Clinical Significance. There is evidence that venous Doppler studies are helpful in predicting severe compromise in fetal growth restriction and other fetal-placental vascular abnormalities.^{82,83} Venous Doppler allows shorter-term prediction of outcome, including perinatal mortality, acid-base status, birth asphyxia, and requirement for intensive neonatal support. Ductus venosus deterioration frequently precedes and strongly predicts changes in BPP that require delivery.⁸⁴ Although MCA Doppler changes do not predict adverse outcome, ductus venosus resistance elevation and depression of the a-wave correlate with an increase in major neonatal complications. By the time that the a-wave has become reversed, each day in utero doubles the odds of stillbirth, independent of gestational age.⁸⁵ When both phases of the ductus venosus are abnormal and are associated with umbilical venous pulsations, the relative risk of neonatal complications exceeds 11.⁸⁶ As with many tests of fetal well-being, perhaps more important than the correlation of poor ductus venosus waveform with poor outcome is the reassurance of normal ductus venosus flow. Even in the presence of significant arterial abnormalities, the preservation of normal ductus venosus flow and normal biophysical variables strongly correlates with normal fetal status, allowing successful extension of the pregnancy at very preterm gestations. There is strong agreement between abnormal venous Doppler parameters and an abnormal BPP in predicting fetuses who need delivery.⁸⁵ However, venous Doppler studies and BPP scores are not strictly concordant; some fetuses show deterioration primarily in umbilical and ductus venosus waveforms and a late decline in

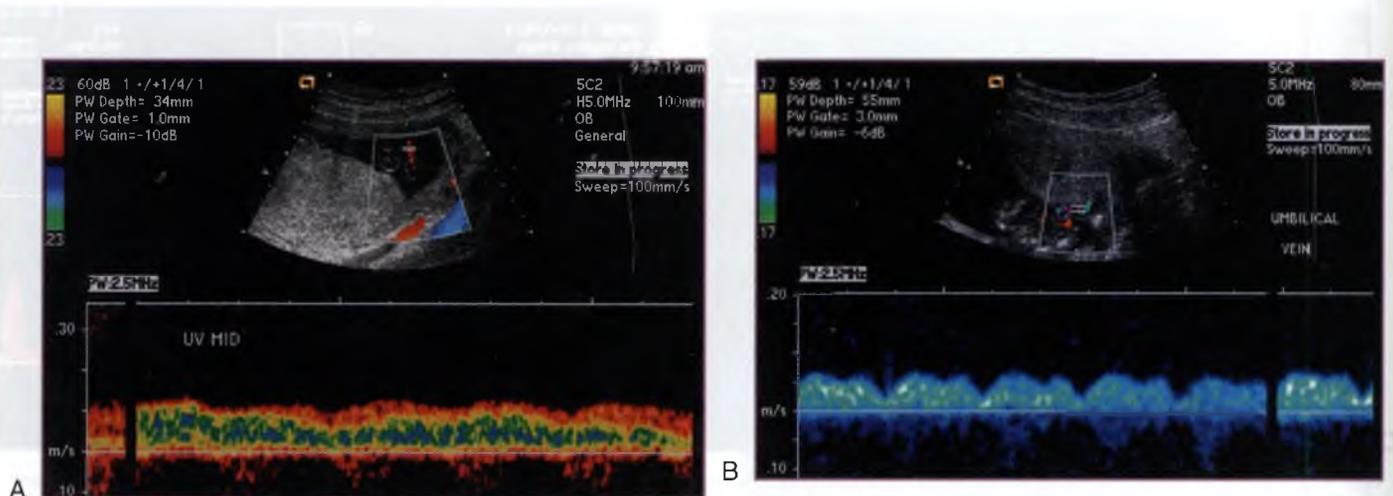

Figure 32-11 Umbilical venous pulsations. A, Moderate pulsatility, increased placental resistance in intrauterine growth restriction. B, Cardiac failure with tricuspid regurgitation reflected as retrograde flow all the way back to the midcord. Notice the timing relationship to arterial pulsations (below line).

fetal behavior. Others demonstrate declining biophysical performance but maintain reasonably normal venous waveforms. These two systems are complementary, and outcome can be optimized with dual application.⁸³

PATTERNS OF DETERIORATION

A systematic progression of Doppler abnormalities has been described in pregnancies with IUGR, but the timing and rapidity of this progression can be quite variable depending on the clinical circumstances.⁸⁷ Placental abnormalities may persist for months before other Doppler parameters deteriorate. As placental resistance increases (e.g., as more placental infarcts occur), the cerebroplacental ratio eventually shifts, reflecting a change in balance between placental and systemic perfusion and resulting in cerebral redistribution. Brain sparing is seen as progressive abnormalities in umbilical artery circulation (i.e., AEDV progressing to REDV), which are associated with increasingly higher diastolic velocities in the MCA. By this time, subjective elements of behavior, such as increasing intervals of quiet sleep (state 1F), decreased velocity of fetal movements (often perceived by the mother as weaker movements), and elements of subjectively decreased amniotic fluid may begin to appear.⁸⁸ With onset of AEDV, progressive redistribution yields overt centralization, and oligohydramnios becomes more common. The NST parameters often become flatter, with overt nonreactivity occurring at or just before deterioration of precordial veins, including a retrograde ductus venosus a-wave. At about this time, reversal of end-diastolic velocities in the umbilical artery may occur (although progression is completed in only 20% of fetuses with severe IUGR), along with progressive loss of fetal breathing movements, loss of fetal tone, and abolition of all movements as the BPP becomes overtly abnormal (Fig. 32-12).⁵²

This stereotypical path of deterioration is not always followed, and it does not always progress at a predictable rate, even for the populations in which these tests have been studied and are assumed to be most helpful. For example, the BPP has significant false-positive and false-negative results in the setting of very preterm growth restriction.⁸⁹ Management strategies cannot be based on the anticipation that one specific finding inevitably means that delivery must occur within a specified period. At earlier gestational ages, responding to absent end-diastolic umbilical artery velocities by delivery may not be necessary and may result in substantial complications of prematurity. In a late preterm or term fetus, a finding of absent end-diastolic umbilical artery flow may be an appropriate trigger for delivery. When IUGR is studied using multifactor testing (i.e., multiple Doppler indices plus biophysical parameters), the overriding principle is that gestational age determines outcome over a wide range.⁹⁰ Studies constitute complex observations of severely compromised, growth-restricted fetuses; they are not RCTs. A system of integrated testing using all of these variables remains to be validated as the optimal method of management.

Practical Aspects of Fetal Testing

WHO, WHEN, AND HOW TO TEST

Maternal risk factors, such as cigarette smoking, hypertension, thrombophilia, diabetes, cocaine and other toxic substance abuse, obesity, and other sources of placental impairment, can dictate surveillance for fetuses. Nuchal translucency and first-trimester maternal serum analytes, a detailed review of fetal anatomy, serial evaluation of growth, amniotic fluid volume, and Doppler patterns set the stage for monitoring protocols. Clinical correlation is essential to determine the optimal testing strategy.

The fetal assessment methods available lack the certainty of multiple RCTs, but there is evidence that outcomes improve in some monitored populations. Box 32-2 shows some factors that should prompt scheduled fetal surveillance. The information in this box is not exclusive because many historical factors and combinations of influences dictate fetal surveillance. For a number of pregnancy complications of vascular origin, Doppler surveillance has been proved effective in RCTs.

When to initiate monitoring has not been established by randomized trial, nor is it likely to be. General guidelines, such as those recommended by the American College of Obstetricians and Gynecologists, suggest starting monitoring at 32 to 34 weeks. If the threshold of viability at a tertiary institution is 24 weeks and the presentation is one of severe fetal growth restriction, monitoring is likely to be started early, repeated often, and tailored to the maternal and fetal status. Testing frequency is also determined by the severity of the disorder and varies from 2 to 6 weeks for general review of fetal growth to continuous monitoring for severe fetal growth restriction with abnormal venous Doppler findings. Examples of onset and testing frequency are given in Table 32-5, which emphasizes the individualization of fetal testing and the important principle of disorder-specific surveillance. Understanding the mechanism by which the high-risk disorder affects the fetus is the key for selecting the monitoring method and adding or altering other variables, such as modifying recommended intervals and prioritizing specific observations.

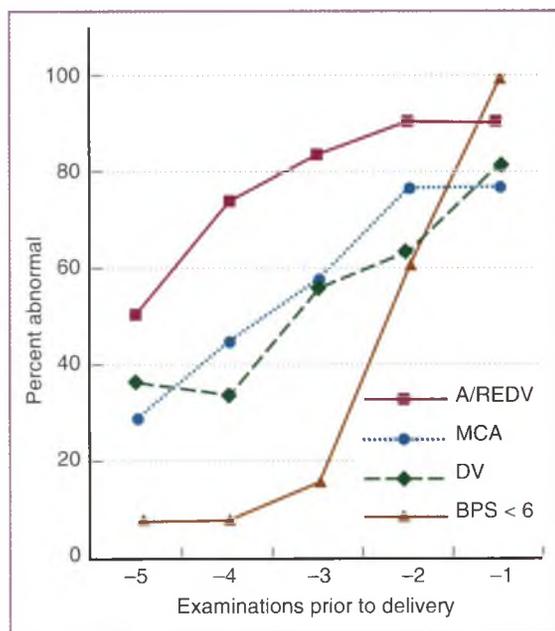

Figure 32-12 Deterioration in Doppler waveforms before delivery for an abnormal biophysical profile score (BPP). All fetuses had prospective Doppler studies, and management decisions were made according to the BPP. A/REDV, absent or reversed end-diastolic velocity; DV, ductus venosus; MCA, middle cerebral artery.

BOX 32-2 INDICATIONS FOR ANTENATAL SURVEILLANCE***MATERNAL CONDITIONS**

Severe hyperthyroidism
Symptomatic hemoglobinopathy
Cyanotic heart disease
Chronic renal disease
Type I diabetes
Marked uterine anomalies

PLACENTAL CONDITIONS

Antiphospholipid antibody syndrome
Systemic lupus erythematosus
Hypertensive disorders, including pregnancy-induced hypertension of all severities
Thrombophilia
Marked placental anomalies

FETAL CONDITIONS

Decreased fetal movement
Oligohydramnios
Polyhydramnios
Intrauterine growth restriction
Post-term pregnancy
Alloimmunization
Macrosomia
Fetal anomalies or aneuploidy
Multiple gestation (all)

MISCELLANEOUS

In vitro fertilization pregnancy
Teratogen exposure
Previous stillbirth
Prior neurologic injury
Previous recurrent abruption
Obesity

*Monitoring of pregnancies with abnormal Doppler parameters and no apparent underlying disorder remains controversial.

Modified from American College of Obstetricians and Gynecologists: Practice bulletin #9: antepartum fetal surveillance, Washington, DC, 1999, ACOG.

IMPACTS OF MONITORING ON PERINATAL MORTALITY AND LONG-TERM OUTCOMES

Use of the BPP and Doppler velocimetry for fetal assessment has been implemented in clinical practice, but it remains difficult to obtain robust data on the impact of this testing in a variety of populations. Lower BPP scores have been associated with higher perinatal mortality rates,³⁴ and early studies comparing the perinatal mortality rate for an untested population to that for a tested, high-risk population demonstrated a lower rate of perinatal mortality in the tested population (Table 32-6).^{20,91,92} Although the strength of this evidence is not ideal, it does suggest that monitoring can identify fetuses at risk and allow for timely delivery to reduce the risk of perinatal mortality.

The impact of Doppler velocimetry, particularly of the umbilical artery, has been more convincingly demonstrated, making it unique among the fetal testing modalities. A Cochrane review of fetal and Doppler ultrasound used in high-risk pregnancies included 18 randomized and quasi-randomized trials, including more than 10,000 women. The study authors concluded that the use of Doppler was associated with a reduction in perinatal deaths (RR = 0.71; 95% CI, 0.52 to 0.98). There

TABLE 32-5 Suggested Antenatal Fetal Surveillance

Condition	Begin Surveillance*	Timing
Pregnancy-induced hypertension	At diagnosis	Weekly BPP ± UA Doppler
Preeclampsia	At diagnosis	Twice weekly BPP ± UA Doppler
Chronic hypertension	28-32 wk	Weekly BPP or MBPP
FGR	At diagnosis	Integrated fetal testing
Gestational diabetes		
A1	At 40 wk	Weekly BPP or MBPP
A2	At 36 wk	Weekly BPP or MBPP
Pregestational diabetes	At 28-32 wk	Twice weekly BPP/MBPP
Diabetes with macrosomia	At diagnosis	Twice weekly BPP/MBPP
Vascular disease	At 24-28 wk	Integrated fetal testing
Postterm	At 41 wk	Twice weekly BPP/MBPP
Multiple gestation, concordant fetus	At 32-34 wk	Weekly BPP/MBPP
FGR		
Multiple gestation, discordant fetus	At diagnosis	Integrated fetal testing
FGR		
BMI >30	At 36 wk	Weekly BPP or MBPP

*Start earlier for severe disease, complicated disease, or prior pregnancy losses. Patient care should be individualized. Some patients also may require biophysical profile scoring, amniotic fluid index, Doppler flow studies, or other testing.

BPP, biophysical profile score; FGR, fetal growth restriction; MBPP, modified BPP, consisting of fetal nonstress test and ultrasound measurement of amniotic fluid maximum vertical pocket depth; UA, uterine artery.

TABLE 32-6 Perinatal Mortality Changes with Biophysical Profile Score Application

Program	Study	N	Perinatal Mortality Rate per 1000	
			Tested	Not Tested
Nova Scotia	Baskett et al, 1987 ⁹¹	5,000	3.1	6.6
Ireland	Chamberlain, 1991 ⁹²	3,200	4.1	10.7
California	Miller et al, 1996 ²⁰	15,000	1.3	8.8

were also fewer inductions of labor among 5633 women from 10 studies (RR = 0.89; 95% CI, 0.80 to 0.99) and fewer cesarean deliveries among 7918 women from 14 studies (RR = 0.90; 95% CI, 0.84 to 0.97).

The assessment of multimodality testing using umbilical artery and fetal Doppler is more complicated because of the number of Doppler techniques, the various thresholds for intervention, and the degree of integration of biophysical variables. Perinatal mortality frequency usually rises from isolated umbilical artery Doppler index elevation to complex Doppler abnormalities, including REDV in the umbilical artery and reversal of the a-wave in the ductus venosus. Further investigation of the efficacy of multivessel Doppler assessment is needed, but at a minimum, it seems that umbilical artery Doppler assessment is efficacious in high-risk pregnancies. An ongoing multicenter RCT of timing of delivery in women found to have fetal growth restriction (i.e., *Trial of Umbilical and Fetal Flow in Europe*

[TRUFFLE]) may help to evaluate the role of the ductus venosus measurement. The aim is to evaluate the use of ductus venosus assessment compared with standard management based on FHR assessment; the primary outcome for this trial is survival without neurodevelopmental impairment at 2 years of age, corrected for prematurity.

Even more important than short-term measures are the impacts on long-term development. Randomized trials are not available that prove the impact of antepartum fetal assessment on long-term neurologic and intellectual health. Given the importance of advancing gestational age on these long-term outcomes and particularly in the context of emerging information regarding the negative consequences of late preterm^{93,94} and early term birth,⁹⁵ additional information is needed regarding the most appropriate thresholds for intervention before 39 weeks.

Summary

The first prenatal visit initiates a process of monitoring, and a customized plan for fetal assessment begins to emerge based on identification of family, historical, and maternal risk factors. Specific fetal information, including data from first- and second-trimester screening, biochemical testing, and growth

evaluation, further refine the plan. As dictated by identified risk factors, management based on multivariable fetal assessment, with BPP scoring as a central element and the liberal addition of Doppler assessment of placental and fetal circulations, can help to prevent iatrogenic prematurity and provide reassurance regarding fetal well-being. In this process, the risks of neonatal injury resulting from prematurity must be balanced against the risks of stillbirth and permanent injury from ongoing pregnancy in the setting of fetal compromise. The details of fetal testing will evolve as further data become available, but the principles of multivariable testing, individualized management based on maternal and fetal conditions, and ongoing investigation to provide validation by reliable outcome measures will continue to apply.

Intrapartum Fetal Surveillance

MICHAEL P. NAGEOTTE, MD

Factors Controlling Fetal Heart Rate

Fetal heart rate (FHR) analysis is the most common means of evaluating a fetus for adequate oxygenation. The rate and regulation of the fetal heart provide important information for the obstetrician. The average FHR is 155 beats/min at 20 weeks' gestation, 144 beats/min at 30 weeks, and 140 beats/min at term. This progression is thought to reflect maturation of vagal tone, with consequent slowing of the baseline FHR. Normal fetuses can have variations of 20 beats/min faster or slower than these baseline values.

The fetal heart is similar to the adult heart in that it has its own intrinsic pacemaker activity that results in rhythmic myocardial contractions. The sinoatrial node, found in one wall of the right atrium, has the fastest rate of depolarization and sets the rate in the normal heart. The next fastest rate is produced by the secondary pacemaker, the atrioventricular node within the atrial septum. The His-Purkinje system carries electrical signals throughout the ventricles at a slower rate than the sinoatrial or atrioventricular node. Complete or partial heart block in the fetus produces variations in rate that are markedly slower than normal. The rate in a fetus with a complete heart block is 60 to 80 beats/min.

FHR variability is important clinically, and its specific amplitude as part of the FHR pattern has prognostic value. The heart rate is the result of many physiologic factors that modulate the intrinsic rate of the fetal heart, the most common of which are signals from the autonomic nervous system.

PARASYMPATHETIC NERVOUS SYSTEM

The parasympathetic nervous system consists primarily of the vagus nerve (cranial nerve X), which originates in the medulla oblongata. The vagus nerve innervates the sinoatrial and atrioventricular nodes. Stimulation of the vagus nerve results in a decrease in FHR in the normal fetus because vagal influence on the sinoatrial node decreases its rate of firing. In a similar fashion, blockade of this nerve in a normal fetus causes an increase in the FHR of approximately 20 beats/min at term.¹ This finding demonstrates a normally constant vagal influence on the FHR, which tends to decrease it from its intrinsic rate.

The vagus nerve is also responsible for transmission of impulses causing beat-to-beat variability of the FHR; blockade of the vagus nerve eliminates this variability. The vagus nerve therefore has two possible effects on the heart: a tonic influence tending to decrease FHR and an oscillatory influence that results in FHR variability.² Vagal tone is not necessarily constant. Its influence increases with gestational age.³ In fetal sheep, vagal activity increases as much as fourfold during acute hypoxia⁴ or experimentally produced fetal growth restriction.⁵

SYMPATHETIC NERVOUS SYSTEM

Sympathetic nerves are widely distributed in the muscle of the heart at term. Stimulation of the sympathetic nerves releases norepinephrine and increases the rate and strength of fetal cardiac contractions, resulting in higher cardiac output. The sympathetic nerves are a reserve mechanism to improve the pumping activity of the heart during intermittent stressful situations. There is normally a tonic sympathetic influence on the heart. Blocking the action of these sympathetic nerves causes a decrease in FHR of approximately 10 beats/min. As with vagal tone, tonic sympathetic influence increases as much as twofold during fetal hypoxia.

CHEMORECEPTORS

Chemoreceptors are found in the peripheral and central nervous systems. They have their most dramatic effects on the regulation of respiration but are also important in control of the circulation. Peripheral chemoreceptors reside in the aortic and carotid bodies, which are located in the arch of the aorta and the area of the carotid sinus, respectively. The central chemoreceptors in the medulla oblongata respond to changes in oxygen and carbon dioxide tension in the blood or in the cerebrospinal fluid perfusing this area.

In the adult, a reflex tachycardia occurs when oxygen is decreased or the carbon dioxide content is increased in the arterial blood perfusing the central chemoreceptors. A substantial increase in arterial blood pressure occurs, particularly when the carbon dioxide concentration is increased. Both effects are thought to be protective, representing an attempt to circulate more blood through the affected areas and thereby decrease the carbon dioxide tension (P_{CO_2}) or increase the oxygen tension (P_{O_2}). In adults, selective hypoxia or hypercapnia of the peripheral chemoreceptors alone produces bradycardia, in contrast to the tachycardia and hypertension that result from central hypoxia or hypercapnia.

The interaction of central and peripheral chemoreceptors in the fetus is poorly understood. It is known that the net result of hypoxia or hypercapnia in the unanesthetized fetus is bradycardia with hypertension. During basal conditions, the chemoreceptors contribute to stabilization of the FHR and blood pressure.⁶

BARORECEPTORS

In the arch of the aorta and in the carotid sinus at the junction of the internal and external carotid arteries are small stretch receptors in the vessel walls that are sensitive to increases in blood pressure. When pressure rises, impulses are sent from

these receptors through the vagus or glossopharyngeal nerve to the midbrain. This results in further vagus stimulation, which tends to slow the heart. This is an extremely rapid response, occurring almost with the first systolic rise of blood pressure. It is a protective, stabilizing attempt by the body to lower blood pressure by decreasing the heart rate and cardiac output when blood pressure is increasing.

CENTRAL NERVOUS SYSTEM

In the adult, the higher centers of the brain influence the heart rate, which is increased by emotional stimuli such as fear and sexual arousal. In fetal lambs and monkeys, the electroencephalogram or electro-oculogram shows increased activity that sometimes is associated with increased variability of the FHR and body movements. When the fetus is sleeping, body movement slows, and FHR variability decreases, suggesting an association between these two factors and central nervous system activity.⁷

The medulla oblongata contains the vasomotor centers. These are integrative centers in which the net result of all the central and peripheral inputs is processed to generate irregular oscillatory vagal impulses, producing acceleration or deceleration of the heart (i.e., FHR variability).

HORMONAL REGULATION

Adrenal Medulla

The fetal adrenal medulla produces epinephrine and norepinephrine in response to stress. Both substances act on the heart and cardiovascular system in a way similar to sympathetic stimulation to produce a faster FHR (i.e., chronotropic effect), greater force of contraction of the heart (i.e., inotropic effect), and higher arterial blood pressure.

Renin-Angiotensin System

Angiotensin II may play a role in fetal circulatory regulation at rest. Its main activity is observed during hemorrhagic stress on a fetus.

Prostaglandins

Various prostaglandins and arachidonic acid metabolites are found in the fetal circulation and in many fetal tissues. Their main roles with respect to cardiovascular function are in regulating umbilical blood flow and maintaining the patency of the ductus arteriosus during fetal life.

Other Hormones

Fetal hormones such as nitric oxide, α -melanocyte-stimulating hormone, atrial natriuretic hormone, neuropeptide Y, thyrotropin-releasing hormone, and cortisol and metabolites such as adenosine participate in the regulation of circulatory function.

BLOOD VOLUME CONTROL

Capillary Fluid Shift

In the adult, when the blood pressure is elevated by excessive blood volume, fluid moves out of the capillaries into interstitial spaces, decreasing the blood volume toward normal. If the adult loses blood through hemorrhage, some fluid shifts out of the interstitial spaces into the circulation, increasing the blood

volume toward normal. There is normally a delicate balance between the pressures inside and outside the capillaries. This mechanism of regulating blood pressure is slower than the almost instantaneous regulation observed with the reflex mechanisms discussed previously. Its role in the fetus is imperfectly understood, although imbalances may be responsible for the hydrops seen in some cases of red cell alloimmunization and the high-output failure sometimes seen with supraventricular tachycardia.

Intraplental Pressures

Fluid moves along hydrostatic pressure gradients and in response to osmotic pressure gradients. The specific role of these factors within the human placenta, where fetal and maternal blood closely approximate, is unclear, but it seems likely that some delicate balancing mechanisms within the placenta prevent rapid fluid shifts between mother and fetus. The mean arterial blood pressure of the mother (≈ 100 mm Hg) is much higher than that of the fetus (≈ 55 mm Hg), but the spiral artery reduces this pressure to less than 70 mm Hg systolic, the pressure in the intervillous space is about 10 mm Hg, and the osmotic pressures are not substantially different.

Frank-Starling Mechanism

The amount of blood pumped by the adult heart is determined in part by the amount of blood returning to the heart. The heart normally pumps the blood that flows into it without excessive damming of blood in the venous circulation. When the cardiac muscle is stretched during diastole by increased venous return of blood, it contracts with greater force and is able to pump out more blood. This mechanism of response to preload is apparently not the same in the fetal heart as in the adult heart. In the fetus, increases in preload produce minor or no changes in combined ventricular output, suggesting that the fetal heart normally operates near the peak of its function curve.

The output of the fetal heart is related to the FHR. Some researchers have shown that spontaneous variations of the FHR are directly related to cardiac output (i.e., as the rate increases, output increases). However, different responses have been observed during right or left atrial pacing studies.⁸ Additional factors are required to explain these differences. In addition to the FHR and preload, cardiac output depends on afterload and intrinsic contractility.^{8,9}

The fetal heart is highly sensitive to changes in afterload, represented by the fetal arterial blood pressure. Increases in afterload dramatically reduce the stroke volume or cardiac output. The fetal heart is incompletely developed, and many ultrastructural differences between the adult and fetal heart account for its lower intrinsic capacity to alter its contraction efficiency. The determinants of cardiac output do not work separately; each interacts dynamically to modulate fetal cardiac output during changing physiologic conditions. In clinical practice, it is reasonable to assume that modest variations of the FHR from the normal range produce relatively small effects on cardiac output. However, at the extremes (e.g., tachycardia of >240 beats/min, bradycardia of <60 beats/min), cardiac output and umbilical blood flow are likely to be substantially decreased.

Umbilical Blood Flow

Umbilical blood flow is approximately 40% of the combined fetal ventricular output, and not all of this blood flow to the placenta exchanges with maternal blood. Umbilical blood flow

is unaffected by acute moderate hypoxia, but it is decreased by severe hypoxia affecting myocardial function. The umbilical cord lacks innervation, and there are no means of increasing umbilical flow. However, variable decelerations in the FHR commonly occur with transient umbilical cord compression, and flow is diminished or stopped for a time, depending on the degree and duration of cord compression or occlusion.

Monitoring the Fetal Heart Rate

The electronic FHR monitor is a device with two components. One establishes the FHR, and the other measures uterine contractions.¹⁰ To recognize the FHR, the device uses the R wave of the fetal electrocardiogram (ECG) complex (i.e., fetal scalp electrode) or modulation of an ultrasound signal generated by movement of a cardiovascular structure (i.e., Doppler ultrasound transducer or cardiometer). Uterine contractions are detected directly by a pressure transducer attached to a catheter within the amniotic cavity (i.e., intrauterine pressure catheter) or by a beltlike external device (i.e., tocodynamometer) that recognizes tightening of the uterus during a contraction. Monitoring with devices attached directly to the fetus or placed within the uterine cavity is called *internal*, and monitoring with devices that are on the maternal abdomen is called *external*.

FETAL HEART RATE DETECTION

Fetal Electrode

The fetal electrode consists of a small, spiral, stainless steel wire that is typically attached to the fetal scalp. A second contact is bathed by the vaginal fluids. The wires traverse the vaginal canal and are connected to a maternal leg plate, which is attached to the fetal monitor. The internal mode gives the most accurate FHR tracing, because this technique directly measures the fetal cardiac electrical signal and true beat-to-beat variability.

Doppler Ultrasound Transducer

The FHR monitoring device most commonly employed is the cardiometer or Doppler ultrasound transducer. This device emits a high-frequency ultrasound signal (approximately 2.5 MHz) that is reflected from any moving structure (e.g., ventricle wall, valvular leaflets), with the reflected signal altered in frequency. The change in frequency with each systole is recognized as a cardiac contraction and is processed by the transducer. The interval between cardiac events is measured (in seconds) and then divided into 60 to yield a rate for each interval between beats. These calculated rates are transcribed onto a paper strip that is moving at a specific speed (usually 3 cm/min). The resulting tracing appears as a wavy line and is a very close representation of true FHR variability. If the intervals between heartbeats are persistently identical, the resultant FHR line is straight, suggesting minimal or absent variability.

Although this device is simple to apply, it is often inconsistent in obtaining a signal because of interference caused by maternal and fetal movements. Improvements in the logic and technology of the monitors have made the external devices more accurate and easier to use. The technique of *autocorrelation* is used to define the timing of the cardiac contraction more accurately. Analysis of a very large number of points on the curve depicting the Doppler frequency shift produces a

signal that much more accurately represents the FHR variability. The signal must be confirmed as fetal rather than maternal in origin.

UTERINE ACTIVITY DETECTION

Intra-amniotic Catheter

The internal means of detecting uterine activity typically uses a soft, plastic, transducer-tipped catheter placed transcervically into the amniotic cavity. The pressure of the baseline uterine tone and that of any uterine contraction is translated into an electrical signal, which is calibrated and displayed directly (as millimeters of mercury [mm Hg]).

Tocodynamometer

The tocodynamometer is an external device that is placed on the maternal abdominal wall over the uterine fundus. Tightening of the fundus with each contraction is detected by pressure on a small button in the center of the transducer, and uterine activity is displayed on the recorder. It acts like a hand placed on the uterine fundus through the abdominal wall to detect uterine activity. This device detects the frequency and duration of uterine contractions but not true contraction intensity. One disadvantage of the tocodynamometer is that it works best with the mother in the supine position. This limitation may not always be compatible with maternal comfort, fetal well-being, or progression of labor. With repositioning of the patient, it is important to reestablish accurate monitoring of the fetal heart and uterine activity.

Fetal Responses to Hypoxia or Acidemia

Studies of chronically prepared animals have shown that a number of responses occur during acute hypoxia or acidemia in the previously normally oxygenated fetus. Little or no change in combined cardiac output and umbilical (placental) blood flow occurs, but there is a redistribution of blood flow favoring certain vital organs—heart, brain, and adrenal glands—and a decrease in blood flow to the gut, spleen, kidneys, and carcass.¹¹ This initial response is presumed to be advantageous to a fetus in the same way as the diving reflex is advantageous to an adult seal. Blood containing the available oxygen and other nutrients is supplied preferentially to vital organs. These responses are temporary compensatory mechanisms that enable a fetus to survive for moderately long periods (e.g., up to 30 minutes) of limited oxygen supply without decompensation of vital organs, particularly the brain and heart.

Close matching of blood flow to oxygen availability to achieve a constancy of oxygen consumption has been demonstrated in the fetal cerebral circulation¹² and in the fetal myocardium.¹³ In studies of hypoxic lamb fetuses, cerebral oxygen consumption was constant over a wide range of arterial oxygen concentrations, because the decrease in arteriovenous oxygen content accompanying hypoxia was offset by an increase in cerebral blood flow. However, during more severe acidemia or sustained hypoxemia, these responses were no longer maintained, and decreases in cardiac output, arterial blood pressure, and blood flow to the brain and heart resulted.¹⁴ These changes may be considered as a stage of decompensation after which tissue damage and even fetal death may follow.¹⁵

Fetal Acid-Base Balance

PHYSIOLOGY

Normal metabolism in the fetus results in the production of carbonic and organic acids. These acids are buffered by various mechanisms that regulate the fetal pH within a very narrow range. Although the concentration of hydrogen ions is extremely low, changes in fetal pH as small as 0.1 unit can have profound effects on metabolic activity and on the cardiovascular and central nervous systems. Extreme changes in pH can be fatal.

The maternal acid-base status can adversely affect the fetal acid-base status. In normal pregnancies, the difference between maternal and fetal pH is usually 0.05 to 0.10 units.¹⁶

Carbonic Acid

Carbonic acid (H_2CO_3) is a volatile acid that is produced from the metabolism of glucose and fatty acids. During fetal oxidative metabolism (i.e., aerobic glycolysis or cellular respiration), the oxidation of glucose uses oxygen (O_2) and produces carbon dioxide (CO_2).

From a practical standpoint, carbonic acid formation is equivalent to carbon dioxide generation, and most of the free hydrogen ion formed is buffered intracellularly. As blood passes through the placenta (or through the lung in the adult), bicarbonate ion (HCO_3^-) reenters erythrocytes and combines with hydrogen ions to form carbonic acid, which then dissociates to carbon dioxide and water. The carbon dioxide formed in the fetus diffuses across the placenta and is excreted by the maternal lung. Carbon dioxide diffuses rapidly across the human placenta, and even large quantities produced by the fetus can be eliminated rapidly if maternal respiration, uteroplacental blood flow, and umbilical blood flow are normal.

The rate of fetal carbon dioxide production is roughly equivalent to the fetal oxygen consumption rate.¹⁷ For carbon dioxide to diffuse from fetus to mother, a gradient must be maintained between the PCO_2 in fetal umbilical blood and that in maternal uteroplacental blood. Adequate perfusion of both sides of the placenta also must be preserved. Because of progesterone-stimulated maternal hyperventilation, the arterial PCO_2 is reduced from a mean of 39 mm Hg in nonpregnant women to a mean of 31 mm Hg during pregnancy. Renal compensation results in increased bicarbonate excretion and plasma levels of 18 to 22 mEq/L during pregnancy.¹⁸

Nonvolatile Acids

Anaerobic metabolism in the fetus results in the production of nonvolatile or fixed organic acids by two mechanisms: use of non-sulfur-containing amino acids, which generates pyruvic and acetoacetic acids, and incomplete combustion of carbohydrates and fatty acids, which produces lactic acid and ketoacids (e.g., β -hydroxybutyric acid).

Because of relatively immature renal function, the fetus is unable to effectively excrete these acids; instead, they are transported to the placenta, where they diffuse slowly (unlike carbon dioxide) into the maternal circulation. The maternal kidney excretes fixed organic acids produced by maternal and fetal metabolism and helps to regenerate bicarbonate. Because the maternal glomerular filtration rate increases significantly during normal pregnancy, the maternal kidney filters and reabsorbs large quantities of bicarbonate daily.

The fetus does have the ability to metabolize accumulated lactate in the presence of sufficient oxygen. However, this is a slow process, and it is not thought to account for a large proportion of lactic acid elimination from the fetal compartment.

Buffers

Dramatic changes in pH are minimized by the action of buffers. The two major buffers are plasma bicarbonate and hemoglobin. Quantitatively less important buffers include erythrocyte bicarbonate and inorganic phosphates.¹⁹

Terms that are used for the expression of buffering capacity include the following:

- *Delta base*: measure of the change (Δ) in the buffering capacity of bicarbonate
- *Base deficit*: bicarbonate values lower than normal
- *Base excess*: bicarbonate values higher than normal

Although the fetus has a limited ability to buffer an increase in acid production with bicarbonate and hemoglobin, the placental bicarbonate pool also may play a role in buffering the fetus against changes in maternal pH or blood gas status. Aarnoudse and colleagues²⁰ studied bicarbonate permeability in the perfused human placental cotyledon model and found that acidification of the maternal circulation to pH 7.06 for 30 minutes did not significantly alter fetal pH. Instead, there was an efflux of total carbon dioxide from the placenta into the maternal circulation in the form of bicarbonate, which was not matched by an influx of total carbon dioxide from the fetal circulation. By this mechanism, bicarbonate transfer could take place between the placental tissue pool and the maternal circulation, whereas the transmission of maternal pH and blood gas changes to the fetal circulation would be minimized.

pH Determination

The pH of a liquid is the negative logarithm of the hydrogen ion concentration in that liquid. It can be used to describe the acid-base status of any body fluid. It is directly related to the concentration of bicarbonate (base) and inversely related to the concentration of carbonic acid (acid). The H_2CO_3 equals $0.03 \times PCO_2$, and the pK equals 6.11 for normal plasma at 37°C. This relationship is best illustrated by the Henderson-Hasselbalch equation for determining the pH of a buffered system, in which pK is the negative logarithm of the acid dissociation constant:

$$pH = pK + \log \frac{[\text{base}]}{[\text{acid}]}$$

In the case of fetal acid-base balance determinations,

$$pH = pK + \log \frac{[HCO_3^-]}{[H_2CO_3]}$$

$$pH = pK + \log \frac{[HCO_3^-](\text{mEq/L})}{0.03[PCO_2](\text{mmHg})}$$

In simplest terms, the HCO_3^- represents the metabolic component, and the H_2CO_3 (or PCO_2) represents the respiratory component.²¹

TABLE 33-1 Terminology

Term	Definition
Acidemia	Increased concentration of hydrogen ions in blood
Acidosis	Increased concentration of hydrogen ions in tissue
Asphyxia	Hypoxia with metabolic acidosis
Base deficit	HCO ₃ ⁻ concentration lower than normal
Base excess	HCO ₃ ⁻ concentration higher than normal
Delta base	Measure of change (Δ) in buffering capacity of bicarbonate
Hypoxemia	Decreased oxygen content in blood
Hypoxia	Decreased level of oxygen in tissue
pH	Negative logarithm of hydrogen ion concentration

Adapted from American College of Obstetricians and Gynecologists (ACOG): Umbilical artery blood acid-base analysis, technical bulletin no. 216, Washington, DC, 1995, ACOG.

TABLE 33-2 Types of Acidemia*

Acidemia*	Definition
Metabolic	Normal PCO ₂ and decreased HCO ₃ ⁻
Respiratory	Increased PCO ₂ and normal HCO ₃ ⁻ (after correction of PCO ₂)
Mixed	Increased PCO ₂ and decreased HCO ₃ ⁻

*Umbilical artery pH < 7.10.

TERMINOLOGY

Acidemia refers to an increase in hydrogen ions in the blood; *acidosis* refers to an increase in hydrogen ions in tissue. Similarly, *hypoxemia* is a decrease in oxygen content in blood, whereas *hypoxia* is a decrease in oxygen content in tissue (Table 33-1).

Acidemia in the newborn can be classified as three types: metabolic, respiratory, and mixed. The type is based primarily on the levels of HCO₃⁻ and PCO₂ (Table 33-2). With marked elevations of the PCO₂, there is a compensatory increase in HCO₃⁻ of 1 mEq/L for each 10 mm Hg increase in PCO₂.²²

FACTORS AFFECTING ACID-BASE BALANCE

For the acid-base balance in the fetus, the placenta acts as lungs and kidneys by supplying oxygen and removing carbon dioxide and various metabolites. The pH in the fetus is controlled within a very tight range. Umbilical blood oxygen content and saturation and fetal arterial delta base values depend primarily on uterine blood flow. Oxygen supply depends on the following:

- Adequate maternal oxygenation
- Blood flow to the placenta
- Transfer across the placenta
- Fetal oxygenation
- Delivery to fetal tissues

Removal of carbon dioxide depends on fetal blood flow to the placenta and transport across the placenta. Fixed-acid equilibrium depends on a continued state of balance between production and removal.

Respiratory Factors

Respiratory acidosis results from increased PCO₂ and subsequently from decreased pH. In the fetus, this picture is usually

associated with decreased PO₂. The most common cause of acute respiratory acidosis in the fetus is a sudden decrease in placental or umbilical perfusion. Umbilical cord compression, uterine hyperstimulation, and abruptio placentae are examples, and transient cord compression is the most common factor.

Conditions associated with maternal hypoventilation or acute maternal hypoxemia can result in fetal hypoxemia and hypercarbia, potentially leading to fetal acidosis, which is a mixed respiratory and metabolic acidosis. Conditions associated with maternal hypoventilation or hypoxia can also result in respiratory acidosis in the fetus and, if severe enough, in metabolic acidosis. Coleman and Rund²³ reviewed the association between maternal hypoxia and non-obstetric conditions (e.g., asthma, epilepsy) during pregnancy. They found that the normal physiologic changes that occur during pregnancy might make early recognition of maternal hypoxia difficult. For example, in a mother with asthma, a pH of less than 7.35 and a PCO₂ higher than 38 mm Hg may indicate respiratory compromise.²⁴ To minimize the risk of concurrent hypoxemia in the fetus, early intubation in mothers who have borderline or poor blood gas values or evidence of respiratory compromise is recommended.

Other conditions can result in acute or chronic maternal hypoventilation during pregnancy. Induction of general anesthesia or narcotic overdose can depress the medullary respiratory center. Hypokalemia, neuromuscular disorders (e.g., myasthenia gravis), and toxic doses of drugs that impair neuromuscular transmission (e.g., magnesium sulfate) can result in hypoventilation or paralysis of the respiratory muscles. Airway obstruction by foreign bodies can cause maternal respiratory acidosis. Restoration of the normal fetal acid-base balance depends on the reversibility of maternal etiologic factors.

Maternal respiratory alkalosis may occur when hyperventilation reduces the PCO₂ and increases pH. Severe anxiety, acute salicylate toxicity, fever, sepsis, pneumonia, pulmonary emboli, and acclimation to high altitudes are etiologic factors. Severe respiratory alkalosis and hypocapnia can cause uterine artery vasospasm, reducing placental perfusion and causing fetal hypoxia and metabolic acidosis. As in respiratory acidosis, restoration of the maternal acid-base balance by appropriate treatment of causative factors results in normalization of fetal blood gases.

Metabolic Factors

Fetal metabolic acidosis is characterized by loss of bicarbonate, high base deficit, and a subsequent fall in pH. This type of acidosis results from protracted periods of oxygen deficiency to a degree that results in anaerobic metabolism. The cause can be fetal or maternal, and it usually implies the existence of a chronic metabolic derangement. Conditions such as growth restriction resulting from chronic uteroplacental hypoperfusion can be associated with fetal metabolic acidosis due to decreased oxygen delivery.

Maternal metabolic acidosis can cause fetal metabolic acidosis and is classified according to the status of the anion gap. In addition to bicarbonate and chloride, the remaining anions required to balance the plasma sodium concentration are referred to as *unmeasured anions* or the *anion gap*. Reduced excretion of inorganic acids (e.g., renal failure) or accumulation of organic acids (e.g., alcoholic, diabetic, or starvation ketoacidosis; lactic acidosis) results in metabolic acidosis characterized by an increased anion gap. Bicarbonate loss (e.g., renal tubular

TABLE 33-3 Fetal Scalp Blood Values in Labor

Measurement	Early First Stage*	Late First Stage*	Second Stage*
pH	7.33 ± 0.03	7.32 ± 0.02	7.29 ± 0.04
Pco ₂ (mm Hg)	44.00 ± 4.05	42.00 ± 5.1	46.30 ± 4.2
Po ₂ (mm Hg)	21.8 ± 2.6	21.3 ± 2.1	16.5 ± 1.4
Bicarbonate (mmol/L)	20.1 ± 1.2	19.1 ± 2.1	17 ± 2
Base excess (mmol/L)	3.9 ± 1.9	4.1 ± 2.5	6.4 ± 1.8

*All values are given as the mean ± standard deviation.

acidosis, hyperparathyroidism, diarrheal states) or failure of bicarbonate regeneration results in metabolic acidosis characterized by a normal anion gap. Fetal responses to these maternal conditions are manifested by a pure metabolic acidosis with normal respiratory gas exchange as long as placental perfusion remains normal.

Prolonged fetal respiratory acidosis (e.g., cord compression, abruptio placentae) can result in accumulation of fixed organic acids produced by anaerobic metabolism. This condition is characterized by blood gas measurements that reflect a mixed respiratory and metabolic acidosis.

Effects of Labor

Each uterine contraction transiently diminishes uterine blood flow, reduces placental perfusion, and impairs transplacental gaseous exchange. A sample of blood may be obtained from the fetal presenting part to help evaluate fetal status during labor. Typical fetal scalp blood values during labor are shown in Table 33-3. This information is of limited value because fetal scalp blood sampling is rarely performed in the United States.

UMBILICAL CORD BLOOD ACID-BASE ANALYSIS

Acid-base analysis of umbilical cord blood provides an objective method of evaluating a depressed newborn's condition, especially with regard to hypoxia and acidemia.¹⁶ Assessing umbilical cord blood pH has become an important adjunct in defining the degree of perinatal hypoxia when there is a question about whether it may be severe enough to result in acute neurologic injury.²⁵ Moreover, the technique is simple and relatively inexpensive.

Technique

For the depressed neonate of any gestational age, the umbilical cord should be immediately clamped and cut to allow delivery of the newborn to pediatric attendants for appropriate resuscitation. A segment of 10 to 20 cm of umbilical cord may then be clamped and cut separately. If other clinical issues require attention, aspiration of blood from this clamped, undisturbed, room-temperature cord segment may be delayed for up to 30 minutes without any effect on the accuracy of the initial blood gas values at the time of clamping. Specimens should be obtained ideally from the umbilical artery and the umbilical vein, but the umbilical artery sample provides a more direct assessment of fetal condition, whereas the umbilical vein reflects placental acid-base status. In cases such as cord prolapse, the umbilical artery pH may be extremely low despite a normal umbilical vein pH.²⁶ Nevertheless, some clinicians still prefer to

use the umbilical vein, which is easier to access for drawing blood, especially in the very premature infant. In one study of 453 term infants, D'Souza and colleagues²⁷ determined that umbilical venous and arterial blood pH values were significantly related to each other and that umbilical venous pH measurements did provide useful information regarding acidemia at birth.

Samples should be drawn in plastic or glass syringes that have been flushed with heparin (1000 U/mL). Commercial syringes (1 to 2 mL) containing lyophilized heparin are also available for obtaining specimens. Kirshon and Moise²⁸ reported that the addition of 0.2 mL of 10,000 U/mL of heparin to 0.2 mL of blood significantly decreased the pH, Pco₂, and bicarbonate values. Any residual heparin and air should be ejected, and the needle should be capped.

A few practical points merit mention. It is not necessary to draw the sample from the umbilical artery immediately if the cord is doubly clamped. Adequate specimens have been obtained from a clamped segment of cord as long as 60 minutes after delivery without significant changes in pH or Pco₂.²⁹ After the specimens have been drawn into the syringe, they are relatively stable at room temperature for up to 60 minutes³⁰ and do not need to be transported to the laboratory on ice.³¹ The same may not be true for specimens obtained from placental vessels.³²

Chauhan and colleagues³³ prepared a mathematical model for calculating the umbilical artery pH for up to 60 hours after delivery. This model permits estimation of fetal pH at birth.

Normal Values

There is no consensus about the most appropriate umbilical artery pH cutoff for defining acidemia, but the mean pH values from four studies are shown in Table 33-4. The mean value for umbilical artery pH appears to be about 7.28. For example, in their study of cord blood respiratory gases and acid-base values, Riley and Johnson²⁶ determined a mean pH of 7.27 ± 0.07 for 3520 unselected women undergoing vaginal delivery.

The mean pH for umbilical venous blood has been reported to be 7.32 to 7.35 in various studies (see Table 33-4). In a study of umbilical venous blood, D'Souza and associates²⁷ reported a mean venous pH of 7.34 ± 0.07. Huisjes and Aarnoudse³⁴ reported good correlation between umbilical venous and arterial pH values.

Although the Apgar scores of premature infants may be low because of immaturity, mean arterial and venous pH and blood gas values are similar to those of the term infant. Mean values for almost 2000 premature infants are summarized in Table 33-5.

Pathologic Fetal Acidemia

What level of umbilical artery pH should be considered abnormal, pathologic, or clinically significant? The former pH cutoff of 7.20 is no longer considered appropriate.^{16,35} Most newborns with an umbilical artery pH lower than 7.20 are vigorous and have no systemic evidence of hypoxia. Evidence suggests that significant morbidity is more likely among neonates with umbilical artery pH values lower than 7.00, especially if associated with a low Apgar score (≤ 3). For example, in a study of 2738 term newborns, hypotonia, seizures, and required intubation were significantly correlated with an umbilical artery pH of less than 7.00 and an Apgar score of 3 or less at 1 minute.³⁶ The investigators concluded that a newborn must be severely depressed for birth hypoxia to be implicated as the cause of seizures.

Goldaber and coworkers,²² in an attempt to better define the critical cutoff for pathologic fetal acidemia, studied the neonatal outcomes of 3506 term newborns. They determined the critical pH cutoff point to be 7.00 (Table 33-6). However, many had no complications and went to the newborn nursery. In a follow-up study from the same institution, King and associates³⁷ described 35 term newborns who appeared well at birth and were triaged to the newborn nursery but were found to have umbilical artery pH values less than or equal to 7.00 on routine screening. The study authors concluded that newborns born

TABLE 33-6 Neonatal Morbidity and Mortality by pH Cutoff

pH	N	Neonatal Deaths	Seizures	Both
7.15-7.19	2236	3 (0.1%)	2 (0.1%)	1 (0.05%)
7.10-7.14	798	3 (0.4%)	1 (0.1%)	0 (0.00%)
7.05-7.09	290	0 (0.0%)	0 (0.0%)	1 (1.1%)

after 35 or more weeks' gestation who had this degree of acidemia at birth but had a stable appearance in the delivery room and no other complications did not have evidence of hypoxia or ischemia during the 48 hours after birth. Fewer than one half of neonates with an umbilical artery pH lower than 7.00 had neonatal complications.³⁸

Human fetuses frequently tolerate much lower cord pH values without obvious injury than previously thought. Andres and colleagues³⁹ presented data from a retrospective cohort study of 93 neonates with an umbilical artery pH less than 7.00 (gestational age range, 23.5 to 42.9 weeks) and with a median pH of 6.92 (range, 6.62 to 6.99). The median pH was 6.75 for neonates with seizures (25th to 75th percentile, 6.72 to 6.88), compared with 6.93 for those without seizures ($P = .02$). The median pH for newborns with hypoxic-ischemic encephalopathy was significantly lower (6.69; 25th to 75th percentile, 6.62 to 6.75) than for those without this diagnosis (6.93; 25th to 75th percentile, 6.85 to 6.97; $P = .03$). The median pH was also less than 6.90 for newborns who required intubation (6.83) or cardiopulmonary resuscitation (6.83) and was significantly lower ($P < .05$) than for newborns without these complications. The median PCO₂ and base deficit values also were significantly higher for neonates with these morbidities.³⁹

Acute Neurologic Injury

The 1-minute and the 5-minute Apgar scores are poor predictors of adverse neurologic outcomes for newborns. The correlation does improve if the scores remain between 0 and 3 at 10,

15, and 20 minutes; however, many of these newborns will be normal, if they survive. Similarly, a low umbilical artery pH in and of itself has poor correlation with adverse outcome.

The American College of Obstetricians and Gynecologists (ACOG)⁴⁰ has established the following essential criteria (all four must be met) to indicate hypoxia proximate to delivery severe enough to be associated with acute neurologic injury:

1. Evidence of a metabolic acidosis in fetal umbilical cord arterial blood obtained at delivery (pH <7 and base deficit ≥ 12 mmol/L). (Rates of neonatal encephalopathy, respiratory complications, and composite morbidity increase to approximately 10% for newborns with a base deficit of 12 to 16 mmol/L. The rate increases to 40% for newborns with umbilical artery base deficit values greater than 16 mmol/L.)
2. Early onset of severe or moderate neonatal encephalopathy in infants born at 34 or more weeks' gestation
3. Cerebral palsy of the spastic quadriplegic or dyskinetic type
4. Exclusion of other identifiable causes, such as trauma, coagulation disorders, infections, or genetic disorders

In two publications, Low and associates^{41,42} described the association between severe or significant metabolic acidosis (determined by the umbilical artery blood gas profile) and newborn complications. Low⁴² proposed a classification of intrapartum fetal asphyxia, the severity of which was based on newborn encephalopathy and other organ system dysfunction.

Other Clinical Events and Umbilical Blood Acid-Base Status

Beyond its use in assessing risk for neurologic injury with no obvious antecedent, umbilical blood gas analysis has been reported in a variety of clinical situations that entail more apparent risk, such as acute chorioamnionitis, nuchal cords, meconium-stained amniotic fluid, prolonged pregnancy, FHR anomalies, operative vaginal delivery, breech delivery, and use of oxytocin.³⁵ Analysis may also prove useful in assessing the interval from delivery of the head to complete delivery in cases of shoulder dystocia.

Acute Chorioamnionitis. In one study of 123 women with acute chorioamnionitis, compared with more than 6000 noninfected women, Maberry and coauthors⁴³ found no significant association between infection and fetal acidemia (Table 33-7). Hankins and colleagues⁴⁴ found no association between acute chorioamnionitis and newborn acidemia. Meyer and colleagues,⁴⁵ however, reported an association between neonatal

blood cultures within the first 24 hours of life as a proxy for fetal sepsis and a decrease in umbilical artery pH compared with controls (7.21 versus 7.26).

Nuchal Cords. In a study of 110 newborns with nuchal cords, Hankins and colleagues⁴⁶ reported that significantly more newborns with nuchal cords were acidemic (umbilical artery pH <7.20), compared with controls (20% versus 12%; $P < .05$); however, there were no significant differences in mean pH (7.25 versus 7.27), P_{CO_2} (49 versus 48 mm Hg), or HCO_3^- (20.5 versus 21.0 mEq/L).

Meconium-Stained Amniotic Fluid. In a study of 53 term pregnancies with moderate to thick meconium, Mitchell and colleagues⁴⁷ reported that approximately one half of the newborns were acidemic and that significantly more acidemic newborns had meconium below the cords compared with controls (32% versus 0%; $P < .05$). However, these investigators used an umbilical artery pH cutoff of 7.25 to define acidemia.

In another report of 323 newborns with meconium by Yeomans and associates,⁴⁸ the frequency of meconium below the cords in acidemic fetuses was significantly increased compared with that for nonacidemic fetuses (31% versus 18%; $P < .05$). Meconium aspiration syndrome, however, was an uncommon event, occurring in only 3% of newborns. Ramin and colleagues,⁴⁹ reported that 55% of meconium aspiration syndrome cases were newborns with an umbilical artery pH greater than 7.20.

In a review of 4985 term neonates born to mothers with meconium-stained amniotic fluid, Blackwell and colleagues⁵⁰ identified 48 cases of severe meconium aspiration syndrome in which umbilical artery pH measurements were obtained. The pH was 7.20 or higher in 29 of these patients and less than 7.20 in 19. There was no difference in frequency of seizures between the two pH groups. The investigators concluded that severe meconium aspiration syndrome occurred in the setting of normal acid-base status at delivery in many of the cases, suggesting that a "preexisting injury or a nonhypoxic mechanism is often involved."⁵⁰

Prolonged Pregnancy. In a study of 108 women with a prolonged pregnancy (≥ 41 weeks' gestation), Silver and colleagues⁵¹ reported a mean umbilical artery pH of 7.25. Moreover, significantly more newborns who were delivered for FHR indications had acidemia than newborns who were not (45% versus 13%; $P < .05$).

Fetal Heart Rate Abnormalities. Gilstrap and colleagues,⁵² in a study of 403 term newborns with FHR abnormalities in the second stage of labor compared with 430 control newborns, reported an association between abnormalities and acidemia (Table 33-8). This was confirmed in a follow-up study.⁵³ Honjo and Yamaguchi⁵⁴ also reported a correlation between second-stage baseline FHR abnormalities and fetal acidemia at birth. Although there may be an association between FHR abnormalities and acidemia, association with adverse long-term neurologic outcomes is uncommon. Nelson and colleagues⁵⁵ reported a population-based study of more than 115,000 children with birth weights of 2500 g or more, 78 of whom developed cerebral palsy and had electronic fetal monitoring during labor. Multiple late decelerations and decreased beat-to-beat variability were associated with an increased risk of cerebral palsy. However, of

TABLE 33-7 Umbilical Artery pH in Patients with or without Acute Chorioamnionitis

Umbilical Artery pH	Patients with Chorioamnionitis (n = 123)	Controls (n = 6769)

all the children with these abnormal FHR findings, only 0.19% developed cerebral palsy.

Method of Delivery. Gilstrap and coworkers⁵⁶ found no significant difference in the frequency of newborn acidemia according to the method of delivery (Table 33-9). This was true even when the indication for delivery was concern about the FHR monitoring information.

Although the mean umbilical artery pH was lower for infants delivered vaginally in breech presentations compared with cephalic presentations in two studies,^{57,58} in a total of 121 breech vaginal deliveries, pH levels were not significantly low from a clinical standpoint (7.23 and 7.16, respectively). The investigators in both studies concluded that uneventful vaginal breech labor and delivery at term was not associated with an increased risk of asphyxia.

Shoulder Dystocia. Most adverse outcomes associated with shoulder dystocia result from physical injury to the brachial plexus,⁵⁹ not acidemia or asphyxia (unless an extremely protracted period is needed to extract the fetus). In a review of 134 infants born after shoulder dystocia, Stallings and colleagues⁶⁰ reported that this complication was associated with a “statistically significant but clinically insignificant” reduction in mean umbilical artery pH levels compared with their obstetric population (7.23 versus 7.27).

Effect of Oxytocin. In a study of 556 women who received oxytocin compared with 704 who did not, Thorp and colleagues⁶¹ found no significant difference in mean umbilical artery pH measurements (7.23 and 7.24, respectively).

MEASURING ACID-BASE STATUS

The fetus maintains its pH within a very limited range and depends on the placenta and the maternal circulation to maintain acid-base balance. Several methods for assessing fetal or newborn acid-base status have been described. Umbilical blood gas analysis is probably the most useful, the easiest, and the least expensive to perform.

Few data are available to justify a policy of umbilical blood gas analysis for all newborns. In a survey of 133 universities in the United States, Johnson and Riley⁶² reported that approximately 27% of centers used cord blood for assessing newborn acid-base status in all deliveries. Two thirds of the programs used umbilical blood for tracing abnormal FHRs or for low Apgar scores. The Royal College of Obstetricians and Gynecologists and the Royal College of Midwives⁶³ recommend routine cord blood measurements for all cesarean deliveries and instrumental deliveries for fetal distress. The ACOG⁴⁰ recommends umbilical cord blood acid-base analysis in the following situations:

- Cesarean delivery for fetal compromise
- Low 5-minute Apgar score
- Severe growth restriction
- Abnormal FHR tracing
- Maternal thyroid disease
- Intrapartum fever
- Multifetal gestations

Characteristics of Fetal Heart Rate Patterns

BASIC PATTERNS

Characteristics of the FHR pattern are classified as baseline features and as periodic or episodic changes.^{64,65} The baseline features are those recorded between uterine contractions. Periodic changes are associated with uterine contractions, and episodic changes are those not obviously associated with uterine contractions.

Baseline Features

The baseline features of the FHR are predominant characteristics that can be recognized between uterine contractions. They are the baseline rate and variability of the FHR.

Baseline Rate. The *baseline rate* is the FHR recorded between contractions. More accurately described, it is the approximate mean FHR rounded to 5 beats/min during a 10-minute segment, excluding the periodic or episodic changes, periods of marked FHR variability, and segments of the baseline that differ by at least 25 beats/min. In any 10-minute window, the minimum baseline duration must be at least 2 minutes; otherwise, the baseline for that period is indeterminate.

The normal baseline FHR is between 110 and 160 beats/min. Rates slower than 110 beats/min are called *bradycardia*, and rates faster than 160 beats/min are called *tachycardia*. Baseline bradycardia and tachycardia are quantified by the actual rate observed in keeping with the definition of baseline rate.

Fetal Heart Rate Variability. Electronic FHR monitoring (EFM) in most cases produces a tracing with an irregular line that demonstrates FHR variability. The irregularities represent

the slight differences in the time interval and calculated FHR that occur from beat to beat. If all intervals between heartbeats were identical, the line would be straight. Fluctuations in the baseline FHR are irregular in amplitude and frequency. A sinusoidal pattern (discussed later) is different from variability in that it has a smooth sine wave of regular frequency and amplitude and is therefore excluded from the definition of FHR variability.

Baseline variability is defined as fluctuations in the FHR of two or more cycles per minute and is quantitated as the peak-to-trough amplitude of the FHR in beats per minute. Variability is *absent* when the amplitude range is undetectable. It is *minimal* when there is an amplitude range that is less than 5 beats/min. Variability is *normal* or *moderate* when the amplitude range is between 6 and 25 beats/min. Variability is *marked* when the amplitude is greater than 25 beats/min⁶⁶ (see Classification and Significance of Baseline Variability, later).

Periodic Heart Rate Patterns

Periodic patterns are the alterations in FHR that are associated with uterine contractions or changes in blood flow within the umbilical cord vessels. These patterns include late decelerations, early decelerations, variable decelerations, and accelerations. In each case, the decrease or increase in the FHR is calculated from the most recently determined portion of the baseline.

Late Decelerations. In late deceleration of the FHR, there is a visually apparent decrease and subsequent return to the baseline FHR that is associated with a uterine contraction. The decrease is gradual; the time from onset of deceleration to nadir is at least 30 seconds. Its timing is delayed, with the nadir of the deceleration occurring late in relation to the peak of the uterine contraction. In most cases, the onset, nadir, and recovery are all late in relation to the beginning, peak, and ending of the contraction, respectively.

Early Decelerations. Early deceleration of the FHR is similar to late deceleration, except that the decrease is coincident in timing, with the nadir of the deceleration occurring at the same time as the peak of the uterine contraction. In most cases, the onset, nadir, and recovery are all coincident with the beginning, peak, and ending of the contraction, respectively.

Variable Decelerations. Variable deceleration is a visually apparent, abrupt decrease (<30 seconds from onset of deceleration to beginning of nadir) in FHR from the baseline. The decrease in FHR is at least 15 beats/min, and its duration from baseline to baseline is at least 15 seconds but not more than 2 minutes. When variable decelerations are associated with uterine contractions, their onset, depth, and duration commonly vary with successive contractions.

Prolonged deceleration is a visually apparent, abrupt decrease in FHR below the baseline of at least 15 beats/min that has a duration between 2 and 10 minutes from onset to return to baseline. If a deceleration lasts 10 minutes or longer, it is a baseline change.

Accelerations. Acceleration is a visually apparent, abrupt increase (<30 seconds from onset of acceleration to peak) in FHR above the baseline. The acme is at least 15 beats/min above the baseline, and the acceleration lasts between 15 seconds and 2 minutes from onset to return to baseline. A prolonged

acceleration is one that lasts at least 2 minutes but less than 10 minutes. If an acceleration lasts for 10 minutes or longer, it is a baseline change.

Accelerations are closely associated with normal FHR variability. Sometimes, it may be difficult to decide whether a recorded pattern represents an acceleration or a normal, long-term variability complex. The final decision is not important, because both have the same reassuring prognostic significance, indicating normal fetal oxygenation.

Quantification. Deceleration is quantified by the depth of the nadir in beats per minute below the baseline. Duration is quantified in minutes and seconds from the beginning to the end of the deceleration. Acceleration is quantified similarly. Decelerations are defined as recurrent or persistent if they occur with more than 50% of uterine contractions in any 20-minute period. Bradycardia and tachycardia are quantified by the FHR in beats per minute.

NORMAL AND ABNORMAL HEART RATE PATTERNS

In the fetus, the normal heart rate pattern (Fig. 33-1) has a baseline FHR of between 110 and 160 beats/min, an FHR variability amplitude between 6 and 25 beats/min, and no decelerative periodic changes, although there may be periodic or episodic accelerations. It is widely accepted in clinical practice that a newborn is normally oxygenated if this normal FHR pattern is traced at the time of delivery.^{4,67,68}

In contrast to the high predictability of fetal normoxia and vigor in the setting of the normal pattern, variant patterns are not as accurate for predicting fetal compromise. However, when these patterns are placed in the context of the clinical case (e.g., progressive change in the patterns, duration of the variant patterns), reasonable judgments can be made about the likelihood of fetal decompensation. With this screening approach, impending intolerable fetal acidosis can be presumed or, in certain cases, ruled out by the use of ancillary techniques (e.g., fetal scalp stimulation, vibroacoustic stimulation).

As a predictor of significant neurologic morbidity such as cerebral palsy, EFM has a very poor specificity and positive predictive value. The positive predictive value of a non-reassuring FHR is 0.14%. This means that for every 1000 fetuses born with a non-reassuring FHR tracing, 1 or 2 of them develop cerebral palsy.⁵⁵ The false-positive rate is greater than 99%. However, these results are from cases in which the clinicians were aware of the FHR patterns and managing the patients accordingly.

Baseline Rate

Bradycardia. Bradycardia is a baseline FHR slower than 110 beats/min. Some fetuses have a baseline FHR of less than 110 beats/min and are cardiovascularly normal. Their baseline FHR represents a variation outside the limits of normal. Others with an FHR slower than 110 beats/min may have congenital heart block and a well-compensated status despite a low FHR.

