe preeclampsia to healthy women (all having a cesarean delivery with spinal anesthesia) found that preeclamptic women had less hypotension (17% versus 53%), despite receiving less fluid preload and (by chance) a larger dose of bupivacaine in their spinal.⁶⁶ A randomized comparison of spinal with epidural anesthesia for cesarean delivery in women with severe preeclampsia found that although hypotension was more frequent after spinal anesthesia and required slightly more ephedrine, the duration of hypotension was short, and neonatal outcomes were similar in both groups.⁶⁷ Regardless of the choice of neuraxial (spinal or epidural) anesthesia, pressors must be immediately available to treat even mild hypotension, because the fetus may not tolerate any decrease in uteroplacental perfusion. Clinical studies in humans have consistently shown that use of α -agonists such as phenylephrine produce better umbilical pH values in the newborn than use of ephedrine.⁶⁸ If maternal heart rate is above 70 beats/min, phenylephrine should be the first-line choice of pressor agents.

If general anesthesia is chosen, the areas of concern are attenuating hypertensive responses during laryngoscopy and intubation, managing a difficult edematous airway, and treating complications related to magnesium therapy such as uterine atony and maternal weakness. A number of adjuncts to rapid-sequence induction have been described and used successfully to control hypertension associated with laryngoscopy (e.g., esmolol, labetalol, lidocaine, remifentanyl, nitroglycerin). At

least one should be included as part of a rapid-sequence induction, and they should be immediately available to treat hypertension if it occurs. Airway management may be difficult. Use of the laryngeal mask airway (LMA) has been described in the setting of HELLP syndrome when there was an inability to intubate or ventilate.⁶⁹ After her cesarean delivery, this patient was ventilated for 8 hours in the ICU using the LMA.

Magnesium therapy has anesthetic interactions. Magnesium sulfate is a uterine relaxant, and additional oxytocics such as Cytotec or Hemabate should be available to treat uterine atony after delivery in addition to the oxytocin infusion. If the mother has a high level of magnesium and exhibits muscle weakness before induction (i.e., not able to lift her head for 5 seconds before anesthetic administration), it may be best to discontinue the magnesium sulfate infusion during the case and let her magnesium level decrease. Nondepolarizing muscle relaxants such as vecuronium or rocuronium should be avoided due to difficulty with reversal and residual weakness in the presence of magnesium. If the patient cannot meet the criteria for safe extubation at the end of the cesarean, she may require a brief period of mechanical ventilation until she is strong enough to protect her airway.

Postpartum issues require intense monitoring in the labor and delivery unit. The mother may need acute and long-term blood pressure control with antihypertensives. Fluid mobilization begins to occur during the first 24 hours after delivery, and this is when she is at greatest risk for pulmonary edema. Monitor urine output, lung fields, and pulse oximetry. Thrombocytopenia may not resolve for several days. If she has an epidural catheter in place, decide when removal is appropriate based on her platelet count and coagulation studies. About one third of eclamptic seizures occur in the postpartum period. A review of 89 cases of eclampsia found that 33% of seizures occurred after delivery and that 79% of those manifested more than 48 hours after the birth.⁷⁰ Most women did not have an antepartum diagnosis of preeclampsia, but most did have prodromal symptoms such as headache and visual changes. If asked to evaluate a postpartum headache, be vigilant and consider late-presenting preeclampsia in the differential diagnosis.

Respiratory Diseases

Asthma and pulmonary thromboembolism are two causes of respiratory insufficiency during pregnancy and the postpartum period. Pregnancy is associated with a fourfold increase in the risk of thromboembolism and is a major contributor to maternal mortality. The British 2006-2008 CMACE report found that the death rate from thromboembolism fell to its lowest rate since 1985.⁵ It attributed the improvement to the guidelines on thromboprophylaxis from the Royal College of Obstetricians and Gynaecologists (RCOG).⁷¹ Obesity was the greatest risk factor for deaths due to thromboembolism.

Deaths in the United States due to thrombotic pulmonary embolism have also declined, accounting for 9.7% of maternal deaths after a live birth in 2010.⁴ ACOG published two practice bulletins on the management of thrombophilias in pregnancy and thromboembolism in pregnancy.^{72,73} ACOG recommends compression stockings be placed before cesarean delivery or other operations and that they remain in place until the patient is ambulatory. Signs or symptoms of a new-onset venous thrombosis in the lower extremities require compression ultrasonography as the recommended diagnostic test. Iliac vein

thrombosis may require MRI for confirmation. Diagnosis of suspected pulmonary embolism can be confirmed or ruled out by ventilation-perfusion scanning or CT pulmonary angiography. One study found that pregnant women with a normal chest radiograph were more likely to have a diagnostic study from a ventilation-perfusion scan, whereas for those with an abnormal screening chest radiograph, CT pulmonary angiography was a better initial test⁷⁴ (see Chapter 54).

High-risk patients with a history of venous thromboembolism, known thrombophilia, or obesity may require pharmacologic prophylaxis with low-molecular-weight heparins (LMWH) such as enoxaparin or dalteparin. Therapeutic anticoagulation is recommended for women with a thrombotic event during the current pregnancy or a highly thrombogenic thrombophilia. A major consideration for patients receiving heparins is timing for placement of neuraxial blocks and removal of epidural catheters. The American Society of Regional Anesthesia (ASRA) has published guidelines that outline the management of regional anesthesia in patients receiving anticoagulant therapy.⁷⁵ If a patient is receiving prophylactic doses of LMWH, the dose should be held for 12 hours before placement of a neuraxial block and should be resumed no sooner than 2 hours after epidural catheter removal. If a patient is receiving therapeutic doses, there must be a 24-hour window before placement and at least 12 hours after epidural catheter removal before resumption of LMWH. If these guidelines cannot be met or anticoagulation must be continued, the patient should receive parenteral medications for labor analgesia or general anesthesia for cesarean delivery.

Asthma is the most common respiratory disease seen in 4% to 8% of pregnant women.⁷⁶ During pregnancy, the goal is to maintain adequate oxygenation of the fetus by preventing hypoxic episodes in the mother. That goal requires optimizing her medications while monitoring lung function. Bedside spirometry can be used by the patient and her caregivers to monitor the forced expiratory volume in 1 second (FEV₁) and peak expiratory flow rate (PEFR). Medications to be avoided in asthmatics during labor and delivery are Hemabate, drugs with unopposed β_1 -antagonist activity, and nonsteroidal anti-inflammatory medications if she is aspirin sensitive. Arterial blood gases can be misinterpreted in the pregnant patient. Alveolar ventilation increases during pregnancy so that P_{O_2} is higher, whereas increases in minute ventilation decrease P_{O_2} by 8 to 10 mm Hg. A pregnant patient with an asthma exacerbation whose arterial blood gas determinations indicate normal (for nonpregnant women) P_{O_2} and P_{CO_2} levels is already hypoxic, hypercarbic, and decompensating (Table 70-7).

TABLE 70-7 Comparative Arterial Blood Gas Values That Indicate Respiratory System Changes during Pregnancy*

Parameter	Nonpregnant Women	Pregnant Women	Morbidly Obese and Pregnant Women
pH	7.40	7.44	7.44
P_{O_2}	95	104	85
P_{CO_2}	40	32	30
Base excess	+1	-3	-4

*See Table 70-1.

During labor, the patient should continue her usual asthma medications and have an albuterol inhaler available for exacerbations. Analgesia with neuraxial blocks reduces oxygen consumption and minute ventilation during labor without sedation or decreased respiratory drive. For cesarean delivery, regional anesthesia is preferred to avoid instrumentation of her reactive airway. Laryngoscopy and intubation can initiate bronchospasm. If general anesthesia is required, induction with ketamine provides bronchodilatation through its sympathomimetic properties, and propofol can suppress airway reflexes better than other induction agents. The volatile anesthetics are excellent bronchodilators, but they can be used only in small doses during cesarean delivery because subsequent uterine atony may occur. When spinal or epidural anesthesia is used for cesarean delivery, the high level of sympathetic blockade can theoretically induce bronchospasm, but that does not seem to occur.

Respiratory failure from pulmonary embolism, asthma exacerbation, or other causes may require endotracheal intubation as part of management. The failed intubation rate (1 failed intubation in 275 attempted intubations) for obstetric patients is thought to be about 10 times higher than the rate for general operating room patients.⁷⁷ Large breasts, mucosal edema, left lateral positioning for uterine displacement, and emergency settings all conspire to increase the difficulty of obstetric intubations. Physiologically, the pregnant patient has reduced functional residual capacity and increased oxygen consumption, which shortens the interval from apnea to desaturation and hypoxia. Data from the American Society of Anesthesiologists (ASA) Closed Claims Project show that failure to adequately manage the airway continues to be among the leading causes of adverse outcomes in obstetric anesthesia liability claims.⁷⁸ Failed intubation, failed ventilation, and aspiration led to claims for maternal death or permanent brain damage and to neonatal death or brain injury. Although not studied, urgent intubations for respiratory failure in an obstetric patient outside the operating room setting presumably have the potential to be even more difficult.

The key to successfully approaching intubation in the pregnant patient is preparation of drugs and equipment and having an algorithm for the next steps if the initial attempt is unsuccessful (Fig. 70-3).⁷⁹ If the patient's airway appears adequate on examination, the anesthesiologist should proceed with induction of anesthesia before intubation. If the procedure is taking place outside the operating room, it follows gathering airway equipment, proper positioning, assuring adequate suction, and pre-oxygenation of the patient. The most experienced anesthesia provider should make the first attempt or be ready to immediately take over if the first attempt is unsuccessful. In most cases, a short-acting induction agent is used for hypnosis: propofol or ketamine if bronchospasm is present or etomidate or ketamine if hemodynamic instability is a concern. Succinylcholine provides rapid-onset muscle relaxation to facilitate laryngoscopy.

If the intubation is successful, endotracheal tube placement must be verified by an end-tidal CO₂ color-change device and auscultation of her lungs. If the attempt is unsuccessful, mask ventilation should be performed while changes are made to the patient's position, to the laryngoscope employed (with consideration given to using a video-laryngoscope), and to having a more experienced provider make the next attempt. If mask ventilation is difficult or impossible, a supraglottic device such

as an LMA should be placed. Patients die from failure to ventilate, not failure to intubate. After ventilation is established and oxygenation has recovered, intubation may be attempted through the LMA using a flexible fiberoptic bronchoscope. If intubation and ventilation fail, a surgical airway must be secured.⁸⁰

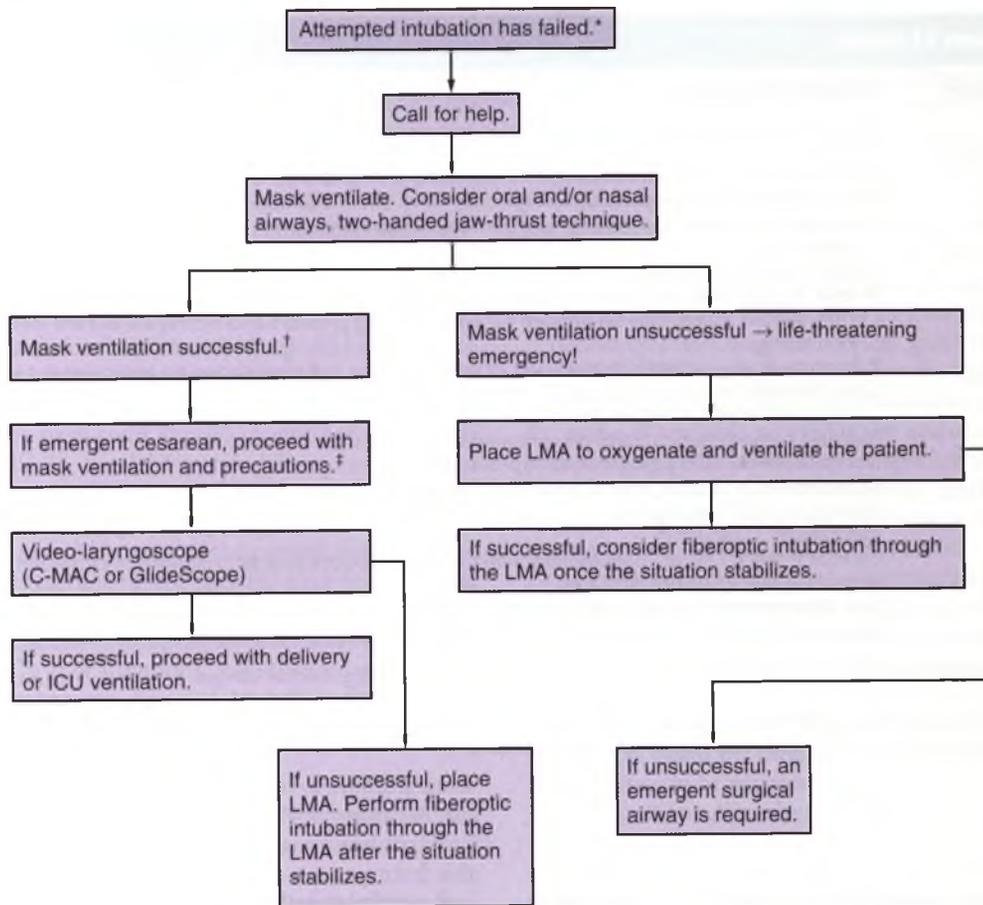

Sepsis

Sepsis associated with pregnancy is most commonly caused by urinary tract infections or pyelonephritis, chorioamnionitis or endomyometritis, septic abortion, necrotizing fasciitis, or septic pelvic thrombophlebitis. In the CMACE report, sepsis was the leading direct cause of maternal death, with invasive group A streptococcal infections responsible for 50% of the deaths.⁵ The worrying aspect of their report was that women deteriorated and died very rapidly, and their recommendations are for early, protocol-driven care that begins before admission to the ICU. The key to successful treatment of sepsis is early initiation of antibiotics and control of the source of infection.⁸¹ Common bacteria cultured in septic pregnant patients are gram-negative rods such as *Escherichia coli*, but bacteremia does not necessarily indicate sepsis. Consultation with infectious disease specialists may be appropriate if the source of infection is unclear or if there is no response to initial antibiotic choices. Imaging modalities such as ultrasound and MRI should be used to localize a pelvic or intraabdominal source of infection.

Sepsis is an infection with a systemic inflammatory response defined as temperature greater than 38°C or less than 36°C, heart rate greater than 90 beats/min, tachypnea greater than 20 breaths/min, and a white blood cell count more than 12,000 cells/mm³ or less than 4000 cells/mm³. However, the physiologic changes of pregnancy and the stress of labor can also cause tachycardia, tachypnea, and an elevated white blood cell count. The systemic inflammatory response in pregnancy results in higher morbidity and mortality rates for conditions such as acute pyelonephritis, varicella infection, and influenza.⁸² In animal studies, it appears that the immune response is functionally different in the pregnant and nonpregnant states.

The use of steroids in sepsis is controversial.⁸³ The 2008 clinical practice guidelines from the Surviving Sepsis Campaign suggest that steroids can be used in a limited set of patients and initiated only after it has been demonstrated that these patients are not responding to conventional measures.⁸⁴ A meta-analysis of 20 trials comparing corticosteroids with placebo or supportive treatment found that studies since 1998 using prolonged low-dose corticosteroid therapy showed a beneficial drug effect on short-term mortality.⁸⁵ If the use of steroids seems appropriate, there is no contraindication for the pregnant woman or her fetus.

Renal insufficiency in pregnancy is often associated with systemic lupus, diabetes, preeclampsia, or sepsis. Because creatinine levels in pregnancy are roughly one half that of a nonpregnant patient, mild renal insufficiency is diagnosed at a creatinine level of 0.9 to 1.4 mg/dL and severe renal insufficiency with a level greater than 3.0 mg/dL.⁸⁶ After renal insufficiency is diagnosed, it is important to avoid nephrotoxins such as gentamicin and nonsteroidal anti-inflammatory drugs. Drug dosing may need to be altered if the primary route of drug excretion is glomerular filtration (e.g., magnesium sulfate). Fluid status should be optimized to maintain renal perfusion, and central monitoring may be necessary to assess filling pressure if urine output is low. Dialysis can be used safely in

* Initial attempts to achieve visualization of the larynx should include manipulating cricoid pressure or releasing it, changing her head position, using different types of laryngoscopes, passing a smaller endotracheal tube, and attempting bougie or Eschmann catheter placement.

† If this is an elective or non-emergent cesarean, consider letting the patient awaken, then proceed with neuraxial anesthesia or awake intubation techniques.

‡ Precautions to consider when proceeding with cesarean delivery under mask general anesthesia include maintaining cricoid pressure (unless an LMA is placed), elevating the head of the bed, administering a drying agent (e.g., glycopyrrolate) to reduce airway secretions, administering metoclopramide to increase esophagogastric barrier pressure, communicating to the surgeons that the cesarean must be completed quickly with the most senior obstetrician operating.

Figure 70-3 Algorithm for the management of difficult intubation in the obstetric patient. This approach is applicable when intubation is required for respiratory failure or cesarean delivery. ICU, intensive care unit; LMA, laryngeal mask airway.

pregnancy if the patient develops hyperkalemia, volume overload unresponsive to diuretics, or metabolic acidosis.

The initial resuscitation of the patient with sepsis should include the following: large-bore intravenous access, blood drawn for cultures, intravenous antibiotics given within 1 hour of diagnosis, fluid resuscitation, and consultation from the critical care service, including perinatologists, anesthesiologists, and intensivists.⁸⁷ Early, goal-directed therapy for hemodynamics in nonpregnant patients includes maintenance of the CVP at 8 to 12 mm Hg, urine output more than 0.5 mL/kg/hr, oxygen saturation greater than 93%, and central mixed venous oxygen saturation greater than 70% (Table 70-8). Blood drawn from a central venous line can be used as a surrogate for true mixed venous saturations, and it represents the balance between global oxygen delivery and oxygen consumption. Normal physiologic changes of pregnancy may alter interpretation because hemodynamics in pregnancy include a higher CVP from expanded

plasma volume, lower mean arterial pressure from reduced systemic vascular resistance, and higher oxygen saturation from increased alveolar ventilation.

The choice of fluids (e.g., isotonic crystalloids versus albumin) is probably not important, although there is concern that use of starch solutions may negatively affect renal function.⁸⁸ Blood products should be used to maintain the hemoglobin level above 7 g/dL and correct coagulopathy if present. Future work will be aimed at determining how to attenuate the systemic inflammatory response and how it is different in pregnancy.⁸²

Substance Abuse

Other than marijuana and alcohol, methamphetamines, cocaine, and opioids such as methadone are the substances abused most frequently during pregnancy. Methamphetamines have become

TABLE 70-8 Management of Sepsis

Management Strategy	Clinical Considerations
Broad-spectrum, intravenous antibiotics	Begin within the first hour of diagnosis. Do not wait until admission to the intensive care unit or for culture results.
Volume expansion	Give crystalloid or colloid as needed for adequate CVP and urine output, but avoid excessive fluids. Blood products may be preferable, especially when anemia or coagulopathy require treatment.
Airway management	If ventilation is needed to maintain oxygenation, intubate early in her course before the airway becomes edematous.
Invasive monitoring	Use protective lung strategies for ventilation: PEEP, low tidal volumes, and permissive hypercapnia. Arterial lines are low-risk, useful for obtaining blood samples, and necessary when using pressors and inotropes. Central venous access may be needed for administering pressors and inotropes, but are less useful for monitoring.
Vasopressor therapy	Pulmonary artery catheters increase risk of complications and have shown no improvement in outcomes. Consider noninvasive cardiac output monitors used with an arterial line, TEE, or esophageal Doppler monitors to obtain hemodynamic information. Maintain hemodynamics,* and prevent metabolic acidosis. Norepinephrine: 0.05 µg/kg/min to improve SVR Dobutamine: 2-10 µg/kg/min if evidence of low cardiac output Epinephrine: 0.01 µg/kg/min Vasopressin: 0.04 U/min
Coagulation	Balance treating DIC or coagulopathy with the use of anticoagulants to prevent microthrombosis.
Corticosteroids	High-dose therapy is not indicated. ⁸² Low-dose therapy may be considered when the patient is unresponsive to fluids and vasopressors. ⁸³ Wean steroids when vasopressors are no longer required.

*Hemodynamic goals: MAP \geq 65 mm Hg, CVP = 8 to 12 mm Hg, urine output \geq 0.5 mL/kg, central venous or mixed venous oxygen saturation \geq 70%.

CVP, central venous pressure; DIC, disseminated intravascular coagulation; MAP, mean arterial pressure; PEEP, positive end-expiratory pressure; SVR, systemic vascular resistance; TEE, transesophageal echocardiography.

the primary substance requiring treatment during pregnancy, accounting for 24% of women admitted for treatment of substance abuse. White, unemployed women in western states accounted for 73% of these admissions.⁸⁹ The perinatal complications include preterm delivery, low Apgar scores, cesarean delivery, and neonatal mortality. These mothers were also found to abuse other substances and have higher rates of domestic violence and adoption.⁹⁰ A systematic review confirmed that amphetamine exposure in pregnancy has a negative impact on birth outcomes, including preterm birth, low birth weight, and small-for-gestational-age infants.⁹¹ The investigators recommended that obstetricians actively inquire about amphetamine exposure during pregnancy and encourage cessation. Cocaine abuse causes adverse perinatal outcomes similar to those seen with amphetamines and results in significantly higher odds of preterm birth (OR = 3.38), low birth weight (OR = 3.66), and small-for-gestational-age infants (OR = 3.23), as well as reducing the gestational age at delivery (median, -1.47 weeks) and the birth weight (median, -492 g).⁹² Additional considerations are nutritional status, social situation, and infections such as human immunodeficiency virus (HIV).

The anesthesia considerations for parturients abusing amphetamines or cocaine are primarily the control of hemodynamics. Their sympathomimetic effects lead to tachycardia and hypertension. If the patient is cooperative, early use of neuraxial analgesia for labor may reduce circulating catecholamines and improve the patient's ability to participate in her care. Catecholamine depletion may lead to refractory hypotension after neuraxial block. Hypotension often responds better to the direct effects of phenylephrine than to ephedrine, which acts through the release of catecholamines. If neither is effective, epinephrine may be required.

If general anesthesia is needed for urgent cesarean delivery, techniques should be used to attenuate the hemodynamic response to intubation. This may include a combined α - and β -blocking agent such as labetalol to control heart rate and provide vasodilation. Using a vasodilator such as hydralazine to treat hypertension could lead to severe tachycardia and arrhythmias unless there is accompanying β -blockade. Other adjuncts to prevent hypertension during induction of general anesthesia may include short-acting opioids such as remifentanyl (1 µg/kg) or lidocaine (1.5 mg/kg). Ketamine, which is a sympathomimetic agent, should be avoided. Methamphetamine abuse is associated with severe tooth decay ("meth mouth"), and the preanesthesia airway examination should include documentation of any loose teeth that may be dislodged during laryngoscopy. Because acute ingestion of cocaine or methamphetamine increases the minimum alveolar concentration (MAC) of the volatile anesthetics, higher concentrations are required. Because the risk of uterine atony above 0.5 MAC of these volatile agents precludes high doses, other anesthetic medications such as benzodiazepines and opioids may also be needed.

Opioid use during pregnancy can be illicit (e.g., heroin) or prescribed (e.g., oxycodone, methadone), but tolerance results from either, and many of the complications are the same. Mothers taking methadone for management of opioid dependence at the time of delivery tend to be younger smokers who receive late prenatal care.⁹³ Infants of mothers taking methadone are at risk for very preterm delivery (<32 weeks), being small for gestational age, admission to the neonatal ICU, and diagnosis of a major congenital anomaly. The use of opioid analgesics during early pregnancy is associated with cardiac and other anomalies, including ventricular septal defects, atrial septal defects, hypoplastic left heart syndrome, spina bifida, and

gastroschisis.⁹⁴ The dose of methadone being taken at delivery correlates with the neonatal abstinence syndrome in a dose-response relationship. A comparison of methadone with buprenorphine for treatment of opioid dependence during pregnancy found that neonates had better outcomes with buprenorphine, including a shorter hospital stay, lower morphine requirement, and shorter duration of treatment for the neonatal abstinence syndrome, but mothers discontinued treatment more often in the buprenorphine group (33% versus 18% of mothers in the methadone group).⁹⁵ Treatment cannot be effective if mothers do not comply.

The anesthesia goals for the patient with opioid tolerance are preventing withdrawal by providing adequate amounts of opioids and maintaining adequate intrapartum and postpartum analgesia.⁹⁶ The parturient should receive her usual dose of methadone while in the labor and delivery unit. Mixed agonist-antagonist opioids such as butorphanol and nalbuphine must be avoided to prevent precipitating withdrawal. Neuraxial analgesia should be used if the patient is cooperative because of the high tolerance these patients have to parenteral opioids. In addition to the local anesthetic and opioid mixtures normally used in neuraxial infusions, the addition of clonidine can be considered. In rare situations, low-dose ketamine infusions (10 to 20 mg/hr) can be used to add antinociceptive action by *N*-methyl-D-aspartate (NMDA) receptor antagonism to other pain control methods.⁹⁷

When cesarean delivery is necessary, spinal or epidural anesthesia is preferred. Preoperative gabapentin (Neurontin, 600 mg given orally) can improve postcesarean analgesia and maternal satisfaction, although increased sedation is a recognized side effect of gabapentin.⁹⁸ Postoperative pain relief should be provided with multimodal therapy that may include long-acting neuraxial morphine, epidural infusions, ketorolac or ibuprofen (depending on tolerance of oral medications), intravenous or oral acetaminophen, transversus abdominis plane blocks, and supplementation with intravenous or oral opioids as needed.⁹⁹

Trauma Management in Pregnancy

Trauma, especially from motor vehicle accidents, is a leading cause of morbidity and mortality during pregnancy, complicating about 1 in 12 pregnancies.¹⁰⁰ Fetal loss in these situations results from maternal hemodynamic instability, placental abruption, or maternal death. An ultrasound study should be performed early in the emergency room to determine gestational age and fetal viability, and fetal monitoring should be continued if the fetus is living and of a viable gestational age.

Pregnancy should not alter any necessary evaluations or treatments for the mother. She should receive all needed diagnostic tests to optimize her management, with shielding for the fetus when possible. Radiation exposure of less than 5 rad (e.g., head CT < 1 rad, abdominal scanning ≈ 3.5 rad) does not pose an increased risk for the fetus.¹⁰¹ Ultrasound and MRI are alternatives that do not use ionizing radiation.

The few indications for an emergent cesarean delivery include a stable mother with a viable fetus in distress unresponsive to intrauterine resuscitation efforts, traumatic uterine rupture, a gravid uterus interfering with intraabdominal repairs in the mother, and a mother who cannot be saved with a fetus that is viable. If the fetus is previsible or dead, care should focus on optimizing the maternal condition. In most circumstances, the mother can tolerate induced labor at a later time better than an immediate laparotomy for cesarean delivery.

The anesthesia considerations focus on protection of her airway, maintaining oxygenation by intubation and ventilation if necessary, stabilizing the cervical spine when indicated, and maintaining hemodynamic stability through uterine displacement, fluid administration, and blood product replacement. If the spine is unstable or cannot be evaluated, a wedge can be placed under the backboard to achieve left uterine displacement if the pregnancy is beyond 20 weeks' gestation. The need for large-bore intravenous access and invasive hemodynamic monitoring is assessed on an individual basis.

In collaboration with the obstetric team and the trauma surgeons, the anesthesiologist continues to provide care for the woman if she requires an operative procedure or delivery of the fetus.¹⁰² Obstetricians and anesthesiologists are knowledgeable about the physiologic changes of pregnancy, the effects of medications on uterine blood flow, and choices of medications and procedures based on their potential teratogenic effects. Often, alternatives can be suggested that are more appropriate for the pregnant patient. After she is stabilized, the teams should discuss the location of postoperative care, whether in the ICU with telemetry for fetal monitoring or on the labor and delivery unit if the mother is stable.

Conclusions

Good care for the complicated pregnant patient is a team effort. Anesthesiologists bring their experience with parturients in the labor and delivery unit, a strong critical care background, and expertise in providing medical care to a wide variety of patients in the operating room. Along with maternal-fetal medicine physicians, consultants relevant to the woman's underlying medical issues, and skilled nurses from the labor and delivery unit and the ICU, anesthesiologists can contribute to the desired positive outcomes for their patients. The ASA Practice Guidelines for Obstetric Anesthesia state, "Recognition of significant anesthetic or obstetric risk factors should encourage consultation between the obstetrician and the anesthesiologist. A communication system should be in place to encourage early and ongoing contact between obstetric providers, anesthesiologists, and other members of the multidisciplinary team."¹⁰³ Multidisciplinary communication is the key.

Intensive Care Considerations for the Critically Ill Parturient

KIMBERLY S. ROBBINS, MD | STEPHANIE R. MARTIN, DO | WILLIAM C. WILSON, MD, MA

Fewer than 1% of pregnant women become critically ill and require admission to an intensive care unit (ICU).¹⁻⁹ Among parturients admitted to an ICU, 47% to 93% of admitting diagnoses are related to an obstetric complication, primarily hypertensive disorders and hemorrhage. Other common causes for admission are respiratory failure and sepsis.

Common non-obstetric indications for ICU admission include maternal cardiac disease, trauma, drug overdose, cerebrovascular accidents, and, rarely, anesthetic complications. In many series, most obstetric ICU admissions occur in the immediate postpartum period and likely result from complications of acute hemorrhage.^{1,4-6,10}

This chapter addresses maternal mortality during critical illness and surveys the monitoring considerations and techniques that are commonly employed for critically ill parturients. We review several commonly encountered conditions requiring ICU management of pregnant patients and discuss the optimal resuscitation strategies for them. The basic physiologic changes of pregnancy that must be understood for optimal management of critically ill obstetric patients are summarized in this chapter, and a more complete review can be found in Chapter 7.

Maternal Mortality

DEFINITION AND EPIDEMIOLOGY

Maternal mortality is defined as the number of direct and indirect maternal deaths per 100,000 live births. Direct obstetric deaths result primarily from peripartum hemorrhage, thromboembolic events, hypertensive disorders of pregnancy, and infectious complications. Indirect obstetric deaths arise from preexisting medical conditions that are aggravated by the physiologic perturbations of pregnancy, including cardiac disease, pulmonary disease, diabetes, and collagen vascular disease (e.g., systemic lupus erythematosus). Figure 71-1 shows specific causes of pregnancy-related mortality for three time periods reported by the Centers for Disease Control and Prevention (CDC).¹¹⁻¹⁴

Maternal mortality rates are periodically surveyed by various local, state, and national agencies. Because these data are primarily collected from death certificates, some have suggested that the numbers underestimate the mortality rate by as much as 50%.¹⁵ Variations in the definition of maternal death, medicolegal concerns, and improper completion of death certificates further confound the data. To address these concerns, the Division of Reproductive Health at the CDC, in collaboration with the American College of Obstetricians and Gynecologists

(ACOG) and along with state health departments, began in 1986 to systematically collect data in the Pregnancy Mortality Surveillance System (PMSS).

Mortality rates declined significantly over the last century in the United States (Fig. 71-2); however, a slight increase has been seen in recent years.^{12,14} Some of this mortality increase has been attributed to better ascertainment of data resulting from prospective collection and the use of multiple source documents. Further complicating interpretation of this apparent increase over time is the fact that the period after delivery for defining a *maternal mortality* changed from 42 days to 90 days to 1 year in some jurisdictions, and it is not uniform across jurisdictions.^{16,17}

The frequency and indications for ICU admissions in developing countries are similar to those in the developed world; however, maternal mortality rates for the obstetric ICU population are significantly higher in developing countries (median, 14%) compared with the developed world (median, 3.4%).

Wide discrepancies in perinatal mortality rates exist among various ethnic populations, even when controlling for age and use of prenatal care.¹⁴ Geographic differences in maternal mortality rates can be partly attributed to racial disparities. The highest maternal mortality rates occur in states with higher percentages of births for African-American women. Data on pregnancy-related mortality in the United States between 1998 and 2005 show a rate of 14.5 deaths per 100,000 live births (10.2 per 100,000 for whites, 37.5 per 100,000 for African Americans), a significant increase from 11.8 deaths per 100,000 live births between 1991 and 1997.¹⁴ Advancing maternal age and lack of education are also associated with an increased risk of death in pregnancy.¹³ This increased risk is likely related to a higher incidence of underlying or undiagnosed chronic disease.

Sixty percent of maternal deaths occur after a live birth. Only 13% occur in the antepartum period, and of these, 3% are related to an induced or spontaneous abortion. For approximately 15% of patients, the outcome is not known but likely follows a live birth. Ectopic pregnancies are associated with only 3% of maternal deaths.¹⁴

PREDICTION OF MATERNAL DEATH IN THE ICU

Prediction of mortality risk for pregnant patients is challenging, partly because of their relatively young age and because of imprecise grading and scoring systems. The overall maternal mortality rate for critically ill gravidas admitted to an ICU is between 0% and 20%, with most series reporting mortality rates of less than 5% for all obstetric ICU admissions.^{1,3-5,8,18}

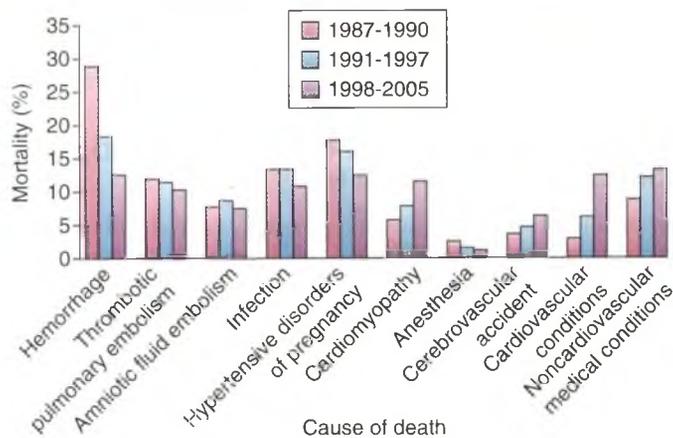

Figure 71-1 Causes of maternal mortality for three time periods. Obstetric deaths are caused by thromboembolic events, hemorrhage, hypertension, infections, and preexisting medical conditions, such as diabetes, systemic lupus erythematosus, pulmonary disease, and cardiac disease, which may be aggravated by the physiologic changes of pregnancy. (From Berg CJ, Callaghan WM, Syverson C, et al: *Pregnancy-related mortality in the United States, 1998 to 2005*, *Obstet Gynecol* 116:1302–1309, 2010.)

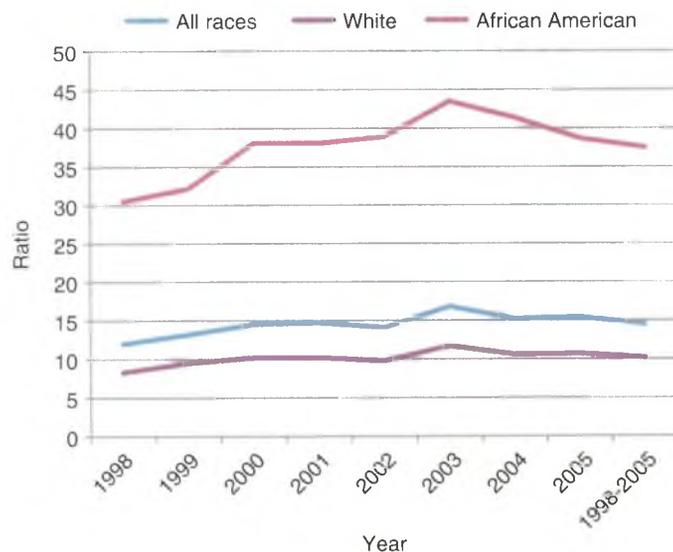

Figure 71-2 Pregnancy-related mortality ratio by race in the United States, 1998-2005. The mortality ratios are the number of deaths per 100,000 live births. (From Berg CJ, Callaghan WM, Syverson C, et al: *Pregnancy-related mortality in the United States, 1998 to 2005*, *Obstet Gynecol* 116:1302–1309, 2010.)

Several illness severity scoring systems have been developed for use in critical care settings, including the Acute Physiologic and Chronic Health Evaluation (APACHE) scoring system,^{19,20} the Simplified Acute Physiologic Score (SAPS),²¹ and the Mortality Prediction Model (MPM).²² These three scoring methods track a wide variety of variables, and each method has been demonstrated to correlate with mortality among nonpregnant adult patients. Several investigators have evaluated the applicability of the scoring systems for critically ill pregnant patients^{18,23-25}; however, none has been shown to accurately reflect the severity of illness or mortality risks of critically ill parturients.

In a study of obstetric ICU patients, the APACHE III score did not accurately predict maternal mortality.²³ In the largest series, 93 gravidas were compared with 96 nonpregnant women. The overall mortality rate for the obstetric population was 10.8%. The APACHE II, SAPS II, and MPM II scoring systems each performed well in predicting mortality for non-obstetric patients (14.7%, 7.8%, and 9.1%, respectively).²⁴ The predicted mortality rate was significantly higher for obstetric patients compared with non-obstetric patients for each of the three scoring tools despite no difference in mortality between the two groups (10.8% versus 10.4%). In a series of 34 obstetric ICU admissions, the predicted mortality rate based on the APACHE II score was 12.9%, but the observed mortality rate was zero.¹⁸

None of these scoring systems includes adjustments for normal obstetric physiologic changes such as decreased blood pressure and increased respiratory rate, and laboratory abnormalities such as elevated liver function test results and low platelet counts, which are common in obstetric disorders such as HELLP syndrome (*hemolysis, elevated liver enzymes, and low platelets*), are not included in the assessment and may limit its potential applicability. The available critical care mortality scoring tools are imprecise for parturients and tend to overestimate mortality risks for critically ill gravidas.

Cardiovascular Monitoring

ARTERIAL BLOOD PRESSURE

Measurement of arterial blood pressure provides a quantitative assessment of the hydraulic pressure head supplying the cardiovascular system and perfusing the tissues. As reviewed in Chapter 7, there are normal pregnancy-related increases in blood volume, stroke volume, and cardiac output (CO), along with decreases in systemic vascular resistance (SVR) and blood pressure.

The mean arterial pressure (MAP) is the average blood pressure during the cardiac cycle. The MAP can be expressed by a cardiovascular equivalent of Ohm's law ($E = I \times R$; energy potential = current \times resistance) as follows: $(MAP - CVP) = CO \times SVR$, in which CVP is the central venous pressure. The blood pressure depends on the CO and the SVR, and because the MAP drops with pregnancy, the SVR must normally decrease more than the increase in CO.

When a pregnant patient is in shock or suffering severe respiratory failure, her blood pressure should be measured using an indwelling arterial catheter. This can be used to determine beat-to-beat blood pressure measurements and provide access for frequent measurement of arterial blood gas values; monitor the dynamic response of the heart to preload and afterload changes occurring with positive-pressure ventilation and reflecting intravascular volume status of the patient.²⁶

DYNAMIC MEASURES OF INTRAVASCULAR VOLUME RESPONSIVENESS

Many prospective investigations have demonstrated that arterial systolic pressure variation (SPV), pulse pressure variation (PPV) derived from an analysis of the arterial waveform, stroke volume variation (SVV) derived from pulse contour analysis, and variation of the amplitude of the pulse oximeter plethysmographic waveform are highly predictive of fluid

responsiveness.^{26,27} These relationships are most robust in mechanically ventilated patients, as commonly occurs with critical illness.

The relationship between variations in systemic arterial pressure that occur with a positive-pressure breath is based on combining the Starling principle (i.e., stroke volume increases during systole in response to the increased blood volume filling the heart during diastole) with the fact that intermittent positive-pressure ventilation induces cyclic changes in the loading conditions of the heart. A positive-pressure breath causes a decreased preload and increased afterload of the right ventricle (RV). The RV preload is reduced in response to the decrease in the venous return pressure gradient that is related in the inspiratory increase in pleural pressure.²⁸ The increased RV afterload is related to the inspiratory increase in alveolar size and transpulmonary resistance to flow. The reduction in RV preload and increase in RV afterload decrease the RV stroke volume, which decreases to a minimum at the end of inhalation.²⁹ The inhalation-induced decrease in RV ejection leads to a decrease in left ventricle (LV) filling after a phase lag of two or three heartbeats because of the time required for pulmonary blood flow to pass through the pulmonary circuit. The LV preload reduction induces a decrease in LV stroke volume, which is at its minimum at the end of a conventional mechanical ventilation breath. The cyclic changes in RV and LV stroke volume are greater when the ventricles are empty (i.e., operating on the steep rather than the flat portion of the Frank-Starling curve [Fig. 71-3]). The magnitude of ventilator-induced changes in LV stroke volume (e.g., PPV, SPV) is an indicator of LV preload dependence.²⁸ In most previously healthy patients, a variation of greater than 12% to 13% has been highly predictive of volume responsiveness (Fig. 71-4).²⁷

The prospective use of dynamic indices of volume responsiveness has not been rigorously studied in critically ill parturients. The FloTrac/Vigileo system (Edwards Lifesciences, Irvine, CA) is one device that automatically measures these parameters and has been shown to accurately reflect volume responsiveness

in parturients undergoing cesarean section.³⁰ All parturients being evaluated should have some form of left lateral tilt to unload the uterine pressure from the inferior vena cava.

PASSIVE LEG RAISING FOR NONVENTILATED, CRITICALLY ILL PARTURIENTS

In the initial stages of resuscitation, many critically ill obstetric patients are not intubated and are breathing spontaneously.