Bradycardia is related to baseline FHR and is distinguished from a deceleration. However, a prolonged deceleration resulting in a new baseline bradycardia may result from vagal activity in response to fetal hypoxia (Fig. 33-2). Decreases in FHR may be caused by the following:

- Sudden drop in oxygenation, such as occurs with placental abruption, maternal apnea, or amniotic fluid embolus

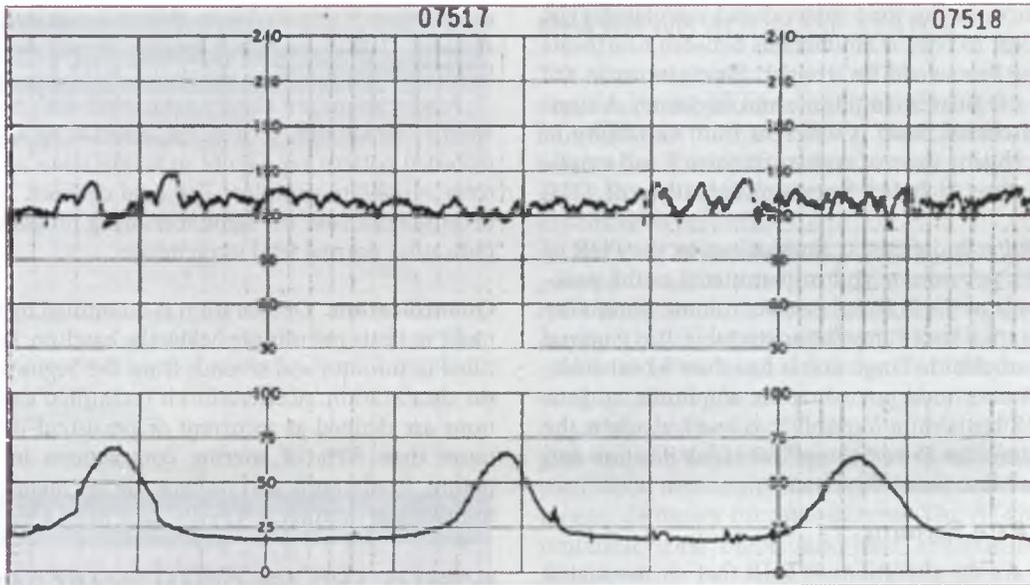

Figure 33-1 Normal fetal heart rate pattern. The tracing exhibits a normal rate (about 130 beats/min), normal variability (amplitude range about 15 beats/min), and absence of periodic changes. This pattern represents a nonacidemic fetus without evidence of hypoxic stress. Uterine contractions are 2 to 3 minutes apart and about 60 to 70 mm Hg in intensity.

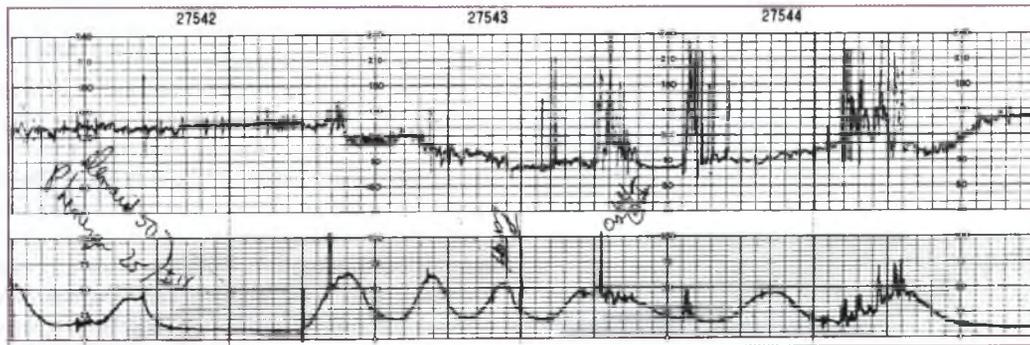

Figure 33-2 Prolonged fetal bradycardia. The prolonged fetal bradycardia resulted from excessive oxytocin-induced hyperstimulation of the uterus after intravenous infusion of meperidine (Demerol) and promethazine (Phenergan) into the same tubing. The heart rate is returning to normal at the end of the tracing after appropriate treatment (signified by the notes *Pit off, O₂ 6 L/min, and side*). Notice that fetal heart rate variability was maintained throughout this asphyxial stress, signifying adequate central oxygenation.

- Decrease or cessation in umbilical blood flow, such as occurs with a prolapsed cord or uterine rupture
- Decrease in uterine blood flow, such as occurs with severe maternal hypotension

Tachycardia. Tachycardia is a baseline FHR faster than 160 beats/min. A duration of at least 10 minutes distinguishes it from an acceleration. With tachycardia, loss of FHR variability is common. Although fetal tachycardia is potentially associated with fetal hypoxia, particularly when it is accompanied by decelerations of the FHR, the more common association is with maternal fever or fetal infection (e.g., chorioamnionitis). In most instances, the fetus is not hypoxic but has an elevated baseline FHR.

It is not uncommon for the FHR baseline to rise in the second stage of labor. Certain drugs also cause tachycardia, such as β -mimetic agents used for attempted tocolysis or illicit drugs such as methamphetamine and cocaine.

Tachycardia should not be confused with the uncommon finding of a fetal cardiac tachyarrhythmia, in which the FHR is faster than 240 beats/min. These arrhythmias may be intermittent or persistent, and they are the result of abnormalities of the intrinsic determinants of cardiac rhythm. Findings of supraventricular tachyarrhythmias should be monitored closely and possibly treated with medical therapy or delivery, because they may be associated with deterioration of the fetal status.

Classification and Significance of Baseline Variability

Based on the amplitude range, FHR variability may be described as absent, minimal, moderate, or marked. The moderate (normal) amplitude range is between 6 and 25 beats/min. If the FHR variability is normal, regardless of what other FHR patterns may be present, the fetus is not experiencing cerebral tissue acidemia because the fetus can centralize the available oxygen and is physiologically compensated. However, if excessive hypoxic stress persists, this compensation may break down,

and the fetus may have progressive hypoxia in cerebral and myocardial tissues. In these cases, the FHR variability decreases and eventually is lost.

There are several possible nonhypoxic causes of decreased or absent FHR variability:

1. Absence of the cortex (i.e., anencephaly)
2. Narcotized or drugged higher centers (e.g., morphine, meperidine, diazepam) (Fig. 33-3)
3. Vagal blockade (e.g., atropine, scopolamine)
4. Defective cardiac conduction system (e.g., complete heart block) (Fig. 33-4)

Periodic Changes in Fetal Heart Rate

Late Decelerations. The two varieties of late decelerations are reflex and nonreflex (Fig. 33-5).^{4,69-71} *Reflex late deceleration* sometimes occurs when an acute insult (e.g., reduced uterine blood flow resulting from maternal hypotension) is superimposed on a previously normally oxygenated fetus in the setting of contractions. These late decelerations are caused by a decrease in uterine blood flow (with the uterine contraction) beyond the capacity of the fetus to extract sufficient oxygen. The relatively deoxygenated fetal blood is carried from the placenta through

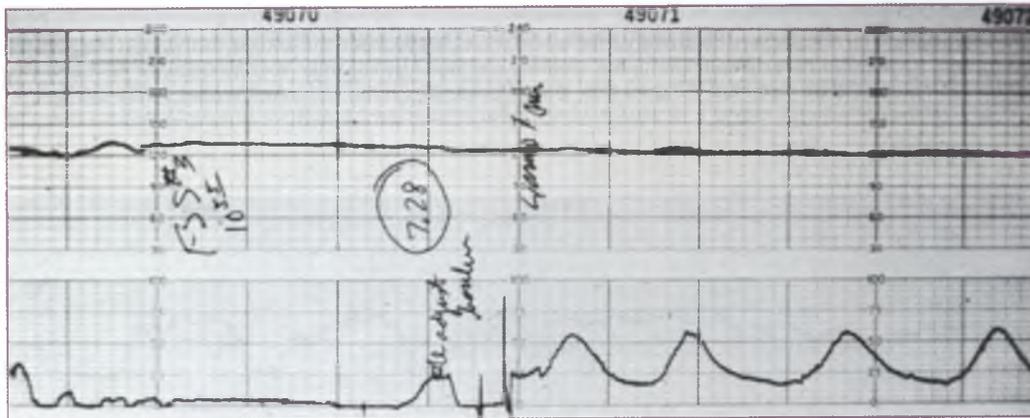

Figure 33-3 No variability of the fetal heart rate. The mother had severe preeclampsia and was receiving magnesium sulfate and narcotics. The normal scalp blood pH (7.28) ensures that the absence of variability is nonasphyxic in origin and that the fetus is not chronically asphyxiated and decompensating. The uterine activity channel has an inaccurate trace in the first half.

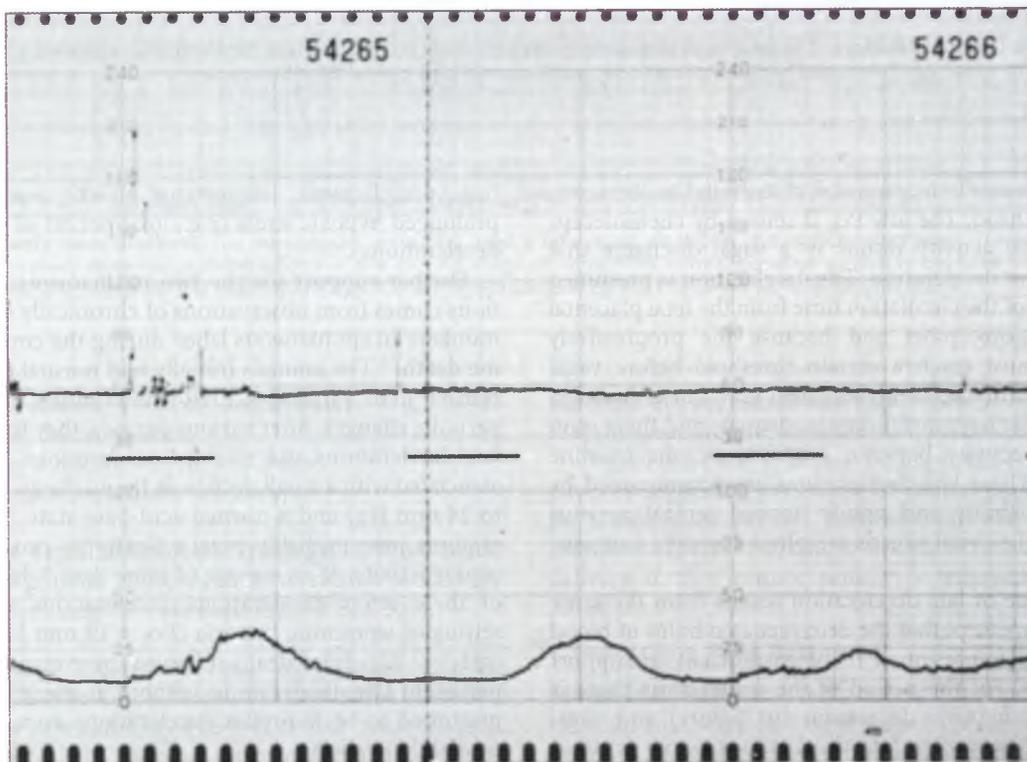

Figure 33-4 Unremitting fetal bradycardia. This tracing does not signify asphyxia, because this fetus had complete heart block, with a ventricular rate of about 55 beats/min. Notice the absence of fetal heart rate variability. There were serious cardiac structural defects, and the fetus died shortly after birth.

Figure 33-5 Late decelerations. The decelerations were recorded by Doppler ultrasound in the antepartum period in a severely growth-restricted (1700-g) term infant born to a 32-year-old preeclamptic primipara. Delivery was done by cesarean section because neither a direct fetal electrocardiogram nor a fetal blood sample could be obtained due to a firm, closed posterior cervix. The infant subsequently did well.

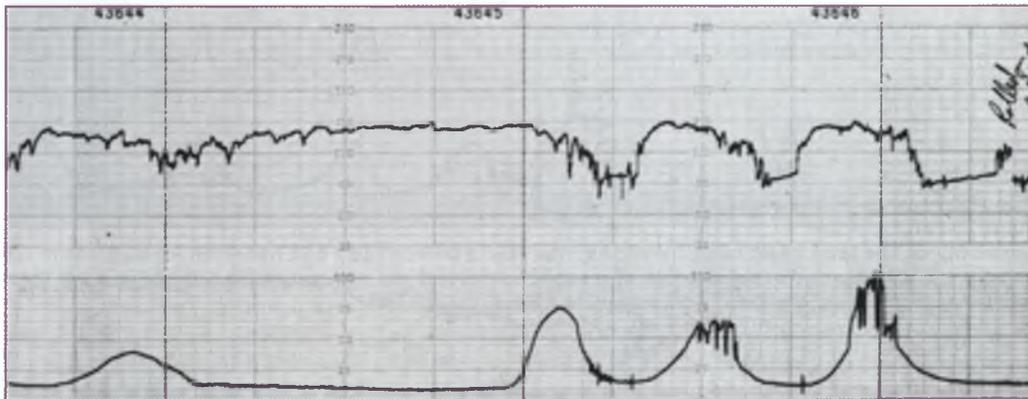

Figure 33-6 Reflex late decelerations. The fetal heart rate pattern was previously normal, but late decelerations appeared after severe maternal hypotension (70/30 mm Hg), which resulted from sympathetic blockade caused by a caudal anesthetic agent.

the umbilical vein to the heart and is distributed to the aorta, neck vessels, and head. The low PO_2 is sensed by chemoreceptors, and neuronal activity results in a vagal discharge that causes the transient deceleration. The deceleration is presumed to be late because of the circulation time from the fetal placental site to the chemoreceptors and because the progressively decreasing PO_2 must reach a certain threshold before vagal activity occurs. Baroreceptor activity also may cause the vagal discharge.⁶⁹ Because oxygen delivery is adequate and there is no additional vagal activity between contractions, the baseline FHR is normal. These late decelerations are accompanied by normal FHR variability and signify normal central nervous system integrity (i.e., vital organs are physiologically compensated) (Fig. 33-6).

The second type of late deceleration results from the same initial mechanism, except that the deoxygenated bolus of blood from the placenta is presumed to be insufficient to support myocardial action. For the period of the contraction, there is direct myocardial hypoxic depression (or failure) and vagal activity.^{69,71} These *nonreflex late decelerations* occur without FHR variability (Fig. 33-7), signifying fetal decompensation (i.e., inadequate cerebral and myocardial oxygenation). They are seen most commonly in states of decreased placental reserve

(e.g., preeclampsia, intrauterine growth restriction) or after prolonged hypoxic stress (e.g., long period of severe reflex late decelerations).

Further support for the two mechanisms of late decelerations comes from observations of chronically catheterized fetal monkeys in spontaneous labor during the course of intrauterine death.⁷² The animals initially had normal blood gas values, normal FHR variability, FHR accelerations, and no persistent periodic changes. After various periods, they first demonstrated late decelerations and retained accelerations. This period was associated with a small decline in PO_2 in the ascending aorta (28 to 24 mm Hg) and a normal acid-base state. These late decelerations were probably vagal reflex types caused by chemoreceptor activity. At an average of more than 3 days after the onset of these reflex decelerations, accelerations were lost in the setting of worsening hypoxia ($PO_2 = 19$ mm Hg) and acidemia (pH = 7.22). Fetal death followed an average of 36 hours of persistent late decelerations without accelerations, which were presumed to be nonreflex decelerations associated with myocardial depression.

Late decelerations should prompt efforts to optimize placental blood flow and maternal oxygenation. The clinician should ensure that maternal blood pressure is normal.

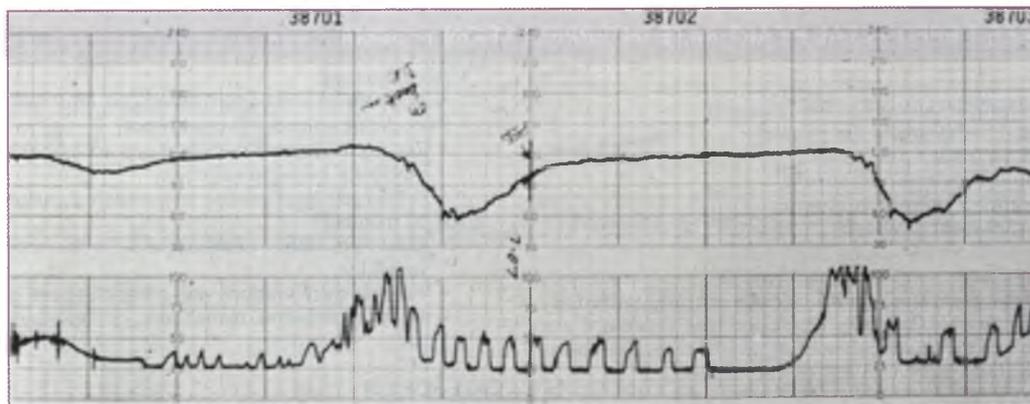

Figure 33-7 Nonreflex late decelerations with virtual absence of fetal heart rate (FHR) variability. The decelerations represent transient asphyxial myocardial failure and intermittent vagal decreases in heart rate. The lack of FHR variability also signifies decreased cerebral oxygenation. Notice the acidemia in fetal scalp blood (pH = 7.07). The infant, a 3340-g girl with Apgar scores of 3 (1 minute) and 4 (5 minutes), was delivered soon after this tracing. Cesarean section was considered to be contraindicated because of a severe preeclamptic coagulopathy.

Figure 33-8 Variable decelerations. The intrapartum recording used a fetal scalp electrode and tocodynamometer. The spikes in the uterine activity channel represent maternal pushing efforts in the second stage of labor. The normal baseline variability between contractions signifies normal central oxygenation despite the intermittent hypoxic stress represented by the moderate variable decelerations.

Variable Decelerations. Variable decelerations (Fig. 33-8) have the following characteristics:

- They vary in duration, depth, and shape.
- Onset and cessation usually are abrupt.

Classification of Fetal Heart Rate Tracings. A three-tiered system for FHR pattern categorization is recommended by ACOG.⁷³ The three categories are described in Box 33-1.

Effect of in Utero Treatment. Fetal oxygenation can be improved, acidemia relieved, and variant FHR patterns abolished by certain modes of treatment. The events that result in fetal stress (recognized by FHR patterns) are provided in Table 33-10 with the recommended treatment maneuvers and presumed mechanisms for improving fetal oxygenation. They should be the primary maneuvers carried out. If the hypoxic event is acute and

the fetus was previously normoxic, there is an excellent chance that the undesired FHR pattern will be abolished.

If the FHR pattern cannot be improved (i.e., nonreassuring patterns suggesting peripheral or central tissue hypoxia persist for a significant period), further diagnostic steps or delivery may be indicated. Certain severe patterns warrant immediate delivery if they cannot rapidly be relieved (Figs. 33-9 and 33-10).

Other Heart Rate Patterns

Sinusoidal Pattern. The sinusoidal pattern has a regular, smooth, sine wave–like baseline with a frequency of approximately 3 to 6 cycles per minute and an amplitude range of up to 30 beats/min that persists for 20 minutes or longer. Another distinguishing feature is the absence of beat-to-beat or short-term variability (Fig. 33-11).

BOX 33-1 THREE-TIERED FETAL HEART RATE INTERPRETATION SYSTEM**CATEGORY I**

Category I FHR tracings include all of the following:

- Baseline rate: 110-160 beats per minute
- Baseline FHR variability: moderate
- Late or variable decelerations: absent
- Early decelerations: present or absent
- Accelerations: present or absent

CATEGORY II

Category II FHR tracings include all FHR tracings not categorized as Category I or Category III. Category II tracings may represent an appreciable fraction of those encountered in clinical care. Examples of Category II FHR tracings include any of the following:

- Baseline rate
 - Bradycardia not accompanied by absent baseline variability
 - Tachycardia
- Baseline FHR variability
 - Minimal baseline variability
 - Absent baseline variability with no recurrent decelerations
 - Marked baseline variability

- Accelerations
 - Absence of induced accelerations after fetal stimulation
- Periodic or episodic decelerations
 - Recurrent variable decelerations accompanied by minimal or moderate baseline variability
 - Prolonged deceleration more than 2 minutes but less than 10 minutes
 - Recurrent late decelerations with moderate baseline variability
 - Variable decelerations with other characteristics, such as slow return to baseline, overshoots, or shoulders

CATEGORY III

Category III FHR tracings include either one of the following:

- Absent baseline FHR variability and any of the following:
 - Recurrent late decelerations
 - Recurrent variable decelerations
 - Bradycardia
- Sinusoidal pattern

FHR, fetal heart rate.

From Macones GA, Hankins GD, Spong CY, et al: *The 2008 National Institute of Child Health and Human Development workshop report on electronic fetal monitoring: update on definitions, interpretation, and research guidelines*, *Obstet Gynecol* 112:661, 2008.

TABLE 33-10 Intrauterine Treatment for Variant Fetal Heart Rate Patterns

Causes	Possible Resulting FHR Patterns	Corrective Maneuver	Mechanism
Hypotension (e.g., supine hypotension, conduction anesthesia)	Bradycardia, late decelerations	Intravenous fluids, position change, ephedrine	Return of uterine blood flow to normal
Excessive uterine activity	Bradycardia, late decelerations	Decrease in oxytocin, lateral position	Return of uterine blood flow to normal
Transient umbilical cord compression	Variable decelerations	Change in maternal position (e.g., left or right lateral, Trendelenburg) Amnioinfusion	Presumably removes fetal part from cord Relieves compression of cord
Head compression	Early or variable decelerations	Push only with alternate contractions	Allows fetal recovery
Decreased uterine blood flow associated with uterine contraction	Late decelerations	Change in maternal position (e.g., left lateral, Trendelenburg) Tocolytic agents (e.g., terbutaline)	Enhanced uterine blood flow toward optimum Decreased contractions or tone
Prolonged asphyxia	Decreasing FHR variability*	Change in maternal position (e.g., left lateral, Trendelenburg), establishment of maternal hyperoxia	Enhanced uterine blood flow toward optimum, increase in maternal-fetal oxygen gradient

*During labor, this usually is preceded by a heart rate pattern signifying asphyxial stress (e.g., late decelerations, usually severe), severe variable decelerations, or a prolonged bradycardia. This is not necessarily so in the antepartum period before the onset of uterine contractions.
FHR, Fetal heart rate.

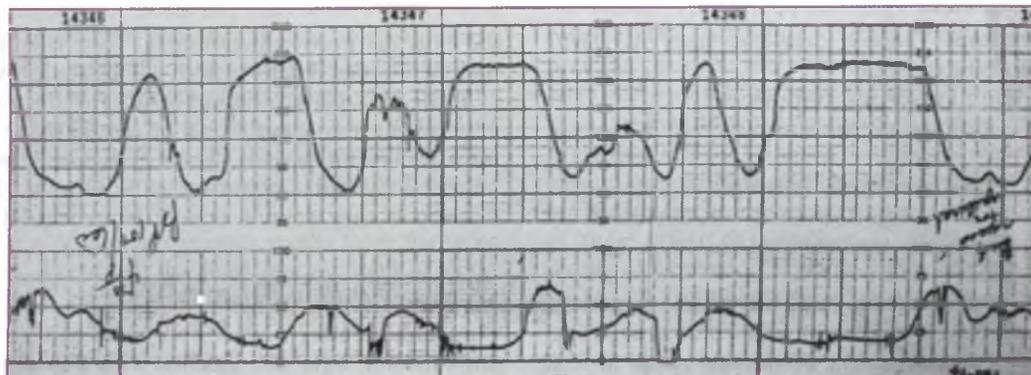

Figure 33-9 Sinister heart rate pattern in a 28-week fetus (gestational age determined after delivery) with baseline tachycardia, absence of heart rate variability, and severe periodic changes. The scalp blood pH was 7.0, and the fetus died shortly after this tracing was made. Cesarean section was not performed because the fetus was thought to be previsible, although it weighed 1100 g. There is much artifact in the uterine activity channel.

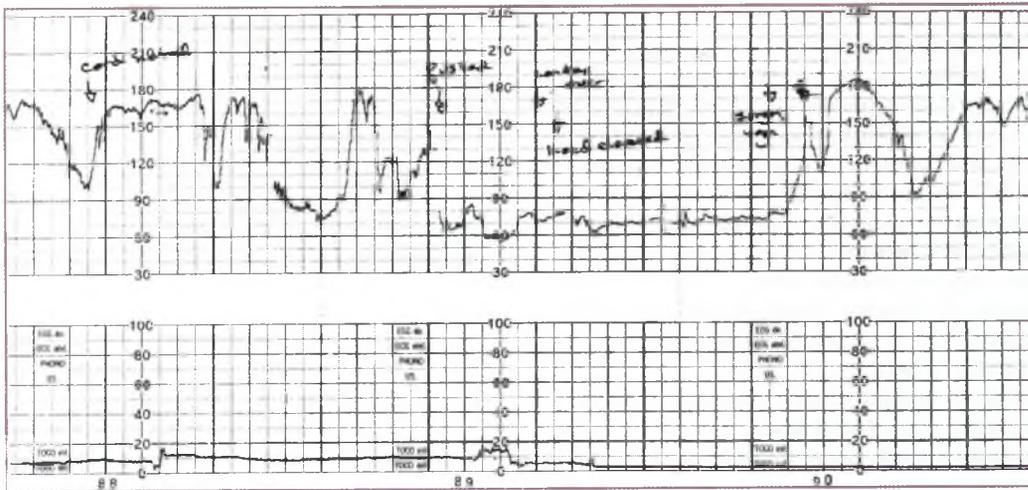

Figure 33-10 Bradycardia resulting from cord prolapse. The infant was delivered by cesarean section and did well.

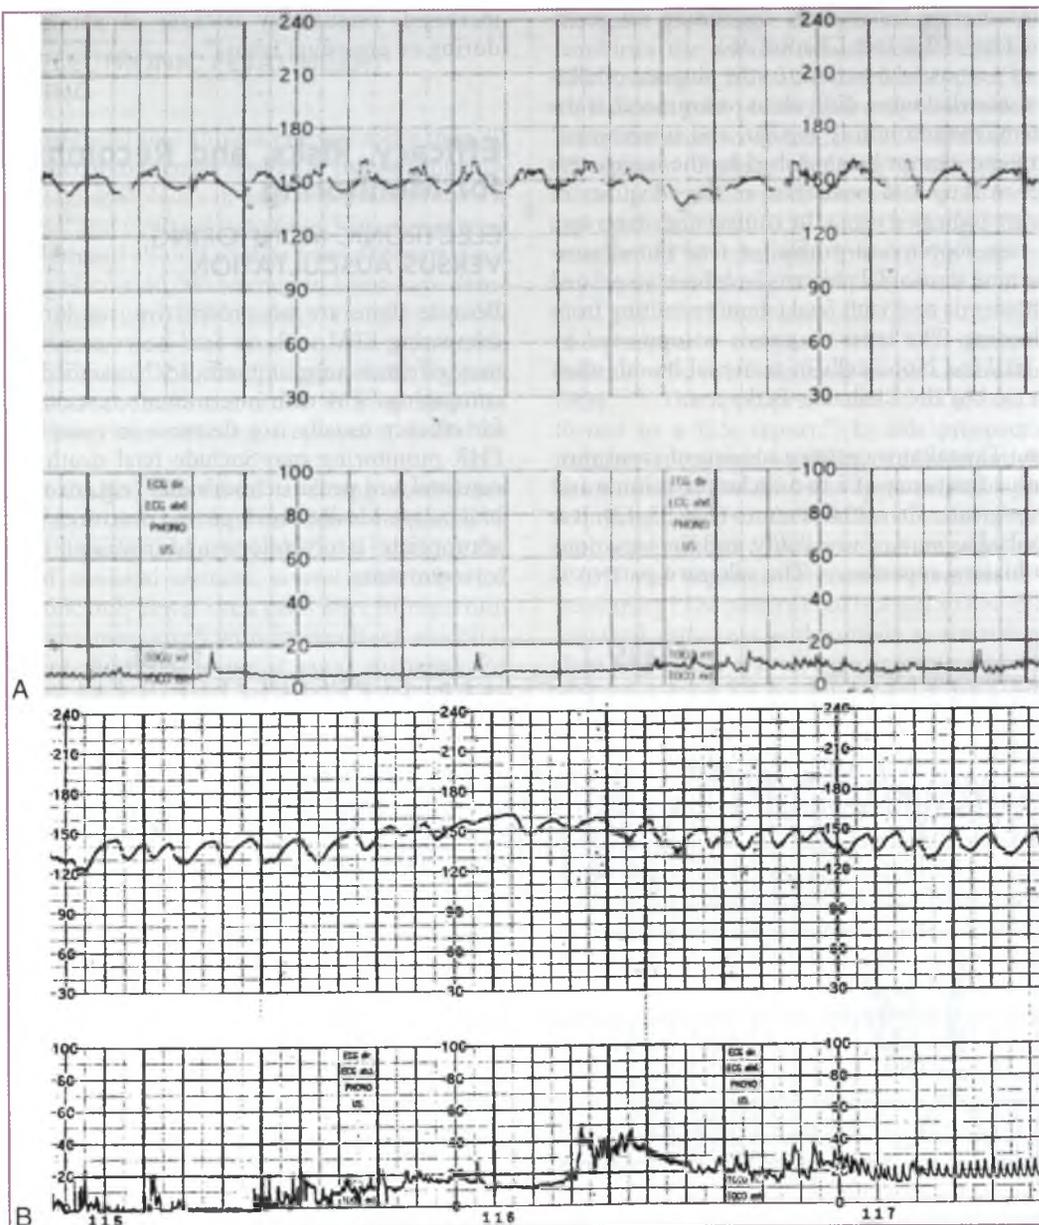

Figure 33-11 Sinusoidal pattern. A and B, Sinusoidal pattern in a term fetus with severe hemolysis caused by Rh disease. The cord hematocrit was 20%, and the infant, delivered by cesarean section, was subsequently normal. Recording was done by direct fetal electrode.

The sinusoidal pattern was first described in a group of severely affected Rh-alloimmunized fetuses but was subsequently identified in fetuses that were severely anemic for other reasons and in severely depressed infants. An essential characteristic of the sinusoidal pattern is extreme regularity and smoothness. Murata and colleagues⁷⁴ implicated elevated levels of arginine vasopressin in producing the sinusoidal pattern. A sinusoidal pattern or variant in an Rh-sensitized patient usually suggests anemia with a fetal hematocrit value of less than 20%.⁷⁵ Hydrops in the fetus suggests a fetal hematocrit of 15% or lower. Many severely anemic, Rh-affected fetuses do not have a sinusoidal pattern but do have a rounded, blunted pattern, and accelerations are usually absent.

Rapid intervention is needed when a sinusoidal pattern is seen in an Rh-sensitized patient and severe hemolysis is confirmed by peak systolic velocity measurement of flow in the middle cerebral artery of the fetus, by cordocentesis, or by the deviation in the amniotic fluid optical density at 450 nm determined by spectrophotometry. Intervention may take the form of delivery or intrauterine transfusion, depending on gestational age and the fetal status (see Chapter 36).

Management of a sinusoidal pattern in the absence of alloimmunization is somewhat more difficult to recommend. If the pattern is persistent, monotonously regular, and unaccompanied by variability and cannot be abolished by the maneuvers described, further workup and evaluation of the adequacy of fetal oxygenation are indicated using the contraction stress test, fetal stimulation test, biophysical profile, or fetal blood sampling. Nonalloimmune sinusoidal patterns have been associated with severe fetal acidemia and with fetal anemia resulting from fetal-maternal bleeding. The latter diagnosis is supported by identification of fetal red blood cells in maternal blood, often subsequently detected by the Kleihauer-Betke test.

Saltatory Pattern. The saltatory pattern consists of rapid variations in FHR with a frequency of 3 to 6 cycles per minute and an amplitude range greater than 25 beats/min (Fig. 33-12). It is qualitatively described as *marked variability*, and the variations have a strikingly bizarre appearance. The saltatory pattern is

seen during labor rather than in the antepartum period. The cause is uncertain, but it may be similar to that of the increased FHR variability seen in animal experiments with brief and acute hypoxia in a previously normoxic fetus. Efforts should be made to optimize placental blood flow and fetal oxygenation if this pattern appears during labor.

CONGENITAL ANOMALIES

Except as described for dysrhythmias, most fetuses with congenital anomalies have essentially normal FHR patterns and respond to hypoxia in a manner similar to the normal fetus. There are several exceptions, including complete heart block and anencephaly. Aneuploid fetuses and fetuses with hypoplastic lungs, meningomyelocele, or hydrocephalus may give no FHR warning of such underlying defects, because they are not necessarily experiencing hypoxia or acidosis. Even though there was no pathognomonic pattern in these fetuses, the rate of cesarean section for fetal intolerance to labor was significantly increased, presumably because of abnormal FHR patterns during or preceding labor.⁷⁶

Efficacy, Risks, and Recommendations for Monitoring

ELECTRONIC MONITORING VERSUS AUSCULTATION

Because there are no prospective, randomized clinical trials comparing EFM with no fetal heart monitoring during labor, most efforts to suggest its efficacy have relied on research reports comparing EFM with intermittent auscultation. The standard for efficacy usually is a decrease in complications, which for FHR monitoring may include fetal death in labor or severe neonatal and pediatric morbidity (e.g., neonatal seizures, cerebral palsy). Ideally, the improved outcomes are accompanied by appropriate interventions and restraint from inappropriate interventions.

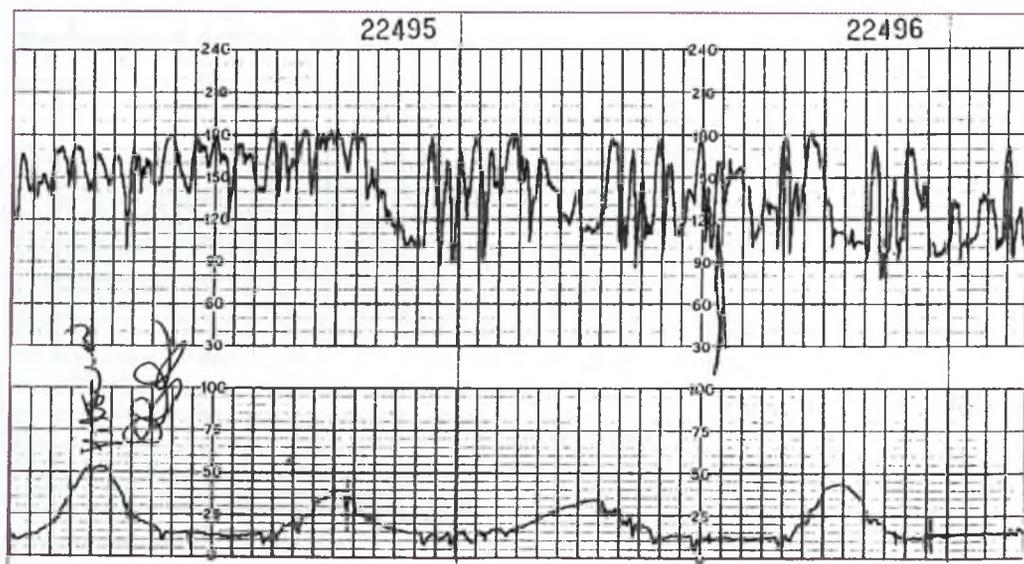

Figure 33-12 Saltatory pattern. The saltatory pattern, which shows excessive fetal heart rate variability of up to 60 beats/min in brief intervals, probably represents mild hypoxic stress.

In a meta-analysis of the nine published clinical studies comparing EFM with intermittent auscultation of the FHR, several conclusions were reached.⁷⁷ In several of these trials, patients with high-risk conditions were not randomized for study inclusion. The use of EFM was associated with significant increases in the rate of cesarean delivery for fetal intolerance to labor, in the overall cesarean delivery rate, and in the use of instrumentation (i.e., vacuum and forceps) for vaginal delivery. However, there was no reduction in overall perinatal mortality for these patients. Because of these findings, either option for monitoring the fetus during labor is acceptable for patients not considered to be at high risk.⁶⁶ The optimal frequency for intermittent auscultation in low-risk patients has not been established, but at a minimum, the FHR should be assessed at least every 30 minutes in the first stage of labor and every 15 minutes in the second stage.⁶⁶ Another method is to auscultate and record the FHR every 15 minutes in the active first stage of labor and every 5 minutes in the second stage, without limiting this approach to low-risk patients.⁷⁸

ADJUNCTS TO ELECTRONIC FETAL HEART RATE MONITORING

When EFM was introduced into clinical practice more than 40 years ago, it was expected to identify fetuses at risk for impending stillbirth or damaging asphyxia in time to prevent problems and improve perinatal and neonatal outcomes. However, several well-designed, randomized clinical studies from different clinical centers involving almost 40,000 women in labor have demonstrated that intrapartum EFM, when compared with intermittent auscultation, does not result in any measurable improvement in outcomes.⁷⁹ This disappointing result suggests that the thinking about the risks associated with intrapartum events and adverse long-term neurologic outcomes should be reevaluated.

These outcome studies did reveal a strong correlation between certain EFM patterns and fetal acidosis as measured by the base deficit and the umbilical artery pH. In considering the specific outcome of neonatal seizures, several trials reported that there were significantly fewer such cases after intrapartum EFM than after labors monitored with intermittent auscultation. This end point, however, is not a good surrogate for long-term neurologic brain damage, because in many of these cases, damage was not evident with repeat examinations as the children grew older.

Because of the work intensity demanded of the nursing staff, the diminishing number of nurses available in hospital labor and delivery units, and the cost of this approach, it is not practical to offer most laboring patients the option of intermittent auscultation. This is particularly true for high-risk patients. As a result, EFM has become the default option for most modern obstetric units. Despite its limitations and disappointments, EFM will likely continue to be used in the management of labor for the foreseeable future.

Because of the significant lack of concordance among observers in the interpretation of monitor data showing anything but a category I pattern, efforts have been made to use EFM by providing appropriate adjuncts. Even so, it continues to have an unacceptably high false-positive rate and occasional false-negative results. Historically, fetal scalp blood sampling was used in an effort to accurately identify the fetus with an acidotic pH. Unfortunately, this cumbersome and technically

challenging procedure was associated with complications, and because it ran into stiff regulatory headwinds, it is no longer an option in most hospitals providing obstetric care. Efforts to obtain a continuous measure of the fetal pH also have been unsuccessful for a number of reasons.

Efforts to directly assess fetal oxygenation (i.e., fetal pulse oximetry) or more closely interpret the fetal ECG (i.e., ST-waveform analysis) have been studied as complementary technologies to improve sensitivity and specificity for the prediction of fetal intrapartum hypoxia or acidosis. Adults experiencing metabolic acidosis, anaerobic metabolism, and hypoxia of the myocardium demonstrate changes in the ECG. There may be depression or elevation of the ST segment and T-wave changes. Increases in the ST segment and T wave of the fetal ECG in response to hypoxia have been demonstrated in fetal animal studies.⁸⁰ The T-wave height compared with QRS height (T/QRS ratio) can be used to express these changes.⁸¹

ST analysis (STAN, Neoventa Medical, Moelndal, Sweden) is a fetal monitoring technology that has been developed to assess the basic physiologic changes associated with hypoxia. STAN combines the routine visual assessment of the intrapartum EFM tracing with an automated analysis of the fetal ECG using a modified, gold-plated fetal scalp electrode. STAN performs a computer analysis of the fetal ECG specific to the detection of ST-segment changes that may predict fetal hypoxia during labor. In a randomized, controlled trial, Swedish investigators reported that fetal ECG analysis using STAN combined with standard EFM techniques lowered the rates of operative delivery for fetal intolerance to labor, severe fetal metabolic acidosis (i.e., pH <7.05 and base deficit >12 mmol/L), and neonatal encephalopathy compared with EFM alone for term laboring patients who were deemed to be candidates for continuous EFM.⁸²⁻⁸⁴ The appropriate use of STAN technology was confirmed in a U.S. report.⁸⁵ In this prospective, uncontrolled, industry-sponsored feasibility study, recently trained clinicians demonstrated the ability to appropriately apply STAN in cases requiring delivery interventions or noninterventions compared with experienced STAN users. A negative predictive value of 95.2% was reported for nonintervention in cases with non-reassuring EFM patterns but normal STAN readings and normal neonatal outcomes with umbilical arterial pH values greater than 7.12. There was an 84% agreement for intervention and a 90% agreement for nonintervention between investigators and three STAN experts when the cases were retrospectively reviewed. These reports are limited to singleton pregnancies in labor at or beyond 36 weeks' gestation.

The STAN system requires a period of time, usually 20 minutes, to assess the fetal ECG and establish the normal and abnormal parameters before it is able to identify significant changes that suggest fetal hypoxia. Other concerns include a 2% to 3% frequency of missing ST data due to poor signal quality or continuous absence of data for unclear reasons. With correct scalp electrode placement and further improvements in processing the ECG signal, it is hoped that these limitations will diminish.

A meta-analysis of five randomized, controlled trials included 15,352 patients randomized to ST-waveform analysis in combination with cardiotocography or to conventional cardiotocography alone for intrapartum fetal monitoring of singleton gestations in cephalic presentation beyond 34 weeks' gestation.⁸⁶ The study authors concluded that the additional use of ST analysis significantly reduced the need for fetal blood

sampling and reduced the incidence of operative vaginal deliveries. However, there was no evidence of a reduced incidence of metabolic acidosis at birth. Because all studies in the meta-analysis were performed in countries where fetal blood sampling is part of the standard obstetric practice, their results may not be applicable to countries such as the United States, where fetal scalp blood sampling rarely occurs.

The National Institutes of Health is funding a randomized, controlled trial of intrapartum ST analysis of the fetal ECG combined with cardiotocography compared with conventional cardiotocography alone (NCT 01131260). Results regarding the efficacy of this combined modality will provide an interesting comparison with those of the European studies reported in

the meta-analysis, all of which used fetal blood sampling in labor.

Assessment and Induction of Fetal Pulmonary Maturity

BRIAN M. MERCER, MD

Respiratory distress syndrome (RDS) results when immature lungs fail to produce adequate surface-acting proteins and phospholipids to reduce alveolar surface tension and prevent alveolar collapse during expiration. Because the work necessary to open a collapsed alveolus is much more than that needed to expand an already open alveolus, the increased work of breathing leads to muscular exhaustion and mechanical respiratory failure. Alveolar collapse, fluid buildup in the immature alveolus, and diminished respiratory gas exchange lead to hypoxia, hypercarbia, and, consequently, acidosis. RDS is the most common major acute morbidity at any gestational age between viability and 36 weeks. Neonatal RDS and complications of its treatment are associated with an increased risk for serious acute and long-term morbidities, including intraventricular hemorrhage (IVH), patent ductus arteriosus, retinopathy of prematurity, and chronic lung diseases, including bronchopulmonary dysplasia. Although the frequency and severity of RDS tend to be worse when delivery occurs remote from term, RDS occurring in the late preterm and early term period can also lead to serious complications or even death.

When preterm delivery is inevitable, treatment is directed to optimizing the timing of delivery, newborn condition, and resources for neonatal care. If continuation of pregnancy is an option, the relative fetal and maternal risks for conservative management versus delivery must be considered. Because cardiopulmonary function is a principal requirement for neonatal survival, identification of fetuses at risk for RDS and methods to induce fetal maturity before preterm birth are important.

Assessment of Fetal Pulmonary Maturity

DIRECT EVALUATION OF AMNIOTIC FLUID

Both invasive and noninvasive tests for prediction of fetal pulmonary maturity have been studied. An optimal test of maturity discriminates between the mature fetus and the fetus likely to suffer RDS. Because central respiratory drive, muscular strength, infection, hypoxia, and hypotension can also alter the clinical course, antenatal pulmonary maturity testing cannot completely differentiate between the mature and the immature fetus. Currently, biochemical and biophysical analyses of the amniotic fluid offer the most accurate means to predict fetal pulmonary maturity. In general, the predictive value of a test indicating maturity is 97% to 100%. The risk for RDS after a test indicating immaturity varies from 5% to almost 100%, depending on gestational age and the degree of immaturity predicted by the test.

Clinical tests to determine fetal pulmonary maturity from amniotic fluid specimens have been available since the early 1970s, when Gluck and coworkers first introduced the lecithin-to-sphingomyelin ratio (L/S ratio).^{1,2} The relative proportions of lecithin (disaturated phosphatidylcholine) and sphingomyelin are stable until the middle of the third trimester, at which time the pulmonary active phospholipid, lecithin, increases relative to the nonpulmonary sphingomyelin. An L/S ratio of at least 2:1 is considered indicative of fetal maturity.

However, the L/S ratio is neither 100% sensitive nor specific. Phosphatidylglycerol (PG) is one of the last pulmonary phospholipids to become evident in the amniotic fluid, and its detection is highly predictive of fetal pulmonary maturity.^{3,4} However, when the test is performed before 36 weeks' gestation, it carries a high false immaturity rate. Each of these traditional tests requires considerable time, technical expertise, and cost to perform. Therefore, the L/S ratio determination and the PG assay are used as secondary tests, should simpler and less expensive automated testing indicate immaturity, or as primary tests in special clinical circumstances. The slide agglutination test for PG can provide more rapid results and requires less technical expertise than traditional thin-layer chromatography.⁵⁻⁷

The TDx FLM assay (Abbott Laboratories, Abbott Park, Ill) evaluates the surfactant-to-albumin (S/A) ratio through evaluation of competitive binding to surfactant and albumin by a ligand that exhibits fluorescence polarization.^{8,9} Although simple to perform, accurate, reproducible, and widely accepted in practice, the TDx FLM assay and its subsequent modification (the TDx FLM II assay) have been removed from the U.S. market by the company because of a change in its analysis platform.

Lamellar bodies are surfactant-containing particles secreted by type II pneumocytes; they are 1 to 5 μm in diameter (1.28 to 6.4 fL).^{10,11} The number of lamellar bodies found in the amniotic fluid increases with the onset of functional fetal pulmonary maturity. The lamellar body count (LBC) is simple to perform, and the laboratory equipment required is available in virtually all hospital clinical laboratories. Because lamellar bodies are similar in size to platelets (2 to 20 fL), their number can be estimated using an automated particle counter calibrated for platelet quantitation. In a study of 833 women who delivered within 72 hours of testing, the LBC compared favorably with the L/S ratio and the PG test in predicting fetal pulmonary maturity, with predictive values of 97.7%, 96.8%, and 94.7%, respectively.¹² In an attempt to introduce standardization in LBC testing, Neerhof and associates formed a consensus group that reached agreement on the following points¹³:

1. Centrifugation is not required to remove cellular debris in the amniotic fluid and should be abandoned.

2. In the absence of centrifugation, a count greater than or equal to 50,000/ μL should be considered to indicate maturity, and a count less than or equal to 15,000/ μL should be considered to indicate immaturity. A transitional count of 15,000 to 50,000/ μL should lead to consideration of an additional test to clarify the result.
3. Because meconium can interfere with the cell counter and can reduce the count, either the LBC should not be performed in the presence of meconium, or clinical judgment should be exercised in interpretation of the results.
4. If there is blood contamination, a hematocrit level should be obtained, and the clinician should be notified if the value is greater than 1%.
5. Although vaginal pool specimens may be acceptable, such specimens should not be analyzed if there is evident mucus, because it can obstruct the counter channels.
6. Severe oligohydramnios can increase the LBC, and polyhydramnios can lead to a false determination of immaturity.

Should centrifugation be performed, a cutoff of 30,000/ μL has been suggested for prediction of fetal pulmonary maturity.^{14,15}

A number of other biochemical analyses have been studied for their predictive value for fetal pulmonary maturity. However, each has either failed to be incorporated into clinical practice or has fallen from usage. Amniotic fluid prolactin, cholesterol palmitate, desmosine, surfactant apoproteins, fluorescent polarization microviscosity, and drop volume have all been related to fetal pulmonary maturity but are uncommonly assessed in clinical practice. Because the relative proportions of the fetal pulmonary phospholipids change with increasing gestational age, the fetal "lung profile," introduced by Kulovich and colleagues in 1979, incorporated relative changes in pulmonary phospholipids with increasing fetal maturation; this profile included the relative fractions of lecithin, PG, and phosphatidylinositol (PI), which typically rises until 35 weeks' gestation and then declines with the appearance of PG in the amniotic fluid.¹⁶ Because this test required two-dimensional thin-layer chromatography, it was impractical in many clinical laboratories and is not used. Indirect markers of fetal pulmonary maturity include amniotic fluid density based on spectrophotometric absorbance at 650 nm, amniotic fluid turbidity, and evaluation for the presence of vernix caseosa in the amniotic fluid. Although each of these measurements is correlated to fetal pulmonary maturity, they are not adequately accurate to supplant biochemical testing.

Functional tests of fetal pulmonary maturity evaluate the ability of an amniotic fluid sample to maintain a stable ring of foam bubbles when diluted and mixed with various reagents, thus demonstrating functional maturity.¹⁷⁻²⁰ Of four tests developed in the 1970s and 1980s—the shake test, the foam stability index (FSI), the automated Lumadex-FSI (Beckman Instruments, Carlsbad, Calif), and the tap test—each was highly predictive of the presence of fetal pulmonary maturity, but false results showing immaturity were common. Like the PG assay and the L/S ratio, functional tests and assessment of indirect amniotic fluid markers have largely been replaced by simpler automated tests. Pragmatically, the PG test, the LBC, and the L/S ratio are currently the most commonly available tests in the United States for assessment of fetal pulmonary maturity from amniotic fluid specimens.

Noninvasive Assessment of Fetal Pulmonary Maturity

Amniocentesis is not without risk, even when it is performed near term. Before ultrasound was used routinely to guide amniocentesis, invasive testing was associated with high rates of complications (19%), including tachycardia and bradycardia (1%), spontaneous membrane rupture (3%), bloody specimens (15%), and failure to obtain fluid (11%).²¹ Although ultrasound guidance is associated with a much lower failure rate (1.6%), there remains a low but significant risk for complications even in experienced hands, including a 0.7% risk for emergent delivery and a 6.6% risk for bloody fluid.²² Because of these concerns, noninvasive markers, including direct and ultrasonographic amniotic fluid visualization, placental grading, fetal biometry, and fetal lung imaging, have been studied for their value in predicting fetal pulmonary maturity.

At term, free-floating particles visualized on ultrasound correlate to the presence of fetal vernix,²³ but such particles may be seen at any gestational age²⁴ and do not correlate well with biochemical fetal pulmonary maturity test results.²⁵ Although a grade III placenta at term has been correlated with a mature L/S ratio, placental grade before preterm birth correlates less well with the L/S ratio (7% immature) and the PG test (25% absent), limiting the usefulness of this finding.²⁶ When assessed at term, a biparietal diameter of at least 92 mm or the presence of a grade III placenta has been found to correlate with the absence of neonatal pulmonary complications,^{27,28} but the correlation with biochemical testing at term and the relationship with pulmonary complications for those delivering preterm are inconsistent.^{29,30} These restrictions severely limit the potential usefulness of biometric and placental grade evaluations for assessment of fetal pulmonary maturity, particularly for women with unsure dating and those who are anticipating preterm delivery.

Noninvasive imaging of the fetal lung has been proposed to predict fetal pulmonary maturity. In evaluations of lung echogenicity, texture, and through-transmission, Cayea and colleagues³¹ and Fried and associates³² found a poor correlation between ultrasound findings and mature amniotic fluid indices. Lecithin has a characteristic magnetic resonance signal that may be amenable to assessment by magnetic resonance spectroscopy or by echoplanar magnetic resonance imaging.^{33,34} Although the preliminary data are interesting, technical difficulties in these modalities remain to be resolved, and the cost related to such testing is likely to be prohibitive.

Impact of Gestational Age on Fetal Pulmonary Maturity Testing

Because fetal pulmonary maturity is highly correlated with gestational age, the predictive value of a testing result varies significantly with the gestational age at which it is performed.³⁵ At term, the risk for RDS resulting from pulmonary immaturity is 1% or less. Although a test result indicating immaturity at term is associated with RDS, the risk is low, and severe disease is unlikely. On the other hand, in a preterm infant delivered remote from term, an amniotic fluid test suggesting fetal pulmonary immaturity carries a high risk for RDS, and severe disease is more prevalent.

Both at and near term, the likelihood of RDS is low after a test result indicating pulmonary maturity. However, significant risks for RDS (19.2%), severe IVH (8.1%), and necrotizing enterocolitis (4.8%) have been found to exist despite a mature

L/S ratio or a positive PG test when preterm birth occurs before 34 weeks.³⁶ Lauria and associates found a similar progressive increase in infant morbidities with decreasing gestational age at delivery, despite the presence of a mature L/S ratio or a positive PG test; they also found a low risk for RDS (8.3%) after an immature result at term.³⁷

Assessment of Fetal Pulmonary Maturity in Special Groups

Several investigators have found a lower incidence of RDS among African-American infants at any cutoff value for the TDx FLM assay.^{38,39} Similarly, female fetuses appear to have higher L/S ratios at any given gestational age and earlier appearance of PG than males.⁴⁰ When matched for gestational age at delivery, twins and singletons have similar rates of morbidities,^{41,42} but twin fetuses may have accelerated TDx FLM results after 31 weeks.⁴³ It remains controversial whether there is an altered risk for RDS in pregnancies affected by Rh isoimmunization, growth restriction, or preeclampsia, compared with gestational age-matched controls.⁴⁴⁻⁴⁸ Regardless of potential differences in the rate of fetal pulmonary maturation or the predictive value of testing in any of these settings, the differences that have been observed do not adequately allow differentiation between those who will and those who will not suffer pulmonary complications, and recommendations for testing and cutoff values for fetal maturity are not altered on the basis of these characteristics.

Diabetes complicating pregnancy can alter the rate of fetal lung development and has been proposed to alter the validity of diagnostic tests for fetal pulmonary maturity. Delayed pulmonary maturity in fetuses of women with class A, B, and C diabetes mellitus (White classification; see Chapter 59), despite a mature L/S ratio of 2:1, has been reported.⁴⁹⁻⁵¹ Alternatively, women with more advanced diabetes (White class D, R, or F) may demonstrate accelerated fetal maturation,⁴⁹ possibly related to uteroplacental dysfunction leading to fetal growth restriction. A case-control study of 295 subjects found the L/S ratio to be comparable between diabetic and nondiabetic women with increasing gestational age, whereas PI levels were significantly higher in women with pregestational diabetes at 33 to 35 weeks' gestation, and the onset of PG production was delayed by 1 to 1½ weeks in the diabetic pregnancies.⁵² The increased risk for RDS despite a mature L/S ratio and the delayed appearance of PG could result in part from increased levels of myoinositol with hyperglycemia,⁵³ because myoinositol enhances PI production to the detriment of PG synthesis.⁵⁴ Maternal blood glucose control appears to be the major factor that influences fetal pulmonary maturation in diabetic pregnancies, because those with good control do not have delayed maturation.^{55,56} PG appears later in poorly controlled diabetic pregnancies.^{57,58}

Some have suggested that an L/S ratio cutoff value of 3:1 should be used in pregnancies complicated by diabetes. Alternatively, the presence of PG is reliable in prediction of fetal pulmonary maturity,⁵⁹ and an S/A ratio of 70 mg/g or greater is a reliable predictor of pulmonary maturity, as is a mature LBC in this setting.^{12,60} Because the potential impact of delayed fetal pulmonary maturation with diabetes is resolved by 38 completed weeks' gestation, well-dated pregnancies with good blood glucose control generally do not require assessment of fetal pulmonary maturity after this gestational age.⁶¹ When a term infant of a diabetic mother has RDS, other possible causes, such

as hypertrophic cardiomyopathy, cardiac malformations, and isolated ventricular septal hypertrophy, should be considered.

Impact of Contaminants on Fetal Pulmonary Testing Results

Because of the presence of nonpulmonary phospholipids, contamination of amniotic fluid with blood can alter the results of nonspecific fetal pulmonary maturity tests for pulmonary phospholipids (Table 34-1). Maternal serum has been shown to have an intrinsic L/S ratio of between 1.3:1 and 1.9:1, raising the possibility that blood contamination could falsely lower a result that should show maturity.^{62,63} On the other hand, a mature result can be considered reassuring, because blood contamination could not be expected to increase an immature value to the level of a mature result. In one study, meconium contamination increased the L/S ratio by 0.1 to 0.2 in preterm infants and by as much as 0.5 after 35 weeks' gestation,⁶⁴ leading the authors to recommend cutoffs of 2.2:1 and 2.5:1 for preterm and term pregnancies, respectively, when meconium staining is present.

The PG test is not affected by blood or meconium contamination. Blood contamination can falsely lower the TDx FLM II assay result, but a mature result reliably predicts fetal pulmonary maturity.⁶⁵ Because red blood cell phospholipids may interfere with the TDx FLM result, some elect not to perform the TDx FLM II assay if there is blood in the specimen.⁶⁶ Dubin suggested that the LBC is not affected by osmotically lysed blood.¹⁰ Others, however, have suggested that blood contamination may alter the LBC in a biphasic manner, initially increasing the count as a result of the presence of platelets, and subsequently decreasing the count as a result of sequestration of lamellar bodies with coagulation.⁶⁷ Because of this, the LBC should be treated with caution if there is greater than 1% contamination with blood.

Assessment of Fetal Pulmonary Maturity from Vaginal Fluid Specimens

Clinical studies support a role for vaginally collected amniotic fluid specimens after preterm premature rupture of the membranes (pPROM). Shaver and coworkers obtained amniotic fluid by amniocentesis and from the vaginal pool of women admitted with pPROM.⁶⁸ There was a close correlation between L/S ratios obtained from vaginal pool specimens and those obtained from amniocentesis ($r = .88$), and there was an 89% concordance with fetal pulmonary maturity. The mean L/S ratio from vaginal pool specimens was not significantly higher than that from amniocentesis (2.6 versus 2.3:1; $P = .06$). Similarly, the correlation coefficient for PG was 0.94, and all patients with a positive amniocentesis result also had PG present in the vaginal pool. Other studies have found no evident lecithin or sphingomyelin in lavage fluid from the vagina in the absence of membrane rupture⁶⁹ and no differences in the L/S ratio between vaginal and amniocentesis specimens.⁷⁰ The LBC can be falsely elevated by vaginal mucus, which can also block Coulter analyzer channels.⁶⁷

Although bacterial degradation or phospholipid production has been suggested to yield inaccurate results after prolonged exposure to amniotic or vaginal fluids, the L/S ratio, PG levels, and PI levels are similar whether fluid was collected directly from the vagina or collected over a period of hours from perineal pads,⁷¹ and RDS did not occur in infants delivered after a mature PG result from vaginal pool fluid in one study.⁷² In

TABLE 34-1 Selected Antenatal Tests for Assessment of Fetal Pulmonary Maturity: Technique, Predictive Values, and Predicted Reliability Based on Contamination and Source

Test	Selected References	Technique	Cutoff	Impact of Contamination		Vaginal Pool Collection	Comments
				Blood	Meconium

[‡]Vaginal fluid may be valid if no blood, meconium, or mucus is present.

FLM, fetal lung maturity; Hct, hematocrit.

another study of 447 women with PROM, PG determinations from vaginal fluid collected via perineal pads were highly predictive of fetal pulmonary maturity (97.8%), and they were similarly predictive of pulmonary immaturity when compared with specimens collected by amniocentesis (33.7%).⁷³ In a study of 60 vaginally collected samples, no cases of RDS occurred after a mature L/S ratio, a mature PG level, or a TDx FLM result greater than 50 mg/g was found.⁸ Regarding vaginally collected fluid for TDx FLM II analysis, a mature S/A ratio (≥ 55 mg/g) had a predictive value of 97.6% in a study of 153 women with pPROM at 30 to 36 weeks, and 24.4% of infants with an immature result (<40 mg/g) suffered RDS.⁷⁴

Because vaginally collected amniotic fluid samples yield results similar to those of amniocentesis specimens, it is reasonable to evaluate free-flowing vaginal fluid samples by L/S ratio, S/A ratio, PG determination, or the LBC provided there is no evident blood, meconium, or mucus in the sample. Perineal collection appears appropriate for L/S ratio and PG determinations, but it is not known whether perineal pad collection is appropriate for TDx FLM II analysis or LBC. Blood and meconium have the potential to alter testing results, as delineated in

the foregoing discussion. Practically, if significant blood or meconium is present in a vaginal pool specimen, consideration should be given to expeditious delivery for fetal indication, rather than conservative management.

Induction of Fetal Pulmonary Maturity

The mainstay of efforts directed toward acceleration of fetal maturation is maternal administration of antenatal corticosteroids before preterm birth. Glucocorticoids act through reversible binding to the promoter region of genes that code for functional and structural proteins in various organs.⁷⁵ In the lung, glucocorticoids induce lipogenic enzymes necessary for surfactant phospholipid synthesis and conversion of unsaturated to disaturated phosphatidylcholine, stimulate production of antioxidants and surfactant proteins (SP-A through SP-D), and induce enzymes responsible for sodium and potassium channel ion and fluid flux.⁷⁶ The physiologic effects of glucocorticoids on the lung include increased compliance and maximal lung volume, decreased vascular permeability, enhanced lung water clearance, parenchymal structural

maturation, and improved respiratory function, in addition to an enhanced response to postnatal surfactant treatment. In addition, glucocorticoids have demonstrated maturational effects in the brain, heart, skin, digestive system, and kidney through cyto-differentiation, enzyme induction, and protein synthesis.

Betamethasone and dexamethasone are long-acting synthetic corticosteroids with similar glucocorticoid potency and negligible mineralocorticoid effects. Because of differences in albumin binding, placental transfer, and glucocorticoid receptor affinity, substantially higher dosages of cortisol, cortisone, hydrocortisone, prednisone, and prednisolone are required to reach dosage equivalency to betamethasone and dexamethasone in the fetus. Women receiving corticosteroids other than betamethasone or dexamethasone should not be considered to have received an adequate dosage to stimulate fetal pulmonary maturation.

Prolactin, ambroxol, aminophylline, Intralipid, and β -adrenergic agents, among others, have also been evaluated as potential treatments to enhance fetal pulmonary maturation, but they have not been consistently effective. Thyroxine has been shown to act directly on the type II pneumocyte to induce surfactant synthesis in animal and human models; however, because thyroxine crosses the placenta poorly, intra-amniotic thyroxine instillation with fetal ingestion would be necessary to achieve therapeutic fetal levels. Thyrotropin-releasing hormone administered to the mother can cross the placenta to induce fetal thyroxine synthesis via production of thyroid-stimulating

hormone. Despite early encouraging results, a meta-analysis of this approach failed to demonstrate benefit of concurrent antenatal maternal thyrotropin-releasing hormone and corticosteroid administration.⁷⁶ In one study, adverse neurologic outcomes—including delayed motor and sensory development as well as social delay—were seen with thyrotropin-releasing hormone exposure.⁷⁷

ANTENATAL CORTICOSTEROIDS

Neonatal Outcomes

First demonstrated to reduce RDS and neonatal death by Liggins and Howie in 1972, antenatal corticosteroid administration is one of the most effective and cost-efficient prenatal interventions for preventing perinatal morbidity and mortality related to preterm birth.⁷⁸ A meta-analysis of 21 randomized clinical trials, including 4269 infants, confirmed that antenatal corticosteroids administered to women at risk for preterm birth significantly reduced the incidences of RDS (relative risk [RR], 0.66), IVH (RR, 0.54), necrotizing enterocolitis (RR, 0.46) and neonatal death (RR, 0.69), without increasing maternal or neonatal infection (Fig. 34-1).⁷⁹ Antenatal corticosteroid administration is effective regardless of infant sex or race.⁸⁰ The beneficial impact of antenatal corticosteroids on perinatal outcomes is similar when pPROM occurs before the onset of treatment (Fig. 34-2).⁷⁹ Although Liggins and Howie's original trial suggested that corticosteroids might increase the risk for fetal death in the setting of maternal hypertension, this was not

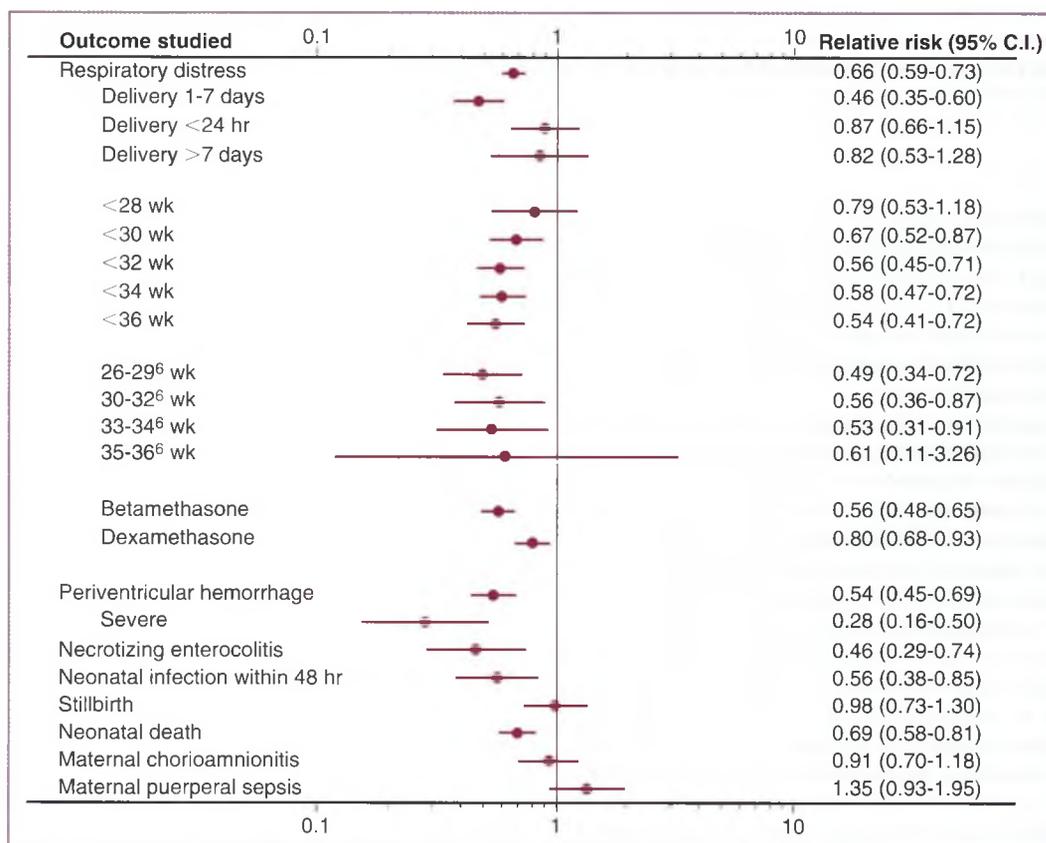

Figure 34-1 Impact of antenatal corticosteroids before anticipated preterm birth on perinatal outcomes. C.I., confidence interval. (Data from Roberts D, Dalziel S: Antenatal corticosteroids for accelerating fetal lung maturation for women at risk of preterm birth, Cochrane Database Syst Rev [3]:CD004454, 2006.)