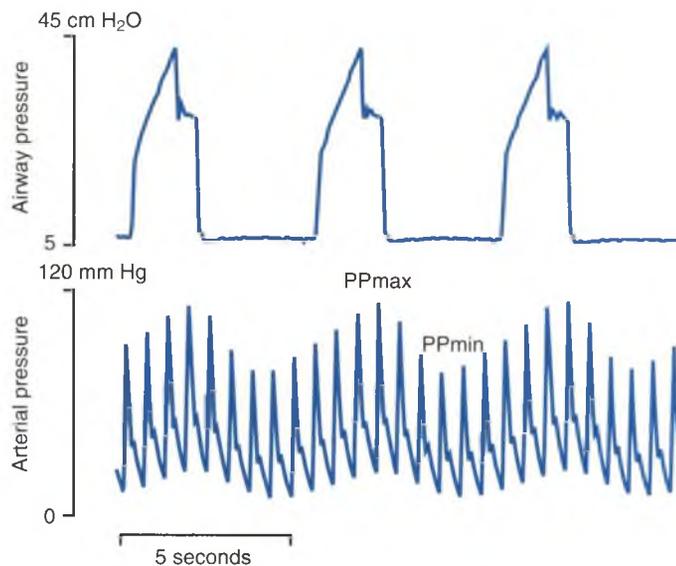

Figure 71-4 Respiratory changes in airway and arterial pressures in a mechanically ventilated patient. The pulse pressure (i.e., systolic minus diastolic pressure) is maximal (PPmax) at the end of the inspiratory period and minimal (PPmin) three heartbeats later (i.e., during the expiratory period). The respiratory changes in pulse pressure (Δ PP) are calculated as the difference between PPmax and PPmin, divided by the mean of the two values, and expressed as a percentage. (From Michard F, Teboul JL: Using heart-lung interactions to assess fluid responsiveness during mechanical ventilation, *Crit Care* 4:282–289, 2000.)

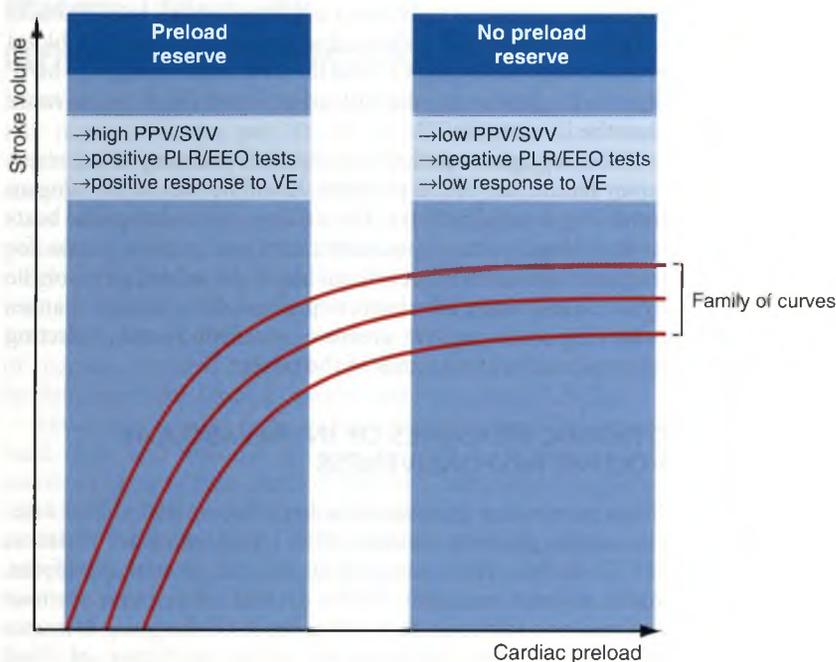

Figure 71-3 Frank-Starling relationship. After the ventricle is functioning on the steep part of the Frank-Starling curve, there is a preload reserve. Volume expansion (VE) induces a significant increase in stroke volume. The pulse pressure volume (PPV) and stroke volume (SVV) variations are marked, and the passive leg raising (PLR) and end-expiratory occlusion (EEO) test results are positive. In contrast, after the ventricle is operating near the flat part of the curve, there is no preload reserve, and fluid infusion has little effect on the stroke volume. There is a family of Frank-Starling curves, depending on the ventricular contractility. (From Marik PE, Monet X, Teboul JL: Hemodynamic parameters to guide fluid therapy, *Ann Intensive Care* 1:1–9, 2011.)

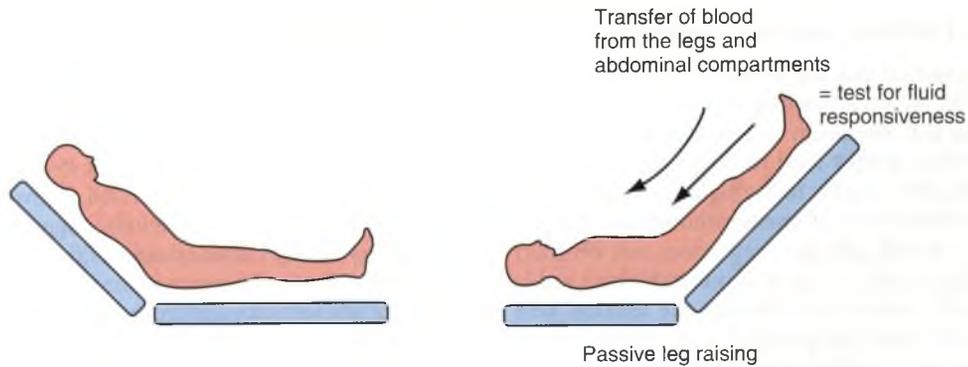

Figure 71-5 Passive leg raising. The passive leg raising test measures the hemodynamic effects of leg elevation up to 45 degrees. A simple way to perform the postural maneuver is to transfer the patient from the semirecumbent posture to the passive leg raising position by using the automatic motion of the bed. (From Marik PE, Monet X, Teboul JL: *Hemodynamic parameters to guide fluid therapy*, Ann Intensive Care 1:1–9, 2011.)

Because ventilator-induced changes in loading are not available for use in nonintubated, spontaneously breathing patients, techniques such as passive leg raising have been proposed for this purpose. Lifting the legs passively from the horizontal position induces a gravitational transfer of blood from the lower limbs to the intrathoracic compartment (Fig. 71-5). If the patient is intravascularly replete (i.e., has a relatively full RV and LV at end diastole), minimal augmentation in stroke volume and systolic blood pressure (SBP) occurs with this maneuver. However, in patients who have relatively low intravascular volume, an increase in these parameters is observed, indicating fluid responsiveness.

CENTRAL VENOUS CATHETERS

Central venous catheters are used in the critically ill parturient when peripheral venous access is difficult or insufficient for fluid replacement, for the administration of medications through the central circulation, for measurements of CVP, and as access to placement of a pulmonary artery (PA) catheter.³¹ The CVP typically increases when patients are massively fluid overloaded and decreases when patients are very dehydrated. However, there are exceptions, and patients who are not at these intravascular volume extremes often register CVP values that do not correlate well with their fluid responsiveness (i.e., need for more or less intravascular volume).

The value of the CVP in guiding intravascular fluid management has been repeatedly evaluated over the past decade, with the repetitive finding that dynamic measures such as SPV are far superior.^{26–30} As shown in Table 71-1, the CVP is no better than flipping a coin (receiver operating characteristic [ROC] value near 0.5) in determining the fluid responsiveness of a critically ill patient.

PULMONARY ARTERY CATHETERIZATION AND PRESSURE MEASUREMENT

After its introduction in the early 1970s,³² the PA catheter (i.e., Swan-Ganz catheter) was widely used in critically ill patients for 2 decades. The therapeutic benefits of PA catheters were challenged in the late 1980s and early 1990s, when a growing body of literature demonstrated no improvement or worse outcomes with

TABLE 71-1 Predictive Value of Techniques Used to Determine Fluid Responsiveness

Method	Technology	AUC*
Pulse pressure variation (PPV)	Arterial pressure analysis	0.94 (0.93–0.95)
Systolic pressure variation (SPV)	Arterial pressure analysis	0.86 (0.82–0.90)
Stroke volume variation (SVV)	Pulse contour analysis	0.84 (0.78–0.88)
Left ventricular end-diastolic area (LVEDA)	Echocardiography	0.64 (0.53–0.74)
Global end-diastolic volume (GEDV)	Transpulmonary thermodilution	0.56 (0.37–0.67)
Central venous pressure (CVP)	Central venous catheter	0.55 (0.48–0.62)

*The area under the receiver operating curve (AUC) is given with 95% confidence intervals.

Data from Marik PE, Monet X, Teboul JL: *Hemodynamic parameters to guide fluid therapy*, Ann Intensive Care 1:1–9, 2011; and Marik PE, Cavallazzi R, Vasu T, Hirani A: *Dynamic changes in arterial waveform derived variables and fluid responsiveness in mechanically ventilated patients: a systematic review of the literature*, Crit Care Med 37:2642–2647, 2009.

their use. Because of their recognized fallibility and the increased reliance on dynamic measures of intravascular volume management, the use of PA catheters has markedly declined over the past decade and is at risk of becoming a lost art in many venues. However, because many experts think that certain conditions of critically ill obstetric patients warrant use of PA catheters, their use in monitoring the parturient is discussed here.

The PA catheter is a multilumen device that allows concomitant monitoring of CVP, PA pressures, pulmonary capillary wedge pressure (PCWP), CO, mixed venous oxygen saturation, and calculations of pulmonary vascular resistance (PVR) and SVR. The CO can be measured using conventional thermodilution technology or calculated using the Fick equation (CO = oxygen consumption/arteriovenous oxygen difference) after sampling mixed venous blood from the distal port or by newer fiberoptic technology that allows continuous monitoring of CO and mixed venous oxygen saturation.

Pulmonary Artery Catheter Insertion Technique

The PA catheter is inserted percutaneously through an introducer sheath in one of the major central veins draining toward the right atrium. The left subclavian and right internal jugular veins are preferred because they tend to direct the catheter in the most anatomically direct paths to the right heart. The right internal jugular has a lower rate of pneumothorax, and the left subclavian site has a lower infection rate, does not obstruct cerebral venous outflow, and is a more comfortable and stable line for prolonged ICU use. Access through the femoral vein offers the advantage of vessel compressibility in patients with a coagulopathy, but it has a higher infection and deep venous thrombosis risk. Because it is most distant from the right heart, imaging guidance is occasionally required to assist placement.

After gaining central venous access from the right internal jugular or left subclavian vein, the PA catheter is advanced through the introducer sheath as characteristic pressure waveforms are read on the bedside monitor. At 15 to 20 cm, the typical CVP waveform is visualized. The 1.5-mL balloon, positioned close to the tip of the catheter, is then inflated, which carries the catheter through the heart by flowing blood. After 25 to 35 cm of insertion, the RV waveform appears with a diastolic reading similar to the previous CVP values, but the systolic values are distinctly higher. After 35 to 45 cm of insertion, the PA waveform appears with a systolic value similar to that seen in the RV waveform, but the diastolic value is elevated from the CVP position. After the PA catheter is inserted to approximately 50 to 60 cm with the balloon still inflated, it travels distally until it wedges in a smaller-caliber PA and occludes blood flow. This results in a PA capillary wedge pressure (PACWP) that has waveforms similar to the CVP, but it is typically a few millimeters of mercury higher. When the balloon is deflated, return of an identifiable PA systolic and diastolic pressure tracing should occur. A portable chest radiograph should be obtained after placement of a PA catheter to verify appropriate catheter positioning and exclude pneumothorax.

Indications for Pulmonary Artery Catheterization

There are several common indications for PA catheter placement in the obstetric population³¹:

1. Hypovolemic shock unresponsive to initial volume resuscitation attempts
2. Septic shock with refractory hypotension or oliguria
3. Severe preeclampsia with refractory oliguria or pulmonary edema
4. Ineffective intravenous antihypertensive therapy
5. Acute respiratory distress syndrome
6. Intraoperative or intrapartum cardiac failure
7. Severe mitral or aortic valvular stenosis
8. New York Heart Association (NYHA) class III or IV heart disease in labor
9. Amniotic fluid embolism (i.e., anaphylactoid syndrome of pregnancy)

The PA catheter is no longer commonly employed in nonpregnant, critically ill patients, except for certain conditions and procedures such as cardiothoracic surgery (including heart and lung transplantation) and liver transplantation. A few small studies initially suggested a decrease in mortality when PA catheters were used to direct therapies,³³⁻³⁵ whereas most others reported an increase in mortality associated with the use of PA catheters³⁶⁻³⁹ or no benefit.⁴⁰⁻⁴² The Canadian Critical Care

Clinical Trials Group prospectively randomized 1994 high-risk surgical patients to receive a PA catheter to direct therapy or to receive standard therapy. They reported no mortality difference with the use of a PA catheter (7.8% versus 7.7% in controls).⁴³ A British trial randomized more than 1000 critically ill patients to management with or without a PA catheter and failed to demonstrate a survival benefit (68.4% versus 65.7% in controls).⁴⁴ The Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) also demonstrated no difference in mortality or length of stay for 433 patients with congestive heart failure randomized to PA catheter or no catheter.⁴⁵

A meta-analysis of 13 trials published since 1985 included 5051 patients randomized to a PA catheter or no PA catheter to guide management. No difference was identified in mortality or hospital length of stay. Conversely, the use of a PA catheter was associated with significantly more frequent use of inotropes and vasodilators.⁴⁶ The available data do not support the routine use of PA catheters for most critically ill patients. Prospective data addressing the role of the PA catheter in the critically ill obstetric patient are lacking.

COMPLICATIONS OF CENTRAL VENOUS AND PULMONARY ARTERY CATHETERS

Complications associated with PA catheter insertion, advancement, and maintenance are listed in Table 71-2.⁴⁷ Minimal data have been published addressing specific complication rates associated with PA catheter use in pregnant women. As with most invasive devices, initial complication rates decline as operator experience increases, and only properly trained or supervised personnel should insert central venous or PA catheters.⁴⁸

Complications encountered at initial insertion include unintended arterial puncture, pneumothorax, and air embolism. Pneumothorax risks are highest with a subclavian approach. Transient cardiac dysrhythmias are commonly encountered during wire insertion for central venous catheters and PA catheter introducers, as well as during advancement of the PA catheter itself. Most dysrhythmias are minor, consisting of premature ventricular contractions or nonsustained ventricular tachycardia, both of which typically resolve during withdrawal or advancement of the PA catheter out of the RV. The overall incidence of transient dysrhythmias during advancement of a PA catheter exceeds 20% in most studies.⁴⁷

Significant dysrhythmias such as sustained ventricular tachycardia or ventricular fibrillation are less common, occurring in less than 1% of patients in most series. They are more likely to be encountered in patients with sepsis, acidemia, cardiac ischemia, and prolonged catheterization.^{47,49}

TABLE 71-2 Complications Related to Pulmonary Artery Catheterization

At Insertion	After Placement
Pneumothorax	Pulmonary infarction
Hemothorax	Pulmonary artery rupture
Chylothorax	Thrombosis
Arterial puncture	Infection
Air embolization	Balloon rupture
Catheter knotting	Endocardial or valvular damage
Cardiac arrhythmias (transient, sustained)	Data misinterpretation

Ultrasound-guided placement results in fewer failed attempts, a shorter time to successful access, and fewer complications such as hematoma, arterial puncture, hemothorax, pneumothorax, nerve injury, and cardiac tamponade compared with placement using landmarks alone.^{50,51}

Infections related to central venous catheters cause significant morbidity. Skin flora, particularly *Staphylococcus* species, are most commonly involved. Endogenous skin bacteria are occasionally cultured from the tip of a PA catheter, and in the absence of bacteremia, they are considered a colonization. The diagnosis of bacteremia or sepsis requires the patient to have a positive blood culture result with the same organism and clinical evidence of systemic infection, such as pus or erythema at the skin insertion site, fever, leukocytosis, or hypotension.⁵² The risk of bacteremia is approximately 0.5% per catheter day; therefore the risk increases with each day the catheter remains indwelling. Bacteremia from central venous catheters accounts for 87% of bloodstream infections in critically ill patients.⁵³ Catheter-related bloodstream infections can be almost eliminated by strict adherence to sterile technique, placement in the subclavian site, use of a 2% chlorhexidine skin preparation, use of antimicrobial-coated catheters, avoidance of antibiotic ointments that can increase fungal colonization, and removal of the catheter as soon as possible.⁵⁴⁻⁵⁶

Thrombosis associated with a central venous catheter is related to the insertion site, duration of placement, and coagulation status of the patient. The subclavian approach is associated with the lowest risk for thrombosis (1.9%), followed by the internal jugular (7.6%), and the highest risk for thrombosis is at the femoral insertion site (22%).⁵⁷⁻⁵⁹ Pulmonary infarction can occur as a result of direct occlusion of a PA branch caused by inward migration of the PA catheter or by thromboemboli.

Catheter knotting can be minimized during placement if the operator remains aware of the centimeter markings on the advancing catheter. As a general rule, the RV is almost always reached when the catheter has been inserted 25 to 35 cm from the jugular vein site, as described previously. Few patients require more than 50 cm of catheter to reach the pulmonary artery. Inflated catheter balloons should be checked before insertion to reduce the risk of air leakage and balloon rupture. Overinflation of the balloon with air (>1.5 mL) should be avoided. Rupture of the PA is a rare complication with high morbidity; it occurs more commonly in patients who are anticoagulated and those with severe PA hypertension. Valvular damage can theoretically occur from prolonged catheter irritation or during manipulation when the catheter balloon is not deflated before retrograde movement.

Monitoring the CVP alone should not be considered equivalent to PA catheter monitoring. Preeclampsia and its complications (e.g., oliguria, pulmonary edema) may prompt central venous access. However, several investigators have described poor correlation between the CVP and PCWP in gravidas with pregnancy-induced hypertension (Fig. 71-6).^{60,61} If an accurate assessment of LV preload is deemed important in the management of the patient's cardiovascular complications, insertion of a PA catheter may be indicated.

HEMODYNAMIC CALCULATIONS

Several hemodynamic parameters (e.g., CO, CVP, pulmonary artery pressure, PACWP) can be calculated by using data obtained from the PA catheter, systemic blood pressure

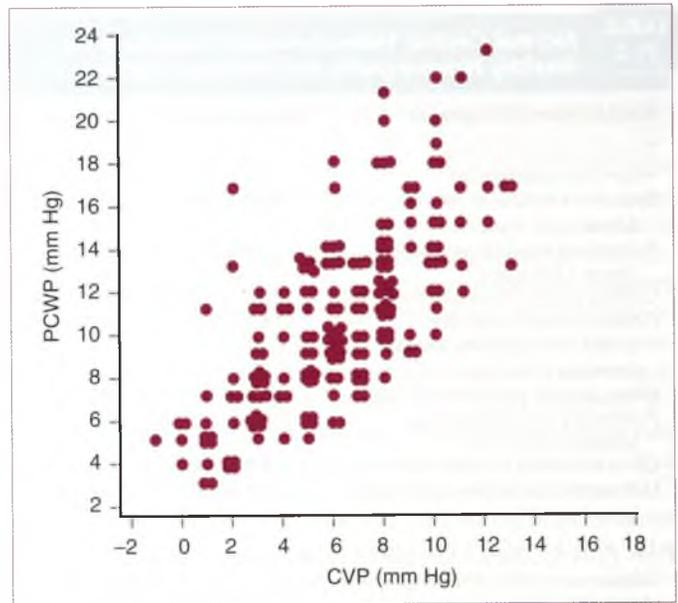

Figure 71-6 Relationship of central venous pressure (CVP) to pulmonary capillary wedge pressure (PCWP) in severe preeclampsia. If an accurate assessment of left ventricular preload is deemed important in the management of the patient's cardiovascular complications, insertion of a pulmonary artery catheter may be indicated. (From Cotton DB, Gonik B, Dorman K, et al: Cardiovascular alterations in severe pregnancy-induced hypertension: relationship of central venous pressure to pulmonary capillary wedge pressure, *Am J Obstet Gynecol* 151:762, 1985.)

BOX 71-1 HEMODYNAMIC PARAMETERS OBTAINED FROM A PULMONARY ARTERY CATHETER

$$SVR = [(MAP - RAP)/CO] \times 80$$

$$PVR = [(PAP - PCWP)/CO] \times 80$$

$$CO = VO_2 / (CaO_2 - CvO_2)$$

$$DO_2 = CO \times CaO_2 \times 10$$

$$VO_2 = (CaO_2 - CvO_2) \times CO \times 10$$

$$CaO_2 = (1.34 \times Hb \times SaO_2) + (0.003 \times PaO_2)$$

$$CvO_2 = (1.34 \times Hb \times SvO_2) + (0.003 \times PvO_2)$$

$$O_2 \text{ extraction} = VO_2 / DO_2$$

$$Qs/Qt = (CcO_2 - CaO_2) / (CcO_2 - CvO_2)$$

CaO₂, arterial oxygen concentration; CcO₂, end-capillary O₂ content; CO, cardiac output; CvO₂, venous oxygen concentration; DO₂, oxygen delivery; Hb, hemoglobin; MAP, mean arterial pressure; O₂, oxygen; PaO₂, arterial partial pressure of oxygen; PAP, pulmonary artery pressure; PCWP, pulmonary capillary wedge pressure; PvO₂, venous partial pressure of oxygen; PVR, pulmonary vascular resistance; Qs/Qt, shunt fraction (amount of blood shunted/total blood flow); RAP, right atrial pressure; SaO₂, arterial oxygen saturation; SvO₂, venous oxygen saturation; SVR, systemic vascular resistance; VO₂, oxygen consumption.

measurements, and the formulas listed in Box 71-1. These hemodynamic parameters can also be expressed in an indexed fashion (e.g., cardiac index), which allows comparison of patients with different body sizes. For example, the original nonindexed CO value is divided by the body surface area (BSA) given in meters squared (m²). Because standard BSA calculations have never been established for pregnancy, using this

TABLE 71-3 Normal Central Hemodynamic Parameters for Healthy Nonpregnant and Pregnant Patients

Hemodynamic Parameter	Nonpregnant	Pregnant
Cardiac output (L/min)	4.3 ± 0.9	6.2 ± 1.0
Heart rate (beats/min)	71 ± 10	83 ± 10
Systemic vascular resistance (dyne × cm × sec ⁻⁵)	1530 ± 520	1210 ± 266
Pulmonary vascular resistance (dyne × cm × sec ⁻⁵)	119 ± 47	78 ± 22
Colloid oncotic pressure (mm Hg)	20.8 ± 1.0	18.0 ± 1.5
Colloid oncotic pressure – pulmonary capillary wedge pressure (mm Hg)	14.5 ± 2.5	10.5 ± 2.7
Mean arterial pressure (mm Hg)	86.4 ± 7.5	90.3 ± 5.8
Pulmonary capillary wedge pressure (mm Hg)	6.3 ± 2.1	7.5 ± 1.8
Central venous pressure (mm Hg)	3.7 ± 2.6	3.6 ± 2.5
Left ventricular stroke work index (g × m × m ⁻²)	41 ± 8	48 ± 6

From Clark SL, Cotton DB, Lee W, et al: Central hemodynamic assessment of normal term pregnancy, *Am J Obstet Gynecol* 161:1439, 1989.

method of expressing hemodynamic data for obstetric patients is controversial.

Paired hemodynamic measurements from 10 healthy women while pregnant (estimated 36 to 38 weeks' gestation) and nonpregnant (11 to 13 weeks after delivery) are presented in Table 71-3.⁶² Using M-mode transthoracic echocardiography (TTE), other investigators demonstrated that many of the physiologic hemodynamic alterations of pregnancy begin early in gestation.⁶³

Positional changes also influence central hemodynamic measurements in the parturient. The standing position increases pulse by 30%, decreases LV stroke work index by 21%, and increases PVR.⁶⁴ Compared with the nonpregnant state, pregnancy seemed to buffer orthostatic hemodynamic changes. The investigators speculated that the increased intravascular volume during pregnancy accounted for this stabilizing effect.

NONINVASIVE CARDIOVASCULAR ASSESSMENT AND MONITORING

The PA catheter was previously considered to be the gold standard for evaluating the hemodynamic status of critically ill patients. However, several prospective studies have demonstrated that PA catheter use to guide therapy does not favorably impact survival and carries substantial risks.⁴³⁻⁴⁶ Transesophageal echocardiography (TEE) and TTE have emerged as semi-invasive and noninvasive tools, respectively, for the bedside assessment of the hemodynamic status of critically ill patients.

The TEE usually is employed in heavily sedated or anesthetized patients, because a large (1.0 cm in diameter, 90 cm long) transducer probe needs to be introduced into the esophagus to collect real-time data. The TEE accurately measures the size of all heart chambers and the function of the RV and LV. The function of the aortic, mitral, and tricuspid valves are also well evaluated by TEE; the pulmonic valve function is less well visualized by TEE but is less clinically relevant. The size of the inferior vena cava, flow profiles of the hepatic and pulmonary veins, and the aorta (except for a portion of the arch) are all seen on TEE. Using measurement tools, the ejection fraction of

TABLE 71-4 Origin of Hypotension

End-Diastolic Cross-Sectional Area	Ejection Fraction	Cause
↓↓	>0.8	Hypovolemia
↑↑	<0.2	Left ventricular failure
Normal	>0.5	Low SVR or severe MR, AR, or VSD

AR, aortic regurgitation; MR, mitral regurgitation; SVR, systemic vascular resistance; VSD, ventricular septal defect; ↓↓, significant decrease; ↑↑, significant increase.

From Cahalan MK: Intraoperative transesophageal echocardiography: an interactive text and atlas, New York, 1996, Churchill Livingstone.

both ventricles can be measured and the stroke volume estimated, giving an accurate measure of CO when the heart rate is multiplied. The TEE can also estimate PA pressures.⁶⁵⁻⁶⁷

TEE is often used for unstable patients to determine the cause of the hypotension, such as inadequate filling or depressed contractility (Table 71-4). TEE can detect abnormalities not detected by the PA catheter, including LV obstruction, structural abnormalities, proximal pulmonary emboli, and valvular disease. It also can evaluate the left atrium and mitral valve because of the proximity of these structures to the transducer, and it appears to be superior in evaluating congenital cardiac defects.

The PA catheter has served as the gold standard for accurate CO measurements, but a few series have demonstrated favorable comparisons between CO data derived from PA catheter and TTE using two-dimensional imaging and Doppler in obstetric patients, including preeclampsics⁶⁸ and other critically ill parturients.^{69,70} Some investigators, however, have shown that echocardiographic estimation of PA pressure is overestimated in 32% of obstetric patients with suspected pulmonary artery hypertension.⁷¹

The major advantage of TTE is that it is noninvasive and does not require sedation or analgesia before or during the examination. TTE devices are less expensive and slightly quicker to employ. However, the imaging quality of TTE is less sharp than images obtained by TEE, especially for evaluating the left atrium or mitral valve and when acquiring diastolic data. It may be challenging to obtain acoustic windows on patients with surgical dressings, and abundant body fat degrades imaging quality.

The critically ill parturient has some features that make the use of TTE advantageous. For example, pregnancy usually results in anterior and left lateral displacement of the heart. Parturients usually receive their care in the left lateral tilted position to avoid aortocaval compression. Because bedside TTE enables differentiation of a variety of life-threatening causes of hypotension, it is increasingly used by intensivists.⁷²

Cardiovascular Disorders

Several cardiovascular disorders may occur as preexisting conditions or develop in parturients, and they can become exacerbated by the progression of pregnancy and labor. The most significant of these cardiovascular conditions and valvular disorders are discussed here. Amniotic fluid embolism and hypertensive disorders of pregnancy, which occur only in pregnant women, are also reviewed.

MITRAL STENOSIS

Mitral stenosis is the most common rheumatic valvular lesion encountered during pregnancy (see Chapter 52). Prevention of tachycardia is important because as the heart rate increases, less diastolic time is available for the left atrium to empty its contents into the LV. The left atrium can also become overdistended, resulting in dysrhythmias (primarily atrial fibrillation, which increases the risk of thromboembolic complications) or pulmonary edema. If preload becomes excessive, pulmonary edema and atrial dysrhythmias can occur. Medical management of patients with mitral stenosis involves activity restriction, treatment of dysrhythmias, β -blockers to control heart rate, and judicious diuretic use. Adequate analgesia and anesthesia during labor and delivery also reduce excessive cardiac demands associated with pain and anxiety.

Another important hemodynamic consideration is the potential for misinterpretation of the invasive monitoring data for these patients. Because of the stenotic mitral valve, PCWP readings do not accurately reflect LV diastolic pressure. In some instances, very high PCWP values are recorded; they are needed to maintain an adequate CO. Overt pulmonary edema is usually not associated with these high readings. During attempts at maintaining a relatively constricted intravascular volume, the CO should be concomitantly monitored and maintained. For each patient, optimal PCWP and CO values should be determined (i.e., values that maintain blood pressure and tissue perfusion).

AORTIC STENOSIS

The major concern in the parturient with aortic stenosis is the potential inability to maintain CO due to severe obstruction or decreased LV preload (see Chapter 52). Unlike those with mitral stenosis, patients with aortic stenosis respond better to an elevated SVR (i.e., reflection of perfusion pressure to the thick, hypertrophic LV) and a relatively hypervolemic state, although the fixed aortic valve outflow obstruction can lead to pulmonary edema if preload is too generous.

The time surrounding labor and delivery is particularly risky for aortic stenosis patients. To maintain adequate CO, adequate venous return to the heart is crucial. Decreased venous return can result from excess blood loss, hypotension, and sympathetic blockade from regional anesthesia and from vena caval occlusion in the supine position. In the past, PA catheterization was advocated for patients with significant aortic stenosis. However, less invasive measures of fluid responsiveness are recommended for optimizing fluid replacement.²⁶

PULMONARY HYPERTENSION

Pulmonary hypertension can arise as a primary lesion or develop from several cardiopulmonary disorders. Primary pulmonary hypertension (PPH) is characterized by an unexplained elevation in PA pressures (>25 to 30 mm Hg). Outcomes are poor for patients with PPH; mean survival is 2.8 years after diagnosis. Maternal mortality rates for patients with pulmonary hypertension are also elevated, with some reports of rates as high as 50%.⁷³⁻⁷⁵

Other causes of pulmonary hypertension include unrepaired congenital shunts such as a ventricular septal defect, atrial septal defect, or patent ductus arteriosus, which result in chronic

overperfusion of the pulmonary vasculature. Over time, PA pressures can become elevated enough to reverse the direction of flow across the shunt. This pathophysiology defines Eisenmenger syndrome. The obstruction to RV outflow caused by the elevated PVR in patients with Eisenmenger syndrome can ultimately lead to right-to-left shunting of deoxygenated blood with resultant hypoxemia. Reductions in blood return to the heart can decrease RV preload so that the pulmonary vasculature is further hypoperfused. The resultant hypoxemia has been associated with sudden death. Intrapartum management requires maintenance of a relatively hypervolemic state and avoidance of interventions that reduce preload or decrease SVR. The estimated mortality rate for those with Eisenmenger syndrome is between 30% and 40% in most studies.^{75,76} In a review of 73 patients with Eisenmenger syndrome, the overall mortality rate was 36%, essentially unchanged in the past 2 decades.⁷⁵ In a small series of 13 patients, only one maternal death occurred.⁷⁷

Placement of a PA catheter can be challenging in pulmonary hypertension patients due to the sluggish PA blood flow. The risk of complications from PA catheterization is slightly increased in the setting of pulmonary hypertension. Some experts think the risks of placement can outweigh the benefits of PA catheterization in patients with solitary pulmonary hypertension, unless a specific indication exists.

AMNIOTIC FLUID EMBOLUS

Clinically overt amniotic fluid embolus (AFE) is a rare but devastating complication that occurs in the peripartum period.⁷⁸ AFE syndrome is characterized by acute onset of hypoxia, acute right ventricular dysfunction, hypotension or cardiac arrest, and coagulopathy occurring during labor, delivery, or within 30 minutes after delivery.⁷⁹⁻⁸¹ Symptoms typically occur proximate to delivery; however, cases have been reported during induced abortion procedures and up to 48 hours postpartum.^{78,80,81}

Several risk factors for AFE have been identified, including age older than 35 years, medical induction of labor, cesarean delivery, operative vaginal delivery, cervical trauma, uterine rupture, placenta previa, abruption, polyhydramnios, eclampsia, and fetal distress.^{78,79,82} However, due to the limitations of retrospective reviews, causality cannot be attributed. A similar constellation of findings can be produced by several other causes, including hemorrhage, uterine rupture, or sepsis, and each should be excluded before assigning a diagnosis of AFE. Estimates of frequency vary from 1.9 to 6/100,000 deliveries in the developed world. The incidence varies greatly depending on the method of ascertainment of cases.^{78,79,82} A recent publication reviewed all 4,508,462 hospital births in Canada from 1991-2009 and identified 120 "confirmed" cases of AFE. In 60% of cases, the diagnosis was excluded after review of the case.⁸²

The combination of sudden cardiovascular and respiratory collapse with a coagulopathy is similar to that observed in patients with anaphylactic or septic shock. In each of these settings, a foreign substance (e.g., endotoxin) is introduced into the circulation. Some authorities have used the terms *anaphylactoid syndrome of pregnancy* and *AFE* interchangeably.

The pathophysiology of AFE is incompletely understood, but it is thought that the release of some compound of fetal, placental, or amniotic fluid origin into the maternal circulation initiates a cascade of events similar to anaphylactoid processes, including the activation and release of mediators such as histamines, thromboxane, and prostaglandins, leading to disseminated

intravascular coagulation (DIC), hypotension, and hypoxia. The inciting factor is presumed to be present in amniotic fluid that is introduced into the maternal circulation, but the precise factors that initiate the sequence have not been identified.

It was previously and erroneously thought that the presence of fetal debris in the pulmonary circulation was diagnostic of AFE. However, fetal debris can be found in the pulmonary circulation in a predominance of normally laboring patients, and it is identified only in 78% of patients who meet diagnostic criteria for AFE.^{80,81}

Management of AFE is entirely supportive. Resuscitation with replacement of blood and clotting factors, adequate hydration and blood pressure support, and ventilatory support with continuous hemodynamic monitoring are required for these patients. If cardiac arrest occurs and the patient is undelivered, providers are encouraged to consider perimortem cesarean delivery after 4 minutes of unsuccessful resuscitative efforts to both improve chances for intact neonatal survival and facilitate maternal resuscitative efforts.

The most recent population-based studies suggest that mortality rates have decreased from early reports of 61% to 22% in the United States.^{78,80} Mortality is typically the result of cardiac arrest, coagulopathy with hemorrhage, or multiorgan failure subsequent to the initial event. Among those who survive, neurologic impairment is common.⁸⁰

Acute Respiratory Failure

Substantial anatomic and physiologic changes occur within the respiratory system of normal parturients during the course of pregnancy (see Chapter 7). Minute ventilation increases during pregnancy and is primarily driven by a 40% increase in tidal volume as the respiratory rate increases only minimally. The levels of carbon dioxide decline, creating a mild respiratory alkalosis. To accommodate for the decreased carbon dioxide, the kidneys excrete bicarbonate (HCO_3^-). Arterial blood gas determinations in a normal pregnant woman therefore reflect a slightly increased pH, decreased PaCO_2 , and decreased serum level of HCO_3^- (i.e., respiratory alkalosis with compensatory metabolic acidosis), as outlined in Table 71-5. As the pregnancy progresses, increasing abdominal girth leads to an upward displacement of the diaphragm, widening of the subcostal angle by 50%, and an increased chest circumference. The end result is a decrease in the functional residual capacity (FRC) by 20%. The FRC is the amount of gas remaining in the lungs at end exhalation during normal tidal breathing. As the FRC decreases, alveoli collapse, and gas exchange decreases.⁸⁶

TABLE 71-5 Changes in Arterial Blood Gas Measurements in Pregnancy

Blood Gas Measurements	Pregnant Women	Nonpregnant Women
pH	7.4-7.46	7.38-7.42
PCO_2 (mm Hg)	26-32	38-45
PO_2 (mm Hg)	75-106	70-100
HCO_3^- (mmol/L)	18-21	24-31
O_2 saturation (%)	95-100	95-100

Adapted from Dildy G, Clark SL, Phelan JP, et al: *Maternal-fetal blood gas physiology*. In *Critical care obstetrics*, ed 4, New York, 2004, Blackwell.

Common causes for respiratory failure during pregnancy include pulmonary edema, infection, and pulmonary embolus.^{87,88} In a study of 43 gravidas requiring mechanical ventilation before delivery, 86% delivered during admission, and of these, 65% underwent cesarean section, with an associated mortality rate of 36% for those delivered by cesarean section. Overall maternal and perinatal mortality rates were high (14% and 11%, respectively).⁸⁷

Debate continues about whether delivery improves the respiratory status of these patients. Tomlinson and colleagues described their experience with 10 parturients who delivered while mechanically ventilated. For all but one patient, the cause of respiratory failure was pneumonia.⁸⁹ The only demonstrable benefit after delivery was a 28% reduction in the fraction of inhaled oxygen (FiO_2) in the ensuing 24 hours. The investigator concluded that routine delivery of these patients was not recommended. This is the only published study designed specifically to address this question. However, data from other series support the conclusion that delivery does not uniformly result in significant maternal improvement. Mortality rates after delivery requiring ventilatory support range from 14% to 58%, and cesarean section may further increase this risk.^{87,88,90}

ACUTE RESPIRATORY DISTRESS SYNDROME

Acute respiratory distress syndrome (ARDS) is a form of non-cardiogenic pulmonary edema. It is characterized by bilateral, patchy alveolar infiltrates without evidence of cardiac failure or increased hydrostatic pressure (i.e., PCWP <18 mm Hg). ARDS can occur insidiously, but it typically manifests with a rapid onset and progresses to severe respiratory failure. ARDS can also be operationally defined by a ratio of the partial pressure of oxygen (PaO_2) to FiO_2 of 200 or less (P/F ratio ≤ 200). Those with P/F ratios between 200 and 300 are characterized as having acute lung injury.

Infections such as influenza, varicella, or herpes simplex virus and noninfectious processes such as severe preeclampsia, eclampsia, and hemorrhage most commonly precipitate respiratory failure in pregnant women.^{87,91} Septic patients are at increased risk for ARDS as a consequence of pulmonary vascular damage, which facilitates the leakage of intravascular fluid into the pulmonary interstitial spaces. Mortality rates are high, and surviving patients often suffer from residual compromise of pulmonary function due to fibrosis and scarring of lung tissue.

Management of ARDS focuses on identifying and treating underlying causes such as sepsis, pancreatitis, transfusion-associated lung injury, AFE, anaphylaxis, and burns. These patients universally require intubation and mechanical ventilation, with an elevated FiO_2 and high levels of positive end-expiratory pressure (PEEP). Hemodynamic support can be required to sustain blood pressure and oxygen delivery (DO_2), and nutrition is required to facilitate lung healing. The required ventilatory support can precipitate additional lung injury, and efforts have been made to devise ventilatory strategies that maintain adequate gas exchange while minimizing secondary lung injury.

MECHANICAL VENTILATION STRATEGIES DURING PREGNANCY

Management of respiratory failure in nonpregnant, critically ill patients has changed over the past decade from the previous

goals of maintaining tidal volumes in the 10- to 15-mL/kg range. These supranormal tidal volumes can lead to alveolar overdistention, impairing gas exchange and predisposing to alveolar damage and release of inflammatory mediators that worsen lung injury.

ARDSNET DATA

In 2000, the ARDSNet group published results of 861 patients with ARDS who were randomized to a traditional tidal volume (12 mL/kg) or to a low tidal volume (6 mL/kg).⁹² The traditional tidal volume group also maintained a goal of 50 cm of H₂O or less, compared with lower peak pressures of 30 cm of H₂O in the low tidal volume group. Low tidal volumes and lower peak pressures were associated with lower mortality (31% versus 40%) and a shorter period of intubation compared with conventional tidal volumes and peak pressure goals.

Decreased FRC, increased metabolic rate, and other normal changes in pulmonary physiology can affect the utility of this approach in pregnant women. The current standard mode of ventilatory support for parturients is to employ volume-control mechanical ventilation using the ARDSNet settings, as previously described.

AIRWAY PRESSURE RELEASE VENTILATION

A newer mode of ventilatory support, which has achieved significant success in treating ARDS patients, is airway pressure release ventilation (APRV).⁹³ This novel ventilation modality has some theoretical advantages over the conventional ARDSNet protocol (i.e., low tidal volumes and lower peak pressures during ventilation) in patients with ARDS,⁹⁴ but prospective trials proving these benefits have not been completed.

Conventional mechanical ventilation begins the ventilatory cycle at a baseline pressure and increases airway pressure to accomplish tidal ventilation with each positive-pressure breath. APRV differs fundamentally from conventional ventilation in that it uses an elevated baseline pressure throughout most of the ventilatory cycle and employs a brief deflation period to let gas exhale out of the lungs to accomplish tidal ventilation, followed by immediate return to the elevated baseline pressure (Fig. 71-7). The high pressure (i.e., time high) facilitates alveolar recruitment and oxygenation, and the pressure release (i.e., time low) aids in carbon dioxide clearance.

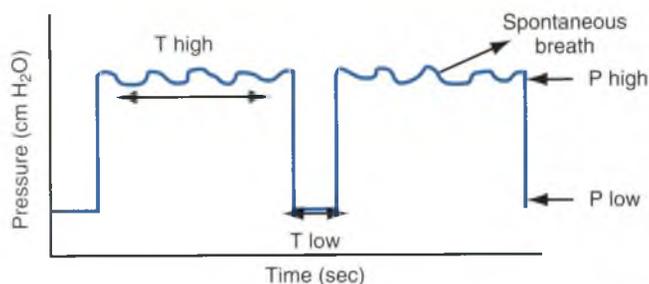

Figure 71-7 Pressure-time curve for airway pressure release ventilation. *P high* is the high continuous positive airway pressure (CPAP), *P low* is the low CPAP, *T high* is the duration of *P high*, and *T low* is the release period or the duration of *P low*. Spontaneous breathing appears on the top of “*P high*.” (From Daoud EG: Airway pressure release ventilation, *Ann Thorac Med* 2:176–179, 2007.)

APRV is well tolerated by patients, requires minimal sedation, and allows spontaneous breathing, which improves ventilation-perfusion mismatching, cardiac performance, and perfusion to a number of tissue beds including the gut and liver.⁹⁵⁻⁹⁷ APRV has been used in parturients,⁹⁸ but no large, randomized trials have been conducted. In a case series, pregnant women with severe life-threatening ARDS were successfully managed with APRV.⁹⁸ The investigators concluded that APRV was lifesaving for their cases and should be considered for other parturients with ARDS.