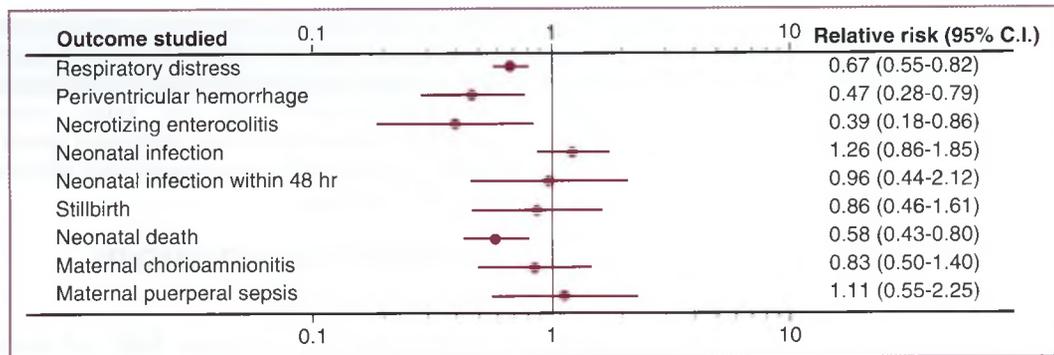

Figure 34-2 Impact of antenatal corticosteroids before anticipated preterm birth on perinatal outcomes when premature rupture of the membranes occurred before initiation of treatment. Figure 34-3 Impact of antenatal betamethasone and dexamethasone before anticipated preterm birth on perinatal outcomes. C.I., confidence interval. (Data from Roberts D, Dalziel S: Antenatal corticosteroids for accelerating fetal lung maturation for women at risk of preterm birth, *Cochrane Database Syst Rev* [3]:CD004454, 2006.)

confirmed in subsequent studies.⁸¹⁻⁸³ It is generally believed that optimal corticosteroid effects are achieved when delivery occurs 24 hours or longer after initiation of therapy, but significant reductions in the rates of IVH (odds ratio [OR], 0.42), neonatal death (OR, 0.31), and need for vasopressors (OR, 0.35) have been observed when delivery occurs before the second dose of betamethasone is administered.⁸⁴

It has been suggested that the immunosuppressive effects of corticosteroids could predispose to maternal or neonatal infection. In a retrospective evaluation of 1260 infants weighing less than 1750 g at birth, administration of antenatal corticosteroids was found to reduce the incidence of RDS, IVH, periventricular leukomalacia, and neonatal death without increasing neonatal sepsis when delivery occurred in the presence of histologic chorioamnionitis.⁸⁵ A retrospective evaluation of 457 pregnancies delivering at 23 to 32 weeks' gestation found no increases in neonatal morbidities after corticosteroid exposure when intrauterine infection or inflammation was evident, and fetal systemic inflammatory response syndrome was less common in this setting if the fetus was exposed to corticosteroid treatment before birth.⁸⁶

Although several studies have suggested that betamethasone might be more protective against periventricular leukomalacia than dexamethasone, review of published trials reveals no apparent difference in efficacy with either agent in terms of

prevention of RDS, IVH, or neonatal death (Fig. 34-3).^{79,87-89} In 2007, a randomized controlled trial that directly compared betamethasone and dexamethasone in 299 pregnancies found similar neonatal outcomes between the two treatments, with the exception of IVH, which was more common after betamethasone (17.0% versus 5.7%; $P = .02$).⁹⁰ Further study to clarify the relative benefits and risks of these two agents is needed. Despite a pharmacokinetic profile similar to that of intramuscular injection, oral administration of dexamethasone is not recommended because it has been associated with an increased risk for neonatal IVH and sepsis when compared with intramuscular injection.^{91,92} Because placental transfer of betamethasone and dexamethasone is rapid, there is no rationale for direct fetal administration.

The potential benefit of antenatal corticosteroids varies according to the a priori risk for fetal morbidity (Fig. 34-4).⁹³ A meta-analysis that evaluated the benefits of antenatal corticosteroids across the spectrum of gestational age found evident benefit with corticosteroid administration up to 34 weeks and 6 days of gestation (see Fig. 34-1).⁷⁹ Although significant benefit was not demonstrated at 35 to 36 weeks' gestation, the relative risk for RDS after antenatal corticosteroid exposure (0.66) was similar to that at earlier gestations. The Collaborative Group on Antenatal Steroid Therapy permitted enrollment of women beyond 34 weeks if an L/S ratio yielded an immature result and

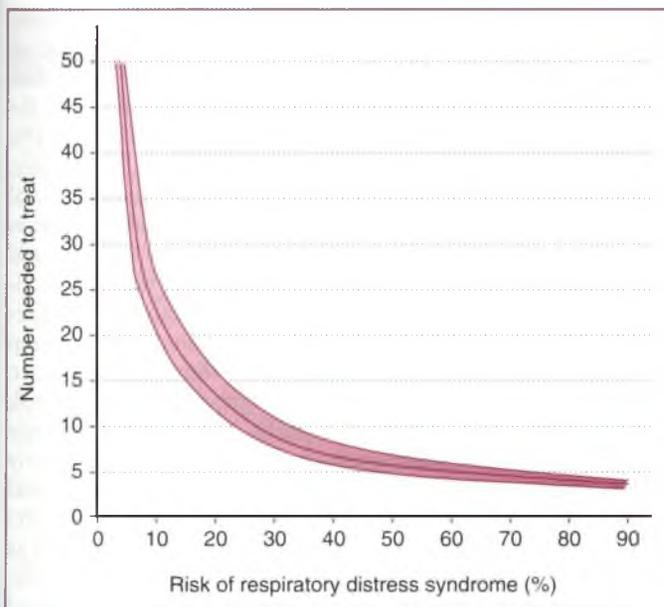

Figure 34-4 Number of women who must be treated with antenatal corticosteroids to prevent one case of neonatal respiratory distress syndrome based on the a priori risk for respiratory distress. Shaded zone shows 95% confidence limits. (From Sinclair JC: Meta-analysis of randomized controlled trials of antenatal corticosteroid for the prevention of respiratory distress syndrome: discussion, *Am J Obstet Gynecol* 173:335, 1995.)

excluded those with a mature result at any gestational age.⁸² Infants born after an immature L/S ratio had a significant reduction in RDS with antenatal dexamethasone exposure (8.7% versus 17.3%; $P = .03$). Amniotic fluid testing for fetal pulmonary maturity differentiates women with fetuses at higher risk for RDS from those who will not benefit from antenatal corticosteroids. Antenatal corticosteroid administration may therefore be considered when an immature fetal pulmonary maturity result is identified between 34 and 36 completed weeks of gestation. The value of antenatal corticosteroid treatment for women anticipated to deliver at 34 to 36 weeks' gestation remains to be determined. In 2010, Shanks and coworkers demonstrated antenatal corticosteroid administration at 34 to 36 weeks' gestation to increase the TDx FLM II by 28.4 mg/g (versus 9.8 mg/g with no treatment, $P < .002$).⁹⁴ On the other hand, Porto and colleagues found no reduction in the diagnosis of respiratory morbidities with antenatal corticosteroid administration at 34 to 36 weeks' gestation in a randomized clinical trial of 320 gravidas.⁹⁵ This issue is the subject of an ongoing randomized placebo-controlled trial by the Eunice Kennedy Shriver National Institute of Child Health and Human Development Maternal-Fetal Medicine Units (NICHD-MFMU) network.

Other Fetal and Neonatal Effects

A number of investigators have evaluated the impact of antenatal corticosteroid exposure on fetal biophysical and heart rate activity. These studies have found that betamethasone and dexamethasone reduce fetal breathing and body movements, with inconsistent findings regarding elevation of the baseline fetal heart rate.⁹⁶⁻¹⁰² Although it is unclear whether antenatal corticosteroids reduce the frequency of nonreactive fetal heart rate patterns, a decrease in the frequency of accelerations after

corticosteroid administration has been reported.¹⁰⁰⁻¹⁰² Overall, the fetal biophysical effects of betamethasone appear to be more pronounced than those of dexamethasone and resolve within 3 to 7 days after administration.^{97,99-102}

The neonatal white blood cell count is generally not affected by maternal glucocorticoid administration.¹⁰³ Sporadic case reports of neonatal Cushing syndrome and adrenal dysfunction have been reported with prolonged antenatal exposure to steroids.^{104,105} However, Terrone and coworkers found no significant decrease in cortisol levels with increasing antenatal corticosteroid exposure after controlling for other variables,¹⁰⁶ and several studies have found normal neonatal responsiveness to adrenocorticotropic hormone stimulation after exposure to antenatal corticosteroids.¹⁰⁷⁻¹⁰⁹ Isolated cases of neonatal hypertrophic cardiomyopathy, a known complication in infants of diabetic mothers and with postnatal corticosteroid exposure, have also been reported after antenatal corticosteroid exposure in the absence of significant maternal glucose intolerance.¹¹⁰ A direct cause-effect relationship and the biologic mechanism of this finding remain to be elucidated.

Maternal Consequences

Antenatal corticosteroid administration has been associated with a transient increase in maternal white blood cell count that becomes evident within 24 hours.¹¹¹ The maternal leukocyte count increases by 4.4×10^3 cells/mL, on average, but it is not expected to rise above $20,000 \times 10^3$ cells/mL. Glucose intolerance can occur, with transient maternal hyperglycemia in nondiabetic women and increasing insulin requirements in diabetic women.^{112,113} Assessment for gestational diabetes is best delayed at least 1 week after corticosteroid administration. Mathiesen and colleagues found that daily insulin requirements increased by 6%, 38%, 36%, 27%, and 17%, respectively, on days 1 through 5 after corticosteroid administration and suggested an algorithm of increasing insulin dosages on those days by 25%, 40%, 40%, 20%, and 10% to 20%, respectively, to compensate for this need.¹¹⁴ In Liggins and Howie's original trial, betamethasone transiently reduced plasma cortisol; levels returned to normal by the 4th day after administration.⁷⁸ In addition to a reduction in basal maternal cortisol (1.9 versus 26.5 $\mu\text{g/mL}$; $P < .001$), McKenna and colleagues demonstrated a decreased maternal response to corticotropin stimulation with antenatal corticosteroids.¹¹⁵ Although betamethasone and dexamethasone have virtually no mineralocorticoid effects, it has been suggested that antenatal corticosteroid administration could predispose pregnant women to pulmonary edema. This issue is confounded by concurrent administration of fluid boluses, administration of tocolytics, and coexisting infection as a cause of preterm labor among women receiving antenatal corticosteroids, all of which can lead to pulmonary edema. Current data do not support an independent role for antenatal treatment with either betamethasone or dexamethasone in the pathogenesis of maternal pulmonary edema.

Repeated Courses

Published research in animals revealed that repeated courses of antenatal corticosteroids resulted in a consistent improvement in lung function at the expense of decreased fetal growth and adverse effects on brain development.¹¹⁶ However, Jobe and coworkers found that both a single course and three weekly courses of antenatal betamethasone caused a dosage-dependent reduction in birth weight in preterm and term lambs, as well as

decreased head size in term lambs.¹¹⁷ Reduced brain growth, nerve growth, and myelination have been demonstrated after exposure to antenatal corticosteroids, particularly with repeated courses.¹¹⁸⁻¹²¹ A review of eight trials demonstrated a consistent pattern of neurologic abnormalities, including altered optic nerve myelination, decreased eye diameter and retinal thickening, altered sciatic nerve development, reduced brain volume, and neuronal degeneration in sheep and monkeys.¹¹⁶ Growth restriction, low body weight, low blood pressure at 3 months, and a persistent decrease in brain weight at 3.5 years were noted in a randomized controlled trial of repeated corticosteroids in sheep.¹²² Postnatal cortisol exposure in rats was associated with reduced total body weight (50%) and brain weight (30%), with a proportional reduction in cerebral (30%) and cerebellar (20%) cell number, suggesting a reduction in cell division during the first 2 weeks of life.¹²³

Retrospective and observational studies in humans have revealed similar effects on fetal pulmonary function and brain growth with multiple courses of antenatal corticosteroids. A review of retrospective and nonrandomized observational studies of antenatal corticosteroids in humans found that multiple courses were associated with significantly reduced RDS (OR, 0.79) and patent ductus arteriosus (OR, 0.56) but no differences in mortality, IVH, bronchopulmonary dysplasia, or necrotizing enterocolitis when compared with a single course.¹²⁴ Overall, these studies revealed no consistent increase in the risk for neonatal sepsis or amnionitis with multiple courses despite an increased rate of endometritis (OR, 3.22). In another study, infants exposed to more than one course of antenatal steroids had smaller head circumferences (28.1 versus 28.4 cm; $P = .01$) and a lower incidence of RDS (34.9% versus 45.2%; $P = .005$).¹²⁵ In an observational study of 447 infants born before 33 weeks' gestation, a dosage-dependent reduction in birth weight (122 g; $P = .01$) and head circumference (1.02 cm; $P = .002$) occurred after three or more courses of antenatal corticosteroids.¹²⁶ In a post hoc analysis of 710 fetuses exposed to various dosages of antenatal corticosteroids in a trial of antenatal thyrotropin-releasing hormone, exposure to more than one course of antenatal corticosteroids was associated with a 32-g decrease in birth weight for infants born before 32 weeks' gestation, and an 80-g reduction for infants born after 32 weeks' gestation.¹²⁷ Although postnatal systemic corticosteroid administration has been shown to reduce chronic lung disease and ventilatory requirements, short-term peripartum treatment of preterm infants is also associated with hyperglycemia, hypertension, hypertrophic cardiomyopathy, and growth failure.¹²⁸

Data are also available from several prospective, randomized clinical trials of repeated antenatal corticosteroids in humans. In a study of 502 women randomized to receive either weekly betamethasone to 34 weeks or no further treatment after an initial course of antenatal corticosteroids, repeated antenatal corticosteroids did not significantly reduce composite morbidity (severe RDS, bronchopulmonary dysplasia, severe IVH, periventricular leukomalacia, sepsis, necrotizing enterocolitis, or death; 22.5% versus 28.0%; $P = .16$).¹²⁹ However, severe RDS (15.3% versus 24.1%; $P = .01$) and composite morbidity were decreased if delivery occurred between 24 and 27 weeks (77.4% versus 96.4%; $P = .03$) after repeated doses. The relative risk for composite morbidity after repeated corticosteroids declined with increasing gestational age at birth. There was no significant relationship between birth weight and repeated steroids (2009 versus 2139 g; $P = .10$), but the effect size was similar to that

previously described. The NICHD-MFMU network study randomly assigned 495 women at 23 to 32 weeks' gestation to receive either weekly betamethasone or placebo 7 to 10 days after an initial course and found no significant reduction in the composite primary morbidity outcome (8.0% versus 9.1%; $P = .67$) with repeated corticosteroid treatments.¹³⁰ However, repeated treatment was associated with less frequent neonatal surfactant administration ($P = .02$), mechanical ventilation ($P = .004$), continuous positive airway pressure ($P = .05$), and pneumothoraces ($P = .03$). The group receiving repeated corticosteroids had more neonates weighing less than the 10th percentile (23.7% versus 15.3%; $P = .02$), and neonates in the group that received four or more courses were significantly smaller. Crowther and colleagues randomly assigned 982 women at risk for preterm birth at less than 32 weeks' gestation after a single course of antenatal corticosteroids to receive repeated weekly betamethasone or weekly placebo.¹³¹ Repeated corticosteroid treatment led to less frequent RDS (33% versus 41%; $P = .01$) and severe lung disease (12% versus 20%; $P = .0003$), as well as less frequent oxygen therapy and shorter duration of mechanical ventilation. Further study is needed to determine the optimal approach to achieve timely antenatal corticosteroid treatment while minimizing fetal exposure. Subsequently, Murphy and coworkers, in a study of repeat antenatal corticosteroids at 14-day intervals for women at 25 to 32 weeks' gestation, revealed no reductions in newborn morbidities or mortality but lower birth weights (2216 versus 2330 g, $P = .0026$) and smaller head circumferences (31.1 versus 31.7 cm, $P < .001$) with treatment.¹³² A recent meta-analysis of nine trials suggests that repeated antenatal corticosteroids reduces the incidence of RDS (RR, 0.83) without affecting the risk for perinatal death (RR, 0.94) but at the risk of reducing birth weight (mean difference, -76 g).¹³³

In 1994, a National Institutes of Health consensus panel reviewed the available literature and published guidelines regarding antenatal corticosteroid administration.¹³⁴ In response to the rapid adoption into clinical practice of repeated antenatal corticosteroid administration to women at high risk for preterm birth and the accumulating data suggesting potential risks associated with this approach, the consensus panel was reconvened in August 2000 to review the available literature regarding repeated corticosteroid administration.¹³⁵ This review reaffirmed the benefits of antenatal corticosteroid administration and recommended against routine administration of repeated courses of corticosteroids. The recommendations of these two conferences are summarized in Box 34-1.

Rescue Antenatal Corticosteroids

The optimal approach to the use of antenatal corticosteroids for lung maturation has yet to be determined; repetitive weekly doses may offer some benefit, but with potential risks to growth and development. In a randomized, placebo-controlled trial of women in recurrent preterm labor between 25 and 32 6/7 weeks' gestation after completion of a single course of antenatal corticosteroids before 30 weeks' gestation, subjects were given either an additional "rescue course" of antenatal corticosteroids (same as the initial dosage) or placebo if they had received their first antenatal corticosteroid course at least 14 days before study entry.¹³⁶ The primary outcome measure was a "composite neonatal morbidity" in infants delivering at less than 34 weeks that was defined as one or more of the following:

BOX 34-1 SUMMARY OF THE 1994 AND 2000 NATIONAL INSTITUTES OF HEALTH CONSENSUS PANEL GUIDELINES REGARDING ANTENATAL CORTICOSTEROIDS FOR FETAL MATURATION

The benefits of antenatal administration of corticosteroids to fetuses at risk for preterm delivery vastly outweigh the potential risks. These benefits include not only a reduction in the risk for respiratory distress syndrome but also a substantial reduction in mortality and intraventricular hemorrhage. Optimal benefit begins 24 hours after initiation of therapy and lasts at least 7 to 14 days.

All pregnant women between 24 and 34 weeks' gestation who are at risk for preterm delivery within 7 days should be considered candidates for antenatal treatment with a single course of corticosteroids.

Treatment consists of two doses of 12 mg of betamethasone given intramuscularly 24 hours apart or four doses of 6 mg of dexamethasone given intramuscularly 12 hours apart. There is no proof of efficacy for any other regimen.

Because treatment with corticosteroids for less than 24 hours is still associated with significant reductions in neonatal mortality, respiratory distress syndrome, and intraventricular hemorrhage,

antenatal corticosteroids should be given unless immediate delivery is anticipated.

The decision to use antenatal corticosteroids should not be altered by fetal race or sex or by the availability of surfactant replacement therapy. Patients eligible for therapy with tocolytics should also be eligible for treatment with antenatal corticosteroids.

In complicated pregnancies when delivery prior to 34 weeks' gestation is likely, antenatal corticosteroid use is recommended unless there is evidence that corticosteroids will have an adverse effect on the mother or unless delivery is imminent.

In preterm premature rupture of the membranes at less than 30 to 32 weeks' gestation in the absence of clinical chorioamnionitis, antenatal corticosteroid use is recommended because of the high risk for intraventricular hemorrhage at these early gestational ages.

Because of insufficient scientific data from randomized clinical trials regarding efficacy and safety, repeat courses of corticosteroids should not be used routinely. In general, such repeat courses should be reserved for patients enrolled in randomized controlled trials.

Adapted from the National Institutes of Health Consensus Development Conference Statement: Effect of corticosteroids for fetal maturation on perinatal outcomes, February 28 to March 24, 1994, Am J Obstet Gynecol 173:246–252, 1995; and National Institutes of Health Consensus Development Panel: Antenatal corticosteroids revisited: repeat courses—National Institutes of Health Consensus Development Conference Statement, August 17–18, 2000, Obstet Gynecol 98:144–150, 2001.

RDS, bronchopulmonary dysplasia, severe intraventricular hemorrhage, blood culture–proven sepsis, necrotizing enterocolitis, or perinatal death. There were 223 patients in the rescue group and 214 in the placebo group. Slightly more than half delivered at less than 34 weeks. The investigators found a significant reduction in composite neonatal morbidity in the rescue corticosteroid group compared with placebo (43.9% versus 63.6%; OR, 0.45, $P = .002$). Among secondary outcomes, there was also a significant decrease in RDS alone, ventilator support, and surfactant use with rescue corticosteroid treatment. There were no differences in perinatal mortality, birth weight, rate of intrauterine growth restriction, or head circumference between groups, although the sample size was insufficient to detect modest differences in these outcomes. The findings of this study appear to justify the use of a rescue approach as a pragmatic alternative to single-course therapy.

Summary

The induction of fetal maturation through timely antenatal administration of betamethasone or dexamethasone is one of the most effective prenatal interventions available for reduction of perinatal morbidity and mortality related to preterm birth. Like many medications with strong effects, antenatal corticosteroids have the potential for significant side effects. The optimal

timing and dosage of antenatal steroids before anticipated preterm birth is the subject of important ongoing research. In the meantime, unless delivery is imminent, a single course of antenatal corticosteroids should be considered when preterm birth before 34 completed weeks is anticipated. Although there is some evidence that a single rescue course of antenatal corticosteroids may be beneficial when preterm birth threatens again remote from prior treatment, repeated courses should not be administered routinely outside the setting of randomized clinical trials. Alternative techniques to promote fetal pulmonary maturation are not recommended. Fetal pulmonary maturity testing through amniotic fluid analysis can be helpful in determining the relative risks for neonatal complications. If amniotic fluid testing indicates fetal pulmonary maturity, aggressive attempts at pregnancy prolongation for infant benefit may not be worthwhile, but an immature result can identify those who may benefit from antenatal corticosteroid administration for pregnancy prolongation. In any case, delivery should not be delayed for the purpose of fetal maturation in the setting of nonreassuring fetal testing, suspected intrauterine infection, or worsening maternal or fetal condition that places the mother or fetus in imminent jeopardy.

Invasive Fetal Therapy

JAN DEPREST, MD, PhD | RYAN HODGES, PhD, MBBS (Hons) |
EDUARDO GRATACOS, MD, PhD | LIESBETH LEWI, MD, PhD

The availability of high-resolution ultrasound imaging and screening programs has made the unborn child a true patient. When fetal malformations, genetic diseases, or in utero acquired conditions are suspected, patients are referred to tertiary care units with specialized skills, technical equipment, experience, and multidisciplinary counselors to define an accurate prognosis and potential options. In some cases, intervention before birth may be desirable. Many interventions do not require direct access to the fetus; examples include transplacental administration of pharmacologic agents for cardiac arrhythmias or of antibiotics in case of fetal infection. Other conditions can be treated only by direct access to the fetus. In utero transfusion of a hydropic fetus to correct anemia in case of Rh isoimmunization, initially described in 1961, was probably the first successful invasive therapeutic procedure. Today, blood transfusion through the umbilical cord, through the intrahepatic vein, or directly into the fetal heart or fetal abdomen is widely available, with good fetal and long-term outcomes when procedures are done by experienced operators.

Some conditions are amenable to surgical correction, and in most cases this is best done after birth. Occasionally, prenatal surgery is required to save the life of the fetus or to prevent permanent organ damage. This can be achieved by correcting the malformation, by arresting the progression of the disease, or by treating some of the immediately life-threatening effects of the condition, delaying more definitive repair until after birth. Because of the potential complications, the risks and benefits of the intervention must be weighed against each other.

A consensus, endorsed by the International Fetal Medicine and Surgery Society (IFMSS), has been reached on the criteria and indications for fetal surgery (Box 35-1).¹ In the 1980s and 1990s, only a few conditions met these criteria, and surgical intervention required maternal laparotomy and partial exteriorization of the fetus through a stapled hysterotomy. These “open” procedures were initially associated with high fetal and maternal morbidity, raising the question for some of the value of claimed benefits. However, open fetal surgery has been revived because of the proven benefits of antenatal repair of myelomeningocele (MMC).

The growing availability of videoendoscopic surgery in the 1990s, combined with earlier experience with fetoscopy, paved the way for the concept of endoscopic fetal surgery. The rationale was that minimally invasive access to the amniotic cavity would reduce the frequency of preterm labor and diminish maternal morbidity. The feasibility of endoscopic fetal surgery was demonstrated in an ovine model,² and the technique was first translated into clinical practice in the form of umbilical cord ligation.^{3,4} Instrument development was boosted by the

so-called Eurofoetus project, which brought together selected European fetal medicine units and an endoscopic instrument maker. These researchers developed new miniature endoscopes and instruments and conducted several clinical studies on complications of monochorionic twins. The successful execution of a randomized trial on laser coagulation of twin-twin transfusion syndrome (TTTS) prompted in Europe wide clinical acceptance of fetoscopy. Table 35-1 displays a list of surgical interventions that are practiced today, with their rationales and presumed benefits.

OPEN FETAL SURGERY

Open fetal surgery is a complex enterprise that should be undertaken only in experienced centers staffed with skilled personnel. Because of the high incidence of preterm labor, prophylactic (preoperative and postoperative) tocolysis is essential, using magnesium sulfate, indomethacin, or nifedipine. Large-bore maternal venous access is established, but fluid administration is conservative and meticulously managed to reduce the risk of pulmonary edema. General endotracheal anesthesia is used, taking advantage of the myorelaxant and uterine contraction suppression qualities of halogenated anesthetic gases. The uterus is exposed by a large laparotomy incision and opened with specially designed, resorbable Lactomer surgical staples (Premium Poly CS 57, U.S. Surgical, Norwalk, CT) to prevent intraoperative maternal hemorrhage. Location of the uterine incision depends largely on placental position, as determined by sterile ultrasound imaging. In case of an anterior placenta, the uterus will require exteriorization to allow access via the posterior uterine wall (Fig. 35-1).

The fetus is partially exposed or exteriorized and monitored by ultrasound, pulse oximetry, or direct fetal electrocardiography.⁵ Additional analgesics, atropine, and pancuronium or vecuronium are given to immobilize the fetus and to suppress the fetal stress response (bradycardia). The fetus is kept warm through the use of intrauterine infusion of Ringer's lactate at body temperature; this also maintains intrauterine volume and pressure, ensuring appropriate uteroplacental circulation. After completion of the fetal portion of the procedure, the uterus is closed in two layers with resorbable sutures, amniotic fluid volume is restored, intra-amniotic antibiotics are administered, and magnesium sulfate is initiated. The hysterotomy is covered with an omental flap. Postoperatively, the patient is treated in the intensive care unit and given aggressive tocolysis with magnesium sulfate and, if required, additional agents.

Complications of open fetal surgery include preterm contractions, maternal morbidity from tocolysis, rupture of

BOX 35-1 CRITERIA FOR FETAL SURGERY

1. Accurate diagnosis and staging is possible, with exclusion of associated anomalies.
2. Natural history of the disease is documented, and prognosis is established.
3. There is currently no effective postnatal therapy.
4. In utero surgery has proved feasible in animal models, reversing deleterious effects of the condition.
5. Interventions are performed in specialized multidisciplinary fetal treatment centers within strict protocols with approval of the local Ethics Committee and informed consent of the mother or parents.

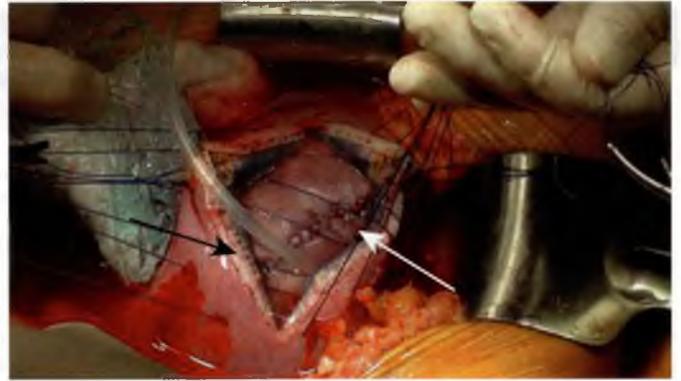

Figure 35-1 View of the hysterotomy at the end of a fetal myelomeningocele repair. The lateral incisional borders have been stapled with resorbable material (arrows), providing hemostasis. The hysterotomy is about to be closed by resorbable monofilament sutures.

TABLE 35-1

Indications and Rationales for in Utero Surgery on the Fetus, Placenta, Cord, or Membranes*

Fetal Surgery	Pathophysiology	Rationale for In Utero Intervention
SURGERY ON THE FETUS		
1. Congenital diaphragmatic hernia	Pulmonary hypoplasia and anatomic substrate for pulmonary hypertension	Reversal of pulmonary hypoplasia and reduced degree of pulmonary hypertension; repair of actual defect delayed until after birth
2. Lower urinary tract obstruction	Progressive renal damage due to obstructive uropathy	Prevention of renal failure and pulmonary hypoplasia by anatomic correction or urinary deviation
3. Sacrococcygeal teratoma	Pulmonary hypoplasia due to oligohydramnios High-output cardiac failure due to AV shunting and/or bleeding Direct anatomic effects of the tumoral mass Polyhydramnios-related preterm labor	Reduction of functional impact of the tumor by ablation of the tumor or (part of) its vasculature Reduction of anatomic effects by drainage of cysts or bladder Amnioreduction preventing obstetric complications
4. Thoracic space-occupying lesions	Pulmonary hypoplasia (space-occupying mass) Hydrops due to impaired venous return (mediastinal compression)	Creation of space for lung development Reversal of the process of cardiac failure
5. Neural tube defects	Damage to exposed neural tube Chronic CSF leak, leading to Arnold-Chiari malformation and hydrocephalus	Prevention of exposure of the spinal cord to amniotic fluid; restoration of CSF pressure correcting Arnold-Chiari malformation
6. Cardiac malformations	Critical lesions causing irreversible hypoplasia or damage to developing heart	Reversal of process by anatomic correction of restrictive pathology
SURGERY ON THE PLACENTA, CORD, OR MEMBRANES		
7. Chorioangioma	High-output cardiac failure due to AV shunting Effects of polyhydramnios	Reversal of process of cardiac failure and hydrops fetoplacentalis by ablation or reduction of flow
8. Amniotic bands	Progressive constrictions causing irreversible neurologic or vascular damage	Prevention of amniotic band syndrome leading to deformities and function loss
9. Abnormal monochorionic twinning; twin-to-twin transfusion; fetus acardiac and discordant anomalies	Intertwin transfusion leading to oligopolyhydramnios sequence, hemodynamic changes; preterm labor and rupture of the membranes; in utero damage to brain, heart, or other organs In utero fetal death may cause damage to co-twin Cardiac failure of pump twin and consequences of polyhydramnios Serious anomaly raising the question of termination of pregnancy Selective fetocide	Arrest of intertwin transfusion; prevention/reversal of cardiac failure and/or neurologic damage including at the time of in utero death; prolongation of gestation Selective fetocide to arrest parasitic relationship, to prevent consequences of in utero fetal death, and to avoid termination of the entire pregnancy

*Historically, in utero treatment of hydrocephalus was attempted but abandoned. In the late 1990s, indications 5 and 6 were added; indications 7 through 9 were typical results of the introduction of obstetric endoscopy in fetal surgery programs. AV, arteriovenous; CSF, cerebrospinal fluid.

membranes, uterine dehiscence, and fetal distress. Postoperative uterine contractions are the Achilles' heel of open fetal surgery, but experience has significantly limited maternal side effects. Amniotic fluid leakage can occur through the hysterotomy site or, more commonly, vaginally because of chorioamniotic

membrane separation or frank membrane rupture. If there is significant postoperative oligohydramnios, delivery may be necessary due to fetal distress. In a prospective case series on MMC repair, patients left the hospital within a few days, a much shorter interval than previously.^{6,7} Delivery by cesarean section

*Cumulative³⁸⁰ or at randomization.¹³ For fetoscopic MMC repair, most of the data ($n = 16$) come from a detailed report,³⁸⁰ unless otherwise specified. In those cases, the outcome variable could be identified only in a larger ($n = 19$) independent neurologic outcome report.³⁷⁰

[†]Defined as the ability to complete the surgery as planned at first attempt.¹ When second attempt included, the rate is 209/210.⁴⁷

[‡]Death at the time of surgery or as a result of it.²

[§]Initially, general anesthesia ($n = 8$) was given.

[¶]FETO involves an elective second invasive procedure at about 34 wk in 75% of cases.³ In another series without this second intervention, however, the gestational age at delivery was similar, 35.6 (28-38) wk.^{17,250}

FETO, fetoscopic endoluminal tracheal occlusion; MMC, myelomeningocele; n.r., not rated; n.s., not specified; pPROM, preterm premature rupture of the membranes.

is mandatory to avoid uterine rupture, though uterine rupture after open fetal surgery has not yet been reported. There is no documented adverse effect on future reproductive outcome, but a 2-year interval until the next pregnancy is advocated.⁸

Available data (Table 35-2) demonstrate that rupture and preterm delivery rates after open fetal surgery are actually not different from those after fetoscopy in the early second half of singleton pregnancies. The best-studied procedure in that respect is that for severe congenital diaphragmatic hernia, for which an initial fetoscopy is typically done at 26 to 30 weeks and potentially a second one at about 34 weeks. This procedure also carries a significant risk for preterm membrane rupture and preterm delivery.

EXIT PROCEDURE

Advanced fetal medicine units require basic knowledge of open uterine surgery, because the peripartum ex utero intrapartum treatment (EXIT) procedure is increasingly used for selected fetal conditions. The purpose of the EXIT procedure is typically to establish functional and reliable fetal airway control while keeping the fetus attached to the uteroplacental circulation. This is accomplished by delivering only a portion of the fetus through a hysterotomy incision. To permit optimal uteroplacental perfusion and hence ample time to perform a potentially complex fetal airway procedure, EXIT is done under maximal uterine relaxation, typically provided by deep inhalational general anesthesia. Therefore, the maternal risks of this procedure are mainly hemorrhagic. Because of the complex interactions that are necessary among anesthesiology, obstetrics, and pediatrics personnel, EXIT procedures require significant advance preparation with roles preassigned to the many physicians and nurses involved. Drills and rehearsals for EXIT, as

well as experience, enhance the safety and efficacy of the procedure.

The number of indications for EXIT has increased, but most share an anticipated difficulty in establishing the neonatal airway (Table 35-3). EXIT was initially used to permit controlled reversal of clipping of the fetal trachea, which was a treatment for congenital diaphragmatic hernia (CDH). Other disorders leading to congenital airway obstruction include laryngeal atresia (congenital high airway obstruction syndrome [CHAOS]) (Fig. 35-2), large head and neck tumors, and other upper airway problems that might cause difficult intubation (e.g., micrognathia). This decision is largely based on the findings of advanced imaging techniques (e.g., magnetic resonance imaging [MRI]); predictive indices regarding the tracheal-esophageal complex have been suggested but are not yet validated.⁹ Another indication for EXIT is the need for fetal cardiopulmonary support during surgery, such as in the EXIT-to-ECMO (extracorporeal membrane oxygenation) procedure for specific cardiac defects, for certain types of conjoined twins, or in surgery for congenital cystic adenomatoid malformation (CCAM) of the lung. It has also been proposed for selected cases of CDH, though the early experience did not support that indication.¹⁰

The maternal anesthetic protocol typically involves rapid-sequence induction with propofol, rocuronium bromide, and remifentanyl, followed by intubation and maintenance of anesthesia by propofol and remifentanyl and 0.2% to 0.5% minimum alveolar concentration of sevoflurane in oxygen. Sevoflurane is preferred to isoflurane because of its faster onset of action and faster elimination to regain uterine tone after cord clamping. To support adequate uteroplacental perfusion, maternal arterial pressure must be well maintained with ephedrine or phenylephrine, which are used for their minimal effect on uterine blood

TABLE 35-3 Ex Utero Intrapartum (EXIT) Therapy Procedure Data

Indication	Mean Gestational Age at EXIT (wk)	Mean EXIT Duration (min)	Long-term Neonatal Survival (%)
Neck mass (n = 19)	36.1 ± 2.6	28.9 ± 15.4	16/19 (84.2)
Reversal of TO (n = 13)	31.8 ± 2.7	26.7 ± 6.3	5/13 (38.5)
CCAM (n = 5)	35.4 ± 4.8	63.8 ± 4.2	4/5 (80)

Figure 35-2 Ex utero intrapartum therapy (EXIT). A baby with prenatally diagnosed congenital high airway obstruction syndrome (CHAOS) has received a tracheostomy on placental circulation. The torso is half out of the uterus, while the rest of the body is still inside. Under the hands of the surgeons run the infusion lines to maintain the amniotic cavity sufficiently filled.

flow. For the fetus, umbilical arterial and venous catheters ensure adequate vascular access for perinatal resuscitation. After the airway procedure is complete, the fetus is completely delivered, the halogenated gas is decreased, and oxytocin 20 IU in 500 mL of normal saline is given as a bolus intravenously. Then oxytocin is infused as a 10 IU in 1000-mL drip and titrated to uterine response. An injection of 10 IU oxytocin in the myometrium may be given as well, and methergine (0.25 mg) and prostaglandin F_{2α} (250 μg) should be readily available. An interesting alternative approach to general anesthesia has been described in small case series^{11,12} utilizing combined spinal-epidural anesthesia, intravenous nitroglycerin for uterine relaxation, and remifentanyl for fetal anesthesia, without any sign of maternal sedation or respiratory depression.

The largest single-center experience, with 43 EXIT procedures, was reported by the Children's Hospital of Philadelphia (CHOP) (see Table 35-3).^{13,14} The most common indications

were fetal neck masses and reversal of tracheal clipping (a procedure no longer performed). A single case of EXIT-to-ECMO was done for a baby with a left CDH and tetralogy of Fallot at 36 weeks. Less common indications were CHAOS, unilateral pulmonary agenesis, and a large lung lesion that was anticipated to cause ventilation problems at birth (the tumor was resected while the fetus was on placental bypass).¹⁵ EXIT also allows elective rather than emergency tracheostomy if intubation fails for other anatomic reasons. The estimated blood loss was 938 ± 532 mL, with an average time on uteroplacental circulation of 33.8 ± 16.9 minutes (range, 8 to 69 minutes). There were no recorded episodes of significant maternal hemodynamic instability in this series. Maternal complications consisted of placental abruption during EXIT (*n* = 1), intraoperative blood transfusion (*n* = 2), and chorioamnionitis believed to have arisen from earlier interventions (*n* = 2). There were no cases of uterine atony or maternal death. One intraoperative fetal death occurred in a fetus with a large cervical lymphangioma who could not be intubated and whose parents had declined a tracheostomy.

Placental histopathologic examination may identify the risk of fetal and neonatal coagulopathy in fetuses undergoing EXIT. In these fetuses, placentas have a higher frequency of fetal thrombotic vasculopathy, a risk factor for thromboembolic disease and cerebral palsy. In this setting, this pathology most likely reflects venous stasis in cases of a thoracic mass, heart failure with a teratoma, or consumptive coagulopathy in arteriovenous malformation. Routine placental examination may therefore provide prognostic information for thromboembolic and hemorrhagic sequelae, providing a useful adjunct to laboratory indices and cranial ultrasonography.¹⁶

FETOSCOPY

Instrumentation

Fetoscopic procedures are minimally invasive interventions that can be considered as a cross between ultrasound-guided and formal surgical procedures. The surgeons involved may be fetal medicine specialists or pediatric surgeons, largely depending on local expertise. Fetoscopy must be organized so that the surgical team can see simultaneously both the ultrasound monitor and the fetoscopic image. Cannulas, instruments, and endoscopes have undergone a tremendous evolution in the past decade, and this process continues. Specifically designed fetoscopes typically

have departed eyepieces to reduce weight and facilitate precise movements. Almost all are flexible fiber endoscopes, and as the number of pixels has increased, image quality has improved markedly. Working length must be sufficient to reach all regions of the intrauterine space, and recently a longer, integrated endoscope has been introduced (Fig. 35-3). Current scope diameters are between 1.0 and 2.0 mm with a 0 degree direction of view and an opening angle of 70 to 80 degrees.

Amniotic access is facilitated by thin-walled, semiflexible, disposable or larger-diameter, reusable but rigid metal cannulas, so that instrument changes are possible. Alternatively, the fetoscopic sheath is introduced directly with the use of a sharp obturator to stab the uterus under ultrasound guidance. Once inside the amniotic cavity, the obturator is replaced by the fetoscope. Technical handbooks and a review article provide details of the use of these instruments and a discussion of distention media.^{3,17,18} Instrument insertion is usually done under local anesthesia, which is injected along the anticipated track of the cannula down to the myometrium.

Iatrogenic Preterm Rupture of the Membranes

Despite the minimally invasive nature of fetoscopy, it continues to be associated with iatrogenic preterm premature rupture

Figure 35-3 Integrated fetoscope. The instrument has a departed eyepiece and, at the back end of the scope, connections for fibers, instruments, and irrigation fluid. (Courtesy Karl Storz Endoskope, Tuttlingen, Germany.)

of the membranes (pPROM) (Table 35-4).¹⁹ Several initiatives have been taken toward treating or preventing this condition,²⁰ including attempts to repair defects with the use of various tissue sealants applied either intracervically or intra-amniotically. These efforts have met with limited success, because fetal membranes have a limited ability to heal.²¹ The use of the amniopatch procedure as a treatment modality for symptomatic iatrogenic pPROM was first described by Quintero and colleagues²² in 1996. In 2011, we reviewed the available experience²³ for patches done after fetoscopy ($n = 17$; 11 [65%] live births) or after needle-based procedures ($n = 19$; 13 [66%]). In both groups, there were 6 cases (17%) of intrauterine fetal demise (IUFD) at various time points. Amniopatch can also be performed for membrane detachment, with a success rate greater than 80%.

Amniopatch. The original procedure for sealing amniotic fluid leakage after membrane rupture described the use of autologous platelets and cryoprecipitate obtained after plasmapheresis. Today, platelet-rich plasma, which works equivalently, has been substituted for cryoprecipitate. Immediately before the procedure, subclinical infection should be excluded by measuring the maternal C-reactive protein and white blood cell count. After administration of local anesthetic, a 22-gauge needle is used to gain access in a safe location devoid of umbilical cord. A few drops of remaining amniotic fluid should be aspirated and analyzed to exclude infection by Gram staining, glucose determination, and culture. Infusion of 100 mL of Hartmann's solution or Ringer's lactate is performed to create a clear fluid pocket, permitting better visualization of the procedure. Subsequently, infusions with 20 mL of platelets, normal saline (which does not contain calcium that would promote the clotting process), and 20 mL of fresh-frozen plasma (FFP) are alternated. Avoidance of contact between these blood products prevents clotting in the lines. During infusion, the fetal heart rate and the accumulation of amniotic fluid are monitored by ultrasonography. In the event of bradycardia, the platelet infusion is stopped and additional saline may be used to dilute the active substances. Usually a total of about 150 mL of platelets, 150 mL of FFP, and 150 mL of amnioinfusion fluid is used throughout the procedure. A maximum of two or three attempts is made.

TABLE 35-4 Risk for Preterm Premature Rupture of the Membranes (pPROM) after Fetoscopic Procedures

Procedure	Risk of pPROM (Time Point at Assessment)	Diameter of Instrument	Reference
Amniocentesis	1-1.7%	22 gauge (0.7 mm)	Borghida, 2000 Tabor, 1996

Fetal Analgesia during Procedures

Pain is a subjective experience that occurs in response to impending or actual tissue damage. The subjective experience of pain requires nociception and an emotional reaction. Nociception requires an intact sensory system, and an emotional reaction requires some form of consciousness. It is difficult to know the extent to which the fetus experiences pain. However, several indirect methods have suggested that the fetus at least *can* feel pain. Robinson and Gregory suggested the importance of providing analgesia to preterm neonates.²⁴ Anand and colleagues,²⁵⁻²⁷ Fisk and coworkers,²⁸ and Giannakouloupoloulos and colleagues²⁹ demonstrated that premature infants and fetuses display several humoral stress responses during invasive procedures. These data indicate that the mid-gestational fetus responds to noxious stimuli by mounting a distinct stress response, as evidenced by an outpouring of catecholamines and other stress hormones as well as hemodynamic changes. And, in analogy to what has been documented in neonates, prenatal stress can be expected to affect later neurodevelopment. Theoretically, pain experienced in utero may be “remembered” by the fetus, which could in turn lead to altered sensory patterns or abnormal behavioral patterns in postnatal life. Consequently, management of fetal pain and associated stress response in utero during invasive fetal interventions is important.²⁸ Even if it remains unknown whether this approach results in improved neurodevelopment and improved long-term outcome, it is prudent to take preemptive action and manage potentially painful procedures accordingly.

Several treatment protocols have been proposed,³⁰ and in general, a policy should be adopted of administering fetal analgesics for any invasive procedures during which the fetus might experience pain, certainly from 18 to 20 weeks onward. Sufentanil (1 to 2 $\mu\text{g}/\text{kg}$) or fentanyl (10 $\mu\text{g}/\text{kg}$) can be given intramuscularly or intravenously to the fetus. If the mother is given general analgesia, the fetus should be sufficiently anesthetized through transplacental passage.³¹ Ongoing research about whether to administer postoperative fetal pain relief for some procedures may lead to new routes of pain relief, such as intra-amniotic injection of long-acting opioids.³²

Complicated Monochorionic Twin Pregnancies

Monochorionic twins constitute about 30% of all twin pregnancies³³; by definition they share a single placenta, and they almost always have vascular anastomoses interconnecting their circulations.³⁴ This makes the well-being of one twin critically dependent on the other. Because the placental circulatory districts are often unequal, monochorionic twins have substantially greater morbidity and mortality than their dichorionic counterparts.³⁵ Vascular anastomoses across monochorionic placentas may create unique complications, such as TTTS, twin reversed arterial perfusion (TRAP) sequence, and, in the event of single IUID, acute exsanguination of the surviving twin into the vascular space of the demised twin. Correct determination of chorionicity is therefore of utmost importance in the management of these high-risk pregnancies and is most reliably achieved by ultrasound scanning in the first trimester.^{36,37}

Invasive fetal therapy has improved the outcome of complicated monochorionic multiple pregnancies. Specifically, laser

coagulation of the vascular anastomoses in TTTS has improved the rate of fetal survival and reduced the frequency of short-term disability.³⁸ Additionally, umbilical cord coagulation and intrafetal ablation have been shown to be effective for selective fetocide in monochorionic multiple pregnancies with severe discordant anomalies or end-stage growth restriction of one twin prior to viability, in selected cases with TTTS, and in TRAP sequence.^{39,40}

Twin-Twin Transfusion Syndrome

TTTS occurs in 8% to 9% of monochorionic twin pregnancies and represents the most important cause of mortality; it typically becomes clinically evident between 16 and 26 weeks' gestation.^{41,42} The pathology is usually explained by unbalanced circulatory sharing between the twins. Placental anastomoses are traditionally denoted as arterioarterial (AA), venovenous (VV), or arteriovenous (AV).⁴³ AA and VV anastomoses are bidirectional anastomoses on the surface of the chorionic plate that form direct communications between the arteries and veins of the two fetal circulations. The flow is bidirectional and depends on the relative interfetal vascular pressure gradients. AV anastomoses are usually considered deep anastomoses. They represent a shared cotyledonary territory that receives arterial supply from one twin and provides venous (well-oxygenated) drainage to the other twin. The supplying artery and draining vein of an AV anastomosis can be visualized on the placental surface as an unpaired artery and vein that pierce the chorionic plate at close proximity to one another.

AV anastomoses allow flow in one direction only and therefore may create imbalance in interfetal transfusion, leading to TTTS unless balanced by oppositely directed transfusion through other superficial or deep anastomoses. Bidirectional AA anastomoses are believed to protect against the development of TTTS, because most non-TTTS monochorionic placentas (84%) have AA anastomoses, whereas the incidence in TTTS placentas is only 24%.² Although these vascular anastomoses are an anatomic prerequisite for the development of TTTS, the pathogenesis of TTTS is probably more complex than a simple net transfer of red blood cells, because usually both twins have similar hemoglobin values.^{44,45} Most probably, hormonal factors are involved as well, with exposure of the recipient to vasoactive mediators produced by the donor, and vice versa.⁴⁶

DIAGNOSIS OF TTTS

The diagnosis of TTTS is based on stringent sonographic criteria of amniotic fluid and bladder filling discordance. In the donor twin, there is oliguric oligohydramnios with a deepest vertical pocket (DVP) of 2 cm or less. In contrast, the recipient twin presents with polyuric polyhydramnios and a DVP cutoff of 8 cm or greater before 20 weeks, and 10 cm or greater after 20 weeks.⁴⁷ In the United States, an 8-cm DVP cutoff throughout gestation is used.⁴⁸ Although growth restriction is often present in the donor twin, it is not essential for the diagnosis of TTTS. In severe cases, sonographic signs of congestive cardiac failure resulting from fluid overload in the recipient include a negative or reversed *a* wave in the ductus venosus, pulsatile flow in the umbilical vein, tricuspid regurgitation, and signs of hypovolemia or increased vascular resistance in the donor with absent or reversed flow in the umbilical artery.

The differential diagnosis includes monoamnicity, discordant growth, isolated polyhydramnios or oligohydramnios, and severe intertwin hemoglobin differences at the time of birth. In TTTS, the intertwin membrane may be difficult to visualize, because it is wrapped tightly around the body of the donor. This may lead to an incorrect diagnosis of monoamnicity. TTTS can occur in monoamniotic pregnancies⁴⁹ and is characterized by polyhydramnios of the common amniotic cavity with discordant bladder sizes. However, monoamniotic twins can move freely, and usually their umbilical cords are entangled, whereas in diamniotic twins with TTTS, the donor is usually stuck against the uterine wall. Severe discordant growth is also often confused with TTTS, because the growth-restricted twin may appear immobilized (“stuck”) due to oligohydramnios, but the appropriately grown twin invariably has normal amniotic fluid or only a mild degree of polyhydramnios that does not fulfill the criteria of TTTS.

The distinction between TTTS and discordant growth is crucial, because most pregnancies with discordant growth have an acceptable outcome without intervention.⁶ Also, the isolated presence of polyhydramnios or oligohydramnios in one sac and normal amniotic fluid in the other precludes the diagnosis of TTTS and should provoke the search for discordant congenital anomalies (e.g., bilateral renal agenesis) as the cause for anhydramnios in one twin. Finally, a severe intertwin hemoglobin difference (with or without a difference in birth weight) diagnosed at the time of birth should not be regarded as TTTS. Severe intertwin hemoglobin differences may arise because of an acute peripartum transfusion during delivery, after double

IUFD and exsanguination of the survivor into the body of the demised co-twin, or because of a chronic net transfusion through tiny anastomoses.⁵⁰ With the exception of twin anemia polycythemia sequence (TAPS), discussed later, an important differentiating feature is that these cases are diagnosed at the time of birth and do not have the typical amniotic fluid discordances required for the diagnosis of TTTS.

PREDICTION OF TTTS

It remains difficult to identify those monochorionic twin pregnancies that will develop TTTS. Nuchal translucency (NT) discordance in the first trimester is associated with an increased risk for subsequent development of TTTS, because it may reflect impaired ventricular function in the hypervolemic recipient twin. An NT discordance of greater than 20% is reported to be present in 25% of monochorionic twin pregnancies and detects 52% of cases complicated by TTTS, but with a positive predictive value of only 36%.⁵¹

In a prospective cohort study including 202 monochorionic twins monitored from the first trimester onward, predictors of TTTS, occurrence of isolated growth discordance, and intrauterine demise were determined in the first trimester and again at 16 weeks. In the first trimester, pregnancies were classified as high risk (80% adverse outcome; 50% survival) if there was either discordant amniotic fluid or a difference of 12 mm or greater in the crown-rump length (Fig. 35-4). At 16 weeks, a high risk (70% adverse outcome; 70% survival) was predicted by the presence of discordant amniotic fluid and discordant

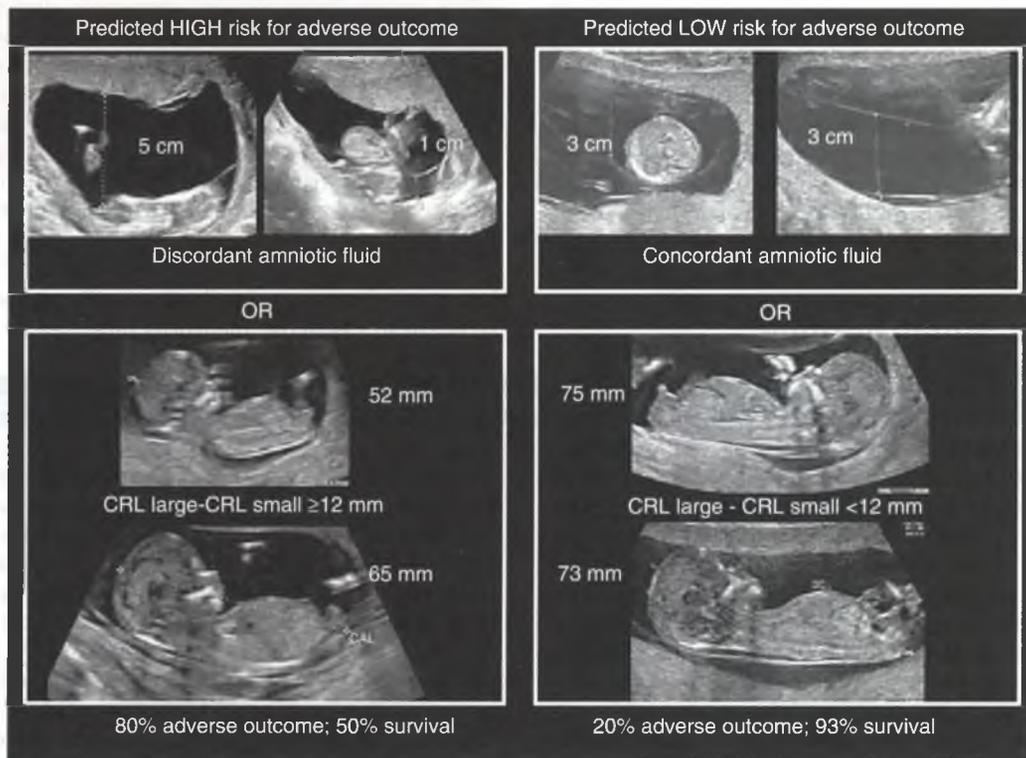

Figure 35-4 Representation of first-trimester risk assessment for the development of discordant growth, twin-twin transfusion syndrome (TTTS), or intrauterine demise. Discordant amniotic fluid in the first trimester generally corresponded with deepest vertical pockets ≤ 3 cm in one sac and ≥ 6.5 cm in the other. Discordance in crown-rump length (CRL) was present if the difference was ≥ 12 mm. (From Lewi L, Gucciardo L, Van Mieghem T, et al: Monochorionic diamniotic twin pregnancies: natural history and risk stratification, *Fetal Diagn Ther* 27:121–133, 2010. Reproduced with permission of the authors and Karger, publishers of *Fetal Diagnosis and Therapy*.)

cord insertions. For cases with only discordant fluid but concordant cord insertions, adverse outcome was predicted by an intertwin difference in abdominal circumference of 6 mm or greater; for cases with concordant fluid but discordant cords, a difference in abdominal circumference of 13 mm or greater predicted adverse outcome. Finally, in the absence of both discordant fluid and cord insertions, an adverse outcome was predicted by a difference in abdominal circumference of 24 mm or more (Fig. 35-5). When the first-trimester scan was combined with assessment of amniotic fluid, intertwin growth discordance, and the site of cord insertions at 16 weeks' gestation, 67% of cases complicated by TTTS, 48% of cases with discordant growth, and 80% of intrauterine deaths from other causes were predicted, as demonstrated in a prospective cohort study on more than 200 cases (see Fig. 35-4).^{52,53}

Nevertheless, given that vascular anastomotic patterns and flows may change unpredictably with placental expansion, it may be impossible to predict TTTS accurately early on.⁵⁴ Most fetal care centers recommend that all monochorionic twin pregnancies be monitored by ultrasound evaluation every 2 weeks. At these examinations, relative amniotic fluid volumes, bladder filling, growth, and visualization of a free-floating intertwin membrane should be evaluated, perhaps with Doppler studies as well. Patients should also be informed of the symptoms of TTTS and advised to seek immediate medical advice if they

notice rapidly increasing abdominal girth or premature contractions.⁵⁵

STAGING OF TTTS

TTTS is currently staged according to the Quintero staging system (Table 35-5).

- In stage I, the donor has bladder filling, and Doppler measurements in both umbilical vessels and the ductus venosus are normal in both twins.
- In stage II, the bladder is not visible in the donor, but both twins have normal Doppler measurements.
- In stage III, there are abnormal Doppler measurements in one or both twins, including absent or reversed end-diastolic flow in the umbilical artery (usually in the donor) or a reversed *a* wave in the ductus venosus and/or venous pulsations in the umbilical vein (typically in the recipient).
- In stage IV, hydrops is present (usually in the recipient).
- In stage V, there is IUFD in one or both twins.

Although the Quintero staging system predicts outcome to a certain extent, it is better to use it to reflect the more severe manifestations of disease than as an indicator of the time sequence of progressive disease, because it is clear that cases can progress directly from stage I to stage V, and TTTS can appear

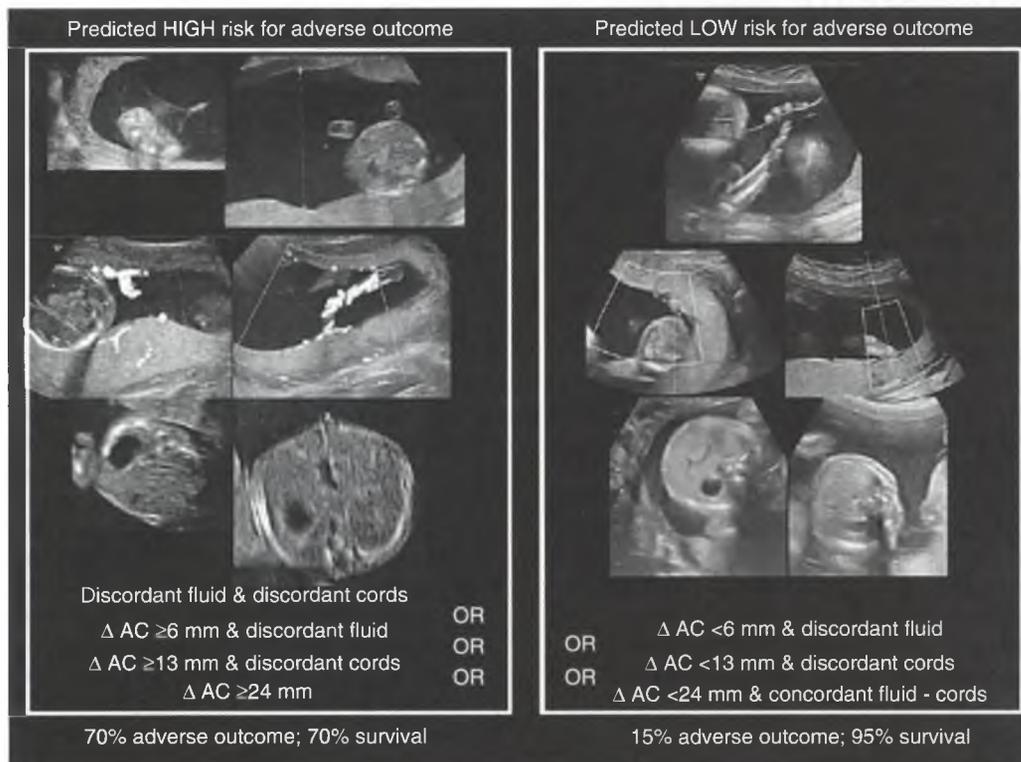

Figure 35-5 Representation of the 16-week assessment for the development of discordant growth, twin-twin transfusion syndrome (TTTS), or intrauterine demise. A discordant cord insertion was defined as a velamentous insertion in one twin with an eccentric insertion (<2 cm from the placental edge) in the other. Adverse outcome was predicted for cases with only discordant fluid but concordant cord insertions by an intertwin difference in abdominal circumference (AC) of ≥ 6 mm, and for cases with concordant fluid but discordant cords by an AC difference of ≥ 13 mm. For concordant fluids and cord insertions, a difference in AC of ≥ 24 mm indicates elevated risk. (From Lewi L, Gucciardo L, Van Mieghem T, et al: *Monochorionic diamniotic twin pregnancies: natural history and risk stratification*, *Fetal Diagn Ther* 27:121–133, 2010. Bladder filling in donor	Absent bladder filling in donor	Abnormal Doppler findings: • Absent/reversed EDF umbilical artery (donor) • Reversed a wave ductus venosus (recipient)	Hydrops fetalis
			STAGE V
			Intrauterine fetal death

*TTTS cases should have a DVP of 8 cm on the recipient side and <2 cm on the donor side. Classification is further determined by the filling status of the bladder in the donor (stage I and II). Additional (Doppler) ultrasound features upgrade stage.

†Most European centers use a cutoff of 10 cm for gestation over 20 weeks. For presentations earlier than 18 weeks, cutoffs have not been agreed upon.

DVP, deepest vertical pool; EDF, end-diastolic flow; TTTS, twin-twin transfusion syndrome.

as stage III from the start. In stage III and beyond, there is obvious and measurable hemodynamic impact, the latter having been reviewed by Van Mieghem et al.^{56,57} Attempts have been made to incorporate a cardiac function score.⁵⁸ The CHOP cardiovascular score reported echocardiographic and peripheral Doppler measurements in 150 TTTS pregnancies. A significant number of fetuses classified as having abnormal cardiac function would have been classified at a lower severity if the Quintero system alone had been used.⁵⁸ However, in a prospective study on 158 cases of TTTS examined before laser procedures, this CHOP cardiovascular score failed to predict perinatal outcome.⁵⁹ Similarly, both the myocardial performance index and speckle tracking have not been shown to be clinically useful.^{56,60} Nevertheless, the burden of abnormal cardiac function in both donor and recipient is undoubtedly severe. It seems likely that fetal echocardiography will form an important adjunct in the management of TTTS cases, but just how it will prove to be useful is not established.