PRONE VENTILATION

Mechanical ventilation in the prone position can improve oxygenation in most ARDS patients, and 50% maintain improved oxygenation after they are returned to the supine position.⁹⁹ Prone positioning during mechanical ventilation is thought to achieve several beneficial physiologic effects: improved aeration of well-perfused dorsal atelectatic lung areas, improved alveolar recruitment, relief of cardiac compression on the lung posteriorly, and improved mobilization of secretions.

Several randomized trials have compared supine with prone positioning in nonpregnant patients with ARDS and acute lung injury. They universally demonstrate improved oxygenation (i.e., decreased alveolar-to-arterial oxygen gradient), especially 1 hour after deployment.¹⁰⁰⁻¹⁰² However, none has demonstrated mortality improvement.

Complications related to prone positioning include pressure sores, endotracheal tube displacement or obstruction, loss of venous access, vomiting, and edema. Data on prone ventilation in pregnant patients have not been obtained. Anticipated problems of deploying prone ventilation in pregnant patients, beyond those already listed for nonparturients, include difficulty suspending the patient’s gravid abdomen off of the bed and difficulties in accomplishing fetal monitoring while prone.

PULMONARY EDEMA

Pregnant women are predisposed to developing pulmonary edema for numerous reasons, including increased plasma volume and CO in conjunction with decreased colloid oncotic pressure, which occurs normally over the course of pregnancy. Alterations in the balance of hydrostatic and oncotic pressure between the pulmonary vessels and the interstitial spaces can cause egress of fluid from the vascular space into the interstitium and manifest clinically as pulmonary edema.

Approximately 1 in 1000 pregnancies is complicated by pulmonary edema. In a review of almost 63,000 pregnancies, Sciscione and coworkers found that pulmonary edema occurred most often during the antepartum period (47%); 39% occurred in the postpartum period and the remaining 14% occurred in the intrapartum period.¹⁰³ In this series, the two most common causes of pulmonary edema were cardiac disease and tocolytic use (25.5% each). The remaining cases were caused by fluid overload (21.5%) and preeclampsia (18%).

The management of patients with pulmonary edema focuses on establishing the diagnosis, determining the cause, and improving oxygenation. Principles for improving oxygenation are similar to those previously discussed for general causes of ARDS.

COLLOID ONCOTIC PRESSURE ABNORMALITIES

Four forces affect fluid balance between vascular and interstitial spaces. The colloid oncotic pressure is the force exerted primarily by albumin and other proteins within the capillary and holds fluid within the vascular space. The oncotic pressure within the interstitial space counterbalances this effect working to hold fluid in the interstitium. Hydrostatic forces exert effects opposite to their corresponding colloid oncotic pressure forces and are present within the vessel and interstitium.

The colloid oncotic pressure decreases over the course of pregnancy, and by term, it approximates 22 mm Hg.¹⁰⁴ This is approximately 3 mm Hg lower than pre-pregnancy values as a result of the dilutional effect of plasma expansion. An isolated decrease in oncotic pressure, as can occur in pregnancy or in patients with nephrotic syndrome, is usually well compensated and does not lead to pulmonary edema unless complicated by additional factors such as increased intravascular pressure or pulmonary injury resulting in increased vascular permeability.¹⁰⁵ Excessive intravenous fluids, blood loss, decreasing colloid oncotic pressure after delivery, and the postpartum autotransfusion effect can place patients at further increased risk for pulmonary edema.

CARDIOGENIC PULMONARY EDEMA

Pulmonary edema due to primary cardiac conditions with or without alterations in colloid oncotic pressure is referred to as cardiogenic (hydrostatic) pulmonary edema. CO is the algebraic product of heart rate and stroke volume. At some point, the heart is no longer able to increase CO in response to increasing preload because of intrinsic cardiac abnormalities or excessive fluid administration, resulting in overload. If LV outflow is restricted, blood intended to empty into the left atrium remains in the pulmonary vasculature, reflected by increased PCWP, LV end-diastolic pressure, and PA pressure. The net result is an increase in the PA hydrostatic pressure. When the PA and pulmonary capillary pressure exceeds the interstitial pressure, fluid is forced out of the pulmonary vasculature into the interstitial spaces, resulting in pulmonary edema.

TTE or TEE can assist in distinguishing whether pulmonary edema is cardiogenic in origin. Evidence of poor ventricular systolic function can be identified by a decreased ejection fraction, as seen in patients with a cardiomyopathy. Echocardiography can also identify valvular abnormalities (e.g., aortic stenosis, mitral stenosis), which can compromise cardiac function and predispose patients to pulmonary edema.

PULMONARY EDEMA IN THE SETTING OF PREECLAMPSIA

Pulmonary edema develops in approximately 2.5% of preeclamptic patients, most commonly in the postpartum period.^{60,106,107} The cause is incompletely understood but is likely multifactorial in origin. Impaired LV function can be a result from the increased SVR, and concomitant diastolic dysfunction can occur, increasing the patient's susceptibility to pulmonary edema, especially in the setting of fluid overload. Preeclamptic patients can lose significant amounts of albumin through the urine and can have decreased albumin production, both of which lower the colloid oncotic pressure. In preeclamptic patients, the pressure can decrease to 18 mm Hg by term and

drop further to 14 mm Hg after delivery.⁶⁰ Endothelial damage also leads to increased capillary permeability.

Preeclamptic patients with pulmonary edema that fails to respond to oxygen, diuresis, and fluid restriction, especially when combined with oliguria, often require additional monitoring to guide optimal therapy. For a series of 10 patients with severe preeclampsia who underwent placement of a PA catheter, the findings were quite varied. Five patients demonstrated a decreased colloid oncotic pressure in the setting of increased PCWP, two patients had LV failure that explained the pulmonary edema, and three patients had increased pulmonary vascular permeability.¹⁰⁸

TOCOLYTIC-INDUCED PULMONARY EDEMA

In the past, the use of parenteral β -agonists such as terbutaline and ritodrine was more common and became associated with the development of pulmonary edema.^{103,109} As the use of parenteral β -agonists for tocolysis has decreased, the incidence of pulmonary edema related to tocolytic use appears to have diminished. Magnesium does not appear to be an independent risk factor for pulmonary edema.¹¹⁰

Shock

Shock is a life-threatening medical condition that occurs when the perfusion of substrates to tissues is inadequate to sustain cellular aerobic respiration. The clinical presentation of shock usually includes a low blood pressure, tissue hypoxia (manifested differently depending on the type), and increased lactic acid levels in the blood. Oxygen deficiency occurs at the tissue level because of inadequate delivery of oxygenated blood, is evidenced by mottled extremities when the cause is cardiogenic shock or hypovolemic shock (most commonly due to hemorrhage) and obstructive shock (e.g., cardiac tamponade, pneumothorax, pulmonary embolus). In the case of distributive shock (e.g., sepsis, neurogenic causes, anaphylaxis), the skin is often warm and vasodilated, but perfusion can be inadequate to other organs (e.g., splanchnic). Shock can also result from conditions that disrupt the uptake or use of oxygen at the cellular level, as occurs in certain septic conditions (e.g., necrotizing myocutaneous infections) and histocytic shock disorders (e.g., cyanide toxicity, carbon monoxide intoxication).

Hemorrhage is the most common cause of hypovolemic shock in the general and obstetric population. Hypovolemic shock can result from other sources of extreme volume depletion, including vomiting, diarrhea, and fluid shifts into the interstitium (e.g., severe burns, inflammatory conditions, anaphylaxis). Cardiogenic shock occurs in older patients in the general population who have coronary artery disease, acute myocardial ischemia, and pump failure. In the obstetric population, significant coronary artery disease is rare, and cardiogenic shock more commonly results from valvular disease, pulmonary artery hypertension, and viral myocarditis.

Some shock conditions disrupt the coupling of Do_2 and oxygen use at multiple levels; for example, anaphylaxis and neurogenic shock cause hypovolemia and vasodilation, which can decrease Do_2 . Sepsis and anaphylaxis are associated with leaky capillaries and development of interstitial edema, which can impair delivery of Do_2 at the tissue level. Sepsis causes vasodilation and hypovolemia, and certain infections are

associated with the release of specific toxins that can impair cardiac function and the uptake and use of oxygen at the cellular level.

In obstetric patients, shock most commonly results from hemorrhage and sepsis. Regardless of the cause, therapy is directed at restoring tissue oxygenation by eliminating the causative factors, ensuring adequate intravascular volume repletion, and improving cardiac function and circulation. Difficulty in diagnosing causative factors and reversing this phenomenon explains the high mortality rates for patients with shock.

SEPSIS AND SEPTIC SHOCK

Definitions of Sepsis

In early 2013, the Surviving Sepsis Campaign published the third edition of evidence-based guidelines for the diagnosis and management of sepsis and septic shock. The definitions reflect the understanding that sepsis conditions exist along a continuum of increasing severity while sharing a common pathophysiology. This continuum begins after the body develops a systemic response to an infection and may progress to multiorgan dysfunction with hemodynamic instability and death.

Sepsis is defined as the presence of probable or documented infection accompanied by systemic manifestations of infection. Severe sepsis occurs when sepsis progresses to include organ dysfunction or tissue hypoperfusion (i.e., infection-induced hypotension, elevated lactate, or oliguria). Septic shock is defined as persistent sepsis-induced hypotension despite adequate fluid resuscitation (Box 71-2 and Table 71-6).¹¹¹

Only a few studies have characterized the hemodynamic effects of septic shock in parturients; however, most provide a clinical picture similar to sepsis in nonparturients. In one small series of 10 obstetric patients with sepsis, SVR and myocardial function were depressed but improved with therapy.¹¹² Mabie and associates described similar findings for a series of 18 parturients with septic shock. The main hemodynamic characteristics of nonsurvivors with septic shock included lower blood pressure, stroke volume, and LV stroke work index compared with survivors.¹¹³ Those with diminished CO on admission had the worst prognosis.¹¹³

BOX 71-2 DIAGNOSTIC CRITERIA FOR SEVERE SEPSIS, SEPSIS-INDUCED TISSUE HYPOPERFUSION, OR ORGAN DYSFUNCTION

Hypotension due to sepsis
Elevated lactate levels
Urine output <0.5 mL/kg/hr for >2 hr despite adequate fluids
Acute lung injury with PaO₂/FiO₂ <250 without pneumonia as source of infection
Acute lung injury with PaO₂/FiO₂ <200 with pneumonia as source of infection
Creatinine >2 mg/dL
Bilirubin >2 mg/dL
Platelet count <100,000/μL
Coagulopathy (INR >1.5)

Data from Levy MM, Fink MP, Marshall JC, et al: 2001 SCCM/ESICM/ACCP/ATS/SIS International Sepsis Definitions Conference, Crit Care Med 31:1250-1256, 2003.

TABLE 71-6 Diagnostic Criteria for Sepsis

Diagnostic Criteria	Clinically Acceptable Definitions, and Diagnostic Ranges
General variables	<p>Infection documented or suspected and some of the following:</p> <ul style="list-style-type: none"> • Fever (core temperature >38.3°C) • Hypothermia (core temperature <36°C) • Heart rate >90 beats/min or >2 SD above the normal value for age • Tachypnea • Altered mental status • Significant edema or positive fluid balance (>20 mL/kg over 24 hr)
Inflammatory variables	<ul style="list-style-type: none"> • Hyperglycemia (plasma glucose >140 mg/dL or 7.7 mmol/L) in the absence of diabetes • Leukocytosis (WBC count >12,000 /μL) • Leukopenia (WBC count <4,000 /μL) • Normal WBC count with >10% immature forms • Plasma C-reactive protein >2 SD above the normal value • Plasma procalcitonin >2 SD above the normal value
Hemodynamic variables	<ul style="list-style-type: none"> • Arterial hypotension (SBP < 90 mm Hg, MAP <70 mm Hg, or an SBP decrease >40 mm Hg in adults or <2 SD below normal for age) • SvO₂ > 70% • Cardiac Index >3.5 L/min/m²
Organ dysfunction variables	<ul style="list-style-type: none"> • Arterial hypoxemia (PaO₂/FiO₂ < 300) • Acute oliguria (urine output <0.5 mL/kg/hr for at least 2 hr despite adequate fluid resuscitation) • Creatine increase >0.5 mg/dL • Coagulation abnormalities (INR > 1.5 or aPTT > 60 s) • Ileus (absent bowel sounds) • Thrombocytopenia (platelet count <100,000/μL) • Hyperbilirubinemia (plasma total bilirubin >4 mg/dL or 70 mmol/L)
Tissue perfusion variables	<ul style="list-style-type: none"> • Hyperlactatemia (>1 mmol/L) • Decreased capillary refill or mottling

aPTT, activated partial thromboplastin time; INR, international normalized ratio; MAP, mean arterial blood pressure; SBP, systolic blood pressure; SD, standard deviation; SvO₂, mixed venous oxygen saturation; WBC, white blood cell.

Incidence and Mortality

In the nonpregnant population in the United States, sepsis is the number one cause of death in the ICU with mortality rates approaching 30%.^{114,114a} The incidence of sepsis in the general population is between 300 and 1031/100,000, depending on the assessment method used. The incidence continues to steadily increase by 13% annually; however, recent data suggest the mortality rate is declining.^{114a,114b} Fortunately, only a small percentage of these deaths are caused by gynecologic or obstetric problems. The incidence of sepsis in the obstetric population is much lower than in that of the general population (0.6% to 0.3%),¹¹⁷ and mortality rates are also low. Bacteremia is not uncommon in obstetric patients, but these patients appear to be less likely to progress to septic shock. The incidence of septic shock in pregnant patients is estimated at 1 in 8000.^{113,115,116}

Mortality rates associated with septic shock in pregnancy are unclear and are derived primarily from small series of cases, but they appear to be much lower than for the nonpregnant population. Estimates range from 12% for severe sepsis to 30% for septic shock patients.^{112,113,115,118,119} Improved outcomes for pregnant patients have been attributed to a younger patient population, type of organisms, sites of infection more easily accessed and treated, and lower rates of coexistent diseases.

Pathophysiology of Sepsis

Sepsis is a complex condition that originates with host invasion by an offending organism. After infection, macrophages are recruited, bind to the organism, and initiate a cascade of responses resulting in the activation of the inflammatory and coagulation cascades and recruitment of additional inflammatory cells, such as leukocytes. Initially, the sepsis response was postulated to be the result of an exaggerated inflammatory response. Initial pharmacologic approaches therefore targeted suppression of the inflammation process, including high-dose corticosteroids and agents to block cytokines such as tumor necrosis factor- α (TNF- α) and interleukin-1 β (IL-1 β).¹²⁰ These approaches were unsuccessful, as expected given the complexity of the sepsis syndrome. Increasingly, the roles of anti-inflammatory mediators and genetics in the sepsis cascade have become appreciated.¹²¹ Activation of the inflammatory cascade after infection releases interleukins, tumor necrosis factors, interferons, prostaglandins, platelet activation factor, oxygen free radicals, nitric oxide, complement, and fibrinolysis.¹²² Sepsis occurs when the release of pro-inflammatory mediators in response to infection exceeds the boundaries of the local environment, leading to a more generalized response. Widespread cellular injury may occur when the immune response becomes generalized; cellular injury is the precursor to organ dysfunction. Postmortem studies have shown widespread endothelial and parenchymal cell injury. Mechanisms proposed to explain the cellular injury include tissue ischemia, cytopathic injury, and an altered rate of apoptosis (programmed cell death).

Hemostatic mechanisms are also affected in severe sepsis. Initiation of the clotting cascade results from macrophages and monocytes involved in production of inflammatory mediators. Endothelial damage also contributes to the procoagulant effect, causing platelet activation and suppression of protein C activity. These derangements in the hemostatic balance lead to clotting factor consumption, fibrin deposition, thrombin generation, and decreased platelets.¹²³ The resultant microthrombi negatively impact end-organ function, contributing to the clinical

features of organ dysfunction that are commonly associated with severe sepsis and septic shock, including oliguria, increasing creatinine levels, ARDS, and hepatic dysfunction. In severe cases, consumption of clotting factors can be substantial enough to cause hemorrhagic complications from DIC. Figure 71-8 shows the sepsis cascade.

Common Causative Organisms

In contrast to the situation for pregnant patients, gram-positive organisms have surpassed gram-negative organisms as the most common cause of sepsis in the general population.¹¹³ Infections in obstetric patients tend to be polymicrobial, and many organisms are part of the normal vaginal flora. The most frequent organisms include groups A, B, and G streptococci, *Escherichia coli*, *Streptococcus oralis*, *Staphylococcus aureus*, and *Citrobacter* and *Fusobacterium* species. The two most common bacterial etiologies of lethal peripartum sepsis identified, however, are group A β -hemolytic *Streptococcus* infection and *E. coli*. The source of infection in pregnant women is typically the genitourinary tract and includes lower urinary tract infections, pyelonephritis, chorioamnionitis, endometritis, and more rarely septic abortion, necrotizing fasciitis, and toxic shock syndrome. Respiratory sources, including bacterial and viral pneumonia, are also encountered.^{112,113,115,116,124}

Clinical Manifestations

The clinical presentation of septic shock results from hypotension primarily from vasodilation but also from intravascular volume depletion because of extravasation of fluid into the interstitium. This decreases blood pressure and also cardiac preload, which leads to a tachycardic response in an attempt to maintain or increase the CO. Later, circulating inflammatory mediators may exert a direct myocardial depressant effect, impairing cardiac performance. Clinically, the patient may have evidence of infection, fever, or positive blood culture results.

In the septic shock state, multiple organ systems are affected. The central nervous system may be affected, and obtundation may occur because of a direct toxin effect on the brain and because of cerebral hypoperfusion. The cardiovascular system is affected in many ways. The vasculature dilates, causing an effective intravascular hypovolemia. Endothelial injury from circulating toxins leads to extravasation of fluids into the interstitium, causing further intravascular volume depletion. Direct myocardial depression may occur. Pulmonary dysfunction is common in sepsis, even when the primary infection is not in the lungs. As the body's entire circulation passes through the lungs, the lungs are exposed to circulating toxins and inflammatory mediators. This can lead to extravasation of fluid into the lung interstitium and acute lung injury, which may progress to ARDS, all of which have deleterious effects on oxygenation.

The gastrointestinal tract is a common source of gram-negative sepsis. Gastrointestinal perfusion may be compromised during periods of hypotension from any type of shock, leading to a compromise in intestinal mucosal integrity and subsequent translocation of vasoactive substances and gut bacteria. This may lead to or worsen sepsis. Renal dysfunction is common, ranging from oliguria to significant kidney injury necessitating dialysis. Causes include renal hypoperfusion from hypotension, kidney injury from circulating cytokines, and nephrotoxic agents such as antibiotics and radiocontrast dye. The hematologic system is also affected. A leukocytosis with neutrophil predominance is seen in early sepsis, but later in

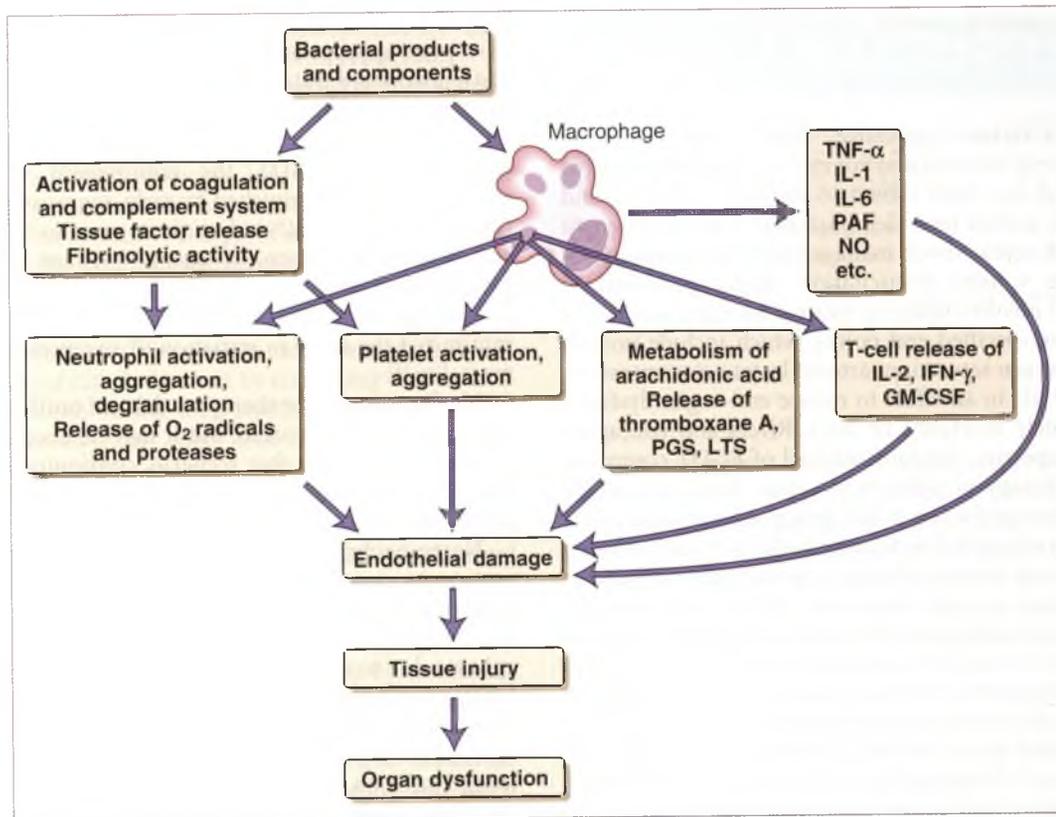

Figure 71-8 The sepsis cascade. Hemostatic mechanisms are affected in patients with severe sepsis, and derangements in the hemostatic balance lead to clotting factor consumption, fibrin deposition, thrombin generation, decreased platelet numbers, tissue injury, and organ dysfunction. GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; IFN- γ , interferon- γ ; LTS, leukotrienes; NO, nitric oxide; PAF, platelet-activating factor; PGS, prostaglandin synthesis; TNF- α , tumor necrosis factor- α . (Adapted from Bone RC: *The pathogenesis of sepsis*, *Ann Intern Med* 115:457-469, 1991.)

sepsis, as immune function declines, leukopenia may be seen. Hyperglycemia typically results from altered adrenal responsiveness, insulin resistance, and increased catecholamines and cortisol levels. Many patients develop a relative adrenal insufficiency and may require therapy with corticosteroids.

Obstetric-Specific Management

If the patient is at a viable gestational age and is undelivered with evidence of sepsis or septic shock, the fetal status should be monitored closely with continuous fetal heart rate monitoring and ultrasound evaluation to estimate fetal weight, assess amniotic fluid volume, and confirm gestational age. Uterine perfusion and oxygenation are adversely affected as sepsis progresses. Contractions are often encountered, possibly as a result of decreased uterine perfusion and decreased Do_2 to the myometrium. Tocolysis should be undertaken with caution because the side effects of the medications (e.g., tachycardia, vasodilation) may impair physiologic adaptations to sepsis. If maternal status can be corrected and fetal status remains reassuring, delivery can be avoided. The decision about whether to proceed with delivery can be challenging, particularly if maternal status is deteriorating. The fetus may not tolerate labor due to poor uterine perfusion and maternal hypoxemia, or the mother may be too unstable to safely undergo a surgical procedure. If the source of infection is the uterus, as in septic abortion or chorioamnionitis, evacuation of the uterus is necessary. In one recent study of severe sepsis and septic shock in pregnancy,

patients with septic shock required delivery very soon after diagnosis, whereas patients with severe sepsis remained undelivered 60% of the time. In viable gestations, emergent delivery by cesarean section was necessary in 71% of patients.¹¹⁹

General Sepsis Management Guidelines

The primary goals of sepsis management are summarized in the most recent Surviving Sepsis Campaign guidelines^{111,125}:

- Protocol for initial resuscitation to the following targets within the first 6 hours of diagnosis:
 - CVP 8-12 mm Hg
 - MAP \geq 65 mm Hg
 - UO \geq 0.5 mL/kg/hr
 - Central venous oxygen saturation 70% or mixed venous oxygen saturation 65%
 - Normalize lactate levels if elevated
- Identification of the source of infection
 - Obtain cultures before initiating antibiotic therapy
 - Do not delay antibiotic start more than 45 minutes to obtain cultures
 - Imaging, when appropriate, to localize source
- Institution of empiric antibiotic therapy within 1 hour of diagnosis
- Source control (e.g., for chorioamnionitis, uterine evacuation is necessary)

Another primary goal introduced with the most recent guidelines includes screening for sepsis and performance

improvement to identify patients who will benefit from implementation of the above approach early in the course of their disease.

Volume Resuscitation. Aggressive fluid replacement to improve circulating intravascular volume is a mainstay of sepsis management and has been shown to improve CO, DO_2 , and survival. Several studies have demonstrated a survival benefit for patients with septic shock managed with protocol-driven, early, aggressive volume resuscitation. Early, goal-directed therapy (EGDT) involves tailoring treatments and resuscitative efforts to achieve specified end points, which include normal mixed venous oxygen saturation, arterial lactate concentration, base deficit, and pH in an effort to reduce end-organ dysfunction and ultimately mortality. In 2001, Rivers and colleagues published a prospective, randomized trial of EGDT compared with standard therapy of patients in septic shock in a single institution.¹²⁶ Therapy for the EGDT group was initiated in the emergency room setting before transfer to the ICU and included placement of central venous catheters with the ability to measure continuous venous oxygen saturation ($ScvO_2$). An elevated $ScvO_2$ level reflects inadequate perfusion and uptake of oxygen in the tissues. Red blood cell transfusions were administered to maintain the hematocrit at 30% or greater, and inotropic agents were added if the $ScvO_2$ level was inadequately corrected (<70%). The protocol called for a 500-mL crystalloid bolus every 30 minutes until the CVP reached 8 to 12 mm Hg. The volume of fluid administered to both groups of patients was similar in the first 72 hours (>13 L), but the EGDT group received more volume in the initial 6 hours of therapy (5 versus 3.5 L). This aggressive approach decreased mortality by 16% (30.5% versus 46.5%).

Clinicians have questioned whether modification of this protocol, particularly elimination of the $ScvO_2$ measure, would produce similar results. In 2006, Lin and coworkers randomized patients to EGDT without measurement of $ScvO_2$ and confirmed survival benefit.¹²⁷ Patients randomized to receive modified EGDT were significantly less likely to die (71.6% versus 53.7%), spent fewer days in the hospital, had shorter periods intubated, and were at less risk for developing sepsis-associated central nervous system and renal dysfunction compared with controls.

Because of this encouraging survival and morbidity data, EGDT is being widely adopted in the management of severe sepsis, but it remains to be confirmed whether this approach will result in similar improved outcomes in a pregnant population. Similarly, the precise end points of resuscitation need to be defined for septic pregnant women.

The most recent Surviving Sepsis Campaign guidelines recommend the following approach to volume resuscitation¹¹¹:

- Crystalloids are the fluids of choice for the initial resuscitation
- Avoid use of hydroxyethyl starches
- Albumin for patients requiring large volumes of crystalloid
- Initial fluid challenge goal minimum of 30 mL/kg crystalloids

Optimization of Hemodynamic Performance. In addition to replacing intravascular volume to improve perfusion and cardiac preload, early pharmacologic interventions to improve vascular tone, cardiac contractility, and cardiac preload confer

a considerable survival advantage.^{111,125-127} If the patient fails to respond appropriately to aggressive fluid resuscitation efforts, vasopressors are indicated to improve vascular tone, resulting in improved cardiac return, CO, peripheral perfusion, and DO_2 . The target is to reach a MAP of 65 mm Hg. In the initial publication on EGDT, the requirement for vasopressors was significantly diminished by early, aggressive fluid resuscitation (37% versus 51%), but there was no difference in the requirement for inotropic agents between the two groups (9% versus 15%).¹²⁶ Vasopressors were initiated to maintain a MAP greater than 65 mm Hg. Use of a similar protocol minimized the delay in initiation of vasopressors and reduced mortality.¹²⁷

Ideally, vasopressor therapy is delayed until adequate volume resuscitation has occurred, but it may be necessary emergently in some patients. In that scenario, continuing efforts to wean the vasopressor are recommended while simultaneous volume replacement continues.

Norepinephrine is the first-line vasopressor for non-obstetric septic patients with diminished blood pressures.¹¹¹ Vasopressor drug preferences have not been defined in the obstetric population of septic patients. Norepinephrine is favored over phenylephrine due to the renal preservation effect (i.e., more efferent renal arterial vasoconstriction than afferent). Norepinephrine is also the endogenous vasopressor and may have other, unrecognized benefits. Norepinephrine should not be given as a prolonged infusion, unless intravascular volume is confirmed to be adequate, preferably by using a dynamic measure of volume responsiveness or echocardiographic evaluation.

If norepinephrine fails to achieve target MAP, epinephrine may be added or substituted. Vasopressin may be added to epinephrine if needed to increase MAP or to decrease norepinephrine dose. The maximum recommended dose for vasopressin is 0.03 unit/min. Low-dose vasopressin infusions are not recommended as first-line therapy in this setting.

Receptors for vasopressin are found in the myometrium, kidneys, bladder, adipocytes, hepatocytes, platelets, and spleen.¹²⁹ The myometrial receptors can theoretically lead to placental underperfusion and fetal stress, but little has been published on this phenomenon in the critical care or obstetric literature. However, intramyometrial injection of vasopressin has been used to significantly decrease blood loss during hysterectomy, presumably through the same mechanism.^{130,131} Accordingly, prolonged infusion of vasopressin should be considered to have risks to the fetus in septic obstetric patients and should be employed only with concomitant fetal monitoring and only as salvage therapy.

Dopamine and phenylephrine are not recommended as first-line agents for septic shock treatment. Their use should be limited to a highly select group of patients.¹¹¹

The most recent Surviving Sepsis Campaign guidelines recommend the following approach to vasopressor use in septic shock¹¹¹:

- Target MAP of 65 mm Hg
- Norepinephrine is first choice agent
- Epinephrine in addition to or in place of norepinephrine when needed to meet MAP goal
- Vasopressin 0.03 unit/min may be added to norepinephrine to improve MAP or decrease norepinephrine dose
- Low-dose vasopressin not recommended as initial therapy
- High-dose vasopressin (>0.03-0.04 unit/min) reserved for salvage therapy

- Dopamine to be used only in select patients, and low-dose dopamine should not be used for “renal protection”
- Phenylephrine is not recommended except in highly select circumstances

Vasopressin. When sepsis is severe, low levels of vasopressin infusion can be required to run concomitantly with the vasopressor therapy. Vasopressin V_1 receptors are located in vascular smooth muscle in the systemic, splanchnic, renal, and coronary circulations.¹²⁸ The target effect of vasopressin is stimulation of the V_1 receptors in the systemic circulation and augmentation of catecholamine function. Vasopressin also enhances the vasoconstrictor action of catecholamines by enhancing the sensitivity of vascular smooth muscle to sympathetic stimulation in a dose-dependent manner, an effect that may restore vascular tone in patients with septic shock.

The V_1 receptors are also found in the myometrium, kidneys, bladder, adipocytes, hepatocytes, platelets, and spleen.¹²⁹ The myometrial V_1 receptors can theoretically lead to placental underperfusion and fetal stress, but little has been published on this phenomenon in the critical care or obstetric literature. However, intramyometrial injection of vasopressin has been used to significantly decrease blood loss during hysterectomy, presumably through the same mechanism.^{130,131} Accordingly, prolonged infusion of vasopressin should be considered to have risks to the fetus in septic obstetric patients and should be employed only with concomitant fetal monitoring and when maternal demise may otherwise occur.

Although vasopressin is widely used in treating septic shock and results in higher systemic pressures than when it is not used, the outcome data supporting its use are controversial, with most efficacy demonstrated in less severe cases. The Vasopressin in Septic Shock Trial (VASST) analyzed patients in septic shock requiring vasopressors for at least 6 hours and showed no increased survival at day 28 between the group randomized to vasopressin (AVP) and those randomized to norepinephrine (35.4% versus 39.3%; $P = .27$). There was no significant interaction term between treatment groups and degree of severity of shock. However, when the groups were stratified into those with more severe hypotension (i.e., requiring more than 15 $\mu\text{g}/\text{min}$ of norepinephrine) and those with less severe hypotension (i.e., requiring less than 15 $\mu\text{g}/\text{min}$ of norepinephrine), the patients with less severe disease had increased survival with AVP at 28 days (26.5% versus 35.7%; $P = .05$) and 90 days (35.8% versus 46.1%; $P = .04$). Because of the marginal degree of significance and multiple comparisons, the investigators state that this finding should be interpreted with caution and considered only for generating hypotheses.¹³² This trial is the largest randomized controlled trial (RCT) powered for mortality that compares low-dose vasopressin with norepinephrine infusion in patients with septic shock.¹³³ The most recent Surviving Sepsis Campaign guidelines recommend vasopressin (0.03 unit/min) may be added to norepinephrine in an effort to increase MAP or decrease norepinephrine dosage. It is not recommended to be used as single initial vasopressor in the setting of septic shock.¹¹¹

Dopamine. Dopamine hydrochloride is one of the most commonly employed first-line vasopressors in the intensive care setting. Dopamine's β - and α -adrenergic effects are dose dependent. Low doses (<3 $\mu\text{g}/\text{kg}/\text{min}$) stimulate predominantly dopaminergic receptors, increasing renal blood flow, but not necessarily renal viability. Moderate doses (5 to 10 $\mu\text{g}/\text{kg}/\text{min}$)

TABLE 71-7 Vasoactive Agents for Management of Septic Shock

Agent	Dose	Hemodynamic Effect
Norepinephrine	0.01-0.19 $\mu\text{g}/\text{kg}/\text{min}$	\uparrow CO, $\uparrow\uparrow$ SVR
Epinephrine	0.05-0.5 $\mu\text{g}/\text{kg}/\text{min}$	\uparrow CO, \downarrow or $\uparrow\uparrow$ SVR, dose dependent
Vasopressin	0.03 unit/min	\uparrow or \downarrow CO, $\uparrow\uparrow$ SVR
Dobutamine	1-20 $\mu\text{g}/\text{min}$	\uparrow CO, \uparrow or \downarrow SVR

CO, cardiac output; SVR, systemic vascular resistance; \uparrow , increased; $\uparrow\uparrow$, significantly increased; \downarrow , decreased.

stimulate dopamine and β -receptors, improving myocardial contractility, CO, and renal perfusion without or with only minimal α -adrenergic effects. As the dose increases (>10 to 20 $\mu\text{g}/\text{kg}/\text{min}$), α -adrenergic effects predominate, resulting in increased SVR in addition to increased CO. In a viable gestation requiring vasopressor support, fetal monitoring is essential because dopamine has decreased uterine perfusion in an animal model.¹³⁴

Dobutamine has primarily β_1 - and some β_2 -adrenergic effects. Dobutamine improves CO with minimal impact on heart rate, but it does decrease PVR and SVR. In the EGDT protocol, dobutamine was used to improve oxygen consumption in patients who failed to respond to fluid resuscitation, dopamine infusion to improve MAP, and red cell transfusion to correct anemia.¹²⁶ Table 71-7 lists other commonly used vasopressor agents for the management of severe sepsis and septic shock.

Culturing Probable Infectious Sources and Initiating Antimicrobial Therapy. Common sources of infection in the obstetric population are the uterus and genitourinary tract, and gram-negative bacteria are the primary organisms. In the non-obstetric population, gram-positive organisms represent most of those isolated in septic patients, followed closely by gram-negative bacteria.¹¹⁷ Samples for cultures should be collected from blood and any suspected site, including the uterus if necessary, for identification of the organisms and antibiotic sensitivities before starting empiric therapy whenever possible.¹¹¹ Empiric antimicrobial therapy targeted at the suspected organisms should be started within 1 hour of presentation and should not be delayed until culture results are available.¹³⁵⁻¹³⁸

In an obstetric and postpartum population, antibiotic coverage usually consists of β -lactam antibiotics (penicillins, cephalosporins, carbapenems and monobactams) with or without an aminoglycoside. Monotherapy with a carbapenem or third- or fourth-generation cephalosporin is as effective as a β -lactam antibiotic in combination with an aminoglycoside in non-neutropenic patients with severe sepsis.¹³⁹ In undelivered patients, tetracycline derivatives and quinolones should be avoided. For patients in whom methicillin-resistant *S. aureus* (MRSA) is suspected, treatment should commence with parenteral vancomycin or linezolid. Because the prevalence of MRSA in many hospitals is higher than 50%, this is the wisest choice for the septic patient. After culture results become available, antibiotic therapy can be refined. Linezolid has been assigned a category C by the U.S. Food and Drug Administration (FDA), and it should be used only when the benefits to the mother

outweigh any theoretical deleterious effects. In nursing mothers, linezolid should be avoided. Although there are no data on excretion of linezolid into human milk, in rats, it is secreted into milk at levels similar to those in plasma.

For clostridial myositis and myonecrosis, high-dose penicillin in combination with clindamycin or metronidazole is appropriate. The decision to use or not use vancomycin empirically depends on the treating physician's clinical estimate about the likelihood that the patient is infected with MRSA. In cases of mixed synergistic infection, appropriate coverage for facultatively aerobic gram-negative rods and obligate anaerobes includes a carbapenem, a β -lactam/ β -lactamase inhibitor, or a third- or fourth-generation cephalosporin in combination with metronidazole.

Because some of the manifestations of streptococcal necrotizing fasciitis are toxin mediated, clindamycin should be used in conjunction with other antibiotics, because as a protein synthesis inhibitor, it shuts down further production of exotoxins and M-protein production by group A streptococci, a phenomenon known as the Eagle effect.¹⁴⁰ Linezolid, a 50S ribosome unit-binding agent, has similar protein synthesis inhibition activity¹⁴¹ against streptococcal pyrogenic exotoxin A. Clindamycin is also active in situations of high bacterial density (i.e., in wounds), against which β -lactams and vancomycin may not be, and it covers most anaerobes of gynecologic origin.

Source Control. After cultures have been obtained, appropriate antibiotic therapy initiated, and stabilization of the patient has begun, attention should focus on source control. This can include removal of indwelling lines and catheters, with replacement if necessary. In some sources of infection, such as urosepsis, aggressive surgical or percutaneous drainage is not usually indicated; in other cases, such as localized extremity abscess, surgical drainage should occur as soon as the patient has stabilized.¹⁴²

In the case of necrotizing myocutaneous infections, especially those resulting from clostridial species and or group A streptococci, immediate source control (i.e., wide surgical excision) is required for the patient's survival. In this scenario, delay in excision of affected tissues can have a dramatic negative effect on the patient's condition.¹⁴³ Evaluation of the abdomen and pelvis by ultrasound or computed tomography (CT) can assist in identification of an intraabdominal, pelvic, or perineal abscess.

When drainage of an intraabdominal or pelvic abscess is necessary, the percutaneous approach is often preferable. In obstetric conditions, evacuation of the uterus by suction curettage (in septic abortion) or delivery of the neonate (in viable gestations) should occur after initiation of antibiotics and stabilization of the patient. Postpartum hysterectomy may be necessary if the patient fails to respond to antibiotics and the uterus is the suspected source.

Adjunctive Therapies in Sepsis Management

Glucose Control. In the critically ill population, hyperglycemia is a common phenomenon attributable to insulin resistance and escalations in glucagon, cortisol, and catecholamine levels, which promote glycogenolysis and gluconeogenesis.¹⁴⁴ In 2001, Van den Berghe and colleagues published a large, prospective RCT that demonstrated that tight glycemic control (blood glucose of 80 to 110 mg/dL) decreased in-hospital mortality by 34% among critically ill patients, most of whom were postoperative patients. Septic patients exhibited an even more

impressive 76% reduction in mortality as a result of aggressive euglycemia with insulin therapy.¹⁴⁵ Other significant benefits to tight glycemic control included fewer ventilator days, less time in the ICU, decreased risk for septicemia, and a reduced need for dialysis. The beneficial effects of tight insulin control were demonstrated in two other small trials.^{146,147} However, in a similar RCT evaluating critically ill medical patients, tight glucose control (i.e., maintaining a blood glucose level below 110 mg/dL) was shown to decrease mortality only for the most severely ill and those who spent more than 3 days in the ICU.¹⁴⁸ Since these studies were published, several additional RCTs and meta-analyses of intensive insulin therapy have been performed.¹⁴⁹⁻¹⁵⁸ The RCTs¹⁴⁹⁻¹⁵⁴ studied mixed populations of surgical and medical ICU patients and found that intensive insulin therapy did not significantly decrease mortality, and several meta-analyses¹⁵⁵⁻¹⁵⁸ confirmed that intensive insulin therapy was not associated with a mortality benefit in surgical, medical, or mixed ICU patients. All of these studies reported a much higher incidence of severe hypoglycemia (glucose \leq 40 mg/dL) with intensive insulin therapy. Furthermore, the larger, most recent NICE SUGAR trial showed that intensive insulin therapy to achieve tight glycemic control was associated with increased risks of severe hypoglycemia and death.¹⁵⁹

Based on the above evidence, the current Surviving Sepsis Campaign guidelines recommend a protocolized approach to blood glucose management in ICU patients with severe sepsis, commencing insulin dosing when two consecutive blood glucose levels are \geq 180 mg/dL and that blood glucose levels be monitored every 1 to 2 hours until glucose values and insulin infusion rates are stable, then every 4 hours thereafter.¹¹¹

Women in the second half of pregnancy are insulin resistant and have higher circulating insulin levels compared with their nonpregnant counterparts. They also have lower fasting glucose levels than nonpregnant women. Aggressive euglycemia in the critically ill pregnant patient likely results in excessive rates of hypoglycemia and cannot be recommended. The optimal blood glucose range in critically ill parturients remains to be defined, but it is likely between 140 and 170 mg/dL.