TREATMENT OF TTTS

The mortality of untreated mid-trimester TTTS has traditionally been reported as greater than 80%, which is especially dramatic because two fetuses are involved. Polyhydramnios may lead to spontaneous abortion or extreme preterm delivery, and IUD may result from cardiac failure in the recipient or poor perfusion in the donor. In view of the poor outcome of untreated mid-trimester TTTS, there is general consensus that treatment should be offered.⁶¹ Even with the latest treatment modalities, the risks of adverse outcome are significant, and after treatment the pregnancy must be monitored carefully and remains at high risk until the delivery. Therefore, the option of a pregnancy termination should be part of every patient's counseling.

Amnioreduction

In the past, serial amnioreduction was the only procedure available to reduce polyhydramnios and intrauterine pressure in the hope of alleviating uterine contractions and prolonging pregnancy. Theoretically, amnioreduction might also improve fetal hemodynamics by reducing the amniotic fluid pressure and thereby enhancing uteroplacental perfusion. Amnioreduction is a relatively simple technique involving aspiration of amniotic

fluid via an 18-gauge needle under local anesthesia until restoration of normal amniotic fluid volume can be measured sonographically. Its shortcoming is its failure to address the cause of the disease, because the vascular anastomoses remain patent. Furthermore, even if amnioreduction can resolve or stabilize stage I or II disease, therapy fails in about one third of cases.⁴⁵ The palliative nature of amnioreduction has several implications. First, after failed amnioreduction, subsequent laser coagulation may be hampered by intra-amniotic bleeding, membrane separation, or unintentional septostomy. Also, even in pregnancies with stable disease, the hostile intrauterine environment persists and may result in the premature birth of two compromised infants, with the associated risk of neonatal death and morbidity.⁶² Finally, in the event of intrauterine demise of one twin, the surviving twin may exsanguinate into the fetoplacental compartment of its demised co-twin, leading to double IUD or hypoxic-ischemic brain damage.^{63,64}

Septostomy

Intentional puncturing of the intertwin septum, or septostomy, with or without amnioreduction, has been suggested, largely on the basis of the rarity of TTTS in monoamniotic twins, to have beneficial effects. However, there is little evidence to support this as a primary therapeutic technique. A randomized trial comparing septostomy with amnioreduction found similar rates of survival of at least one twin. However, patients undergoing septostomy were more likely to require only a single procedure.⁶⁵ Nevertheless, septostomy brings with it the potential risks of cord entanglement resulting from an iatrogenic monoamniotic state, and it makes laser coagulation of the vascular anastomoses for progressive disease technically much more challenging. To minimize the risks of iatrogenic monoamnioticity, the technique of fetoscopic microseptostomy⁶⁶ has been proposed, although proof of any survival benefit is so far lacking.

Selective Feticide

Feticide was suggested as a treatment for TTTS in 1993, as a desperation attempt to salvage one twin in complicated cases of TTTS.⁶⁷ This concept was revived in 2002 for the treatment of stage III/IV TTTS⁶⁸ with the rationale that, in these advanced stages, laser coagulation has such a high chance for single IUD

that it acts as a selective feticide. Therefore, it was presumed that cord coagulation would be a simpler way to perform feticide and would better protect the surviving twin. The most important drawback of this approach is its theoretical maximal survival rate of 50%. However, with the inherent complications of the procedure, the overall survival rate of the remaining twin is only 70% to 85%.^{5,39,40,69} Also, it may be unacceptable for many parents to sacrifice one twin without obvious structural pathology, and it may not be easy to determine which twin has the higher risk of adverse outcome. Therefore, this technique should be reserved for selected cases, such as TTTS pregnancies with severe discordant anomalies, with an inaccessible vascular equator, with pPROM of the recipient sac, with imminent IUFD due to end-stage cardiac failure or growth restriction, or with recurrent disease after fetoscopic laser coagulation of the vascular anastomoses.⁶⁹

Fetoscopic Laser Coagulation

Provided that all anastomosing vessels can be visualized and treated, selective occlusion arrests the transfusion of blood and vascular mediators from donor to recipient and thereby makes the placenta functionally dichorionic. Laser coagulation of the vascular anastomoses was first reported by De Lia and coworkers in 1990.⁷⁰ They described coagulation of all vessels crossing the intertwin membrane. The procedure became much more popular when Nicolaides' group described a percutaneous approach, and since a randomized trial proved this to be the most effective therapy, it should be the standard of care.^{38,71} Fetoscopic laser coagulation is usually performed from 16 weeks onward; before that time, the amniotic membrane may still be separated from the chorion, hampering amniotic access and increasing postoperative leakage. In early cases, the donor is unlikely to be completely stuck, because the amniotic membranes still contribute to amniotic fluid production. Moreover, the degree of polyhydramnios in the recipient's sac is unlikely to equal the typical 8-cm cutoff, because fetal urine flow is still limited.⁷² Fetoscopic laser coagulation after 26 weeks has similar outcomes as before 26 weeks, and it is offered in Europe.⁷³ It also appears to be associated with less major neonatal morbidity than repeated amnioreduction.⁷⁴ From 32 weeks onward, elective preterm delivery should be considered if lung maturation is documented.

Preoperatively, all patients undergo a detailed ultrasound study for disease staging and to exclude discordant anomalies. The cervical length is measured, because it is a strong predictor of preterm delivery (with a cervical length of <20 mm, 60% are delivered before 24 weeks, and only 20% after 32 weeks).⁷⁵ Some centers perform cervical cerclage in cases of short cervix.⁷⁶ Prophylactic antibiotics (intravenous cefazolin, 2 g) and prophylactic tocolytics (oral nifedipine, 20 mg) are used. For most cases, fetoscopic laser coagulation is performed percutaneously through a 3- to 4-mm incision with local anesthesia. For laser coagulation, a neodymium-yttrium aluminum garnet (Nd:YAG) laser (minimal power requirements, 60 to 100 W) or a diode laser (30 to 60 W) with fibers of 400 to 600 μm provides optimal efficacy. Fibers are inserted through a working channel, keeping the fiber in a stable position, and irrigation fluid may also be useful.

First, the positions of the fetuses, umbilical cord insertions, and placenta are mapped by ultrasound. To gain entry into the amniotic space, the sheath can be introduced either directly or through a cannula. For direct introduction, the sheath is loaded

with its accompanying trocar. The sheath is inserted into the amniotic cavity, and once it is inside, the trocar is removed and replaced by the fetoscope. During the procedure, the sheath can be moved backward and forward, but it cannot be withdrawn without losing access to the amniotic cavity. The use of cannulas obviates this problem, because the port remains during the entire procedure and different instruments and scopes can be introduced. Semiflexible, thin-walled cannulas in a variety of sizes accommodate curved instruments.

Under ultrasound guidance, the cannula or fetoscopic sheath is inserted into the recipient's sac (Fig. 35-6). Preferentially, the site of the trocar insertion is remote from the donor's sac to avoid the risk of unintentional septostomy, and the trocar aims for a 90-degree angle with the anticipated vascular equator, because this provides the best opportunity for an optimal coagulation. The vascular equator normally cannot be visualized on ultrasound unless there is a marked difference in echogenicity between the two placental districts.⁷⁷ However, with a placenta covering the entire anterior uterine wall, there is often little choice, and the best available entry site is used, at all times avoiding maternal bowel, large vessels, and, as much as possible, the placenta. Occasionally, vision is hampered by blood or debris; in these cases, amnioexchange with warmed Hartmann's solution (heated by a blood warmer or a special amnioirrigator) can improve visibility.^{78,79}

Three fixed landmarks are used to identify anastomosing vessels: the recipient's and the donor's cord insertions and the intertwin membranes (Fig. 35-7). The intertwin septum and its placental insertion are easily identified as a thin white line on the chorionic surface. From there, blood vessels leaving the donor usually cross under the septum in the direction of the recipient. Anastomosing vessels can also be identified starting from the recipient's or donor's cord insertion. The purpose of the procedure is to visualize the entire vascular equator and to coagulate all visible anastomoses. Arteries are distinguishable from veins because they cross over the veins and have a darker color due to their lower oxygen saturation.⁸⁰ Not uncommonly, it may be impossible to determine whether vessels anastomose or not, because of the position of the intertwin septum, placenta, or fetus or other physical limitations. In such instances, these vessels are coagulated as well, because the aim is to separate the two fetal circulations completely. Coagulation is performed at a distance of approximately 1 cm and ideally at a 90-degree angle, using a non-touch technique (see Fig. 35-7), starting at one placental border and finishing at the other end. A sequential approach selecting AV anastomoses first has been advocated.⁸¹ Sections of 1 to 2 cm are coagulated with shots of 3 to 4 seconds, according to the tissue response. Laser energy is adapted to the source used, the diameter of the vessels, and the tissue response. Typically, an Nd:YAG laser is set at 50 to 70 W and a diode laser at 30 to 40 W. The use of excessive laser power levels should be avoided, because this may cause vessel perforation and fetal hemorrhage. Large vessels can be coagulated from various angles to obtain progressive narrowing and eventual coagulation. Alternatively, compression of large vessels by the cannula and subsequent coagulation from within the cannula at a lower power setting may be helpful to achieve complete vessel occlusion. Once all vessels have been coagulated, the vascular equator is followed once more from one side to the other to ascertain that all anastomoses have indeed been fully coagulated and that flow has not resumed. The procedure is completed by amnioreduction until normal amniotic fluid volume

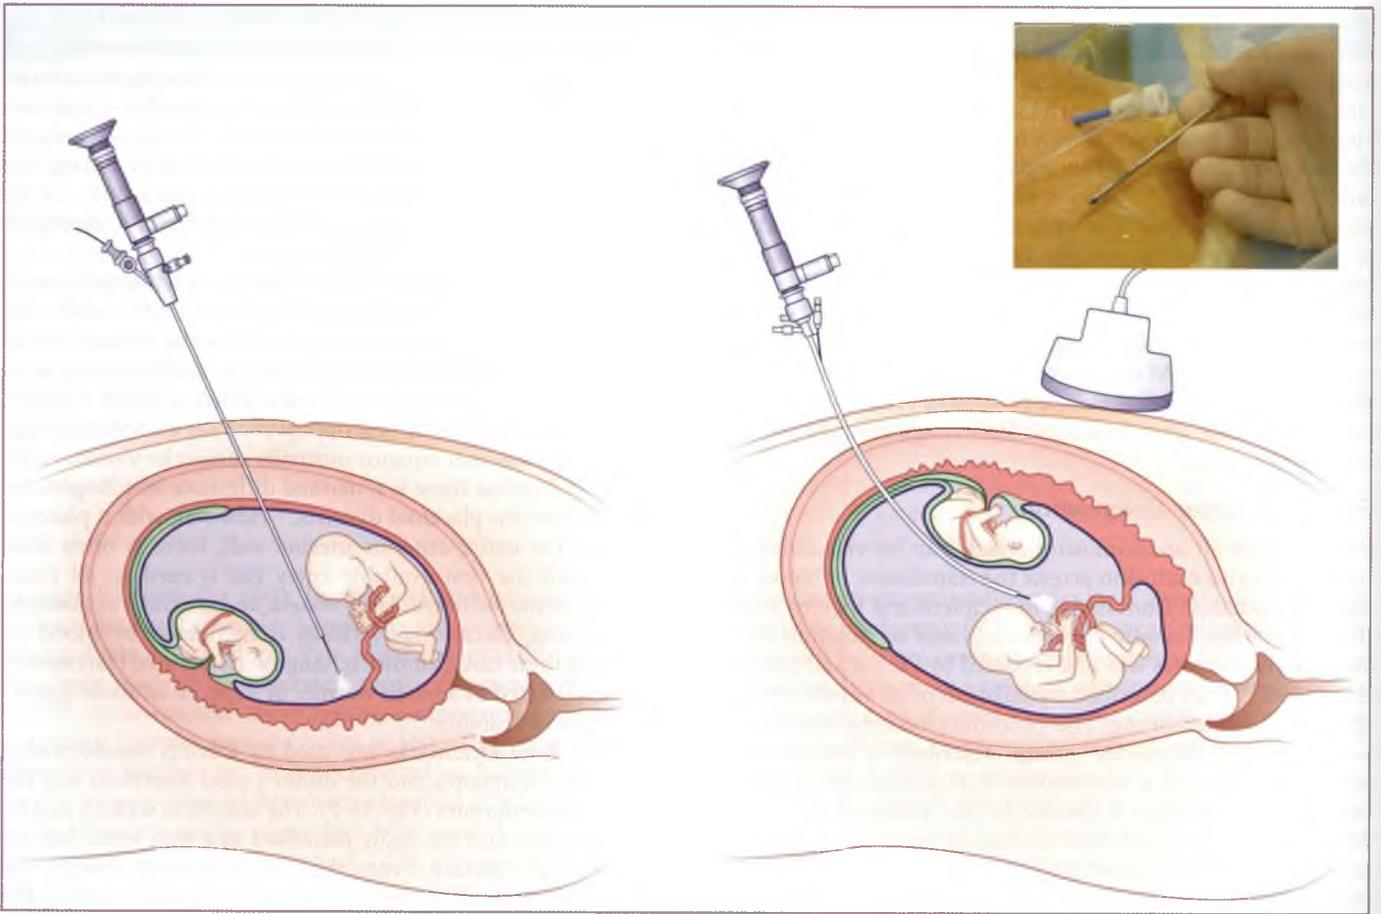

Figure 35-6 Schematic drawing of fetoscopic laser coagulation. With a posterior placenta, some use direct insertion of the scope through the sheath without a cannula (*left*). In the case of an anterior placenta (*right*), a curved sheath and flexible cannula are used (*insert*). This allows change of instruments, for a minimal increase in diameter. (Drawing by K. Dalkowski; reprinted with permission of Endopress Karl Storz.)

(DVP, 5 to 6 cm) is measured ultrasonically. The cannula or sheath is removed under ultrasound guidance to detect any significant bleeding from the uterine wall.

With an anterior placenta, the recipient's sac as well as the anastomosing vessels may be much more difficult to access. Instruments for anterior placentas have been developed, but it is unclear whether they improve performance. Nonflexible rod lens telescopes have been fabricated with angles of inclination up to 30 degrees or with an associated deflecting mechanism for the laser fiber.⁸² Steerable fiberscopes have been used for an anterior placenta but are limited by suboptimal image quality due to poor light transmission (unpublished observations). Also, side-firing laser fibers have been developed for anterior placentas.⁸³ So far, similar outcomes have been reported for anterior and posterior placentas.^{37,47} This may be because outcome is determined by other factors than treatment failure, such as miscarriage or unequal placental sharing. For the difficult anterior placenta, we usually use a curved sheath with a semiflexible 0-degree fiberoptic scope and coagulate from within the cannula at a lower power setting (5 to 15 W). Coagulation from within the cannula facilitates vessel obliteration because correction is possible to a more perpendicular angle and the vessel is compressed by the cannula. At the same time, the cannula prevents inadvertent fiber contact with the

placenta. With the difficult anterior placenta, transplacental entry is more common and may become apparent only after amnioreduction, but it should not be associated with a worse outcome.⁸⁴

Postoperatively for the first few days, a ultrasonography is performed daily to document fetal viability, amniotic fluid volume, and changes in the phenotypic features of TTTS, particularly bladder filling and Doppler parameters. Postoperative transient hydropic changes or absent or reversed *a* wave in the ductus venosus may occur in the donor twin.^{85,86} These usually are not associated with a poor prognosis and possibly reflect a hemodynamic adaptation to the interruption of the transfusion process. Also, for donors with absent end-diastolic flow before laser treatment, reappearance of positive end-diastolic flow is observed in 53%. Laser coagulation may equalize previously discordant umbilical venous blood flow between donor and recipient.^{87,88} Catch-up fetal growth has also been described. Although laser therapy appears to prevent the increased arterial stiffness in donor twins treated by amnioreduction,⁸⁹ it remains to be demonstrated whether it also reduces the incidence of cardiac sequelae in recipient twins. A 7% prevalence of pulmonary valve stenosis was reported in recipients managed primarily by amnioreduction,⁹⁰ whereas a similar prevalence of 7% to 8% was observed in recipients managed by laser.^{91,92} At present,

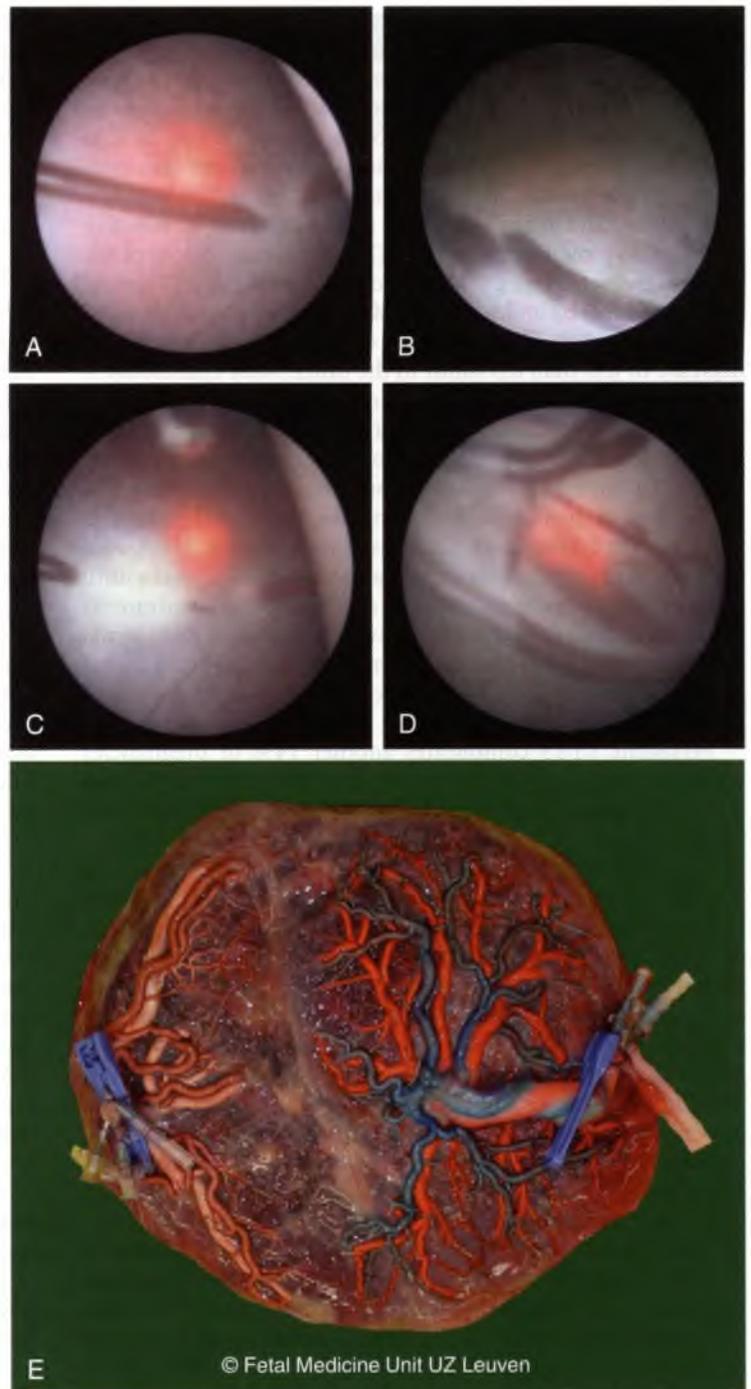

Figure 35-7 Arteriovenous anastomosis at the time of inspection (A) and during coagulation (B). C, Vessels crossing the membranes; this is not necessarily where they anastomose. D, An arterioarterial anastomosis. E, Injected placenta after successful laser coagulation.

all of our patients undergo detailed echocardiography before and after laser coagulation to document the influence of laser treatment on cardiac function.

Complications

Fetal complications after laser treatment include postoperative fetal demise, isolated severe intertwin hemoglobin discordance, and persistent TTTS. Postoperative single IUFD occurs in about 33% and double IUFD in 4% of pregnancies. Single IUFD seems to affect donors and recipients equally.⁹³ Whereas double IUFD seems to be related to large missed unidirectional

anastomoses, several factors may explain single death, such as unequal placental sharing, intraoperative transfusion imbalances, missed anastomoses, or severe cardiac dysfunction.⁹⁴ About 60% of IUFDs are diagnosed within 24 hours and 75% within 1 week of the intervention.⁵⁵ In contrast, with amnioreduction, IUFD of one or both fetuses usually occurs remotely from the procedure. Also, a surviving twin after laser coagulation appears far less likely to be anemic⁹⁵ or to sustain neurologic complications,⁹⁶ compared with single IUFD survivors after amnioreduction,⁹⁷ when the anastomoses remain patent.

Another previously unrecognized fetal complication is the development of severe intertwin hemoglobin discordance without other signs of TTTS a few days to several weeks after laser treatment; this is now referred to as twin anemia polycythemia sequence (TAPS).⁹⁸⁻¹⁰⁰ TAPS may complicate up to 13% of double survivors of laser photocoagulation but also may occur spontaneously in fewer than 1% of monochorionic pregnancies, and it is more likely in the presence of selective intrauterine growth restriction.¹⁰¹ Doppler measurement of the middle cerebral artery peak systolic velocity (MCA-PSV) identifies such cases by an increase in MCA-PSV of greater than 1.5 multiples of the median (MoM) in one twin and a concomitant decrease of less than 0.8 MoM in the other. Most commonly, it is the recipient who develops anemia, whereas the donor becomes polycythemic. Reverse transfusion through missed, small, unidirectional anastomoses on the chorionic surface may be responsible for this complication.⁹⁴ Because of the frequent occurrence of hemoglobin discordance, close surveillance is recommended after laser treatment, with weekly MCA-PSV measurements for the first month and then every 2 weeks until delivery. Initial treatment consists of cordocentesis with intrauterine transfusion of the anemic twin. However, if the anemia recurs rapidly, and especially if remote from viability, a repeat laser procedure with backup cord coagulation or primary cord coagulation should be considered.

Persistent TTTS complicates another 14% of pregnancies with two surviving fetuses 1 week after laser treatment⁴⁵ and appears to be related to missed, large, unidirectional anastomoses.⁶² Persistent TTTS is diagnosed by recurrent polyhydramnios in the recipient and persistent oligohydramnios with oliguria in the donor. Depending on gestational age, possible treatment options include repeat laser coagulation if the technical conditions are anticipated to be better than before, with backup cord coagulation if laser is not feasible, amnioreduction, or elective delivery. A randomized trial is underway to investigate whether a modified surgical approach, known as the "Solomon" technique, may reduce TAPS and recurrent TTTS. This approach consists of, first, selective coagulation of anastomoses, and, second, additional superficial coagulation on the membranes along the complete vascular equator, from one placental margin to the other (NTR1245; see www.trialregister.nl/trialreg/admin/rctview.asp?TC=1245).

A number of other, rarer complications have been described, most of which occur after amnioreduction as well. These are congenital skin loss, ischemic limb lesions, microphthalmia, and intestinal atresia.¹⁰²⁻¹⁰⁵ These anomalies have also been described in untreated TTTS and in TTTS treated by other methods and therefore may originate from the disease process itself.¹⁰⁶ Similarly, rare incidences of limb or umbilical cord constriction resulting from amniotic membrane disruption can occur, as they can after any invasive intrauterine procedure.¹⁰⁷

Pregnancy complications include pPROM, placental abruption, chorioamnionitis, and miscarriage. Yamamoto and colleagues⁸⁴ addressed the pregnancy complications in a series of 175 laser procedures. At less than 28 weeks, pPROM occurred in 23% of cases and was associated with a poor outcome. Clinical chorioamnionitis complicated 2% of pregnancies and was always preceded by pPROM. Finally, 7% of pregnancies resulted in miscarriage.

Maternal safety of fetoscopic interventions remains a priority, but direct maternal mortality has not been reported to the Eurofoetus registry.¹⁰⁸ Cases of transient maternal mirror

syndrome, placental abruption, chorioamnionitis, and bleeding requiring transfusion have been registered. In the Eurofoetus randomized controlled trial (RCT), there was no severe maternal morbidity (i.e., no woman required admission to the intensive care unit or blood transfusion), although three placental abruptions occurred at the end of the amnioreduction (two in the amnioreduction group and one in the laser group), all requiring immediate delivery.³⁸

Amnioreduction versus Laser Coagulation

The Eurofoetus RCT studied 142 enrolled patients with stage I to IV disease diagnosed between 15 and 26 weeks' gestation; it demonstrated that fetoscopic laser coagulation is currently the best available first-line treatment option for TTTS (Table 35-6). Compared with amnioreduction, the laser treatment was associated with a significantly higher likelihood of the survival of at least one twin to 28 days of life (76% versus 56%). Also, the median gestational age at delivery was higher in the laser group than in the amnioreduction group (33.3 versus 29.0 weeks' gestation), with 42% and 69% of women, respectively, delivering at less than 32 weeks. Also, infants in the laser group had a lower incidence of cystic periventricular leukomalacia (6%, compared with 14% in the amnioreduction group). Importantly, the Eurofoetus trial demonstrated that more than half of severe cerebral lesions identified postnatally appear to have an antenatal origin.^{24,109} A systematic review of this trial and two other observational studies confirmed that laser coagulation appears to be more effective in the treatment of TTTS, with less perinatal neurologic morbidity and mortality.¹¹⁰ Another U.S. RCT comparing laser coagulation with amnioreduction⁴⁷ was discontinued because of poor recruitment. Enrollment was limited to patients with stage II disease diagnosed before 22 weeks' gestation who failed to respond to a single amnioreduction. In this small trial, the 30-day survival rate of at least one twin was 65% with laser treatment and 75% with amnioreduction. This low survival rate with laser contrasts strongly with the 70% rate reported in other series.^{72,75} Several factors may explain the lower survival rate in this RCT, including low patient numbers, relatively limited experience with the technique, and relatively limited knowledge of placental vascular anatomy.

Huber and coworkers¹¹¹ demonstrated a significant trend of reduced survival after fetoscopic laser treatment with increasing stage in a consecutive series of 200 pregnancies. The percentage of pregnancies with survival of both twins was 75.9% for stage I, 60.5% for stage II, 53.8% for stage III, and 50% for stage IV. At least one twin survived in 93.1% at stage I, 82.7% at stage II, 82.5% at stage III, and 70% at stage IV (Table 35-7). The survival rate of donors (70.5%) was similar to that of recipients (72.5%). In a U.S. series, there was no difference in overall perinatal survival by stage, but the chance of dual survival was stage dependent (I, 79%; II, 76%; III, 59%; IV, 68%; $P < .01$), primarily because stage III pregnancies were associated with decreased donor twin survival ($P < .01$).¹¹²

Several studies have demonstrated better outcomes with increasing operator experience.¹¹³ Hecher and colleagues documented improved survival,¹¹⁴ later gestational age at delivery, and a decrease in neurodevelopmental impairment¹¹⁵ with increasing experience. Finally, cases with amnioreduction before laser treatment may have caused a prejudicial degree of recipient cardiac dysfunction. In view of the available evidence, use of serial amnioreduction should be restricted to cases with side-by-side insertion of the umbilical cords, with large anastomoses

TABLE 35-6 Characteristics and Outcomes of Study Participants in the Eurofoetus Trial*

	Laser n = 72	Amnioreduction n = 70	P value

between the umbilical cord vessels, or with a gestational age of 26 weeks or more and stage I disease with technical limitations to visualize the equator.

With regard to long-term follow-up, a follow up study on survivors from cases managed in Hamburg (children aged 14 to 44 months), neurologic problems were observed in 22% of survivors, including 11% mild cases and 11% severe.¹¹⁶ In a later series by the same group, 7% of infants showed minor and 6% showed major neurologic abnormalities.¹¹⁵ The reduced neurologic impairment in the second report may be explained by increased operator experience. These results were significantly better than the 16% minor and 26% major abnormalities reported in a cohort treated with amnioreduction.¹¹⁷ In another series, treatment with fetoscopic laser coagulation by the Leiden group resulted in a 17% incidence of neurodevelopmental

impairment and a 7% rate of cerebral palsy at 2 years of age.¹¹⁸ The latter rate was significantly lower than the 26% cerebral palsy rate after amnioreduction in an earlier report by the same group.¹¹⁹ In all of these series, neurologic impairment affected donors as frequently as recipients (see Table 35-7).

The long-term neurodevelopmental follow-up from the Eurofoetus trial has now also been reported, albeit with mixed results, on children up until the age of 6 years. The number of children lost to follow up was low ($n = 10$). There were no differences in the rate of cerebral palsy between those who received fetoscopic selective laser coagulation (9/69, 13%) and those who received amniodrainage (6/41, 15%). Neurodevelopmental assessment using Ages and Stages Questionnaires were better in the laser group at age 5 only; by age 6, there were no longer any differences when children were assessed by the Wechsler

Intelligence Scale for Children. It has been suggested the discrepancy between these findings and those of the previous (nonrandomized) studies may be caused by underestimation of neurodevelopmental impairment in the amniodrainage group in this follow-up study. In the original Eurofoetus study, more neonates in the amniodrainage group had severe neurologic anomalies diagnosed that led to either neonatal death or the withdrawal of intensive care. If this group of children had survived, a much greater difference in neurodevelopmental outcome at age 6 would be expected. If this is indeed true, fetoscopic laser therapy continues to afford the best short- and long-term neurodevelopmental outcomes compared with alternatives.^{120,121}

MEASURES TO IMPROVE THE OUTCOME OF TTTS

Although laser coagulation is associated with better survival rates and possibly less neurologic impairment than amnioreduction, the ideal treatment has not yet evolved. A first goal should be to reduce the number of missed anastomoses, because these may lead to death of both twins, severe intertwin hemoglobin discordance, persistent TTTS, and co-twin death or neurologic impairment in the event of single IUFD.^{45,55,71} Also, severe cerebral lesions are more common after failed laser surgery.²⁴ In a series using dye injection of placental vessels, missed anastomoses were present in 33% of examined placentas.¹²² Another suggestion is that surgical results would be optimized by concentrating experience with this procedure in a few

centers of excellence that can achieve a sufficient case load. It has also been proposed that a sequential selective technique with coagulation of all AV anastomoses from donor to recipient before coagulation of those from recipient to donor would decrease the number of donor deaths.⁸¹ Complete bichorionization by additional superficial lasering between anastomoses may be helping. However, the benefit of these technical adaptations still need to be addressed in a prospective randomized trial.

Careful case selection may also help to improve outcome. Although combined stage I and II cases had better outcomes after laser treatment than after amnioreduction in the Eurofoetus randomized trial, only 11 patients had stage I disease.⁴⁷ Quintero and coworkers actually reported a survival benefit of amnioreduction in stage I, with intact survival rates of 100% compared with 86% after laser treatment.⁷⁵ An RCT is now underway investigating fetoscopic laser surgery versus expectant management for stage I TTTS (information at <http://clinicaltrials.gov/ct2/show/NCT01220011>).

Selective cord coagulation may also be offered in selected cases with an inaccessible vascular equator, additional severe discordant anomalies, pPROM of the recipient sac, or imminent IUFD due to end-stage cardiac failure or growth restriction.⁶⁹ Preoperative antenatal identification of significant brain damage by ultrasonography or MRI and use of late selective feticide by cord occlusion may reduce the number of infants with severe developmental impairments. This approach necessarily raises some ethical questions, especially because prediction of the extent of neonatal impairment on antenatal imaging

may be insufficiently accurate. Nevertheless, parents who opt for fetal surgery are also usually given the choice of immediate termination of pregnancy. It therefore seems reasonable to have the option of a late selective feticide when severe cerebral damage is diagnosed before or after in utero treatment.

Finally, iatrogenic pPROM remains a major complication of all invasive antenatal procedures. Postnatally, fetoscopically induced membrane defects are easily identifiable and show minimal evidence of spontaneous healing.^{123,124} Sealing ruptured membranes with intra-amniotic injection of platelets and clotting factors^{23,125,126} may be successful in two out of three cases. Alternatively, placement of collagen plugs or scaffolds can be contemplated, although the efficacy of this procedure has not been demonstrated.¹²⁷

Selective Feticide for Other Complications

Umbilical cord ligation has become an historical procedure.^{3,4} Needle-based coagulation techniques using laser, monopolar, and radiofrequency energy^{96-98,128-131} involve the insertion of a 14- to 17-gauge needle into the fetal abdomen under ultrasound guidance, aiming for the intra-abdominal rather than umbilical vessels. This technique is attractive for its simplicity, the smaller membrane defect produced, and the intuitive expectation that the risk for pPROM would be less. However, intrafetal coagulation may be effective only for the low-flow conditions associated with TRAP sequence and may be less able to arrest the flow in a monochorionic twin with two heartbeats.

Early on, laser, or later, bipolar coagulation of the umbilical cord is possible for all indications from 16 weeks onward.^{5,69} For early interventions, a small, double needle loaded with a 1-mm fetoscope and a 400- μ m laser fiber can be used.^{132,133} The advantage of laser is the relatively small access diameter and optimal visual control, but it may fail beyond 20 weeks because of the larger size of the umbilical cord vessels.^{39,40,71,134} For later gestational ages, ultrasound-guided bipolar cord coagulation has been introduced. There are 2.4- or 3-mm reusable or disposable forceps available, depending on the target cord diameter. Under ultrasound guidance, a portion of the umbilical cord is grasped, and coagulation is begun at low power, approximately 20 W for approximately 15 seconds, with progressive increments until the appearance of turbulence and steam bubbles, indicating local heat production and, hence, tissue coagulation (usually between 27 and 45 W). Higher initial energy settings are avoided to prevent tissue carbonization, which can cause the cord to adhere to the blades of the forceps and possibly also cord perforation. Confirmation of arrest of flow distal to the occlusion is obtained by color Doppler ultrasonography after relief of the forceps. For safety, two additional cord segments (preferably at a site more proximal to the target fetus) are coagulated. After completion, normal amniotic fluid volume should be reestablished. Septostomy should be avoided. Postoperatively, serial MCA-PSV evaluations are performed to detect any fetal anemia.

Intrafetal needle-based coagulation has been described using laser, monopolar, or radiofrequency energy. The latter has become quite popular and has the advantage that the hardware steers the coagulation process safely and effectively. It was initially introduced for TRAP sequence but is used more widely now.^{128,134,136}

RESULTS OF SELECTIVE FETICIDE IN MONOCHORIONIC TWINS

The survival rates of series reporting at least 10 cases of umbilical cord coagulation in monochorionic twins are summarized in Table 35-8. In dichorionic and monochorionic triplets, the technique resulted in a similar survival rate of 79%.⁶⁹ About half of the losses occurred in the postnatal period and were attributable to very preterm birth, typically after pPROM.^{5,40,69} The other half of the deaths were cases of intrauterine demise of the healthy co-twin, split evenly between death within 24 hours of the surgery, for which potential causes are vessel perforation, incomplete cord coagulation, and, in the case of laser coagulation, exsanguination of the surviving twin. Postoperative anemia diagnosed by PSV-MCA measurements within 24 hours and requiring an intrauterine transfusion occurred in 2% to 3% of cases but resulted in a normal outcome in all instances.^{5,69} Late IUFD was diagnosed up to 10 weeks after the procedure and was typically related to cord entanglement after (inadvertent) septostomy. The last finding supports the use of cord transection after septostomy, just as in monoamniotic gestations.⁶⁹

The specific coagulation energy settings and optimal time points in gestation that offer the best outcomes overall is uncertain. In a systematic review, Rossi and D'Addario reported an overall survival rate of 79% in the co-twin, with a 15% risk of IUFD and a 4% risk of neonatal death.¹³⁷ They confirmed that the risk of fetal death is 6.5-fold higher within the 2 weeks following the procedure. Survival appears to be almost 30% more likely when the procedure is performed after 18 weeks' gestation. With regard to the technique used, co-twin survival appeared to be greater after radiofrequency ablation (86%) or bipolar cord coagulation (82%) than after laser cord coagulation (72%) or cord ligation (70%). However, the incidence of neonatal death was higher after radiofrequency (6%) or bipolar coagulation (6%) than after laser coagulation (3%) or ligation (2%).

Bebbington and colleagues¹³⁸ published a retrospective review of radiofrequency ablation (RFA) compared to bipolar umbilical cord occlusion for cases of severe TTTS, discordance for fetal anomalies, and severe intrauterine growth restriction. Fifty-eight successful cases of RFA and 88 successful cases of bipolar laser occlusion were identified from 1996 to 2010. Despite the smaller-caliber instrument for RFA, there appeared to be no advantages in terms of obstetric outcomes. Survival rates of the co-twin were higher in the bipolar group (87% versus 70%, $P = .01$), and rates of pPROM were not significantly reduced (27% versus 14%, $P = .5$). The mean gestational age at the time of the procedure was 20 weeks and the median gestation at birth was 34 weeks in both groups. In another series, Paramasivam and colleagues¹³¹ reported on the use of RFA in 35 monochorionic pregnancies at a median gestation of 17 weeks. Co-twin survival was just under 90%, with a median gestational age at birth of 36 weeks. There was one miscarriage, two stillbirths, and one termination of pregnancy after abnormal MRI of remaining fetus in this study. There was no apparent difference based on indication.

INDICATIONS FOR SELECTIVE FETICIDE IN MONOCHORIONIC TWINS

Monochorionic twin pregnancies appear to have an especially high risk of severe discordant structural anomalies.¹³⁹ In a

*Cases of multifetal pregnancy reduction are not presented in this table.

GA, gestational age; L-AAVV, laser photocoagulation of the arterioarterial and venovenous anastomoses; RFA, radiofrequency ablation; TRAP, twin reversed arterial perfusion; TTTS, twin-twin transfusion syndrome.

prospective report of 200 monochorionic twin pairs identified during the first trimester, major congenital anomalies occurred in 6% of twin pairs, and in all cases only one fetus was affected.⁶ The exact mechanism of this increased prevalence in monozygotic twins is debated, including errors in zygotic splitting resulting in abnormalities such as midline defects.¹⁴⁰ In monozygotic monochorionic twins, vascular events during embryogenesis or during later fetal life may account for at least part of the brain and cardiac anomalies that occur.^{50,141}

Discordance in karyotypes has been reported for almost all common human aneuploidies (trisomy 13,¹⁴² trisomy 21,¹⁴³ monosomy 45,X⁹⁶). Our series of selective feticide includes six such cases of discordant chromosomes in monochorionic twins (46,XY/47,XY,+21; 46,XX/47,XX,+13; two cases of 46,XY/45,X; and two cases of 46,XX/45,X).¹⁴⁴ These rare heterokaryotic monochorionic twins can be diagnosed prenatally only if an amniocentesis is performed of both amniotic sacs, which is therefore recommended in the event of discordant anatomic anomalies in monochorionic twins.

Severe early discordant growth in monochorionic twins, which carries a high risk of demise of the growth-restricted

twin, may also constitute an indication for selective feticide to protect the surviving twin against the adverse effects of spontaneous demise of its co-twin. In the absence of TTTS, a difference in birth weight of greater than 25% occurs in about 7% to 15% of monochorionic diamniotic twin pregnancies. Although the incidence is similar to that reported in dichorionic twin pregnancies, the mortality and neurologic morbidity of severe discordant growth are significantly higher in monochorionic twin gestations because of the almost uniformly present vascular anastomoses.^{145,146} Unequal placental sharing of the single monochorionic placenta is almost certainly involved in the pathogenesis of birth-weight discordance in monochorionic twins,¹⁴⁷ with birth-weight discordance correlating strongly with placental territory discordance.^{117,148}

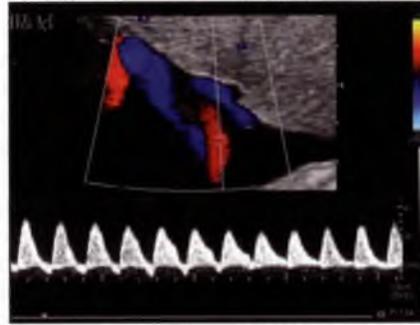

Gratacos and coworkers suggested a classification system for severe growth-discordant monochorionic twin pregnancies according to the umbilical artery Doppler flow in the smaller twin: positive (type I), persistent absent or reversed (type II), or intermittent absent or reversed end-diastolic flow (type III).¹⁴⁹ These three types correlate with different clinical behaviors and different placental sharings and anastomotic patterns (Fig. 35-8).

MC Twin with Growth under 10th Percentile with Doppler Changes in Umbilical Artery

"Typical" A/REDF

Intermittent A/REDF

Surveillance with biophysical profile, nonstress test, and Doppler
 Admission and lung maturation in a tertiary unit from 28 weeks onward with nonstress test – two weekly Doppler and BPP
 Active intervention if deterioration
 Selective feticide prior to viability
 Delivery when viable

Doppler less reliable
 Undefined good surveillance scheme
 Admission and lung maturation in a tertiary unit from 28 weeks onward with nonstress test – two weekly Doppler and BPP
 Elective preterm delivery at 32-33 weeks
 Selective feticide when evolution to TTTS or hydrops
 Higher risk for IUFD and neurologic impairment in survivors

Figure 35-8 Algorithm for monochorionic (MC) twin pregnancies complicated by selective intrauterine growth retardation. A/REDF, absent or reversed end-diastolic flow; BPP, biophysical profile; TTTS, twin-twin transfusion syndrome; IUFD, intrauterine fetal death.

Growth-discordant monochorionic twin pregnancies with positive end-diastolic flow (type I) usually have the best prognosis, with the lowest risks of deterioration (0%), unexpected IUFD of the growth retarded twin (2.6%), and parenchymal brain lesions in the larger twin (<5%).⁵⁰ Type I cases have placental sharing and vascular anastomoses similar to those in uncomplicated pregnancies. In contrast, growth-discordant monochorionic twin pregnancies with persistent absent or reversed end-diastolic umbilical velocity have the worst prognosis, carrying the highest risk of fetal deterioration (90%) but a low risk of unexpected IUFD of the growth-retarded twin (0%) and a relatively low risk of parenchymal brain lesions in the larger twin (<5%).

Type II cases have a pattern of vascular anastomoses similar to that observed in type I cases but with a more pronounced unequal placental sharing.⁵⁰ Selective feticide by umbilical cord coagulation is considered an option in previable type II cases.⁶⁹ Laser coagulation of the vascular anastomoses, as performed for TTTS, has been described. Quintero and colleagues⁸³ reported experience with 11 cases managed by laser coagulation of the vascular anastomoses and compared it with 17 cases managed expectantly; there was no significant difference in survival or neurologic morbidity between treated and expectantly managed patients.¹⁵⁰ Also, in the 11 cases managed by laser coagulation, 5 were complicated by IUFD of the growth-retarded twin, and in 4 cases with 2 survivors, the degree of growth discordance remained stable or increased after surgery.

The type III cases with discordant growth and intermittent absent or reversed end-diastolic flow have the most unpredictable course, carrying a low risk of fetal deterioration (11%) but a high risk of unexpected IUFD of the growth-retarded twin (15%) and of parenchymal brain lesions in the larger twin (20%).⁵⁰ In 20% of cases, the larger twin showed signs of

hypertrophic cardiomyopathy, although this did not result in an increased rate of short-term neurologic or cardiac complications.¹⁵¹ Placentas of type III cases are more unequally shared and more commonly have large AA anastomoses compared with placentas from cases with positive or persistent absent end-diastolic flow.

TWIN REVERSED ARTERIAL PERFUSION SEQUENCE

An extreme manifestation of TTTS is the TRAP sequence, which complicates about 1% of monochorionic twin pregnancies. In TRAP, blood flows from an umbilical artery of the pump twin in a reversed direction into the umbilical artery of the perfused twin, via an AA anastomosis. The perfused twin's blood supply is by definition deoxygenated, and this results in variable degrees of deficient development of the head, heart, and upper limb structures. Two criteria seem to be necessary for the development of a TRAP sequence. The first is an AA anastomosis, and the second is discordant development¹⁵² or a cardiac intrauterine death of one twin, allowing for reversal of blood flow. The increased burden to perfuse the parasitic twin puts the pump twin at risk for congestive heart failure and hydrops.¹⁵³ Because of the rarity of the disorder, the natural history of antenatally diagnosed cases is still poorly documented, with reported survival rates for the pump twin varying between 14%¹⁵⁴ and 90%.¹⁵⁵ Data on long-term outcome are not available, although the risk of cardiac and neurodevelopmental sequelae may be high as a result of vascular imbalances in utero.^{156,157}

Within ultrasound screening programs, TRAP is now diagnosed in the first or early second trimester. In the absence of a

defined natural history, these cases are challenging. Several parameters have been suggested to indicate poor prognosis, such as a high weight ratio of the acardiac twin to the pump twin,¹⁵⁸ a rapid increase in the acardiac mass,¹⁵⁹ and small differences in the umbilical artery Doppler values.^{160,161} These parameters were, however, studied in the late second and third trimesters and do not necessarily apply in the early second trimester, when spontaneous resolution as well as sudden death of the pump twin remain unpredictable.

Early intervention is an option at or after 16 weeks' gestation. The risk of miscarriage is higher if a breach of the membranes is performed before obliteration of the coelomic cavity. As the basis of a potential intervention protocol, Lewi and colleagues documented the natural history of 26 pregnancies diagnosed with TRAP sequence in the first trimester,¹⁶² of which 2 were terminated and 24 were given prophylactic intervention at or after 16 weeks' gestation. In 8 (33%) of 24 cases, spontaneous fetal death of the pump twin occurred before the planned intervention. In 5 (21%) of the 24 cases, there was spontaneous cessation of flow, and in 11 (46%) of these cases, there was continued flow to the acardiac twin at the time of intervention (at 16 to 18 weeks' gestation). In the latter group, 90% of infants survived the "prophylactic" intervention, and in 90% delivery occurred after 32 weeks' gestation. This report highlighted the hidden mortality in TRAP sequence between the first and second trimesters. In the half of the cases that exhibited spontaneous cessation of blood flow to the acardiac twin, 85% of the co-twins died or suffered brain damage.

For those pregnancies that do reach 16 weeks, early prophylactic intervention rather than later intervention may preclude the technical difficulties of achieving arrest of flow in larger and often hydropic acardiac masses, as well as cardiac failure. This observation supports a protocol of offering prophylactic, minimally invasive intervention if no spontaneous arrest of flow has occurred by 16 weeks' gestation, recognizing that the pump twin may survive without any intervention in at least half of cases. For later procedures, umbilical cord coagulation and needle-based intrafetal coagulation techniques are both suitable treatment options.

The largest experience with fetoscopic laser coagulation for this indication was by Hecher and coworkers ($N = 60$), who reported an 80% survival rate.¹⁶³ In 15% of their cases, additional bipolar coagulation was necessary to arrest umbilical flow. Intrafetal coagulation techniques constitute a good alternative and may be the preferred method when access is difficult because of a short umbilical cord or placental location.^{97,106,128}

Chorioangioma

Chorioangiomas are hamartomas of the primitive chorionic mesenchyme that arise from angioblastic tissue. They occur in 1% of microscopically examined placentas and as such are the most common nontrophoblastic placental tumor. Small tumors usually go undiagnosed unless the placenta is carefully examined. Typically, they remain asymptomatic if they are small (i.e., <4 cm).¹⁶⁴ Larger tumors, occurring in 1:3500 to 1:9000 births, are associated with polyhydramnios (18% to 35%), oligohydramnios, nonimmune fetal hydrops, cardiomegaly with or without heart failure, growth restriction, thrombocytopenia, premature labor (10%), fetal malformations, and IUFD (16%).¹⁶⁵ Maternal complications include microangiopathic hemolytic anemia and thrombocytopenia, consumptive

coagulopathy, toxemia, abruptio placentae, fetomaternal transfusion, hemolysis, and hemoglobinuria.

The pathophysiology includes excessive transfer of fluid into the amniotic cavity from an increased tumoral vascular area, venous obstruction or functional insufficiency within the placenta, and fetal heart failure. Heart failure may result from the combination of a hyperdynamic fetal circulation or mass return of poorly oxygenated blood from the nonfunctional placental area, anemia, and hypoalbuminemia. The overall mortality rate is approximately 30% in the case of large angiomas, half of them due to IUFD. The most frequent cause of fetal loss cited in the literature is prematurity, followed by fetal heart failure and hydrops. Poor prognostic factors include tumor size, polyhydramnios, cardiac failure, and location close to the umbilical cord insertion.^{166,167}

In utero treatment is focused on fetuses at risk for IUFD, but there are no validated selection criteria. Beyond the point of ex utero viability, delivery is the treatment of choice, except in the case of anemia, when transfusion may be attempted. Before viability, in utero therapy can be offered in cases of "imminent" or evident fetal heart failure consisting of intrauterine fetal transfusion^{168,169} with or without interruption of the vascular supply, documented by either ultrasound-guided¹⁷⁰⁻¹⁷¹ or endoscopic^{166,176-178} techniques.

Sacroccygeal Teratoma

Sacroccygeal teratoma (SCT) is the most common neoplasm in the newborn and yet it is rare, with an incidence of 1:35,000 live births. It is three to four times more common among female newborns. SCTs are believed to originate from the pluripotent cells in the Hensen node of the primitive streak. These cells can differentiate into embryonic tumors (mature and immature teratomas) or extraembryonic tumors (choriocarcinomas and yolk sac teratomas). The midline distribution of SCTs could be explained by the aberrant migration of the primordial germ cells. Other, less frequent teratoma locations are the anterior mediastinum, pineal area, retroperitoneal area, neck, stomach, and vagina.

SCTs are an extragonadal form that arise in the presacral area; they can extend into the pelvis and abdominal cavity or develop more exteriorly. Extension forms the anatomic basis for the classification by the American Academy of Pediatrics, Surgical Section (Box 35-2), but this is a descriptive surgical classification that does not provide prognostic information regarding the likely prenatal or postnatal course. Local extension can cause secondary problems (Table 35-9).

BOX 35-2 TYPES OF SACROCCYGEAL TERATOMA AS DEFINED BY THE AMERICAN ACADEMY OF PEDIATRICS

- Type I: Predominantly external, with minimal intrapelvic extension
- Type II: Mainly external, with significant intrapelvic extension
- Type III: Visible external, but predominantly internal
- Type IV: Internal, although external parts may be visible

From Altman RP, Randolph JG, Lilly JR: *Sacroccygeal teratoma: American Academy of Pediatrics Surgical Section Survey—1973*, *J Pediatr Surg* 9:389-398, 1974.

Ultrasound examination by experienced sonographers allows a high rate of detection of SCT, even as early as the first trimester.¹⁷⁹ Ultrasound is usually sufficient, together with Doppler studies, for documenting location and measuring the impact of the tumor, but MRI can be used adjunctively for differential diagnosis of type III and type IV.¹⁸⁰ Because the presence of an abnormal karyotype is rare with isolated SCT, amniocentesis is usually not required as part of the workup.¹⁸¹

After in utero diagnosis, most pregnancies proceed without incident. In rare cases, preterm labor develops, usually linked to the occurrence of polyhydramnios. Fetal demise may occur, usually from high-output cardiac failure associated with a large AV fistula.^{182,183} A fast-growing tumor markedly increases metabolic demands, leading to fetal anemia. Less common causes of anemia are hemorrhage within the tumor or into the amniotic

fluid. These latter complications are of greater concern at the time of birth.¹⁸⁴⁻¹⁸⁶ SCT may also cause obstetric problems such as preterm labor with polyhydramnios or, for large tumors, dystocia or rupture at the time of birth. SCT may further induce a complex maternal syndrome characterized by edema and hypertension, referred to as maternal mirror syndrome.¹⁸⁷ The leading cause of death from SCT in the postnatal period is malignant invasion, but this is not the case before birth. Postnatal surgery for resection of the lesion has a low mortality and morbidity in skilled hands.

PROGNOSTIC FACTORS

Although the finding of a fetal SCT has in general a favorable prognosis, there is a subset that will develop problems during pregnancy. Bond and coworkers¹⁸³ determined that 10 of 10 hydropic fetuses and 9 of 9 with placentomegaly died (Tables 35-10 and 35-11). As a proof of the principle that the fetal decompensation arises from the adverse circulatory influence of the SCT, prenatal resection of the tumor has been shown to reverse fetal hydrops and allow fetal survival.¹⁸⁸

It may be questioned whether hydrops is a critical parameter for predicting outcome, because in the Bond series,¹⁸³ two fetuses without hydrops died. Also, in a later report by Hedrick and colleagues, fetuses in two of the five IUFs showed no hydrops¹⁸⁶ but actually had reversed flow in the ductus venosus with normal cardiac output.¹⁸⁹ The others had increased cardiac output. It would seem logical that tumor size would also be related to the risk of cardiac failure. Westerburg and colleagues¹⁹⁰ could not confirm that tumor size was predictive of demise, but the highest death risk occurred in fetuses with the most highly vascularized tumors, regardless of size. Hydrops was defined as subcutaneous edema and either ascites, pleural effusion, or pericardial effusion, and absence of hydrops was identified as a

TABLE 35-10 Occurrence of Hydrops* and Outcome after Sacrococcygeal Teratoma

Author, Year	Cases (No. with Hydrops)	Survival and Hydrops Data	Proposed Criteria for in Utero Management
Bond et al, 1990	48 (10)	Overall mortality: 17/48 Survival with hydrops: 0/10 Death without hydrops: 2/17 (one with placentomegaly)	Survival in presence of placentomegaly: 0/9 One death without hydrops but with placentomegaly
Holterman et al, 1998	21 (1)	Overall mortality: 33% Hydrops present in only 1	Solid tumors and polyhydramnios are risk factors
Westerburg et al, 2000	17 (12)	Overall mortality: 8/17 Survival with hydrops: 4/12 including fetal therapy in 3 out of 4 Death without hydrops: 0/5	Size is not an independent predictor Hydrops is an ominous sign and is more likely with highly vascular and mainly solid tumors Improved survival to be expected with combination of factors
Neubert et al, 2004	7 (1)	Overall mortality: 2/7 Survival with hydrops: 0/1 Death without hydrops: 1/6 (fetus with ascites and born prematurely)	Suggest balanced decision on ultrasound signs of heart failure (hydrops, placentomegaly, cardiomegaly) and the use of Doppler studies. Risk for prematurity is other concern.
Benachi et al, 2006	44 (3)	Overall mortality: 11/44 (25%) Survival with hydrops: not specified	Mortality is confined to group 2—those with large (>10 cm) diameter and fast growth or high vascularity OR with cardiomegaly or other signs of heart failure (dilation of vena cava) (these are the ones at highest risk)
Wilson et al, 2009	23 (4)	Total perinatal mortality 11/23 (48%) Survival with hydrops: not specified	Tumor growth rate >150 cm ³ per week appears to be a predictor of increased perinatal mortality

*Hydrops was defined as subcutaneous edema with either ascites, pleural effusion, or pericardial effusion.

From Benachi A, Durin L, Maurer SV, et al: Prenatally diagnosed sacrococcygeal teratoma: a prognostic classification, *J Pediatr Surg* 41:1517-1521, 2006.

TABLE 35-11 Proposed Classification of Sacrococcygeal Teratoma Based on Prenatal Tumor Development

Category	No.	Mean Gestational Age at Diagnosis	Prenatal Interventions in This Case Series	Mean Gestational Age at Birth
Group 1: small tumors (<10 cm) with a poor vascularity and slow growth	13	24.0 ± 1.6	No fetal intervention	38.0 ± 0.47
Group 2: large (>10 cm) tumors with fast growth (>8 mm/wk) and high vascularity OR high-output cardiac failure (cardiomegaly and increased diameter of inferior vena cava)	21	23.2 ± 0.9	One embolization and one cyst puncture for obstetric reasons	31.0 ± 1.03
Group 3: large (>10 cm) tumors, but predominantly cystic, poorly vascularized, or slowly growing	10	22 ± 1.2	None apart from cyst puncture for obstetric reasons	37 ± 0.3

From Benachi A, Durin L, Maurer SV, et al: Prenatally diagnosed sacrococcygeal teratoma: a prognostic classification, *J Pediatr Surg* 41:1517–1521, 2006.

specifically positive prognostic sign, with all nonhydropic fetuses surviving. In contrast, eight of nine hydropic fetuses experienced antenatal demise. Later gestational age at delivery (37.7 versus 27.5 weeks) was predictive of survival, and presence of polyhydramnios was not.

Benachi and coworkers looked for features of cardiac failure in 44 fetuses with SCT (mean gestational age at diagnosis, 22.8 weeks), most of them identified through second-trimester ultrasound screening.¹⁹¹ The prenatal loss rate (13%) was similar to the rate of postnatal loss (12%), and prematurity occurred in 45%. They divided cases into three groups based on clinical and ultrasound presentation, in a way comparable to what was suggested by Westerburg earlier (see Table 35-11). Larger, faster-growing tumors with significant effect on cardiac function (group 2, $N = 21$) led to earlier delivery and a greater incidence of polyhydramnios. Eleven of these 21 infants died in the neonatal period (52%), but 8 (72%) of the 11 who died were nonhydropic. Survivors from this group had significant morbidity, such as intraventricular hemorrhage, pulmonary hypertension (and other steal syndromes), and acute renal failure, and three infants had a rectal perforation or sepsis requiring colostomy.

A good prognosis in cases with smaller tumors and those with less circulatory impact was confirmed in another study from the Harris Birthright Centre (London). Makin and colleagues reported on 29 cases diagnosed in the prenatal period.¹⁹² Of the 17 who did not require fetal intervention, one died because of associated anomalies. The long-term outcome (average, 39 months) was excellent, with one child having constipation. There were 12 fetal interventions including laser ablation ($n = 4$, all for hydrops), alcohol sclerosis ($n = 3$, all for hydrops), cystocentesis ($n = 2$, to facilitate delivery), and amniodrainage ($n = 2$, polyhydramnios), and vesicoamniotic shunt ($n = 1$, fetal bladder obstruction). Although 9 of the 12 fetuses with prenatal intervention survived until birth (mean gestational age at birth, 33 weeks), 6 of the 7 cases with hydrops at presentation resulted in fetal or neonatal demise.

PRENATAL TREATMENT

On the basis of these studies, it can be inferred that small tumors (<7 cm) are without significant impact on the fetus and that these pregnancies can be followed with serial sonography to term delivery. Larger or more vascular tumors (no cutoff has been defined) should be followed more carefully, with

measurements of tumor size and amniotic fluid volume and with Doppler studies of cardiovascular function and tumor vascularity. The method of delivery should be altered only when direct trauma to the sacral tumor or dystocia is feared. Recently, Rodriguez and colleagues described a tumor volume-to-fetal weight ratio (TFR) as an early prognostic classification for fetal SCT.¹⁹³ In a series of 10 fetuses, those with a TFR less than or equal to 0.12 calculated before 24 weeks' gestation had improved prognosis. Conversely, the four fetuses who became hydropic had a TFR greater than 0.12. This finding now needs validation by others.

Currently, prenatal intervention is done based on the presence of presumed risk factors for fetal death, such as hydrops or other signs of heart decompensation. Interventions include drainage of polyhydramnios, correction of fetal anemia, and shunting of secondary urinary obstruction. Clinical experience with any of these interventions is very scarce (Table 35-12). Successful bladder shunting was first reported (at 28 weeks) by Jouannic, and since then by others.^{191,192,194} Fetal anemia can be documented noninvasively, by measurement of the peak systolic velocity in the middle cerebral arteries, and easily corrected.¹⁹⁵

The best-studied intervention is in utero resection of an anatomically resectable tumor (American Pediatric Surgical Association [APSA] category I or II) by open fetal surgery under direct intraoperative cardiac monitoring to assess complications of fetal surgery in a timely manner. In one study, one fetus required cardiac resuscitation during the procedure, probably because of hemorrhage. Four days later, that fetus developed ductus arteriosus constriction, was delivered at 27.9 weeks because of chorioamnionitis, and died 6 hours later. One survivor had rectal stenosis from the use of the stapler on the stalk, and other morbidities as well, which were believed to be related to embolic events that may have occurred during surgery. One long-term survivor developed chronic lung disease, probably as a result of prematurity (27.6 weeks). Among these four fetuses operated on in utero, there was one recurrence. The same researchers later advocated restriction of such surgery to isolated cases with type I SCTs, gestational age 20 to 30 weeks, absence of placentomegaly (placental thickness measured at the cord insertion placental location, >35 to 45 mm), an early hydrops, and combined cardiac output 1600 to 1900 mL/kg/min adjusted for gestational age. Wilson updated the Philadelphia experience on 23 fetuses. One third were lost antenatally, half due to termination of pregnancy; three IUGFs occurred

Jouannic et al, 2001	1	None; obstructive uropathy	Intrauterine shunting for bladder obstruction	39 wk; intact outcome including renal function
Lam et al, 2002	1	Cardiac enlargement, tricuspid regurgitation, placentomegaly, no hydrops	18-gauge needle, thermocoagulation	IUFD 2 days later, unknown cause; no immediate hemorrhage
Paek, 2001	4	—	Radiofrequency ablation, 15-gauge needle	2 IUFD; 2 born alive with collateral damage
Hedrick et al, 2004	4	High-output cardiac failure	Tumor resection	29 wk (range, 27.6-31.7 wk); 3 survivors, 1 neonatal death; 1 with severe embolic problems
Perrotin, 2006	1	Polyhydramnios, tricuspid regurgitation, cardiac enlargement, subcutaneous edema, pericardial effusion, fetal anemia	IUT and 20-gauge needle, histoacryl embolization 0.7 mL	29 wk; 1300-g fetus, 1300-g tumor; alive and well at 1 year
Benachi et al, 2006	44	Cyst puncture for obstetric reasons or obstructive uropathy (group 2 tumors): in utero intervention attempted	Embolization and cyst punctures (5) or shunting (4)*	Failed embolization of middle sacral artery; group 2 fetuses had poorer survival despite therapy
Ruano et al, 2009	1	Hydrops, severe heart failure	Percutaneous laser ablation of feeding vessel	IUFD 2 days later; significant intratumoral hemorrhage

*“(5)” and “(4)” indicate the number of punctured fetuses. IUFD, intrauterine fetal demise; IUT, intrauterine transfusion.

due to hydrops or rapid tumor growth (>150 cm³/wk). Recently, they also proposed that fetuses be delivered early in selected cases with gestational age greater than 27 weeks when fetal surgery is not possible.¹⁹⁶

Less invasive techniques have also been described. Lam's group used monopolar thermocoagulation by a needle directed toward the feeding vessels.¹⁹⁷ Ruano and coworkers¹⁹⁸ used laser, but in both cases the fetus died postoperatively. Speculations about gas embolization, hyperkalemia from tissue necrosis, hemorrhage, and hyperthermia have been made. A more recently reported method is RFA, but this is also not without risks. Although dissemination of energy with RFA can be better predicted than when using interstitial laser or monopolar cautery, considerable morbidity has resulted from collateral damage to adjacent structures.

OUTCOMES

The most important (albeit rare) cause of death in the postnatal period is malignant invasion. For that reason, patients must be closely monitored. Those with mature tumor histology have an undisputedly favorable prognosis.¹⁹⁹ Rescorla and coworkers reported a neonatal mortality rate of 5.6%, leaving 117 cases for follow-up.²⁰⁰ Tumors initially reported as benign teratoma had a significant recurrence rate (11%) at 6 to 34 months after resection. In tumors with mature features on histology (most being endodermal stromal tumors), recurrences occurred in fewer than 20% and were usually successfully treated with adjuvant chemotherapy. Only 1 of the 24 patients with an immature teratoma had benign recurrence (mature teratoma).

De Backer and colleagues reviewed 70 cases, almost one third with late postnatal diagnoses; 84% were treated by surgery only.

Five patients (7%) had recurrence, all with malignancy in the secondary tumor, and two of these patients died.²⁰¹ The authors claimed that recurrence was more likely if the coccyx was not removed at the time of primary surgery, and this observation has been supported by others as well.²⁰² Among 14 survivors in the CHOP experience, 2 had late recurrences, one in a mature tumor and the other in an immature tumor, both recurring as an endodermal sinus tumor.

SCT can cause collateral damage to pelvic organs, with some damage occurring in utero and other damage attributable to surgical resection. For instance, in utero bladder rupture and urinary tract obstruction have been reported. Also, functional rectal and urinary problems may be more frequent when a considerable portion of the tumor is in the pelvis, which might elongate the pelvic plexus and sacral nerves.²⁰³ In the larger Paris experience, temporary colostomy was the most common complication, occurring in 1 of 13 patients in the group with small tumors and in 3 of 11 survivors in the group with fast-growing larger tumors. The morbidity in the third group was mainly related to postoperative scarring or local infection. Long-term bladder or bowel function was not reported. Urologic sequelae were most common (>40%), and this may have been related to tumor growth as well as to surgical trauma during removal. In a retrospective study of 14 infants investigated with urodynamics for urinary tract dysfunction after postnatal resection at Children's Hospital in Boston, both detrusor overactivity (8/14) and underactivity (2/14) were documented.²⁰⁴ Reflux was frequent (50%), and hydronephrosis was present in 6 of 14 patients. Abnormal sphincteric function was very common (>80%). Four were catheterized, and 5 of the 14 were being given anticholinergics. Antireflux surgery was performed in 6 of 14. Data on renal function were not reported.

This study did not report on the anatomic features of the initial tumor, which makes it impossible to determine whether the damage resulted from the surgery or from the preexisting tumor.

In conclusion, the prenatal diagnosis of SCT should prompt detailed ultrasonography to rule out associated anomalies and to assess the tumor anatomy and vascularity to provide predictive information about potential fetal consequences (e.g., pelvic compression, cardiac failure, fetal anemia) or obstetric complications (e.g., polyhydramnios). Overall, the prognosis for SCT is good, especially if the tumor remains small. The anatomic extent of the tumor has neither direct prenatal prognostic value nor oncologic prognostic significance. However, cases exhibiting large tumor size, a fast growth pattern, and high tumor vascularization appear to have a poorer outcome. The development of hydrops is particularly ominous, but that may be a late sign for fetal intervention. A decision for prenatal intervention in the previable period is probably best made on the basis of a combination of indicators, such as signs pointing to cardiac failure or indicating an increased chance of early delivery.

Isolated Congenital Diaphragmatic Hernia

ETIOLOGY AND CONSEQUENCES OF CDH

The prevalence of CDH ranges between 1 and 4 per 10,000 births, making it a rare disease. Based on birth rates for 2008 in the 27 countries of the European Union, between 542 and 2168 children with CDH may be born yearly.²⁰⁵ The exact etiology of the condition remains unknown. The term *CDH* does not designate one, single clinical entity, and outcomes are accordingly diverse. The embryology and molecular and genetic mechanisms behind the disease are beyond the scope of this chapter but are excellently reviewed elsewhere.²⁰⁶ Most cases are left sided (LCDH), and 13% are right sided (RCDH); bilateral lesions, complete agenesis, and other rarities comprise fewer than 2%. CDH can occur in association with other anomalies (in which case the mortality rate is greater than 85%) or as an isolated condition.

Ultrasound screening programs have led to prenatal diagnosis of CDH in two thirds of the cases (Fig. 35-9). Diagnosis of

Figure 35-9 Sonographic images of a fetus with congenital diaphragmatic hernia. A, Measurement of the lung-to-head ratio (LHR) in a section through the four-chamber view using the "longest axis method" and "tracing method." B, Measurement of LHR 1 day after balloon insertion, with changed echogenicity. C, Herniation of the liver. D, Visualization of the major vessels helps identify the position of the liver.

CDH should prompt referral to a tertiary center that is experienced in assessing this anomaly and managing CDH in the perinatal period.²⁰⁷ A comprehensive diagnostic and prognostic workup comprises advanced imaging, genetic testing, and multidisciplinary counseling so that parents can make a well-informed decision.²⁰⁸ Isolated CDH is theoretically a surgically correctable defect in the diaphragm, but beginning with herniation of abdominal contents into the thorax, lung development is adversely affected. Relative or severe hypoplasia of both lungs may ensue, with fewer airway branches and abnormal pulmonary vessels as well as reduced lung compliance. This causes postnatal ventilatory insufficiency and pulmonary hypertension, and the fetus may die before the defect can be surgically repaired. Despite optimal tertiary neonatal care, the mortality rate of CDH still is as high as 30%. Survivors may have several morbidities, such as bronchopulmonary dysplasia and persistent pulmonary hypertension, gastroesophageal reflux, and feeding problems; less frequently, they have thoracic deformations after successful repair.^{209,210}

PRENATAL ASSESSMENT OF CDH

Although the fetal diaphragm can be visualized with high-resolution equipment even in the first trimester, the diagnosis of CDH is typically suggested when abdominal organs are visualized in the chest or cardiac deviation is noticed on a four-chamber cardiac view (see Fig. 35-9). Left-sided CDH typically manifests with a rightward shift of the heart and mediastinum and coincident presence of echolucent stomach and intestines. The existence of abdominal viscera in the thorax may be identified by the presence of peristalsis. The liver may also be herniated in left-sided CDH, but it is more difficult to differentiate liver from lung sonographically (see Fig. 35-9).

Right-sided CDH cases are more difficult to diagnose because liver has similar appearance to mid-trimester fetal lung. However, the right lobe of the liver typically shifts the heart and mediastinum to the left, and this abnormal arrangement provides the major clue to the presence of a diaphragmatic defect. Doppler interrogation of the umbilical vein and hepatic vessels or the location of the gallbladder may be used as additional landmarks to define the position of the liver. Cardiac compression and polyhydramnios are indirect signs of right-sided CDH.

The main differential diagnoses are other pulmonary pathologies, such as cystic masses (cystic adenomatoid malformation; bronchogenic, enteric, and neuroenteric cysts; mediastinal teratoma; and thymic cysts), bronchopulmonary sequestration, or bronchial atresia. In these conditions, intraabdominal organs are not displaced.

After the diagnosis of CDH, the first goal is to exclude additional abnormalities. Karyotyping is an essential step, but the finding of normal chromosomes does not exclude other genetic conditions and syndromes. Modern genetic techniques are therefore increasingly used^{211,212} and have been reviewed elsewhere.²¹³ A customized array targeting genes previously linked to CDH has been developed and applied to fetuses with apparently isolated CDH.²¹⁴ In almost 4%, a genomic imbalance was found, and two of three analyses identified genes earlier tied to CDH. Today, genome-wide comparative hybridization is technically feasible and applicable to CDH.²¹⁵ However, the interpretation of the detected copy number variations (CNVs)—particularly those that exhibit reduced penetrance or variable expression, incidental findings not clearly related to the anomaly

involved, or unclassified variants—remains difficult. In addition to genetic analyses, detailed imaging of fetal structures helps rule out associated anomalies. These include, in descending order of frequency, cardiac defects (52%) and genitourinary (23%), gastrointestinal (14%), and central nervous system anomalies (10%).²¹⁶

INDIVIDUALIZED PRENATAL PREDICTION OF CDH OUTCOME

In view of the considerable potential morbidity associated with prenatal management in the worst cases, accurate prediction of anticipated outcomes is crucial. Individual prediction is primarily based on estimation of lung size, which is a proxy for pulmonary hypoplasia. This can be done by ultrasonography²¹⁷ or by fetal MRI-volumetry.²¹⁸ Assessment of the pulmonary circulation may predict pulmonary hypertension. Lastly, the presence of liver herniation is also predictive.^{218,219} More accurate prediction is possible by combining these elements.^{220,221}

Two-Dimensional Ultrasonography

The most widely used prediction methods are based on assessment of lung size and determination of liver herniation into the thorax by ultrasound, with the so-called lung-to-head ratio (LHR), first described by Metkus in 1996.²²² At the level of the four-chamber view, the area of the lung contralateral to the lesion is measured. The impact of pulmonary hypoplasia is estimated by calculating the lung area and divided by the head circumference measured in the standard biparietal view. Peralta and later Jani and their colleagues demonstrated that the most accurate method for lung measurement is by tracing the lung contours rather than using the transverse or longest diameter (Fig. 35-10).^{223,224} Accurate measurement of the LHR has a significant learning curve.²²⁵

Figure 35-10 At the level of the four-chamber view, the area of the lung contralateral to the lesion is measured and expressed as a function of the head circumference. The most accurate method for measurement is by tracing the lung contours rather than using the transverse or longest diameter.

Peralta and coworkers defined reference ranges for the right and left lung areas between 12 and 32 weeks' gestation. In that period, the lung area increases 16-fold but the head circumference only 4-fold, demonstrating that LHR is actually dependent on gestational age. For that reason, the LHR measurement of an actual index case is better expressed as a function of what is expected in a control of the same gestational age: i.e., observed LHR (O) is divided by the expected (E) LHR. Formulas are used for this purpose and are specific for the measuring technique and the side of the lesion.^{223,226} The prognostic value of the O/E LHR was validated in 354 fetuses with unilateral isolated CDH evaluated between 18 and 38 weeks' gestation, in terms of both mortality and morbidity (Fig. 35-11; Table 35-13).^{227,228} It has also been shown that prediction is more accurate later in gestation.²²⁹ More recently, the predictive value of the O/E LHR was confirmed in a Canadian cohort as well as in a meta-analysis.^{217,230}

Three-Dimensional Techniques

Three-dimensional (3D) ultrasonography and MRI both allow measurement of absolute lung volumes. Experience with 3D

ultrasound has been disappointing, mostly because it has not been possible to measure the ipsilateral lung in 44% of cases.²³¹ However, others have questioned this, and there are prospective ongoing studies to assess the predictive value of 3D ultrasound volumetry.^{232,233}

MRI allows better visualization of the ipsilateral lung than does 3D ultrasonography.²³⁴⁻²³⁶ MRI lung volumetry may become the method of choice after others have validated the findings from a European study that demonstrated the predictive value of lung size in terms of survival, analogous to what was demonstrated for ultrasound.²³⁷ MRI can also demonstrate the presence of liver herniation, and it has the potential to quantify the degree of liver herniation, allowing this parameter to be used as a continuous rather than a binary variable, which may refine prediction.

There is no clear consensus regarding the landmarks needed to define or quantify liver herniation. Defining these may overcome the relative ambiguity concerning "intrathoracic" liver. Several reference points have been proposed. Walsh and colleagues measured the distance between the most apical part of the liver and the dome of the chest. This distance can be

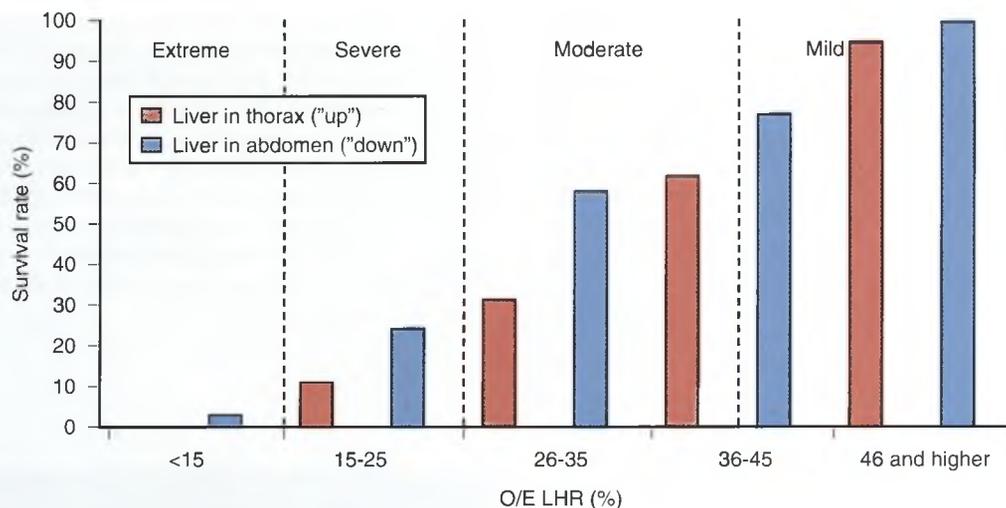

Figure 35-11 Relationship of lung-to-head ratio (LHR) and liver position to survival. The observed (O) LHR is divided by the expected (E) LHR based on gestational age.

TABLE 35-13 Neonatal Outcome as a Function of LHR in Fetuses with Left-Sided Isolated Congenital Diaphragmatic Hernia and Liver Herniation

Degree of Pulmonary Hypoplasia	LHR	Expectant Management*		FETO†

†Jani JC, Nicolaides KH, Gratacos E, et al: Fetal lung-to-head ratio in the prediction of survival in severe left-sided diaphragmatic hernia treated by fetal endoscopic tracheal occlusion (FETO), *Am J Obstet Gynecol* 195:1646–1650, 2006.

FETO, fetoscopic endoluminal tracheal occlusion; LHR, lung-to-head ratio; n.a., not applicable (fetuses were not eligible for FETO).

expressed as a proportion of the distance between the diaphragmatic remnant and the thoracic apex.²³⁴ Others have considered the liver to be intrathoracic when part of the liver is above a reference line drawn from the lower tip of the xiphoid (at midsagittal view) perpendicular to the corresponding vertebral body. The volume of the herniated liver is then expressed as a fraction of the total thoracic volume: the so-called liver-to-thorax ratio (LiTR). In cases with liver herniation (LiTR >0%), the lung volume and the amount of liver in the chest are independent of each other.²³⁶ Overall, the current published data suggest (albeit not conclusively) that liver is truly an independent predictor of outcome, compared to LHRs. The literature on MRI findings in this condition is growing, and in a recent meta-analysis we demonstrated that side of the defect, the position of the liver, and the (O/E) total fetal lung volume as determined on MRI were predictive of outcome.²³¹

Lung Vascularization

A great advantage of ultrasonography is the ability to visualize and measure blood flow without the need for contrast agents. Efforts have been made to document prenatal lung vascular development, but the predictive value of this parameter is not well validated. Measurements of the number of branches, vessel diameters, flow velocimetry or volume, and reactivity to maternal oxygen inhalation can be displayed. Sokol and coworkers demonstrated that the diameter of the ipsilateral-branch main pulmonary vessel is related to outcome.²³⁸ Ruano and associates established nomograms for branch main pulmonary artery diameters.²³⁹ They also investigated the predictive value of 3D power Doppler ultrasonography of the entire lung vasculature in terms of survival as well as the occurrence of pulmonary hypertension.²⁴⁰ Moreno-Alvarez and colleagues investigated the relation between O/E LHR and pulsed Doppler findings in 95 fetuses with CDH and a similar number of controls. They measured the pulsatility index, peak early-diastolic reversed flow, and peak systolic velocity in the proximal branches (first intrapulmonary branch of the main pulmonary artery) of the contralateral lung, as well as the “fractional moving blood volume,” which is a measure of lung tissue perfusion. There was a strong correlation between the reduction of lung tissue perfusion, increased intrapulmonary artery impedance, and lung growth, as evaluated by O/E LHR.^{241,242}

PRENATAL INTERVENTION FOR CDH

In recent years, different strategies have been used to identify optimal candidates for fetal therapy for CDH; these were reviewed by Deprest and associates.²⁴³ Today, the clinical procedure consists of percutaneous fetoscopic endoluminal tracheal occlusion (FETO). The procedure is believed to work because it prevents egress of lung fluid, thereby increasing airway pressure, which promotes pulmonary tissue proliferation, increases alveolar airspace, and encourages maturation of pulmonary vasculature.²⁴⁴ In experimental conditions, sustained tracheal occlusion was shown to reduce the number of type II pneumocytes and hence surfactant expression, which can be improved by in utero release (“plug-unplug sequence”).²⁴⁵

Deprest, Gratacos, and colleagues first described tracheal occlusion as an experimental endoscopic technique using an endoluminal device, which opened the door to a percutaneous, clinically less morbid technique (Fig. 35-12).²⁴⁶ Together with the miniaturization of endoscopes, this has obviated the need

for open surgery or minilaparotomy.²⁴⁷ Morbidity was also reduced by substituting local anesthesia instead of general or locoregional anesthesia and giving fetal analgesia rather than immobilization.²⁴⁸ Soon after the start of the Fetal Endoscopic Tracheal Occlusion Task Force in Europe, the results of the single-center RCT sponsored by the National Institutes of Health (NIH) in the United States were published.²⁴⁹ Survival rate after FETO was greater than 75%, which was no different from the unexpectedly high survival rate in the group managed expectantly. However, most patients in that trial had moderate pulmonary hypoplasia. Because only three patients had an LHR lower than 1.0 (corresponding at 26 to 29 weeks to an O/E LHR of 25% to 27%), the trial was not conclusive for fetuses with severe pulmonary hypoplasia, which were the subject of the clinical study at that time ongoing in Europe.

The FETO Task Force strived to insert the balloon at 26 to 28 weeks' gestation and then to reverse the occlusion at 34 weeks. The latter intervention was included mainly because of experimental observations indicating that this would improve lung maturation.²⁴⁵ Further, prenatal removal of the balloon allowed transfer of the patient to another tertiary center where vaginal delivery would be possible. In utero reversal was achieved either by fetoscopy (50%) or by ultrasound-guided puncture (19%). In the European experience, prenatal removal improved survival chances.²⁴⁷ In the trial by Harrison and colleagues and a later study by Ruano's group, in which the balloon was always removed at the time of birth, similar survival rates were reported (50%; $n = 11$).²⁵⁰

Prenatal balloon removal may not always be possible, for instance if pPROM or preterm labor supervenes. In those cases, the fetal airway must be liberated at the time of delivery, which seems safest when the fetus remains on placental circulation (EXIT procedure, 21%), although in an emergency it can be done postnatally (7%). The technical difficulty of this procedure should not be underestimated. In the series reported by Jani, Nicolaidis, and colleagues, there were difficulties with balloon removal in 10 cases, typically when delivery occurred in a facility that had no experience or only limited experience with fetal or neonatal bronchoscopy. Because failure of balloon removal may lead to neonatal death, it must be avoided.^{247,248,251} Ideally, the patient should remain near the FETO center until delivery or be transferred to a referral center that is able to offer continuous availability of specialists to manage the fetal airway at delivery.

Use of the percutaneous technique with small-diameter endoscopes in the FETO trial reduced the risk of pPROM and early delivery, compared with the results in the NIH-sponsored RCT.²⁴⁹ In the FETO trial ($n = 210$), pPROM occurred within 3 weeks after FETO in 16.7%; the rupture rate before 34 weeks was 25%. Delivery occurred at a median of 35.3 weeks and before balloon removal at 34 weeks in only 30.9%. Compared with earlier data from the antenatal CDH registry, FETO should increase the survival rate among fetuses with severe left-sided CDH from 24.1% to 49.1%, and among those with right-sided CDH from 0% to 35.3% ($P < .001$).²⁵² Short-term morbidity among survivors with severe pulmonary hypoplasia should exceed expectations, being close to that of moderate pulmonary hypoplasia.²²¹ Obviously, fetal intervention does not alter the size of the diaphragmatic defect, so the requirement for repair remains.

Survival has been shown to be dependent on the O/E LHR measured before the procedure.^{48,253} This is explained by the

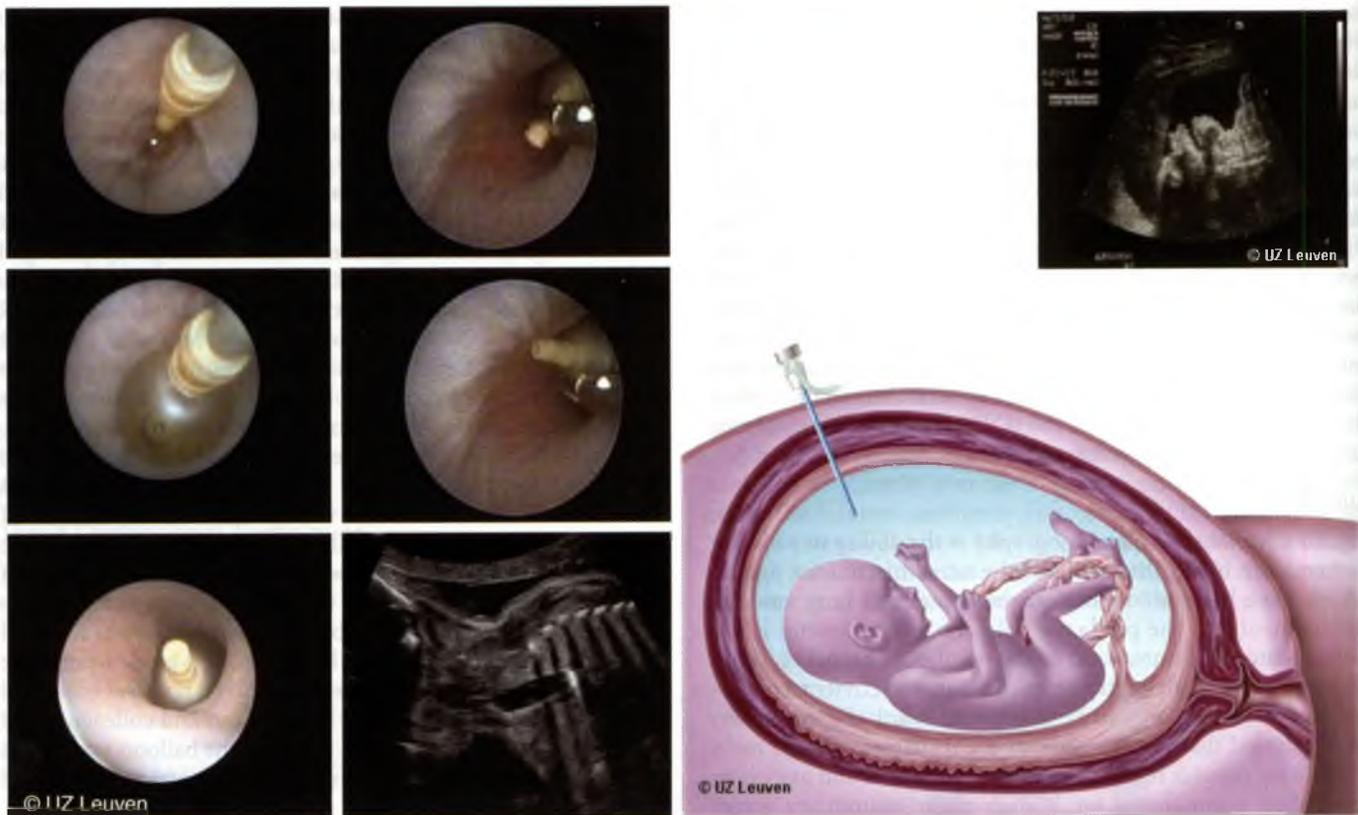

Figure 35-12 Left, top to bottom, Fetoscopic images of balloon insertion. The catheter loaded with the balloon is inserted, the balloon is inflated between carina and vocal cords, and the catheter is then detached. Middle, upper two images, The balloon is retrieved by fetoscopic extraction using a 1-mm forceps. Middle, bottom: ultrasound image of the balloon in place. Right, Schematic drawing of cannula insertion toward the mouth, with ultrasound image at upper right.

relationship between the surface of the airway epithelium and lung size. Smaller lungs have reduced ability to produce lung liquid and therefore create less airway pressure after occlusion. Other predictors are determined by the procedure itself, and many are interdependent. Survival is increased with increasing gestational age at delivery, absence of pPROM, and removal of the balloon more than 24 hours before delivery.²⁴⁷

Balloon occlusion increases tracheal dimensions after birth, a condition termed *tracheomegaly*.²⁵⁴⁻²⁵⁶ Tracheomegaly does not have an obvious clinical impact, except for a barking cough on effort.²⁵⁷ Over time, the widening becomes less significant.²⁵⁴ This experience mirrors the observations from animal experiments, but serious long-term side effects cannot be excluded.²⁵⁸ In Germany, there is a protocol for performing tracheal occlusion later in gestation, which may not be as effective due to a lesser lung response.²⁵⁹

TRIALS COMPARING FETO WITH EXPECTANT MANAGEMENT

FETO has demonstrated the potential for increasing survival and reducing morbidity (see Table 35-13), especially among those with severe pulmonary hypoplasia who had balloon insertion at 27 to 30 weeks' gestation and removal at 34 weeks. Later balloon insertion is associated with a less vigorous lung response.²⁵⁹ Increased survival rates with this protocol were also confirmed in a Brazilian randomized trial.^{260,261} However,

with limited numbers and relatively short follow-up, FETO remains an investigational procedure. To investigate further, an RCT has been initiated.^{262,263} In fetuses with moderate hypoplasia (NCT00763737), occlusion is done at 30 to 32 weeks' gestation and removal at 34 weeks. Both trials take place under the acronym TOTAL (Tracheal Occlusion To Accelerate Lung growth); information is available at www.totaltrial.eu. Postnatal care is standardized according to a consensus protocol.^{264,265}

Congenital Thoracic Malformations

Congenital thoracic malformations (CTMs) are a heterogeneous group of rare disorders that may involve the airways or lung parenchyma. Although CTMs are rare, they may lead to considerable morbidity and mortality. The availability of imaging methods has improved antenatal and postnatal diagnosis but has also introduced complexities to the classification and management of CTMs. Antenatally diagnosed lesions may spontaneously regress before birth, but evidence upon which to advise parents about management options is lacking. In this section, we focus on two conditions that cause the most controversy: congenital cystic adenomatoid malformation (CCAM) and the related malformation, pulmonary sequestration (PS). Notably, it is accepted that some conditions such as bronchogenic cysts and bronchial atresia may be difficult to distinguish until resection.

BOX 35-3 DIFFERENTIAL DIAGNOSIS OF CONGENITAL THORACIC MALFORMATIONS (CONSENSUS PAPER BY EUROPEAN RESPIRATORY SOCIETY)

From Kotecha S, Barbato A, Bush A, et al: Antenatal and postnatal management of congenital cystic adenomatoid malformation, *Paediatr Respir Rev* 13:162–171, 2012.

Prenatally, an accurate pathologic diagnosis is not possible. Instead, detailed descriptions of the appearance of the lesions must suffice (Box 35-3; Fig. 35-13). The classification and nomenclature of CTMs have been reviewed.²⁶⁶ In a consensus paper from the European Respiratory Society, the following principles were advanced regarding CTM observed on prenatal imaging^{267,268}:

1. What is actually seen should be described, without embryologic or pathologic speculation that may later be proved wrong. A simple catch-all term, *congenital thoracic malformation*, should replace the old nomenclature in clinical discussions.
2. A CTM should be described as solid or cystic; if it is cystic, the cysts should be described as single or multiple, large or small (ideally with the size measured rather than estimated), thin or thick walled, and with purely fluid contents or otherwise.
3. The CTM should be described in the context of the rest of the respiratory system, together with any relevant extrathoracic features.

The European Surveillance of Congenital Anomalies (EUROCAT), a network of population-based registries that captures 29% of births in the European Union, reported 222 fetuses with CTMs, yielding an incidence of 4.44/10,000 (including live births, fetal deaths, and terminations of pregnancy), or 3.52 per 10,000 live births. Of the 222 fetuses, 52 had CCAM alone, for an incidence of 1.04/10,000. The separately reported annual proportion of PS ranges between 0.15% and 6.45% of all CTMs.²⁶⁸

CONGENITAL CYSTIC ADENOMATOID MALFORMATION

CCAM is a dysplastic or hamartomatous tumor with overgrowth of terminal bronchioles and reduction in the number

of alveoli. The term *congenital adenomatoid malformation* was introduced in 1949, with *cystic* added in later publications that described types 1 through 3.^{269,270} Types 0 and 4 were subsequently proposed, the hypothesis being that the full range of these lesions extends from type 0, an essentially tracheobronchial defect, to type 4, an alveolar defect. On this basis, the term *congenital pulmonary airway malformation* was proposed instead of CCAM, because only types 1 through 3 were adenomatoid, and only types 1, 2, and 4 were cystic.²⁷⁰ However, as shown in Table 35-14, this classification has not been universally accepted. It seems more likely that types 0, 3, and 4 represent different pathogenetic processes. Such complexities show the inadvisability of embryologic speculation based on pathologic appearance.

CCAM usually appears as a thoracic mass involving only one pulmonary lobe. In approximately 40% of patients, the CCAM has a systemic vascular supply, similar to bronchopulmonary sequestration (BPS), and these forms are defined as hybrid CCAM-BPS. The classic pathologic classification as proposed by Stocker established mainly three types,²⁷¹ but a more comprehensive system was later proposed (see Table 35-14). More recently, the CHOP published a simplified classification of microcystic (solid sonographic appearance) and macrocystic types that can be used clinically.²⁷²

Most CCAMs are detected antenatally. Although many CCAMs regress or even disappear during pregnancy, most remain detectable postnatally on computed tomographic scans. Vigilance is required to detect a large or enlarging CCAM that risks pulmonary compression and fetal hydrops. The presence or absence of fetal hydrops is crucial in determining not only prognosis but appropriate management. Antenatal surveillance using the ratio of the mass area to head circumference (HC), known as the CCAM volume ratio (CVR), has been proposed as a prognostic measure for the development of hydrops.²⁷³ The CCAM volume (in milliliters) is sonographically measured by using the formula for an ellipse:

$$\text{CCAM volume} = \text{Length} \times \text{Height} \times \text{Width} \times 0.52$$

$$\text{CVR} = \text{CCAM volume} \div \text{Head circumference}$$

When the CVR is greater than 1.6, an 80% risk for fetal hydrops is predicted. Sonographic follow-up frequency based on the CVR has been proposed (weekly for CVR <1.2, twice weekly for CVR 1.2–1.6, even more often for CVR >1.6), but this protocol has not been validated. Cardiac function, placental thickness, amniotic fluid volume, and cervical length, if required, should be measured as well.

PULMONARY SEQUESTRATION

PS is divided into intralobar and extralobar types. They are localized lesions comprising lung parenchyma receiving their blood supply via aberrant systemic arteries that lack continuity with the upper respiratory tract.²⁷⁴ These vessels can be detected using two-dimensional or 3D ultrasound with Doppler.^{275,276} Extralobar sequestrations have their own covering visceral pleura, whereas intralobar types are circumscribed lesions within otherwise normal lung. Intralobar sequestrations are typically located in the posterior basal segment of the left lower lobe and extralobar sequestrations beneath the left lower lobe. The mass has an increased echogenicity or MRI signal intensity

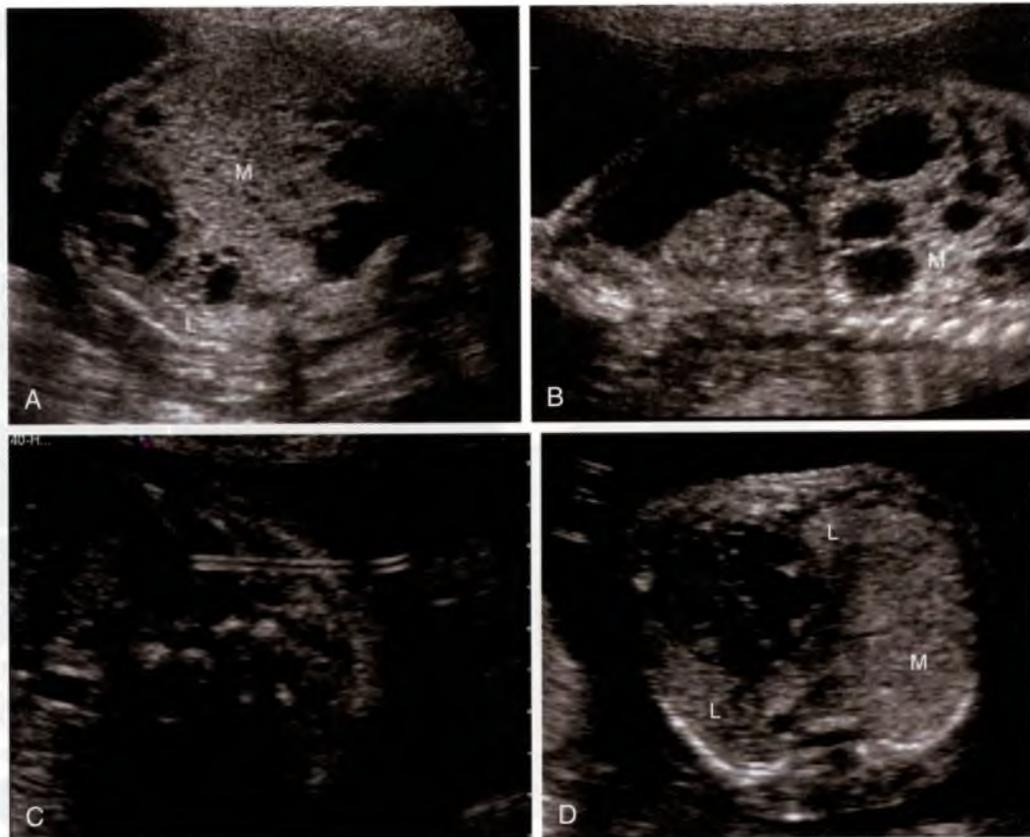

Figure 35-13 Congenital cystic adenomatoid malformation (CCAM). A, A massive right CCAM mass (M) with pronounced mediastinal shift is seen. Notice the small size of the compressed left lung (L). B, Hydrops fetalis was present; ascites can be seen. C, A shunt was placed in the largest cavity. D, Resolution of the hydrops was seen within 1 week. Cross section through the thorax shows expansion of the ipsilateral and contralateral lungs, repositioning of the heart, and reduction of the mass.

TABLE 35-14 Comparison of Two Proposed Classifications of CCAMs

Stocker, 2002	Langston, 2003
Type 0 CCAM —Acinar atresia	Bronchogenic cyst
Type 1 CCAM —Cysts up to 10 cm. The cysts are lined by pseudostratified ciliated cells that are often interspersed with rows of mucous cells.	Bronchial atresia
Type 2 CCAM —Sponge-like, multiple small cysts (<2 cm) and solid pale tumor-like tissue. The cysts resemble dilated bronchioles separated by normal alveoli. Striated muscle is seen in 5%.	<ul style="list-style-type: none"> • Isolated • With systemic AV connection (intralobar sequestration) • With connection to GI tract • Systemic arterial connection to normal lung
Type 3 CCAM —Solid. There is an excess of bronchiolar structures separated by small air spaces with cuboidal lining (fetal lung).	CCAM, large cyst type (Stocker type 1)
Type 4 CCAM —Cysts up to 10 cm. The cysts are lined by flattened epithelium resting on loose mesenchymal tissue.	<ul style="list-style-type: none"> • Isolated • With systemic AV connection (hybrid/intralobar sequestration)
	CCAM, small cyst type (Stocker type 2)
	<ul style="list-style-type: none"> • Isolated • With systemic AV connection (hybrid/intralobar sequestration)
	Extralobar sequestration
	<ul style="list-style-type: none"> • Without connection to GI tract • With connection to GI tract
	Pulmonary hyperplasia and related lesions
	<ul style="list-style-type: none"> • Laryngeal atresia • Solid or adenomatoid CCAM (Stocker type 3) • Polyalveolar lobe
	Congenital lobar overinflation
	Other cystic lesions: lymphatic cyst, enteric cyst, mesothelial cyst, simple parenchymal cyst, regressed type 1 pleuropulmonary blastoma

AV, arteriovenous; CCAM, congenital cystic adenomatoid malformation; GI, gastrointestinal.

From Stocker JT: Congenital pulmonary airway malformation: a new name and expanded classification of congenital cystic adenomatoid malformation of the lung, *Histopathology* 41(Suppl):424–431, 2002; and Langston C: New concepts in the pathology of congenital lung malformations, *Semin Pediatr Surg* 12:17–37, 2003.

due to fluid entrapment, similar to type 3 CCAM lesions. It may be difficult to differentiate the lesion from bronchial atresia if the normal part of the lung becomes compressed. Microscopically, they show dilated airspaces, some lined by bronchiolar-type epithelium, with or without inflammation and fibrosis (see Table 35-14). Features of type 2 CCAM are seen in up to 60% of cases.^{271,277} Rarely, an "airway" connects the sequestration to the esophagus or stomach or ectopic pancreatic tissue is present within the sequestration. PS, especially extralobar types, can be associated with other malformations.

PRENATAL MANAGEMENT OF CCAM AND PULMONARY SEQUESTRATION

For fetuses with macrocystic CCAM (unilocular or multilocular) who become hydropic, fetal intervention to protect residual lung tissue should be considered because of the very poor prognosis of expectant management alone. In a systematic review by Knox and colleagues,²⁷⁸ in utero therapy was associated with significantly improved survival in hydropic fetuses (odds ratio [OR] = 19.28; 95% confidence interval [CI], 3.67 to 101.27), although no randomized trials were identified. Nevertheless, particularly in significantly preterm gestations, fetal intervention is likely to be lifesaving. Proposed antenatal and perinatal interventions include steroid administration, intrauterine puncture or shunting of macrocystic masses (Fig. 35-14), thermocoagulation, and lobectomy via hysterotomy.

Percutaneous puncture and thoracoamniotic shunting of macrocystic masses both have the advantage of minimal invasiveness.²⁷⁹ Wilson and associates²⁸⁰ reviewed their experience with 23 cases with shunt insertion at a mean gestational age of 21 to 22 weeks. The mean CVR in this group was 2.4 and fell

to 0.7 after shunting. The mean interval between shunt and delivery was 11.8 weeks (36.3 weeks' gestational age at birth).²⁸⁰ The overall survival rate was 74%, with one fetal and five neonatal deaths, correlating with a shorter shunt-to-delivery interval. Thoracic deformation has been observed but seems uncommon.²⁸¹ Several other case reports and small series have reported results in the same range. For hydropic fetuses after 32 weeks' gestation, delivery is typically recommended. However, it has been proposed that intervention be considered up to 37 weeks, with a rationale of potentially improving hydrops while the fetus remains on placental support, allowing further lung maturation.²⁸²

For fetuses with microcystic CCAM who develop hydrops and therefore are not amenable to shunting or drainage, the use of prenatal steroids at dosages typically given for fetal lung maturation may result in resolution of hydrops fetalis.^{283,284} Tsao and Curran and their colleagues reported on 13 fetuses with microcystic CCAM and hydrops or a CVR greater than 1.6 who were given prenatal steroids.^{283,285} Hydrops resolved in 78% of cases, and the survival rate was 85%. The mechanism is currently unknown, but it is postulated that steroids accelerate maturation or involution of the lesion. In view of this research, steroids seem a reasonable first-line therapy or medical adjunct in high-risk cases. To explore this issue more definitively, the same group has now embarked on an RCT (see www.clinicaltrials.gov, study NCT00670956).

For solid lesions, lobectomy via open fetal surgery can be considered. In a series of 22 fetuses undergoing surgery between 21 and 31 weeks' gestation, there were 11 long-term developmentally normal survivors.²⁸⁶ Hydrops resolved in 1 to 2 weeks, followed by normalization of the position of the mediastinum, with the remaining lung undergoing impressive catch-up

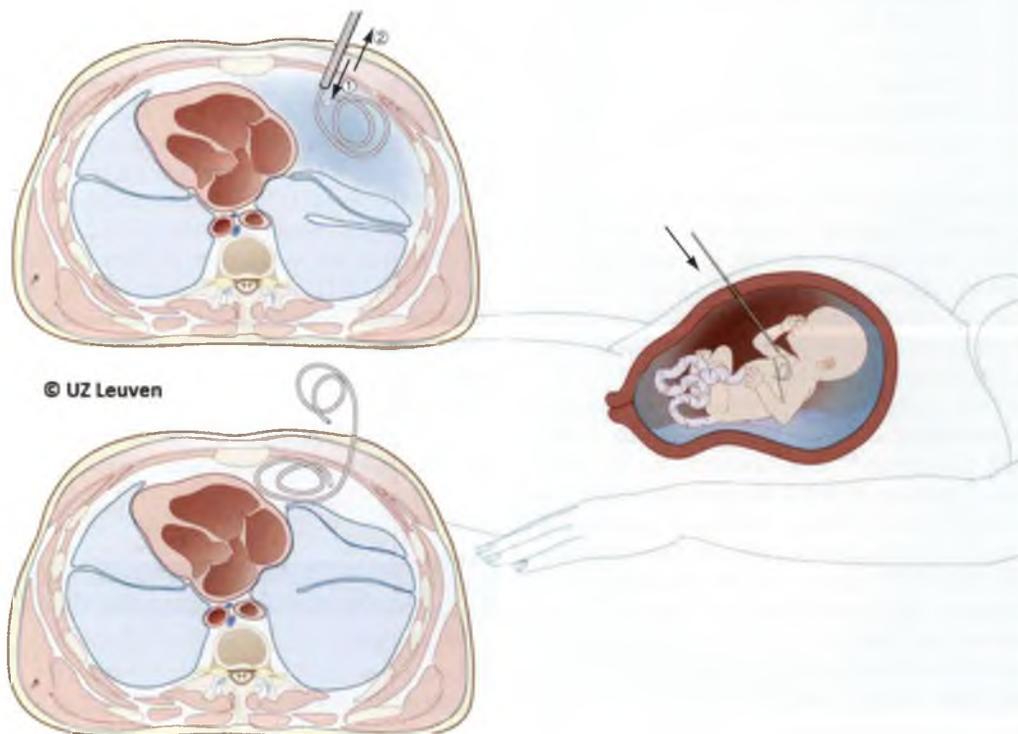

Figure 35-14 Insertion of thoracic shunt. Schematic representation of a thoracic shunt being inserted (top left and right) and deployed (bottom left). (From Van Mieghem T, Baud D, Devlieger R, et al: *Minimally invasive fetal therapy*, Best Pract Res Clin Obstet Gynaecol 26:711–725, 2012.)

growth. Causes of fetal death despite fetal surgery were preterm labor and/or chorioamnionitis ($n = 2$) and fetal hemodynamic compromise leading to intraoperative death in six fetuses and postoperative death in another two cases. To prevent intraoperative death, all prerequisites for fetal resuscitation, such as gaining access to the fetal circulation and appropriate monitoring techniques, should be foreseen. If the CVR is high late in pregnancy (>34 weeks) and respiratory distress is anticipated, EXIT procedure with lobectomy in a tertiary care center may be considered.¹⁴ For prenatal management of CCAM and for PS, minimally invasive techniques have been reported as well. Selective occlusion of the systemic vessel using thermocoagulation (by laser or electrosurgery) or sclerosing agents has been reported with good outcomes.^{287,288}

These results contrast with those after intralesional thermocoagulation performed when no feeding vessel can be visualized (as in most CCAMs). Of the four reported cases, two fetuses survived, both with regression of hydrops.²⁸⁹⁻²⁹² In the four PS cases in which laser ablation was directed to the feeding vessel, all of the fetuses survived.^{282,288,293,294} Sclerosing agents may be an alternative, having perhaps less potential collateral damage but the theoretical disadvantage of embolization.^{287,295}

OTHER THORACIC LESIONS

Fetal pleural effusion or hydrothorax is a symptom of other typical pathologies. Pleural effusions have the potential to cause mediastinal shift, abnormal venous return, and secondary lung compression, in addition to being a cause of fetal hydrops and IUD. Most pulmonary effusions are lymphatic in origin, but they may be part of other problems (25% of cases), including aneuploidy (7%).²⁹⁶ Pulmonary effusions may be bilateral, pointing to pulmonary lymphangiectasia; this carries a poor prognosis despite fetal treatment, because the abnormal lymphatics preclude normal gas exchange in the lung. The principal indication for fetal intervention in case of pleural effusion is generalized fetal hydrops with fluid found in at least one other body cavity, with or without abnormal cardiac function. In the presence of fetal hydrops, the estimated survival rate with pulmonary effusion is about 30%, but it is 80% without hydrops.

Therefore treatment of pulmonary effusion is not warranted unless hydrops is present.²⁷⁸ Survival rates of 60% or more have been observed in large case series. Even when thoracentesis is performed as a first procedure, the effusion may recur within days. After effusion aspiration, cardiac anatomy can be better inspected, and the source of the effusion can be determined from cell content, biochemistry, and karyotyping.

Pleurodesis has been accomplished by injecting a sclerosing agent into the affected hemithorax, but in case of failure it may hamper later shunt placement.²⁹⁷ Thoracoamniotic shunting using a double-pigtail catheter or serial thoracenteses can be performed,²⁹⁸ but there is no evidence that serial puncture is better than shunting. The complication rates are approximately 15% for iatrogenic pPROM²⁹⁹ and 5% to 10% for direct fetal loss. Shunt dislodgment has been described, and posterior insertion may prevent the fetus from pulling the shunt out. Preterm birth is common, with a mean gestational age at birth of 34 to 35 weeks. After delivery, ventilatory support is often needed, and thoracentesis or drainage may be required, with dietary or parenteral supplementation. The overall short-term outcome is good.

Lower Urinary Tract Obstruction

PATHOPHYSIOLOGY

Congenital abnormalities of the genitourinary tract occur in as many as 0.4% of births. Lower urinary tract obstruction (LUTO) is a descriptive term for a number of heterogeneous conditions that are relatively common (1 in 5000 to 8000 male neonates). Posterior urethral valves is by far the most common type (at least one third in autopsy series), but other conditions give a similar clinical picture, including stenosis of the urethral meatus, anterior valves, urethral atresia, ectopic insertion of a ureter, and (peri)vesical tumors. LUTO leads to bladder distention, shaped to the level of the occlusion (keyhole sign), with compensatory hypertrophy and hyperplasia of bladder wall smooth muscle. Over time, compliance and elasticity decrease and may cause poor postnatal bladder function. Elevated bladder pressure prevents urinary inflow from above, and the ureterovesical angle may change, resulting in reflux hydronephrosis. Progressive pyelectasis and calyctasis compress the delicate renal parenchyma within the encasing serosal capsule, leading to functional abnormalities within the medullary and eventually the cortical regions. Focal compressive hypoxia probably contributes to the progressive fibrosis and perturbations in tubular function, resulting in the urinary hypertonicity that is observed. The eventual result is renal insufficiency. Concurrently, amniotic fluid volume falls, and as a consequence—depending on gestational age—pulmonary hypoplasia evolves. This condition is reproducible in animal models, and more importantly, reversal of the obstruction both experimentally and clinically leads to reaccumulation of amniotic fluid.³⁰⁰

LUTO SHUNT CASE SELECTION

Because untreated LUTO can result in lethal pulmonary hypoplasia and renal failure in the neonate, careful selection of candidates for antenatal intervention is paramount to ensure that procedures to relieve LUTO are offered only to fetuses with sufficient renal function.³⁰¹⁻³⁰³ However, fetal renal function cannot be determined with a single urine sample. The best prediction is obtained by two or more sequential vesicocenteses several days apart.³⁰² The commonly recognized prognostic thresholds are shown in Table 35-15.

The prenatal evaluation of fetuses with the sonographic findings of LUTO must be comprehensive, and coexisting structural and chromosomal anomalies must be excluded before intervention can be considered.³⁰⁰ Female fetuses very often have more complex syndromes of cloacal malformation that do not necessarily benefit from in utero shunt therapy. In the presence of oligohydramnios or anhydramnios, karyotypes can be obtained by transabdominal chorionic villus or fetal blood

TABLE 35-15 Fetal Urine Prognostic Thresholds

Electrolytes	Good Prognosis	Poor Prognosis
Sodium (mmol/L)	<90	>100

Total protein (mg/dL)	<20	>40
β_2 -microglobulin (mg/L)	<6	>10

sampling or via structural assessment of the fetus after amnioinfusion.

OUTCOMES FOR ANTENATAL THERAPY FOR LUTO

A vesicoamniotic shunt bypasses the urethral obstruction and diverts fetal urine into the amniotic space; this allows drainage of the upper urinary tract and prevents pulmonary hypoplasia and physical deformations by restoring amniotic fluid volume. In the initial experience, good outcomes were reported.³⁰⁴ In the largest and longest-term documented experience from Baird and colleagues, the type of urinary obstruction (postnatally diagnosed) was highly predictive of long-term renal outcome.³⁰⁵ Fetuses with posterior urethral valves had better outcomes than those with urethral atresia or the prune-belly syndrome. Most children are developmentally normal, but some lag in growth, and pulmonary problems may persist in others. Among 18 survivors in Baird's series, 6 had acceptable renal function, 4 had mild insufficiency, and 6 required dialysis and transplantation.

Other case series have had similar results, suggesting that even with favorable pre-procedure urine profiles, up to half of survivors have chronic renal insufficiency in childhood.^{306,307} The systematic review by Clark and colleagues³⁰⁷ indicated a lack of high-quality evidence to reliably support the clinical practice of vesicoamniotic shunting despite an apparent improvement in perinatal survival (odds ratio [OR] = 2.5; 95% confidence interval [CI], 1.0 to 5.9; $P < .03$). Subgroup analysis indicated that improved survival was most likely in fetuses with

a defined "poor prognosis" (based on a combination of ultrasound appearance and fetal urinary analytes), with an OR of 8.0 (95% CI, 1.2 to 52.9; $P < .03$). Improved perinatal survival was subsequently confirmed in a systematic review in 2010 by Morris and colleagues, but the risk of long-term postnatal renal compromise remained uncertain.^{308,309} Accordingly, a multicenter RCT, referred to as a PLUTO trial, was instituted, and a report is due soon.³⁰⁰ In this study, fetuses with LUTO were randomized to either vesicoamniotic shunt or observation when the treating clinician was uncertain of the need for a shunt.

The ongoing uncertainty in patient selection for fetal bladder shunting demonstrates a need for improvement in predicting long-term postnatal renal function. Several complex algorithms have been proposed, including serum markers (β_2 -microglobulin) and even renal biopsy.^{303,310} It has also been suggested that fetal cystoscopy might improve patient selection,^{311,312} but currently available instruments are the limiting factor: they are too large and too difficult to direct percutaneously to the bladder neck, which is often the area of interest (Fig. 35-15). Both fetoscopic antegrade catheterization and hydroablation or laser ablation of urethral valves have now been described. Ruano reported on 23 fetuses with LUTO in a prospective trial,³¹³ suggesting that prenatal laser ablation of the posterior urethral valve by fetal cystoscopy may prevent renal function deterioration and improve postnatal outcome. A later systematic review of this novel approach concluded that it was still too early for it to be translated into clinical practice outside of a research trial.³⁰⁹

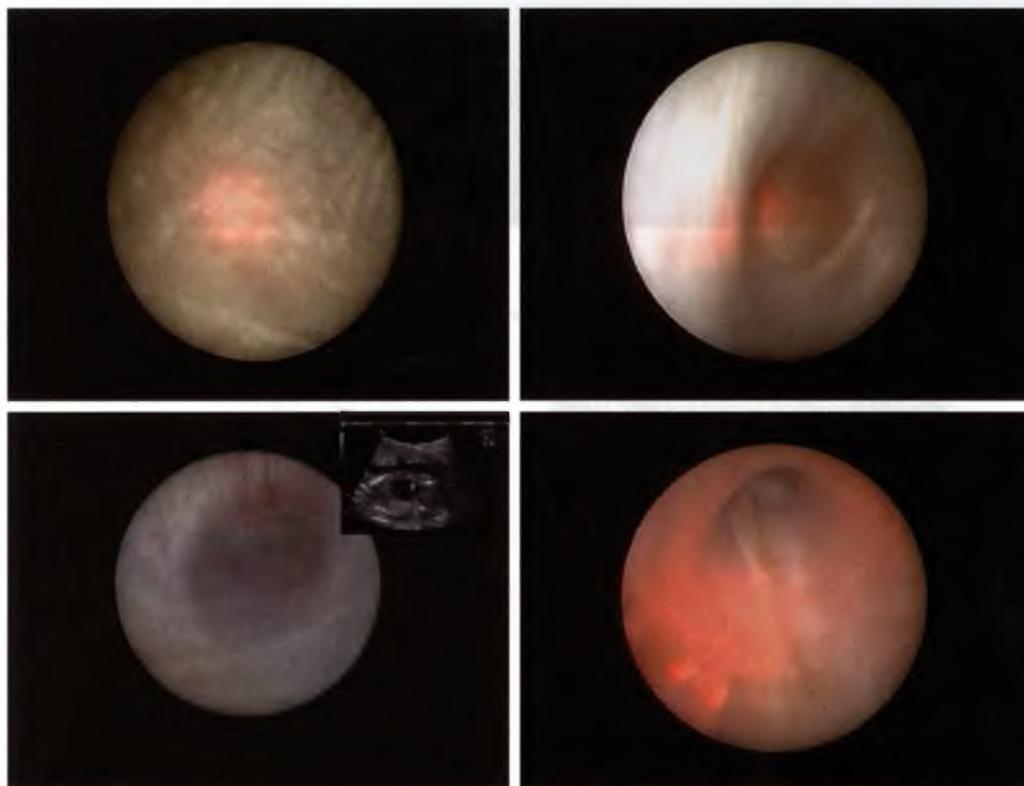

Figure 35-15 Lower urinary tract obstruction. In utero cystoscopy images of (clockwise from top left) a trabeculated bladder, the bladder neck, the ureteral orifice of a bladder with reflux, and laser ablation of the valves. Inset, Ultrasound image of enlarged bladder. Images were obtained through a 1.3-mm fetoscope (17,000 pixels).

Congenital Heart Defects

RATIONALE AND CASE SELECTION

Despite improvements in neonatal (surgical) care and the development of dedicated follow-up programs for infants with congenital heart disease, the outcome of fetuses with hypoplastic left heart syndrome (HLHS) remains poor. This syndrome has become the chief indication for antenatal intervention. Postnatal surgery, which results in a far from optimal single-ventricle Fontan-type circulation,³¹⁴ has a considerable mortality rate, leading to a total survival of less than 65%.³¹⁵ Moreover, half of the long-term survivors have poor neurodevelopmental outcome,³¹⁶ which may in part have an antenatal origin. Indeed, a preferential return of oxygenated blood toward the right ventricle and lower body rather than toward the left ventricle and the brain may lead to suboptimal brain oxygenation in utero.^{317,318} About 5% of HLHS cases develop in the second trimester and are progressive (Fig. 35-16A).³⁰⁷

In these cases, which are often a result of outlet valve obstruction, fetal balloon valvuloplasties may allow for intrauterine

ventricular recovery and growth. Antenatal intervention theoretically reduces intraventricular pressure, improves coronary perfusion (reducing ischemic damage), allows ventricular growth, and avoids induction of myocardial fibroelastosis, thus enabling improved functional (biventricular) postnatal repair. Because one third of fetuses with congenital heart defects have associated extracardiac malformations or aneuploidy, detailed sonography and amniocentesis must be performed.

ANTENATAL INTERVENTION FOR CONGENITAL HEART DEFECTS

Despite initial disappointing attempts with prenatal balloon valvuloplasty for aortic valve stenosis, researchers in Linz, Austria, and in Boston, Massachusetts, pursued the idea of prenatal intervention for severe aortic stenosis. The current criteria for intervention and techniques for needle-based access to the fetal heart are outlined in Table 35-16.

The technical aspects of the procedure have become relatively standard. A cardiocentesis using a Seldinger technique is performed with ultrasound guidance, and the working sheath

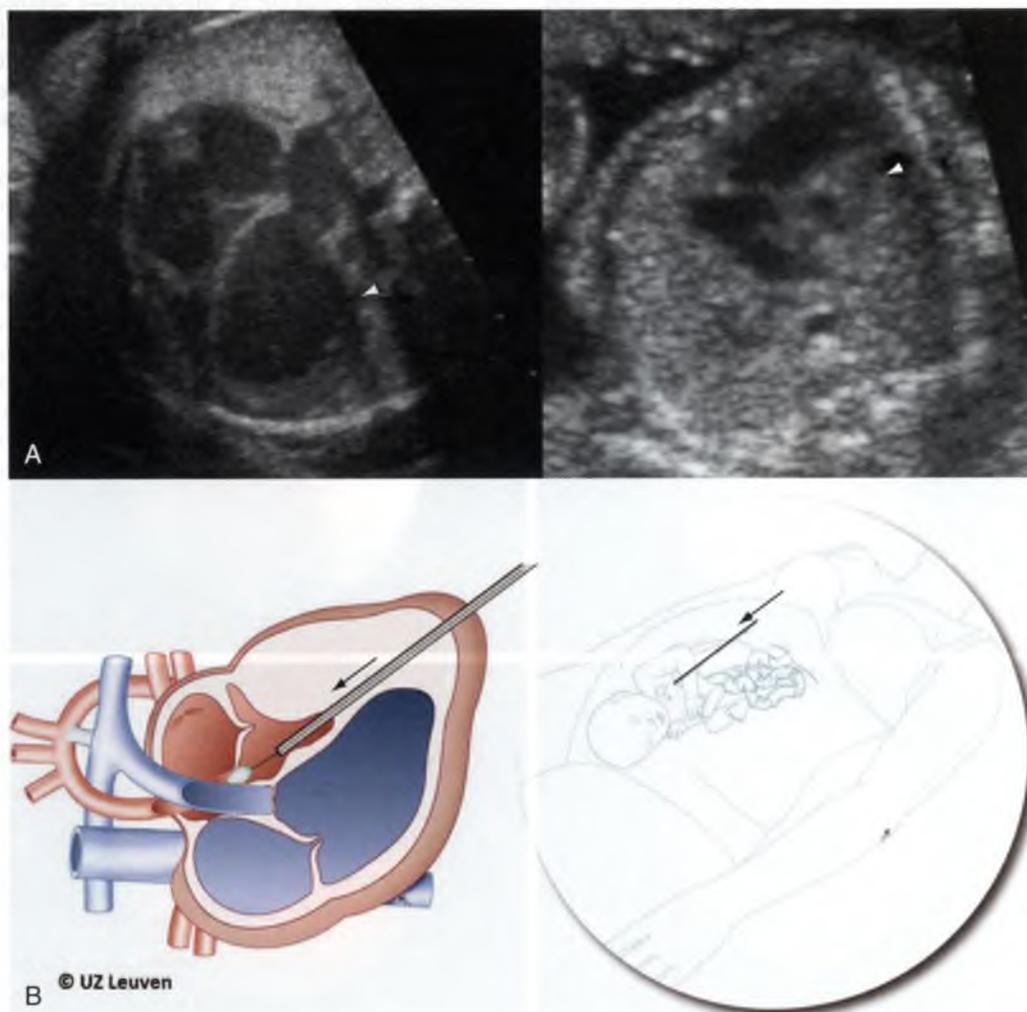

Figure 35-16 A, Ultrasound image (*right panel*) is a cross section at the level of the fetal chest, demonstrating the four-chamber view in a fetus with aortic stenosis. Notice that the left ventricle (*arrowhead*) is dilated. Dilation occurs before the development of hypoplasia, which can be seen (*arrowhead*) in another fetus (*left panel*). is advanced into the target area. The procedure is typically done using local or locoregional anesthesia with fetal analgesia and immobilization. Initially the laparotomy rate in Boston was as high as 27%, but this dropped to 10% in the most recent 50 cases.³¹⁹ For HLHS, an 18- or 19-gauge needle is inserted into the fetal left ventricle at the level of the apex and in alignment with the left ventricular outflow tract (see Fig. 35-16B). A guidewire and a catheter with a coronary dilation balloon are advanced through the aortic valve, which is dilated to 120% of the valve annulus. The anesthesiologist should be an experienced member of the team, not only for maternal sedation but also when fetal resuscitation must be coordinated: Inotropic medication, other vasoactive agents, or blood may be necessary to correct fetal acidosis or anemia and must be given in appropriate dosages and volumes for the fetal circulatory volume.

There are no specifically designed, commercially available intracardiac devices as there are for fetal surgery in other anatomic areas. Needles chosen should be as small as possible (but still steerable enough) and must enable convenient insertion of the balloon system of choice (16 to 19 gauge). Typically, needles are longer than 15 cm and have a short bevel. The semirigid sheath remains in the heart while the actual balloon system is advanced over the guidewire. The choice of balloon is guided by the target valve diameter, but in practice, right-sided interventions allow larger balloon systems than left-sided ones (the pulmonary valve being larger than the aortic valve). Excessive insertion of the balloon or guidewire is prevented by placing markings on the device. Under ultrasound guidance, the valve is dilated with a balloon up to 1.2 to 1.5 times the size of the annulus. Compared with children's valves, fetal valves are typically more rudimentary, more difficult to dilate, and more likely to undergo recurrent stenosis, in particular when the procedure is done earlier in pregnancy.

Similar percutaneous cardiac balloon procedures have been proposed for HLHS with a highly restrictive foramen ovale (atrial septostomy)³²⁰ and for pulmonary atresia with an intact

ventricular septum.³²¹ Data on these rarer cases are scarce, with only medium-term outcomes (Table 35-17).

Technical Outcome of Antenatal Interventions for Congenital Heart Defects

Technical success, defined as successful inflation and dilation, has been achieved in 70% of cases. Success can often be documented by the appearance of aortic regurgitation. Perioperative complications are common and include bradycardia necessitating fetal resuscitation (17% to 38%), hemopericardium (13%), ventricular thrombosis (15% to 20%), and IUFD (8% to 13%).³²² Significant left ventricular growth may be observed in utero, yet only 33% to 67% of the technically successful procedures lead to a postnatal biventricular repair.

Given appropriate technique, maternal morbidity is rare, except when uterine exposure is needed or when fetal deterioration requires immediate abdominal delivery. The interventions remain invasive, with quoted pPROM rates of 2% to 7%.^{323,324} Long-term outcomes are not yet available.

Atrial Septostomy for Hypoplastic Left Heart Syndrome

Significant restriction of the atrial septum is present in 7% of transpositions of the great arteries and in 22% of patients with HLHS³²⁵; in 6%, the atrial septum is completely closed. This condition leads to increased pulmonary vein pressure and left atrial hypertension in utero, as well as to pulmonary venous arterialization and possibly hydrops. After birth, pulmonary venous return to the left atrium is increased, and obstruction to pulmonary venous drainage leads to a further rise in pulmonary pressure, with severe hypoxemia, pulmonary edema, and hemorrhage. On the other hand, a nonrestrictive foramen ovale is essential for successful correction of HLHS after birth, to avoid pulmonary congestion and allow oxygenation of the body. Therefore, prenatal detection of atrial septum restriction, with early delivery and early septostomy or surgery, improves

outcome. Serial Doppler examination of the pulmonary arterial and venous return and detection of a high-velocity jet from left to right across the foramen ovale, which are indicative of raised left atrial pressure secondary to a restrictive foramen, may be used to select cases amenable to treatment in the prenatal period.

Experience with fetal balloon dilation is limited, and with thermal septostomy it is at best sporadic. The small second- or early third-trimester fetal atrium may limit the size of the balloon that can be used, and the small atrial wall is more prone to cardiac tamponade (compared with ventricular puncture). The Boston group recently published their updated experience of prenatal atrial septoplasty in 21 fetuses with HLHS and an intact or highly restrictive atrial septum. In this series, interatrial communication was successfully achieved using either balloon dilation or a stent in all cases. Fetuses with an interatrial defect of 3 mm had improved oxygen saturation at birth and required urgent postnatal left atrial decompression less often. However, two fetuses died in utero, and postnatal surgical survival remained low at 58%.³²⁰ With future experience, the benefit of prenatal intervention to avert sudden deterioration after birth may translate to improved survival statistics.³²⁶ Alternatively, thermally induced defects appear to be too small and to close early. Overall, limited technical and functional success rates have been reported (in 6 of 17 cases).³²⁷

Balloon Valvuloplasty for Hypoplastic Left Heart Syndrome

In their most recent and largest series published in 2009, the Boston group reported experience with prenatal aortic valvuloplasty in 70 fetuses with aortic stenosis and evolving HLHS. The procedure was deemed technically successful in 52 (74%) of treated fetuses, of whom 17 (33%) achieved biventricular circulation. One pregnancy was terminated, and eight others did not reach viability (13% of the total; 4% after technically unsuccessful procedures). Prenatal aortic valvuloplasty was shown to alter the growth and function of some left heart structures

(aortic valve, ascending aorta, mitral valve) but did not change the growth velocity of the left ventricle, affording new insights into understanding of evolving HLHS. Importantly, in fetuses with a larger left ventricle at enrolment, aortic valvuloplasty did increase the likelihood of a biventricular circulation postnatally. Based on this experience, a multivariate threshold scoring system comprising the size of the aortic valve, mitral valve, left ventricle, and left ventricular pressure was developed to identify fetuses able to survive postnatally with a biventricular circulation and thereby improve patient selection for prenatal intervention.³²⁸

Balloon Valvuloplasty for Pulmonary Atresia

Congenital critical pulmonary atresia with intact ventricular septum leads ultimately to hypoplasia of the right heart. The 5-year survival rate is only 64%, with only one third of patients having biventricular circulation at the 10-year follow-up.³²⁹ Fetuses with coronary fistula are unsuitable for decompression after delivery, because they depend for their cardiac perfusion on the high pressure status. The rationale for treatment is to prevent or delay progression of ventricular hypoplasia and to optimize right ventricular function, particularly when there is severe tricuspid regurgitation and hydrops.