Corticosteroids. Empiric administration of high-dose corticosteroids does not improve survival among unselected septic patients and may worsen outcomes due to secondary infection.^{160,161} However, as the pathophysiology of sepsis has become better understood, the contribution of relative adrenal insufficiency in critically ill septic patients and the potential benefits of selective lower-dose corticosteroid replacement have reemerged.

Stresses such as pain, fever, anxiety, hypovolemia, and severe illness can stimulate marked increases in cortisol levels. In septic shock, the adrenal gland can become less responsive to adrenocorticotropic hormone (ACTH, cosyntropin) and fail to mount adequate corticosteroid production. In the setting of septic shock, cortisol levels may be increased overall, but the magnitude of increase after ACTH administration may be blunted. This phenomenon is described as relative adrenal insufficiency.^{162,163}

An RCT by Annane and coworkers demonstrated a survival benefit (mortality rate of 37% versus 47% for controls) for patients with septic shock treated with low-dose hydrocortisone and fludrocortisone.¹⁶⁴ Patients with documented blunted adrenal responsiveness (maximum cortisol increase \leq 9 μ g/dL after ACTH stimulation test using 250 μ g of cosyntropin) also benefited from a reduced need for vasopressor support. All of these patients had elevated baseline cortisol levels.

The Corticosteroid Therapy of Septic Shock (CORTICUS) trial, an RCT involving 499 patients with septic shock, followed groups receiving placebo or hydrocortisone (50 mg) intravenously every 6 hours for 5 days, followed by a tapering regimen.¹⁶⁵ In this large study, administration of the low-dose steroid did not improve 28-day mortality (35% versus 32% for the placebo group). This was also true in two predefined subgroups (those with inadequate versus adequate adrenal reserve) established using the cosyntropin stimulation test. The CORTICUS investigators recommended against using the cosyntropin stimulation test to differentiate between those who would or would not benefit from low-dose steroid augmentation. Regardless of the baseline cortisol levels, the hydrocortisone group had faster reversal of shock than other patients (3.3 versus 5.8 days for the placebo group).

A 2004 meta-analysis (pre-CORTICUS trial)¹⁶⁶ and a 2009 meta-analysis (post-CORTICUS by the same investigator)¹⁶⁷ suggest that low-dose steroid replacement is beneficial in severe sepsis and septic shock (SBP < 90 mm Hg for more than 1 hour after adequate volume replacement). Likewise, the Surviving Sepsis Campaign guidelines recommend against using intravenous hydrocortisone as a treatment of adult septic shock patients if adequate fluid resuscitation and vasopressor therapy are able to restore hemodynamic stability, and they suggest not using the ACTH (cosyntropin) stimulation test to identify the subset of patients who should receive hydrocortisone. Steroids should be tapered when vasopressors are no longer required.¹¹¹

The degree of adrenal suppression in pregnant or postpartum septic shock patients and the impact of low-dose steroids on outcomes in this population remain unstudied. The maternal benefits are likely analogous to the nonpregnant adult data. However, fetal effects (also incompletely understood) must be considered. For the septic shock patient who remains undelivered, care should be taken in the choice of corticosteroids. Beta-methasone and dexamethasone cross the placenta and can improve neonatal outcomes for the premature infant. However, both have been associated with worse neonatal outcomes when administered repeatedly in large doses.¹⁶⁸

Other Supportive Therapies for Severe Sepsis. The 2012 Surviving Sepsis guidelines outline recommendations regarding additional supportive therapies for severe sepsis.¹¹¹ Patients with sepsis-induced ARDS should be ventilated with a lung-protective strategy as described earlier in the chapter. A tidal volume of 6 mL/kg of predicted body weight should be targeted, and the upper limit goal for plateau pressures should be 30 cm H₂O or less. PEEP should be applied to avoid alveolar collapse at end-expiration (atelectotrauma) and higher PEEP strategies in patients with moderate and severe ARDS as described by the Berlin definition (PaO₂/Fio₂ 101 to 200 and ≤100, respectively).¹⁶⁹ Mechanically ventilated patients should be maintained with the head of the bed elevated to 30 to 45 degrees in order to limit aspiration risk and the development of ventilator-associated pneumonia. Sedation should be minimized, and specific titration endpoints should be targeted. Neuromuscular blocking agents (NMBAs) should be avoided if possible; however, a short course of NMBAs (<48 hours) in patients with early sepsis-induced ARDS and PaO₂/Fio₂ of 150 mm Hg or less is reasonable.

Red blood cell transfusion should occur only when hemoglobin concentration decreases to less than 7.0 g/dL to target a hemoglobin concentration of 7.0 to 9.0 g/dL. This conservative transfusion strategy applies after tissue hypoperfusion resolves

and in the absence of extenuating circumstances, such as myocardial ischemia, severe hypoxemia, acute haemorrhage, or ischemic heart disease. Patients with severe sepsis should also receive daily pharmacologic prophylaxis against venous thromboembolism unless contraindicated. This can be accomplished with daily subcutaneous low-molecular weight heparin (LMWH) versus twice or three times daily unfractionated heparin. Despite the fact that LMWH is excreted renally, dalteparin at prophylactic dose has been demonstrated not to accumulate in critically ill patients with creatinine clearance less than 30 mL/min. Chemical prophylaxis should be combined with mechanical prophylaxis, such as intermittent compression devices. Stress ulcer prophylaxis should be administered as well, with a proton pump inhibitor (rather than an H₂ blocker) in patients with bleeding risk factors (coagulopathy, mechanical ventilation for >48 hours, and possibly hypotension). Patients should receive oral or enteral nutrition within 48 hours after a diagnosis of severe sepsis/septic shock. Full caloric feeding should be avoided in the first week; low-dose feeding (up to 500 kcal/day) should be used instead, with a formula with no specific immunomodulating supplementation, advancing only as tolerated. Renal replacement therapy is sometimes required in patients with severe sepsis, and similar survival rates have been shown with both intermittent and continuous techniques. Continuous therapies are suggested, however, to facilitate fluid balance in hemodynamically unstable septic patients. Lastly, as with all critically ill patients, early discussion of goals of care and prognosis should be undertaken with patients and their families.

Obstetric Hemorrhage and Hemorrhagic Shock

INCIDENCE AND ETIOLOGY

Obstetric hemorrhage is the leading cause of maternal death after an intrauterine gestation. The overall incidence of maternal death due to hemorrhage is 1.4 case per 100,000 live births. When ectopic gestations are excluded, placental abruption was the most common cause of death (18.5%).¹⁷⁰ The cause of hemorrhage varies by pregnancy outcome. Maternal deaths after a live birth are most likely associated with postpartum hemorrhage. Stillbirths are most likely associated with death due to placental abruption, and undelivered pregnancies occur most often with lacerations or uterine ruptures.¹⁷⁰ A greater risk of death due to hemorrhage is seen among nonwhite women compared with non-Hispanic white women and with advancing age. In an analysis of maternal morbidity and mortality, hemorrhage accounted for 39% of near-miss morbidities. The investigators estimated that 46% of these near-miss events were preventable and were related to communication issues, policies and procedures, failure to identify high-risk status, failure to transfer to a higher level of care, or inappropriate care. Presence of a significant disease state, such as preeclampsia, was also a contributor.¹⁷¹

Causes of obstetric hemorrhage associated with an intrauterine gestation include placental abruption or previa, uterine rupture, surgical lacerations, invasive placentation, uterine inversion, and postpartum hemorrhage usually due to atony or retained products of conception. The source of hemorrhage can usually be determined by assessment of the patient. Concealed hemorrhage (e.g., abruption or liver capsule rupture in HELLP syndrome) is also possible and should be considered in a patient with evidence of shock and no obvious source of hemorrhage.

TABLE 71-8 Clinical Staging of Hemorrhagic Shock by Volume of Blood Loss

Severity of Shock	Findings	Blood Loss (%)	Volume (mL)*
None	None	Up to 20	Up to 900
Mild	Tachycardia (<100 beats/min) Mild hypotension Peripheral vasoconstriction	20-25	1200-1500
Moderate	Tachycardia (100-120 beats/min) Hypotension (80-100 mm Hg) Restlessness Oliguria	30-35	1800-2100
Severe	Tachycardia (>120 beats/min) Hypotension (<60 mm Hg) Altered consciousness Anuria	>35	>2400

*Based on an average blood volume of 6000 mL at 30 weeks' gestation.

Obstetric hemorrhage has been arbitrarily defined as an estimated blood loss of more than 500 mL in a vaginal delivery or more than 1000 mL for cesarean section.¹⁷² Other definitions describe a hematocrit decreased by 10% or the need for transfusion.¹⁷³ However, estimates of blood loss are inaccurate and can vary widely. The true incidence of obstetric hemorrhagic shock is unclear.

CLINICAL STAGING OF HEMORRHAGE

Because of the normal blood volume expansion in pregnancy, clinical signs of hypovolemia are often delayed. Relatively minor signs such as orthostatic hypotension and tachycardia typically do not appear until at least 25% to 30% of the blood volume is lost. Table 71-8 outlines the clinical staging of hemorrhagic shock, depending on severity.

MANAGEMENT

The goal of management of hemorrhagic shock is to identify and control the bleeding source while restoring circulating blood volume and clotting factors. Baseline laboratory evaluation is recommended on recognition of hemorrhage and should include a complete blood cell count, type and cross-match, fibrinogen, prothrombin time (i.e., international normalized ratio [INR]) and activated partial thromboplastin time (aPTT). A basic metabolic panel may be useful to assess renal function and electrolyte disturbances. These laboratory tests should be repeated at regular intervals until the situation has resolved. The Lee-White whole blood clotting time test can be used as a crude method to assess for the presence of DIC. Whole blood is collected in an unheparinized tube and observed. A stable clot should form in 5 to 15 minutes. When bleeding is massive (>1 blood volume in 24 hours), treatment with a 1:1:1 ratio of packed red blood cells, fresh-frozen plasma (FFP), and platelets¹⁷⁴ should commence immediately, and the hospital massive

TABLE 71-9 Colloid Infusions

Colloid	Dose (mL)	Crystalloid Volume Expansion Equivalent	Estimated Duration of Effect (hr)
Albumin			
5% solution	250-1000	4-5 × crystalloid	24
25% solution	100-200	20-25 × crystalloid	24
Hetastarch	500-1000	Similar to 5% albumin	24-36
Dextran (70)	500	1050 mL over 2 hr	24

transfusion protocol should be triggered. Ongoing evaluation using thromboelastography should be employed.¹⁷⁵

Volume Replacement Therapy

Adequate and timely replacement of circulating volume is essential in the management of hemorrhagic shock. This is accomplished by administering crystalloid solutions such as normal saline or colloids such as albumin or blood products.

Choice of the most appropriate combination of fluids to replace circulating volume is controversial. Crystalloid solutions appear to be as effective as colloid solutions in most settings.¹⁷⁶ The Advanced Trauma Life Support (ATLS) course has proposed widely accepted standards for management of the trauma patient. For the patient in hemorrhagic shock, initial resuscitation with 2 L of crystalloid solution is followed by packed red blood cell transfusions.¹⁷⁷

The degree of volume resuscitation is also a matter of debate. Historically, aggressive, early fluid resuscitation was thought to result in improved outcomes. However, later data suggest that excessive fluid resuscitation may destabilize clot formation and stability, worsen hypothermia, and contribute to hemodilution without providing the expected benefit in survival. Most traumatologists recommend resuscitation to allow for permissive hypotension, which maintains SBP in the 80 to 90 mm Hg range until bleeding is controlled.¹⁷⁷⁻¹⁷⁹

Colloid Solutions

Colloid solutions are intravenous fluids containing molecules larger than 10,000 daltons. Packed red cells are considered to be a colloid, but this discussion focuses on additional colloid products. The major advantage provided by a colloid solution is the significant increase in plasma volume compared with a crystalloid solution. Colloid solutions increase intravascular colloid oncotic pressure and draw fluid into the intravascular space. In achieving this effect, extravascular volume can become depleted, and fluid resuscitation should include adequate administration of crystalloids. The degree of plasma expansion depends on the availability of extravascular fluid. In certain clinical settings such as sepsis, surgical trauma, or preeclampsia, vascular permeability is altered, and colloid solutions can escape into extravascular spaces, particularly the lungs, and lead to pulmonary edema. The available colloid solutions include albumin, dextran, and hetastarch. Table 71-9 compares the effects of these agents.

Albumin solutions are available in concentrations of 5% or 25%. A 25-g infusion of albumin temporarily increases intravascular volume by roughly 450 mL over 60 minutes as a result of its considerable oncotic activity. Albumin is cleared rapidly from the circulation, particularly in patients with shock or sepsis.

Dextran solution contains large glucose polymers with mean molecular weights of 40,000 daltons (Dextran 40) or 70,000 daltons (Dextran 70). Dextran 40 is rarely used for the purposes of volume expansion. A 500-mL infusion of 6% Dextran 70 should rapidly expand intravascular volume by more than 1000 mL. Adverse effects of dextran administration include increased bleeding risk and allergic reaction. Anaphylactic reactions affect 1 in 3300 patients receiving dextran. In higher doses (>20 mL/kg/24 hr), dextran may interfere with platelet function, clotting factor activation, and fibrin function. It also may interfere with laboratory cross-matching of blood. Dextran should be used cautiously in patients with hypovolemia due to hemorrhage who may already have a coagulopathy and require further cross-matching of blood.

Hydroxyethyl starch (hetastarch) is a synthetic molecule available in a 6% solution in normal saline (Hespan) or lactated electrolyte solution (Hexend). Like the other available colloid solutions (albumin and dextran), hetastarch induces intravascular volume expansion by increasing oncotic pressure. The effects of hetastarch can persist 24 to 36 hours. As with dextran, it can have a negative impact on the clotting system. Hetastarch can prolong prothrombin and partial thromboplastin times, decreasing platelet counts and reducing clot tensile strength. It therefore should be used cautiously in patients who may have a coagulopathy. Hexend is a newer hetastarch formulation with average molecular weight 670 kDa (range, 450 to 800 kDa) in addition to electrolytes and lactate similar to those of plasma levels. It may have less significant impact on the coagulation profile compared with other colloids and therefore may offer an advantage in the setting of hemorrhage.¹⁸⁰

Blood Component Therapy

Blood product replacement is the cornerstone of successful management of hemorrhagic shock. The variety of blood product components available for transfusion is summarized in Table 71-10, along with their anticipated effects. Whole blood has not been separated into the various components and therefore offers an advantage because it contains clotting factors and platelets in addition to red blood cells. The major limitation to the use of whole blood is the inability to store the product beyond 24 hours. After 24 hours of extravascular storage, platelets and granulocytes are completely lost, and 2,3-diphosphoglycerate is depleted, significantly compromising the oxygen-carrying capacity of the red blood cell. Prolonged storage results in depletion of clotting factors and increasing levels of potassium and ammonia. For these reasons, whole blood is typically separated into its

individual components and stored for later use; it is essentially unavailable in the United States. Individual components are administered to address specific derangements according to clinical indications. The routine administration of clotting factors after every 4 to 6 units of packed red blood cells was previously thought not to improve outcomes.¹⁸¹ However, experience in the military trauma setting has demonstrated that higher ratios of FFP to packed red blood cells result in a survival benefit,^{182,183} and it is thought that this may be helpful in civilian practice, including the treatment of obstetric hemorrhage.

A single unit of packed red blood cells has a hematocrit of approximately 80% and increases the hemoglobin level by 1 g/dL in a 70-kg individual. Removal of white blood cells from the unit of blood (i.e., leukocyte-poor blood) decreases the risk of febrile transfusion reactions. A patient with evidence of acute hemorrhage (>30% blood volume loss), a hemoglobin level between 6 and 10 g/dL with evidence of tachycardia and hypotension, or a hemoglobin level less than 6 g/dL should be considered a candidate for transfusion.^{184,185}

Dilutional thrombocytopenia can occur as a result of massive transfusion in a hemorrhaging patient. After replacement of one blood volume, 35% to 40% of a patient's platelets usually remain; platelet replacement is therefore recommended in the setting of bleeding and significant thrombocytopenia. Platelet counts equilibrate within 10 minutes and can be assessed immediately after completion of the transfusion.

FFP is extracted from whole blood within 6 hours of collection and frozen. A single unit of FFP contains 700 mg of fibrinogen in addition to factors II, V, VII, IX, X, and XI. It is indicated for the replacement of multiple clotting factors in patients with acute hemorrhage and evidence of DIC. The goal is to correct clotting factor deficiencies and to achieve a post-transfusion serum fibrinogen level of approximately 100 mg/dL.

Cryoprecipitate is obtained from FFP and contains factor VIII (80 to 120 units), fibrinogen (200 mg), von Willebrand' factor, and factor XIII. One unit of cryoprecipitate and one unit of FFP will have a similar effect on the fibrinogen level (increase of 10 to 15 mg/dL). Despite its smaller volume, cryoprecipitate more efficiently raises the fibrinogen level than FFP due to its more concentrated formulation.

Complications of Transfusion

Complications resulting from blood component transfusion can vary from infections to immunologic responses. Table 71-11 outlines the frequency of various transfusion-related complications.

TABLE 71-10 Blood Components

Component	Contents	Indications	Volume	Shelf Life	Expected Effect
Packed RBCs	Red cells, some plasma, few WBCs	Correct anemia	300 mL	21 days	Increase Hct 3%/unit, Hgb 1g/unit
Leukocyte-poor blood	RBCs, some plasma, few WBCs	Correct anemia, reduce febrile reactions	250 mL	21-24 days	Increase Hct 3%/unit, Hgb 1g/unit
Platelets	Platelets, some plasma, RBCs, few WBCs	Bleeding due to thrombocytopenia	50 mL	Up to 5 days	Increase total platelet count 7500 mL/unit
Fresh-frozen plasma	Plasma, clotting factors V, XI, XII	Treatment of coagulation disorders	250 mL	2 hr thawed, 12 mo frozen	Increase total fibrinogen 10%-15%/unit
Cryoprecipitate	Fibrinogen, factors V, VIII, XIII, von Willebrand factor	Hemophilia A, von Willebrand disease, fibrinogen deficiency	40 mL	4-6 hr thawed	Increase total fibrinogen 10-15 mg/dL/unit

Hct, hematocrit; Hgb, hemoglobin; RBCs, red blood cells; WBCs, white blood cells.

TABLE 71-11 Transfusion-Related Risks

Disease or Disorder	Incidence
Hepatitis B	1/137,000
Hepatitis C	<1/1,000,000
Human immunodeficiency virus-1	<1/1,900,000
Bacterial contamination	1/38,565
Acute hemolytic reaction	1/250,000-1/1,000,000
Delayed hemolytic reaction	1/1,000
Transfusion-related acute lung injury	1/5,000

Data from Goodnough LT, Brecher ME, Kanter MH, Aubuchon JP: *Transfusion medicine. First of two parts—blood transfusion*, N Engl J Med 340:438–447, 1999; and American Association of Blood Banks: *Circular of Information for the Use of Human Blood and Blood Components*, December 2009.

Minor transfusion reactions are relatively common occurrences and are not caused by hemolysis. Common clinical findings include low-grade fever, urticaria, and hives and result from exposure to incompatible platelet or white blood cell antigens. The use of leukocyte-poor packed red blood cells minimizes these types of reactions. Nonhemolytic reactions do not require discontinuation of the transfusion. Symptoms can be managed with antipyretic agents and antihistamines as needed.

Severe reactions after transfusion are usually a result of a hemolytic reaction from administration of an incompatible unit of blood. Historically, administration of ABO-incompatible blood was thought to occur in 1 case per 600,000 units, but later information suggests that it occurs with much greater frequency (1 case per 25,000 units). Administrative error is the culprit in most of these events, underscoring the need for accurate accounting of transfused units, particularly in an emergent situation.¹⁸⁶ Cardiovascular decompensation with DIC, fever, and renal failure usually develop rapidly after initiation of an incompatible transfusion. Treatment entails immediate discontinuation of the transfusion and supportive care.

Additional Supportive Measures

Red Blood Cell-Saving Devices. In patients at risk for excessive intraoperative blood loss (e.g., suspected placenta accreta), use of an autologous transfusion device (Cell Saver) should be considered.^{172,187} Theoretic risks of inducing amniotic fluid embolism have caused some concern regarding the use of intraoperative cell salvage during cesarean section. However, several reports have validated its safety in this situation.¹⁸⁸⁻¹⁹¹ After delivery of the fetus and clearing the operating field of amniotic fluid, the suction device is changed, and blood is collected into the Cell Saver. In approximately 3 minutes, a unit of blood with a hematocrit of 50% is generated. In one study comparing patients who received blood salvage and autotransfusion during cesarean section with those receiving allogeneic blood transfusions, no differences in the rates of infection, coagulation abnormalities, or respiratory problems were identified.¹⁸⁹ This technology may be particularly valuable for patients who have the potential for severe blood loss or have religious preferences mandating the avoidance of transfused blood products.

Acute Normovolemic Hemodilution. Acute normovolemic hemodilution (ANH) offers an additional option for patients at significant risk for intraoperative hemorrhage. The principle is to dilute the patient's circulating volume so that when bleeding

occurs, it has a lower hematocrit. This is accomplished by collecting blood from the patient preoperatively and placing it into special storage bags that can be obtained from the blood bank. Simultaneously, the patient is given crystalloid solution in a 3:1 ratio, resulting in a dilutional effect that decreases the maternal hematocrit. Intraoperatively, after achieving control of the blood loss or at the discretion of the surgeon, the patient's blood is reinfused, resulting in an increase in the hematocrit. Potential advantages include preservation of clotting factors and decreased likelihood of an allogeneic transfusion and therefore a decreased risk of infectious morbidity, alloimmunization, and immunologic complications. Adverse fetal effects have not been described during this process.^{192,193}

ANH is a time-consuming process and is not appropriate for an acutely hemorrhaging patient. Suggested criteria for ANH include a high likelihood of transfusion; preoperative hemoglobin level of 12 g/dL or higher; absence of clinically significant coronary, pulmonary, renal, or liver disease; absence of severe hypertension; and absence of infection and risk of bacteremia.¹⁹⁴

Other Measures. Supplemental oxygenation and elevation of the lower extremities are usually recommended in the setting of hemorrhage. The use of antishock (MAST) trousers has fallen out of favor after a randomized trial failed to demonstrate a survival benefit.¹⁹⁵

Massive transfusion and blood loss place the patient at significant risk for concomitant abnormalities, which can compromise successful resuscitation. Maintenance of the airway and ventilation cannot be ignored. Management of the hemorrhaging patient should also include regular assessment of coagulation abnormalities and recurrent bleeding, correction of electrolyte abnormalities (particularly calcium and potassium), and maintenance of temperature above 35°C. After control of bleeding is achieved, resuscitation is considered complete if the following goals are met:¹⁹⁶

- Normal or hyperdynamic vital signs
- Hematocrit higher than 20% (transfusion threshold determined by the patient's age)
- Normal serum electrolyte levels
- Normal coagulation function and platelet count of at least 50,000
- Restoration of adequate microvascular perfusion, as indicated by
 - pH = 7.40, with normal base deficit
 - Normalized serum lactate level
 - Normal mixed venous oxygenation
 - Normal or high CO
- Normal urine output

Definitive Therapy for Hemostasis

Control of obstetric hemorrhage must take into consideration the apparent cause of the hemorrhage. For example, one of the most common causes of postpartum hemorrhage is uterine atony, which can be expected to respond to uterine massage and uterotonic agents as first-line therapy. Hemorrhage due to placenta accreta or previa requires a surgical intervention in the setting of hemorrhage. Recombinant factor VIIa (rFVIIa [NovoSeven]) is approved for the management of bleeding in hemophiliacs, but its role is emerging as an off-label adjunctive therapy for the control of catastrophic, coagulopathic bleeding.¹⁹⁷ rFVIIa activates factor X, enhancing thrombin

production and the formation of a stable clot. It is not intended as first-line therapy for the control of hemorrhage, and most investigators recommend use of rFVIIa only after other attempts to control hemorrhage have failed. This includes any necessary surgical approach, appropriate replacement of blood products, and correction of severe acidosis, hypothermia, and hypocalcemia.^{198,199} rFVIIa has been employed for the control of obstetric hemorrhage.²⁰⁰⁻²⁰³ Table 71-12 outlines pharmacologic agents useful in controlling hemorrhage from an atonic uterus.

A newer hemostatic agent, prothrombin complex concentrate (PCC), contains factors II, VII, IX, and X, and it has been employed as an alternative to FFP or factor VIIa alone.²⁰⁴ Rapid reversal of the INR is achieved with PCC in patients on vitamin K antagonist therapy. Factor VIIa and PCC can be advantageous compared with FFP in patients with volume restrictions. However, comparative trials are needed to evaluate the various PCC products, FFP, and rFVIIa with regard to clinically significant outcomes, including dose-related hemostatic effects.

Hemorrhage after a vaginal delivery should prompt a thorough evaluation for and repair of cervical or vaginal lacerations, particularly if an instrumented delivery was performed. If uterine atony fails to respond to uterine massage and uterotonic agents, evaluation for potential retained placental fragments should be performed. Ultrasound may be of assistance in this assessment process, particularly if uterine curettage is necessary.

Intrauterine pressure packs to control life-threatening postpartum hemorrhage have been successful in some cases.^{205,206} However, the technique used to place the packing is integral to its success and can be challenging. Other investigators have attempted to provide packing by modifying various inflatable devices such as Foley catheters, Rüsçh urologic balloon catheters, or Sengstaken-Blakemore tubes.²⁰⁷⁻²¹⁰ Devices specifically designed for local treatment of postpartum hemorrhage have

been introduced, including the SOS Bakri tamponade balloon catheter and the ebb balloon (BridgeMaster Medical, Abingdon-on-Thames, England).²¹¹ The SOS Bakri tamponade balloon catheter has been placed for vaginal delivery and cesarean section.

Surgical Approach to Control Obstetric Hemorrhage. If uterine hemorrhage after vaginal delivery fails to respond to the previous measures, exploratory laparotomy should be performed. If the bleeding is encountered at cesarean section, the same techniques for control of hemorrhage may be applied. The B-Lynch uterine body compression suture has been performed successfully to control hemorrhage due to unresponsive uterine atony and is demonstrated in Figure 71-9.^{212,213} The B-Lynch suture has also been performed in conjunction with placement of an SOS Bakri balloon to achieve hemostasis.²¹⁴

Suture ligation of the ascending uterine arteries (O'Leary suture) is a technically straightforward option to perform in most scenarios. O'Leary reported the successful use of this technique (Fig. 71-10) in the setting of postpartum and postcesarean bleeding.^{215,216} The uterine artery can be visualized and accessed anteriorly or posteriorly. Uterine artery ligation offers the advantage that the uterine arteries are readily accessible with uterine manipulation, and minimal or no vessel dissection is necessary. Hypogastric (internal iliac) artery ligation is more technically challenging, requiring dissection of the retroperitoneal space through the broad ligament. Bilateral ligation is usually necessary to achieve adequate reduction in pulse pressure. The surgeon must be familiar with pelvic vascular anatomy to avoid ureteral injury or inadvertent ligation of the common or exterior iliac artery, which will obstruct blood flow to the lower extremity. If possible, ligation of the vessel should occur below the branch of the superior gluteal artery, as demonstrated

TABLE 71-12 Pharmacologic Agents Useful for Controlling Uterine Atony

Agent	Dose	Considerations/Side Effects
Oxytocin (Pitocin)	10-40 units/L IV 10 units IM	IV bolus may cause PVCs, decreased SVR, tachycardia, and hypotension
Methylergonovine (Methergine)	0.2 mg IM every 2-4 hr, max 5 doses	Increased SVR, increased MAP, increased CVP Side effects include pulmonary edema, seizures, intracranial hemorrhage, retinal detachment, and coronary vasospasm Avoid in patients with hypertension
PG 15-methyl F _{2α} (Hemabate)	0.25 mg IM every 15-90 min, max dose 2 mg	Diarrhea Bronchoconstriction Increased CO, increased heart rate, and increased right heart pressure Increased PVR Decreased SVR Decreased coronary artery perfusion Avoid in patients with asthma
Dinoprostone (PGE ₂)	20 mg per rectum or vagina every 2 hr	Diarrhea, nausea, vomiting Tachypnea, pyrexia, tachycardia Decreased SVR Decreased MAP Increased CO
Misoprostol (Cytotec, PGE ₁)	800-1000 µg per rectum	Diarrhea, vomiting Abdominal pain Headache
Recombinant factor VIIa (NovoSeven)	200 µg/kg initial dose; may repeat with 100 µg/kg at 1 and 3 hr after the first dose	Indicated for persistent bleeding despite adequate first-line therapies May increase risk of thromboembolic events

CO, cardiac output; CVP, central venous pressure; IM, intramuscular; IV, intravenous; MAP, mean arterial pressure; PG, prostaglandin; PVC, premature ventricular contraction; PVR, pulmonary vascular resistance; SVR, systemic vascular resistance.

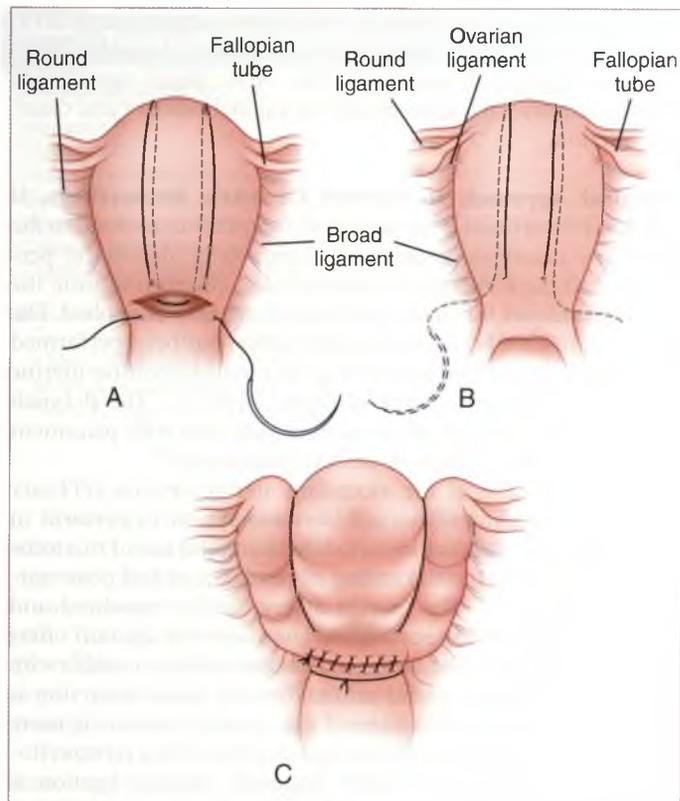

Figure 71-9 B-Lynch surgical technique. A, Anterior view of the B-Lynch stitch placement. B, Posterior view of the B-Lynch stitch placement. C, Anterior view of the completed procedure. (From B-Lynch C, Coker A, Lawal AH, et al: *The B-Lynch surgical technique for the control of massive postpartum haemorrhage: an alternative to hysterectomy? Five cases reported*, BJOG 104:372, 1997. Reprinted with permission.)

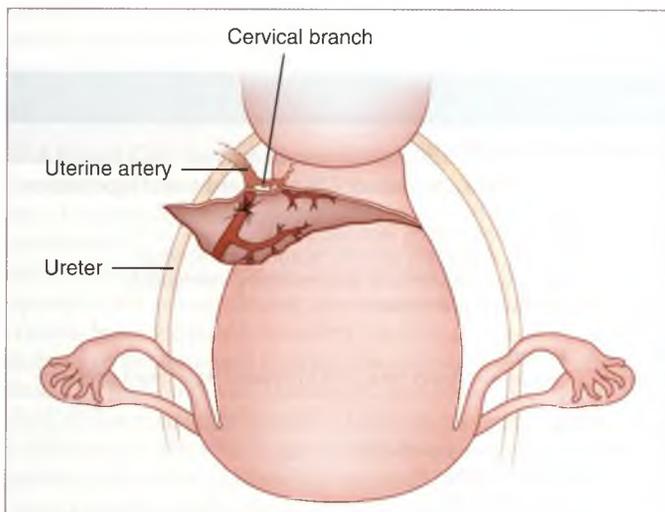

Figure 71-10 Anterior approach to the uterine artery ligation technique for postpartum obstetric hemorrhage.

in Figure 71-11. Because of the technical challenges and questionable efficacy of the procedure (i.e., controlled hemorrhage in only approximately 40% of cases), hypogastric artery ligation is not commonly performed.²¹⁷

The incidence of emergent peripartum hysterectomy for obstetric hemorrhage is less than 0.4 to 0.9 cases per 1000

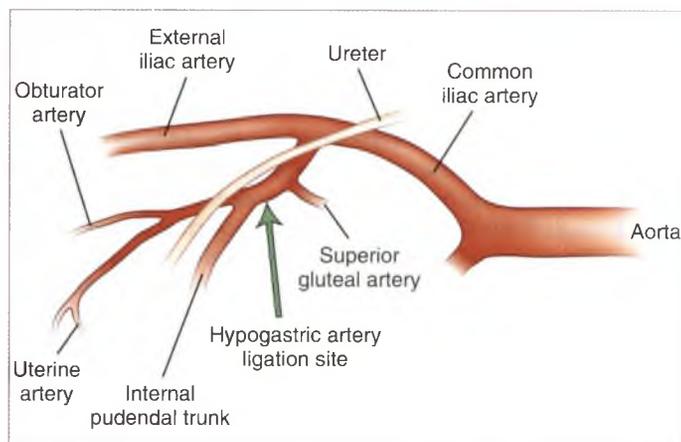

Figure 71-11 Localization of the hypogastric artery along the right pelvic side wall.

deliveries.²¹⁸⁻²²⁶ Abnormal placentation (i.e., previa or accreta), uterine atony, and uterine rupture account for most cesarean hysterectomies. Identified risk factors include cesarean delivery, prior cesarean delivery, multiparity, and advancing maternal age.²²²⁻²²⁸ One study reported peripartum hysterectomy data from a national database between 1998 and 2003 and included more than 18,000 hysterectomies. Although some case series have suggested that invasive placentation appears to be supplanting uterine atony as the leading indication for peripartum hysterectomy, these data suggest they may be equally common.^{218,219,222,229} The incidence of invasive placentation appears directly related to prior uterine surgery, and as cesarean section rates increase, cesarean hysterectomy for this indication can be expected to increase.

Complications associated with emergency peripartum hysterectomy include excessive blood loss and need for blood product replacement, fever, wound infection, ureteral injury, thromboembolic events, cardiac arrest, and death.^{218,220,221,229} Supracervical hysterectomy and total hysterectomy have been described for the management of obstetric hemorrhage, although data are lacking to suggest whether one approach is superior.

Pelvic Artery Embolization. Selective pelvic artery embolization is increasingly used for the management of obstetric hemorrhage. Multiple case series have demonstrated success rates exceeding 90%, with minimal complications.²³⁰⁻²⁴¹ The procedure can be successfully achieved even when active bleeding is not demonstrable at the time of arteriography.^{242,243} In addition to avoiding the morbidity of surgical exploration, it preserves future fertility.²³³⁻²⁴⁵

The procedure is typically performed in the interventional radiology suite. The femoral artery is accessed, and diagnostic arteriography is performed with fluoroscopic imaging to localize the target arteries for embolization. Several options are available for arterial occlusion, including an absorbable gelatin sponge (Gelfoam) or another type of particulate material.

Potential adverse results from the procedure include ischemia or tissue necrosis, infection, nephrotoxicity due to contrast medium, bleeding at the access site, and failure of the embolization. Failure of pelvic artery embolization does not preclude a subsequent surgical attempt at hemorrhage control, but after hypogastric artery ligation is performed, successful

arteriographic embolization is much more difficult to achieve. Between 0% and 17% of patients subsequently require hysterectomy.^{234-243,246}

Trauma in Pregnancy

TRAUMA EPIDEMIOLOGY

Trauma is a leading cause of non-obstetric deaths in the United States, complicating 6% to 7% of all pregnancies.²⁴⁷ It is estimated that almost 4000 fetuses are lost annually due to complications from trauma in pregnancy.²⁴⁸ Most incidents are considered minor, with only 4 cases per 1000 deliveries requiring hospitalization. Of those requiring admission, 24% to 38% proceed to delivery during the hospitalization.²⁴⁹⁻²⁵² Motor vehicle collisions (MVCs) and falls account for most traumatic events among pregnant women, followed by domestic violence, assault, and suicide attempts.^{247,253-256} Domestic violence escalates during pregnancy and is estimated to affect 20% of pregnant patients.²⁵⁷ Homicide is most often the result of a gunshot wound (58%), stabbing (18%), strangulation (14%), or battery (8%).²⁵⁸ A high index of suspicion for domestic violence is warranted for any pregnant woman presenting for evaluation after a traumatic injury.

INJURY SEVERITY SCORING

The Injury Severity Score (ISS) is often used for nonpregnant patients to quantify the risk of an adverse outcome.²⁵⁹ Unfortunately, the ISS does not translate well to the pregnant population and has not been shown to reliably predict outcomes in this group. El-Kady and colleagues published a large population-based study of more than 10,000 trauma evaluations for pregnant women.²⁴⁹ Patients were divided into those delivering during the admission for trauma and those discharged to deliver at a later date. Falls were most common among women requiring delivery, followed by MVCs. As expected, the likelihood of abruption, uterine rupture, maternal death, and adverse neonatal outcomes, including fetal and neonatal death, was significantly higher for the group that delivered during the trauma admission. Women discharged undelivered after trauma had improved maternal outcomes compared with the delivered patients, but they remained at increased risk for preterm delivery, abruption, and need for blood products compared with uninjured controls.

These risks could not accurately be predicted by the ISS. Adverse fetal and neonatal outcomes were not increased after discharge. In contrast, in the group that delivered during the trauma admission, a high ISS (>10) was associated with the highest risk of adverse outcome. However, a lower ISS score (<10) was still associated with a significant increase in serious adverse events, including abruption, uterine rupture, and maternal or fetal death. The Revised Trauma Score (RTS), which includes the Glasgow Coma Scale, appears to be just as limited in its ability to accurately predict pregnancy outcome after trauma.²⁶⁰

INJURY PATTERN RELATIONSHIP TO GRAVID UTERUS

The gravid uterus is vulnerable to injury after blunt trauma, such as occurs with MVCs, assaults, and falls. The most common

mechanism of severe injury for the pregnant woman is an MVC. Three-point restraint seat belts are safe for pregnant women, and they decrease the risk of serious maternal injury and fetal loss.²⁶¹⁻²⁶⁴ Proper use of seat belts is a significant predictor of maternal and fetal outcomes after an MVC.^{262,265,266} Approximately one third of pregnant women do not wear seat belts because of discomfort, inconvenience, or fears of hurting the baby. Prenatal education significantly improves proper seat belt use.²⁴⁸ The addition of airbags does not appear to be problematic for pregnant patients and may further reduce the risk of injury.²⁶³

COMMON MATERNAL INJURIES ASSOCIATED WITH FETAL DEMISE

The severity of the MVC is most strongly associated with adverse fetal outcomes.²⁶⁶ However, even minor collisions can result in fetal demise; an estimated 90 to 369 losses per year result from MVCs. In one large series of 5352 injured pregnant women, minor trauma during the first or second trimester was found to be independently associated with fetal demise, with an adjusted odds ratio of 1.78 and 1.65, respectively.²⁵⁶ Placental abruption is a particularly concerning complication after blunt trauma and MVCs, because it may lead to premature labor and delivery, concealed hemorrhage, consumptive coagulopathy, fetomaternal hemorrhage, fetal hypoxemia, and death.

Detection of an abruption presents a challenge in the patient without vaginal bleeding. Abruption occurs in approximately 7% of patients after trauma, but the severity of the injury does not appear to correlate with the presence of an abruption or predict outcome. Most placental abruptions occur in patients after relatively minor trauma and without evidence of serious injury.^{247,255,267-269} Unfortunately, a negative ultrasound result does not reliably exclude the presence of a placental abruption. At best, the sensitivity of ultrasound to detect abruption is 25%.²⁷⁰ Sonographic findings correlate with fetal outcome. Fetal mortality correlated with the estimated percentage of placental detachment, the location (retroplacental), and size (>60 mL) of hemorrhage.^{270,271}

GENERAL TRAUMA MANAGEMENT CONSIDERATIONS

On initial presentation, the pregnant trauma patient should be evaluated similarly to the nonpregnant patient (i.e., airway, breathing, circulation, disability, and exposure). Assessment and stabilization of the airway, breathing, and circulation are the primary steps, followed by systematic evaluation for evidence of traumatic injuries. Rapid confirmation of gestational age and assessment of fetal well-being are necessary. This assessment can be performed during any required maternal stabilization efforts.

Care should be taken to provide displacement of the gravid uterus off the aorta and vena cava. Compression of the great vessels occurs after the uterus reaches a size consistent with 20 weeks' gestation, and it decreases CO. Displacement can be accomplished manually, by moving the patient to a lateral position, or by placing a wedge under the hip.

The evaluation of a pregnant trauma patient must take into consideration the physiologic changes of pregnancy that affect the clinical presentation. Pregnant women near term have expanded their circulating blood volume by 40% to 50%. As a result, significant intraabdominal or intrauterine blood loss can

occur with minimal changes in maternal vital signs. Prognosis is worse if the patient develops hypotension and tachycardia.²⁶⁹ In a viable gestation, a reassuring fetal heart rate tracing demonstrates adequate uterine perfusion and acts as a barometer of maternal status. As maternal cardiovascular status deteriorates, uterine perfusion suffers, which manifests as contractions and fetal heart rate abnormalities. Fibrinogen levels decrease in the setting of hemorrhage as a result of consumption. In pregnancy, fibrinogen levels are substantially elevated, and low or even normal-range fibrinogen levels should raise concern about the pregnant patient.

BLUNT ABDOMINAL TRAUMA

Because of the gravid uterus, patterns of traumatic injury are somewhat different in pregnant patients after blunt abdominal trauma, particularly after MVCs. Upper abdominal injury to the spleen and liver are more common, whereas bowel injuries occur less frequently.^{272,273} Traumatic uterine rupture occurs, but less commonly with minor trauma.^{249,274} The risk increases with increasing severity of trauma and size of the uterus. Most ruptures occur in the fundal or posterior regions. With traumatic rupture of the uterus, fetal mortality approaches 100%.