Combined risk scores based on tricuspid and pulmonary valve size, in combination with assessment of right atrial pressure, have been proposed as an aid in patient counseling and assessment.³³⁰ Reported technical success rates are high, and in some fetuses there has been improved circulation and resolution of hydrops, allowing prolongation of pregnancy. However, it is uncertain whether these results represent an improvement over the natural history.

The Boston group has also published their initial experience of fetal pulmonary valvuloplasty in 10 fetuses with evolving right heart hypoplasia. Six of the 10 cases were technically successful, there were no fetal deaths, and maintenance of valvar patency and improved growth of right heart structures was

demonstrated.³²¹ Defining which fetuses are likely to benefit from this procedure may be more troublesome, because the postnatal outcomes for many infants with pulmonary atresia and intact ventricular septum are more favorable.³²⁶

Myelomeningocele Repair

Neural tube defects are a major source of mortality and morbidity. The 5-year mortality rate among patients with spina bifida undergoing neonatal repair is 79 per 1000 births. Mortality can be as high as 35% among patients with symptoms of brainstem dysfunction, and 81% of children have hydrocephalus requiring treatment. More than 70% of survivors with neural tube defects have an IQ greater than 80, but only 37% can live independently as adults. Most have anal sphincteric dysfunction and lower extremity paralysis.³³¹

ANTENATAL IMPACT OF MYELOMENINGOCELE

The prevalence of neural tube defects is approximately 9 per 10,000 births, making it one of the most frequent congenital anomalies affecting the central nervous system.³³² MMC is the most common abnormality arising from defects in distal neural tube closure. It is characterized by extrusion of the meninges and the spinal cord through the overlying defect in fetal skin and muscle (Fig. 35-17). To explain the consequences of this local defect, a two-hit hypothesis has been proposed. The *first hit* refers to the primary failure in the closure of the spinal canal early in embryonic life (fourth week of gestation). The *second hit* involves the sequelae from exposure of the spinal cord and extruded nerves to direct trauma and neurotoxic agents in the amniotic fluid, which progressively damages the developing nervous system.³³³⁻³³⁵

The adverse effects of MMC occur both at the level of the lesion and also upstream in the brain. The abnormal anatomy involving the spinal cord, typically in the lumbar area, exerts a

downward displacement upon the cerebellar vermis and brainstem into the spinal canal. The resulting Chiari II malformation (CM II), which involves cerebellar, respiratory, and cranial nerve dysfunction and is present in approximately 35% of patients, may impair normal circulation of cerebrospinal fluid through the fourth ventricle, leading to secondary hydrocephalus. This in turn affects the neurocognitive prognosis and late morbidity. More than 80% of children require lifelong shunting to divert cerebrospinal fluid into the peritoneal cavity. Approximately 50% of children have shunt complications during the first year of life.³³⁶ CM II is almost invariably present between 19 and 25 weeks' gestation, and it may be present already in the first trimester.

The developmental impact is highly dependent on the level and extent of the lesion.^{337,338} Although local damage to the spinal cord and peripheral nerves becomes evident at birth, it remains irreversible despite immediate postnatal surgical repair. Among the long-term survivors, major disabilities include paralysis and bowel, bladder, and sexual dysfunction. The motor deficit leads to progressive orthopedic deformities of the spine (scoliosis) and the lower limbs. Most (70%) of children with MMC have an IQ greater than 80, and half of them are able to live independent lives.³³⁹ Parents nevertheless should be prepared for a child with a significant need for care.

PRENATAL DIAGNOSIS

The most obvious clue to MMC is a cystic mass protruding from the dorsal vertebral bodies, which show locally splayed ossification centers.³⁴⁰ Lumbar lesions are by far the most common, followed by sacral, thoracic, and cervical lesions. The spinal findings are usually combined with secondary signs in the brain. The anomalies first noted by the ultrasonographer include ventriculomegaly, microcephaly, a concave shape of the frontal calvarium (the so-called lemon sign), and obliteration of the cisterna magna with either an apparently "absent" cerebellum or abnormal anterior curvature of the cerebellar hemispheres (banana sign) (Fig. 35-18).^{341,342} The lemon sign is present in about 1% of normal pregnancies and in up to 98% of fetuses with open spinal defect before 24 weeks' gestation, after which it gradually disappears.³⁴¹ The distortion or absence of the cerebellum as part of the CM II is observed in 95% of cases of spina bifida aperta but does not resolve with advancing gestation. To determine the upper level, landmarks on transverse views of the spine are the most caudal rib (corresponding to the T12 vertebra) and the superior edge of the iliac crest (corresponding to L5). Such detailed spine evaluation is best done at a reference center, because experience and case load are important factors for accuracy. More advanced imaging techniques, including 3D multiplanar and 3D tomographic ultrasonography, four-dimensional volume contrast imaging, and MRI (Fig. 35-19), may be useful and are typically of added value later in pregnancy.³⁴³

First- and second-trimester aneuploidy screening programs may detect these fetal spinal anomalies. An easily detectable marker of open spina bifida is localized within the brain in the same midsagittal plane of the fetal face as for assessment of the nuchal fold and the nasal bone. In normal fetuses, the fourth cerebral ventricle presents as an *intracranial translucency* (IT) parallel to the NT, whereas in fetuses with open spina bifida, IT may be absent (Fig. 35-20).³⁴⁴ This is believed to be the result of caudal displacement of the cerebellum compressing the

Figure 35-17 Meningomyelocele. In myelomeningocele, the spinal cord is bulging through the defect into the subarachnoid space. This causes more displacement and traction on spinal roots. The yellow line is dura mater; the blue line is the arachnoid membrane. Blue shading indicates cerebrospinal fluid. fourth ventricle and hence is an early manifestation of the CM II. In most cases of open spina bifida, the diameter of the brainstem is increased and the distance between the brainstem and the occipital bone is decreased.³⁴⁵

FETAL SURGERY: EXPERIMENTAL BASIS AND EARLY EXPERIENCE

If a spinal column defect remains covered rather than being an open lesion (e.g., spina bifida occulta), fetuses do not develop the same severe sequelae as in open defects.³⁴⁶ Fetal intervention essentially aims at isolating the defect from the toxic and traumatic intrauterine environment. This procedure is based on extensive experience in an animal model in which surgically induced defects at spinal levels L1 through L4 in lambs at 75 days' gestation provoked the typical phenotype at birth.³⁴⁷ Secondary repair 25 days after the initial lesion was created resulted in near-normal postnatal motor function, intact sensation, and urinary and stool continence.^{348,349} Also, the CM II lesion has been reversed by the intrauterine closure.^{350,351}

To test this finding in humans, teams from the CHOP and from Vanderbilt at Nashville, Tennessee, gathered significant experience with fetal surgical repair, which ultimately laid the

basis for the Management of Myelomeningocele Study (MOMS) (see Fig. 35-20). The indications and outcomes are displayed in Table 35-18. The technique of prenatal closure of the defect is identical to the postnatal surgical procedure. The fringe of full-thickness skin is incised circumferentially down to the fascia, and the sac is mobilized medially. It is then excised from the

placode, with all epithelial tissue removed to avoid inclusion cysts later on. Because the spinal cord in the fetus is extremely frail, no attempt is made to reneuralize the placode. The defect is then closed with dura, undermined fascia, or both. The skin is closed primarily, which at times requires lateral relaxing incisions or dermal graft material.

None of the human fetal surgeries failed, and the overall survival rate was 94%, with three prematurity-related deaths. The group from CHOP reported on 50 selected patients who underwent surgery at 20 to 25 completed weeks' gestation.^{6,352} On follow-up, there was a dramatic improvement in hindbrain herniation before birth, and postnatal neurologic outcome compared favorably to historical controls.³⁵²⁻³⁵⁵ The need for ventriculoperitoneal (VP) shunting was halved, for all levels of lesions (43% versus 84%); 57% of fetuses with thoracic or lumbar lesions demonstrated better leg function than would be expected for the anatomic level of the defect, although 17% had worse than expected function. The Vanderbilt group initially operated on 29 patients between 24 and 30 weeks' gestation, and by 2005 they had reported a total of 178 patients (see Table 35-18).^{354,356} In a matched control study, the rates of short-term prematurity-related complications were identical to the complications of premature infants born early for reasons other than fetal surgery.³⁵⁷ To prepare a clinical trial, a retrospective cohort study was performed, comprising 104 fetal and 189 postnatal repairs with follow-up for longer than 1 year. In this case series, shunt dependent hydrocephalus was reduced after fetal repair, at least for fetuses with lesions below L2 (Table 35-19).³⁵⁸ Lesions higher than L3 may not share the benefit of fetal surgery. The effect of fetal repair was better when repair was done before or at 25 weeks' gestation, rather than later.³⁵⁹

The entry criteria for the prospective MOMS trial are summarized in Box 35-4. The primary hypothesis was that surgical coverage of lesions above S1 between 19 and 25 completed weeks of gestation would improve outcomes when compared with postnatal repair.³⁶⁰ The first primary outcome was a composite of fetal or neonatal death or need for placement of shunt by the age of 12 months. A second primary outcome at 30 months was a composite of mental development (Mental Development Index of the Bayley Scales of Infant Development II) and motor function with adjustment for lesion level.

With the use of deep general inhalational anesthesia for adequate fetal anesthesia and uterine relaxation, maternal laparotomy is performed to expose the uterus. The fetus is manually positioned so that the MMC sac is in the center of the planned hysterotomy. The fetus is given an intramuscular injection of fentanyl and vecuronium. The actual MMC repair is not different from what is typically done after birth. The uterus is closed in two layers with prior restoration of amniotic fluid and

antibiotic administration and covered with an omental patch. Prophylactic tocolytics include magnesium sulfate (24 hours), indomethacin (48 hours), and oral nifedipine after discontinuation of magnesium sulfate until 37 weeks' gestation. The typical hospital stay is 4 days. Elective cesarean delivery by lower uterine incision is performed at 37 weeks.

RESULTS OF FETAL SURGERY FOR MYELOMENINGOCELE

In 2010, the MOMS trial was concluded at a planned interim analysis of 183 out of the 200 anticipated patients because of efficacy.³⁶⁰ The results are summarized in Table 35-20. In line with the earlier clinical trials, fetal surgery improved MMC-related infant outcomes. The first primary outcome (death or need for shunt) occurred in 68% of the infants in the prenatal surgery group and in 98% of those operated on postnatally ($n = 158$). Actual rates of shunt placement were 40% in the prenatal surgery group and 82% in the postnatal surgery group. Prenatal surgery also resulted in improvement in the composite score for mental development and motor function at 30 months ($n = 64$; $P = .007$). The mental development score was not different, but there was a marked improvement in motor function. There were also improvements in several secondary outcomes, including hindbrain herniation by 12 months and ambulation

BOX 35-4 INCLUSION AND EXCLUSION CRITERIA FOR PARTICIPATION IN THE MOMS TRIAL

INCLUSION CRITERIA

- Maternal age ≥ 18 yr
- Gestational age at randomization 19 wk 0 days to 25 wk 6 days
- Normal karyotype
- S1-level lesion or higher
- Confirmed CM II on prenatal ultrasonography and MRI

EXCLUSION CRITERIA

- Multiple-gestation pregnancy
- Insulin-dependent pregestational diabetes
- Additional fetal anomalies unrelated to MMC
- Fetal kyphosis ≥ 30 degrees
- History of incompetent cervix and/or short cervix < 20 mm by ultrasound scan
- Placenta previa
- Other serious maternal medical condition
- Obesity defined by body mass index ≥ 35
- Previous spontaneous singleton delivery at < 37 weeks' gestation
- Maternal-fetal Rh isoimmunization
- Positive maternal HIV or hepatitis B or known hepatitis C positivity
- No support person to stay with the pregnant woman at the center
- Uterine anomaly
- Psychosocial limitations
- Inability to comply with travel and follow-up protocols

Walking independently on examination	26/62 (42%)	14/67 (21%)	2.01 (1.16-3.48), P = .01
Walking status			P = .03
None	18/62 (29%)	29/67 (43%)	
Walking with orthotics or devices	18/62 (29%)	24/67 (36%)	
Walking without orthotics	26/62 (42%)	14/67 (21%)	
WeeFIM score‡			
Self-care	20.5 ± 4.2	19.0 ± 4.2	P = .02
Mobility	19.9 ± 6.4	16.5 ± 5.9	P = .003
Cognitive	23.9 ± 5.2	24.1 ± 5.9	P = .67

*On the Bayley Scales of Infant Development II, the Mental Development Index and the Psychomotor Development Index are both scaled to have a population mean (±SD) of 100 ± 15, with a minimum score of 50 and a maximum score 150. Higher scores indicate better performance.

†For the difference between the motor-function level and the anatomic level, positive values indicate function that is better than expected on the basis of the anatomic level.

‡On the WeeFIM evaluation, the score on the self-care measurement ranges from 8 to 56, and scores on the mobility and cognitive measurements range from 5 to 35, with higher scores indicating greater independence.

CI, 95% confidence interval; GA, gestational age; MOMS, Management of Myelomeningocele Study; ns, not significant; RR, relative risk. From Adzick NS, Thom EA, Spong CY, et al: A randomized trial of prenatal versus postnatal repair of myelomeningocele, *N Engl J Med* 364:993-1004, 2011.

by 30 months (42% of patients could walk independently after fetal surgery, compared with 21% in the postnatal group; $P = .01$). By serendipity, the lesion level in the prenatal repair group was more severe than in the postnatal group ($P = .02$), which makes the results even more remarkable.

In the MOMS study, fetal surgery for MMC resulted in a level of function two or more levels better than that expected based on the anatomic lesion. These differences are not only statistically significant but also clinically relevant.³⁶¹ Children born after fetal surgery were less likely to have hindbrain herniation, and if they did have it, it was milder. Their need for surgical intervention after in utero coverage of the MMC was also lower, including decreased needs for postnatal VP shunt insertion and release of tethered cord. The trial observations were consistent with earlier findings in the observational studies described previously. Though long-term follow-up is not yet available, it is reasonable to hope for a durable outcome, as was earlier demonstrated in observational studies.

The successes of this procedure, however, have come at a price. There were two fetal deaths in the prenatal treatment group, one during surgery and the other due to prematurity. This was balanced in the postnatal surgery group by two additional deaths (relative risk [RR] = 1.03), which were due to the consequences of CM II. Delivery after fetal surgery took place at a mean of 34.1 weeks in the fetal surgery group and 37.3 weeks in the postnatal repair group ($P < .001$); delivery occurred before 30 weeks in 13% and 0%, respectively. There were also clinically relevant maternal complications and side effects, including pulmonary edema, placental abruption, and hemorrhagic complications at birth requiring blood transfusion (9%). Several prolonged hospitalizations and/or readmissions for oligohydramnios were required in the interventional group (21% versus 4%; $P = .001$), membrane rupture (46% versus 0%; $P < .001$), and preterm delivery (79% versus 15%; $P < .001$).³⁶² One in three women undergoing fetal surgery also had an area of thinning or dehiscence of the uterine scar at the time of cesarean delivery, although none formally presented with clinically ruptured uterus. The possibility of uterine dehiscence may have an as yet undefined and unquantified effect on the index and on future pregnancies.⁸

After the MOMS trial, longer-term follow-up studies were carried out. In a 2-year follow-up report on 30 children who underwent surgery prenatally, the presence of a VP shunt was correlated with a significant decrease in all testing scores. The lower shunt rate after fetal repair, together with a better outcome without a shunt, made normal cognitive development a more likely result.³⁵² Danzer reported the 5-year follow-up of children at CHOP. Their mean verbal intelligence, performance intelligence, and full intelligence quotients were in the normal population range. High or average scores were found in 90% or more of the children for those parameters and in 60% for processing speed. Unshunted children had a better full intelligence quotient and better processing speed than those who required a shunt. Their functional status regarding self-care, mobility, and cognitive independence was lower than in normal, age-matched controls. Complete independence was achieved by 84% for cognition, 38% for self-care, 62% for mobility, and 58% for total functional outcome. Again, outcomes were better when no shunt was required.^{363,364} The majority of children achieved neurocognitive and neurofunctional independence. Almost one third, however, continued to require maximal assistance when carrying out self-care tasks. Functional studies confirmed previous findings by

other centers that showed only minimal impact of prenatal MMC surgery on continence function.^{365,366}

FETOSCOPIC SURGERY

Endoscopic coverage of MMC was clinically attempted first by Bruner and colleagues between 1994 and 1997 ($n = 4$).³⁶⁷ Unfortunately, two of the four fetuses died during or after surgery. Farmer and coworkers from San Francisco also reported success in one of three attempts at fetoscopic coverage of an MMC defect using a patch.³⁶⁸ Despite a successful antenatal intervention, that baby still required a standard postnatal repair and VP shunt. The other two attempts failed technically, leading to the demise of one fetus and standard postnatal surgery and VP shunting in the other. In Europe, the group in Bonn had a comparable experience.^{369,370} Of 19 fetoscopic procedures performed between 20 and 25 weeks at that center, 3 procedures were abandoned, and 3 fetuses or neonates eventually died. The remaining 13 (68%), who were successfully operated on and survived, were matched for level of lesion and gestational age to infants undergoing postnatal repair. In summary, the complication rate (membrane rupture, oligohydramnios, chorioamnionitis) was higher in the fetal surgery group, and the gestational age at delivery earlier (32 versus 39 weeks; $P = .001$), leading to a higher chance for respiratory distress syndrome. In concordance to what was meanwhile observed for open surgery, the neurologic outcome after fetoscopic surgery was better (two gained segments, better preserved knee-jerk and anal reflexes). Although this independent audit proved the benefit of fetal intervention, the authors concluded that the observed complications must be addressed before fetoscopic surgery may be considered a clinical alternative for MMC.³⁷⁰

Amniotic Band Syndrome

Amniotic band syndrome (ABS) is a rare condition that occurs in about 1 of every 1200 to 15,000 live births.^{371,372} Its exact cause remains unclear, and several pathogenetic theories have been proposed to explain the wide range of clinical manifestations. The intrinsic theory, advanced by Streeter in 1930, suggests ABS begins with a primary defect in the embryonic germinal disc. This theory explains the central malformations (e.g., craniofacial or visceral abnormalities, the limb-body wall complex) but poorly explains the involvement of extremities. Conversely, the extrinsic theory, advanced by Torpin in 1965, begins with an early amniotic rupture (either idiopathic or secondary to trauma) that causes the fetus to partially dislodge into the extra-amniotic space. Secondary formation of amniochorionic mesodermal bands leads to constriction of fetal elements. Van Allen (1981) proposed a vascular theory whereby vascular disruption early in pregnancy would explain the huge diversity of observed malformations. Moerman attempted to unify these observations by dividing the various phenotypes of amniotic band syndrome into three different entities: constrictive amniotic bands, amniotic adhesions, and limb-body wall complex.³⁷³ Under this theory, the constrictive amniotic bands are believed to be caused by primary amnion rupture with entanglement of fetal parts by the amniotic strands. Adhesive bands result from a broad fusion between intact amniotic membranes and disrupted fetal parts. The limb-body wall complex is most likely induced by a vascular disruption, often complicated by rupture of the unsupported amnion.

BOX 35-5 PRENATAL CLASSIFICATION OF AMNIOTIC BANDS

1. Amniotic bands without signs of constriction
2. Constriction without vascular compromise (normal vascular Doppler studies compared to opposite side)
 - a. Without or only mild lymphedema
 - b. With severe lymphedema
3. Severe constriction with progressive arterial compromise, flow measurements distal and proximal of the constriction band
 - a. Abnormal distal Doppler studies when compared to contralateral extremity
 - b. No vascular flow to extremity
4. Bowing or fracture of long bones at constriction site
5. Intrauterine amputation

From Hüsler MR, Wilson RD, Horii SC, et al: When is fetoscopic release of amniotic bands indicated? Review of outcome of cases treated in utero and selection criteria for fetal surgery, *Prenat Diagn* 29:457-463, 2009.

The natural history of amniotic bands cannot be easily predicted. Constrictive amniotic bands may lead to distal edema, flow impairment, and eventually amputation, but spontaneous resolution has been described as well.^{374,375} An additional life-threatening problem may be the umbilical cord entrapment, which can lead to IUFD.³⁷⁶ Given these findings, follow-up of amniotic bands on a weekly basis is reasonable. As long as Doppler studies are normal (taking the contralateral side as a reference), expectant management seems justified.

When the outcome is not predictable, patient selection and accurate timing of intervention for prenatal treatment are difficult. Hüsler and colleagues³⁷⁷ proposed a prenatal classification based on the postnatal classification earlier introduced by Weinzwieg (Box 35-5), which is based on signs of constriction, the presence of lymphedema, and Doppler studies of the affected limb compared with the opposite side.

Several cases of successful intrauterine release of amniotic bands have demonstrated the feasibility of a fetoscopic procedure. Outcomes, usually favorable, were reviewed by Richter and associates.³⁷⁸ In all cases, the intervention involved release of fetal limbs as indicated by progressive deterioration. The instrumentation for these procedures is not well defined, but a good-quality fetoscope and optical scissors or laser fibers (or both) are required. The procedure can be done under local anesthesia. It might not always be possible to visualize or to dissect and cut the bands without risk for collateral damage, especially if they are covered within a constrictive ring in an edematous area (Fig. 35-21). Floating membranes may further compromise adequate visualization. After the procedure, partial to full disappearance of the signs as well as recovery of flow and/or function may be obtained, but postnatal surgery is often necessary.

In a review of 10 cases of fetoscopic release of an amniotic band, Richter and colleagues reported pPROM in 78% before 34 weeks³⁷⁸ and preterm birth in 67%. The high pPROM rate may be related to the inherent membrane abnormality. In 8 (90%) of the 9 cases, the band could be cut to some extent, but only in 3 cases (33.3%) was a complete release possible. Reduction in edema and restoration of blood flow was variable. In summary, fetoscopic release may reverse the cascade of flow

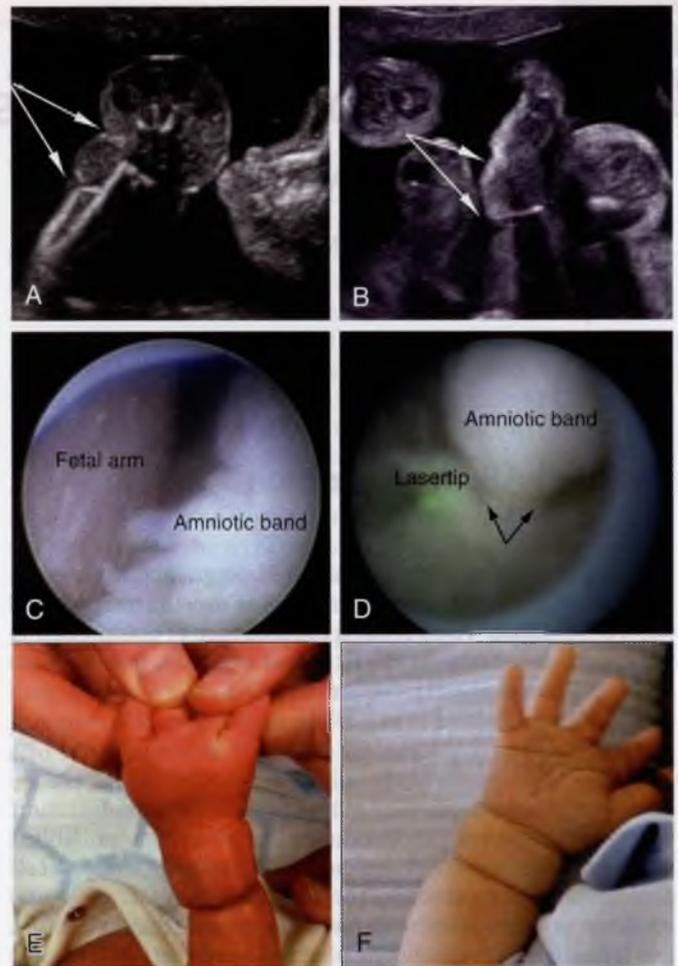

Figure 35-21 Amniotic bands. A, Ultrasound image of right forearm at 23 weeks. There is significant edema at the distal part. Two notches created by the amniotic band are visible (arrows). B, Sonogram of the right arm and hand 1 month after fetoscopic release of the band. There is a decrease of the edema, and the two notches are still visible (arrows). C, Fetoscopic visualization of the fetal forearm at the left and the amniotic band tissue at the right. D, Sectioning of the band with the use of a diode laser. The arrows mark the region of the band already cut. E, At birth, amniotic band tissue is still present around the arm, infiltrating into the subcutis. F, One month after birth, the location where the amniotic band had been is still visible, but there is no edema, and the hand and fingers have a normal range of motion. (From Richter J, Wergeland H, Dekoninck P, et al: Fetoscopic release of an amniotic band with risk of amputation: case report and review of the literature, *Fetal Diagn Ther* 31:134-137, 2012.)

impairment leading to amputation, but functional salvage of the limb is possible in only two thirds of cases.

ACKNOWLEDGMENTS

We thank the European Commission for supporting the development of fetoscopy and its instrumentation, by Eurofoetus (Biomed 2), EuroTwin2Twin (5th Framework programme, QLGI-CT-2002-01632) and EuroSTEC (6th framework programme, 2006-37409) and the Industria-Academia Partnership Marie Curie Grant of the European Commission (PIAP-GA-2009-251356).

Hemolytic Disease of the Fetus and Newborn

KENNETH J. MOISE, Jr., MD

Red Cell Alloimmunization

TERMINOLOGY

Once called *red cell isoimmunization* in pregnancy, the formation of antibodies to red cell antigens is now termed *red cell alloimmunization*. The perinatal consequence of this process is hemolysis and anemia in the fetus and newborn, or hemolytic disease of the fetus and newborn (HDFN).

EPIDEMIOLOGY

The widespread adoption of guidelines for the administration of antenatal and postpartum rhesus immune globulin (RhIG) has resulted in a marked decline in the prevalence of red cell alloimmunization caused by the RhD antigen. Cases, however, continue to occur because of maternal sensitization in the first two trimesters of pregnancy, inadvertent omission of RhIG, and inadequate dosing after delivery when there has been an excessive fetomaternal hemorrhage. Immune globulins to prevent alloimmunization to other red cell antigens are unlikely to be developed by pharmacologic companies. Thus red cell alloimmunization in pregnancy is likely to continue to complicate pregnancies for the foreseeable future. A recent analysis of 305,000 women in a national first-trimester screening program in The Netherlands revealed that anti-E was the most common antibody associated with HDFN (Fig. 36-1).¹ Anti-D was the second most common antibody, followed by anti-Kell and anti-c.

PATHOGENESIS

It is well established that the fetal-maternal interface is not an absolute barrier, and there is evidence that considerable trafficking of many types of cells occurs between the fetus and the mother throughout gestation. In most cases, the antigenic load of a putative antigen on the fetal erythrocytes and erythrocytic precursors is insufficient to stimulate the maternal immune system. However, in the case of a large fetomaternal hemorrhage before birth or at delivery, B lymphocyte clones that recognize the foreign red cell antigen are established. The initial maternal production of IgM is short-lived and is followed by a rapid change to an IgG response. A human antiglobulin titer can usually be detected by 5 to 16 weeks after the sensitizing event.

After the initial antigenic exposure, memory B lymphocytes await the appearance of red cells containing the putative antigen

in a subsequent pregnancy. If stimulated by fetal erythrocytes, these B lymphocytes differentiate into plasma cells that can rapidly proliferate and produce IgG antibodies and an increase in the maternal titer. Maternal IgG crosses the placenta and attaches to fetal erythrocytes that have expressed the paternal antigen. These cells are then sequestered by macrophages in the fetal spleen, where they undergo extravascular hemolysis, producing fetal anemia. Fetal sex may play a significant role in the fetal response to maternal antibodies. Ulm and associates² reported that the chance for hydrops fetalis was increased 13-fold in RhD-positive male fetuses compared with their female counterparts; the adjusted odds ratio for perinatal mortality was 3.38 in male fetuses.

Several important physiologic responses occur in fetuses as a result of this anemia. An enhanced bone marrow production of reticulocytes is noted when the fetal hemoglobin deficit, compared with norms for gestational age, exceeds 2 g/dL, and erythroblasts from the fetal liver occur at a hemoglobin deficit of 7 g/dL or greater.³ Cardiac output increases, and 2,3-diphosphoglycerate levels are enhanced.

Hydrops fetalis, a collection of fluid in at least two serous compartments, typically heralds end-stage disease, and it occurs with hemoglobin deficits of 7 g/dL or greater.³ This may be related to the gestational age when the anemia occurs. In one series of fetuses found to have severe anemia prior to 22 weeks' gestation, more than 70% did not exhibit signs of hydrops on ultrasound.⁴ The initial ultrasound finding of hydrops is usually fetal ascites, followed later by pleural effusion and finally scalp edema. The exact pathophysiology of this condition is unknown. Reduced serum albumin levels have been reported, presumably resulting from depressed synthesis by the fetal liver, which shifts to an erythropoietic function.⁵ This results in a decrease in colloid osmotic pressure.⁶ However, congenital analbuminemia is not associated with hydrops fetalis, and experimental removal of fetal plasma proteins and replacing them with saline in an animal model does not produce hydrops.^{7,8} An alternative hypothesis suggests that tissue hypoxia resulting from anemia enhances capillary permeability. Iron overload secondary to ongoing hemolysis may contribute to free radical formation and endothelial cell dysfunction.⁹ Central venous pressures do appear to be elevated in the hydropic fetus with HDFN.⁶ This may cause a functional blockage of the lymphatic system at the level of the thoracic duct as it empties into the left brachiocephalic vein. This theory is supported by reports of poor absorption of donor red blood cells infused into the intraperitoneal cavity in cases of hydrops.¹⁰

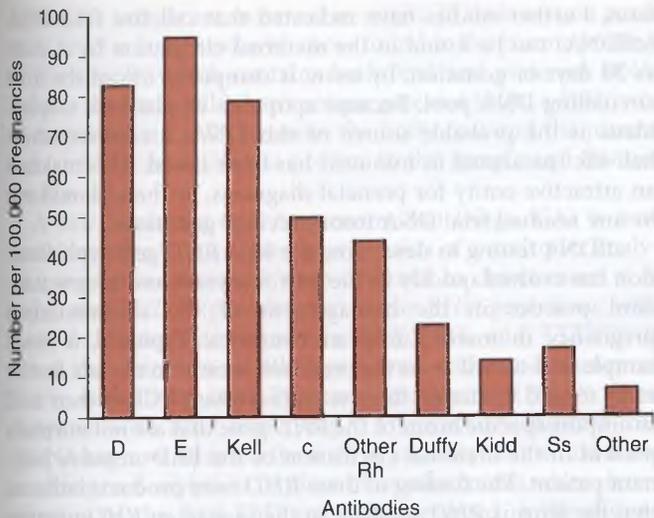

Figure 36-1 Hemolytic disease of the fetus and newborn (HDFN). Graph showing incidence of maternal anti-red cell antibodies associated with HDFN at the time of a first-trimester antibody screen in a Dutch population of 305,000 pregnant women. (From Koelewijn JM, Vrijkotte TG, van der Schoot CE, et al: Effect of screening for red cell antibodies, other than anti-D, to detect hemolytic disease of the fetus and newborn: a population study in the Netherlands, *Transfusion* 48:941, 2008.)

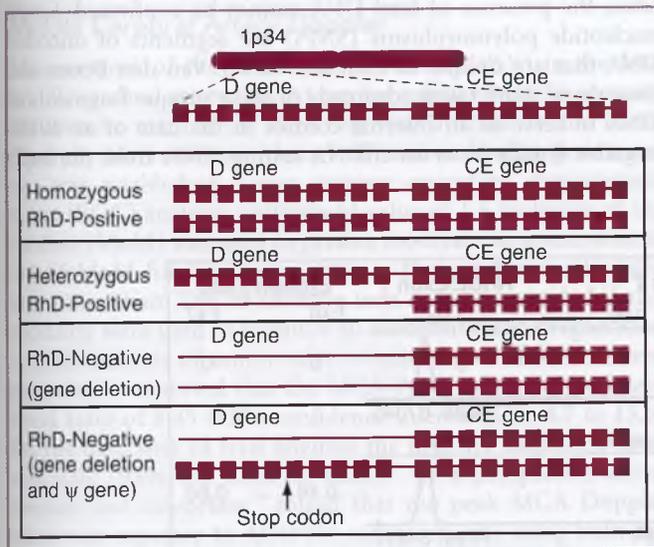

Figure 36-2 Schematic diagram of Rh gene locus on chromosome 1. Four genotypes are demonstrated: homozygous RhD-positive, heterozygous RhD-positive, typical RhD-negative, and RhD-negative with pseudogene (ψ).

GENETICS

Although the RhD, C/c, and E/e antigens were once thought to be the product of three distinct genes, the presence of only two genes localized to the short arm of chromosome 1 has now been verified.¹¹ Each of the two genes—an *RHD* gene and an *RHCE* gene—is 10 exons in length, and there is 96% homology between them (Fig. 36-2). This has led some to conclude that these genes represent a duplication of a common ancestral gene. Production of two distinct proteins from the *RHCE* gene probably occurs as a result of alternative splicing of messenger RNA.¹² One nucleotide difference, a change from cytosine to thymine

in exon 2 of the *RHCE* gene, results in a single amino acid change of a serine to proline. This causes the expression of the C antigen as opposed to the c antigen.¹³ A single cytosine-to-guanine change in exon 5 of the *RHCE* gene produces a single amino acid change of (proline to alanine), resulting in formation of the e antigen instead of the E antigen.¹⁴

In most individuals, the RhD-negative serotype results from a gene deletion of both *RHD* genes. However, several unique gene arrangements can occur. An *RHD* pseudogene has been described in 69% of South African blacks and 24% of African Americans.¹⁵ In this situation, all 10 exons of the *RHD* gene are present; however, translation of the gene into a messenger RNA product does not occur because of the presence of a stop codon in the intron between exons 3 and 4. Therefore, no RhD protein is synthesized, and the patient is serologically RhD negative.

Finally, the red cells of 0.3% of whites and 1.7% of African Americans exhibit a weak response when serologic RhD typing is undertaken.¹⁶ In the past, these individuals were reported as *Du positive*, and the term was later changed to *weak D positive*. Further genetic studies have indicated that these individuals belong to one of two populations. In the first group, a reduced number of RhD antigens are expressed on the patient's red cells. One hundred and one subtypes of this group of weak D patients have been described.¹⁷ The second population of weak D patients are known as *partial D's*. These patients exhibit amino acid substitutions in the active RhD epitopes of the D antigen on the surface of their red cells. These changes can result in "missing" portions of the epitopes, allowing the patient to form antibodies to these deleted portions if they are exposed to intact RhD-positive red cells. The D variants are typically categorized into types II to VI, with more than 88 subtypes reported.¹⁸ Alloimmunization to partial D has been reported to result in severe HDFN and even fetal hydrops.¹⁹

DIAGNOSIS

Maternal Antibody Determination

Red cell alloimmunization is first detected when the maternal serum is reacted with a preselected panel of indicator red cells containing known antigens. The antibody screen is called positive or negative. If an antibody is detected, it is first identified to determine its clinical significance; a titer is then obtained. The human antiglobulin titer (indirect Coombs) is used to determine the degree of alloimmunization, because it measures the maternal IgG response. By convention, titer values are reported as the reciprocal of the last dilution tube that showed a positive agglutination reaction; that is, a titer of 16 is the equivalent of a dilution of 1:16. Variation in results between laboratories is not uncommon, because many commercial laboratories use enzymatic treatment of red cells to prevent failure of detection of low-titer samples. However, in a single laboratory, the titer should not vary by more than one dilution if the two samples are run in tandem. This means that an initial titer of 8 that returns at 16 may not represent a true increase in the amount of antibody in the maternal circulation. In addition, the clinician should be aware that the newer gel microcolumn assays that are commonly used by laboratories today will result in higher titers than the older conventional tube testing. In one study, the mean titer was increased 3.4-fold with the gel technology.²⁰ A critical titer is defined as the titer associated with a significant risk for fetal hydrops. If a critical titer is present, further fetal surveillance is required. This titer varies with the

institution and the methodologies used; however, most centers use a critical value for anti-D, and most other antibodies, of 32.

Paternal Zygosity

In cases of a heterozygous paternal genotype, 50% of the fetuses do not express the involved red cell antigen and therefore escape the hemolytic effects of the maternal anti-red cell antibody. In these cases, further maternal and fetal testing can be eliminated. Most red cell antigens are inherited through co-dominant alleles. As an example, for the E/e antigen, an individual can be homozygous E/E, homozygous e/e, or heterozygous E/e. Using anti-E and anti-e reagents, the E/e genotype of an individual can be easily determined by simply testing the red cells. This is not the case, however, for RhD, as there is no "d" antigen (and therefore no anti-d reagent is available) because it represents a gene deletion and a lack of translation to a protein. In the case of RhD, quantitative polymerase chain reaction (PCR) can be used to test for the number of copies of the D gene by comparing the DNA peak to that of the *RhCE* gene, which is always present as two copies in all individuals (Fig. 36-3).²¹ The assay has also proved effective in detecting the *RHD* pseudogene.

Fetal Genotype Testing

In the past, a heterozygous paternal genotype for the *RHD* gene led to a recommendation to undertake amniocentesis to determine the fetal RhD status using DNA isolated from amniocytes.²² This allowed 50% of patients to receive routine obstetric care when the fetus was found to be RhD negative.

Based on a concept that cell-free tumor DNA could be found in the peripheral circulation of patients with cancer, Lo and colleagues²³ were the first to report the presence of the *RHD* gene in the plasma of women pregnant with an RhD-positive

fetus. Further studies have indicated that cell-free fetal DNA (cffDNA) can be found in the maternal circulation by as early as 38 days of gestation; by term, it comprises 6% of the total circulating DNA pool. Because apoptosis of placental trophoblasts is the probable source of this DNA, a relatively short half-life (measured in minutes) has been noted. This makes it an attractive entity for prenatal diagnosis, as there should not be any residual fetal DNA from previous gestations.

cffDNA testing to determine the fetal *RHD* genotype detection has evolved quickly in the past few years and is now standard practice in the management of the alloimmunized pregnancy in many European countries. Typically, a blood sample is obtained from the pregnant patient in the late first or early second trimester. Reverse transcriptase PCR is then used to amplify specific exons of the *RHD* gene that are not normally present in the maternal circulation of the RhD-negative pregnant patient. The finding of these *RHD* exon products indicates that the fetus is *RHD* positive. In the case of an *RHD*-negative fetus, there is no amplification of the *RHD* exons. When the fetal *RHD* genotype is reported to be negative, like the mother's, an *RHD*-negative result cannot be used to verify the presence of fetal DNA. In these cases, fetal sex determination must be undertaken to confirm that fetal DNA is present. If gene products of the Y chromosome are detected in reflex testing, then the *RHD*-negative result can be considered valid (male, *RHD*-negative fetus). However, in the case of an *RHD*-negative female fetus, the presence of fetal DNA cannot be confirmed. Single nucleotide polymorphisms (SNPs) are segments of uncoded DNA that are unique to each individual. Van den Boom and coworkers²⁴ have taken advantage of these unique fragments of DNA to serve as an internal control in the case of an *RHD*-negative female fetus on cffDNA testing. SNPs from the buffy

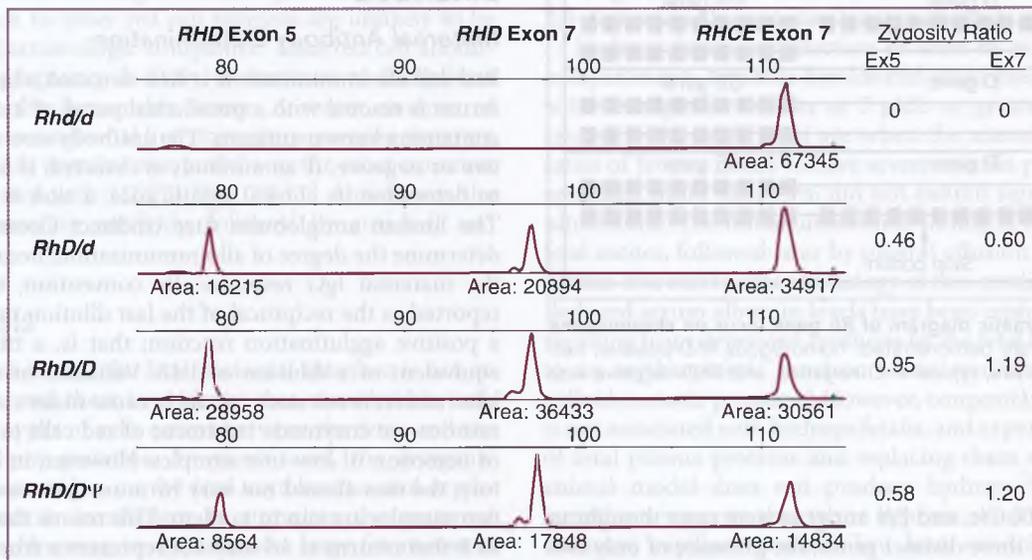

Figure 36-3 Paternal zygosity testing. Quantitative fluorescent polymerase chain reaction (PCR) was used to amplify exons 5 and 7 of the *RHD* gene as well as exon 7 of the two *RHCE* genes (used as internal controls). PCR products were analyzed on an automated sequencer. The ratio of *RHD* exon 5 or 7 peak areas was compared with the peak area derived from the two copies of exon 7 of the *RHCE* genes. *Top row:* *RHD*-negative genotype (*Rhd/d*); no peak is seen for *RHD* exon 5 or *RHD* exon 7. *Second row:* *RHD*-positive, heterozygous state (*RhD/d*); peaks for *RHD* exons 5 and 7 are approximately half of the peak area seen for the *RHCE* genes (ratios of 0.46 and 0.60). *Third row:* *RHD*-positive, homozygous state (*RhD/D*); peaks for the *RHD* exons 5 and 7 are approximately equal to the peak area for the *RHCE* genes (ratios of 0.95 and 1.19). *Fourth row:* *RHD*-positive, one copy of *RHD* gene and one copy of the *Rhd* pseudogene (*RhDψ*) noted. The *RHD* exon 5 primers detect only *RHD*, not *RhDψ*, whereas the *RHD* exon 7 primers detect both *RHD* and *RhDψ*, explaining the copy number discrepancy in the *RHD/Dψ* sample (peak ratios of 0.58 and 1.20 versus the *RHCE* genes). (Courtesy of Daniel Bellissimo, PhD, Molecular Diagnostics Laboratory, Blood Center of Wisconsin, with permission.)

coat of the sample are maternal in origin. In their assay, a panel of 92 SNPs is compared with those found in the plasma portion of the sample, which contains both fetal and maternal DNA. Because the fetus will inherit unique paternal SNPs, a difference of more than six SNPs between the buffy coat and the plasma indicates that fetal DNA is present in the sample and the test result is valid.

A new Sensigene test (Sequenom; San Diego, CA) is now available in the United States that consists of a multiplex analysis using the mass array system designed to detect exons 4, 5, and 7, and *RHD Ψ* (pseudogene) of the *RHD* gene along with three Y-chromosome sequences (SRY, DBY, and TTTY2). It allows the detection of RhD genotype with an accuracy of 97.1%, a sensitivity of 97.2%, and a specificity of 96.8% when compared with RhD serotyping.²⁵ These results indicate that cffDNA has now achieved the level of accuracy that would allow its widespread adoption in place of amniocentesis when determination of the fetal RhD status is warranted in the alloimmunized pregnancy.

cffDNA testing to determine the fetal antigen status is available in Europe for the C, c, E, and Kell (K1) antigens, but this testing is not yet available in the United States.²⁶ For a non-RhD antibody, amniocentesis can be used in the case of a heterozygous paternal genotype to test fetal DNA to determine the fetal antigen status for the majority of the red cell antigens associated with HDFN.

Middle Cerebral Artery Doppler

Measurement of the peak systolic velocity (PSV) in the fetal middle cerebral artery (MCA) has been shown to be an accurate noninvasive method for detecting fetal anemia. In the initial report by Mari and coworkers,²⁷ normative data for gestational age was established. Using receiver operating characteristic curve (ROC) analysis, a threshold value of 1.5 multiples of the median (MoM) was used to predict moderate to severe anemia (<0.65 MoM for fetal hemoglobin). These authors calculated that more than 70% of invasive tests could be avoided if this modality were used to monitor all alloimmunized pregnancies. A meta-analysis of noninvasive monitoring of alloimmunized pregnancies reported that the MCA-PSV had a positive likelihood ratio of 8.45 (95% confidence interval [CI], 4.7 to 15.6) for the detection of fetal anemia; the negative likelihood ratio was 0.02 (95% CI, 0.001 to 0.25).²⁸ In a prospective series, Oepkes and coworkers²⁹ found that the peak MCA Doppler value was superior to Δ OD450 measurements using both the Queenan and Liley curves in the detection of severe fetal anemia. The accuracy of MCA Doppler assessment was 85%, compared with 76% for the Liley curve and 81% for the Queenan curve. These data have led to the widespread acceptance of the MCA-PSV as the primary surveillance tool for detecting fetal anemia in the red cell alloimmunized pregnancy.

To accurately measure the MCA-PSV, the anterior wing of the sphenoid bone at the base of the skull is located. Color or power Doppler is then used to locate the MCA vessel closest to the transducer, although the more distant MCA will give similar results (Fig. 36-4).³⁰ The Doppler gate is then placed in the proximal MCA as the vessel arises from the carotid siphon, as measurements in the more distal aspect of the vessel will be inaccurate because of reduced peak velocities. In the original description by Mari, the angle of insonation between the Doppler beam and the vessel was maintained near zero, to more closely estimate the true velocity. A recent study, however,

Figure 36-4 Middle cerebral artery showing location of Doppler gate. Arrow indicates location for correctly measuring the peak velocity.

indicated that angle-correction software can be used to correct an insonation angle of up to 30 degrees, with good correlation to the true velocity.³¹ An additional consideration is that the pulse repetition frequency should be optimized to the approximate peak velocity (Fig. 36-5). These adjustments optimize the appearance of the waveform and make the true peak velocity more discernible. Peak systolic measurements should be made with electronic calipers; automated software to trace the waveform typically underestimates the true peak velocity. Finally, the fetus should be in a quiescent state during the Doppler examination, as accelerations of the fetal heart rate can result in a false depression in the MCA-PSV, especially late in the third trimester.³² Measurements can be initiated at as early as 16 to 18 weeks' gestation and should be performed weekly (Fig. 36-6). Values should be reported in MoM to account for changes in gestational age. Internet-based calculators are available (see www.perinatology.com/calculators2.htm).

CLINICAL MANAGEMENT

Severe HDFN is usually not present in the patient's first alloimmunized pregnancy; subsequent gestations are generally associated with a worsening degree of fetal anemia.

First Affected Pregnancy

Once an antibody reported to cause HDFN has been detected in an initial maternal antibody screen, a titer should be obtained to assess the amount of antibody present (Fig. 36-7). If the value remains below a critical value (32 for anti-D and most other antibodies; 8 for anti-Kell [see Anti-K, later]), titers are obtained every month until approximately 24 weeks' gestation, and then every 2 weeks thereafter. Paternal blood is drawn to determine if the patient's partner is positive for the involved red cell antigen and to investigate his zygosity. DNA techniques are employed in the case of RhD; for other antigens, serology is used to determine the paternal genotype. In cases of a heterozygous paternal genotype for RhD, cffDNA is used to determine the fetal RhD status. In the case of other red cell antigens,

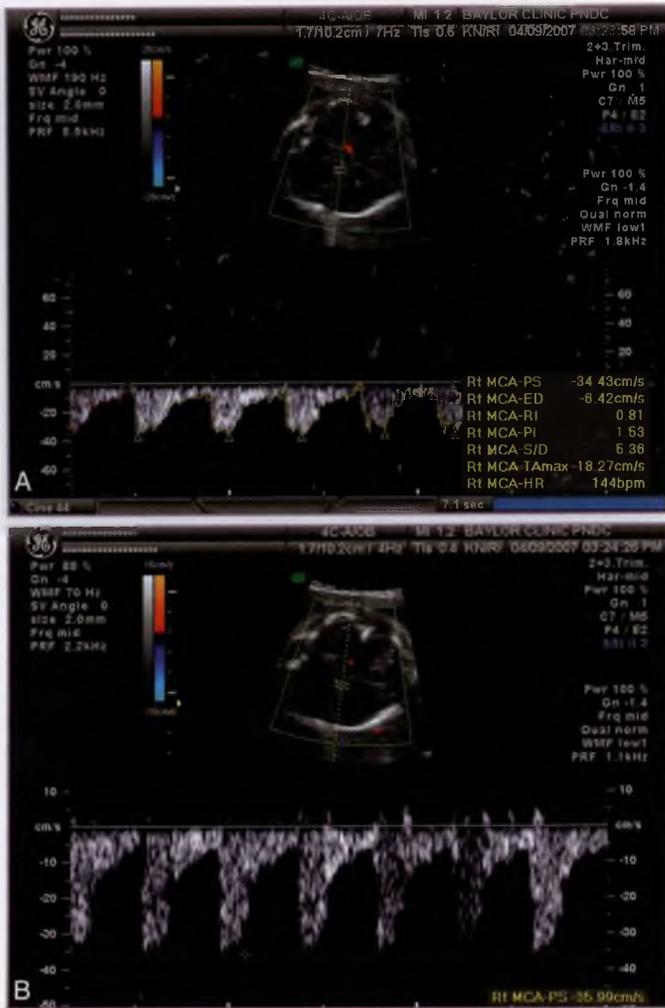

Figure 36-5 Optimization of Doppler parameters. A, Baseline and pulse repetition frequency (PRF) not optimized; automated software is used to measure a peak velocity of 34 cm/sec. B, Doppler baseline changed to 10 cm/sec, PRF optimized; manual caliper is used to measure a peak velocity of 36 cm/sec.

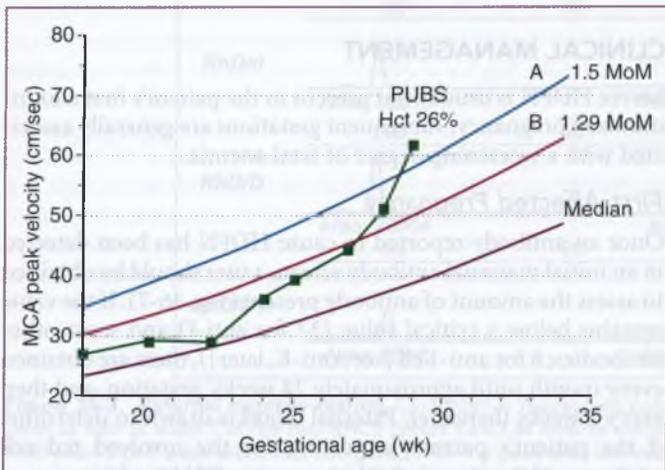

Figure 36-6 Serial Doppler determinations of the peak systolic velocity in the fetal middle cerebral artery (MCA). Zone A indicates moderate to severe anemia (>1.5 multiples of the median [MoM]). Zone B indicates mild anemia. Hct, hematocrit; PUBS, percutaneous umbilical blood sampling.

amniocentesis is performed after 15 weeks' gestation to determine the fetal antigen status.

If the paternal blood typing is negative for the involved red cell antigen, further maternal and fetal monitoring is unwarranted as long as paternity is ensured. When the patient's partner is not available for testing or paternity is in question, cfDNA allows accurate assessment of the fetal RHD status. A homozygous paternal phenotype or genotype indicates an antigen-positive fetus and negates the need for cfDNA or amniocentesis for fetal typing.

If there is evidence of an antigen-positive fetus, Doppler assessment of the MCA is performed serially at 1- to 2-week intervals starting at around 24 weeks' gestation. An MCA-PSV greater than 1.5 MoM is an indication for cordocentesis for fetal hematocrit determination and intrauterine transfusion (IUT) as needed. Antenatal testing (nonstress test or biophysical profile) should be initiated after 32 weeks' gestation. Induction by 38 weeks' gestation should be considered.

Previously Affected Fetus or Infant

If the patient has a new partner and there is a history of a previous perinatal loss related to HDFN, a previous need for IUT, or a previous need for neonatal exchange transfusion, paternal red cell typing and zygosity testing should be undertaken. In the case of a partner who tests negative for the involved red cell antigen with ensured paternity, no further testing is necessary. A complicated previous pregnancy with the patient's same partner should result in a referral to a perinatal center with experience in the management of severely alloimmunized pregnancies. In these cases, maternal titers are not predictive of the degree of fetal anemia. In the case of an antigen-positive fetus by cffDNA or amniocentesis, serial MCA-PSV testing should begin at as early as 16 weeks of gestation and repeated every 1 to 2 weeks. In the rare case in which these pregnancies do not require IUTs, the remaining management should be identical to that used in a first affected pregnancy.

TREATMENT

Access Site for Intrauterine Transfusion

The cord insertion proximate to the fetal umbilicus should be avoided because vagal innervation is thought to be present, increasing the likelihood of fetal bradycardia. Weiner and coworkers³³ also noted that puncture of the midsegment of the umbilical cord was associated with a 2.5-fold higher incidence of fetal bradycardia, compared with puncture at the placental insertion. Therefore, the cord insertion into the placenta is the preferred site for access. The vessel of interrogation should be the umbilical vein instead of one of the umbilical arteries. In one series of 750 diagnostic or therapeutic cordocentesis procedures, the incidence of fetal bradycardia was 21% with puncture of the umbilical artery but only 3% with umbilical venous puncture.³³ Several authors conjectured that this higher incidence of bradycardia may be the result of spasm of the muscularis of the umbilical artery. Other centers have advocated use of the intrahepatic portion of the umbilical vein in an effort to prevent fetal bradycardia. Nicolini and coworkers³⁴ reported a 2.3% incidence of fetal bradycardia using this approach in 214 procedures. These authors proposed that absence of the umbilical artery at the anatomic level of the intrahepatic vein explained their low incidence of fetal bradycardia. An additional advantage proposed by the authors was that blood loss from the cord puncture site would be minimized by absorption from the peritoneal cavity.

Despite these theoretical advantages, IUTs using the intrahepatic vein have been reported to be associated with an increase in fetal stress hormones (noradrenaline, cortisol, and β -endorphin).^{35,36} Similar changes in hormone levels were not detected when the cord placental insertion was used as the site of transfusion. Puncture of the intrahepatic vein is technically more challenging than placental insertion, predominantly because of fetal movement. The fetus must present with its

spine toward the maternal back to allow access. Most centers in the United States, therefore, use the umbilical cord insertion into the placenta as the primary site of access for IUT. However, in cases of poor visualization, use of the intrahepatic vein is an option.

Direct cardiac puncture has been reported as a method of access for IUT, but it has been associated with a high rate of fetal death, so its use cannot be advocated. In one series of 158 cases of diagnostic cardiocentesis for the prenatal diagnosis of hemoglobinopathies, the corrected fetal loss rate was 5.6%, significantly higher than the 1% loss rate usually identified for cordocentesis.³⁷

Method of Intrauterine Transfusion

Until the direct intravascular transfusion (IVT) was introduced in the mid 1980s, the intraperitoneal transfusion (IPT) was the method of IUT for almost 20 years. With the advent of ultrasound-directed fetal blood sampling, direct transfusion of cells into the umbilical circulation became the preferred method for IUT. Experience in hydropic fetuses indicated that the absorption of transfused red cells from the peritoneal cavity is compromised. Harman and colleagues³⁸ compared the direct IVT and IPT techniques, matching patients for severity of disease, placental location, and gestational age at the start of transfusions. Several important differences in outcome were noted. When the fetuses were divided into nonhydropic and hydropic groups at the time of the first transfusion, a 13% greater survival rate was observed in nonhydropic fetuses for IVT compared with IPT; in the hydropic fetuses, the rate of survival was almost doubled with IVT. IVT resulted in fewer neonatal exchange transfusions than IPT and a shorter stay in the intensive care nursery. Direct IVT, therefore, has become the preferred method of transfusion of the anemic fetus. Advocates of direct IVT often transfuse to a final hematocrit (Hct) value of 50% to 65%. This allows a reasonable interval between procedures, based on a projected decline in Hct of 1% per day. However, caution should be exercised in transfusing the fetus to nonphysiologic values for hematocrit. Welch and coworkers³⁹ demonstrated that a marked rise in whole blood viscosity is associated with fetal hematocrit values greater than 50%.

The IPT remains a practical method for delivery of red cells to the nonhydropic fetus if there is difficulty with access to the umbilical cord or intrahepatic umbilical vein. Bowman⁴⁰ proposed a formula for calculating the IPT volume that has withstood the test of time. The volume of red cells to be infused (in milliliters) is calculated by subtracting 20 from the gestational age in weeks and multiplying the result by 10. Blood in the peritoneal reservoir can be expected to be absorbed over a 7- to 10-day period.

A combined IVT-IPT technique has been proposed, using the hypothesis that the intraperitoneal infusion of blood can serve as a reservoir that allows a slow absorption of red cells and produces a more stable hematocrit between procedures.⁴¹ The technique involves administering enough packed red cells by IVT to achieve a final fetal Hct of 35% to 40%, followed by a standard volume for the IPT. In one study, the decline in Hct per day was markedly improved with this technique (0.01% per day) compared with IVT alone (1.14% per day).

Data on IUTs in twin gestations are limited to case reports. In one series of nine pregnancies complicated by RhD alloimmunization, five required IUT.⁴² In four of the five cases, the twins were dizygotic, based on first-trimester ultrasound. In one

case, only one fetus was RhD negative, illustrating the need to sample each fetus for antigen testing. In one case of monozygotic gestation, the IUT of one fetus was quickly followed by movement of donor red blood cells through intraplacental anastomoses, as illustrated by a positive Kleihauer-Betke stain at the time of blood sampling of the second twin. In subsequent IUTs, the transfusion of only one member of the twin pair resulted in adequate levels of hemoglobin in both twins. Therefore, caution against overtransfusion should be observed in the monozygotic gestation. The intrahepatic portion of the umbilical vein may be the preferred target for vascular access when transfusing a twin gestation if the corresponding placental cord insertions are difficult to identify.

Donors of red cells used for IUT must undergo the same rigorous infectious disease testing that occurs for any allogeneic donation. A unit collected in the previous 72 hours theoretically improves the longevity of the red cells in the fetal circulation. Some centers perform an extended cross-match with the mother to prevent sensitization to new red cell antigens. Red cells to be used for IUT should be cytomegalovirus seronegative. The unit should be packed to a final hematocrit of 75% to 85%, the leukocyte number reduced using specialized micropore filters, and the unit irradiated with 25 Gy to prevent graft-versus-host reaction.

Intrauterine Transfusion Technique

Some centers perform IUTs in a specialized area proximate to the labor and delivery suite. Once a viable gestation age is achieved, performing the procedures in an operating room setting is prudent in case an emergency delivery is required. Conscious sedation can be used for the procedure and is best managed in an operating room setting with the assistance of an anesthesiologist. A mobile automated hemocytometer to quickly determine the fetal hematocrit is better than using a runner to take samples to a distant hematology laboratory. Preoperative prophylactic antibiotics consisting of a first-generation cephalosporin are used by many centers; preoperative tocolytic agents are optional.

Once access to the fetal circulation is obtained, an initial sample should be sent for hematocrit, reticulocyte count, and Kleihauer-Betke stain. A paralytic agent is usually then administered to cause cessation of fetal movement. Vecuronium at a dosage of 0.1 mg/kg of estimated fetal weight by ultrasound has a rapid onset of action and is not associated with fetal tachycardia. The total amount of red cells to transfuse depends on the initial fetal hematocrit, fetoplacental blood volume, and hematocrit of the donor unit. If the donor unit has a hematocrit of approximately 75%, the estimated fetal weight in grams using ultrasound can be multiplied by a factor of 0.02 to determine the volume of red cells to be transfused to achieve a hematocrit increment of 10%.⁴³ Other coefficients can be used to calculate larger hematocrit increments if needed (Table 36-1).

Once the final desired target hematocrit is achieved, a Kleihauer-Betke stain may be useful at the end of the procedure to determine the amount of fetal red cells that remain in circulation. In the extremely anemic fetus, the initial hematocrit should not be increased by more than fourfold to allow the fetal cardiovascular system to compensate for the acute change in viscosity. In this circumstance, a repeat procedure is undertaken 48 hours later to normalize the fetal hematocrit. Hydrops typically reverses after one or two intravascular transfusions; placentomegaly is the last feature of the hydropic state to reverse.

TABLE 36-1 Transfusion Coefficient for Calculating Transfusion Volume

Target Increase in Fetal Hematocrit	Transfusion Coefficient
10%	0.02
15%	0.03
20%	0.04
25%	0.05
30%	0.06

The timing of subsequent transfusions is the subject of ongoing debate. At our center, we use empiric intervals of 10 days, 2 weeks, and then every 3 weeks for the second, third, and subsequent procedures. Other experts recommend that the interval be calculated on the basis of an anticipated decline in fetal hemoglobin of 0.4 g/dL/day, 0.3 g/dL/day, and 0.2 g/dL/day for the first, second, and third transfusion intervals.⁴⁴ However, a more rapid decline in hematocrit in the first transfusion interval can be anticipated in hydropic fetuses than in those without hydrops (1.88% per day versus 1.08% per day).⁴⁵ The accuracy of the MCA-PSV to detect fetal anemia before the first IUT has led many to conclude that this modality would also be useful in determining the timing of subsequent transfusions. Detti and colleagues⁴⁶ proposed that the MCA-PSV may be used to time the second IUT if a modified threshold of 1.32 MoM (instead of 1.5 MoM) be used to detect moderate-severe anemia. The second transfusion interval (between the second and third transfusions) cannot be accurately assessed with MCA-PSV, probably because of the change in fetal red cell rheology resulting from the presence of donor red cells in conjunction with increased oxygen delivery to peripheral tissues. Using a threshold of greater than 1.5 MoM for the MCA-PSV to determine the timing of the third IUT, Scheier and associates⁴⁴ demonstrated a detection rate of only 64% for a fetal hemoglobin deficit of more than 6 g/dL. Currently a multicenter randomized clinical trial is being undertaken through the University of Adelaide comparing an empiric normogram to an elevated MCA-PSV of greater than 1.5 MoM to determine the need for subsequent transfusions (Australian New Zealand Clinical Trials Registry #ACTRN12608000643370; accessible at www.anzctr.org.au).

Severely Anemic Early-Second-Trimester Fetus in a Previous Pregnancy

The pregnant patient with a history of early-second-trimester recurrent pregnancy loss resulting from HDFN is especially challenging. Despite improved ultrasound resolution, targeting an umbilical vessel at less than 22 weeks' gestation can be technically challenging. The procedure-related loss is 10-fold increased compared with procedures undertaken later in gestation.⁴ Conception through artificial insemination with RhD-negative donor semen, surrogate pregnancy, and preimplantation diagnosis in the case of a heterozygous paternal genotype should be presented as options to the couple.⁴⁷

If the couple elects to proceed with conception in the face of a previous early fetal death resulting from HDFN, several therapeutic approaches can be attempted. Ruma and colleagues⁴⁸ used immunomodulation in a series of nine patients, seven of whom had experienced a previous perinatal loss. The authors' protocol consisted of a single-volume plasmapheresis every other day for three procedures in the 12th week of gestation, with 5% albumin used for volume replacement. The patient's IgG pool was replaced after the third procedure by administering a 1-g/kg loading dose of intravenous immune globulin (IVIG) diluted in normal saline. A second dose of 1 g/kg IVIG was given the following day. The patients were then treated with a weekly dose of 1 g/kg IVIG until 20 weeks' gestation. All nine pregnancies were ultimately given IUTs, with subsequent neonatal survival. Procedures in the treated pregnancies occurred on average 3 weeks later than the index pregnancy, and the fetal Hct was 65% higher at the time of the first IUT as compared with the IUT in the index pregnancy. Thus, a combination of plasmapheresis to initially lower the maternal antibody level followed by IVIG appears to be effective in prolonging the interval to the first IUT in this select group of high-risk patients.