Pelvic fractures are typically related to trauma as a result of an MVC. A pelvic fracture should raise concern about a significant bleeding risk and coexistent intraabdominal trauma, such as splenic or hepatic laceration or urinary tract injury. Open pelvic fractures carry a high mortality rate for mother and fetus, and they often require a colostomy. Closed pelvic fracture is not a contraindication to vaginal delivery if the birth canal is not compromised. The decision should be based on the stability of the fracture and presence of pelvic deformities. Fetal head injuries are more common when a pelvic fracture is sustained.²⁷⁵

PENETRATING ABDOMINAL TRAUMA

Gunshot and stab wounds are the most common penetrating injuries in pregnant women. They are usually a result of assault or a suicide attempt. The enlarged uterus increases the likelihood that the uterus and fetus will sustain injury; therefore, the prognosis is usually less favorable for the fetus. Penetrating trauma to the lower abdomen carries a lower likelihood of maternal bowel injury. The impact of gunshot wounds is less predictable and varies according to entry site and angle, size of the uterus, and distance from the gun. Visceral injuries occur in 19% of pregnant patients, compared with 82% in nonpregnant patients. Mortality rates are correspondingly lower for pregnant victims (3.9 versus 12.5%).²⁷⁶ Stab wounds are more likely to involve the upper abdomen during pregnancy, and in such settings, bowel injury should be considered.^{276,277}

ABDOMINAL EVALUATION AFTER TRAUMA

Evaluation of the patient after blunt or penetrating abdominal trauma includes an assessment of the likelihood of intraabdominal bleeding. Focused abdominal ultrasound for trauma (FAST) and CT are commonly employed for this purpose.

Diagnostic peritoneal lavage (DPL) is less commonly used because of the widespread use of FAST, but it may be employed in the hemodynamically unstable patient to rule out bleeding or gross visceral perforation. DPL is performed by entering the abdomen through a small midline incision halfway between the

umbilicus and symphysis pubis. If 10 mL of blood or more is immediately aspirated, the DPL result is positive; if not, a liter of saline is infused into the peritoneal cavity, and the recovered lavage fluid is examined for evidence of blood, bile, or bowel contents. DPL, although lacking organ specificity, remains the most sensitive test for mesenteric and hollow viscus injuries.

FAST examinations are rapid, noninvasive, and can be repeated many times. FAST and DPL fail to evaluate retroperitoneal and diaphragmatic injuries and poorly identify solid organ injuries. Exploratory laparotomy is recommended when there is suspicion of bowel perforation or active hemorrhage. In the pregnant patient, DPL may occasionally be employed to evaluate the peritoneal fluid characteristics after equivocal CT or FAST results. Tetanus toxoid prophylaxis should be used for the same indications as in the nonpregnant patient.

FETAL DELIVERY AND MONITORING

Delivery timing and route are dictated by maternal and fetal status and must be individualized. If laparotomy is necessary, hysterotomy is not automatically indicated. If there is evidence of uterine injury, delivery may be necessary. Pregnancy should not preclude the use of diagnostic testing considered to be otherwise indicated in the trauma patient. No single diagnostic radiologic imaging study can provide enough radiation exposure to adversely affect a developing fetus. Radiation exposure of less than 5 rads has not been associated with fetal abnormalities or pregnancy loss, and the radiation delivered by abdominal and pelvic CT scans fall substantially below this threshold.²⁷⁸ Magnetic resonance imaging (MRI) does not employ ionizing radiation, and no adverse fetal effects have been reported from in utero exposure.²⁷⁸ Table 71-13 lists the anticipated dose of radiation exposure to the fetus from commonly required examinations for a trauma patient.

External fetal heart rate and contraction monitoring are recommended after blunt trauma in a viable gestation. Pearlman and coworkers performed a prospective study monitoring patients for a minimum of 4 hours after blunt trauma. Eighty-eight percent of the patients had no visible trauma; 2.4% were critically injured. Most patients had contractions, and 70% required admission beyond the initial 4-hour observation period. Of these, 19% went on to deliver, with one fetal death. The abruption incidence in this subgroup was 9.4%. No adverse events occurred in the group of patients if contractions did not occur more frequently than every 15 minutes. However, all women suffering an adverse perinatal outcome contracted every 2 to 5 minutes at some point during the initial 4-hour

TABLE 71-13 Estimated Fetal Radiation Exposure from Common Procedures for a Trauma Patient

Radiologic Examination	Fetal Radiation Exposure (cGy)*
Chest (PA/lateral)	<<0.1
Abdomen	0.15-0.26
Pelvis	0.2-0.35
Hip	0.13-0.2
CT of head	<<0.1
CT of abdomen	0.04
CT of pelvis	2.5

*1 cGy = 1 rad.

CT, computed tomography; PA, posterior-anterior.

observation period. Severity of injury did not predict abruption or adverse outcomes.²⁵⁵ Other investigators have since validated the concept that fewer than one contraction every 15 minutes is not associated with an adverse outcome after blunt trauma to pregnant patients.^{247,267,272} Data from five series enrolling 921 pregnant trauma patients indicate an overall abruption rate of 3% (29 of 921), with 8 fetal injuries and 12 fetal deaths reported.^{252,255,267,272,279}

A minimum of 4 hours of fetal heart rate and contraction monitoring is recommended after blunt trauma to pregnant women, regardless of injury severity. Beyond the initial observation period, the recommended duration for monitoring is not clear, particularly for patients with evidence of contractions. Investigators recommend at least 24 hours because most serious complications appear to occur soon after the traumatic event.

ASSESSMENT OF FETOMATERNAL HEMORRHAGE EXTENT AND RhoGAM NEEDS

Fetomaternal hemorrhage is another potential concern after blunt trauma. A Kleihauer-Betke test can provide an estimate of the amount of fetal blood within the maternal circulation, which is particularly important in determining if additional doses of RhoGAM are necessary in Rh-negative women. The test is based on the detection of fetal hemoglobin. If the presence of fetal hemoglobin within maternal red cells reflects a hemoglobinopathy, the result will be falsely elevated (Fig. 71-12). Spontaneous fetomaternal hemorrhage can occur throughout pregnancy in the absence of any identified precipitating event, but the volumes appear to be low.²⁸⁰

Fetomaternal hemorrhage is thought to occur with greater frequency after blunt trauma, and Kleihauer-Betke testing is often recommended, but the available data suggest that a positive Kleihauer-Betke test result does not alter management. In five studies enrolling 1047 pregnant women who had Kleihauer-Betke testing performed after blunt trauma, 104 (10%) had evidence of fetomaternal hemorrhage.^{247,252,255,272,281} In only two cases did the result potentially alter management; one case was a significant hemorrhage requiring delivery as a result of a

non-reassuring fetal assessment, and one underwent umbilical cord blood sampling but did not require transfusion or delivery. For the remainder, the result did not appear to affect management. In another study, no difference was found in the frequency of positive Kleihauer-Betke test results between normal controls and pregnant women being evaluated for trauma.²⁸¹

Burns in Pregnancy

BACKGROUND

According to the American Burn Association, 40,000 people annually require hospitalization due to burns. Of these, 60% are admitted to one of the 125 specialized burn centers in the United States. Each of these centers admits about 200 patients per year, compared with the average of 3 burn admissions to nonspecialized burn centers.^{282,283} Although current U.S. statistics are not available, burn injuries appear to be more common in developing countries, as evidenced by fewer case reports from the United States. In two larger series of burns in pregnancy collected in India and Iran, approximately 7% of burn victims were pregnant patients. Burns resulting from flames or scald account for 78% of cases; the remainder were caused by contact with a hot object (8%), an electrical source (4%), or a chemical agent (3%) or had other causes (6%).²⁸⁴

CLASSIFICATION

Burns are characterized by the depth and size of the involved area. Partial-thickness burns (formerly classified as first-degree and second-degree burns) involve superficial skin layers and are capable of reepithelialization. These burns are painful, blistering injuries that can be red, white, or pink. These wounds are usually managed with topical agents and dressings. If healing does not occur within 3 weeks, management converts to that for a more serious burn.

Full-thickness burns (formerly classified as “third-degree burns”) are the most severe and do not regenerate epithelium. These burns are not blistering and are painless. They can be gray, white, or brown. Early surgical excision of the eschar is the current standard of management in the United States. Full-thickness wounds hold the greatest potential for scarring, contractures, and infection and should be referred to a burn center.^{285,286}

Prognosis of pregnant and nonpregnant patients is directly related to the percentage of body surface area involved. Figure 71-13 demonstrates one method of estimating the percentage of total body surface burned in nonpregnant adults. A modification for the pregnant patient has not been created, but the gravid abdomen should be taken into account when estimating body surface area involvement. The severity of the burn increases in proportion to the degree of involvement (Table 71-14).

OUTCOMES

Severe burns are morbid events with significant short-term and long-term consequences. The pregnancy does not appear to negatively impact the outcome after a burn, but the burn can significantly impact pregnancy outcome. Maternal and fetal survival most depend on the severity of the burn.^{282,283,287} In one of the largest series of burns in pregnancy, Maghsoudi and colleagues prospectively collected data on 51 pregnant burn victims

$$\text{Fetal red blood cells} = \frac{\text{MBV} \times \text{maternal Hct} \times \% \text{ fetal cells (KB)}}{\text{Newborn Hct}}$$

If KB result is 0.9% : 0.9% of maternal blood volume (MBV) is fetal origin.

MBV is assumed to be 5000 mL for an average-size woman at term.

Maternal hematocrit (Hct) should be measured; assume approximately 35%.

Normal Hct for term newborn infant can be assumed to be 50%, if the patient is undelivered.

$$\text{Fetal red blood cells} = \frac{5000 \times 0.35 \times 0.009}{0.5} = 31.5 \text{ mL}$$

Therefore, the fetus has hemorrhaged 31.5 mL of red cells into the maternal circulation. At term, the neonatal blood volume is 125 mL/kg. If the Hct is assumed to be approximately 50% at term, the actual amount of blood lost is 63 mL. In a term infant assumed to weigh 3500 g, the blood volume is approximately 438 mL, and the fetus has lost 7% of its blood volume.

Figure 71-12 Calculation of the volume of fetomaternal hemorrhage using the Kleihauer-Betke (KB) results.

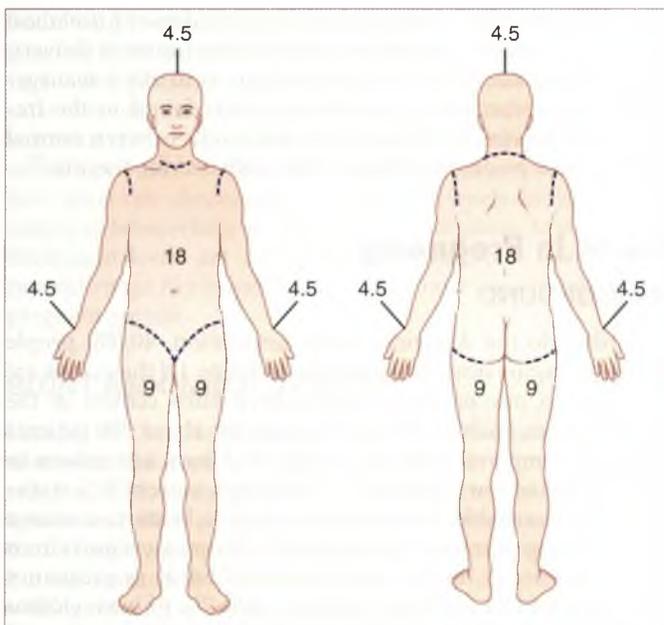

Figure 71-13 Body surface areas. The diagram depicts the relative percentage of the total body surface area of defined anatomic areas in nonpregnant adults. (From Wolf SE, Herson DN: Burns. In Townsend CM, Beauchamp RD, Evers BM, et al, editors: Sabiston's textbook of surgery, ed 17, Philadelphia, 2004, Saunders.)

TABLE 71-14 Classification of Burn Severity

Classification	Body Surface Area Percentage
Minor	<15% partial thickness <2% full thickness
Moderate	15%-25% 2%-10% full thickness
Major	>25% >10% full thickness Any burn involving face, eyes, ears, feet, or perineum Inhalation injury or electrical injury

admitted to a referral burn center in Iran over a 9-year period.²⁸³ The overall maternal mortality rate was 39%, and the fetal mortality rate was 45%. The most significant predictor of maternal and fetal mortality was total body surface area involvement exceeding 40% and the presence of inhalation injury. These patients suffered severe burns; the mean burn surface area was 38%. For nonsurvivors, the mean burn surface area was 69%. Other studies have found similar results.²⁸²

MANAGEMENT

Management of the pregnant burn patient is approached similarly to that of a nonpregnant patient. Acute management of the burn victim should address aggressive fluid resuscitation, evaluation for inhalation injury and airway maintenance, assessment of carbon monoxide poisoning and anemia, prevention of infection, and wound management.

The initial priority is recognition of smoke inhalation injury, carbon monoxide poisoning, and airway management. Carbon

monoxide crosses the placenta easily, and fetal hemoglobin has a higher affinity for carbon monoxide than adult hemoglobin. Hyperbaric oxygen may play a role in treating carbon monoxide poisoning.²⁸⁸ Early intubation should be considered to maximize Do_2 in a patient with inhalation injury and to protect against aspiration.

Fluid losses after a serious burn are substantial as a result of third spacing due to edema and evaporative loss from damaged skin. The fluid deficit is easily underestimated in a pregnant patient. The normal physiologic adaptations of pregnancy, including up to 40% increase in blood volume, 40% increase in CO, and 20% decrease in SVR are not reflected in the fluid replacement strategies recommended for nonpregnant burn patients. The commonly used Parkland formula recommends replacement with lactated Ringer solution (4 mL/kg of body weight per percent of body surface area burned). Fifty percent of the calculated replacement volume is administered over the initial 8 hours, and the remainder is given over the next 16 hours. In one report, the Parkland formula underestimated fluid requirement in a pregnant burn patient by almost 10 L.²⁸⁹ Given the lack of guidelines for pregnant patients, fluid resuscitation should be individualized to achieve hemodynamic stability, adequate urine output, and uterine perfusion. Electrolyte disturbances should also be anticipated and addressed.

Burns are associated with a significant hypermetabolic state and markedly increased nutritional requirements. Hypermetabolism can be minimized by providing adequate pain relief; aggressive wound management with excision, grafting, and occlusive dressings; and managing temperature and adequate fluid replacement. Attention to adequate nutrition is essential and usually requires enteral and parenteral feeds.²⁹⁰

Wound infection and sepsis are significant risks after burn injury. Bacteremia results from colonization of the burn area. The most common organisms encountered are *S. aureus*, *Pseudomonas aeruginosa*, and *Candida albicans*.²⁹¹ Aggressive management of the wound with excision of the eschar, grafting, and occlusive dressings in addition to topical and systemic antibiotics reduce the risk of infectious complications. The patient may be at increased risk for venous thromboembolic events.

Assessment of fetal well-being in a viable gestation should not be overlooked. Intravascular depletion, hypoxemia, hypermetabolism, and infection can adversely affect the fetus. Continuous monitoring is recommended in a viable gestation, particularly during the early stages of management. If the abdomen is involved by burn, direct auscultation may be limited and continuous fetal heart rate monitoring not feasible. Sterile coverings are available for the heart rate monitor and ultrasound probes to minimize infection risk. Vaginal ultrasound assessment may also be considered in some situations.

Contractions and preterm labor are to be expected, particularly in a severely burned pregnant patient, although the frequency is unknown. Few data are available to guide the use of tocolytic medications. Tocolysis should therefore be undertaken cautiously with an appreciation of the hemodynamic effects and other side effects of the drug. Hypovolemic patients may not tolerate β -agonists such as terbutaline, because they may already be in a high-output state. Because of the high fetal mortality rates associated with severe burns, delivery may be the most judicious alternative for a viable gestation. Most investigators recommend cesarean section for the usual obstetric indications. Delivery by cesarean section through a burned abdomen

and vaginal delivery through a burned perineum have been reported.^{289,292-294}

Cardiopulmonary Resuscitation and Perimortem Cesarean Section

Cardiac arrest in a pregnant patient is a rare event. According to the available data on U.S. maternal mortality, most maternal deaths occur after a live birth. However, 13% occur while the patient remains undelivered. Of these, 3% are related to a spontaneous or induced abortion.²⁹⁵ The data do not reflect the frequency of cardiac arrest occurring in the antepartum period with subsequent maternal survival. In a review of 38 patients delivered in the perimortem period by cesarean section, the causes included trauma, cardiac abnormalities, embolism, magnesium overdose, sepsis, intracranial hemorrhage, anesthetic complications, eclampsia, and uterine rupture.²⁹⁶ The causes of cardiac arrest in pregnant women are more likely to be acute than chronic in nature and therefore may be more amenable to aggressive interventions. Perimortem cesarean section is a rarely performed procedure, partly due to the few instances of witnessed maternal cardiac arrest and the lack of understanding of the procedure and its role in the management of this group of patients.

Several physiologic changes of pregnancy can negatively impact attempts at cardiopulmonary resuscitation (CPR):

- Aortocaval compression by the gravid uterus in the supine position
- Reduced functional residual capacity and increased oxygen consumption
- Reduced chest wall compliance
- Delayed stomach emptying and decreased esophageal sphincter tone that increase the aspiration risk
- Increased CO requirements for uterine perfusion

Particular attention should be paid to relieve aortocaval obstruction by the pregnant uterus in the supine position. CPR can provide only 30% of CO when the patient is supine.²⁹⁷ The compression on the vena cava and aorta are relieved in the left lateral position, but compressions are more difficult to perform. Beyond a rotation of more than 27 degrees from horizontal, managing the patient's body weight and performing compressions are challenging. Eighty percent of the force generated in the supine position is preserved at this angle.^{296,298} Manual displacement of the uterus while maintaining the patient supine to facilitate chest compressions may be considered. Early intubation is recommended to minimize aspiration risk. The use of sodium bicarbonate to correct maternal acidosis should be undertaken with caution because of concerns regarding the potential for worsening fetal acidosis. Electrocardioversion can be performed in a pregnant patient; the recommendations are the same as for nonpregnant patients.²⁹⁹

Rapid restoration of maternal circulation and reversal of hypoxia are the most effective ways to minimize negative impact on the fetus. However, if return of spontaneous circulation does not occur, attention must then be directed to evacuation of the uterus by cesarean section. The purpose of advocating cesarean section in the setting of maternal cardiac arrest is to improve the likelihood of an intact neonatal outcome and simultaneously improve maternal resuscitative efforts. In 1986, Katz and associates initially advocated performing a cesarean section at 4 minutes after instituting cardiopulmonary resuscitation (CPR).³⁰⁰ This recommendation was based on the theory that

TABLE 71-15 Perimortem Cesarean Deliveries with Surviving Infants with Reports of Time from Maternal Cardiac Arrest to Delivery of the Infant, 1985-2004

Time (min)	Gestational Age (wk)	Number of Patients
0-5	25-42	8 (normal infants)
		1 (retinopathy of prematurity and hearing loss)
		3 (condition not reported)
6-10	28-37	1 (normal infant)
		2 (neurologic sequelae)

emptying the uterus would improve CO generated by chest compressions once the obstructing uterus was emptied. Maternal neurologic injury could be avoided if cerebral perfusion improved by 6 minutes, the time at which cerebral injury occurs after cessation of blood flow. They then reviewed the literature and reported neonatal outcomes at various time intervals after delivery. From these data, it is clear that delivery within 5 minutes of arrest was most likely to result in good neonatal outcomes.^{80,300}

Katz and colleagues²⁹⁶ reviewed 34 published cases of perimortem cesarean section between 1985 and 2004 to assess whether the 4-minute rule was valid. In this series, 79% (30 of 38) delivered live infants (including three sets of twins and one set of triplets). Data were available regarding the arrest-to-delivery interval for 25 infants and are presented in Table 71-15. Similar to the data from earlier series, prolonging the arrest-to-delivery interval decreased the likelihood of intact survival, although apparently normal neonates were delivered even in the group requiring more than 15 minutes.

In a Danish population study reviewing perimortem cesarean section between 1993 and 2008, none of the 12 perimortem cesarean sections performed was accomplished in the recommended 5-minute window after arrest. The overall maternal survival rate was 15% (8 of 55) for all patients after maternal arrest and 17% (2 of 12) for those who were delivered by perimortem cesarean. Both survivors were delivered within 15 minutes. Emergency skills training increased the likelihood that a perimortem cesarean would be performed.³⁰¹

Given the rarity of this event, a clear understanding of the impact on maternal survival is limited. Improved maternal circulation and survival are a well-described phenomenon. In the series by Katz and coworkers, 20 (59%) of 34 cases provided information regarding maternal hemodynamic status and indicated a beneficial effect on maternal resuscitation efforts after perimortem cesarean. None of the cases reported worsened maternal status as a result of perimortem cesarean; 12 women had sudden and profound improvement at the time of

emptying the uterus.²⁹⁶ In the Danish series, 67% of women experienced improved CO. For the perimortem cesarean group of patients, the mortality rate was 83% (10 of 12), compared with 67% for the group that remained undelivered. Neonatal outcome data on the five neonatal survivors is limited. Three appeared to have no adverse sequelae, one had evidence of neurologic impairment, and one became lost to follow-up.

Six of the 43 patients who suffered cardiac arrest and did not undergo perimortem cesarean survived the event. Follow-up information on the outcomes for this group of patients was not reported.³⁰¹ In the perimortem cesarean group, several factors contributed to delay in delivery, including relocation of the patient to an operating room and assessments of fetal well-being. Relocating the patient from a labor room to an operating room significantly impacts the ability to achieve delivery within the recommended 5-minute window in a simulated environment. Fifty-seven percent of cases were accomplished in 5 minutes if the patient was not relocated, compared with 14% if relocation took place. This demonstrates the challenges inherent in performing a timely delivery under these circumstances.³⁰²

The following guidelines are suggested for the management of maternal cardiac arrest with a viable gestation:

1. Begin maternal CPR immediately and establish an airway.
2. Establish intravenous access simultaneously.
3. Institute cesarean delivery if there is no spontaneous return of circulation by 4 minutes.
4. Sterile technique not necessary, and the patient need not be moved to an operating room.
5. Continue CPR efforts during and after delivery.
6. Continuous fetal monitoring is not possible due to interference from resuscitative efforts. The maternal response (or lack thereof) to resuscitative efforts dictates whether perimortem cesarean section is necessary.

Cesarean section in anticipation of cardiac arrest in an unstable patient is not recommended. This may inadvertently

precipitate a worse maternal outcome. If CPR is effective at restoring spontaneous circulation, perimortem cesarean section is not recommended. When perimortem cesarean section is indicated, it is usually best to proceed at the site of the arrest (which may be in the labor room), rather than transporting the patient and the team to the operating room, because the wasted transport time delays fetal extraction and affects survival.³⁰²

Two cases of cardiac arrest in pregnancy were reported in which a perimortem cesarean section was performed as part of the resuscitation process, resulting in good maternal and neonatal outcomes. The investigators cite the importance of training for this rare event, emphasizing the benefits of simulation.³⁰³

Brain Death and Somatic Support of the Parturient

Brain death is defined as the complete absence of brain function and is determined clinically by lack of consciousness, movement, respiratory effort, and most reflexes. It is confirmed by lack of activity on an electroencephalogram. It is considered distinct from coma and persistent vegetative state (Table 71-16).³⁰⁴ Maternal brain death has been rarely reported in the obstetric and critical care literature. Two reviews on the topic identified only 12 reported cases since 1982.^{304,305} Two additional cases were also identified.^{307,308} The most common reason for brain death was subarachnoid hemorrhage, followed by trauma and infection.³⁰⁹

After brain death occurs, the options include immediate delivery, withdrawal of maternal support, or prolongation of maternal life to improve neonatal prognosis by advancing gestational age. The challenges in providing life support to the brain-dead gravida cannot be underestimated. They include hemodynamic instability, panhypopituitarism, ventilatory

TABLE 71-16 Features of Coma, Persistent Vegetative State, and Brain Death

Condition	Self-awareness	Suffering	Motor Function	Sleep-Wake Cycles	Respiratory Function	EEG Activity	Cerebral Metabolism	Life Expectancy	Neurologic Recovery
Persistent vegetative state	Absent	No	No purposeful movement	Intact	Normal	Polymorphic delta/theta, sometimes slow alpha	Reduced by 50% or more	Usually 2-5 yr	Nontraumatic: rare after 3 mo Traumatic: rare after 12 mo
Coma	Absent	No	No purposeful movement	Absent	Depressed, variable	Polymorphic delta or theta	Reduced by 50% or more (variable)	Variable	Usually recovery, PVS, or death in 2-4 wk
Brain death	Absent	No	None or only reflex spinal movements	Absent	Absent	Electrocerebral silence	Absent	Death within 2-4 wk (Harvard criteria)	No recovery

EEG, electroencephalographic; PVS, persistent vegetative state.

Adapted from *The Multi-Society Task Force on PVS: Medical aspects of the persistent vegetative state—first of two parts*, N Engl J Med 330:1499-1508, 1994.

TABLE 71-17 Intensive Care Management of Pregnant Patients with Severe Neurologic Injury

Condition	Therapy	Physiologic Goal
Respiratory failure	Controlled hyperventilation PEEP	Physiologic hypercarbia, decrease intracranial pressure, avoid neurogenic pulmonary edema
Fluid-resistant hypotension	Left lateral position vasopressors	Maintain uteroplacental circulation
Hypothermia	Warming blankets	Prevent fetal bradycardia and IUGR
Hyperthermia	Cooling blankets	Prevent fetal death
Nutritional support	Enteral or parenteral insulin	Maintain positive nitrogen balance (energy intake 126-147 kJ/kg IBW), avoid hyperglycemia
Panhypopituitarism	DDAVP, thyroxine, cortisol	Adjust for central diabetes insipidus and adrenocortical insufficiency
Infection prevention	Frequent cultures, line changes	Prevent sepsis
DVT prophylaxis	Heparin	Prevent pulmonary embolism
Preterm labor	Betamethasone or dexamethasone; consider tocolysis	Prolong gestation
General condition	Expert nursing care	

DDAVP, 1-deamino-8-D-arginine vasopressin; DVT, deep venous thrombosis; IBW, ideal body weight; IUGR, intrauterine growth restriction; PEEP, positive end-expiratory pressure.

support, temperature regulation, nutrition, infectious complications, hypercoagulability, and premature contractions (Table 71-17).²⁹⁷ Given these challenges, it is surprising that two patients experienced a latency exceeding 100 days, with a mean latency of longer than 50 days from the diagnosis of brain death.^{304-306,308,309} Delivery timing is based on assessment of fetal well-being or maturity unless there is evidence of maternal

deterioration. Preparation for immediate bedside cesarean section should be made. Discussion of the ethical and legal considerations that surround these cases is beyond the scope of this chapter.

The Neonate

Neonatal Morbidities of Prenatal and Perinatal Origin

JAMES M. GREENBERG, MD | VIVEK NARENDRAN, MD |
KURT R. SCHIBLER, MD | BARBARA B. WARNER, MD | BETH E. HABERMAN, MD

Obstetric Decisions and Neonatal Outcomes

The nature of obstetric clinical practice requires consideration of two patients: mother and fetus. The intrinsic biologic interdependence of one with the other creates unique challenges not typically encountered in other realms of medical practice. There often is a paucity of objective data to support the evaluation of risks and benefits associated with a given clinical situation, forcing obstetricians to rely on their clinical acumen and experience. Family perspectives must be integrated in clinical decision making, along with the advice and counsel of other clinical providers. We review how to best use neonatology expertise in the obstetric decision-making process.

THE PERINATAL CONSULTATION AND ROLE OF THE NEONATOLOGIST

Collaboration between the obstetrician and neonatologist promotes optimal perinatal care during pregnancy and especially around the time of labor, eliminating ambiguity and confusion in the delivery room and ensuring that patients and families understand the rationale for obstetric and postnatal management decisions. The neonatologist can provide information regarding risks to the fetus associated with delaying or initiating preterm delivery and can identify the optimal location for delivery to ensure that skilled personnel are present to support the newborn infant.

In addition to contributing information about gestational age-specific outcomes, the neonatologist can anticipate neonatal complications related to maternal disorders such as diabetes mellitus, hypertension, and multiple gestations or prenatally detect fetal conditions such as congenital infections, alloimmunization, and anomalies. If a lethal condition or high risk of death in the delivery room is anticipated, the neonatologist can assist with the formulation of a birth plan and develop parameters for delivery room intervention.

Preparing parents by description of delivery room management and resuscitation of a high-risk infant can demystify the process and reduce some of the fear anticipated by the expectant family. Making parents aware that premature infants are susceptible to thermal instability can reduce their anxiety when the newborn is rapidly moved after birth to a warming bed. The need for resuscitation is determined by careful evaluation of cardiorespiratory parameters and appropriate response according to published Neonatal Resuscitation Program guidelines.¹

COMMON MORBIDITIES OF PREGNANCY AND NEONATAL OUTCOME

Complications of pregnancy that affect infant well-being may be immediately evident after birth, such as hypotension related to maternal hemorrhage, or may manifest hours later, such as hypoglycemia related to maternal diabetes or thrombocytopenia related to maternal preeclampsia. Anemia and thyroid disorders related, respectively, to transplacental passage of maternal immunoglobulin G (IgG) antibodies to platelets or to thyroid may manifest days after delivery.

Diabetes during pregnancy can serve as a typical example. Infants born to women with diabetes are often macrosomic, increasing the risk of shoulder dystocia and birth injury. After delivery, these infants may have significant hypoglycemia, polycythemia, and electrolyte disturbances, which require close surveillance and treatment. Lung maturation is delayed in an infant of a diabetic mother (IDM), increasing the incidence of respiratory distress syndrome (RDS) at a given gestational age. The IDM also has delayed neurologic maturation, with decreased tone typically leading to delayed onset of feeding competence. Less common complications include an increased incidence of congenital heart disease and skeletal malformations. Most neonatal complications of maternal diabetes are managed without long-term sequelae, but they may prolong length of hospital stay. Neonatal complications for the IDM are a function of maternal glycemic control. Careful screening by physicians and attention by patients can reduce neonatal morbidity due to maternal diabetes.

Chorioamnionitis has diverse effects on the fetus and on neonatal outcome. It is associated with premature rupture of the membranes and preterm delivery. Elevated levels of proinflammatory cytokines may predispose neonates to cerebral injury.² Although suspected or proven neonatal sepsis is more common in the setting of chorioamnionitis, many neonates born to mothers with histologically proven chorioamnionitis are asymptomatic and appear unaffected, and pregnancy outcomes are normal. Animal models and associated epidemiologic data suggest that chorioamnionitis can accelerate fetal lung maturation as measured by surfactant production and function. However, preterm infants born to mothers with chorioamnionitis are more likely to develop bronchopulmonary dysplasia (BPD).³⁻⁵ The neonatal consequences of chorioamnionitis are likely related to the timing, severity, and extent of the infection and the associated inflammatory response.

The effects of preeclampsia on the neonate include intrauterine growth restriction (IUGR), hypoglycemia, neutropenia, thrombocytopenia, polycythemia, and electrolyte abnormalities such as hypocalcemia. Most of these problems result from placental insufficiency leading to diminished oxygen and nutrient delivery to the fetus. With delivery and supportive care, most resolve with time, although some patients require treatment with intravenous calcium or glucose, or both, in the early neonatal period. Similarly, severe thrombocytopenia may require platelet transfusion therapy. Some studies suggest that preeclampsia may protect against intraventricular hemorrhage (IVH) in preterm infants, perhaps because of maternal treatment or other unknown factors.⁶ Unlike intrauterine inflammation, preeclampsia does not appear to accelerate lung maturation.⁷ Predicting the consequences of maternal preeclampsia on neonatal outcome remains difficult.⁸

Maternal autoimmune disease may affect the neonate through transplacental transfer of autoantibodies. Symptoms are a function of the extent of antibody transfer. Treatment is supportive and is based on the affected neonatal organ system. For example, maternal Graves disease may cause neonatal thyrotoxicosis requiring treatment with propylthiouracil or β -blockers. Maternal lupus or connective tissue disease is linked to congenital heart block that may require long-term atrial pacing after delivery. Myasthenia gravis during pregnancy can promote a transient form of the disease in the neonate. Supportive therapy during the early neonatal period addresses most issues associated with maternal autoimmune disorders. Passively transferred autoantibodies gradually clear from the neonatal circulation with a half-life of 2 to 3 weeks.

Neonatal outcome associated with maternal nutritional status during pregnancy is of growing interest. The Dutch Famine of 1944 to 1945 created a unique circumstance for studying the consequences of severe undernutrition during pregnancy (caloric intake <1000 kcal/day). Mothers experienced significant third-trimester weight loss, and offspring were underweight.⁹ Low maternal body mass index (BMI) is associated with increased risk of preterm delivery.¹⁰ There is growing evidence that infants undernourished during fetal life are at higher risk for adult diseases such as atherosclerosis and hypertension. Poor maternal nutrition during intrauterine life may signal the fetus to modify metabolic pathways and blood pressure regulatory systems, with long-term health consequences

lasting into late childhood and beyond.¹¹ Conversely, maternal overnutrition, as defined by excessive caloric intake, predisposes mothers to insulin resistance and large-for-gestational-age infants. Maternal BMI and birth weight have increased over time, even though mean gestational age at delivery has declined.^{12,14} Elevated maternal BMI is associated with excess stillbirth and neonatal mortality but not with preterm birth. However, maternal obesity (BMI >30) was a risk factor for developmental delay within a cohort of extremely preterm infants.¹⁵

Neonatal anemia may be a consequence of perinatal events such as placental abruption, ruptured vasa previa, or fetal-maternal transfusion. At delivery, the neonate may be asymptomatic or may display profound effects of blood loss, including high-output heart failure or hypovolemic shock. The duration and extent of blood loss, along with any fetal compensation, determines the neonatal clinical status at delivery and subsequent management. In the delivery room, prompt recognition of acute blood loss and transfusion with O-negative blood can be a lifesaving intervention.

Neonates from a multifetal gestation are, on average, smaller at a given gestational age than their singleton counterparts. They are also more likely to be delivered before term and therefore are more likely to experience complications associated with low birth weight (LBW) and prematurity. Identical twins may also experience twin-twin transfusion syndrome. The associated discordant growth and additional problems of anemia, polycythemia, congestive heart failure, and hydrops may further complicate the clinical course after delivery, even after amnioreduction or fetoscopic laser occlusion. Cerebral lesions, such as periventricular white matter injury and ventricular enlargement, may occur more frequently in the setting of twin-twin transfusion syndrome.¹⁶ Additional epidemiologic studies and long-term follow-up are needed to further address this issue.

Congenital malformations constitute significant challenges for caregivers and families. Prenatal diagnosis offers an opportunity to plan for delivery room management and provide anticipatory guidance. The site of delivery should be chosen based on optimizing the availability of appropriate expertise. The neonatologist can facilitate appropriate delivery coverage and ensure availability of appropriate equipment, medications, and personnel.

Table 72-1 summarizes some of the important considerations associated with neonatal management of congenital mal-

TABLE 72-1 Neonatal Management of Congenital Malformations

Malformation	Management Considerations
Clefts	Alternative feeding devices (e.g., Haberman feeder), genetics evaluation, occupational and physical therapy
Congenital diaphragmatic hernia	Skilled airway management, pediatric surgery, immediate availability of mechanical ventilation, nitric oxide, ECMO
Upper airway obstruction or micrognathia	Skilled airway management, otolaryngology, genetics evaluation and management, immediate availability of mechanical ventilation, tracheostomy tube placement
Hydrothorax	Skilled airway management, nitric oxide, ECMO, chest tube placement, immediate availability of mechanical ventilation
Ambiguous genitalia	Endocrinology, urology, genetics available for immediate evaluation
Neural tube defects	Sterile, moist dressing to cover defect and prevent desiccation; intravenous fluids, neurosurgery, urology, orthopedics evaluation and management
Abdominal wall defects	Saline-filled sterile bag to contain exposed abdominal contents and prevent desiccation, IV fluids, pediatric surgery, genetics evaluation/management
Cyanotic congenital heart disease	Intravenous access, prostaglandin E ₁ , immediate availability of mechanical ventilation

ECMO, extracorporeal membrane oxygenation.

formations. Management considerations include availability of expertise and equipment needed for optimal management. This list reflects the importance of multidisciplinary input for optimal management of patients with congenital malformations. Patients typically are best delivered in a setting where experienced delivery room attendants are available. If needed consultative services or equipment is not readily available, arrangement should be made for prompt transfer to a tertiary care center. Successful transports depend on clear communication between centers. For example, prompt notification of the delivery of an infant with gastroschisis ensures that the delivering hospital can provide adequate intravenous hydration and protection of exposed viscera, and it alerts the referral center to prepare for immediate pediatric surgery intervention on arrival.

In settings of premature, preterm, or prolonged rupture of the membranes and premature labor, mothers are frequently treated with antibiotics and tocolytic agents. Maternal medications administered during pregnancy for non-obstetric diseases can have a significant impact on the neonate. A common challenge in many centers evolved from the treatment of opiate-addicted mothers with methadone or buprenorphine.^{17,18} The symptoms of neonatal abstinence syndrome vary as a function of the degree of prenatal opiate exposure and age at delivery. Many infants appear neurologically normal at delivery, only to exhibit symptoms on the first, second, or even third day of postnatal life. Infants with neonatal abstinence syndrome typically demonstrate irritability, poor feeding, loose and frequent stools, and in severe cases, seizures. Treatment options for neonatal abstinence syndrome include nonpharmacologic interventions (e.g., swaddling, minimal stimulation), methadone, and non-narcotic drugs such as phenobarbital. These infants often require hospitalization for many days or weeks until their irritability is under sufficient control to allow care in a home setting.

There is clinical evidence that neonates may exhibit similar symptoms after withdrawal from antenatal nicotine exposure.^{19,20} The consequences of other illicit drug use during pregnancy have been widely studied but are more difficult to assess because of difficulties with diagnosis and confounding variables. Maternal cocaine abuse has been associated with obstetric complications such as placental abruption. Vascular compromise may predispose neonates to cerebral infarcts and bowel injury. Developmental delay and behavioral problems are observed, and associated factors such as poverty, lack of prenatal care, and low socioeconomic status also contribute.

Alloimmune hemolytic disorders such as Rh hemolytic disease and ABO incompatibility can cause neonatal morbidity ranging from uncomplicated hyperbilirubinemia to severe anemia, hydrops, and high-output congestive heart failure (see Chapters 36 and 37). Rh hemolytic disease has become uncommon, but it still must be considered as a cause of unexplained hydrops, anemia, or heart failure in infants born to Rh-negative mothers, especially if there is a possibility of maternal sensitization. ABO incompatibility is common, with up to 20% of all pregnancies potentially at risk. The responsible isohemagglutinins have a weak affinity for blood group antigens, and the degree of hemolysis and subsequent jaundice varies from patient to patient. Indirect immunoglobulin (Coombs) testing has limited value in predicting clinically significant jaundice. The neonatal morbidity is typically restricted to hyperbilirubinemia requiring treatment with phototherapy.

Complications of Prematurity

The mean duration of a spontaneous singleton pregnancy is 282 days or 40 menstrual weeks (38 postconceptional weeks). An infant delivered before completion of 37 weeks' gestation is considered preterm by the World Health Organization. Infant morbidity and mortality increase with decreasing gestational age at birth. The risk of poor outcome, defined as death or lifelong handicap, increases dramatically as gestational age decreases, especially for very-low-birth-weight (VLBW) infants (Fig. 72-1).

Beyond the increased mortality risk, prematurity is associated with increased risk of morbidity in almost every major organ system. BPD, retinopathy of prematurity, necrotizing enterocolitis (NEC), and IVH are particularly linked to the preterm state. IUGR and increased susceptibility to infection are not restricted to the preterm infant but are complicated in the immature infant. Table 72-2 summarizes common complications of prematurity by organ system.

Between 1983 and 2004, the rate of preterm birth increased in the United States by 30%, from 9.6% to 12.5%. Three major causes have been identified to explain the rise (see Chapter 40): improved gestational dating associated with increased use of early ultrasound,²¹ a substantial rise in multifetal gestations associated with assisted reproductive technology, and an increase in indicated preterm births.²² The last category is important because decisions affecting the timing and management of preterm delivery can have a profound effect on neonatal outcome. The risk of death before hospital discharge doubles when the gestational age decreases from 27.5 weeks (10%) to 26 weeks (20%). Delaying delivery for even a few days may substantially improve outcome, especially before 32 weeks, assuming that the intrauterine environment is safe to support the fetus. However, in some clinical situations with a high potential for preterm delivery, it is difficult to assess the quality of the intrauterine environment. Three common examples are preterm, premature rupture of the membranes (see Chapter

TABLE 72-2 Common Complications of Prematurity by Organ System

Organ System	Morbidity
Pulmonary	Respiratory distress syndrome Bronchopulmonary dysplasia Pulmonary hypoplasia
Cardiovascular	Apnea of prematurity Patent ductus arteriosus Apnea and bradycardia
Gastrointestinal, liver	Hypotension Necrotizing enterocolitis Dysmotility, reflux Feeding difficulties
Central nervous system	Hypoglycemia Intraventricular hemorrhage Periventricular leukomalacia
Visual	Retinopathy of prematurity
Skin	Excess insensible water loss Hypothermia
Immune/ Hematologic	Increased incidence of sepsis and meningitis Anemia of prematurity

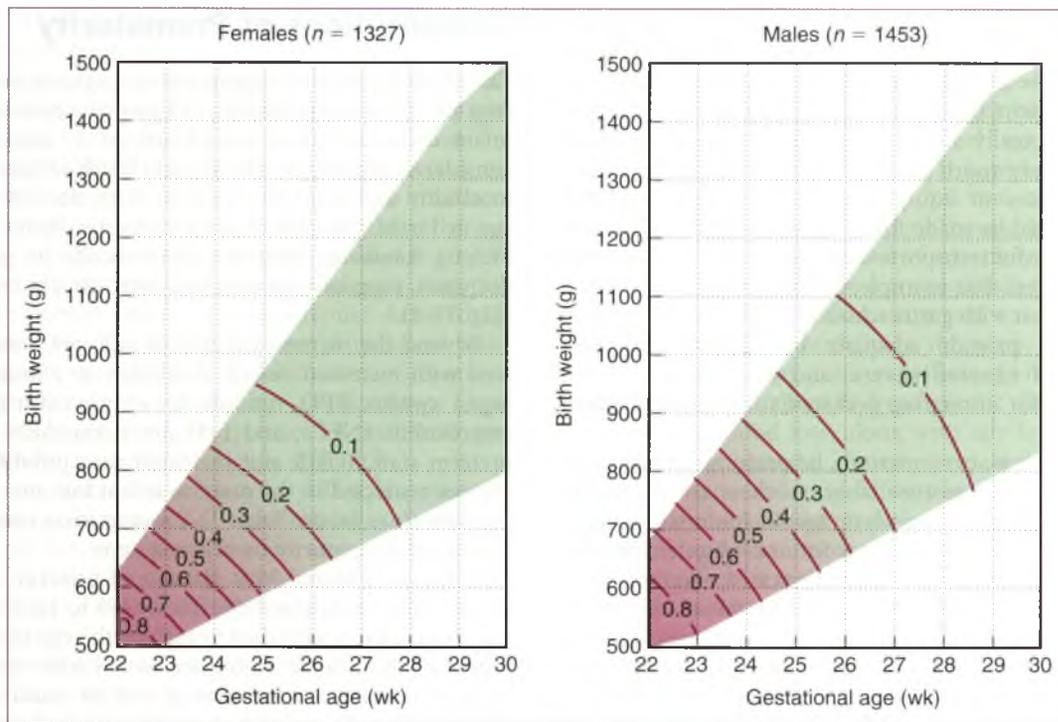

Figure 72-1 Estimated mortality risk by birth weight and gestational age. Mortality risk for female and male infants with low birth weight or early gestational age, or both, is based on singleton infants born in National Institute of Child Health and Human Development (NICHD) Neonatal Research Network centers between January 1, 1995, and December 31, 1996. Numeric values represent age- and weight-specific mortality rates per 100 births. (From Lemons JA, Bauer CR, Oh W, et al: *Very low birth weight outcomes of the National Institute of Child Health and Human Development Neonatal Research Network, January 1995 through December 1996*. NICHD Neonatal Research Network, *Pediatrics* 107:E1, 2001. With permission of the American Academy of Pediatrics.)

42); placental abruption (see Chapter 46); and preeclampsia (see Chapter 48). In each case, prolonging gestation to allow continued fetal growth and maturation in utero is accompanied by an uncertain risk of rapid change in maternal status with a corresponding increased risk of fetal compromise. Tests of fetal well-being are discussed in Chapter 32, and clinical decision making in obstetrics is addressed in Chapters 34, 38, 40, 42, 46, 47, and 48.

Obstetric decisions about the timing of delivery in the setting of uncertain in utero risk significantly contribute to the increase in late preterm births occurring after 32 to 34 weeks. The contribution of elective delivery must also be considered. Although perinatal mortality continues to decrease, in part due to a decline in stillbirths (see Chapter 45),²² interest in understanding the extent of morbidity associated with late preterm deliveries has intensified because of the large number of these late preterm infants and the potential for avoiding morbidities such as temperature instability, feeding problems, hyperbilirubinemia requiring treatment, suspected sepsis, and respiratory distress. Infants born at 35 weeks' gestation are nine times more likely to require mechanical ventilation than those born at term.²³

Most complications of late preterm delivery are easily treated, but their economic and social impacts are substantial, and the long-term sequelae are not well understood. For example, brain growth and development proceeds rapidly during the third trimester and continues for the first several years of life. An infant

born at 35 weeks' gestation has approximately one half of the brain volume of a term infant. Although IVH is unusual after 32 weeks' gestation, regions that include the periventricular white matter continue to undergo rapid myelination during this period. Studies demonstrate an association between late preterm delivery and long-term neurodevelopmental problems, including learning disabilities and attention deficit disorders.²⁴⁻²⁸ Additional neurologic and epidemiologic studies are required to define any mechanistic connection between late preterm delivery and these long-term outcomes.

Late preterm infants experience excess infant mortality (death before 12 months) compared with their full-term counterparts. The mortality rate for infants born at 34 to 36 weeks' gestation is three times higher than for those delivered at 40 weeks.²⁹ Growing recognition of the morbidity and mortality risks associated with preterm delivery deserves close scrutiny and further study. Table 72-3 compares estimates of complication rates between preterm and late preterm infants.

Extremely preterm infants, typically defined as those born before 32 weeks' gestation or weighing less than 1500 g, comprise only 1.5% to 2% of all deliveries, whereas the late preterm population accounts for 8% to 9% of all births. Even uncommon complications in the later preterm population may represent a significant health care burden. Efforts focused on the elimination of elective deliveries before 39 weeks have resulted in a genuine, sustainable reduction of late preterm

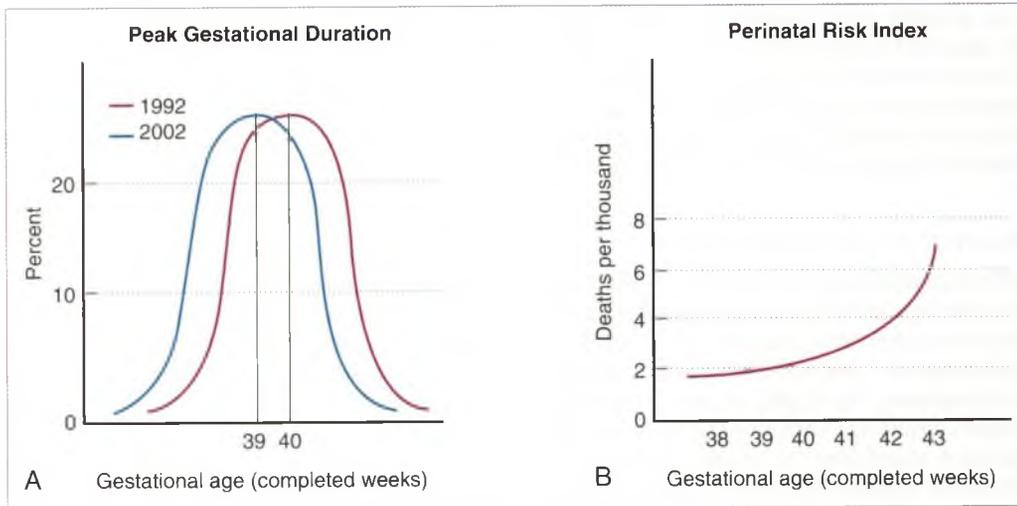

Figure 72-2 Peak gestational age and risk of intrauterine fetal demise. A, Change in peak gestational duration between 1992 and 2002. The duration of gestation decreased by 1 week during that decade, from 40 weeks to 39 weeks. B, The risk of intrauterine fetal demise increases with increasing gestational age, especially beyond 40 weeks. The risk of intrauterine fetal demise likely influences obstetric decision making regarding the timing of delivery in pregnancies approaching 40 weeks' gestation. (Data from Davidoff MJ, Dias T, Damus K, et al: *Changes in the gestational age distribution among U.S. singleton births: impact on rates of late preterm birth, 1992 to 2002*, *Semin Perinatol* 30:8–15, 2006; Yuckin PL, Wood L, Redman CW: *Risk of unexplained stillbirth at different gestational ages*, *Lancet* 1:1192–1194, 1987; and Smith GC: *Life-table analysis of the risk of perinatal death at term and post term in singleton pregnancies*, *Am J Obstet Gynecol* 184:489–496, 2001.)

TABLE 72-3 Estimated Complication Rates for Preterm and Late Preterm Infants

Complication of Prematurity	Preterm Incidence*	Late Preterm Incidence†
Respiratory distress syndrome	65% surf RX <1500 g 80% <27 wk ³⁶⁶	5%
Bronchopulmonary dysplasia	23% <1500 g ³⁴	Uncommon
Retinopathy of prematurity	Approx 40% <1500 g ^{35,367,368}	
Intraventricular hemorrhage with ventricular dilatation or parenchymal involvement	11% <1500 g ³⁴	Rare
Necrotizing enterocolitis	5%-7% <1500 g ³⁴	Uncommon
Patent ductus arteriosus	30% <1500 g ³⁴	Uncommon
Feeding difficulty	>90%	10%-15% ³⁶
Hypoglycemia	NA	10%-15% ³⁶

†Defined as 32–38 wk or 1500–2500 g, or both.

NA, not available; surf RX, surfactant treatment.

deliveries.³⁰ As the number of late preterm infants continues to rise, clinicians and policy makers are likely to focus additional attention on the causes and prevention of such deliveries (Fig. 72-2).

DECISIONS AT THE THRESHOLD OF VIABILITY

Decisions regarding treatment of infants at the limit of viability are often the most difficult for families and health care professionals, in part due to the lack of clarity in defining that limit, which has fallen by approximately 1 week every decade over the

past 45 years. Most developed countries identify the limit of viability at 22 to 25 weeks' gestation.^{31–33} Making decisions at this early gestational age requires accurate information regarding mortality and morbidity for this population. At 22 weeks (22 0/7 days to 22 6/7 days), survival is rare and typically is not included in studies of survival or long-term outcome. The rate of survival to hospital discharge for infants born at 23 weeks' gestation (23 0/7 to 23 6/7 days) ranges from 15% to 30%. Survival increases to between 30% and 55% for infants born at 24 weeks' gestation.^{32,34–39}

The Vermont-Oxford Network reported weight-based survival rate for more than 4000 infants born weighing between 401 and 500 g (mean gestational age, 23.3 ± 2.1 weeks) from 1996 to 2000. Seventeen percent survived to hospital discharge.⁴⁰ Whereas mortality rates fall for each 1-week increase in gestational age at delivery, long-term neurodevelopmental outcomes do not improve proportionately. Between 30% and 50% of infants born at less than 25 weeks' gestation have moderate to severe disability, including blindness, deafness, developmental delays, and cerebral palsy (CP).^{32,35,37} The National Institute of Child Health and Human Development (NICHD) reported neurodevelopmental outcomes for more than 5000 infants born between 22 and 26 weeks' gestation from 1993 to 1998. Bayley mental development index (MDI) and nonverbal development index (NDI) scores improved, and blindness was reduced, but rates of severe CP, hearing loss, shunted hydrocephalus, and seizures were unchanged.⁴¹

Birth weight and sex affect survival rates. Higher weights within gestational age categories and female sex consistently show a survival advantage and better neurodevelopmental outcomes.^{34,41} Survival and long-term outcomes of very preterm infants are improved with delivery at a tertiary center rather than neonatal transfer from an outlying facility.^{42–44} When families desire resuscitation or dating is uncertain, every attempt

should be made to transfer the mother to a tertiary care center for delivery. Maternal transfer to a tertiary center and administration of corticosteroids (see Chapter 34) are the only antenatal interventions that have been significantly and consistently related to improved neonatal neurodevelopmental outcomes.⁴¹ Other attempted strategies are discussed in Chapters 34, 41, and 40.

Planning for Delivery at the Limits of Viability

Ideally, discussion between physicians and parents should begin before the birth in a non-emergent situation and should include obstetric and neonatal care providers. Even during active labor, communication with the family should be initiated as a foundation for postnatal discussions. The family should understand that plans made before delivery are influenced by maternal and fetal considerations and based on limited information. Information that becomes available only after delivery, such as birth weight and neonatal physical findings, may change the infant's prognosis.³²

Neonatal Resuscitation at the Limits of Viability

If time allows before delivery of an infant whose gestational age is near the threshold of viability, a thoughtful birth plan developed by the parents in consultation with maternal-fetal medicine specialists and the neonatologist should be established. The neonatologist can assist families in making decisions regarding a birth plan for their infant by providing general information about the prognosis, the hospital course, potential complications, survival, and general health and well-being of infants delivered at a similar gestational age. When time does not permit such discussions, careful evaluation of gestational age and response to resuscitation are instrumental in assisting families in making decisions regarding viability or nonviability of an extremely premature infant. The presence of an experienced pediatrician at delivery is recommended to assess weight, gestational age, and fetal status and to provide medical leadership in decisions to be made jointly with families.^{31,33} In cases of precipitous delivery when communication with the family has not occurred, physicians should use their best judgment on behalf of the infant to initiate resuscitation until the family can be brought into the discussion, erring on the side of resuscitation if the appropriate course is uncertain.^{31,45}

Under ideal circumstances, the health care team and the infant's family should make shared management decisions regarding these infants. The American Medical Association (AMA) and American Academy of Pediatrics (AAP) endorse the concept that "the primary consideration for decisions regarding life-sustaining treatment for seriously ill newborns should be what is best for the newborn" and recognize parents as having the primary role in determining the goals of care for their infant.^{1,31,46} Discussions with the family should include local and national information on mortality and long-term outcomes. Every effort should be made to use up-to-date data. Health care providers tend to be more pessimistic when considering outcomes based solely on experience and subjective reasoning.⁴⁷ Parental participation should be encouraged with open communication regarding personal values and goals.

Decisions concerning resuscitation should be individualized to the case and the family but should begin with parameters for care that are based on global reviews of the medical and ethical literature and expertise. The Nuffield Council on Bioethics in the United Kingdom has proposed parameters for treating

extremely premature infants that parallel guidance from the AAP.^{1,31} If the gestational age or birth weight is associated with almost certain early death and anticipated morbidity is unacceptably high, resuscitation is not indicated. Exceptions to comply with parental requests may be appropriate in specific cases, such as for infants born at less than 23 weeks' gestation or with a birth weight less than 400 g. If the prognosis is more uncertain and survival is borderline with a high rate of morbidity (e.g., 23 to 24 weeks' gestation), parental views should be supported.

Decisions regarding the care of extremely preterm infants are always difficult for everyone involved. Parental involvement, active listening, and accurate information are critical to an optimal outcome for infants and their families. Although parents are considered the best surrogate for their infant, health care professionals have a legal and ethical obligation to provide appropriate care for the infant based on medical information. If agreement with the family cannot be reached, it may be appropriate to consult the hospital ethics committee or legal counsel. If the situation is emergent and the responsible physician concludes that the parents' wishes are not in the best interest of the infant, it is appropriate to resuscitate despite parental objection.³⁶

RESPIRATORY PROBLEMS

No aspect of the transition from fetal to neonatal life is more dramatic than the process of pulmonary adaptation. In a normal term infant, the lungs expand with air, pulmonary vascular resistance rapidly decreases, and vigorous, consistent respiratory effort ensues within a minute of separation from the placenta. The process depends on crucial physiologic mechanisms, including production of functional surfactant, dilatation of high-resistance pulmonary arterioles, bulk transfer of fluid from airspaces, and physiologic closure of the ductus arteriosus and foramen ovale. Complications such as prematurity, infection, neuromuscular disorders, developmental defects, and complications of labor may interfere with neonatal respiratory function. This section reviews common respiratory problems of neonates.

Transient Tachypnea of the Newborn

Definition. Transient tachypnea of the newborn (TTN), commonly known as *wet lungs*, is a mild condition affecting term and late preterm infants. This is the most common respiratory cause of admission to the special care nursery. TTN by definition is self-limited, with no risk of recurrence or residual pulmonary dysfunction. It rarely causes hypoxic respiratory failure.⁴⁸

Pathophysiology. During the last trimester, a series of physiologic events leads to changes in the hormonal milieu of the fetus and the mother to facilitate neonatal transition.⁴⁹ Rapid clearance of fetal lung fluid is essential for successful transition to air breathing. The bulk of this fluid clearance is mediated by transepithelial sodium reabsorption through amiloride-sensitive sodium channels in the respiratory epithelial cells.⁵⁰ The mechanisms for such an effective "self-resuscitation" soon after birth are not completely understood. Traditional explanations based on Starling forces and vaginal squeeze for fluid clearance account for only a fraction of the fluid absorbed.

Risk Factors. This condition is classically seen in infants delivered near term, especially after cesarean birth before the onset of spontaneous labor.^{51,52} Absence of labor is accompanied by impaired surge of endogenous steroids and catecholamines necessary for a successful transition.⁵³ Additional risk factors such as multiple gestations, excessive maternal sedation, prolonged labor, and complications resulting from excessive maternal fluid administration have been less consistently observed.

Clinical Presentation. The clinical features of TTN include a combination of grunting, tachypnea, nasal flaring, and mild intercostal and subcostal retractions along with mild central cyanosis. The grunting can be fairly significant and is sometimes misdiagnosed as RDS due to surfactant deficiency. The chest radiograph usually shows prominent perihilar streakings that represent engorged pulmonary lymphatics and blood vessels. Fluid in the fissures is a common, nonspecific finding. Clinical symptoms rapidly improve within the first 24 to 48 hours after birth. TTN is a diagnosis of exclusion, and other potential causes of respiratory distress in the newborn should be excluded. The differential diagnosis of TTN includes pneumonia/sepsis, air leaks, surfactant deficiency, and congenital heart disease. Other rare diagnoses are pulmonary hypertension, meconium aspiration, and polycythemia.

Diagnosis. TTN is primarily a clinical diagnosis. Chest radiographs typically demonstrate mild pulmonary congestion with hazy lung fields. The pulmonary vasculature may be prominent. Small accumulations of extrapleural fluid, especially in the minor fissure on the right side, may be seen.

Management. Management is mainly supportive. Supplemental oxygen is provided to keep the oxygen saturation level greater than 90%. Infants are usually given intravenous fluids and not fed orally until their tachypnea resolves. Rarely, infants need continuous positive airway pressure (CPAP) to relieve symptoms. Diuretic therapy is not effective.⁵⁴

Neonatal Implications. TTN can lead to significant morbidity related to delayed initiation of oral feeding, which may interfere with parental bonding and establishment of successful breastfeeding. The hospital stay is prolonged for both mother and infant. Current perinatal guidelines⁵⁵ that recommend scheduling of elective cesarean birth only after 39 completed weeks of gestation should reduce the incidence of TTN (Fig. 72-3).

Pulmonary Hypoplasia

Lung development begins during the first trimester when the ventral foregut endoderm projects into adjacent splanchnic mesoderm (see Chapter 15). Branching morphogenesis, epithelial differentiation, and acquisition of a functional interface for gas exchange ensue through the remainder of gestation and are not completed until the second or third year of postnatal life. Clinical conditions associated with pulmonary hypoplasia and approaches to prevention and treatment are discussed in this section.

Perturbation of lung development at any time during gestation may lead to clinically significant pulmonary hypoplasia. Two general pathophysiologic mechanisms contribute to pulmonary hypoplasia: extrinsic compression and neuromuscular dysfunction. Infants with aneuploidy (e.g., trisomy 21) and those with multiple congenital anomalies or hydrops fetalis have a high incidence of pulmonary hypoplasia.

Oligohydramnios, whether caused by premature rupture of membranes or diminished fetal urine production, can lead to pulmonary hypoplasia. The reduction in branching morphogenesis and surface area for gas exchange may be lethal or clinically imperceptible. Clinical studies link the degree of pulmonary hypoplasia to the duration and severity of the oligohydramnios. Similarly, pulmonary hypoplasia is a hallmark of congenital diaphragmatic hernia and is caused by extrinsic compression of the developing fetal lung by the herniated abdominal contents. The degree of pulmonary hypoplasia in congenital diaphragmatic hernia is directly related to the extent of herniation. Large hernias occur earlier in gestation. In most cases, the contralateral lung is also hypoplastic.

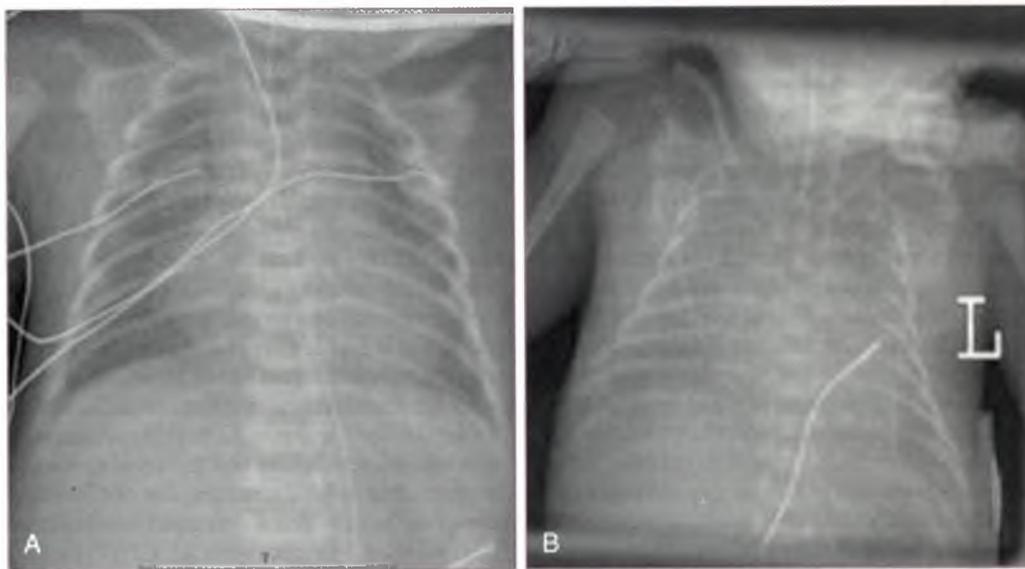

Figure 72-3 Radiographic appearance of transient tachypnea of the newborn (TTN) and respiratory distress syndrome (RDS). A, The radiographic characteristics of TTN include perihilar densities with fairly good aeration bordering on hyperinflation. B, Neonates with RDS have diminished lung volumes on chest radiographs, reflecting atelectasis associated with surfactant deficiency. Diffuse, ground-glass infiltrates along with air bronchograms make the cardiothymic silhouette indistinct.

Lindner and colleagues⁵⁶ reported a significant mortality risk for infants born to women with premature rupture of the membranes and oligohydramnios before 20 weeks' gestation. Their retrospective analysis found a 69% short-term mortality risk. However, the remaining infants did well and were discharged with apparently normal pulmonary function. Prediction of clinical outcome is difficult in these infants.

Prenatal diagnosis and treatment of pulmonary hypoplasia are discussed in Chapter 35. Postnatal treatment for pulmonary hypoplasia is largely supportive. Some infants with profound hypoplasia have insufficient surface area for effective gas exchange. These patients typically display profound hypoxemia, respiratory acidosis, pneumothorax, and pulmonary interstitial emphysema. At the other end of the spectrum, some infants have no clinical evidence of pulmonary insufficiency at birth but have diminished reserves when stressed. In between is a cohort of patients with respiratory insufficiency that is responsive to mechanical ventilation and pharmacologic support. Typically, these patients have adequate oxygenation and ventilation, suggesting adequate gas exchange capacity. However, many develop pulmonary hypertension. The pathophysiologic sequence begins with limited cross-sectional area of resistance arterioles, followed by smooth muscle hyperplasia in these same vessels.

Early use of pulmonary vasodilators such as nitric oxide is the mainstay of management for increased pulmonary vasoreactivity. Optimizing pulmonary blood flow reduces the potential for hypoxemia that is thought to stimulate pathologic medial hyperplasia. If oxygenation, ventilation, and acid-base balance are maintained, nutritional support over time can allow sufficient lung growth to support the infant's metabolic demands. In many cases, the process is lengthy, requiring mechanical ventilation and treatment with pulmonary vasodilators such as sildenafil, bosentan, or prostacyclin for weeks to months. Just as prenatal prognosis is difficult to assess, predicting outcome for patients with pulmonary hypoplasia managed in the neonatal intensive care unit is hampered by limited data.

Respiratory Distress Syndrome

RDS is a significant cause of early neonatal mortality and long-term morbidity. However, significant advances have been made in the management of RDS in recent decades, with a consequent decrease in associated morbidity and mortality.

Perinatal Risk Factors. The classic risk factors for RDS are prematurity and LBW. Factors that negatively affect surfactant synthesis include maternal diabetes, perinatal asphyxia, cesarean section without labor, and genetic factors (i.e., white race, history of RDS in siblings, male sex, and surfactant protein B deficiency).⁵⁷ Congenital malformations that lead to lung hypoplasia (e.g., diaphragmatic hernia) are also associated with significant surfactant deficiency.

Prenatal assessment of fetal lung maturity and treatment to induce fetal lung maturity are discussed in detail in Chapter 34.

Clinical Presentation. Symptoms, which are typically evident in the delivery room or shortly thereafter, include tachypnea, nasal flaring, subcostal and intercostal retractions, cyanosis, and expiratory grunting. The characteristic expiratory grunt results from expiration through a partially closed glottis, providing continuous distending airway pressure to maintain functional residual capacity and thereby prevent alveolar collapse. These

signs of respiratory difficulty are not specific to RDS and can occur from a variety of pulmonary and nonpulmonary causes, such as transient tachypnea, air leaks, congenital malformations, hypothermia, hypoglycemia, anemia, polycythemia, and metabolic acidosis. Progressive worsening of symptoms in the first 2 to 3 days, followed by recovery, characterizes the typical clinical course. This timeline (curve) is modified by administration of exogenous surfactant with a more rapid recovery. Classic radiographic findings include low-volume lungs with a diffuse reticulogranular pattern and air bronchograms. The diagnosis can be established chemically by measuring surfactant activity in tracheal or gastric aspirates, but this is not routinely done.⁵⁸

Management Principles

General Measures. Infants are managed in an incubator or under a radiant warmer in a neutral thermal environment to minimize oxygen requirement and consumption. Arterial oxygen tension (P_{aO_2}) is maintained between 50 and 80 mm Hg, with saturations between 88% and 96%. Hypercarbia and hyperoxia are avoided. Heart rate, blood pressure, respiratory rate, and peripheral perfusion are monitored closely. Because sepsis cannot be excluded, screening blood culture and complete blood counts with differential are performed, and infants are started on broad-spectrum antibiotics for 48 hours, until culture results are available.

Surfactant Therapy. Surfactant replacement is one of the safest and most effective interventions in neonatology. The first successful clinical trial of surfactant use was reported in 1980 using surfactant prepared from an organic solvent extract of bovine lung to treat 10 infants with RDS.⁵⁹ By the early 1990s, widespread use of surfactant led to a progressive decrease in RDS-associated mortality.

Two strategies for treatment are commonly used: prophylactic surfactant, in which surfactant is administered before the first breath to all infants at risk of developing RDS, and rescue therapy, in which surfactant is given after the onset of respiratory signs. The advantages of prophylactic administration include a better distribution of surfactant when instilled into a partially fluid-filled lung and the potential to decrease trauma related to resuscitation. Avoiding treatment of unaffected infants and related cost savings are the advantages of rescue therapy. Biologically active surfactant can be prepared from bovine, porcine, human, or synthetic sources. When administered to patients with surfactant deficiency and RDS, these preparations improve oxygenation, decrease the need for ventilator support, and decrease air leaks and risk of death.⁶⁰ The combined use of antenatal corticosteroids and postnatal surfactant improves neonatal outcome more than postnatal surfactant therapy alone.

Continuous Positive Airway Pressure. In infants with acute RDS, CPAP appears to prevent atelectasis, minimize lung injury, and preserve surfactant function, allowing infants to be managed without endotracheal intubation and mechanical ventilation. Early delivery room CPAP therapy decreases the need for mechanical ventilation and the incidence of long-term pulmonary morbidity.^{61,62} Increasing use of CPAP has led to decreased use of surfactant and a decreased incidence of BPD.⁶³

Common complications of CPAP include pneumothorax and pneumomediastinum. Rarely, the increased transthoracic pressure leads to progressive decrease in venous return and decreased cardiac output. Brief intubation and administration of surfactant followed by extubation to CPAP is an additional

RDS treatment strategy that is increasingly used in Europe and Australia.⁶⁴ Prospective, randomized trials comparing early delivery room CPAP with early prophylactic surfactant therapy for extremely-low-birth-weight (ELBW) infants found equivalence (defined by death or bronchopulmonary dysplasia).⁶⁵

Mechanical Ventilation. The goal of mechanical ventilation is to limit volutrauma and barotrauma without causing progressive atelectasis while maintaining adequate oxygenation and gas exchange. Complications associated with mechanical ventilation include pulmonary air leaks, endotracheal tube displacement or dislodgement, obstruction, infection, and long-term complications such as BPD and subglottic stenosis.

Complications of Respiratory Distress Syndrome. Acute complications include pneumothorax, pneumomediastinum, pneumopericardium, and pulmonary interstitial emphysema. The incidence of these complications has decreased significantly with surfactant treatment. Infection, intracranial hemorrhage, and patent ductus arteriosus occur more frequently in VLBW infants with RDS. Long-term complications and comorbidities include BPD, poor neurodevelopmental outcomes, and retinopathy of prematurity. Incidence of these complications is inversely related to decreasing birth weight and gestation.

New therapies under evaluation for the treatment of RDS include early inhaled nitric oxide and supplementary inositol for prevention of long-term pulmonary morbidity (e.g., BPD).⁶⁶⁻⁶⁸ Noninvasive respiratory support techniques such as synchronized nasal intermittent positive-pressure ventilation (SNIPPV) and use of high-flow nasal cannulas are being studied to decrease ventilator-associated lung injury.^{69,70}

Bronchopulmonary Dysplasia

The classic form of BPD was first described⁷¹ in a group of preterm infants who were mechanically ventilated at birth and who later developed chronic respiratory failure with characteristic chest radiographic findings. These infants were larger, late preterm infants with lung changes attributed to mechanical ventilation and oxygen toxicity. Smaller, extremely preterm infants with lung immaturity and prenatal exposure to antenatal glucocorticoids have developed a more subtle form, called *new BPD*.⁷² This disease primarily occurs in infants who weigh less than 1000 g and who have very mild or no initial respiratory distress. The clinical diagnosis is based on the need for supplemental oxygen at 36 weeks' corrected gestational age.⁷³ A physiologic definition of BPD based on the need for oxygen at the time of diagnosis has become the basis for the diagnosis of BPD.⁷⁴

Clinically, the transition from RDS to BPD is subtle and gradual. Radiographic manifestations of classic BPD include areas of shifting focal atelectasis and hyperinflation with or without parenchymal cyst formation. Chest radiographs of infants with the new BPD show bilateral haziness reflecting diffuse microatelectasis without multiple cystic changes. These changes lead to ventilation-perfusion mismatching and increased work of breathing. Preterm infants with BPD gradually wean off respiratory support and oxygen or continue to worsen with progressively severe respiratory failure and pulmonary hypertension and are at high risk for death.

Pathophysiology. Risk factors predisposing preterm infants to BPD include extreme prematurity, oxygen toxicity, mechanical ventilation, and inflammation.⁷⁵ The pathologic findings characterized by severe airway injury and fibrosis in the old BPD

have been replaced in the new BPD with large, simplified alveolar structures, impaired capillary configuration, and various degrees of interstitial cellularity or fibroproliferation.⁷⁶ Airway and vascular lesions tend to be associated with more severe disease.

Oxygen-induced lung injury is an important contributing factor. Exposure to oxygen in the first 2 weeks of life and as chronic therapy has been associated in clinical studies with the severity of BPD.^{77,78} In animal models, hyperoxia has mimicked many of the pathologic findings of BPD. Results of two large, randomized trials enrolling preterm infants have suggested that the use of supplemental oxygen to maintain higher saturations resulted in worsening pulmonary outcomes.^{79,80}

Concerns regarding oxygen toxicity are reflected in the latest update of the neonatal resuscitation guidelines. Blended oxygen or, if not available, room air is recommended for initial resuscitation of preterm infants in the delivery room, along with continuous monitoring by pulse oximetry.⁸¹

Barotrauma and volutrauma associated with mechanical ventilation have been identified as major factors causing lung injury in preterm infants.^{82,83} Surfactant replacement therapy is beneficial in decreasing symptoms of RDS and improving survival. The efficacy of surfactant to decrease the incidence of subsequent BPD is less well established. Chronic inflammation and edema associated with positive-pressure ventilation cause surfactant protein inactivation.

As intrauterine inflammation is increasingly recognized as a cause of preterm parturition, antenatal inflammation is gaining more attention in the pathogenesis of BPD and other morbidities of prematurity.⁸⁴ Chorioamnionitis is strongly associated with impaired pulmonary and vascular growth, a typical finding in the new BPD.

Most deliveries before 30 weeks' gestation are associated with histologic chorioamnionitis, which except for preterm initiation of labor is otherwise clinically silent. The more preterm the delivery, the more often histologic chorioamnionitis is detected. Increased levels of proinflammatory mediators in amniotic fluid, placental tissues, tracheal aspirates, lung, and serum of ELBW preterm infants support an important role for intrauterine and extrauterine inflammation in the development and severity of BPD. The proposed interaction between the proinflammatory and anti-inflammatory influences on the developing fetal and preterm lung is detailed in Figure 72-4. Several animal models and preterm studies demonstrate that mediators of inflammation including endotoxins, tumor necrosis factor, interleukin 1 (IL-1), IL-6, IL-8, and transforming growth factor- α can enhance lung maturation but concurrently impede alveolar septation and vasculogenesis, contributing to the development of BPD.⁸⁵⁻⁸⁸ Chorioamnionitis alone is associated with BPD, but the probability is increased when these infants receive a second insult such as mechanical ventilation or postnatal infection.⁸⁹⁻⁹¹

Maternal genital mycoplasma infection, particularly with *Mycoplasma hominis* and *Ureaplasma urealyticum*, is associated with preterm delivery.⁹² Numerous studies have isolated these organisms from amniotic fluid and placentas in women with spontaneous preterm birth (i.e., preterm birth due to preterm labor or preterm rupture of the membranes). After the birth, these organisms colonize and elicit a proinflammatory response in the respiratory tract, leading to BPD.

The unpredictable incidence of BPD, despite adjusting for LBW and prematurity, suggests a genetic predisposition to the

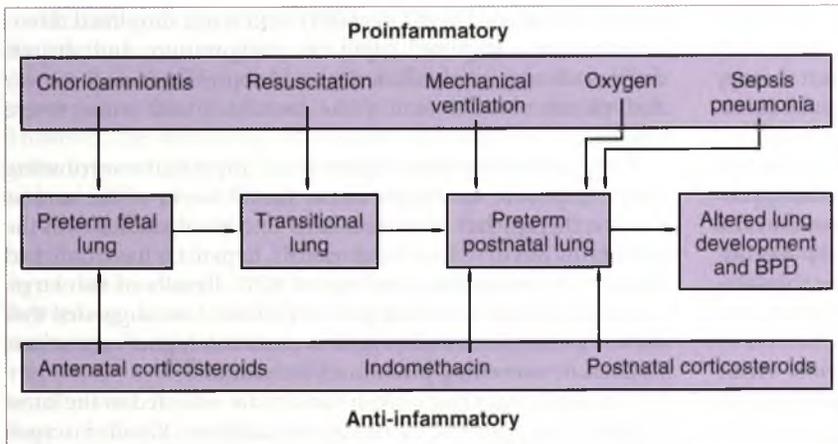

Figure 72-4 Role of inflammation in the pathogenesis of bronchopulmonary dysplasia (BPD).

occurrence and the severity of BPD. Expression of genes critical to surfactant synthesis, vascular development, and inflammatory regulation are likely to play a role in the pathogenesis of BPD. Twin studies have shown that the BPD status of one twin, even after correcting for contributing factors, is a highly significant predictor of BPD in the second twin. After controlling for covariates in this particular cohort, genetic factors accounted for 53% of the variance in the liability for BPD.⁹³ Genetic polymorphisms in the inflammatory response are increasingly recognized as important in the pathogenesis of preterm parturition (see Chapter 39), and may be similarly important in the genesis of inflammatory morbidities in the preterm neonate as well.

Long-Term Complications. Infants with BPD have significant pulmonary sequelae during childhood and adolescence. Reactive airway disease occurs more frequently with increased risk of bronchiolitis and pneumonia. Up to 50% of infants with BPD require readmission to hospital for lower respiratory tract illness in the first year of life.⁹⁴

BPD is an independent predictor of adverse neurologic outcomes. Infants with BPD have lower average IQs, academic difficulties, delayed speech and language development, impaired visual-motor integration, and behavioral problems.⁹⁵ Sparse data suggest an increased risk of attention deficit disorders and memory and learning deficits. Delayed growth occurs in 30% to 60% of infants with BPD at 2 years. The degree of long-term growth delay is inversely proportional to birth weight and directly proportional to the severity of BPD.

Prevention Strategies. Several strategies to decrease the incidence of BPD have been tried, including administration of surfactant in the delivery room, antioxidant superoxide dismutase, and vitamin A supplementation; optimizing fluid and parenteral nutrition; aggressive treatment of patent ductus arteriosus; minimizing mechanical ventilation; limiting exposure to high levels of oxygen; and preventing infection. Table 72-4 enumerates current strategies and their relative effectiveness in preventing BPD.⁹⁶ Large, controlled clinical trials and meta-analyses have not demonstrated a significant impact of these pharmacologic and nutritional interventions.⁹⁷ The multifactorial nature of BPD suggests that targeting individual pathways is unlikely to have a significant effect on outcome. Strategies that address several pathways simultaneously are more promising.

TABLE 72-4 Bronchopulmonary Dysplasia Prevention Strategies

Intervention	Relative Effectiveness*	Evidence or Quality of Data
Antenatal steroids	+	Strong
Early surfactant	++	Strong
Postnatal systemic steroid	++	Moderate
Vitamin A	+	High
Antioxidants	-	Moderate
Permissive hypercapnia	+++	Minimal
Fluid restriction	++	Moderate
High-frequency ventilation	±	Moderate
Delivery room management	++++	Animal data
Inhaled nitric oxide	+	Minimal
Continuous positive airway pressure used early	+++	Moderate

*Relative effectiveness of each intervention to reduce the severity of bronchopulmonary dysplasia. The range of symbols from - through ++++ is based on published literature and clinical experience.

Meconium-Stained Amniotic Fluid and Meconium Aspiration Syndrome

The significance and management of meconium-stained amniotic fluid has evolved with time. Meconium is found in the fetal intestine by the second trimester. Maturation of intestinal smooth muscle and the myenteric plexus progresses through the third trimester. Intrauterine passage of meconium is unusual before 36 weeks' gestation, and it does not typically occur for several days after preterm delivery. The potential for intrauterine meconium passage increases with each week of gestation thereafter.⁹⁸ The physiologic stimuli for passage of meconium are still incompletely understood. Clinical experience and epidemiologic data suggest that a stressed fetus may pass meconium before birth. Infants born through meconium-stained amniotic fluid have a lower pH and are likely to have non-reassuring fetal heart tracings.⁹⁹ Meconium-stained amniotic fluid occurs in 12% to 15% of all deliveries and occurs more frequently in cases of post-term gestation and in African Americans births.¹⁰⁰

In contrast to meconium-stained amniotic fluid, meconium aspiration syndrome is unusual. Meconium aspiration syndrome is a clinical diagnosis that includes delivery through

meconium-stained amniotic fluid along with respiratory distress and a characteristic radiographic appearance of the chest. Approximately 2% of deliveries with meconium-stained amniotic fluid are complicated by meconium aspiration syndrome, but the reported incidence varies widely.^{101,102} The severity of the syndrome also varies. The hallmarks of severe disease are the need for positive-pressure ventilation and the finding of pulmonary hypertension. Severe meconium aspiration is associated with significant mortality and morbidity risks, including air leak, chronic lung disease, and developmental delay.

A relationship between meconium-stained amniotic fluid and meconium aspiration syndrome has been presumed since the 1960s, when the strategy of tracheal suctioning in the delivery room to prevent meconium aspiration was proposed.¹⁰³ By the 1970s, this practice was clinically established and affirmed by retrospective reviews. Oropharyngeal suctioning on the perineum before delivery of the chest to complement tracheal suctioning was also recommended.

Additional studies did not verify the benefit of tracheal suctioning. Tracheal suctioning did not affect the incidence of meconium aspiration syndrome in vigorous infants in a large, prospective, randomized trial.¹⁰⁴ Another prospective, randomized, controlled study of 2514 infants to determine the efficacy of oropharyngeal suctioning before delivery of the fetal shoulders in infants born through meconium-stained amniotic fluid also found no reduction in meconium aspiration syndrome.¹⁰⁵ Amnioinfusion during labor to dilute the concentration of meconium to prevent meconium aspiration has been studied, but a randomized trial found no reduction in the incidence or severity of meconium aspiration with this method.¹⁰⁶ Results of these well-designed clinical trials reinforce the notion that meconium-stained amniotic fluid may not have a true mechanistic, pathophysiologic connection with meconium aspiration syndrome.

In 2001, Ghindini and Spong¹⁰⁷ questioned the connection between meconium-stained amniotic fluid and meconium aspiration syndrome. Reports describe infants born through clear amniotic fluid with respiratory distress, pulmonary hypertension, and other clinical characteristics of meconium aspiration syndrome.¹⁰⁸ Experimental data suggest that factors promoting fetal acidosis and hypoxemia promote remodeling of resistance pulmonary arteries. These same factors can promote intrauterine meconium passage. However, the remodeling perhaps exacerbated by inflammation from infection or by meconium, produces a clinical syndrome currently called meconium aspiration syndrome.^{109,110}

The incidence of meconium aspiration syndrome has decreased in several centers during the past several years, perhaps as a consequence of improvements in obstetric assessment and management,^{111,112} including a reduction in the incidence of post-term deliveries. Our center has experienced a decline in meconium aspiration syndrome while concurrently pursuing a policy of no routine tracheal suctioning for infants born through meconium-stained amniotic fluid.