A second approach is to use IPTs early in the second trimester to empirically provide red cells to the fetus that will not be destroyed by the maternal red cell antibodies. The larger target of the peritoneal cavity is more easily accessible than the umbilical vessels at these early gestations. Fox and coworkers⁴⁹ reported a series of six pregnancies with a previous perinatal loss rate of 66%. Patients were treated with biweekly IPTs starting at 15 weeks' gestation—a volume of 5 mL was used up to 18 weeks' gestation; a 10-mL volume was used thereafter. Four of the six patients received 0.8 g/kg/week of IVIG as well. Overall survival in this highly selected population was 86%.

Timing of Delivery

Until the introduction of the direct IVT, fetuses with HDFN were routinely delivered by 32 weeks' gestation. Hyaline membrane disease and the need for neonatal exchange transfusions for the treatment of hyperbilirubinemia were common. As experience with IVT became widespread, several centers began to question this policy of premature delivery. Klumper and colleagues⁵⁰ compared perinatal mortality for IUTs undertaken before and after 32 weeks' gestation. Perinatal loss occurred in 3.4% of 409 early IUTs and in 1% of 200 procedures performed after 32 weeks' gestation. Most experienced centers now perform the final IUT at up to 35 weeks' gestation, with delivery anticipated at 37 to 38 weeks. Finally, the administration of maternal oral phenobarbital may be considered in the 7 to 10 days before delivery. This has been proposed to induce hepatic maturity to allow improved conjugation of bilirubin. One retrospective study has demonstrated a reduction in the need for neonatal exchange transfusions for hyperbilirubinemia.⁵¹

Outcome

Experienced referral centers have reported excellent rates of survival with the intravascular IUTs. In the largest series reported to date—740 procedures in 254 fetuses treated at a national referral center in The Netherlands between 1988 and 2001—the overall perinatal survival was 89%.⁵² Hydrops fetalis was associated with a decreased rate of survival to 78%. A 1.6% rate of perinatal loss was associated with each procedure. Similarly, a series of 284 transfusions in 84 pregnancies in Stockholm over a 20-year period revealed an overall survival of 92%.⁵³

Suppression of fetal erythropoiesis is not uncommon after several IVTs. These infants are born with a virtual absence of reticulocytes, and their red cell mass is almost entirely composed of donor red cells. Because exchange transfusion is rarely required, passively acquired maternal antibodies remain in the neonatal circulation for weeks. This results in a 1- to 3-month period in which up to 75% of these infants may need "top-up" red cell transfusions.⁵⁴ Weekly reticulocyte counts and hematocrit levels should be assessed until a rising reticulocyte count is noted for at least 2 consecutive weeks. Threshold-for-transfusion hematocrit values of less than 30% in the symptomatic infant or less than 20% in the asymptomatic infant have been suggested. Iron therapy in these neonates is unnecessary because of their elevated stores as a consequence of the in utero hemolytic disease and IUT therapy. Recombinant erythropoietin has been attempted in these infants with minimal effect on their reticulocytosis.⁵⁵ This may be related to the very high circulating maternal antibodies that remain in the neonatal circulation, as they often do not require exchange transfusions after birth as a result of the effective in utero therapy.

The advent of IVT has resulted in improved survival for the severely anemic fetus with hydrops. In a series of 16 hydropic fetuses who survived to 10 years of age, two of the infants (12.5%) were found to exhibit severe neurologic morbidity.⁵⁶ The LOTUS study recently reported the neurodevelopmental outcome of 281 children with HDFN who were treated with IUTs.⁵⁷ Median age at follow-up was 8.2 years (range, 2 to 17 years). Cerebral palsy was detected in 2.1%, severe developmental delay in 3.1%, and bilateral deafness in 1.0% of the study population. This compared with an incidence of cerebral palsy in the general Dutch population of 0.2% to 0.7% and a rate of severe neurodevelopmental delay of 2.3%. In a multivariate regression analysis including only preoperative risk factors, only severe hydrops fetalis was independently associated with neurodevelopmental impairment (odds ratio = 11.2; 95% CI, 1.7 to 92.7).

Other long-term studies on children and adults who have been treated with IUTs are scarce in the literature. Dickinson and colleagues⁵⁸ investigated cardiac function at a median age of 10.6 years (range, 3.6 to 15.8) in children requiring IUTs for the treatment of their fetal anemia and compared their results with those of matched controls. The study group was found to have evidence of a 10% decrease in left ventricular mass and a 9% decrease in left atrial area. The authors speculated that these findings may result from the prenatal effects of anemia on cardiomyocyte proliferation and differentiation, predisposing these children to adult cardiac disease.

PREVENTION

Formulations

All current rhesus immune globulin (RhIG) products available in the United States (RhoGAM, Ortho-Clinical Diagnostics; HyperRHO S/D, Talceris Biotherapeutics-USA; Rhophlac, ABO Pharmaceuticals; and WinRho-SDF, Cangene Corp.) are polyclonal antibody products derived from human plasma. The latter two products are purified by ion-exchange chromatography and can therefore be administered by either the intravenous or the intramuscular route. All current products undergo micropore filtration to eliminate viral transmission. No cases of viral infection related to RhIG administration been reported in the United States, although an outbreak of hepatitis C related

to RhIG was reported in Ireland in the 1970s.⁵⁹ A novel polyclonal recombinant antibody known as rozrolimupab (Symphogen, Copenhagen) has been used in phase one and two clinical trials and has demonstrated no serious or adverse effects. When compared with plasma-derived anti-D antibodies, a similar dosage-dependent rate of erythrocyte clearance of RhD red cells from the circulation of volunteers was noted.⁶⁰

Administration

All pregnant patients should undergo an antibody screen at the first prenatal visit. If there is no evidence of anti-D alloimmunization in the RhD-negative woman, patients in the United States should receive 300 µg of RhIG at 28 weeks' gestation.⁶¹ The American Association of Blood Banks (AABB) recommends that a repeat antibody screen be obtained before antenatal RhIG administration, even though the incidence of alloimmunization before 28 weeks is very low. Severe maternal sensitization does occasionally occur before 28 weeks, and by not performing the antibody screen, the clinician loses the opportunity to detect a potentially salvageable anemic fetus. It is therefore prudent to repeat the antibody screen. The maternal blood sample can be drawn at the same office visit as the RhIG injection, as the peak anti-D titer will not occur for 2 to 7 days.⁶² Although there are no data to provide guidance, some experts recommend that a second dose of RhIG be given if the patient has not delivered by 40 weeks' gestation.

After the administration of antenatal RhIG, some patients exhibit an anti-D titer of 2 to 4 at the time of their antibody screen during labor. In one study of 96 patients, all were found to have a positive anti-D antibody screen if they presented to labor and delivery at less than 37 weeks' gestation.⁶³ By 42 weeks' gestation, this had decreased to 10% of the patients.

The RhD antigen is expressed on the fetal red blood cell as early as 38 days after conception.⁶⁴ This has led to the recommendation to administer RhIG for early pregnancy events such as spontaneous abortion, elective abortion, threatened abortion, and ectopic pregnancy, where the background rate of subsequent sensitization is 2% to 3%.⁶⁵

A dose of 50 µg of RhIG is effective until 12 weeks' gestation because of the small volume of red cells in the fetoplacental circulation. From a practical standpoint, most hospitals and offices do not stock this dosage of RhIG; therefore, a standard dose of 300 µg is often given. Evidence for the use of RhIG in other scenarios that breach the fetoplacental barrier is lacking. RhIG should also be administered for such events as hydatidiform mole, genetic amniocentesis and chorion villus biopsy, fetal death in the second or third trimester, blunt trauma to the abdomen, late amniocentesis, and external cephalic version. In ongoing pregnancies when RhIG is administered in the first or second trimester for one of these indications, a repeat dose should still be given at 28 weeks' gestation. Alternatively, if the antenatal dose was given in the late second trimester (e.g., at 22 weeks for suspected placental abruption), the dose should be repeated 12 weeks later (i.e., at 34 weeks' gestation in that example).

Current recommendations in North America indicate that 300 µg of RhIG should be administered within 72 hours of delivery if umbilical cord blood typing reveals an RhD-positive infant. In a Cochrane review of six selected randomized trials, Crowther and coworkers⁶⁶ found that postpartum RhIG administration lowered the incidence of RhD alloimmunization at 6 months after birth by 96% (95% CI, 94% to 98%).

A dose of 300 µg of RhIG is sufficient to protect from sensitization caused by a fetomaternal hemorrhage (FMH) of 30 mL of fetal whole blood. If RhIG is inadvertently omitted after delivery, some protection has been proven with administration within 13 days; recommendations have been made to administer it as late as 28 days after delivery. If delivery occurs less than 3 weeks from the administration of RhIG used for antenatal indications such as amniocentesis for fetal lung maturity or external cephalic version, a repeat dose is unnecessary unless a large FMH is detected at the time of delivery.

Approximately three in 1000 deliveries are associated with an excessive FMH.⁶⁷ Maternal risk factors identify only 50% of these cases. The AABB therefore recommends that all deliveries be screened for FMH. A qualitative test, the rosette test, is usually performed first. Results are reported as positive or negative. A negative result warrants administration of a standard dose of RhIG. If the rosette is positive, a Kleihauer-Betke stain or fetal cell stain using flow cytometry is performed. AABB standards indicate that the percentage of fetal blood cells should then be multiplied by a factor of 50 (based on a standard blood volume of 5 L for all pregnant women) to determine the volume of the FMH. This is then divided by 30 to determine the number of vials of RhIG to administer. If the calculation results in a fraction of a unit of 0.5 or greater, the number of vials required is rounded up to the higher whole integer. Another vial is usually added to the calculation to ensure that sufficient RhIG is administered. Despite these recommendations, when the College of American Pathologists (CAP) sent a test sample with a known level of FMH to 1450 blood banks, they found that 11.5% would have recommended excess RhIG and 9.2% would have recommended an insufficient amount.⁶⁸ This led CAP to provide an on-line calculator to assist in reducing such errors (www.cap.org/apps/docs/committees/transfusionmedicine/RHIGCALe.zip). In cases of the extreme levels of FMH that may accompany third-trimester fetal demise, or after the transfusion of a mismatched unit of RhD positive red cells, no more than five units of intramuscular RhIG should be administered in a 24-hour period because of volume limitations. If a large dosage of RhIG is necessary, an alternative method would be to give the entire calculated dose intravenously in divided increments (maximal amount for each increment, 3000 IU or 600 µg) every 8 hours. The administration of RhIG after a postpartum tubal ligation is controversial. The possibility of a new partner in conjunction with the availability of in vitro fertilization might make the use of RhIG in these situations prudent. In addition, RhD sensitization would limit the availability of blood products if the patient later required a transfusion. RhIG has not been shown to be effective once alloimmunization to the RhD antigen has occurred.

The "Weak D" Dilemma

Monoclonal typing sera are now routinely used for RhD typing. Many of the weak D and D variants cannot be detected unless a Coombs phase is performed during the typing procedure. For prenatal testing, this is no longer recommended by the AABB.⁶⁹ Therefore, some pregnant patients who exhibit reduced numbers of intact RhD antigens or partial RhD antigens on their red cells will be reported as *RhD negative*. These patients will therefore be candidates for RhIG. Although not systematically studied, this practice has the potential to reduce the chance for alloimmunization in cases of rare RhD phenotypes.

Confusion can arise if the pregnant patient was previously a blood donor. In this case, current practice is to employ the indirect Coombs test in the RhD typing, which will detect most partial RhDs and RhD variants. These individuals are called RhD positive. Such a practice prevents the potential for alloimmunization in RhD-negative individuals should they receive a blood unit from these atypical donors. The conflicting results of a RhD-positive result before pregnancy with a RhD-negative result during pregnancy (with the need for RhIG) can be easily explained to the patient, based on the different methods of red cell typing that have been employed.

Mass Screening of RhD-Negative Women with cffDNA

Approximately 38% of RhD-negative women with an unknown paternal blood type will carry an RhD negative fetus. Several countries in Europe have studied the potential for mass screening with cffDNA to limit the use of RhIG to only those patients with an RhD-positive fetus. The primary driver for this endeavor is to reduce costs. Szczepura and colleagues⁷⁰ conducted a cost analysis of mass testing to target antenatal anti-D prophylaxis in England and Wales. The first theoretical scenario involved cffDNA testing for fetal RhD testing in all nonimmunized Rh-negative pregnant patients. Antenatal RhIG was to be withheld if an RhD-negative fetus was detected. Standard cord serology after birth would continue to be performed to determine need for postpartum RhIG. In the second scenario, cffDNA would be drawn from all RhD-negative women and the decision to withhold both antenatal and postnatal RhIG would be based on the results. Cord serology would be eliminated at birth. The breakeven costs for cffDNA testing in scenario one was \$29, and \$39 for scenario two. More importantly, missed opportunities for prevention of new annual cases of RhD alloimmunization in England and Wales ranged from 1 to 54 cases for scenario one and 14 to 744 cases in scenario two, based on the inaccuracy of the cffDNA assay. At this time, only The Netherlands has implemented the use of prenatal cffDNA in all RhD-negative pregnancies to determine the need for RhIG as a national policy.

Hemolytic Disease of the Fetus and Newborn Caused by Non-RhD Antibodies

More than 60 different anti-red cell antibodies have been associated with HDFN (Table 36-2). A recent national first-trimester screening program in The Netherlands found that non-RhD antibodies occurred in 1 in 304 pregnancies.¹ Slightly more than 50% of these were associated with a potential risk for HDFN based on paternal testing for the involved antigen. Clinical outcomes indicated that the frequency of severe HDFN was 26% in cases of anti-Kell and 10% for anti-c. A review of a large series of IUTs from one referral center indicated that 10% of IUTs were secondary to Kell disease, and 3.5% of IUTs were secondary to anti-c alloimmunization. Anti-E, anti-e, and anti-Fy^a have been reported to require IUT in single cases in another large series of IUTs.^{52,53}

Anti-Rhc

Anti-c antibody has been associated with severe HDFN of a magnitude similar to that caused by anti-D. In one series, more than half of pregnant patients had a history of a previous blood

transfusion.⁷¹ Hackney and colleagues⁷² found that 25% of c-antigen-positive fetuses exhibited severe HDFN; 7% of the total group were hydropic and 17% required IUTs.

Anti-RhC, -RhE, and -Rhe

Antibodies against the rhesus antigens C, E, and e are usually found at a low titer in conjunction with anti-RhD antibody (e.g., anti-D, 128; anti-C, 2). Their presence may be additive to

the hemolytic effect of the anti-D on the fetus.⁷³ IUTs are only rarely reported when these antibodies occur as the sole finding.^{74,75}

Anti-RhG

In some patients, the anti-D and anti-C titers are observed to be equal; alternatively, the value of the anti-C titer may actually exceed that of the anti-D (e.g., anti-D, 128; anti-C, 256). In these cases, one should suspect the presence of anti-RhG. Consultation with a blood bank pathologist should be undertaken to clarify whether anti-RhG is present. High-titer anti-G can be associated with significant fetal disease necessitating IUT.⁷⁶ Importantly, if invasive fetal procedures are indicated, RhIG should be administered to prevent the formation of anti-D.

Anti-K (K1)

The K1 antigen is one of 25 antigens in the Kell system. However, antibody to this antigen is the leading cause of HDFN related to Kell. K1 is found on the red cells of 9% of whites and 2% of blacks, with virtually all antigen-positive individuals being heterozygous (Table 36-3). These gene frequencies are calculated to yield approximately a 5% risk for an affected fetus in the Kell alloimmunized pregnancy if the paternal antigen status and zygosity are unknown. Because the majority of cases of alloimmunization are the result of transfusion (blood is not routinely cross-matched for the Kell in the United States), the first step in the treatment of these patients should be to determine the paternal Kell type. The Kell antibody is noted to cause fetal anemia by two distinct mechanisms—fetal splenic sequestration of sensitized red cells and suppression of the fetal erythropoiesis.⁷⁷ For this reason, a lower maternal critical titer of 8 is usually used to initiate fetal surveillance.

Anti-k (K2)

This antibody has only rarely been associated with the need for IUT.⁷⁸ Maternal titers in these cases were 8 to 16, indicating that like the anti-K1 antibody, anti-k may produce fetal erythropoietic suppression at lower maternal titers than are typically used for a critical value in cases of anti-RhD.

TABLE 36-3 Antigen Frequencies and Zygosity for Red Cell Antigens Associated with HDFN

Anti-M and Anti-N

Anti-M and anti-N are naturally occurring IgM antibodies that typically are cold agglutinins. In a series of almost 400 cases of anti-M detected during first-trimester screening, there was no conversion to an IgG response and no association with HDFN.¹

Anti-Duffy

The Duffy antigen system consists of two antigens, Fy^a and Fy^b. Anti-Fy^b antibodies have not been associated with HDFN. Anti-Fy^a is usually associated only with neonatal jaundice.⁷⁹

Anti-Kidd

The Kidd system antigen system consists of two antigens, Jk^a and Jk^b. Antibodies to these antigens are usually associated with only mild HDFN.

Future Therapy

Hall and associates⁸⁰ developed transgenic mice for the human *HLA-DR15* gene and then immunized them to purified human RhD protein. Four candidate peptides were developed that represented significant epitopes for helper T cells; these were then administered intranasally to the immunized mice. A blunted antibody response was noted when the mice were rechallenged with the purified RhD protein. If confirmed in subsequent clinical trials, such therapy may prove useful in the treatment of the severely alloimmunized pregnant patient and may negate the need for IUTs.

Summary and Recommendations

- An antibody screen should be undertaken at the first prenatal visit in all pregnancies.
- In the RhD-negative patient without alloimmunization, a repeat antibody screen should be performed at 28 weeks' gestation, followed by the administration of 300 µg of rhesus immune globulin. RhIG should be given after delivery, with the dosage based on the results of routine testing for fetomaternal hemorrhage.
- In the first alloimmunized pregnancy, maternal titers can be used to guide the need for fetal surveillance. A critical titer of 32 for anti-D and other antibodies, and a critical titer of 8 for anti-Kell, should be used as a threshold to begin surveillance with serial MCA-PSV Doppler ultrasound.
- Fetal RhD genotype testing through cfDNA in the case of heterozygous paternal genotype can eliminate the 50% of patients who are unaffected. Amniocentesis to obtain fetal DNA can be used to determine the fetal genotype in cases of alloimmunization to other red cell antibodies associated with HDFN.
- A value of greater than 1.5 MoM for the MCA-PSV Doppler scan indicates the need for cordocentesis and possible intrauterine transfusion.
- In previously affected pregnancies, maternal titers should NOT be used to guide the need for fetal surveillance—MCA-PSVs should be started at 16 to 18 weeks' gestation.

Nonimmune Hydrops

ISABELLE WILKINS, MD

Hydrops fetalis is the term used to describe generalized edema in the neonate. This edema is accompanied by collections of fluid in serous spaces. In the past, most cases of hydrops fetalis were caused by severe erythroblastosis from Rh alloimmunization. Potter was the first to describe nonimmune hydrops fetalis in a group of infants without erythroblastosis whose mothers were Rh-positive.¹

Since first described 60 years ago, nonimmune hydrops (NIH) has become more common than hydrops from alloimmunization. Santolaya and associates reported a series of 76 hydropic fetuses, of which 87% were nonimmune.² Sohan and associates³ reported that only 4 of 87 patients, or 4.5%, assessed at a fetal medicine unit were cases of red cell alloimmunization, and Ismail and coworkers⁴ reported 63 prenatally detected cases of which eight (12.7%) were immune. Graves and Baskett examined all babies born at their institution with hydrops and reported that 76% of cases were nonimmune.⁵ More recently, Trainor and Tubman reported their experience over three time periods and showed that the percentage of nonimmune cases of hydrops at delivery increased dramatically from 0% in 1974 to 80% in 2002.⁶

The incidence of NIH at delivery in published accounts is approximately 1 in 1500 to 1 in 3800.^{5,7,8} A large, unselected prenatal ultrasound screening clinic in Finland had a similar rate of 1 in 1700.⁹ Trainor and Tubman did not include stillbirths and found a rate of 1.34 per 1000 live births.⁶ Reviews from ultrasonography referral centers, however, show an incidence between 1 in 150 and 1 in 766 as found by sonographic examination.^{2,10,11}

NIH is a heterogeneous disorder with a large number of possible causes and associations. Overall, the prognosis is poor: a perinatal mortality rate of 52% to 98% is typical.^{3,4,9,12,13} Elucidation of the cause is of primary importance, because treatment of and prognosis for this disorder are determined by the underlying fetal condition, but the task may be difficult. Most studies reflect the rate of prenatal detection of etiology, which is lower than the rate after delivery or at autopsy. Both are important in counseling families and discussing recurrence risks, but only prenatal detection is useful in guiding management and therapy. In most series, a cause is found in approximately 51% to 85% of cases before delivery but in up to 95% after delivery, depending in part on parental acceptance of autopsy and karyotyping.^{3,4,9,11-14} It is clear that both success in determining etiology and survival statistics differ between early and late gestation, largely because of the different gestational ages at which the various causes become evident. In general, diagnosis before 24 weeks of gestation occurs in more-severe cases, in which the cause is easier to ascertain but perinatal survival is worse.^{3,4,9,10-12}

Initial Signs and Symptoms

Although NIH is a clinical diagnosis concerning the neonate, the condition can be determined antenatally by obstetric sonographic examination with a success rate of nearly 100%. The indication for ultrasonography varies in different series. In 1986, Watson and Campbell found that 63% of cases of NIH were discovered on routine ultrasonography, whereas another 30% of patients were referred because of suspected hydramnios.¹⁵ Graves and Baskett found that NIH was less commonly discovered on routine ultrasonography than on ultrasonography ordered for a specific indication.⁵ The most common indications in their population were hydramnios, size greater than dates, fetal tachycardia, and pregnancy-induced maternal hypertension. Other frequently cited indications for ultrasound evaluation have included abnormal serum screening, decreased fetal movement, and antenatal hemorrhage.^{10,16}

Maternal complications of pregnancy are increased in NIH. Hydramnios, pregnancy-induced hypertension, severe anemia, postpartum hemorrhage, preterm labor, birth trauma, gestational diabetes, a retained placenta, or difficult delivery of the placenta are all frequently mentioned in large series.^{5,7,12,17,18}

An uncommon maternal complication of fetal hydrops is called mirror syndrome. This condition is rarely a presenting complaint and may develop during conservative management of such pregnancies. Patients generally experience edema or pulmonary edema, and they may have hypertension and proteinuria. The similarity to severe preeclampsia has led some authors to refer to this as pseudotoxemia. The patients may be gravely ill but recover after delivery. The syndrome may also develop after the birth, as it did in two mothers in one series.¹² Although no series exist to direct management, most authors do not advise continuation of the pregnancy.^{10,19-21} A case report of fetal hydrops from parvovirus infection with concomitant maternal mirror syndrome was self-limited. As the fetal hydrops reversed, so did maternal symptoms, and a term delivery subsequently occurred.²² Stepan and Faber reported a similar case in which maternal levels of soluble fms-like tyrosine kinase-1 (sFlt-1) were extremely elevated initially and dropped after fetal transfusion, which resulted in resolution of both maternal and fetal symptoms.²³ Espinoza and colleagues found elevated levels of soluble vascular endothelial growth factor receptor-1 (sVEGFR-1), an antiangiogenic factor related to the pathogenesis of preeclampsia, in all four patients with mirror syndrome studied.²⁴

ULTRASONOGRAPHY

Ultrasound examination is essential to the diagnosis of NIH, and criteria for identification of the disorder in the fetus are

based exclusively on ultrasound findings. The fluid that accumulates may include ascites, pleural effusions, pericardial effusions, and skin edema. Several definitions of fetal NIH have been proposed on the basis of the quantity and distribution of excess fetal water. Variations in these definitions have made direct comparisons among published series inexact. Mahony and coworkers defined hydrops as generalized skin edema with or without an associated serous effusion.²⁵ Although others have also used this definition,²⁶ NIH is more commonly defined as edema with one or more effusions, or effusions in at least two spaces—that is, two of the following must be present: ascites, pleural effusion, pericardial effusion, or skin edema.^{27,28}

The degree of severity of hydrops is generally subjective. Hutchison and associates⁷ described a score based on the total number of serous space effusions. Because the only requirement for the definition of NIH was edema, it was possible to have a score of 0 (zero) with no serous involvement. This score was not predictive of outcome in this series, as the overall perinatal mortality rate was close to 100%. Saltzman and colleagues described a different scoring system, in which each effusion was quantified.²⁹ With their system, they were able to predict which cases were likely to be caused by fetal anemia and which were from other causes. Although they included isoimmunized pregnancies in their series, other forms of anemia followed the same general pattern.

Fluid in one of these spaces may be an early finding in a fetus destined to develop hydrops. At the very least, a careful search for fluid in other serous spaces is warranted. Such fetuses should undergo follow-up over time to ensure that hydrops is not developing. In general, these fetuses have a better prognosis than fetuses with hydrops.^{30,31}

FETAL FLUID ACCUMULATION

Sonographically, ascites appears as an echolucent rim of varying size in the fetal abdomen (Fig. 37-1). A small rim of ascites may be hard to distinguish from a similarly located area of echo dropout common with normal fetuses.²⁷ One possible distinguishing feature is that a true rim of fluid should be visible all the way around the abdomen in the transverse viewing plane. Longitudinally, the edge of the liver, bladder, or diaphragm may be outlined. When ascites is more marked, the entire liver is

Figure 37-1 Transverse sonographic image of the fetal abdomen at the level of the stomach. A large rim of ascites is seen in the abdominal wall.

outlined and the bowel is compressed (Fig. 37-2). In these more extreme cases, the diagnosis is relatively easy.

Pleural effusions may be unilateral or bilateral. Although the effusions may appear as small rims of fluid outlining the pleural space and diaphragm, more commonly they are large and compress the lung (Fig. 37-3). It is uncommon for a unilateral effusion to shift the mediastinum, but in such a case, an extrinsic fluid-filled mass, such as a diaphragmatic hernia or another space-occupying lesion, is likely to be present. Pulmonary hypoplasia is a frequent cause of death in neonates with NIH, and the size of the pleural effusion may help to predict this complication.¹⁸

Pericardial effusions are smaller in total volume and are therefore more difficult to see than ascites or pleural effusions (Fig. 37-4). Some authors have proposed that pericardial effusions indicate cardiac decompensation and that this is the earliest sign of hydrops in fetuses with cardiac lesions.²⁷ Among 19 patients with NIH of mixed etiology, Carlson and colleagues found that an end-diastolic biventricular dimension, as measured in an M-mode examination, of less than the 95th percentile was highly predictive of survival.³²

Skin edema is usually a generalized process, although it is easiest to see with ultrasonography over the chest wall or scalp,

Figure 37-2 Longitudinal sonographic image of the fetus, with ascitic fluid outlining the liver (large arrow). The small arrow shows pleural effusion above the diaphragm.

Figure 37-3 Transverse sonographic image of the fetal chest. Bilateral pleural effusions are seen.

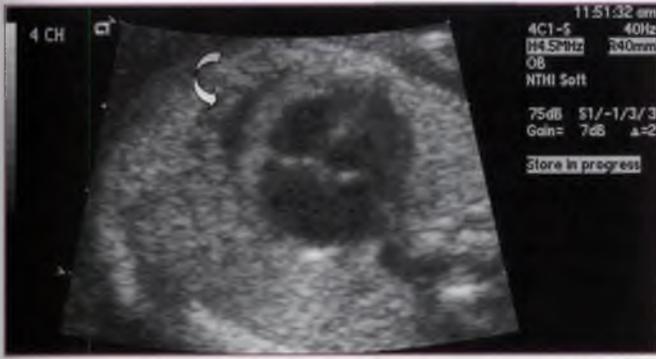

Figure 37-4 Transverse sonographic image of the fetal chest. The arrow points to a small pericardial effusion.

Figure 37-5 Transverse sonographic image of the fetal chest. Skin edema is seen over the chest wall. Rib is marked by a large arrow and skin edge by a small arrow.

where soft tissue is typically thin and any thickness can be appreciated (Fig. 37-5). The usual definition of edema is greater than 5 mm of subcutaneous tissue. This may be misleading if the fetus has redundant skin folds or is macrosomic.

Placental thickening is frequently considered a sign of hydrops as well. Abnormal thickening is generally defined as greater than 6 cm,^{28,33} although some authors have used a cutoff of 4 cm.^{34,35} With hydramnios, the placenta may appear compressed and thin. When therapeutic amniocenteses are performed because of severe hydramnios, the placenta may “thicken” by the end of the procedure, and this occurrence implies that hydrostatic pressure was responsible for the thinned appearance.³⁶

According to various authors, hydramnios is present in 40% to 75% of cases of NIH. Although the definition of hydramnios differs among these series, when the condition is present, it is often severe and would therefore be detected by any quantifying technique. In some cases of fetal hydrops, oligohydramnios is present, and many authors consider this an ominous or late finding. Although oligohydramnios is generally associated with poor pregnancy outcome, the prognosis for patients with NIH depends on the underlying cause rather than simply on this sonographic feature.

Etiology

One of the greatest challenges in the management of a fetus with NIH is ascertaining the cause of the disorder. Unfortunately, causes are numerous, and new associations continually appear in the literature. The causes may be divided into several broad categories, which are helpful in organizing an approach to this often-frustrating problem (Box 37-1).

Many of the conditions listed in Box 37-1 are placed into a category somewhat arbitrarily. For example, many anatomic cardiac lesions have a chromosomal basis. Similarly, viral syndromes that lead to NIH may be associated with fetal anemia, with fetal malformation complexes, or with myocarditis. Some of the syndromes in Box 37-1 are extremely rare, and others are more common. Many are congenital anomalies, whereas others are acquired. Classifying them differently may be helpful when considering management, recurrence risk, or possible fetal therapy.

Box 37-1 is not a list of etiologic factors but, rather, a list of conditions associated with NIH. The pathophysiology of NIH is well worked out in only a few disorders. Furthermore, not all cases have the same pathophysiologic mechanism. A review by Machin tried to elucidate some of these mechanisms.³⁷ As he pointed out, hydrops is generally a common end stage for a variety of diseases reached by several pathways. He proposed five basic disease processes that lead to hydrops: cardiovascular failure, chromosomal abnormalities, thoracic compression, twinning, and fetal anemia. He believed that each of these has a common pathway for the development of hydrops, and he suggested that most causes could be placed into one of these groups.

CARDIOVASCULAR CAUSES

Fetal cardiac abnormalities are among the most common causes of hydrops in most series. Congenital heart disease is a common problem, with an incidence of 8 or 9 per 1000 liveborn infants. Malformations of the cardiovascular system are of varying degrees of complexity and seriousness, but it is not always clear why some of these fetuses experience hydrops whereas others are born in a well-compensated condition.³⁸ No forms of congenital heart disease reliably lead to hydrops, although one would expect that more-minor abnormalities are less likely to cause the ultimate decompensation of the fetus. Overall, a structural malformation of the heart with associated fetal hydrops carries an extremely poor prognosis, with a mortality rate approaching 100%.^{39,40}

Fetal structural heart disease is diagnosed sonographically and generally has a poor prognosis regardless of the presence of hydrops. In a recent case series of 73 fetuses diagnosed with congenital heart disease, 15% had trisomies and 41% died before 28 days of life.⁴¹ In a case series of 104 fetuses with pericardial effusions, 37 (36%) had other signs of hydrops and 39 (38%) had structural heart disease.³⁰ Therefore, the combination of hydrops and structural heart disease should prompt studies for fetal chromosomal abnormalities. Because of the poor prognosis associated with hydrops when an abnormal karyotype is involved, such fetuses are generally not considered candidates for in utero fetal therapy or for active intervention with early delivery and vigorous resuscitation.

Cardiac arrhythmias are also an important cause of hydrops, but the prognosis is entirely different from that for structural

heart disease. Arrhythmias may be of several types, including tachyarrhythmias, bradyarrhythmias, and dysrhythmias. Tachyarrhythmias associated with hydrops are usually associated with a better prognosis than are most other causes of NIH and are amenable to in utero therapy.^{28,42-44} If an arrhythmia is associated with underlying structural heart disease, the prognosis is as poor as for heart disease without arrhythmia.⁴⁵ Bradyarrhythmias with hydrops carry a very poor prognosis, although more-recent series show much better outcomes.⁴⁶⁻⁴⁹

Premature closure of the foramen ovale is generally idiopathic and can occur at any time during gestation. It can be diagnosed by careful ultrasound examination of the fetal heart, with Doppler studies and color Doppler studies as useful adjuncts to imaging. Generally, this diagnosis is made only after the onset of hydrops, and prognosis is therefore poor.

Premature closure or narrowing of the ductus arteriosus also has been associated with fetal hydrops.⁵⁰⁻⁵² In one case, it was associated with a coarctation of the aorta.⁵³ In other reported

cases, the mother was receiving indomethacin for the arrest of preterm labor.⁵⁴ Moise and associates described narrowing of the ductus in response to maternal indomethacin ingestion but found it to be measurable and reversible.⁵⁵ Vanhaesebrouck and colleagues described NIH with neonatal ileal perforation in fetuses exposed to indomethacin for the arrest of preterm labor.⁵⁶

A variety of other cardiac abnormalities can lead to hydrops. For example, neoplasias such as rhabdomyomas and teratomas may be present with hydrops. In such cases, one should seek a family history of tuberous sclerosis, because this autosomal dominant disorder may present in this fashion.^{57,58}

Cardiac failure from myocarditis is responsible for at least some cases of hydrops in fetuses that have congenital infections.⁵⁹ Such cases have been documented with fetal parvovirus B19, with cytomegalovirus (CMV), and much more rarely with toxoplasmosis (see Infection, later).

Various noncardiac lesions can lead to high-output cardiac failure, a presumed mechanism of hydrops. Sacrococcygeal teratomas are large vascular tumors that act as arteriovenous shunts and may be associated with hydrops on this basis.^{60,61} The majority of these tumors are well tolerated by the fetus, however, and do not lead to hydrops.⁶² Open fetal surgery with resection of the tumor has been attempted in cases associated with fetal hydrops, but only one success has been reported to date.⁶³

Placental tumors may lead to hydrops. These are most commonly chorioangiomas, which are vascular and probably act as arteriovenous shunts.^{7,20,64-68}

Other causes of presumed high-output failure associated with fetal hydrops include fetal adrenal neuroblastomas, multiple cases of which have been reported. These rare tumors most likely lead to heart failure based on increased catecholamine release, much as they would in a child with the same lesion. Other angiomas that may lead to hydrops have been described in the umbilical cord⁶⁹ and in a fetus in the angio-osteohypertrophy syndrome.⁷⁰

CHROMOSOMAL ABNORMALITIES

Chromosomal abnormalities are fairly common in cases of fetal hydrops, and they may cause the disorder by any of several mechanisms.³⁷ Among chromosomally abnormal fetuses with hydrops, cystic hygromas are common.⁷¹ Cystic hygromas are strongly associated with hydrops, particularly among fetuses diagnosed prior to 20 weeks.² The chromosomal abnormality most frequently seen in these fetuses is 45,X, or Turner syndrome. On the other hand, fetuses with this phenotype may also have trisomy 21 or a normal karyotype.^{72,73} Among fetuses with a 45,X karyotype, two common structural abnormalities can lead to the development of hydrops. Although one is cystic hygroma, fetuses with this condition also frequently have a tubular coarctation of the aorta. There is some controversy about which of these is the more important mechanism for causing NIH.³⁷

Other chromosomal abnormalities have also been described in fetuses with hydrops. The most common are trisomy 21, trisomy 18, trisomy 13, and triploidy. Sex chromosome abnormalities that result in Turner syndrome, such as 45,X/46,XX, have also been reported, as have a large number of more unusual autosomal rearrangements. Structural cardiac lesions are common in aneuploid fetuses and may be associated with hydrops. If no structural cardiac lesion is found, the pathophysiology for the development of hydrops in this situation is

unclear. The myeloproliferative disorder common in neonates with Down syndrome has been described in four fetuses with Down syndrome and NIH.⁷⁴

When the karyotype is abnormal, the prognosis is poor, and important information can be given to the parents about recurrence risk and diagnosis in future pregnancies. The overall rate of chromosome abnormality among fetuses with hydrops varies between 7% and 45%, with higher rates among those in whom hydrops is detected before 24 weeks.^{2-4,9,11,12,71,75} Obtaining a fetal karyotype is an essential part of the workup of any fetus with hydrops.

THORACIC ABNORMALITIES

Increases in intrathoracic pressure may lead to the development of hydrops by obstructing venous return and altering cardiovascular hemodynamics. Most of these conditions involve space-occupying lesions of the thorax.

Cystic adenomatoid malformation of the lung is divided into several different subtypes, depending on the size and distribution of the cysts. In most cases, if pulmonary hypoplasia is not life threatening, this lesion is amenable to surgery in the neonate. These fetuses may develop hydrops, however, which markedly worsens the prognosis.⁷⁶

Most cases of cystic adenomatoid malformation of the lung associated with hydrops involve a single large cyst and a shift of the mediastinum. Continuous drainage of the solitary cyst by means of pleuroamniotic shunt placement or cyst aspiration has been proposed.⁷⁷ When cysts are microscopic or otherwise not amenable to shunt placement and hydrops is present, open fetal surgery has been performed. Although the outcomes have been poor, some of the fetuses have survived; left untreated, they most likely would not have.⁷⁷⁻⁷⁹ A substantial proportion of prenatally diagnosed cystic adenomatoid malformations resolve spontaneously or regress substantially, including cases with NIH, leading some authors to continue expectant management and illustrating why randomized trials are needed to determine the efficacy of these fetal interventions.⁸⁰

Other types of masses or lesions in the chest may also be associated with hydrops, including diaphragmatic hernias, hamartomas or other neoplasms of the lung or chest, pulmonary extralobar sequestration syndrome, and various bronchogenic cysts. Diaphragmatic hernia is the most common of these lesions, but it is unusual for these fetuses to experience hydrops.

Unilateral hydrothorax may present as a space-occupying lesion in the chest and is frequently associated with hydrops. Bilateral hydrothorax may be indistinguishable from other causes of NIH, as one of the features of hydrops is pleural effusion. In such cases, the effusions are the primary event and the hydrops is a secondary problem. Many authors have considered unilateral or bilateral fetal hydrothorax to be analogous to neonatal chylothorax.^{81,82} Because there are no chylomicrons in the fetus, this is not known with certainty, and in most cases no particular surgery is performed on the presumably abnormal lymphatic system after the birth.⁸³ Overall, these fetuses have a relatively poor prognosis because pulmonary hypoplasia is frequently present. In the neonate, isolated pleural effusion without hydrops has a much more favorable prognosis, with a 15% mortality rate.⁸⁴

Some authors recommend diagnostic fetal thoracentesis when unilateral or bilateral hydrothorax is suspected. In cases

of isolated hydrothorax, lymphocytes predominate in the fluid obtained, although Eddleman and coauthors reported two cases in which this test was misleading.⁸⁵ There are many reports of placement of pleuroamniotic shunts for continual drainage of this space, resulting in a survival rate of 40% to 70%.^{81,82,84,86}

The rate of aneuploidy in association with fetal hydrothorax or isolated pleural effusion is high. Rodeck and associates placed shunts prior to the availability of a fetal karyotype, and one of eight fetuses had Down syndrome.⁸³ Petrikovsky and colleagues reported three consecutive cases of pleural effusion, all of which involved aneuploid fetuses.⁸⁷ However, recent reports showed a lower rate in apparently isolated cases.^{81,82}

TWINNING

When one of a set of twins is determined to have fetal hydrops, the differential diagnosis requires special considerations. If it is known that the twins are dizygotic, then the cause is probably unrelated to the twin pregnancy, and the diagnostic approach to the twin with hydrops should be similar to that for any other fetus with the condition. In the case of monozygotic twins, the hydrops is probably related to abnormal vessels in the placenta, resulting in twin-to-twin transfusion syndrome.

In the twin-to-twin transfusion syndrome, the fetus with hydrops may be either the donor or the recipient.¹⁷ In the classic situation, the donor twin has growth restriction and oligohydramnios, and the recipient twin has plethora, hydramnios, and perhaps hydrops. Presumably, this scenario results from volume overload and congestive heart failure; however, it is also possible for the donor twin to have hydrops, in which case the pathophysiology is likely to be related to anemia.

Twin-to-twin transfusion syndrome carries a poor prognosis, particularly when it is found early in gestation or when hydrops is present. Various aggressive therapies have been proposed for this situation, including serial amniocenteses, in utero laser ablation of communicating placental vessels, and transabdominal needle septostomy of the dividing membrane. In patients with hydrops, the condition is clearly advanced, and more aggressive treatment with laser ablation is warranted. Several large series have shown conflicting results, particularly in long-term follow-up of surviving twins.⁸⁸⁻⁹²

FETAL ANEMIA

Anemia is a well-known cause of fetal hydrops, and the model used to elucidate the pathophysiology of this condition is alloimmunization. Because immune hydrops has been extensively studied, this anemia is the most studied mechanism for the development of NIH as well, although its pathophysiology is still not completely understood.⁹³

One of the most common causes of hydrops in patients from Asia or the eastern Mediterranean region is α -thalassemia.^{11,93,94} Absence of all four α globin chain alleles (homozygous α -thalassemia-1) causes formation of abnormal fetal γ globin chain tetramers, hemoglobin Bart (γ_4), which have a very high oxygen affinity and deliver almost no oxygen to fetal tissues. Thus, there is massive tissue hypoxia. Fetuses with this disorder commonly develop hydrops as early as 20 weeks' gestation. Because long-term survival of fetuses with homozygous α -thalassemia is extremely rare, there is no current recommendation for treatment. However, proper diagnosis is important for counseling and prenatal diagnosis in future pregnancies.

Fetomaternal hemorrhage is relatively common and, in rare instances, may be massive enough to cause fetal hydrops.^{95,96} In most cases, the etiology of the fetomaternal hemorrhage or transfusion is unknown. This diagnosis can be made by using a Kleihauer-Betke stain to examine peripheral maternal blood for the presence of fetal cells. It is also possible to detect a fetomaternal hemorrhage by an abnormally elevated maternal serum α -fetoprotein level. Although the hemorrhage may be self-limited, if a fetus has developed hydrops, many authors have advocated more-aggressive management because of the risk for demise. There have now been several case reports of fetuses that have undergone serial transfusions with resolution of hydrops and ultimately good outcomes.⁹⁶⁻⁹⁹

Fetal hemorrhage with subsequent anemia and hydrops formation has also been reported. It has usually been associated with an intracranial hemorrhage, and in the absence of a history of trauma, one should suspect a fetal coagulation deficiency, such as alloimmune thrombocytopenia.^{100,101}

Glucose-6-phosphate dehydrogenase deficiency is a common X-linked condition in African Americans and persons of Mediterranean heritage. This disorder is characterized by hemolytic crises, usually in response to various stimuli including sulfa drugs, aspirin, and fava beans. Female carriers are usually asymptomatic. There are two reports of affected male fetuses developing anemia and hydrops after maternal ingestion of these substances.^{102,103}

A number of other inherited erythrocyte enzyme deficiencies may cause fetal anemia and, in rare cases, fetal hydrops.^{104,105} Examples include glucose phosphate isomerase deficiency and pyruvate kinase deficiency. These conditions commonly lead to chronic hemolytic anemia, but rarely to severe anemia, in fetal life.

Congenital leukemia may cause anemia and hydrops, and leukemic infiltration of the myocardium has also been demonstrated.¹⁰⁶ Transmission of maternal antibodies to erythroid precursors in a mother who had acquired red blood cell aplasia has been reported. Transfusions to the fetus reversed the hydrops and resulted in a healthy liveborn infant with a normal outcome.¹⁰⁷

On the basis of the velocity of blood flow in the middle cerebral artery, Mari and associates predicted anemia in fetuses with immune hydrops.¹⁰⁸ This has been substantiated in subsequent trials and is now widely accepted.¹⁰⁹⁻¹¹¹ The same findings appear to be true in fetuses affected by anemia from other causes, including NIH. The most studied model is in parvovirus-induced anemia (see Parvovirus, later).¹¹²⁻¹¹⁵

INFECTION

A great deal of literature concerns congenital infection as a cause of NIH. Although many different viruses, bacteria, and parasites cause congenital infection, the effects on the fetus are variable, and no infection predictably results in hydrops fetalis. In addition, although researchers have long believed anemia to be the common mechanism for the development of hydrops in these fetuses, myocarditis, hepatitis, or other pathways yet to be elucidated may also be involved.

Syphilis

Congenital syphilis is a well-known cause of fetal hydrops. One can confirm the diagnosis by obtaining a positive serologic test result in the mother. A dark-field examination of amniotic fluid may also be helpful.¹¹⁶ A fetus with syphilis and hydrops faces a poor prognosis compared with one with a milder case of

congenital syphilis. Management remains the same, however: treating the infection in the mother. In one recently reported case, fetal anemia was also present, and transfusion was used as part of the ultimately successful therapy.¹¹⁷

Cytomegalovirus

CMV is a common, perinatally acquired infection. Although approximately 20% to 30% of maternal primary infections are transmitted to the fetus, fewer result in symptomatic CMV in the fetus or neonate.^{118,119} Symptomatic fetuses may show growth restriction, placentomegaly, polyhydramnios or oligohydramnios, hydrops, microcephaly, echogenic bowel, or intracerebral calcifications (see Chapter 51).^{118,120}

Parvovirus

The most frequent manifestation of infection with parvovirus B19 is fifth disease, or erythema infectiosum. This common infection is usually acquired in childhood but may be acquired by a pregnant woman from an infected child. It causes a characteristic rash, flulike symptoms, and arthralgias that may be mild. Fetal infections clearly occur, but the transmission rate is not established.

A study from Germany of more than 1000 women with documented seroconversion showed a fetal death rate of 6.3%. All cases of fetal death occurred at less than 20 weeks of gestation, and in that period the fetal death rate was 11%. The risk for NIH was 4%.¹²¹ There is improved detection of maternal infection by supplementing serologic testing with the polymerase chain reaction for viral genome in maternal blood.¹²²

Other Infections

Various other infectious agents have been related to hydrops in at least a few cases.¹²³⁻¹³¹ These include adenovirus, *Toxoplasma gondii*, herpes simplex, rubella, coxsackievirus, influenza virus, enterovirus, and *Listeria*. In some cases, an infectious process is suspected but no causative organism can be identified.^{132,133}

METABOLIC DISEASE

A variety of genetic metabolic diseases, particularly lysosomal storage diseases, can cause hydrops in the fetus.¹³⁴ For example, Gaucher disease, generalized (GM₁) gangliosidosis, Salla disease, sialidosis, mucopolysaccharidosis types IV and VII, and Tay-Sachs disease can all manifest in this manner.¹³⁵⁻¹³⁹ Gaucher disease is the most common of these disorders and has been reported the most frequently, but its occurrence with hydrops is rare.¹⁴⁰ These conditions can recur in subsequent pregnancies because they are typically inherited in an autosomal recessive fashion. Establishing the correct diagnosis is therefore extremely important. This can be accomplished by analysis of oligosaccharides in fetal or neonatal urine or blood, by enzyme analysis and carrier testing in the parents, or by histologic examination of appropriate fetal tissues.^{134,141,142} Several authors have recently recommended approaches to the diagnostic workup for these disorders based on their experience. As there are many possible disorders in patients with no family history, they suggest stepwise testing schemes.^{143,144}

OTHER MALFORMATIONS

A variety of chondrodysplasias may manifest with fetal hydrops. Pretorius and coworkers found all such cases to be associated

with fatal dwarfing syndromes.¹⁴⁵ In these cases, the chest is compressed, and the neonates die of respiratory insufficiency. The most common skeletal dysplasias described with fetal hydrops are short rib–polydactyly syndrome, thanatophoric dysplasia, and achondrogenesis. Skeletal dysplasia can be diagnosed fairly easily with ultrasonography by measuring the extremities relative to head and abdominal size, but classifying the type of chondrodysplasia in a fetus by ultrasonography alone may be difficult. After birth, radiographic studies, as well as examination of other phenotypic features of the neonate, can be used to determine the specific type of chondrodysplasia. Because many of the lethal types are inherited recessively, the recurrence rate is high. For several of these disorders, the gene responsible has been identified, and detection of the genetic abnormality in fetal or neonatal tissue specimens can therefore be accomplished.

A number of other genetic syndromes have also been associated with fetal hydrops. These include congenital myotonic dystrophy, a heterogeneous group of disorders characterized by multiple joint contractures and collectively referred to as arthrogryposis, multiple fetal pterygia, Neu-Laxova syndrome, and Pena-Shokeir syndrome type I.^{71,146,147}

Urinary tract malformations have been described in conjunction with hydrops in numerous reports; however, close examination of these cases reveals that most involve isolated ascites with a urinary tract malformation. This condition, known as urinary ascites, is common, well described, and generally self-limited. It rarely progresses to hydrops.

Various intraabdominal processes related to the gastrointestinal tract commonly appear with ascites, but in rare cases they are associated with hydrops. These include meconium peritonitis, small bowel volvulus, and various intestinal atresias.

OTHER CAUSES

Diabetes is frequently cited as a cause of NIH, and several large series have included a few cases in which preexisting maternal diabetes was the only etiology.¹⁴⁸ It is not clear whether these fetuses were structurally normal. Other authors have found no association between maternal diabetes and NIH.¹⁷

Several maternal medications have been reported to be associated with NIH in the fetus. Indomethacin and other anti-inflammatory medications may be associated with ductal narrowing (see Cardiovascular Causes, earlier).⁵¹ In addition, mycophenolate (also associated with fetal and neonatal anemia) has been reported, as have propylthiouracil (PTU) and enalapril.¹⁴⁹⁻¹⁵¹

The list of associations given here is certainly not complete. Numerous case reports describe other syndromes or malformations associated with fetal hydrops. In some of these cases, the association may not be causative or may be unproven, but in others it is more convincing. The literature is constantly being updated, not only with series but with case reports, and this discussion is therefore not exhaustive.

Experimental Management of Idiopathic Cases

Various management strategies have been attempted for patients with NIH of unknown etiology. Shimokawa and associates¹⁵² injected albumin on two occasions into the peritoneal cavity of

a fetus with hydrops, and hydrops subsequently resolved. This group later published a series of 21 patients treated with a combination of red blood cell transfusions and serial albumin injections. Improvements occurred only in fetuses without pleural effusions, but in this group, five of seven fetuses (72%) survived.¹⁵³ Lingman and colleagues attempted direct intravascular albumin transfusion on five occasions in a fetus later found to have a lysosomal storage disease.¹⁵⁴ Doppler studies and blood counts before and after the procedures indicated effective plasma expansion and peripheral vasodilation. Goldberg and associates placed a peritoneal-amniotic shunt in a second-trimester fetus with NIH of unknown etiology and massive ascites.¹⁵⁵ Although the ascites resolved, other features of hydrops developed, and the fetus ultimately died.

Diagnostic Approach to the Fetus with Hydrops

The workup of a patient with a diagnosis of fetal hydrops should be directed at possible causes. Because the diagnosis is confirmed with ultrasonography, this is frequently the first test performed. During a careful ultrasound examination, the known causes of NIH should be kept in mind. Many of the fetal conditions, congenital anomalies, and malformation sequences that are known causes of hydrops are found or eliminated on the initial ultrasound examination. Twins, cardiac arrhythmias, and hydrothorax are all examples of ultrasonography-derived diagnoses. The blood-flow velocity of the middle cerebral artery should be assessed to screen for fetal anemia, as should other Doppler studies including flow in the ductus venosus. A fetal echocardiogram should be performed.

If the examination is unsatisfactory, it should be repeated later to delineate fetal anatomy as well as possible. Although the underlying diagnosis is far more predictive of outcome than are any specific ultrasonographic parameters, the initial examination can be used to assess the severity of the hydrops and to initiate antenatal testing, if appropriate, depending on gestational age. Assessing the severity of the hydrops is particularly important if the fetus is observed for some length of time or if fetal therapy is attempted. Ultrasound parameters can be followed longitudinally to attempt to predict further fetal decompensation or fetal response to in utero therapy.

A history should be taken, with particular attention to ethnic background and any family history of genetic diseases or congenital anomaly, consanguinity, and recent maternal infections or exposures and maternal medications. Once again, careful scrutiny of the listed causes of hydrops gives direction to the types of questions that should be asked of the mother and family.

The initial testing of the mother should include the elimination of immune causes of hydrops with blood typing and the indirect Coombs test. A screen for hemoglobinopathies, a Kleihauer-Betke test to look for fetal red blood cells in the maternal circulation, and titers for syphilis, parvovirus, and the TORCH infections (toxoplasmosis, rubella, cytomegalovirus, and herpes simplex) are also useful at this time. Some of these tests may not be immediately available, but blood should be drawn and sent to the laboratory.

A fetal karyotype should be obtained in most cases. With the availability of fluorescence in situ hybridization (FISH), the major aneuploidies (trisomies 21, 18, and 13, and monosomy

X) can be rapidly detected in amniotic fluid cells. If infection is suspected, amniotic fluid and maternal blood should be sent for polymerase chain reaction testing or culture. Fetal blood can also be used for a rapid karyotype, and it can be sent for other tests, such as a complete blood count and platelet count, to rule out fetal anemia or thrombocytopenia. If blood is obtained, serology tests can be performed and the specimen can be cultured.

Fetal serum or amniotic fluid can be frozen or sent for other studies, such as screening for lysosomal storage diseases, if these are suspected. Although optical density 450 values are increased in many cases of NIH,¹⁵⁶ this is not clinically useful information, so the study is not generally indicated. Amniotic fluid may be sent for lung-maturity studies when appropriate. A frozen sample of amniotic fluid may be useful for future viral DNA hybridization studies or oligosaccharide analysis if not ordered initially.

Management

Management approaches are difficult to generalize because they depend on the prognosis, which is based on the etiology, gestational age, and signs and symptoms. Before the fetus becomes viable, the prognosis is usually grave regardless of the etiology. This should be explained to the parents, who should be given the option of terminating the pregnancy. If the underlying etiology is amenable to fetal therapy, this should be frankly discussed with the family, but generally the parents should be warned that diagnostic error is always possible and that the overall prognosis for patients with NIH is still grim.

Unfortunately, many cases of NIH are detected during the third trimester. If the patient presents in preterm labor or if symptomatic hydramnios exists, difficult decisions need to be made about whether to administer tocolytic medications or to allow labor to continue. It may be warranted to continue tocolysis, as long as the mother is stable, while the fetal evaluation is being pursued. If a potentially reversible cause of hydrops is found, consultation with neonatologists may help with counseling the family about the advisability of prolonging the pregnancy while fetal therapy is initiated, as opposed to prompt delivery and postnatal treatment. If a fetal diagnosis with a poor prognosis seems fairly certain, however, a frank discussion with the family may lead to the discontinuation of tocolytic medication.

Patients who present with or later show signs of maternal compromise, such as preeclampsia or antenatal hemorrhage, should be managed without regard to fetal outcome, as it is so poor. Management decisions are particularly difficult in idiopathic cases because the prognosis is uncertain. Even though the overall prognosis is poor in idiopathic cases, every attempt should be made to prolong pregnancies when the patient presents in the third trimester (to 32 or 34 weeks' gestation), to maximize neonatal survival, unless there are signs of fetal or maternal decompensation. If significant or symptomatic hydramnios is present, it may be treated with therapeutic amniocenteses, indomethacin, or, more conservatively, bed rest and conventional tocolytic therapy.

Fetal decompensation may be difficult to measure, but the usual biophysical parameters are nonetheless useful. If a reactive fetal heart rate tracing becomes abnormal, it should be interpreted as a sign of acute decompensation. Similarly, oligohydramnios, a decrease in fetal movement, and poor fetal tone are

all ominous signs. Unless there is evidence that hydrops is resolving or that treatment has otherwise been effective, there does not seem to be any reason to prolong a pregnancy past 34 weeks' gestation or the attainment of a mature lung profile.

Huhta has suggested a cardiovascular scoring system to measure the degree of cardiovascular compromise using intracardiac, venous, and umbilical artery Doppler.¹⁵⁷ This may be used longitudinally to follow fetuses for decompensation in cases of hydrops.^{157,158}

Recurrence Risks

After the delivery of a fetus with NIH, investigation of the cause should continue in the nursery, if necessary. If the fetus is still-born or dies during the early neonatal period, every attempt should be made to obtain a postmortem examination directed at finding the underlying cause of the problem. Without this information, counseling the patient and her family about future pregnancies is frustrating. Overall, recurrent hydrops fetalis is unusual, and for most families the prognosis is good for a normal pregnancy in the future. However, there are numerous case reports of recurrent pregnancies with hydropic fetuses.¹⁵⁹⁻¹⁶⁴ It is not wise, therefore, to reassure families that idiopathic hydrops is not going to recur, and future pregnancies should be carefully monitored.

Delivery Considerations

Delivery of a fetus with hydrops should be attended by an experienced pediatric team prepared to deal with a sick neonate. Some authors have recommended the liberal use of cesarean section to avoid asphyxia and birth trauma, although no objective data support this approach.¹²⁴ Pre-delivery thoracentesis or paracentesis has also been advocated to enable immediate

postnatal resuscitation or, in the case of a large fetal abdominal girth, to facilitate vaginal delivery.^{28,165-167} One series showed increased survival in neonates born later in gestation with normal Apgar scores.¹⁶⁸ Pleural effusion was also associated with poorer chances for survival. No fetus in that series born before 30 weeks survived.

Immediate problems of the neonate are likely to center on respiratory support and fluid management. Virtually all neonates with hydrops require mechanical ventilation, and edema may make intubation difficult.^{169,170} Postnatal drainage of pleural or peritoneal fluid may be required to maintain oxygenation. Some authors reserve these procedures for extreme cases, whereas others propose a more liberal use of fluid drainage.^{169,171,172} Fluid restriction, careful management of electrolytes, judicious use of albumin and diuretics, correction of anemia, and continuous assessment of intravascular volume are all important issues in the first few days of life.

Summary

Although there have been many advances in our understanding of the causes of fetal NIH, it remains a difficult clinical problem. Many conditions have been associated with fetal hydrops, but few shed light on the pathophysiology of its development. Once the diagnosis of NIH is established, a careful search for causative fetal pathology should be undertaken. Unfortunately, the results of such a search may not be available when difficult management decisions need to be made. Recent advances in fetal therapy have increased the number of fetal conditions for which treatment is possible. However, the overall rates of morbidity in mother and fetus, and of mortality in the fetus, remain high.

Multiple Gestation: Clinical Characteristics and Management

FERGAL D. MALONE, MD | MARY E. D'ALTON, MB, BCh, BAO

The incidence of multiple gestation continues to increase, now accounting for more than 3% of all live births in the United States (Table 38-1).¹ Over the past several decades, the rate of twin births in the United States has increased annually to a current rate of 33.2 per 1000 total births, representing a 76% increase since 1980, although the rate since 2005 has slowed to approximately 1% yearly.¹ The two major factors accounting for the increases are the widespread availability of assisted reproductive technologies and increasing maternal age at childbirth. The number of triplet, quadruplet, and higher-order multiple births peaked in 1998 and has dropped slightly or remained static recently, most likely because of voluntary limits imposed by many assisted reproduction centers in the number of embryos transferred and because of the availability and acceptance of multifetal pregnancy reduction (MFPR) procedures.² For example, in 2009, there were 5905 triplet births, 355 quadruplet births, and 80 quintuplet or higher-order births in the United States. Because perinatal and maternal morbidity and mortality are increased in multiple gestation, contemporary data about pregnancy outcomes and management options are essential. Congenital abnormalities are also increased in multiple gestation, making management decisions more complex, because the fates of sibling fetuses are necessarily linked. For these reasons, women with complicated multiple gestation are increasingly cared for under the supervision of an appropriately trained specialist.^{3,4}

Perinatal Mortality and Morbidity

Prematurity, monochorionicity, and growth restriction pose the main risks to fetuses and neonates in multiple gestations. Perinatal deaths have decreased, but the risk for prematurity has not changed significantly. The mean duration of pregnancy is 35.3 weeks for twin gestations, 31.9 weeks for triplets, and 29.5 weeks for quadruplets.¹ The mean gestational age at birth in multiple pregnancies can be misleading because it obscures the true incidence of extreme prematurity, which has greater clinical significance. Although the incidence of very premature delivery (before 32 weeks) for singletons in the United States is 1.6%, 11% of twin and 37% of triplet gestations are delivered before 32 weeks.¹ The perinatal mortality rate for twins is significantly higher than for singletons at all gestational ages. In the United States, infant mortality rates for twins, triplets, quadruplets, and quintuplets were 5, 20, 47, and 94, respectively, per 1000 live births.⁵ Mortality rates are significantly higher among same-sex twins compared with discordant-sex twins, indicating that prematurity and complications of monochorionicity explain the

increased mortality in twin gestations. The risk that twins will weigh less than 1500 g at birth is 10 times the risk for singletons. These increased risks are more pronounced in male-male pairs, in black infants, and in infants of younger mothers.⁶

Perinatal outcome data for higher-order multiple gestations (triplets or greater) are quite limited. Stillbirth rates increase from 6.8 per 1000 for singletons to 16.1 for twins and to 21.5 for triplets, and infant mortality rates increase from 5 to 23.4 and to 51.2 per 1000 births, respectively.⁷ The incidence of preterm delivery before 28 weeks in triplet pregnancies is 14%, with a perinatal mortality rate of approximately 100 to 150 per 1000.^{8,9} Perinatal mortality in triplet gestations is significantly worse in dichorionic than in trichorionic pregnancies.⁹ In addition, the rate of spontaneous loss before 24 weeks for triplet pregnancies with confirmed cardiac activity is as high as 20%.¹⁰ Once cardiac activity is confirmed at 10 to 14 weeks in a triplet pregnancy, the risk for miscarriage before 24 weeks is 4.4%.¹¹ Some quadruplet pregnancy series have suggested perinatal mortality rates ranging from 0 to 67 per 1000 quadruplet births.^{12,13} However, caution is needed when interpreting studies of higher-order multiple gestations, because often only pregnancies reaching "viability" are included, producing an overly positive view of perinatal outcome.

Perinatal morbidity is also more likely in multiple gestations. Although multiple gestation accounts for only 3% of all births in the United States, infants of multiple gestations comprise almost one quarter of very-low-birth-weight infants.¹⁴ The incidence of severe handicap among neonatal survivors of multiple gestation is also increased: 34.0 and 57.5 per 1000 twin and triplet survivors, respectively, compared with 19.7 per 1000 singleton survivors.¹⁵ Twins account for 5% to 10% of all cases of cerebral palsy in the United States.¹⁶ The risk of producing at least one infant with cerebral palsy from one pregnancy has been reported to be 1.5% for twin, 8.0% for triplet, and 42.9% for quadruplet gestations.¹⁷

In the United States, mean birth weight is significantly lower for twin neonates (2333 g) and triplet neonates (1700 g) than for singletons (3316 g).¹ Among all multiple births, the infant mortality rate was 28.73 in 2008, five times the rate of 5.83 for singleton births.