Treatment of severe meconium aspiration syndrome has dramatically improved in recent years, leading to decreases in morbidity and mortality. Significant advances have come from treatment of pulmonary hypertension with selective pulmonary vasodilators, including inhaled nitric oxide, sildenafil, and bosentan. These agents improve oxygenation and allow less injurious ventilator strategies with reduced morbidity from air leak and chronic lung disease. Exogenous surfactant administration may be another useful treatment modality. Although the

mechanism is unclear, this intervention reduces ventilation-perfusion mismatch and probably reduces the risk of ventilator-associated lung injury.¹¹³

The current state of knowledge regarding meconium-stained amniotic fluid and meconium aspiration syndrome presents challenges for obstetricians and neonatologists. Although the incidence of meconium aspiration syndrome has decreased, the reasons for the decline are not readily apparent. The Neonatal Resuscitation Program¹ protocol for delivery room management does not recommend tracheal suctioning for vigorous infants, implying that airway management to support ventilation should take precedence. Meconium or other material obstructing the airway should be cleared, but suctioning an unobstructed airway at the expense of delaying initiation of effective ventilation may be deleterious. A collaborative approach between obstetrician and neonatologist is paramount. Personnel skilled in the establishment of ventilation and airway patency should attend any infant expected to be depressed at delivery.

Pulmonary Hypertension

At delivery, the normal transition from fetal to neonatal pulmonary circulation is mediated by a rapid, dramatic decrease in pulmonary vascular resistance. Endothelial cell shape change, relaxation of pulmonary arteriolar smooth muscle, and alveolar gaseous distention all contribute to this process.¹¹⁴ Several pathologic processes, including congenital malformations, sepsis, and pneumonia, can alter this sequence to produce neonatal pulmonary hypertension. It typically accompanies pulmonary hypoplasia, in which diminished surface area for gas exchange and inadequate pulmonary blood flow lead to hypoxia and remodeling of the resistance pulmonary arterioles. These vessels are more prone to constriction under conditions of acidosis and hypoxemia, resulting in the right-to-left shunting of deoxygenated blood that is characteristic of neonatal persistent pulmonary hypertension. In neonates, pulmonary hypertension tends to mimic prenatal physiology when pulmonary vascular resistance is necessarily high.

First principles of management include optimal oxygenation and ventilation through elimination of ventilation-perfusion mismatch. When positive-pressure ventilation is employed, over-distention must be avoided to minimize the risk of lung injury and BPD. Treatment of pulmonary hypertension has been revolutionized by pharmacologic interventions that specifically reduce pulmonary vascular resistance. Of these, nitric oxide is the best studied, with clear evidence of efficacy for treatment of pulmonary hypertension in the setting of meconium aspiration syndrome or sepsis.¹¹⁵ Clinical experience with other pulmonary vasodilators, including sildenafil, bosentan, and prostacyclin, is increasing and has proved useful in certain clinical situations.¹¹⁶

Excessive proliferation of medial smooth muscle or its presence in vessels ordinarily devoid of smooth muscle complicates the treatment of pulmonary hypertension. This pathologic remodeling can occur in utero or during postnatal life. The stimuli for this process are not understood, but they typically include hypoxic stress of extended duration and volutrauma associated with mechanical ventilation. Pulmonary vasodilators become less effective as remodeling progresses, prompting clinicians to pursue gentle ventilation strategies.¹¹⁷ By focusing on preductal rather than postductal oxygen saturations, lower ventilator settings can be achieved, reducing the risk of remodeling.

GASTROINTESTINAL PROBLEMS IN THE NEONATAL PERIOD

NEC is a devastating complication of prematurity, and the most common gastrointestinal emergency in the neonatal period. It affects 1% to 5% of NICU admissions.¹¹⁸ The reported incidence is 4% to 13%¹¹⁹ in VLBW infants (<1500 g). NEC is characterized by an inflammation of the intestines, which can progress to transmural necrosis and perforation. The onset is typically within the first 2 to 3 weeks of life, but it can occur well beyond the first month. The mortality rate for NEC ranges from 10% to 30% for all cases and up to 50% for infants requiring surgery.¹¹⁹⁻¹²² As more preterm and LBW infants survive the initial days of life, the number of infants at risk for NEC has increased. From 1982 to 1992, although the overall U.S. neonatal mortality rates declined, the mortality rates for NEC increased.¹²³

A variety of antenatal and postnatal exposures have been suggested as risk factors for NEC.^{120,121,124} Gestational age and birth weight are consistently related to NEC. Among prenatal factors, indomethacin tocolysis has been most often reported. Some studies reported a reduced incidence of NEC among infants treated with antenatal steroids.¹²⁵⁻¹²⁷

Initial trials on the use of indomethacin as a tocolytic showed no adverse neonatal effects, although sample sizes were small.^{128,129} Subsequent case reports and retrospective reviews suggested that indomethacin might be associated with adverse neonatal outcomes, including NEC.^{130,131} Others found no association^{132,133} of indomethacin tocolysis with NEC when used as a single agent, but they did find an increased risk when it was used as part of double-agent tocolytic therapy. A meta-analysis of randomized controlled trials and observational studies from

1966 through 2004 found no significant association between indomethacin tocolysis and NEC in either study type, although the pooled sample size of the published randomized controlled trials limited statistical power.¹³⁴ A retrospective cohort study of 63 antenatally indomethacin-exposed infants found an association with early-onset NEC (\leq first 14 days of life) after controlling for a variety of covariates (adjusted odds ratio [aOR] = 7.2; CI, 2.5 to 20.6).¹³⁵ A larger, multicenter study is needed to corroborate these results, and the risks of indomethacin must be weighed against the benefits in preventing preterm birth.

Postnatal interventions to prevent NEC include the use of human milk and probiotics. Decreased incidence of NEC correlates with ingestion of human milk. A meta-analysis of randomized controlled trials evaluating use of human milk and NEC found a fourfold decrease (relative risk = 0.25; 95% confidence interval [CI], 0.06 to 0.98) with the use of human milk.¹³⁵ Mothers of infants at risk, particularly those younger than 32 weeks' gestation, should be encouraged to supply breast milk. Providing early prenatal and postnatal counseling on the use of human milk increases the initiation of lactation and neonatal intake of mother's milk without increasing maternal stress or anxiety.¹³⁶ The role of probiotics is promising but remains controversial, with no consensus regarding organism or dose,¹³⁷ and additional data are required for the highest-risk group, ELBW infants.

NEC may manifest slowly or as a sudden catastrophic event. Abdominal distention occurs early, with bloody stools in 25% of cases.¹¹⁸ The radiographic hallmark is the presence of pneumatosis intestinalis or portal venous gas (Fig. 72-5). Progression may be rapid, resulting in bowel perforation with evidence of free air on the radiograph. Early management consists of bowel decompression, intravenous antibiotics, and respiratory

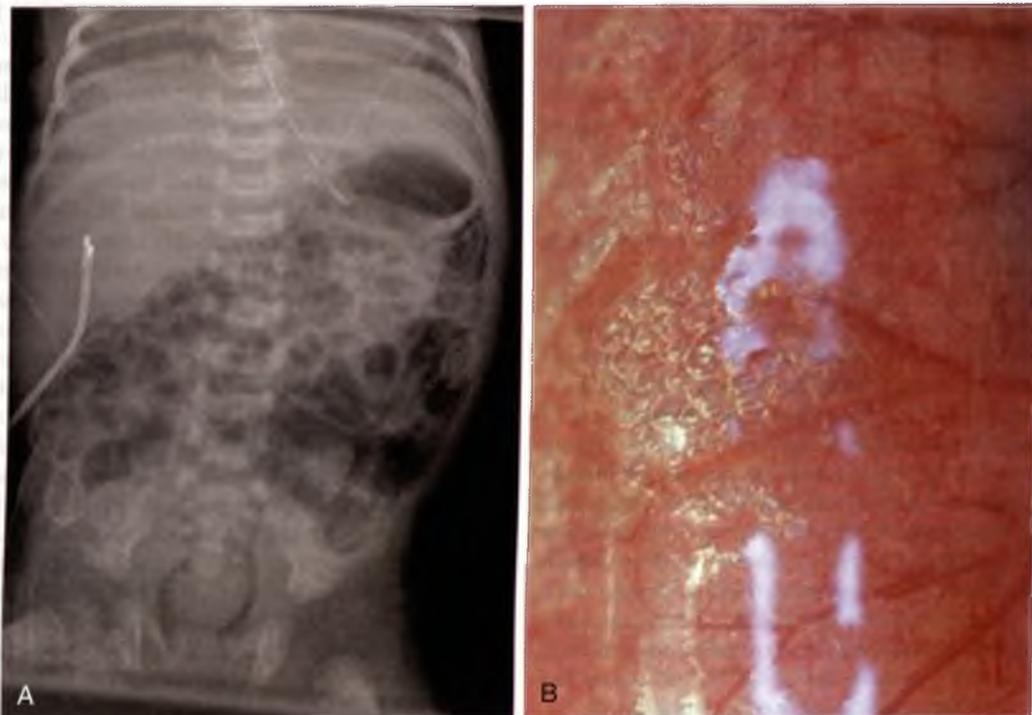

Figure 72-5 Diagnosis and pathology of necrotizing enterocolitis. A, Typical radiographic appearance of necrotizing enterocolitis, demonstrating pneumatosis and intramural gas. B, Intraoperative photograph of the small bowel, which contains intramural gas.

and cardiovascular support as indicated. The single absolute indication for surgical intervention is pneumoperitoneum.

For infants who survive NEC, the morbidity rate is high, including high rates of growth failure, chronic lung disease, and nosocomial infections.¹³⁷⁻¹³⁹ Lengths of stay and hospital costs are significant, particularly for surgical cases of NEC.¹³⁹ Long-term neurologic outcomes are adversely affected. NEC is an independent risk factor for CP and developmental delay.^{137,138,140} For infants needing surgery for NEC, depending on the amount of bowel lost, there is risk of short gut syndrome requiring parenteral nutrition and small bowel and liver transplantation. NEC is the single most common cause of the short gut syndrome in children.^{31,141,142}

Hyperbilirubinemia

Hyperbilirubinemia is common; 60% of term infants and 80% of preterm infants develop jaundice in the first week of life.¹⁴³ Bilirubin levels are elevated in neonates due to increased production coupled with decreased excretion. Increased production is related to higher rates of red blood cell turnover and shorter red blood cell life span.¹⁴⁴ Rates of excretion are lower because of diminished activity of glucuronosyltransferase, limiting bilirubin conjugation, and increased enterohepatic circulation. In most cases, jaundice has no clinical significance because bilirubin levels remain low, and it is transient. Less than 3% of patients develop levels greater than 15 mg/dL.¹⁴³ Risk factors for development of severe jaundice are outlined in Box 72-1.

Some important risk factors have their origin in the prenatal and perinatal environment. Hyperbilirubinemia is seen more frequently in IDMs. The pathogenesis of increased bilirubin in IDMs is uncertain but has been attributed to polycythemia and to increased red blood cell turnover.^{145,146} Prenatally, maternal blood group immunization may result from blood transfusion or fetal-maternal hemorrhage. Although the prevalence of Rh(D) immunization has significantly decreased with the advent of prevention programs, including use of Rh immune globulin, antibodies to other blood group antigens may occur. ABO hemolytic disease, a common cause of severe jaundice in newborns, rarely causes hemolytic disease in the fetus. Other antibodies associated with hemolytic disease in the fetus and newborn are discussed in Chapter 36. A fetus who is apparently unaffected in utero may have continued postnatal hemolysis,

and physicians caring for the newborn should be notified about any maternal sensitization.

Other perinatal factors associated with severe hyperbilirubinemia include delivery before 38 weeks' gestation. Infants born at 36 to 37 weeks have an almost sixfold increase of significant hyperbilirubinemia¹⁴⁷ and require close surveillance and monitoring, especially if breastfed.¹⁴⁸ Feeding difficulties, which also are common for the near-term infant, increase this risk still further and may result in delayed hospital discharge or readmission for the infant. Bruising and a cephalohematoma, which are more common after instrumented or difficult deliveries, also increase the risk. Polymorphisms of genes coding for enzymes mediating bilirubin catabolism may contribute to the development of severe hyperbilirubinemia.¹⁴⁹

The primary consequence of severe hyperbilirubinemia is neurotoxicity. Kernicterus is a neurologic syndrome resulting from deposition of unconjugated bilirubin in the basal ganglia and brainstem nuclei and from neuronal necrosis.¹⁵⁰ Acute or chronic clinical features may include tone and movement disorders such as choreoathetosis and spastic quadriplegia, mental retardation, and sensorineural hearing loss.¹⁵¹

Several factors influence the neurotoxic effects of bilirubin, making the prediction of outcome difficult. Bilirubin more easily enters the brain if it is not bound to albumin or is unconjugated or if there is increased permeability of the blood-brain barrier.¹⁵¹ Conditions that alter albumin levels such as prematurity or that alter the blood-brain barrier such as infection, acidosis, and prematurity affect bilirubin entry into the brain. There is no serum level of bilirubin that predicts outcome. In early studies of infants with Rh hemolytic disease, kernicterus developed in 8% of infants with serum bilirubin concentrations of 19 to 24 mg/dL, in 33% with levels of 25 to 29 mg/dL, and in 73% of infants with levels 30 to 40 mg/dL.¹⁵⁰

Levels of indirect bilirubin below 25 mg/dL in otherwise term healthy infants without hemolytic disease are unlikely to result in kernicterus without other risk factors, as indicated in a study of 140 term and near-term infants with levels above 25 mg/dL, in which no cases of kernicterus occurred.¹⁵² Kernicterus has been reported in otherwise healthy, breastfed, term newborns at levels above 30 mg/dL.¹⁵³ One of the most important of these risk factors is prematurity. The less mature the infant, the greater the susceptibility of the neonatal brain.¹⁵⁰ At what level more subtle neurologic abnormalities appear remains unclear.¹⁴⁸

Management of hyperbilirubinemia is aimed at the prevention of bilirubin encephalopathy while minimizing interference with breastfeeding and unnecessary parental anxiety. Key elements in prevention include systematic evaluation of newborns before discharge for the presence of jaundice and its risk factors, promotion and support of successful breastfeeding, interpretation of jaundice levels based on the hour of life, parental education, and appropriate neonatal follow-up based on time of discharge.¹⁴⁸ Treatment of severe hyperbilirubinemia should be initiated promptly when identified. Guidelines for treatment with phototherapy and exchange transfusion vary with gestational age, the presence or absence of risk factors, and the hour of life. Nomograms to guide patient management are available from the American Academy of Pediatrics.¹⁴⁸ Kernicterus is largely preventable. Close collaboration between prenatal and postnatal caretakers ensures accurate dissemination of information regarding risk factors for parents and clinical providers to facilitate prompt recognition and treatment of significant hyperbilirubinemia.

BOX 72-1 COMMON CLINICAL RISK FACTORS FOR SEVERE HYPERBILIRUBINEMIA

- Jaundice in the first 24 hr
- Visible jaundice before discharge
- Previous jaundiced sibling
- Exclusive breastfeeding
- Bruising, cephalohematoma
- East Asian, Mediterranean, or Native American race
- Maternal age >25 yr
- Male sex
- Unrecognized hemolysis (i.e., ABO, Rhesus, anti-c, C, E, Kell, and other minor blood group antigens)
- Glucose-6-phosphate dehydrogenase deficiency
- Infant of a diabetic mother

Adapted from Centers for Disease Control and Prevention: Kernicterus in full-term infants—United States, 1994-1998, MMWR Morb Mortal Wkly Rep 50:491-494, 2001.

Feeding Problems

Feeding problems related to complications of prematurity, congenital anomalies, or gastrointestinal disorders contribute significantly to length of stay for hospitalized newborns. In a study of children referred to an interdisciplinary feeding team, 38% were born before term.¹⁵⁴ Premature infants with a history of neonatal chronic lung disease, neurologic injury such as IVH or periventricular leukomalacia (PVL), and those with a history of NEC are at highest risk for long-term feeding problems. These medically complex infants often have other comorbidities, such as tracheomalacia, chronic aspiration, and gastroesophageal reflux that interfere with normal maturational patterns of feeding. Premature infants with complex medical problems often require prolonged intubation and mechanical ventilation with delayed initiation of enteral feeding, all of which have been associated with subsequent feeding difficulties. Because of these medical interventions and neurologic immaturity, the infants often have difficulty integrating sensory input. These factors combine to increase the risk of developing oral aversion.

Infants with congenital anomalies are at high risk for feeding disorders. Infants with tracheoesophageal fistula with esophageal atresia often have difficulty feeding due to tracheomalacia, recurrent esophageal stricture, and gastroesophageal reflux, which are known associates of this disorder. Infants with congenital diaphragmatic hernia have an extremely high incidence of oral aversion and growth problems in addition to the pulmonary complications. Surviving infants and children with congenital diaphragmatic hernia have a 60% to 80% incidence of associated gastroesophageal reflux that can persist into adulthood.¹⁵⁵⁻¹⁶⁰ Often, the gastroesophageal reflux is severe, refractory to medical therapy, and requires a surgical antireflux procedure. Infants with congenital diaphragmatic hernia often have inadequate caloric intake due to fatigue or oral aversion and increased energy requirements leading to poor growth. These infants typically require supplemental tube feedings by nasogastric, nasojejunal, or gastrostomy feeding tube. Feeding difficulties may last several years and are often accompanied by behavioral-based feeding difficulties.

Infants with congenital or acquired gastrointestinal abnormalities frequently have associated feeding difficulties. Infants with conditions such as gastroschisis with or without associated intestinal atresias often require prolonged hospitalization because of a low tolerance of enteral feedings and a higher risk of NEC after gastroschisis repair.^{161,162} They often have dysmotility and severe gastroesophageal reflux with oral aversion.¹⁶³ A small percentage of patients have long-term intolerance of enteral feedings and require prolonged total parenteral nutrition (TPN). Patients requiring long-term TPN may develop liver injury or cholestasis, and they ultimately may require liver and small bowel transplantation. Depending on the length and function of the remaining bowel, infants who develop short bowel syndrome due to NEC also have difficulties tolerating enteral feeds. Like patients with gastroschisis, infants with severe short bowel syndrome may require prolonged TPN and eventually develop liver and intestinal failure requiring transplantation.

Investigational Strategies

Premature infants and infants with congenital anomalies or acquired gastrointestinal abnormalities are at high risk for long-term feeding problems. It is important to counsel families

regarding this risk. Minimizing iatrogenic oral aversion is crucial. Involving a feeding specialist early in a medically complex infant's course may lessen the impact.

NEONATAL MANAGEMENT OF NEUROLOGIC PROBLEMS

Hypoxic-Ischemic Encephalopathy

Injury to the brain sustained during the perinatal period was once thought to be a common cause of death or severe, long-term neurologic deficits in children.¹⁶⁴ Later data show that only 10% of brain injury is related to perinatal or intrapartum events.^{165,166} There is increasing recognition that events occurring well before labor contribute more significantly to brain injury. Despite improvements in perinatal practice, the incidence of hypoxic-ischemic encephalopathy has remained stable at 1 to 2 infants per 1000 term births.^{167,168} Strategies for prevention of brain injury have been mainly supportive, because prevention has been difficult due to a lack of clinically reliable indicators and the fact that the initiating event often occurs before the onset of labor. Because the brain injury that develops is initiated by the hypoxic-ischemic event and affected by a reperfusion phase of injury, newer strategies targeting this process of ongoing injury are being developed for neuroprotection.^{169,170}

Definition of Asphyxia. In hypoxic-ischemic encephalopathy, cerebral blood flow is impaired, likely because of interrupted placental blood flow leading to impaired gas exchange.¹⁷¹ If gas exchange is persistently impaired, hypoxemia and hypercapnia develop with resultant fetal acidosis, a state referred to as *asphyxia*. Severe fetal acidemia, defined as an umbilical arterial pH of less than 7.00, is associated with an increased risk of adverse neurologic outcome.^{172,173} However, even with this degree of acidemia, few infants develop significant encephalopathy and sustained neurologic injury.¹⁷⁴ Fetal scalp blood sampling and umbilical cord gas data are not sensitive enough to predict long-term neurologic impairment.

Clinical Markers. Other clinical measures to identify fetal stress such as fetal heart rate abnormalities, meconium-stained amniotic fluid, low Apgar scores, and the need for cardiopulmonary resuscitation (CPR) in the delivery room do not reliably identify infants at high risk for brain injury when used in isolation. Despite the widespread use of electronic fetal heart rate monitoring, which detects changes in fetal heart rate related to fetal oxygenation, there has been no reduction in the incidence of CP.¹⁷² In 2005, an American College of Obstetricians and Gynecologists (ACOG) Practice Bulletin¹⁷³ concluded that electronic fetal heart rate monitoring has a high false-positive rate for predicting adverse outcomes and is associated with an increase in operative deliveries without any reduction in CP.

Meconium-stained amniotic fluid is commonly seen during labor, but no data exist to associate it with adverse neurologic outcome. Apgar scores were originally introduced to identify infants in need of resuscitation and not to predict neurologic outcome. Apgar scores are not specific to an infant's acid-base status but can reflect drug use, metabolic disorder, trauma, hypovolemia, infection, neuromuscular disorders, and congenital anomalies. However, a persistently low Apgar score after 5 minutes despite intensive CPR has been associated with increased morbidity and mortality.^{171,173-177} The combination of

a low 5-minute Apgar score with other markers such as fetal acidemia and the need for CPR in the delivery room predicts a significantly increased risk of brain injury.^{178,179} Investigators documented a 340-fold increased risk of seizures and associated moderate to severe encephalopathy associated with a 5-minute Apgar score of 5 or less, delivery room intubation or CPR, and an umbilical arterial cord pH of less than 7.00.¹⁷⁹

Neonatal Encephalopathy. Neonatal encephalopathy is clinically characterized by depressed level of consciousness, abnormal muscle tone and reflexes, abnormal respiratory pattern, and seizures.¹⁸⁰ These findings may result from a hypoxic-ischemic event but can also be caused by other conditions such as metabolic disorders, neuromuscular disorders, toxin exposure, and chromosomal abnormalities or syndromes. Not all infants with neonatal encephalopathy develop permanent neurologic impairment.

The Sarnat staging system is used to classify the degree of encephalopathy and predict neurologic outcome.¹⁷⁴ Infants with mild encephalopathy (Sarnat stage 1) typically have a favorable outcome. Between 20% and 25% of infants with moderate encephalopathy (Sarnat stage 2) develop long-term neurologic compromise, and infants with severe encephalopathy (Sarnat stage 3) have a greater than 80% risk of death or long-term neurologic sequelae.¹⁸⁰

Multiorgan Injury. In addition to neurologic compromise, the interruption of placental blood flow can result in systemic organ injury. Animal models and clinical studies have demonstrated that the kidney is exquisitely sensitive to reductions in renal blood flow.^{181,182} The result of decreased renal perfusion is acute tubular necrosis with various degrees of oliguria and azotemia.

Other organ systems are also sensitive to reduced blood flow. Decreased blood flow to the gastrointestinal tract can lead to luminal ischemia and an increased risk of NEC. Decreased pulmonary blood flow can result in persistent pulmonary hypertension of the newborn. Lack of blood flow to the liver can result in hepatocellular injury and impaired synthetic function leading to hypoglycemia and disseminated intravascular coagulation. Fluid retention and hyponatremia can develop due to the combination of impaired renal function and the release of antidiuretic hormone. Suppression of parathyroid hormone release can lead to hypocalcemia and hypomagnesemia. These electrolyte abnormalities can further affect myocardial function. Muscle can be affected by electrolyte abnormalities and direct cellular injury leading to rhabdomyolysis.¹⁷¹

Neuropathology. The reduction in cerebral blood flow associated with a hypoxic-ischemic event sets off a complex cascade of regional circulatory factors and biochemical changes at the cellular level. Hypoxia induces a switch from normal oxidative phosphorylation to anaerobic metabolism, leading to depletion of high-energy phosphate reserves, accumulation of lactic acid, and inability to maintain cellular functions.^{170,183} The end result is cellular energy failure, metabolic acidosis, release of glutamate and intracellular calcium, lipid peroxidation, buildup of nitric oxide, and eventual cell death.^{170,180,184} This process of cellular injury is being targeted for neuroprotection strategies.

Neuroimaging. Diffusion-weighted magnetic resonance imaging (MRI) has become the standard for defining the extent and timing of brain injury. Diffusion-weighted techniques can detect signal changes due to reduced water diffusion in the brain within the first 24 to 48 hours of the insult.^{171,185-187}

Magnetic resonance spectroscopy can also detect alterations in metabolites such as lactate, *N*-acetyl aspartate, choline, and creatinine in specific regions of the brain that indicate injury.^{185,188} However, MRI is difficult to perform in an unstable patient, and computed tomography (CT) may be preferable as the initial study for term infants and ultrasound for preterm infants.

Neuroprotection Strategies. The brain can be cooled by selective cooling of the head or systemic hypothermia. This therapy has been studied to reduce neurologic injury due to neonatal hypoxic-ischemic encephalopathy. Five large, randomized, controlled trials collectively demonstrated a significant reduction in a combined outcome of death or long-term major neurodevelopmental disability at 18 months of follow-up.¹⁸⁹ Additional work is required to define populations most likely to benefit from treatment, as well as duration of the therapeutic window, optimal target temperatures, and safety for preterm infants. Since these studies, many other randomized clinical trials have shown that hypothermia by selective head cooling or whole body cooling is associated with a reduction in death and severe neurodevelopmental disability at 18 months of age for term infants with moderate to severe hypoxic-ischemic encephalopathy.¹⁹⁰

Therapeutic hypothermia has become the standard of care for infants of 36 or more weeks' gestation with moderate to severe hypoxic-ischemic encephalopathy. It should be initiated as soon as possible after birth. Head cooling and total body cooling appear equally efficacious and have similar safety profiles.¹⁹¹

Future efforts are focused on early identification of infants at the greatest risk for hypoxic-ischemic injury and on defining the therapeutic window for effective treatment that was initially thought to be limited to within 6 hours of delivery. Ongoing studies are evaluating the benefit of late hypothermia (>6 hours after birth). Infants at highest risk have evidence of a sentinel event during labor, have pronounced respiratory and neuromuscular depression at delivery with persistently low Apgar scores, need delivery room resuscitation, have severe fetal acidemia (umbilical artery pH < 7.00 or base deficit \geq 16 mEq/L), have an early abnormal neurologic examination result, have seizures, and have abnormal amplitude-integrated electroencephalography (aEEG) results.^{170,180,192-194} Possible pharmacologic adjunctive therapies in addition to hypothermia are being investigated.^{195,196}

Investigational Strategies. Hypoxic-ischemic brain injury due to intrapartum asphyxia is a rare but serious cause of long-term neurodevelopmental disability. It is often difficult to define a specific intrapartum event because the initiating event may occur before the onset of labor. Early identification of at-risk newborns by neuroimaging techniques, aEEG findings, history, and clinical examination may provide an opportunity to ameliorate the effects of ongoing brain injury using neuroprotective strategies. The goal of these therapeutic interventions is the reduction of long-term neurodevelopmental disabilities including CP.

Intraventricular Hemorrhage

IVH or germinal matrix hemorrhage occurs most commonly in preterm infants and is a major cause of mortality and long-term disability. Bleeding originates in the subependymal germinal matrix but may rupture through the ependyma into the ventricular system. IVH is graded as four categories:

Grade I: bleeding is localized to the germinal matrix

Grade II: bleeding into the ventricle but the clot does not distend the ventricle

Grade III: bleeding into the ventricle with ventricular dilation

Grade IV: intraparenchymal extension

Incidence. The diagnosis is made most commonly by cranial ultrasound with most hemorrhages occurring within 6 hours of birth and 90% within the first 5 days of life.¹⁹⁷ The incidence of IVH has decreased significantly with improvements in perinatal care such as maternal transfer and antenatal steroids. From 1990 to 1999, the incidence of IVH for infants weighing less than 1000 g at birth was 43%, and 13% of cases were grade III or grade IV. Between 2000 and 2002, the overall incidence of IVH decreased to 22%; 3% of cases were severe despite improvements in survival.¹⁹⁸ Lower gestational age is associated with an increased risk of severe IVH.¹⁷⁵

Pathogenesis. Anatomic and physiologic factors have been implicated in the pathogenesis of IVH. The germinal matrix is composed of thin-walled blood vessels that lack supportive tissue. These fragile vessels have a tendency to rupture spontaneously or in response to stress such as hypoxia-ischemia, changes in blood pressure or cerebral perfusion, and pneumothoraces. In addition to these structural factors, premature infants have an immature cerebrovascular autoregulation system, the so-called pressure-passive circulation in response to systemic hypotension, which makes them more susceptible to hemorrhage.^{182,197,199} Immaturities in the coagulation system and increased fibrinolytic activity of premature infants may also play a role.^{176,200-202}

Outcomes. Although infants with grade I or II IVH were thought to have outcomes similar to those without cranial ultrasound abnormalities, a study by Patra and colleagues suggests that ELBW infants with grade I or II IVH have worse neurodevelopmental outcomes at 20 months' corrected age compared with those with normal cranial ultrasound scans.²⁰³ About 35% of infants with grade III IVH have adverse neurologic outcomes. Among those who develop posthemorrhagic hydrocephalus requiring surgical intervention, the disability rate increases to about 60%.¹⁷⁶ Grade IV IVH is associated with the highest mortality rates, and 80% to 90% are associated with a poor neurologic outcome.¹⁷⁷

Antenatal Prevention. The only therapies shown to decrease the incidence of IVH among premature infants are antenatal corticosteroid administration and maternal transfer to a tertiary care center for delivery. Many studies have shown that the administration of corticosteroids before preterm delivery to induce lung maturity has significantly reduced the incidence of RDS, mortality, and severe IVH. According to a meta-analysis of four trials of 596 infants from 24 to 33 weeks' gestation, prenatal corticosteroid therapy was associated with a relative risk reduction for IVH of 0.57 (CI, 0.41 to 0.78).¹⁷⁸ Maternal transfer to a tertiary care center for gestational age less than 32 weeks decreased the incidence of death or major morbidity, including IVH.⁴³ Antenatal phenobarbital, vitamin K, and magnesium sulfate have failed to demonstrate a consistent decrease in rates of overall IVH, severe IVH, or death.²⁰⁴⁻²⁰⁶

Postnatal Prevention. The goal of postnatal prevention has been blood pressure stabilization to prevent fluctuations in cerebral perfusion, correction of coagulation disturbances, and

stabilization of germinal matrix vasculature.¹⁹⁷ Postnatal administration of phenobarbital and muscle paralysis can stabilize blood pressure, but neither has decreased the incidence of IVH or neurologic impairment.^{207,208} Routine use of paralytics to prevent IVH in ventilated patients is not recommended. Fresh-frozen plasma and ethamsylate to promote platelet adhesiveness and correct coagulation disorders also do not reduce the incidence of IVH.^{206,209-211}

Indomethacin remains the most promising preventive therapy for IVH due to its ability to constrict the cerebral vasculature, inhibit prostaglandin and free radical production, and mature the germinal matrix vasculature.^{209,212-214} Prophylactic indomethacin decreases the incidence of severe IVH. Follow-up studies have shown slight improvement in cognitive function in infants who received prophylactic indomethacin but no difference in the incidence of CP.²¹⁵⁻²¹⁷ Prophylactic indomethacin is reserved for preterm infants at high risk for IVH until further studies clarify the appropriate candidates for prophylaxis.

Posthemorrhagic Hydrocephalus. The most serious complication of IVH is posthemorrhagic hydrocephalus due to obstruction of cerebrospinal fluid (CSF) flow. This occurs when multiple blood clots obstruct CSF reabsorption channels, leading to transforming growth factor-1 β (TGF-1 β)–stimulated production of extracellular matrix proteins such as fibronectin and laminin and to scar formation.²¹⁸ Progressive ventricular dilation can worsen brain injury due to damage of periventricular white matter by increased intracranial pressure and edema.¹⁷⁹ Treatment such as serial lumbar punctures, diuretics, and intraventricular fibrinolytic therapy are ineffective and may even be harmful.²¹⁹ Although surgical shunt placement carries significant risks of shunt complications and infection, it remains the definitive therapy for progressive posthemorrhagic hydrocephalus.

Investigational Strategies. IVH due to a fragile germinal matrix and an unstable cerebrovascular autoregulatory system remains a significant cause of neurologic morbidity in preterm infants. Infants with cardiorespiratory complications are at highest risk. Antenatal corticosteroids are the most effective preventive therapy currently available. Despite significant reduction in the incidence of severe IVH, new prevention and treatment strategies for hydrocephalus are needed.

Periventricular Leukomalacia

PVL refers to injury to the deep cerebral white matter in two characteristic patterns: *focal periventricular necrosis* and *diffuse cerebral white matter injury*. This type of brain injury typically affects premature infants and is a common cause of CP. Preterm infants who have suffered an IVH or have cardiopulmonary instability are at the highest risk. Other intrauterine factors such as infection, premature prolonged rupture of the membranes, first-trimester hemorrhage, placental abruption, and prolonged tocolysis have been associated with increased risk of PVL.^{182,220-223}

The reported incidence of PVL detected by ultrasound examination among VLBW infants is 5% to 15%.²²⁴ However, ultrasound often fails to identify the more subtle evidence of diffuse white matter injury, and MRI may be a more sensitive imaging study. The incidence of PVL diagnosed at autopsy is much higher, indicating that the true incidence of PVL is likely underestimated.

Neuropathology. Focal necrosis most commonly occurs in the cerebral white matter at the level of the trigone of the lateral ventricles and around the foramen of Monro.²³⁴ These sites make up the border zones of the long penetrating arteries. Classically, these lesions undergo a coagulative necrosis that results in cyst formation or focal glial scars.¹⁸² A more diffuse type of injury may also occur in conjunction with focal necrosis, but it is more frequently recognized as an independent entity. Diffuse white matter injury seems to affect premyelinating oligodendrocytes and leads to global loss of these cells and an increase in hypertrophic astrocytes.^{182,224-226} This loss of oligodendrocytes leads to white matter volume loss and ventriculomegaly.

Pathogenesis. PVL is primarily caused by hypoxia-ischemia that leads to neuronal injury from exposure to free radicals, toxic levels of proinflammatory cytokines, and excessive concentrations of excitatory neurotransmitters such as glutamate.¹⁸² Vascular anatomic factors also seem to play a role. PVL tends to occur in arterial end zones or so-called border zones.²²⁷ The arterial supply comprises long, penetrating arteries, which terminate deep in the periventricular white matter; basal penetrating arteries, which supply the immediate periventricular area; and short, penetrating arteries, which supply the subcortical white matter. Focal necrosis occurs most commonly in the anterior and posterior periventricular border zones, because in premature infants, these vessels are immature. Diffuse white matter injury may also occur due to vascular immaturity. In early gestations (24 to 28 weeks), there are few anastomoses between the long and short penetrators. Arterial border zones may occur in the subcortical and remote periventricular areas, resulting in a more diffuse type of injury.²²⁴

The preterm brain is vulnerable to ischemia due to impaired cerebrovascular regulation. Preterm infants exhibit a pressure-passive circulation; a decrease in systemic blood pressure is associated with a decrease in cerebral perfusion, which leads to ischemia.^{224,228-230} Immature oligodendrocytes seem to be more sensitive to free radical injury, cytokine effects, and the presence of glutamate.

Clinical Outcomes. The most common long-term sequela of PVL is spastic diplegia, a form of CP in which the lower extremities are more affected than the upper extremities. The descending fibers of the motor cortex, which regulate function of the lower extremities, traverse the periventricular area and are most likely to be injured. More severe injury with lateral extension may be associated with spastic quadriplegia or other manifestations such as cognitive, visual, or auditory impairments.

Investigational Strategies. PVL is a major cause of neurologic morbidity in premature infants, especially those weighing less than 1000 g at birth. Prevention is currently the only strategy for managing PVL. Avoidance of fluctuations in blood pressure and cerebral vasoconstrictors such as extreme hypocarbia are important because of the known immaturity in cerebrovascular autoregulation of preterm infants. Future investigations targeting the cascade of oligodendroglial death may be promising.

Perinatal Stroke

Arterial ischemic stroke in neonates is defined as a cerebrovascular event around the time of birth with resultant clinical or radiographic evidence of focal cerebral arterial infarction. Most occur in the distribution of the middle cerebral artery.^{184,231-233}

Arterial ischemic stroke accounts for most perinatal ischemic strokes. When the diagnosis is based on symptoms in the neonatal period, the reported incidence is 1 case in 4000 live births.^{184,234,235} The incidence of perinatal ischemic strokes that were asymptomatic in the neonatal period and diagnosed at a later time is unknown.

Clinical Presentation. Neonatal seizures are the most common clinical presentation of arterial ischemic stroke, and they usually are focal in origin without other signs of neonatal encephalopathy.^{184,236} However, some infants are systemically ill, and the diagnosis is made with neuroimaging to rule out evidence of hypoxic-ischemic injury or bleeding. Neonates with focal neurologic signs account for less than 25% of cases.^{231,235,237,238}

Perinatal stroke may also be identified retrospectively in initially well-appearing infants who present in later months with signs of hemiparesis, developmental delay, or seizures.^{184,239} In these cases, neuroimaging reveals a remote injury that is often in the territory of the middle cerebral artery.

Pathophysiology and Risk Factors. The mechanisms of perinatal stroke are thought to be multifactorial. Regional ischemia with subsequent hypoxia and infarction plays a role. A relative hypercoagulable state in newborns due to the presence of fetal hemoglobin, polycythemia, and activation of coagulation factors in the fetus and mother around the time of birth seems to increase the risk of a thromboembolic event that leads to stroke.^{184,240} Risk factors for perinatal stroke include maternal and placental disorders, neonatal hypoxic-ischemic injury, hematologic disorders, infection, cardiac disorders, trauma, and drugs.¹⁸⁴ A combination of risk factors often is identified.

Neuroimaging and Electroencephalographic Assessment. Although cranial ultrasound is the easiest to perform, it is not a sensitive indicator of perinatal stroke.¹⁸³ Little information exists on prenatal cranial ultrasound. However, prenatal ultrasound scans may demonstrate areas of unilateral echolucencies, which may represent areas later identified as prenatal stroke. CT imaging can usually be performed readily in neonates and usually does not require sedation. CT evidence of perinatal ischemic stroke includes focal hypodensity with or without intraparenchymal hemorrhage, abnormal gray-white differentiation, and evidence of volume loss or porencephaly if the injury is remote¹⁸⁴ (Fig. 72-6).

Diffusion-weighted MRI is the most sensitive method, especially in the setting of early infarction. MRI can demonstrate restricted diffusion within a vascular distribution for acute stroke and chronic changes such as encephalomalacia, gliosis, and ventriculomegaly for remote events. MR angiography may be useful in some cases to confirm arterial occlusion, although is not commonly used unless a vascular malformation is suspected. Functional MRI may be valuable in the future to understand how the brain reorganizes after perinatal stroke.^{231,241,242} EEG may be useful to detect subclinical seizures that may cause secondary brain injury.²³¹

Further diagnostic studies focused on risk factors for perinatal ischemic stroke should include blood tests for coagulation disturbances and genetic predispositions, urine toxicology for metabolic disorders and toxins such as cocaine, an echocardiogram, infectious workup that includes a lumbar puncture, maternal testing for acquired coagulation disorders (e.g., antiphospholipid antibodies), and an assessment of the placenta.¹⁸⁴

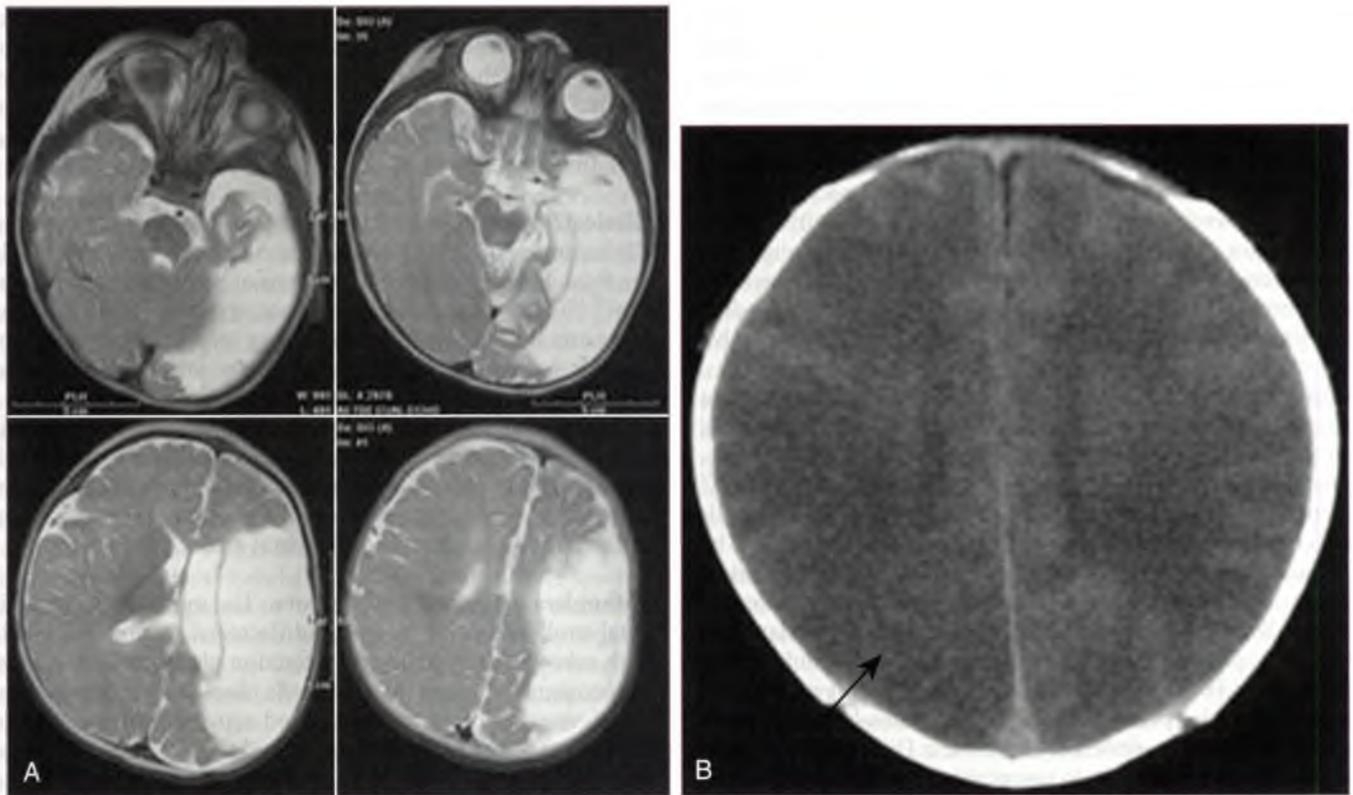

Figure 72-6 Diagnostic imaging studies of neonatal stroke. A, Magnetic resonance imaging study of a 6-month-old infant demonstrates a large region of encephalomalacia involving most of the left temporal lobe and large regions of the left frontal and parietal lobes. The distribution is consistent with a remote infarction of the left middle cerebral artery. The infant had a history of sepsis and disseminated intravascular coagulation during the early neonatal period. An ultrasound scan obtained when the infant was 1 day old was unremarkable. B, Computed tomography of a 1-day-old, term infant who presented with a focal seizure. The perinatal history was unremarkable. There is loss of gray-white matter differentiation involving the right parietal and occipital regions (arrow). There is a smaller area of involvement in the right frontal region. A cranial ultrasound examination was normal.

Outcome. Perinatal ischemic stroke is the most common cause of hemiplegic CP.¹⁸⁴ Although not all survivors of perinatal stroke suffer long-term disabilities, 50% to 75% of infants who suffered a perinatal stroke have a neurologic deficit or seizures.^{227,231,243-245} Lee and colleagues reported a population-based study of neonatal arterial ischemic stroke showing that 32% of infants with arterial ischemic stroke who presented with symptoms in the neonatal period eventually developed CP, whereas 82% of infants diagnosed retrospectively developed CP.²²⁷ Because the patients identified retrospectively had presented because of hemiparesis, they were more likely to be classified as having CP.

Investigational Strategies. Perinatal ischemic stroke is a major cause of long-term neurologic disability. Treatment is purely supportive, and management consists of rehabilitation focusing on muscle strengthening and prevention of contractures. Neuroprotective strategies and approaches to prevention are needed. Advanced neuroimaging techniques to better understand how the brain reorganizes after this type of injury are currently being used as research tools.

Cerebral Palsy

As early as 1862, William John Little described the relationship between children with motor abnormalities and pregnancy

complications such as difficult labor, neonatal asphyxia, and premature birth.¹⁸⁵ CP is a clinical diagnosis that refers to a group of nonprogressive motor impairments. In 2005, the International Committee on Cerebral Palsy Classification defined CP as “a group of developmental disorders of movement and posture, which cause activity limitations that are attributed to nonprogressive disturbances that occurred in the developing fetal or infant brain. The motor disorders of CP are often accompanied by disturbances of sensation, cognition, communication, perception, and behavior or by a seizure disorder.”¹⁸⁶ Despite improvements in perinatal care, the prevalence of CP has remained relatively unchanged over the past 50 years, with an incidence of 1.5 to 2.5 cases per 1000 live births.^{180,246,247}

Classification. Traditionally, CP has been classified by topography based on the affected limb involvement (i.e., monoplegia, hemiplegia, diplegia, triplegia, and quadriplegia) and a description of the predominant type of tone or movement abnormality (i.e., spastic, dyskinetic, ataxic, hypotonic, or mixed). The International Committee on Cerebral Palsy Classification has proposed a new system that also takes into account the presence or absence of associated impairments, other anatomic involvement besides limbs, radiologic findings, and causation (Box 72-2).

BOX 72-2 COMPONENTS OF CEREBRAL PALSY CLASSIFICATION

1. Motor abnormalities
 - a. Nature and typology of the motor disorder: the observed tonal abnormalities assessed on examination (e.g., hypertonia, hypotonia) and the diagnosed movement disorders (e.g., spasticity, ataxia, dystonia, athetosis)
 - b. Functional motor abilities: the extent to which the individual is limited in his or her motor function in all body areas, including oromotor and speech function
2. Associated impairments
 - a. Presence or absence of associated nonmotor neurodevelopmental or sensory problems, such as seizures, hearing or vision impairments, and attentional, behavioral, communicative, or cognitive deficits
 - b. Extent to which impairments interact in individuals with cerebral palsy
3. Anatomic and radiologic findings
 - a. Anatomic distribution: parts of the body (e.g., limbs, trunk, bulbar region) affected by motor impairments or limitations
 - b. Radiologic findings: neuroanatomic findings on computed tomography or magnetic resonance imaging (e.g., ventricular enlargement, white matter loss, brain anomaly)
4. Causation and timing
 - a. Whether there is a clearly identified cause, as is usually the case with postnatal cerebral palsy (e.g., meningitis, head injury) or when brain malformations are present
 - b. Presumed time frame during which the injury occurred, if known

Adapted from Bax M, Goldstein M, Rosenbaum P, et al: Proposed definition and classification of cerebral palsy, April 2005, *Dev Med Child Neurol* 47:571–576, 2005.

Etiology. CP is a result of injury to the developing brain that occurs during prenatal, perinatal, or postnatal life. Between 75% and 80% of cases of CP have been attributed to events during pregnancy. Ten percent are attributable to intrapartum events such as birth asphyxia,^{165,248,249} and 10% have postnatal causes such as head injury or central nervous system (CNS) infection.^{187,188} Risk factors of CP include prematurity, multiple gestation, growth restriction, intracranial hemorrhage, PVL, infections, placental pathology, genetic syndromes, structural brain abnormalities, birth asphyxia or trauma, and kernicterus. The origins of CP tend to be multifactorial, but in some cases, no cause is identified. Some of the more common risk factors are discussed in this section; the roles of intracranial hemorrhage, PVL, and birth asphyxia contributing to CP were discussed previously.

Prematurity. Prematurity and LBW seem to be the most important risk factors for CP; an increased prevalence of CP is associated with decreasing gestational age and decreasing birth weight compared with term infants. It is also important to consider the rates of CP and neurosensory impairments in term infants. Msall and colleagues reported rates of disability for term infants as follows: 0.2% for CP, 2% to 3% for cognitive impairment, 0.1% to 0.3% for hearing loss, and 0.1% for visual impairment.²⁵⁰

With improvements in survival for ELBW infants (<1000 g at birth), there are concerns that disability rates will increase. Several investigators have reported increasing neurodevelopmental disability rates for ELBW infants born in the 1990s, with rates for CP of 8% to 19%, rates for developmental disability of

19% to 49%, rates for hearing impairment of 1% to 4%, and rates for visual impairment of 1% to 4%.^{35,37,140,251–253} When extreme prematurity is considered, Shankaran and coworkers showed that surviving infants born at the threshold of viability—birth weight less than 750 g, gestational age less than 24 weeks, and a 1-minute Apgar of 3 or lower—had neurodisability rates of 60%, with almost one third of infants having CP.²⁵⁴

The increase in disability rates is thought to be linked to heavy use of postnatal steroids to treat neonatal chronic lung disease and high rates of sepsis during this period. Poor neurodevelopmental outcomes have been associated with widespread use of postnatal steroids in the 1990s, and routine use of this therapy to treat chronic lung disease is discouraged.^{233,255–257} The association between sepsis and CP has also been identified in multiple studies.

Because further reduction in the mortality rates for ELBW infants is unlikely, strategies to reduce neonatal morbidity are increasingly important. Decreased rates of CP have been reported for ELBW infants born between 2000 and 2002, a period associated with increased use of antenatal steroids, decreased use of postnatal steroids, and decreased incidence of nosocomial sepsis.¹⁹⁸ Chronic lung disease is an independent risk factor for neurodevelopmental disability, for which improved strategies are needed. Inhaled nitric oxide for preterm infants with respiratory failure has been studied, and improved cognitive outcomes for infants treated with inhaled nitric oxide have been reported,^{258,259} but this has not been consistently observed for ELBW infants.^{260,261}

Multiple Births. The risk of developing CP is significantly higher in multiple gestations compared with singleton births. Data from CP registries show that the risk of developing CP for twins is four to five times greater than for singletons. For triplets, the risk is 12 to 13 times greater.^{180,193,262,263} Although twins comprise only 1.6% of the population, they have a 5% to 10% incidence of CP.²⁶⁴ The higher rate of CP for multiple births may be related to preterm birth or to other complications, such as placental and cord abnormalities, intraplacental shunting, structural anomalies, and difficulties at delivery.

The incidence of CP increases as birth weight decreases. Infants with birth weights of less than 1500 g comprise 0.9% of singletons, 9.4% of twins, 32.2% of triplets, and 73.3% of quadruplets.^{193,265} Population-based registries have analyzed the risks of CP per 1000 neonatal survivors related to birth weight groups as follows: 66.5 for infants weighing less than 1000 g, 57.4 for infants weighing 1000 to 1499 g, and 8.9 for infants weighing 1500 to 2499 g.¹⁹² However, twins with birth weight greater than 2500 g have a threefold to fourfold increased risk of developing CP compared with singletons.¹⁹³ It is unclear why this risk increases near term, but it is thought to result from an increased risk of asphyxia or fetal growth restriction, which occurs more commonly for multiples.

The risk of CP is increased with the fetal death of a co-twin and is higher in same-sex compared with unlike-sex twins.^{266–269} When both twins are born alive and one twin dies in infancy, the risk is even greater than when one twin died in utero, with same-sex twins having a greater risk than unlike-sex twins.¹⁹³ These data suggest that monochorionicity plays a significant role in the pathogenesis of CP, likely due to the placental vascular anastomoses.

The incidence of multiple gestations has significantly increased as a result of assisted reproductive technology (ART). The increased risk of CP associated with ART largely reflects

the higher percentage of preterm births, because ART is typically not associated with monochorionicity unless monozygotic division occurs. However, a Danish study suggests that IVF pregnancies may carry an increased risk of CP not attributable to birth weight or gestation.¹⁹⁴ This increased risk of CP associated with ART requires further study (see Chapter 40).

Growth Restriction. There is much debate in the literature about whether infants with fetal growth restriction have an increased incidence of CP. Many investigators have reported an increased risk of CP for infants who are small for gestational age (SGA).²⁷⁰⁻²⁷⁵ However, fetal growth restriction is a separate entity. Fetal growth restriction refers to failure of a fetus to grow at a predicted rate using fetal growth standards rather than neonatal growth standards. These fetal growth standards are derived using ultrasound measurements of healthy fetuses in utero at each gestational age and can take into account variables such as fetal sex, ethnicity, parity, and maternal height and weight.²⁷⁶⁻²⁷⁸ SGA refers to infants who are statistically smaller than average at a given gestational age, but it does not take into account potential causes of SGA such as chromosomal anomalies, congenital infections, structural brain malformations, or constitutionally small stature.

Studies of the risk of CP often use birth weight alone to define the population of interest, which may explain the observed increased risk of CP associated with LBW. This increased risk of CP may reflect the effects of IUGR, because these cohort studies include more mature SGA infants and preterm infants with equivalent birth weights.^{279,280} The terminology used affects how the data may be interpreted.

Many studies have demonstrated that SGA term or preterm infants born after 33 weeks' gestation have the highest risk of developing CP.²⁷²⁻²⁷⁴ The Surveillance of Cerebral Palsy in Europe (SCPE) Collaborative Group reported that infants born between 32 to 42 weeks' gestation and with a birth weight less than the 10th percentile were four to six times more likely to develop CP than infants with a birth weight between the 25th and 75th percentiles.^{280,281} For infants born before 33 weeks' gestation with fetal growth restriction, the association is less clear, because this population has the highest risk of adverse neurodevelopmental outcomes. It is difficult to separate the risk due purely to growth restriction from the effect of prematurity in general. Other factors that increase the risk of CP include the SGA severity, male sex, and asphyxia.²⁸²

Growth-restricted infants may be more susceptible to intrapartum hypoxia, which leads to adverse neurologic outcomes. Data from the Collaborative Perinatal Project showed that infants with IUGR had incidences of CP similar to those for non-IUGR infants when examined at 7 years of age in the absence of intrapartum hypoxia. However, when intrapartum hypoxia was identified, the children with IUGR had an increased incidence of neurodevelopmental disability compared with those without IUGR.²⁰⁹ The relative risk of CP due to intrapartum hypoxia was lower in one study of SGA infants compared with appropriate-for-gestational-age (AGA) infants.²⁷⁵ Based on these conflicting results, it seems clear that other factors may be involved.

Perinatal Infections. Maternal, intrauterine, and neonatal infections have been associated with CP. Congenital viral infections such as the TORCH group (e.g., toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex virus [HSV], syphilis) may account for 5% to 10% of cases of CP.²⁸³ Maternal infection and inflammation have been associated with an

increased incidence of preterm birth and are risk factors for the development of CP.

Intra-amniotic infection, also called *clinical chorioamnionitis*, is associated with premature rupture of the fetal membranes and subsequent preterm birth.^{284,285} Chorioamnionitis increases the risk of CP through several likely mechanisms. Numerous studies have shown that IVH and PVL are associated with maternal chorioamnionitis and premature rupture of the membranes.^{222,223,286-288} Histologic chorioamnionitis without clinical signs of intra-amniotic infection has been linked to an increased likelihood of congenital IVH, PVL, and CP.²⁸⁹⁻²⁹³

Laboratory and clinical evidence supports the hypothesis that intrauterine infection and inflammation lead to the production of proinflammatory cytokines, which are responsible for white matter brain injury and ultimately for CP. These cytokines are potentially toxic to developing oligodendrocytes, reduce myelination, and injure fetal white matter.^{282,286,294,295} Various cytokines can have a direct toxic effect on cerebral white matter by increasing the production of nitric oxide synthase, cyclooxygenase, associated free radicals, and excitatory amino acids.^{283,295-298} This relationship between elevated cytokine levels and the development of white matter injury has been seen in preterm and term infants. A fourfold to sixfold increased risk of white matter injury has been associated with elevated levels of IL-1 β from amniotic fluid and from umbilical cord blood in preterm infants.^{2,299} In a study of term infants who went on to develop CP, stored blood samples had significantly increased levels of the cytokines IL-1, IL-8, IL-9, tumor necrosis factor- β , and RANTES (regulated on activation, normal T cell expressed and secreted).³⁰⁰ The combination of intrauterine infection and intrapartum hypoxia has been correlated with a dramatic increase in the incidence of CP.³⁰¹

Neonatal infection can promote the development of CP through direct CNS damage (e.g., meningitis) or a systemic inflammatory response syndrome (SIRS) that leads to sepsis, shock, and multiorgan system failure.²⁸³ Preterm infants who develop infection seem to be at higher risk for CP.^{302,303} A study of 6093 ELBW survivors born between 1993 and 2001 found an 8% incidence of CP among infants who did not develop a postnatal infection and a 20% incidence of CP among infants whose hospital course was complicated by sepsis, NEC, or meningitis.²⁵³ The infected infants also had an extremely high risk of cognitive impairment (defined as a Bayley MDI lower than 70 at 18 months) compared with noninfected infants (33% to 42% versus 22%).²⁵³ Another study of ELBW survivors found that NEC requiring surgical intervention was associated with a significant increase in the incidence of CP and developmental disabilities compared with those without NEC.¹³⁷

Placental Abnormalities. The placenta supplies nutrients to the developing fetus and is a barrier that protects the fetus from infectious organisms, toxins, trauma, and immune mediators. Placental abnormalities can predispose the fetus to adverse outcomes. Placental abnormalities associated with CP can fall into three categories. The first encompasses events that occur during or before labor, also known as *sentinel lesions*, which can cause fetal hypoxia. These lesions include uteroplacental separation, fetal hemorrhage, and umbilical cord occlusion.³⁰⁴ The second category comprises thromboinflammatory processes that affect fetal circulation and includes fetal thrombotic vasculopathy, chronic villitis, meconium-associated fetal vascular necrosis, and fetal vasculitis related to chorioamnionitis.^{304,305} The third category includes processes that cause decreased placental

reserve, such as chronic placental insufficiency, chronic villitis, chronic abruption, chronic vascular obstruction, and perivillous fibrin deposition.³⁰⁶ Evaluation of the placenta in determining the cause of neonatal encephalopathy may provide some insight into the fetal intrauterine environment and its contribution to the neurologic impairment.

Coexisting Impairments. Historically, CP has been defined strictly by the location and degree of motor impairment. However, associated coexisting impairments such as disturbances in sensation, cognition, communication, perception, and behavior are common, as are seizures. A new definition that includes these coexisting impairments has been proposed.^{186,247} A Dutch population study of children with CP reported that 40% had seizures, 65% had cognitive deficits (IQ < 85), and 34% had visual impairments.³⁰⁷ Hearing impairments and feeding difficulties are also common.

Investigational Strategies. Strategies to reduce CP have focused on preventing asphyxia and premature birth because these factors seem to be the most significant contributors to the development of CP. Strategies commonly used to reduce intrapartum hypoxia, such as fetal heart monitoring, maternal oxygen administration, repositioning, and strict guidelines for oxytocin use, have not affected the rate of CP. Fetal heart rate monitoring may even increase the prevalence of CP by increasing the risk of chorioamnionitis.^{308,309} Fetal heart rate monitoring increases the rate of operative interventions without any reduction in the rate of CP.¹⁷³ Reduction of perinatal intracranial injuries associated with the decreased use of forceps and vacuum extraction in the past 20 years is a positive trend that may contribute to a reduction in the incidence of CP.^{180,310}

Preterm birth accounts for approximately 35% of CP cases.³¹¹ It seems logical that strategies to reduce the incidence of preterm birth will reduce the incidence of CP, provided we do not increase the risk of an in utero insult. Prevention of preterm birth has proved elusive, making strategies to reduce morbidity more immediately promising. However, the literature has identified some strategies that may reduce the rate of preterm birth: limiting the number of embryos transferred with in vitro fertilization, smoking cessation programs, screening and treatment of asymptomatic bacteriuria during pregnancy, antiplatelet drugs to prevent preeclampsia, progesterone to prevent preterm birth, and selected use of cervical cerclage for women with a previous preterm birth and short cervix.^{312,313} Antenatal steroids decrease the incidences of several morbidities strongly associated with CP, including IVH, PVL,^{178,314} RDS, and chronic lung disease. Postnatal steroids to treat neonatal chronic lung disease, however, are associated with a significantly increased risk of CP.^{255,315-317}

Another strategy to reduce CP in preterm infants is the administration of magnesium sulfate before delivery. Magnesium sulfate can stabilize vascular tone, reduce reperfusion injury, and reduce cytokine-mediated injury.^{318,319} Several observational studies have found an association between maternal administration of magnesium sulfate for preeclampsia or preterm labor and a reduced risk of CP.³²⁰⁻³²³ However, others have reported no protective effect for magnesium.³²⁴⁻³²⁹

The Australasian Collaborative Trial of Magnesium Sulphate examined the efficacy of magnesium sulfate given to women at risk for preterm birth before 30 weeks' gestation solely for neuroprotection. This study was a large, randomized, controlled trial ($N = 1062$), and the investigators reported a lower

incidence of CP, although it was not statistically significant (6.8% versus 8.2%), and there were no serious harmful effects to women or their children.²⁰⁶

Marret and coworkers, working with the PREMAG trial group, showed that magnesium sulfate given to pregnant women before 33 weeks' gestation with planned or expected delivery within 24 hours did not produce any differences in the total death or severe white matter injury rates at hospital discharge, but it was associated with significant reductions in rates of late death or gross motor dysfunction at 2 years of age.^{330,331}

The largest study ($N = 2241$) evaluating the effect of magnesium sulfate for the prevention of CP by Rouse and colleagues and the NICHD Maternal-Fetal Medicine Network showed a reduction in the rate of moderate or severe CP.³³² In 2010, the ACOG Committee on Obstetric Practice and the Society for Maternal-Fetal Medicine issued a statement recommending the use of magnesium sulfate before anticipated early preterm birth for fetal neuroprotection, although they did not specify a specific gestational age³³³ (see also Chapter 40).

CP is a significant adverse event with origins in pregnancy. Many risk factors have been identified, although no etiologic factor is found in some cases. Strategies to reduce asphyxia and prevent preterm birth have not significantly decreased rates of CP. Because most CP is related to extremely preterm birth and the survival rates of these ELBW infants is improving, strategies to reduce neonatal brain injury such as the use of antenatal steroids are the most promising. Future trials of antenatal neuroprotection for preterm infants may prove beneficial to combat inflammatory or cytokine-mediated brain injury.

INFECTIOUS DISEASE PROBLEMS

Neonatal Infection

Neonatal infection is a significant cause of neonatal morbidity and mortality for preterm and term infants (see Chapter 51). The risk of infection is inversely related to gestational age. The clinical manifestations of neonatal infection vary by pathogen and age of acquisition. The spectrum of pathogens causing neonatal infection is broad and has changed over the decades,³³⁴ but the cornerstones of management remain prevention whenever possible, early detection, and focused treatment.

Compared with older children and adults, the neonatal host defense is blunted by incomplete development and experience with self versus non-self discrimination.³³⁵ All components of the immune system are deficient. Nonspecific immunity is defective at several levels. Skin and mucosal barriers are immature, especially in preterm infants. Levels of nonspecific antibacterial proteins such as lysozyme and lactoferrin are low. Neutrophil numbers are low, with limited storage pools available to clear bacteria. Key neutrophil functions, including chemotaxis, phagocytosis, and intracellular killing, are limited. The neonate is poorly equipped to clear transient bacteremia and localize bacterial infection.

Specific humoral and cell-mediated immune functions are also limited. Circulating immunoglobulin levels are very low compared with adult levels. The neonate acquires virtually all of its circulating immunoglobulin G (IgG) from the mother through transplacental transport. The bulk of this antibody is transferred during the third trimester, making the preterm infant profoundly deficient. B-cell function is immature. The primary antibody response to infection mediated by the infant is production of immunoglobulin M (IgM). Although T

lymphocytes are present at birth, their function is almost undetectable by standard functional assays.

The nature of neonatal immune function accounts for the clinical manifestations of most early-onset infections. Nonspecific signs such as lethargy, poor feeding, temperature instability, decreased tone, apnea, and altered perfusion may or may not be present. Fever is uncommon, as are localized processes such as cellulitis, abscesses, or osteomyelitis. When present, they are usually accompanied by bacteremia. Similarly, bacteremia must always be suspected in neonates with meningitis or urinary tract infections.

Group B β -Hemolytic Streptococci. The group B β -hemolytic streptococci (GBS) were first recognized as a cause of early-onset neonatal sepsis in the 1970s. By the 1990s, GBS was a leading cause of serious neonatal infections. GBS is a common colonizing constituent of the vagina and rectum in 10% to 30% of pregnant women. GBS colonization is more common in African-American women and in those with a history of a neonate with GBS disease or a history of a GBS urinary tract infection.

Epidemiologic studies demonstrated that most invasive, early-onset neonatal GBS disease involves vertical transmission from mother to fetus during labor. This observation led to studies of intrapartum antibiotic prophylaxis with penicillin G or ampicillin. The success of this strategy prompted the publication of guidelines for intrapartum antibiotic prophylaxis by the Centers for Disease Control and Prevention.³³⁶ A follow-up study completed in 2005 confirmed the success of this strategy.³³⁷ Most invasive, serious GBS cases now seen are in infants born to mothers with negative GBS screening cultures who presumably converted to GBS-positive carrier status in the interval between screening and delivery.³³⁸ Rapid GBS screening technology may allow identification of these women when they present in labor.³³⁹ There is some concern that intrapartum antibiotic prophylaxis may be associated with a higher incidence of serious bacterial infections later in infancy. This was most pronounced when broad-spectrum antibiotics were used for intrapartum prophylaxis rather than penicillin G.³⁴⁰ The advantages of intrapartum antibiotic prophylaxis to reduce the risk of invasive neonatal GBS disease clearly outweigh any risks, especially if penicillin is employed.

Chorioamnionitis. The relationship between chorioamnionitis and neonatal infection is complex and remains incompletely understood. Some studies demonstrate a direct correlation between chorioamnionitis and neonatal infection. Other poor neonatal outcomes, including RDS and BPD, are also associated with chorioamnionitis.^{91,341} However, other clinical series and studies using animal models reach essentially the opposite conclusion—that chorioamnionitis protects against these same outcomes.^{342,343} Some of the confusion is grounded in definitions of chorioamnionitis. Clinical chorioamnionitis, as characterized by maternal fever and uterine tenderness, is probably a very different disease from the clinically silent histologic chorioamnionitis commonly seen in preterm deliveries.^{344,345} Whether these represent different disease entities or are different manifestations of the same disease spectrum is not clear. The fetal response to infection has important consequences for neonatal outcome. Studies using proteomic analysis of amniotic fluid show promise for relating the diagnosis of chorioamnionitis to neonatal clinical course.^{346,347}

Viral Infections

Cytomegalovirus. Human CMV is transmitted horizontally (i.e., direct person-to-person contact with virus-containing secretions) and vertically (i.e., from mother to infant before, during, or after birth), and through transfusion of blood products or organ transplantation from previously infected donors. Vertical transmission of CMV to infants occurs by one of the following routes of transmission: in utero by transplacental passage of maternal blood-borne virus, through an infected maternal genital tract, and postnatally by ingestion of CMV-positive human milk.^{348,349}

Approximately 1% of all liveborn infants are infected in utero and excrete CMV at birth. Risk to the fetus is greatest in the first one half of gestation. Although fetal infection can occur after maternal primary infection or after reactivation of infection during pregnancy, sequelae are far more common in infants exposed to maternal primary infection; 10% to 20% of these infants manifest neurodevelopmental impairment or sensorineural hearing loss in childhood.³⁵⁰

Congenital CMV infection is usually clinically silent. Some infected infants who appear healthy at birth subsequently develop hearing loss or learning disabilities. Approximately 10% of infants with congenital CMV infection exhibit evidence of profound involvement at birth, including IUGR, jaundice, purpura, hepatosplenomegaly, microcephaly, intracerebral calcifications, and retinitis.³⁵¹ Although ganciclovir has been used to treat some infants with congenital CMV infection, it is not recommended routinely because of insufficient efficacy data. One study of ganciclovir treatment provided to infants with congenital CMV with CNS involvement suggested that treatment decreased progression of hearing impairment.³⁵² Because of the potential toxicity of long-term ganciclovir therapy, additional investigation is required before a recommendation can be made.

Infection acquired in the intrapartum period from maternal cervical secretions or in the postpartum period from human milk usually is not associated with clinical illness. Infections resulting from transfusion of blood products from CMV-seropositive donors and from human milk to preterm infants have been associated with serious systemic infections, including lower respiratory tract infection. Transmission of CMV by transfusion to newborn infants has been reduced by using CMV-antibody negative donors, by freezing erythrocytes in glycerol, and by removal of leukocytes by filtration before administration.³⁵³ CMV transmission by human milk is decreased by pasteurization.³⁵⁴ However, freeze-thawing is probably not effective.³⁵⁵ If fresh donor milk is needed for infants born to CMV antibody-positive mothers, provision of milk from only CMV antibody-negative women should be considered.

Hepatitis B. The hepatitis B virus (HBV) is a DNA virus whose important components include an outer lipoprotein envelope containing the hepatitis B surface antigen (HbsAg) and an inner nucleocapsid containing the hepatitis B core antigen. Only antibody to HbsAg (anti-HbsAg) provides protection from HBV infection. Perinatal transmission of HBV is highly efficient and usually occurs from blood exposure during labor and delivery. In utero transmission of HBV is rare, less than 2% of perinatal infections in most studies. The risk of an infant acquiring HBV from an infected mother as a result of perinatal exposure is 70%

to 90% for those born to mothers who are HBsAg and hepatitis B e antigen (HBeAg) positive. The risk is 5% to 20% for infants born to mothers who are HBeAg negative.

Age at the time of acute infection is the primary determinant of risk of progression to chronic HBV infection. More than 90% of infants with perinatal infection develop chronic HBV infection. Between 25% and 50% of children infected at 1 to 5 years of age become chronically infected, whereas only 2% to 6% of older children or adults develop chronic HBV infection.³⁵⁶

The goals of HBV prevention programs are to prevent acute HBV infection and to decrease the rates of chronic HBV infection and HBV-related chronic liver disease. Over the past 2 decades, a strategy has been progressively implemented in the United States to prevent HBV transmission. It includes universal immunization of infants beginning at birth, prevention of perinatal HBV infection by routine screening of all pregnant women and appropriate immunoprophylaxis of infants born to HBsAg-positive women and infants born to women with unknown HBsAg status, routine immunization of children and adolescents who have previously not been immunized, and immunization of previously nonimmunized adults at increased risk for infection.

Two types of products are available for hepatitis B immunoprophylaxis. Hepatitis B immune globulin (HBIG) provides short-term protection (3 to 6 months) and is indicated only in postexposure circumstances. Hepatitis B vaccine is used for pre-exposure and postexposure protection and provides long-term protection. Preexposure immunization with hepatitis B vaccine is the most effective means to prevent HBV transmission. To decrease the HBV transmission rate, universal immunization is necessary. Postexposure prophylaxis with hepatitis B vaccine and HBIG or hepatitis B vaccine alone effectively prevents infection after exposure to HBV. The effectiveness of postexposure immunoprophylaxis is related to the time elapsed between exposure and administration. Immunoprophylaxis is most effective if given within 12 to 24 hours of exposure. Serologic testing of all pregnant women for HBsAg is essential for identifying those whose infants will require postexposure prophylaxis beginning at birth.

Hepatitis B vaccines are highly effective and safe. These vaccines are 90% to 95% efficacious for preventing HBV infection. Studies of preterm infants and LBW infants (<2000 g) have demonstrated decreased seroconversion rates after administration of hepatitis B vaccination. However, by 1 month of age, medically stable preterm infants should be immunized, regardless of initial birth weight or gestational age. Routine postimmunization testing for anti-HBsAg is not necessary for most infants. However, postimmunization testing for HBsAg and anti-HBsAg at 9 to 18 months is recommended for infants born to HBsAg-positive mothers. One report suggests a high prevalence of occult infection in children born to HBsAg-positive mothers despite immunoprophylaxis.³⁵⁷

Immunization of pregnant women with hepatitis B vaccine has not been associated with adverse effects on the developing fetus. Because HBV infection may result in severe disease in the mother and chronic infection in the newborn infant, pregnancy is not considered a contraindication to immunization. Lactation is also not a contraindication to immunization.

Herpes Simplex Virus. Neonatal HSV infections range from localized skin lesions to overwhelming disseminated disease. The latter has a case-fatality rate in excess of 50% despite

prompt initiation of antiviral therapy. Vertical transmission is the likely mode of transmission for most cases. Mothers with a history of disease appear to convey at least some type-specific immunity to the neonate. Most mothers of severely infected infants have no recognized history of HSV and no evidence of active disease on physical examination. No screening protocols for HSV are available, and there is no vaccine.^{358,359}

Human Immunodeficiency Virus. Landmark studies in the 1990s demonstrated the value of intrapartum antiretroviral therapy to reduce the risk of maternal to fetal transmission of human immunodeficiency virus (HIV). Improvements in the quality and availability of rapid HIV testing hold out the promise for more timely and accurate identification of infected women and their newborn infants.^{360,361} The risk of congenital HIV is reduced to approximately 1% when HIV-positive mothers receive antiretroviral therapy during labor and treatment is continued for the neonate within 12 hours of delivery. Breastfeeding is contraindicated, unless there is no access to clean water and infant formula.

Laboratory diagnosis of HIV infection during infancy depends on detection of virus or viral nucleic acid. Cord blood should not be used for this early test because of possible contamination by maternal blood. A positive result identifies infants who have been infected in utero. Approximately 93% of infected infants have detectable HIV DNA at 2 weeks, and almost all HIV-infected infants have positive HIV DNA polymerase chain reaction (PCR) assay results by 1 month of age. A test within the first 14 days of age can facilitate decisions regarding initiation of antiretroviral therapy. Transplacental passage of antibodies complicates use of antibody-based assays for the diagnosis of infection in infants, because all infants born to HIV-seropositive mothers have passively acquired maternal antibodies.

Antiretroviral therapy is indicated for most HIV-infected children. Initiation of therapy depends on virologic, immunologic, and clinical criteria. Because HIV infection is a rapidly changing area, consultation with an expert in pediatric HIV is recommended.

Rubella. Humans are the only source of rubella infection. Peak incidence of infection is in late winter and early spring. Before widespread use of the rubella vaccine, rubella was an epidemic disease, with most infections occurring in children. The incidence of rubella has decreased 99% from the prevaccine era. Although the number of susceptible people has decreased since introduction and widespread use of the rubella vaccine, serologic surveys indicate that approximately 10% of the U.S.-born population older than 5 years of age is susceptible. The percentage of susceptible people who are foreign born or from areas with poor vaccine coverage is higher. The risk of congenital rubella syndrome is highest among infants of women born outside the United States. Epidemiologic data suggest that rubella is no longer endemic in the United States.³⁶²

Congenital rubella syndrome is characterized by a constellation of anomalies that may include ophthalmologic (e.g., cataracts, microphthalmos, pigmentary retinopathy, congenital glaucoma), cardiac (e.g., patent ductus arteriosus, peripheral pulmonary artery stenosis), auditory (e.g., sensorineural hearing impairment), and neurologic (e.g., meningoencephalitis, behavioral abnormalities, mental retardation) abnormalities. Neonatal manifestations of congenital rubella syndrome

include growth retardation, interstitial pneumonia, radiolucent bone disease, hepatosplenomegaly, thrombocytopenia, and dermal erythropoiesis (i.e., blueberry muffin lesions). The occurrence of congenital defects varies with timing of the maternal infection.

Detection of rubella-specific IgM antibody usually indicates recent postnatal infection or congenital infection in a newborn infant, but false-positive and false-negative results occur. Congenital infection can be confirmed by stable or increasing rubella-specific IgG levels over several months. Rubella virus can be isolated most consistently from throat or nasal swabs by inoculation of the appropriate cell culture. Blood, urine, CSF, and pharyngeal swab specimens can also yield virus from congenitally infected infants.

Infants with congenital rubella should be considered contagious until at least 1 year of age, unless nasopharyngeal and urine cultures are repeatedly negative for rubella virus. Infectious precautions should be considered for children up to 3 years of age who are hospitalized for congenital cataract extraction. Caregivers of these infants and children should be made aware of the potential hazard to susceptible pregnant contacts.

Sexually Transmitted Infections

Chlamydia. In the newborn period, *Chlamydia trachomatis* is associated with conjunctivitis and pneumonia. Acquisition of *C. trachomatis* occurs in approximately 50% of infants born vaginally to infected mothers and in some infants delivered by cesarean section with intact membranes.³⁶³ Neonatal chlamydial conjunctivitis is characterized by ocular congestion, edema, and discharge developing a few days to several weeks after birth and lasting 1 to 2 weeks. Pneumonia in infants is usually an insidious, afebrile illness occurring between 2 and 20 weeks after birth. It is characterized by a staccato cough, tachypnea, and rales detected on physical examination. Pulmonary hyperinflation and infiltrates are demonstrated on the chest radiograph.

The recommended topical prophylaxis with silver nitrate, erythromycin, or tetracycline for all newborn infants for gonococcal ophthalmia does not prevent chlamydial conjunctivitis or extraocular infections.³⁶⁴ Infants with chlamydial conjunctivitis are treated with oral erythromycin base or ethylsuccinate (50 mg/kg/day in four divided doses) for 14 days. Oral sulfonamides may be used after the immediate neonatal period for infants who do not tolerate erythromycin. Because the efficacy of treatment is about 80%, follow-up of infants is recommended. In some instances, a second course of therapy may be required.

Chlamydial pneumonia is treated with oral azithromycin (20 mg/kg/day) for 3 days or erythromycin base or ethylsuccinate (50 mg/kg per day in four divided doses) for 14 days. Detection and treatment of *C. trachomatis* infections before delivery is the most effective way to reduce the risk of neonatal conjunctivitis and pneumonia.

Gonococcal Infections. Infection with *Neisseria gonorrhoeae* in the newborn infant usually involves the eyes. Other types of gonococcal infections include arthritis, disseminated disease with bacteremia, meningitis, scalp abscess, or vaginitis.

Microscopic examination of Gram-stained smears of exudates from the eyes, skin lesions, synovial fluid, and when clinically warranted, CSF may be useful in the initial evaluation. Identification of gram-negative intracellular diplococci in these

smears can be helpful, particularly if the organism is not recovered in culture. *N. gonorrhoeae* can be cultured from normally sterile sites such as blood, CSF, and synovial fluid.

For routine ophthalmia neonatorum prophylaxis of infants immediately after birth, a 1% silver nitrate solution or a 1% tetracycline or 0.5% erythromycin ophthalmic ointment is instilled into each eye. Prophylaxis may be delayed for as long as 1 hour after birth to facilitate parent-infant bonding. Topical antimicrobial agents cause less chemical irritation than silver nitrate and are now preferred. None of the topical agents is effective against *C. trachomatis*.³⁶⁴

When prophylaxis is administered, infants born to mothers with known gonococcal infection rarely develop gonococcal ophthalmia. However, because gonococcal ophthalmia or disseminated disease occasionally can occur in this situation, infants born to mothers known to have gonorrhea should receive a single dose of ceftriaxone (125 mg given intravenously or intramuscularly). Preterm and LBW infants are given 25 to 50 mg/kg of ceftriaxone to a maximum dose of 125 mg.

Infants with clinical evidence of ophthalmia neonatorum, scalp abscess, or disseminated disease should be hospitalized. Cultures of the blood, eye discharge, or other sites of infection such as CSF should be performed to confirm the diagnosis and determine antimicrobial susceptibility. Tests for concomitant infection with *C. trachomatis*, syphilis, and HIV should be performed.

Recommended treatment, including for ophthalmia neonatorum, is a single dose of ceftriaxone (25 to 50 mg/kg given intravenously or intramuscularly, not to exceed 125 mg). Infants with gonococcal ophthalmia should receive eye irrigations with saline solution immediately and at frequent intervals until the discharge is eliminated. Topical antimicrobial treatment alone is inadequate and is unnecessary when recommended systemic antimicrobial treatment is provided. Infants with gonococcal ophthalmia should be hospitalized and evaluated for disseminated infection. Recommended therapy for arthritis and septicemia is a course of ceftriaxone or cefotaxime for 7 days. If meningitis is documented, treatment should continue for a total of 10 to 14 days.

Syphilis. Congenital syphilis remains a significant public health problem. It is contracted from an infected mother through transplacental transmission of *Treponema pallidum* at any time during the pregnancy or birth. Intrauterine syphilis can result in stillbirth, hydrops fetalis, or preterm birth. Infants can present with edema, hepatosplenomegaly, lymphadenopathy, mucocutaneous lesions, osteochondritis, pseudoparalysis, rash, or snuffles at birth or within the first 2 months of life. Hemolytic anemia or thrombocytopenia may be identified on laboratory evaluation.

Untreated infants, regardless of whether they have manifestations in infancy, may develop late manifestations, usually after 2 years of age and involving the bones, CNS, eyes, joints, and teeth. Some consequences of intrauterine infection may not become apparent until many years after birth.

Definitive diagnosis is established by identification of spirochetes by microscopic dark-field examination or by direct fluorescent antibody tests of lesion exudates or tissue such as the placenta or umbilical cord. A presumptive diagnosis is possible using nontreponemal and treponemal tests. The use of only one type of test is insufficient for diagnosis, because false-positive nontreponemal test results occur with various medical

conditions, and false-positive treponemal test results can occur with other spirochetal diseases.

No newborn infant should be discharged from the hospital without determination of the mother's serologic status for syphilis.³⁶⁵ All infants born to seropositive mothers require a careful examination and a quantitative nontreponemal syphilis test. The laboratory test performed for the infant should be the same as that performed for the mother to facilitate comparison of titer results. An infant should be evaluated for congenital syphilis if the maternal titer has increased fourfold, if the infant titer is fourfold greater than the mother's titer, or if the infant has clinical manifestations of syphilis. The infant should be evaluated if born to a mother with positive nontreponemal and treponemal test results if the mother has any of the following conditions. First, the syphilis has not been treated, or treatment has not been documented. Second, syphilis during pregnancy was treated with a nonpenicillin regimen. Third, syphilis was treated less than 1 month before delivery, because treatment failures occur and efficacy cannot be assumed. Fourth, syphilis was treated before pregnancy but with insufficient follow-up to assess the response to treatment and current infection status.

Evaluation for syphilis in an infant should include a physical examination, a quantitative nontreponemal syphilis test of serum from the infant, a Venereal Disease Research Laboratory (VDRL) test of the CSF and analysis of the CSF for cells and protein concentration, long bone radiographs, and a complete blood cell and platelet count. Other clinically indicated tests may include a chest radiograph, liver function tests, ultrasonography, ophthalmologic examination, and an auditory brainstem

response test. Pathologic examination of the placenta or umbilical cord using specific antitreponemal antibody staining is also recommended.

Infants should be treated for congenital syphilis if they have proven or probable disease demonstrated by one or more of the following: physical, laboratory, or radiographic evidence of active disease; positive placenta or umbilical cord test results for treponemes using direct fluorescent antibody-*T. pallidum* staining or dark-field test; a reactive result on VDRL on testing of CSF; or a serum quantitative nontreponemal titer is at least fourfold higher than the mother's titer using the same test and preferably the same laboratory. If the infant's titer is less than four times that of the mother, congenital syphilis can still be present. When circumstances warrant evaluation of an infant for syphilis, the infant should be treated if test results cannot exclude infection, if the infant cannot be adequately evaluated, or if adequate follow-up cannot be ensured.

Infants with proven congenital syphilis should be treated with aqueous crystalline penicillin G. The dosage should be based on chronologic, not gestational, age. The dose of penicillin G is 100,000 to 150,000 U/kg/day, which is administered as 50,000 U/kg per dose intravenously every 12 hours during the first 7 days of life and then every 8 hours thereafter for a total of 10 days. Alternatively, 50,000 U/kg/day of penicillin G procaine given intramuscularly for 10 days may be considered, but adequate CSF concentrations may not be achieved with this regimen.