The risk for infant death increases with the increasing number of infants in the pregnancy. The infant mortality rate for twins (27.33) was nearly 5 times, and the rate for triplets (59.70) was 10 times, the rate for single births (5.83).¹⁸

However, there is no evidence that twin or triplet neonates have outcomes different from those of gestational age-matched singletons. Singleton, twin, and triplet neonates, *when matched*

TABLE 38-1 Incidence of Multiple Births in the United States

Year	Twins	Triplets	Quadruplets	Quintuplets and Higher Order
2009	137,217	5905	355	80
2008	138,660	5877	345	46
2007	138,961	5967	369	91
2006	137,085	6118	355	67
2005	133,122	6208	418	68
2004	132,219	6750	439	86
2003	128,665	7110	468	85
2002	125,134	6898	434	69
2001	121,246	6885	501	85
2000	118,916	6742	506	77
1995	96,736	4551	365	57

by gestational age at delivery, have similar birth weights and similar rates of morbidity and mortality.¹⁹

Maternal Mortality and Morbidity

Given the low rate of maternal mortality in developed countries and the small sample sizes in published series, the incidence of maternal death in contemporarily managed multiple gestations is uncertain, but maternal morbidity is significantly increased in mothers with multiple gestations and is apparently related to the number of fetuses. Twin pregnancies are associated with significantly higher risks for hypertension and placental abruption,²⁰ in addition to higher risks for preterm labor (78%); preeclampsia (26%); hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome (9%); anemia (24%); preterm premature rupture of membranes (pPROM) (24%); gestational diabetes (14%); acute fatty liver (4%); chorioendometritis (16%); and postpartum hemorrhage (9%).⁸ No differences in the frequency of complications were noted between spontaneous triplets and those arising from ovulation induction or in vitro fertilization (IVF). Preterm birth occurs in nearly all quadruplet pregnancies, and the risk for gestational hypertension ranges from 32% to 90%.^{12,13} In addition, preeclampsia in higher-order multiple gestations occurs at an earlier gestational age, is more severe, and more likely to have an atypical clinical presentation than preeclampsia in singleton gestations.^{8,21}

Maternal Adaptations

The normal maternal physiologic adaptations seen in singleton pregnancy are exaggerated in multifetal gestation.^{22,23} Serum levels of progesterone, estradiol, estriol, human placental lactogen, human chorionic gonadotropin (hCG), and α -fetoprotein (AFP) are all significantly higher in multiple than in singleton gestations.

Heart rate and stroke volume are significantly increased in gravidas with twins during the third trimester, leading to a significant increase in cardiac output and cardiac index compared with singleton pregnancies. In one study of 119 twin pregnancies, stroke volume was increased by 15%, heart rate by 4%, and cardiac output by 20%, compared with singletons.²⁴ These increases most likely occur because of increased myocardial contractility and blood volume in the setting of multiple gestation.

Systolic and diastolic blood pressures mirror the changes seen during singleton pregnancy, with an even greater drop in pressures noted during the second trimester in twin pregnancy. However, at term, mean maternal blood pressures are significantly higher in multiple compared with singleton pregnancies.²⁵ Depending on the number of fetuses, plasma volume increases by 50% to 100%, which may lead to dilutional anemia.²⁶

Uterine volume increases rapidly in multiple gestation. A 25-week twin-gestation uterus is equal in size to a term singleton uterus.²⁷ Uterine blood flow increases significantly, related to increased cardiac output and decreased uterine artery resistance.²⁸ In multiple gestations, the normal increase in tidal volume and oxygen consumption is probably increased further, which may lead to an even more alkalotic arterial pH than in singleton gestations. Similarly, the normal increase in glomerular filtration rate and size of the renal collecting system is probably more marked in women with multiple gestations.

Recommendations for maternal weight gain for twin pregnancy increase to 37 to 54 lb in the setting of normal-weight, 31 to 50 lb for overweight, and 25 to 42 lb for obese patients.²⁹ Although specific recommendations have not been issued, ideal weight gain for higher-order multiple gestations is probably greater than for twin gestations, with a suggested weight-gain goal of 1.5 lb/wk during the first 24 weeks of pregnancy.³⁰

Ultrasonography in Multiple Gestation

Routine prenatal ultrasonography has proved valuable for early detection of multiple gestation.³¹ It is only after identification of a multiple gestation that steps can be taken to reduce the perinatal and maternal morbidity associated with the condition. Prenatal ultrasonography in multiple gestation is useful for the following:

- Confirming a diagnosis of multiple gestation
- Determining chorionicity
- Detecting fetal anomalies
- Guiding invasive procedures
- Evaluating fetal growth
- Measuring cervical length
- Confirming fetal well-being
- Preparing for the delivery

DIAGNOSIS OF MULTIPLE GESTATION

Positive sonographic diagnosis of multiple gestation can be made by visualizing multiple gestational sacs with yolk sacs by 5 weeks of gestation and multiple embryos with cardiac activity by 6 weeks. If two gestational sacs are seen on early ultrasound studies, the chance of delivering twins is 57%, but this increases to 87% if two embryonic poles with cardiac activity are visualized.³² If three gestational sacs are seen on early ultrasound, the chance of delivering triplets is 20%, increasing to 68% if three embryonic poles with cardiac activity are visualized. In addition to twins, the early sonographic visualization of two intrauterine fluid collections may represent a singleton in a bicornuate uterus, a singleton with a subchorionic hemorrhage, or a vanishing twin.

CHORIONICITY

Because 20% of twins are monochorionic and such pregnancies are associated with a higher perinatal mortality risk, accurate

determination of chorionicity is essential for clinical management. In most women, sonographic assessment can accurately determine chorionicity. Sonographic determination of chorionicity should be sought for all multiple gestations and is best performed in the first trimester. Before 8 weeks' gestation, clearly separate gestational sacs, each surrounded by a thick echogenic ring, is suggestive of dichorionicity. If separate echogenic rings are not visible, monochorionicity is likely. In such situations, counting the number of yolk sacs may assist in establishing amnionicity. Two fetal poles with two yolk sacs in a monochorionic gestation suggests diamnionicity, whereas the presence of two fetal poles with only one yolk sac suggests a monoamniotic gestation. However, the specificity of this finding for monoamnionicity is uncertain.³³⁻³⁵ The sensitivity of first- and second-trimester ultrasound for predicting monochorionicity is approximately 90%; the specificity falls from 99% for first-trimester sonography to 95% in the second trimester (Table 38-2).³⁶ Later in gestation, if the fetuses are discordant for sex or two distinct placentas are seen, a dichorionic gestation can be confirmed with confidence (Fig. 38-1). In the absence of these findings, monochorionicity is possible, and other sonographic features should be assessed.

The visualization of only one placental mass has a positive predictive value for monochorionicity of only 42%, because many dichorionic gestations develop apparent fusion of

separate placentas as pregnancy progresses.³⁷ Counting the number of layers in the dividing membrane, near its insertion into the placenta, is 100% predictive of dichorionicity but is not as reliable in predicting monochorionicity.³⁸ When this method is used, it is assumed that the placentation is monochorionic if only two layers are present; the presence of three or four layers suggests dichorionicity. The use of a membrane thickness cutoff value of 2 mm has also been reported to correctly assign chorionicity in more than 90% of cases, but the reproducibility of this measurement has been questioned.³⁹ Visualization of a triangular projection of placenta between the layers of the dividing membrane (known as the *twin-peak* or *lambda* sign) is also useful in diagnosis of dichorionicity, but its absence is not as reliable for predicting monochorionicity. Although each of these sonographic features individually has a poor positive predictive value for monochorionicity, use of a composite sonographic approach (i.e., one placenta, sex concordance, thin dividing membrane, and absence of the twin-peak sign) may yield a positive predictive value for monochorionicity of 92%.³⁷

The use of transvaginal sonography in the first trimester, together with this composite approach, produces correct assignment of chorionicity and amnionicity in almost 100% of cases.³³ If the initial ultrasound examination is not performed until the second trimester, its precision in assigning chorionicity declines.⁴⁰ Although the sensitivity is not perfect, the specificity for monochorionicity is almost 100% when this approach is used in the first trimester, falling to 95% in the second trimester.³⁶

TABLE 38-2 Statistical Accuracy of Antenatal Prediction of Monochorionicity

	Sensitivity (%)	Specificity (%)	Predictive Value (%)	
			Positive	Negative
Overall	88.9	97.7	92.6	96.5
1st trimester	89.8	99.5	97.8	97.5
2nd trimester	88	94.7	88	94.7

DETECTION OF FETAL ANOMALIES

Careful sonographic surveys of fetal anatomy are indicated in multifetal pregnancies, because the risk for congenital anomalies is increased. The accuracy of ultrasonography for detecting congenital fetal anomalies in multiple gestations has not been adequately studied in large series. Smaller, single-center series have tried to establish the predictive value of prenatal ultrasound for the detection of anomalies in multiple gestations. In a series of 24 anomalous fetuses in twin gestations, serial ultrasonography at a specialist center achieved an 88% detection rate, with 100% specificity, for the prenatal diagnosis of anomalies.⁴¹ An 83% rate of detecting fetuses with Down syndrome in twin pregnancies was achieved by combining risks derived from maternal age and nuchal translucency thickness measurement at 10 to 14 weeks' gestation, with a 5% false-positive rate.⁴² The finding of increased nuchal translucency in one fetus of a monochorionic pair may also presage the development of twin-twin transfusion syndrome (TTTS).

EVALUATION OF FETAL GROWTH

Serial ultrasonography is the most accurate method to assess fetal growth in cases of multiple gestation. Intrauterine growth of twins is similar to that of singletons until 30 to 32 weeks' gestation, when the abdominal circumference measurements of twins begin to lag behind those of singletons.⁴³ Composite assessments of fetal weight appear to be superior to individual biometric parameters (e.g., abdominal circumference, femur length) for predicting growth discordance.⁴⁴

Although individual growth curves for twin and triplet gestations have been described, singleton fetal weight standards are still commonly used to assess growth in multiple gestation.

Because growth restriction is a dynamic process and sibling fetuses are immediately available for comparison, we consider it reasonable to assess growth in multiple gestation with serial evaluations, based on singleton growth curves, using as many biometric parameters as possible and comparing sibling estimated fetal weights for discordance. Until recently, there was uncertainty regarding the degree of intertwin growth discordance that was considered clinically significant. The ESPRIT trial prospectively followed 1028 unselected twin pregnancies with detailed serial sonographic assessment.⁴⁵ Perinatal morbidity increased only when the degree of growth discordance exceeded 18%, a threshold that surprisingly was the same regardless of chorionicity. Growth discordance greater than 20% has also been shown to be an important predictor for adverse perinatal outcomes, even when individual fetal sizes are appropriate for gestational age.⁴⁶

It is unclear whether adverse outcomes seen with significant weight discordance are related to continuation of pregnancy in a hostile intrauterine environment or to iatrogenic prematurity. We use significant weight discordance as an indication for close fetal surveillance rather than an indication for immediate delivery. Decisions regarding delivery are then made based on the results of tests of fetal well-being, together with gestational age, rather than solely on the basis of significant weight discordance.

MEASUREMENT OF CERVICAL LENGTH

Ultrasound surveillance of cervical length in multiple gestation can identify those at increased risk for preterm delivery. The largest study of cervical length assessment in this setting followed 1163 twin pregnancies after cervical measurement at 22 to 24 weeks' gestation.⁴⁷ The median cervical length was 35 mm, and in only 8% of twin pregnancies was the cervix less than 20 mm long.

The technique of sonographic measurement of cervical length does not differ from that described for singleton gestations (see Chapter 41). The optimal interval at which to perform sonographic assessments of cervical length during multifetal gestation is unclear. Our practice has been to measure cervical length every 2 weeks from 16 to 24 weeks in the cases of multiple gestation deemed to be at highest risk for preterm delivery (e.g., higher-order multiple gestations, history of a preterm singleton birth). For all other multiple gestations, we perform sonographic assessment of cervical length at the time of sonography for fetal anatomy or growth. The major limitation of routine cervical length assessment for multiple gestations is the lack of a proven effective intervention when a short cervix is noted.⁴ Notably, progesterin supplementation does not reduce the risk for preterm birth in multiple gestations, and cervical cerclage actually increases that risk (see later discussion on prophylaxis of preterm birth, and Chapter 40).

CONFIRMATION OF FETAL WELL-BEING

Ultrasonography is useful to confirm fetal well-being in multiple gestations. The nonstress test (NST) in multiple gestation is discussed later (see Fetal Surveillance). The biophysical profile may also be of benefit in multiple gestation if an NST is not reassuring or when an NST is impractical to perform, as it may be in cases of higher-order multiple gestation. There is no evidence that routine biophysical profile testing in the absence of

specific additional high-risk factors has any benefit in multiple gestations.⁴

Doppler velocimetry may also be used to evaluate fetal well-being in multiple gestations. Umbilical artery systolic-to-diastolic ratios are similar in singleton and twin gestations. A deterioration in this ratio may occur before the sonographic detection of growth restriction. Normal Doppler velocimetry indices of other fetal vessels, such as the middle cerebral artery and the descending aorta, are similar for singleton, twin, and triplet fetuses.⁴⁸ We employ Doppler velocimetry of the umbilical artery whenever multiple gestation is complicated by significant growth restriction or discordance.

Sonographic measurement of amniotic fluid volume is an important tool to evaluate fetal well-being. In a dye-dilution study of diamniotic twin pregnancies, the amniotic fluid volume in each amniotic sac was noted to be independent of the volume in the neighboring sac and was similar to singleton fluid volumes.⁴⁹ There is no agreement on the optimal sonographic method to assess amniotic fluid volume in multiple gestations. Methods in use include the following^{50,51}:

- A single overall amniotic fluid index without reference to the dividing membrane
- Individual amniotic fluid indices for each sac
- Largest two-diameter pocket in each sac
- Subjective assessment of the relative distribution of fluid between sacs

No one method, however, has been shown to be optimal for predicting perinatal outcome in multiple gestation.

Prenatal Diagnosis

Prenatal diagnosis and genetic counseling are especially important in the management of multiple gestation because of the higher risk for fetal anomalies in multifetal gestation and the positive association between twinning and maternal age.

In dizygotic twin pregnancies, each fetus has its own independent risk for aneuploidy; thus, there is an additive increased risk for at least one abnormal fetus. Furthermore, both monozygotic and dizygotic pregnancies have increased risk for structural anomalies. Because postzygotic nondisjunction can result in heterokaryotypic twins, monozygotic twins may not necessarily be concordant for chromosomal abnormalities. Because of this phenomenon, and because the diagnosis of monochorionicity is rarely made with certainty, consideration should be given to sampling each gestation separately whenever prenatal diagnosis is indicated.

The role of ultrasonography to detect fetal anomalies in multiple gestations was discussed previously.

RISKS OF CHROMOSOMAL ABNORMALITIES

Risks for Down syndrome and other chromosomal aneuploidies have been calculated for twin gestations at various maternal ages. In the population studied by Rodis and coworkers, the risk for a 33-year-old woman that one fetus in a twin pregnancy would have Down syndrome was similar to that for a 35-year-old woman with a singleton gestation.⁵² These specific risks vary according to the incidence of dizygotic twinning, which is influenced by maternal age and race. After correction for different rates of dizygosity based on maternal age and race, it has been suggested that invasive prenatal diagnosis should be offered to women in the United States with twin gestations who are 31

TABLE 38-3 Risk of at Least One Chromosomal Abnormality in White Singleton and Twin Gestations Based on Maternal Age at the Time of Amniocentesis

Maternal Age (yr)	Singleton Gestation		Twin Gestation

Reprinted with permission from the American College of Obstetricians and Gynecologists.

years of age or older (Table 38-3).⁵³ In a triplet gestation, the same calculus applies: The chance that a 28-year-old woman will have at least one fetus with Down syndrome may be similar to that of a 35-year-old woman with a single fetus. These alterations in risk assessment for chromosomal abnormalities are important, because invasive prenatal diagnosis may be considered at an even earlier maternal age for gravidas with higher-order multiple gestations. However, advances in multiple-marker screening have made maternal age alone obsolete as a threshold for offering invasive tests of fetal karyotype. Thus, a policy of offering chorionic villus sampling (CVS) or amniocentesis to all women with twin pregnancy who are 31 or 33 years of age or older cannot be justified.⁵⁴ All women, regardless of age, should be made aware of the relative advantages and disadvantages of screening versus diagnostic tests for fetal aneuploidy. Women with multiple gestations who are concerned about aneuploidy risk should be counseled and supported to make their own personal decision about choosing a screening test, a diagnostic test, or no testing at all.⁵⁴

FIRST-TRIMESTER SCREENING FOR ANEUPLOIDY

With the availability of late first-trimester multifetal pregnancy reduction procedures in higher-order multiple gestations, interest in first-trimester screening tests for fetal abnormalities has increased. First-trimester combined screening for aneuploidy with nuchal translucency, hCG, and pregnancy-associated plasma protein A (PAPP-A) has effectively become standard-of-care in the United States for singleton pregnancies.⁵⁴ However, the data are insufficient to generate recommendations for the widespread use of this combined screening for multiple gestations. First-trimester free β -hCG and PAPP-A levels are about twice as high in twin pregnancies as in singleton pregnancies.⁵⁵

In studies of normal twin pregnancies, average first-trimester free β -hCG levels were 1.86 multiples of the median (MoM), and PAPP-A levels were 2.10 MoM.^{55,56} In addition, chorionicity and use of assisted reproductive techniques, such as IVF and intracytoplasmic sperm injection, have a significant impact on first-trimester maternal serum marker levels, making their interpretation in the setting of multiple gestations even more complex. PAPP-A and free β -hCG levels are significantly lower in monochorionic twin pregnancies than in dichorionic, and PAPP-A levels are lower in IVF than in spontaneously conceived pregnancies.⁵⁷⁻⁵⁹

Although some centers have implemented first-trimester combined serum and sonographic screening for twin gestations, we continue to rely on increased nuchal translucency thickness because of the limitations of serum marker results in this setting. Data supporting combined screening are quite limited, with insufficient numbers of affected pregnancies to allow robust data interpretation. In one study of 448 twin gestations, this form of combined screening was estimated to be able to deliver an 88% detection rate for Down syndrome, with a 7.3% screen-positive rate.⁶⁰ In another series of 24 multiple gestations and 79 singleton control subjects, the distribution of nuchal translucency measurements, including 95th percentile values, was similar in all cases, implying that this form of screening could be implemented using established normative data from singleton populations.⁶¹ Care also needs to be taken when interpreting nuchal translucency measurements in monochorionic twins, as an increased measurement in one fetus may represent early TTTS rather than elevated aneuploidy risk.⁶² One of the main benefits of nuchal translucency measurement in the multiple gestation population is that, if MFPR is being planned, this measurement can be useful in deciding which fetus or fetuses to target for reduction.

SECOND-TRIMESTER SERUM SCREENING FOR ANEUPLOIDY

Screening for Down syndrome in singleton pregnancies using maternal serum levels of AFP, hCG, unconjugated estriol, and inhibin-A, together with maternal age, during the second trimester is now less commonly performed because of the widespread availability of first-trimester screening. In twin pregnancies, experience with such screening remains limited. Average levels of AFP, hCG, and unconjugated estriol are increased 2.04-fold, 1.93-fold, and 1.64-fold, respectively, in twin compared with singleton pregnancies.⁶³ In one prospective evaluation of screening with multiple serum markers in twins, the screen-positive rate remained at 5%, but no cases of Down syndrome were detected in the study population.⁶⁴ Using statistical modeling and maintaining a 5% false-positive rate, the authors estimated that 73% of monozygotic twins and 43% of dizygotic twins with Down syndrome would be detected. In another series of 420 twin pregnancies, AFP and hCG levels were twice the levels seen in singletons.⁶⁵ The authors postulated that risk prediction from singletons could be extrapolated to twin gestations using a twin correction method in which the MoM value is divided by the mean MoM of the twin population. This process with AFP and hCG screening was predicted to yield a 51% detection rate for Down syndrome, with a 5% rate of false-positive results.⁶⁵ Although second-trimester serum screening for Down syndrome represents an improvement over the use of maternal age alone, it is also clear that the accuracy of such an approach is considerably less than that of serum screening in singleton pregnancies.⁵⁵ Given the effective alternative of nuchal translucency sonography, we do not routinely offer second-trimester serum marker evaluation for aneuploidy screening with multiple gestations.

SCREENING FOR NEURAL TUBE DEFECTS

A second-trimester maternal serum AFP level greater than 2.0 or 2.5 MoM has traditionally been used to screen for neural tube defects in singleton gestations, but is uncommonly employed today because of the widespread availability and increased accuracy of sonographic evaluation of fetal anatomy. Serum screening for neural tube defects in multiple gestations cannot identify which fetus is affected. Given the widespread use of ultrasound, maternal serum AFP screening has little if any value as a screen for neural tube defects in multiple gestations. We now rely exclusively on sonographic evaluation of the fetal posterior cranial fossa and the spine itself to diagnose or exclude neural tube defects in multiple gestations. These sonographic features, such as the “lemon” sign, representing scalloping of the frontal bones, and the “banana” sign, representing downward displacement of the cerebellum toward the foramen magnum, are valid in multiple gestations.

GENETIC AMNIOCENTESIS

Genetic amniocentesis in twins is most commonly performed with an ultrasound-guided double-needle approach.^{59,63,66} After the first sac has been entered and amniotic fluid aspirated, several milliliters of the blue dye indigo carmine are instilled and the needle is removed. A new needle is then placed into the second sac, and aspiration of clear fluid confirms successful sampling of two separate sacs. Methylene blue dye should not

be used because of the risks for fetal hemolytic anemia, small-intestine atresia, and fetal demise. This procedure can be extended sequentially to perform triplet and quadruplet genetic amniocenteses.⁶⁷ Careful sonographic mapping of placentas and sacs is mandatory to assist in future management plans when karyotype results return, which may be as long as 2 weeks later if rapid diagnostic techniques such as polymerase chain reaction (PCR) or fluorescence in situ hybridization (FISH) are not used.

The rate of pregnancy loss after genetic amniocentesis in twins has been difficult to elucidate with certainty because of the significant heterogeneity between published studies. In a recent meta-analysis of studies published between 1990 and 2011, the overall pregnancy loss rate before 24 weeks' gestation in twins after amniocentesis was 2.5%.⁶⁸ No difference was noted in loss rates between single and double uterine needle insertion techniques. How much of this loss rate was the result of the higher background rate of loss seen in twins compared with the procedure-related rate of loss is impossible to quantify. It is generally considered wise to counsel the patient carrying twins that amniocentesis has a somewhat increased risk for loss above the background rate of loss with twins, but the exact increase remains unclear.⁵⁹ No data exist on loss rates for amniocentesis with higher-order multiple gestation or on loss rates for early amniocentesis (<14 weeks) with multiple gestations. However, early amniocentesis is no longer recommended for either singleton or multiple gestations, because its safety compares unfavorably with that of CVS.⁶⁶

CHORIONIC VILLUS SAMPLING

Chorionic villus sampling is usually performed for twin gestations at 10 to 14 weeks. The needle tip must be kept under constant sonographic visualization to ensure that both chorion frondosum sites have been separately sampled. If monochorionicity has been confirmed, a single-placenta sampling procedure is reasonable. A combination of transabdominal and transcervical approaches to the two placentas of a dichorionic pregnancy may ensure that separate placental sites have indeed been sampled.^{59,67} Because as many as 2% to 4% of samples show evidence of twin-twin contamination, the cytogenetic laboratory should be made aware that a twin CVS has been performed. As with twin amniocentesis, careful sonographic mapping of placentas and sacs is mandatory to assist in future management plans after karyotype results become available. As with twin amniocentesis, data on the safety of twin or triplet CVS are limited because of the significant heterogeneity between published studies. In a recent meta-analysis that included studies published between 1990 and 2011, the overall pregnancy loss rate before 24 weeks' gestation after CVS for twins was 3.4%.⁶⁸ No difference was noted in loss rates between transabdominal and transcervical techniques, nor between single and double uterine needle insertion techniques.

Antepartum Management

The incidence and range of maternal and fetal complications in multiple gestation suggest that these pregnancies should be managed under the supervision of an appropriately trained specialist.^{3,4,69} In a nonrandomized study comparing the outcomes of 67 triplet gestations managed by maternal-fetal medicine specialists with the outcomes of 24 triplet gestations

managed by generalist physicians, significant increases in gestational age at delivery and birth weight were observed for the cases managed by specialists,⁶⁹ as well as significant reductions in length of stay in neonatal intensive care units and in cost. Interventions to improve outcome cannot reasonably be expected to be effective unless multiple gestations are detected early in pregnancy. This supports our practice of offering routine ultrasonography to all pregnant women.

PRETERM LABOR AND DELIVERY

Preterm birth occurs in more than 50% of twin and 75% of triplet gestations.^{6,70} Although multiple gestations contributed 3% of all births in the United States, they accounted for 17% of all births before 37 weeks' gestation and 22.3% of births before 32 weeks' gestation in 2009.⁷¹ In addition to patient education about early signs of preterm parturition, other parameters that may forecast preterm delivery include sonographic assessment of cervical length and cervicovaginal assays for fetal fibronectin. A study of cervical length assessment in 1163 twin pregnancies⁴⁷ found a median cervical length of 35 mm at 22 to 24 weeks' gestation; the cervix was less than 20 mm in only 8%. Among women with a cervical length less than 20 mm, 24% ultimately delivered before 32 weeks' gestation. A subsequent meta-analysis comprising 3523 twin pregnancies concluded that a cutoff of less than 20 mm in cervical length at 20 to 24 weeks' gestation was the optimal threshold to predict significantly increased risk for preterm birth.⁷² A cervical length of less than 20 mm in a twin pregnancy at 20 to 24 weeks' gestation was associated with a 10-fold positive likelihood ratio for preterm birth before 32 weeks' gestation. Available data for guiding the role of cervical length assessment in higher-order multiple gestations are limited. In a study of 66 triplet gestations, a cervical length cutoff of 20 mm at 24 weeks' gestation was significantly associated with preterm delivery.⁷³

Although a positive cervicovaginal fetal fibronectin assay at 24 weeks has not been shown to be a significant predictor of preterm delivery in twins, a positive assay at 28 weeks was significantly associated with a 29% rate of spontaneous preterm birth at less than 32 weeks (odds ratio, 9.4)⁷⁰ compared with 4% for a twin gestation with negative fetal fibronectin.⁷⁰ The main value of a single negative fetal fibronectin test in twins is the high negative predictive value for subsequent preterm delivery.^{4,74}

Interventions to prevent preterm labor and prolong pregnancy for patients with multiple gestations have been disappointing. There is no evidence that prophylactic cervical cerclage or prophylactic tocolytic agents are beneficial.^{74,75} An observational study of 128 twin pregnancies with cervical length less than 2.5 mm at 18 to 26 weeks' gestation revealed no benefit for any outcome measure after cerclage placement.⁷⁶ There are no randomized trials indicating a benefit to cerclage for a shortened cervix in multiple gestations. In an observational study of 59 triplet gestations, 20 received prophylactic cervical cerclage, and the remaining 39 were expectantly managed.⁷⁷ There were no significant differences in mean gestational age at delivery or any other measure of neonatal outcome.

Cerclage placement has been considered in selected women with multiple gestation when sonographic surveillance of cervical length has already demonstrated progressive cervical shortening, but a meta-analysis of data from four prospective trials found a twofold increase in preterm birth in women with twins and short cervix who received a cerclage.⁷⁵ Current data are

insufficient to exclude or confirm a benefit of cerclage in multiple gestation.^{4,75,78} We therefore reserve cervical cerclage for women with multiple gestation who also meet historical criteria for cervical insufficiency (see Chapter 41).

Based on studies showing reduced rates of preterm birth after treatment with progesterone compounds in singleton gestations at risk for preterm birth,^{79,80} prophylactic progesterone was investigated in a randomized, placebo-controlled trial of 661 twin pregnancies. Weekly intramuscular injections of 17 α -hydroxyprogesterone caproate had no effect on outcome. Forty-two percent of treated women delivered before 35 weeks, compared with 37% for those who received placebo injections.⁸¹ Subsequent trials of vaginal progesterone, as well as a meta-analysis, also failed to demonstrate any benefit of progesterone in prevention of preterm birth in high-risk twin pregnancies, including those with a short cervix and those with a history of prior preterm birth, although the sample sizes were modest for these secondary analyses.^{78,82}

Long-term maintenance administration of tocolytic drugs (e.g., oral terbutaline or nifedipine, rectal indomethacin, subcutaneous infusion of terbutaline) does not prolong pregnancy or prevent prematurity in multiple gestation.⁷⁴ Caution is advised when tocolytic agents are given to women with multiple gestation because of the significant potential for maternal cardiovascular and pulmonary morbidity. The combination of one or more tocolytic agents, corticosteroids, and intravenous fluid replacement in the setting of the increased blood volume of multiple gestation leads to a significant risk for pulmonary edema. We suggest that acute tocolysis be reserved for women with confirmed preterm labor, to delay delivery and allow transport to an appropriate medical center and antenatal treatment with betamethasone. Betamethasone (12 mg intramuscularly, two doses, 24 hours apart) is given whenever there is a high risk for delivery between 24 and 34 weeks of gestation. Use of repeated courses of antenatal corticosteroids is discussed in Chapter 34.

Bed rest, at home or in the hospital, does not prolong pregnancy or prevent preterm labor or delivery for patients with multiple gestations.⁴ Retrospective studies suggested that hospitalization and bed rest might improve outcome in multiple gestation, but subsequent prospective trials and meta-analyses do not support this intervention. A review of six randomized trials involving more than 600 multiple gestations noted a trend toward a decrease in low-birth-weight infants with inpatient bed rest.⁸³ However, there was no decrease in very-low-birth-weight infants, and inpatient bed rest was actually associated with an increased risk for delivery before 34 weeks' gestation in women with uncomplicated twin pregnancies. There have been no recent prospective trials evaluating the role of bed rest at home for patients with multiple gestation. Because it is extremely difficult to standardize home bed rest and, consequently, difficult to refute the possibility of potential benefit, we advise modified rest at home only for women with higher-order multiple gestations, starting at approximately 20 weeks of gestation.³

Outpatient uterine-activity monitoring does not prolong pregnancy or prevent preterm labor and delivery in either singleton or multiple gestations.⁸⁴ A meta-analysis of six randomized trials showed no significant benefit of home uterine-activity monitoring to reduce the risk for preterm birth in twin gestations.⁸⁵ A randomized trial of weekly nurse contact, daily nurse contact, or daily nurse contact plus home uterine-activity monitoring conducted in 2422 women at risk for preterm birth found no differences in frequency of birth before 35 weeks' gestation

overall and, specifically, no benefit in the 844 women with twin gestations.⁸⁴ Outpatient uterine-activity monitoring has not been studied in women who have undergone fetal reduction procedures in higher-order multiple gestation or in utero fetal surgery.

PREECLAMPSIA

Pregnancy-related hypertension, including gestational hypertension and preeclampsia, is increased in multifetal gestations, ranging from 10% to 20% in twin, 25% to 60% in triplet, and up to 90% in quadruplet pregnancies.^{8,13,21,86,87} The incidence of preeclampsia may be further increased in multiple pregnancies that follow assisted reproductive technologies, but it does not appear to be related to zygosity.^{88,89} The most likely explanation for the strong association between increasing number of fetuses and increasing incidence of preeclampsia is the larger placental mass.⁹⁰ When preeclampsia occurs in higher-order multiple gestations, it more often occurs earlier, is more severe, and is atypical.^{4,8,21,86} A multicenter study of 87 twin and 143 singleton gestations with preeclampsia demonstrated lower gestational age at delivery, lower birth weight, and a higher rate of cesarean delivery among the twin gestations.⁹¹ These data emphasize the importance of specialist supervision of multiple gestations and regular monitoring for early signs and symptoms of preeclampsia. To date, however, no prophylactic interventions (e.g., low-dose aspirin, calcium supplementation) have been found to prevent or reduce the incidence of preeclampsia in these high-risk pregnancies. In one study in which 688 women with multiple gestation were randomized to receive low-dose aspirin or placebo between 13 and 26 weeks' gestation, the incidence of preeclampsia was 12% with aspirin and 16% with placebo, a difference that was not significant (relative risk, 0.7; 95% confidence interval, 0.5 to 1.1).⁹²

OTHER MATERNAL COMPLICATIONS

Daily supplementation with at least 60 to 120 mg of elemental iron and 1 mg of folic acid is recommended because of the increased risk for iron- and folate-deficiency anemia in multiple gestation.⁸⁶ Surveillance for other potential maternal complications of higher-order multiple gestations, including acute fatty liver of pregnancy, gestational diabetes, urinary tract infections, and intervertebral disk disease, is important as well.^{4,8} Conflicting data exist as to whether the incidence of gestational diabetes is higher in twin than in singleton pregnancies.⁸⁶ Although there are no data to guide timing or frequency of screening for gestational diabetes in multiple gestations, it may be reasonable to perform glucose challenge testing at 20 to 24 weeks' gestation, followed by a repeat screen at 28 to 32 weeks' gestation. In particular, multiple gestation is a risk factor for the development of acute fatty liver of pregnancy, perhaps because of the increase in placental mass.⁹³ Acute fatty liver should be carefully considered in the differential diagnosis if hepatic dysfunction is found in a woman with multiple gestation.

FETAL SURVEILLANCE

As described earlier, serial sonographic assessment of fetal growth is recommended in multiple gestations. We evaluate fetal weight and growth discordance every 3 to 4 weeks from approximately 18 weeks' gestation in dichorionic twins, or every 2 weeks if growth restriction or growth discordance (>20%) is discovered. For monochorionic twins, as well as all higher-order

multiple gestations, serial growth scans are performed every 2 weeks from approximately 16 weeks' gestation.^{45,94} Although some clinicians routinely monitor all multiple gestations using weekly NST or biophysical profiles beginning at 34 weeks, this practice has not been validated by prospective studies.⁴ Surveillance with NST or biophysical profile is reserved for multiple pregnancies with the following indications:

- Significant growth restriction in either fetus
- Growth discordance (>18%)⁴⁵
- Oligohydramnios
- Decreased fetal movement
- Maternal medical complications

Fetal testing for monoamniotic twins, TTTS, demise of one fetus, and anomalous twins is discussed later (see Special Considerations in Management).

As soon as the diagnosis of significant growth discordance is confirmed, fetal testing should begin intensively. In our practice, this consists of twice-weekly NST supplemented by biophysical profiles and umbilical artery Doppler velocimetry. If absent or reversed end-diastolic flow is discovered, delivery should be considered if gestational age is sufficiently advanced that the healthy twin would not be significantly compromised by delivery. Selecting the appropriate time for delivery is extremely difficult in such cases, because an effort that is intended to save a twin that may already be significantly compromised may lead to iatrogenic morbidity in the healthy twin. Daily, or twice-daily, fetal testing should be performed in cases of absent or reversed end-diastolic flow until delivery is accomplished.⁹⁴

Determination of fetal lung maturity is rarely required in the management of multiple gestations. If, however, it is deemed useful to document fetal lung maturity, because of potential discordance in lung maturity indices between fetuses, each amniotic sac should be separately sampled.⁴

Intrapartum Management

TIMING OF DELIVERY

In many cases, the timing of delivery of a multiple gestation will be dictated by obvious clinical concerns, such as preterm labor, preeclampsia, or poor fetal growth. There remains considerable debate, however, regarding the optimal timing of delivery for multiple gestations that approach term without any apparent antenatal complications. The nadir of perinatal mortality for dichorionic twin pregnancies occurs at approximately 38 weeks, and for triplets at about 35 weeks.^{4,95} All twin fetuses should therefore be delivered by 39 weeks of gestation because of the rising perinatal morbidity and mortality beyond that date. The rate of stillbirth in multiple gestations at 39 weeks surpassed the risk for singleton gestations at greater than 42 weeks' gestation in one study.⁹⁶ A retrospective review of 5594 twin pregnancies demonstrated an increase in the rate of stillbirth beyond 36 weeks' gestation.⁹⁷ The lowest rate of perinatal morbidity and mortality occurred at 37 weeks' gestation. The ESPRIT trial assessed the ongoing risk for perinatal morbidity and mortality in 1001 twin gestations.⁹⁸ The incidence of unexpected fetal death for uncomplicated dichorionic twins was zero after 33 weeks' gestation, suggesting that it is reasonable to allow such pregnancies continue to 38 weeks' gestation before a scheduled delivery in the absence of complications.

For uncomplicated monochorionic twins, even in the setting of intensive fetal surveillance, the risk for sudden death after 32

weeks' gestation remains a possibility, reaching 5% in one retrospective study.⁹⁹ Given the concerns for higher risk for sudden unexpected fetal demise, together with potentially devastating impact on neurologic outcome for the surviving fetus, it has been suggested that planned delivery of uncomplicated monochorionic twins should be considered by 34 to 35 weeks' gestation. However, the prospective risk for unexpected fetal death in otherwise uncomplicated monochorionic twins at 34 weeks' gestation was only 1.5% in the ESPRIT trial.⁹⁸ The risk for a composite measure of perinatal morbidity fell from 41% at 34 weeks to only 5% at 37 weeks' gestation, suggesting that it was reasonable to allow uncomplicated monochorionic gestations followed with close fetal surveillance to continue to planned delivery at 37 weeks' gestation. In our practice, we counsel patients about the prospective risk for fetal death after 34 weeks' gestation, and individualize the decision with each woman regarding the preferred timing of delivery between 34 and 37 weeks' gestation.

PREPARATIONS

Prostaglandins for induction and oxytocin for induction or augmentation of labor are acceptable in twin gestation. An attempt at vaginal birth after a previous low transverse cesarean delivery is considered by some to be an acceptable alternative to scheduled repeated cesarean birth in twin gestation.¹⁰⁰ However, there are no randomized studies that confirm the safety of vaginal birth after cesarean (VBAC) in multiple gestation. A multicenter registry of 186 attempts at VBAC in twin pregnancies reported a 65% success rate.¹⁰⁰ Thirty of 66 women who delivered the first twin vaginally required cesarean birth for the second twin. Maternal and perinatal morbidity and mortality rates were similar in women with twins who attempted VBAC and those who delivered by repeat cesarean delivery in this observational study.¹⁰⁰ However, such studies to date have lacked power to address the safety of this approach.

Intrapartum management of the parturient with a multiple gestation requires multidisciplinary cooperation. Adequate obstetric and nursing staff, together with an anesthesiologist and at least one neonatologist or pediatrician, should be present for delivery. Intravenous access and prompt availability of blood products should be ensured.¹⁰¹

As soon as possible after admission to the delivery unit, ultrasonography should be performed to determine fetal presentations and size before choosing the mode of delivery. Electronic fetal heart monitoring should be available; this is usually best achieved by placing a fetal scalp electrode for the first twin and using an external monitor for the second twin. If a trial of labor is chosen, continuous lumbar epidural anesthesia should be strongly recommended, because it allows a full range of obstetric interventions to be performed rapidly if needed. Vaginal deliveries should be performed in an operating room, because emergent cesarean section may be required for the second twin in a small number of cases—approximately 4% in one large prospective trial.¹⁰² Before vaginal delivery of a second twin, prompt availability of ultrasonography in the operating room may be very helpful in confirming presentation and fetal well-being.

VERTEX-VERTEX TWINS

The vertex-vertex presentation occurs in 40% to 45% of all twin pregnancies. In the absence of obstetric indications for cesarean delivery, vaginal birth should be planned regardless

of gestational age.^{101,103-106} Routine cesarean delivery for all vertex-vertex twins is not supported by the literature; no improvement in perinatal outcome has been found.¹⁰⁷

After delivery of the first twin, the cord should be clamped. No blood samples should be obtained until after delivery of the second twin. Unless the presentation is obviously vertex by clinical examination, ultrasonography should be performed to confirm presentation of the second twin and to exclude a funic presentation. With the availability of continuous electronic fetal heart monitoring, there is no absolute indication to deliver the second twin within a specified time limit. However, active intervention to complete the delivery (amniotomy, if safe, and oxytocin augmentation) is encouraged by studies that link length of delivery interval to fetal acid-base status. In one series of 118 cases of twin deliveries, significant negative correlations were noted between the length of the delivery interval and umbilical cord pH and base excess.¹⁰⁸ The rate of umbilical arterial pH of 7.00 or less was zero when the delivery interval was less than 15 minutes, increasing to 6% for an interval of 16 to 30 minutes, and to 27% for intervals longer than 30 minutes. Undue delay may also allow time for the fully dilated cervix to contract, thereby limiting the range of options for urgent delivery of the second twin should a problem develop. The cesarean section rate for the second twin also increases with increasing delivery interval.¹⁰³

VERTEX-NONVERTEX TWINS

Vertex-breech or vertex-transverse presentation occurs in 35% to 40% of all twin pregnancies. Selection of mode of delivery depends on (1) the size of the second twin, (2) the presence of growth discordance (estimated weight of second twin at least 25% greater than first twin), and (3) the availability of obstetric staff skilled in assisted breech delivery, internal podalic version, and total breech extraction. In the absence of an appropriately skilled obstetrician, or if the second twin is significantly larger than the first, cesarean delivery is recommended.

Another option is external cephalic version of the second twin immediately after delivery of the first. This method is successful in up to 70% of cases of vertex-nonvertex twins.¹⁰⁹ Vaginal delivery is not always possible after successful external version of the second twin and may be associated with complications, such as cord prolapse and placental abruption, that require emergent cesarean delivery of the second twin. For these reasons, breech extraction may be a better alternative, with success rates of more than 95%.¹¹⁰ It has also been suggested that external cephalic version should no longer be attempted for a second twin because of the very high rate of emergency cesarean delivery required for the second twin.^{101,110,111}

Vaginal breech delivery of the second twin appears to be reasonable in appropriately selected cases. The adverse perinatal outcome associated with breech second twins is more often related to prematurity or growth restriction than to mode of delivery.¹⁰³ A liberal cesarean delivery policy for the nonvertex second twin has not significantly improved perinatal outcome. For fetuses with birth weights of 1500 g or more, there is no apparent benefit to cesarean delivery over vaginal breech delivery for the nonvertex second twin.¹⁰³ Data for fetuses with estimated birth weights less than 1500 g are insufficient to make such a firm conclusion, but vaginal breech delivery of such fetuses is not absolutely contraindicated. In a series of 141 twin deliveries in which the second twin was nonvertex, including 35 cases of vaginal delivery, there was no evidence of benefit from

cesarean delivery when gestational age was greater than 24 weeks and the birth weight exceeded 1500 g.¹¹² It seems reasonable to offer vaginal breech delivery for the nonvertex second twin with an estimated birth weight between 1500 and 3500 g, provided it is not significantly larger than the first twin and the head is not hyperextended. An estimated fetal weight of 2000 g as a lower threshold of fetal size allows for the imprecision of fetal ultrasound in accurately predicting birth weight.

If a vaginal breech delivery is planned for the second twin, the delivery of the presenting vertex twin is performed as previously described. If the second twin is in a frank or complete breech presentation and the fetal heart tracing is reassuring, membranes may be left intact until engagement of the presenting part, and an assisted breech delivery can be performed.

If the second twin is in a transverse lie or a footling breech presentation, or if fetal testing is not reassuring, membranes should be left intact until the feet can be secured in the pelvis, after which immediate amniotomy and total breech extraction should be performed.¹⁰³ Whenever total breech extraction is indicated, it should be performed as soon as possible after delivery of the first twin, while the cervix is still fully dilated.¹⁰¹ Active management of the second stage after delivery of the first twin appears to be crucial in reducing the requirement for cesarean delivery of the second twin and to optimize outcomes. In one series of 130 patients from a single center undergoing planned vaginal twin birth, the incidence of cesarean delivery of the second twin was zero with a policy of breech extraction of the nonvertex or unengaged second twin.¹¹³

NONVERTEX FIRST TWIN

Breech-vertex or breech-breech presentation occurs in 15% to 20% of all twin pregnancies. Such cases are almost always managed by cesarean delivery. Historically, this was practiced because of concern about interlocking fetal heads in breech-vertex twins. However, this complication is so rare that some centers offer vaginal delivery when the breech twin of a breech-vertex pair meets the selection criteria for singleton vaginal breech deliveries. Among 239 vaginal deliveries in which the first twin was breech, there was no evidence of depressed Apgar scores or increased neonatal deaths when the first twin's weight was greater than 1500 g.¹¹⁴ However, low Apgar scores and neonatal deaths were significantly increased for first twins weighing less than 1500 g who were delivered vaginally from breech presentation. External cephalic version of a breech-presenting twin has also been described.¹¹⁵ In the absence of prospective studies validating these approaches, cesarean section for the nonvertex first twin is likely to be the optimal mode of delivery.

HIGHER-ORDER MULTIPLE GESTATIONS

Although case series of successful vaginal delivery of triplets exist, there are no prospective series large enough to establish the safety of vaginal over cesarean birth of higher-order multiples.^{106,116,117} In one series of 26 viable triplet pregnancies with a planned trial of labor, 88% successfully delivered all three fetuses vaginally.¹⁰⁶ Although the study was not powered to detect a significant difference in perinatal mortality, it is interesting to note that four mortalities occurred in the vaginal birth group, whereas none occurred in a control group of 47 triplet pregnancies delivered by cesarean. Another review suggested that there was a sixfold increased risk for stillbirth

and a threefold increased risk for neonatal death when vaginal delivery of viable triplets was attempted.¹¹⁸ Because of practical difficulties in adequately monitoring three or more fetuses in labor and through delivery, we recommend cesarean delivery under regional anesthesia for all patients with three or more live fetuses that are of a viable gestational age. There is no conclusive evidence to recommend one type of uterine incision over another in higher-order multiple gestation.

ASYNCHRONOUS DELIVERY

Asynchronous delivery, or delayed-interval delivery, refers to delivery of one fetus in a multiple gestation that is not followed promptly by birth of the remaining fetus or fetuses. This extremely rare scenario is acceptable only in the management of extreme prematurity, when the remaining fetus is either pre-viable or would be at very high risk for severe complications of prematurity if delivered. Clinical conditions that typically contraindicate asynchronous delivery include monochorionicity, intra-amniotic infection, placental abruption, and the coexistence of preeclampsia.

In a report of 24 twins and triplets managed with delayed-interval delivery, a protocol of amniocentesis of the remaining sac to exclude infection, ligation of the cord of the delivered fetus with absorbable suture near the placenta, aggressive tocolysis, placement of a cerclage, broad-spectrum antibiotics for up to 7 days, bed rest, and close surveillance were instituted.¹¹⁹ The mean latency interval was 36 days; the range was 3 to 123 days. In 16 of the 24 cases, the gestational age was 24 weeks or less at the time of presentation; 10 (63%) of these reached 24 weeks, and 8 (44%) of the 18 remaining infants survived. In another, more recent series of 38 twin and 12 triplet pregnancies managed at a single center, a standardized protocol was followed to manage asynchronous delivery.¹²⁰ This consisted of high ligation of the umbilical cord of the first fetus after delivery, chlorhexidine vaginal washing, tocolysis, antibiotics (as dictated by cervical culture results), and avoidance of cervical cerclage. Among twin pregnancies with initial delivery before 25 weeks' gestation, 9 of 18 (50%) second twins survived. Among seven triplet pregnancies with initial delivery before 25 weeks' gestation, only 2 of 14 (14%) remaining triplets survived.¹²⁰

Given the limitations of these data, it is essential that careful counseling be provided and informed consent be obtained from the mother regarding risks to her health before such management is attempted. Eligible women should be monitored closely for the development of chorioamnionitis or maternal sepsis. Cervical cerclage and tocolytic agents should be used with extreme caution and only after excluding chorioamnionitis. Data are insufficient to comment on the role of prophylactic antibiotics or amniocentesis in this setting.

Special Considerations in Management

TWIN-TWIN TRANSFUSION SYNDROME

Background and Pathogenesis

TTTS occurs because of an imbalance in blood flow through vascular communications in the placenta, which leads to overperfusion of one twin and underperfusion of its co-twin (Fig. 38-2). It occurs exclusively in monochorionic twin pregnancies and is estimated to occur in at least 15% of such pregnancies.¹²¹ Theoretically, TTTS should not occur in dichorionic twin

Figure 38-2 Twin-twin transfusion syndrome. Twin-twin transfusion syndrome resulted in pregnancy loss at 22 weeks' gestation; the plethoric recipient twin is on the left and the anemic donor twin on the right. (Courtesy of Steven Ralston, MD, New England Medical Center, Boston.)

pregnancies, but it has been demonstrated at least once in a fused dichorionic twin gestation.¹²² The precise incidence of TTTS is extremely difficult to define, because the syndrome is associated with a wide spectrum of clinical presentations, ranging from the vanishing-twin phenomenon in the first trimester to unexplained fetal demise in the third trimester.

TTTS occurs when the normal anatomic arrangement of a paired artery and vein supplying and draining a placental cotyledon is abnormal. Instead, an arteriovenous (AV) anastomosis occurs on the placental surface, whereby a single unpaired artery carrying blood from the donor twin to a placental cotyledon connects directly into a single unpaired vein carrying blood from that cotyledon back to the recipient twin.¹²³ Although these vessels run along the surface of the placenta separately, they enter the same placental cotyledon. It is theorized that these AV anastomoses result in net transfusion of blood from the donor to the recipient fetus. However, such AV anastomoses are present in up to 70% of monochorionic placentas, whereas the clinical syndrome of TTTS is far less common (15%).¹²⁴ Therefore, a protective mechanism must be in place that prevents TTTS from developing in the majority of

monochorionic pregnancies. It has been suggested that arterio-arterial anastomoses are bidirectional and that the presence of a large number of such anastomoses in a monochorionic placenta may compensate for unidirectional AV anastomotic flow, thereby preventing the appearance of TTTS in many otherwise uncomplicated monochorionic pregnancies.¹²⁴⁻¹²⁶

Clinical and Sonographic Features

The clinical features of TTTS can be explained by the placental architecture findings just described. The donor fetus is relatively hypoperfused, demonstrating signs of intrauterine growth restriction and oligohydramnios. Eventually, anhydramnios develops, and this fetus attains the typical "stuck twin" appearance because of inability to visualize the dividing membrane separate from the fetal body. Fetal blood sampling studies have demonstrated that the donor fetus has a significantly lower hematocrit than the recipient fetus (36% versus 47%).¹²⁷ Echocardiographic studies have not shown any specific pattern of abnormal findings among donor fetuses.¹²⁸ In contrast, the recipient fetus is relatively hyperperfused, becomes hypertensive, and produces increasing amounts of atrial and brain natriuretic peptides in an effort to handle its larger blood volume.¹²⁹ Recipient fetuses demonstrate biventricular hypertrophy and diastolic dysfunction, which tends to be progressive without definitive therapy.¹³⁰ This results in significant polyhydramnios and increasing intrauterine pressure. Uterine overdistention and raised intrauterine pressure may then contribute to increased rates of preterm labor or pPROM, as well as exacerbating hypoperfusion of the donor fetus through compression effects. Echocardiographic features in the recipient twin include ventricular hypertrophy and dilation, tricuspid regurgitation, and cardiac failure.¹²⁸ Additionally, acquired progressive right ventricular outflow tract obstruction, possibly leading to right ventricular outflow atresia, has been described in up to 9% of recipient fetuses.¹³¹

Prenatal diagnosis of TTTS depends on a high degree of clinical suspicion in monochorionic pregnancies, and it is because of this concern that monochorionic twin pregnancies are typically subjected to a sonographic surveillance program every 2 weeks from 16 weeks' gestation onward. The typical ultrasonographic criteria required for diagnosis of TTTS include the following:

- Presence of a single placenta
- Sex concordance
- Significant growth discordance (approximately 20%)
- Discrepancy in amniotic fluid volume between the two amniotic sacs (usually oligohydramnios and polyhydramnios)
- Discrepancy in size of the umbilical cords
- Presence of fetal hydrops or cardiac dysfunction
- Abnormal umbilical artery Doppler findings, such as absent end-diastolic flow in the donor fetus

Not all sonographic criteria need to be met to make the diagnosis of TTTS, and none of the criteria is specific for TTTS. For example, a significant growth discrepancy between monochorionic fetuses is not required to make a diagnosis of TTTS, because acute TTTS is known to occur; it leads to marked inequality in amniotic fluid volume in each sac but with insufficient time for significant fetal size discordance to become apparent. The most important criterion is a significant discrepancy in amniotic fluid volume, with a maximal vertical pocket of less than 2 cm around the donor fetus and a maximal vertical

pocket greater than 8 cm around the recipient fetus before 20 weeks' gestation (or greater than 10 cm after 20 weeks' gestation). An early sonographic marker of TTTS may be significant discrepancy in nuchal translucency measurements at 10 to 14 weeks' gestation in a monochorionic twin.⁶² The differential diagnosis of significant growth discordance or stuck twin phenomenon includes uteroplacental insufficiency, structural or chromosomal fetal abnormalities, abnormal cord insertion, and intrauterine infection (e.g., cytomegalovirus infection). Additionally, abnormal cord insertions frequently coexist with TTTS, with marginal and velamentous cord insertions being found in 22% and 9% of monochorionic twins respectively.¹³² It is unclear whether such cord insertion abnormalities contribute to the development or severity of TTTS.¹³³

Because great clinical variability exists in the appearance of TTTS, sonographic scoring criteria have been proposed to classify severity. The clinical value of scoring systems to improve fetal outcome has not yet been determined, but such criteria may foster comparison of published treatment strategies. The most commonly used system is the Quintero staging, which uses the following markers, with the stage being assigned on the basis of the worst sonographic features documented¹³⁴:

Stage I: Donor twin bladder still visible, fetal Doppler values normal

Stage II: Donor twin bladder no longer visible, fetal Doppler values normal

Stage III: Donor twin bladder no longer visible, fetal Doppler values critically abnormal

Stage IV: Presence of hydrops

Stage V: Intrauterine death of one or both fetuses

Fetuses with TTTS may not show an orderly progression through these stages. The ultimate prognosis does not appear to be directly related to the stage at initial diagnosis.¹³⁵ Diagnosis of stage I TTTS does not necessarily imply that disease progression will occur, with progression rates between 10% and 45% for stage I disease.^{135,136}

Management

Because the diagnosis of TTTS is essentially one of exclusion, management first involves excluding other causes of significant growth discordance or stuck twin phenomenon. This requires careful sonographic assessment of fetal anatomy (in particular, the presence of normal fetal kidneys), cardiac function, and placental cord insertions for both fetuses. Although consideration should be given to the performance of amniocentesis to exclude chromosomal anomaly or infection, this procedure may interfere with subsequent management if fetoscopic laser therapy is a possibility.¹³⁷ It is preferable, therefore, to defer amniocentesis until the time of definitive fetal therapy. Expectant management of severe TTTS is associated with high rates of perinatal mortality, as high as 80% to 100% if the diagnosis is made before 24 weeks' gestation.¹³⁸ If only one twin dies, there is a significant risk (as high as 26%) of profound neurologic handicap in the surviving twin.¹³⁹ As described earlier, because as many as 70% of cases of stage I TTTS may remain stable or regress, it is unclear whether aggressive invasive fetal therapy should be provided in such early-stage disease.^{135,136} The role of fetoscopic laser coagulation of placental anastomoses in such early-stage disease is currently the subject of international randomized clinical trials.

Three possible management approaches have been described for the treatment of severe TTTS before 24 to 26 weeks'

gestation (Quintero stages II to IV): serial reduction amniocenteses, amniotic septostomy, and selective fetoscopic laser coagulation of placental anastomoses. Serial reduction amniocenteses were suggested as a path to equilibrate amniotic fluid volume across the dividing membrane and to reduce overall intrauterine pressure.¹⁴⁰ Amniotic septostomy involves deliberate perforation of the dividing membrane, with the putative mechanism of action being equalization of fluid across the dividing membrane.¹⁴¹ However, both of these techniques have been effectively abandoned in the setting of severe TTTS because they do nothing to interfere with the underlying placental disease pathology, and because convincing data have now established the superiority of fetoscopic laser coagulation of the placental vessels.^{135,142,143}

LASER THERAPY FOR SEVERE TTTS

When severe TTTS (Quintero stages II to IV) is diagnosed prior to 24 to 26 weeks' gestation, the most effective management option is selective fetoscopic laser coagulation of the anastomotic vessels on the surface of the placenta, using a fetoscopically placed neodymium-yttrium aluminum garnet (neo-YAG) laser or diode laser.^{142,143} The primary study demonstrating the superiority of selective fetoscopic laser coagulation was published in 1994 by the Eurofoetus Consortium.¹⁴² This multicenter trial randomized 142 women with severe TTTS before 26 weeks' gestation to serial reduction amniocenteses or fetoscopic laser coagulation. The study was stopped early because of a significant advantage for those assigned to laser therapy. Compared with the group undergoing amniocenteses, the laser ablation group had significantly prolonged median gestational age at delivery (33 versus 29 weeks), significantly more cases with at least one survivor at 6 months of age (76% versus 51%), and significantly fewer instances of major neurologic damage among surviving infants at 6 months of age (5% versus 10%).¹⁴²

The surgical technique involves placement of a 2-mm fetoscope into the polyhydramniotic recipient twin's sac under ultrasound guidance with local or regional anesthesia, and the vessels on the surface of the placenta are inspected. Whereas a straight fetoscope is used for posterior placental locations, fetoscopes with angled lenses or curved sheaths have been specifically developed for anterior placentas. AV anastomoses are easily identifiable as a single unpaired artery coming from the donor side and entering a foramen on the placental surface, together with a single unpaired vein exiting the same area on the placental surface with blood flowing toward the recipient twin. Selective laser coagulation involves placement of a 0.4-mm laser fiber through the fetoscope and ablating all visible anastomoses that communicate between the fetuses. It is critical that all vascular communications that connect the two fetal circulations be ablated, because this should prevent reverse fetal transfusion and reduce neurologic injury if one fetus dies. This selective approach to laser ablation also involves leaving intact those vessels that drain an area of placenta both to and from one particular fetus. Such paired placental vessels do not contribute to the TTTS pathologic process and may be critically important to the survival of the donor fetus in particular. Amnioreduction is also performed as part of the same procedure. The logical advantage of selective fetoscopic coagulation over reduction amniocenteses or amniotic septostomy is that it is the only therapy that directly treats the underlying pathophysiology of TTTS. By ablation of the AV anastomoses, the net

transfusion of blood from donor to recipient can be reduced. Ablation of all placental anastomoses that connect the fetuses essentially makes the pregnancy dichorionic.

Some technical refinements of the fetoscopic laser coagulation procedure are currently being investigated. Some authors have claimed that the sequence in which placental vessels are ablated may be important for determining the rate of survival of the donor fetus. With the original selective coagulation procedure, almost 30% of donor fetuses still died within 4 weeks of the procedure.^{135,144} It has been claimed that if AV anastomoses that shunt blood from the donor toward the recipient are ablated first (followed later by ablation of anastomoses that direct blood toward the donor), this might reduce the degree of donor fetal hypotension and result in improved donor fetal survival. Insufficient data, however, have been provided to support this concept, and it is unclear how practical it would be to be able to precisely identify the direction of blood flow in all anastomoses. Another refinement, known as the Solomon technique, is to join the areas of ablated vessels on the placental surface by further laser coagulation, to leave a coagulated line along the vascular equator of the placenta. The objective of this technique is to further reduce the chances of missing small residual anastomoses on the placental surface. A randomized trial is underway to evaluate this technique.¹³⁵

After TTTS treatment, intensive fetal surveillance should be performed when viability is reached. Betamethasone administration is recommended because of the high likelihood of early delivery. Delivery should be based on usual obstetric indications, although cesarean section is likely. If complete laser separation of shared vessels in the placenta has been confidently achieved, and if TTTS features resolve, it may be reasonable to maintain the pregnancy until 37 weeks. However, given the difficulty in confirming with certainty that all placental anastomoses have been ablated, it may also be reasonable to electively deliver TTTS cases at 34 weeks, after successful earlier therapy. Two neonatal resuscitation teams should be present at delivery. Surviving infants are at increased risk for long-term morbidity, including cardiomyopathy and periventricular leukomalacia, and therefore neonatal cranial imaging and follow-up echocardiography are recommended.

Perinatal outcome after fetoscopic laser coagulation appears to depend on operator experience, with the procedure probably having a steep learning curve. In a review of the nine largest series of laser procedures, encompassing 1367 cases, overall perinatal survival rate was 66% (range, 54% to 82%) with at least one twin surviving in 72% of cases (range, 73% to 90%).¹³⁵ The incidence of complete pregnancy loss before 24 weeks' gestation was 7% (range, 3% to 14%), and the incidence of pPROM was 15% (range, 8% to 28%). Other short-term complications of laser treatment include surgical failure leading to residual patent anastomoses, which occurs in up to 19% of cases and may result in recurrent TTTS in 10% of cases, as well as fetal demise or neurologic injury.¹⁴⁵ When TTTS recurs after laser therapy, options for further management are quite limited, as a repeat fetoscopic laser procedure can be particularly challenging. In a review of 1367 laser procedures, a second laser procedure was performed in only 4% of cases (range, 0% to 11%) and overall survival of only 50% is to be expected.¹³⁵

Another unusual complication after fetoscopic laser treatment for TTTS is twin anemia polycythemia sequence (TAPS). TAPS can be diagnosed when the middle cerebral artery peak systolic velocity is greater than 1.5 MoM in one fetus (usually

an anemic ex-recipient fetus), and the peak systolic velocity is less than 0.8 MoM in the other fetus (usually a polycythemic ex-donor fetus), but without any obvious amniotic fluid discrepancy. TAPS may occur in up to 13% of cases of TTTS that have been treated with laser, but it may also be seen spontaneously in up to 5% of monochorionic twin pregnancies that had never been diagnosed with TTTS.¹⁴⁶ TAPS is a particularly challenging clinical condition with minimal data available to guide management choices. Options for management include preterm delivery, intrauterine fetal transfusion, selective fetocide, and repeat fetoscopic laser coagulation. Intrauterine fetal transfusion, while logical for the anemic fetus, has a risk for worsening polycythemia in the other fetus. Repeating the fetoscopic laser procedure is also particularly challenging because of the normal amniotic fluid volumes and the quite likely tiny size of residual anastomoses. Additionally, spontaneous resolution of TAPS has also been described.¹⁴⁷ Until prospective data on outcomes of TAPS cases with various treatment options are available, management should be individualized in all cases.

Studies of long-term outcome after laser treatment for TTTS have also confirmed that a significant number of survivors have neurologic impairment. In one series reporting on 2-year follow-up of 115 survivors after laser treatment for TTTS, 17% had neurodevelopmental impairment, mostly cerebral palsy or developmental delay.¹⁴⁸ Long-term outcome results after 6 years of pediatric follow-up have also been published from the Eurofoetus randomized trial of laser versus reduction amniocenteses.¹⁴⁹ This study demonstrated a 12% incidence of neurologic impairment in survivors to age 6 years after laser therapy, which was significantly better than the 17% incidence seen in survivors after reduction amniocenteses. In a review of 256 long-term survivors after laser therapy, followed to 3 years of age at a single German center, the incidence of severe neurologic impairment was 7%, and in a further 8% minor or moderate impairment was noted.¹⁵⁰ Such long-term outcome data will be very helpful in counseling patients about to undergo laser therapy for TTTS, and to encourage appropriate long-term follow-up studies of all surviving neonates.

MONOAMNIOTIC TWINS

Monoamniotic twinning results in a single amniotic sac containing both twins and occurs in approximately 1% of monozygotic gestations. Prenatal diagnosis is established when a dividing membrane cannot be identified by an experienced sonographer in a twin gestation. The diagnosis is also confirmed after sonographic identification of entangled umbilical cords (Fig. 38-3). This feature has been reported in almost all prenatally diagnosed cases and can be seen by color Doppler ultrasonography at as early as 10 weeks' gestation.^{151,152} It can be difficult to visualize the dividing membrane sonographically in certain situations, especially in the early first trimester. Another technique that has been used to diagnose monoamnioticity is sonographic visualization of only one yolk sac in a monochorionic twin gestation at less than 10 weeks' gestation, although the specificity of this finding is unclear.³³⁻³⁵

Monoamniotic twins historically carried a higher risk for perinatal morbidity and mortality than diamniotic twins, with a perinatal mortality rate greater than 50%.¹⁵³ However, more recent series and reviews of prenatally diagnosed cases of monoamniotic twins suggest mortality rates of about 13%.¹⁵⁴ In some centers, perinatal mortality rates as low as 2% have

Figure 38-3 Monoamniotic twin pregnancy. A, Color Doppler image of entangled umbilical cords, which is typical of monoamniotic twin pregnancy. B, Pulsed Doppler image of the same patient in which two separate heart rates are clearly visible within the Doppler gate. C, Pathology image of the placenta from the same patient after delivery, showing both cord insertion sites in the placenta being close together and with entangled umbilical cords. (Courtesy of Dr. Jennifer Donnelly, Rotunda Hospital Dublin, Dublin, Ireland.)

been documented, after excluding anomalous fetuses.¹⁵⁴ The increased perinatal risk may be secondary to premature delivery, growth restriction, congenital anomalies, vascular anastomoses between twins, and umbilical cord entanglement or cord accidents. Because umbilical cord accidents (e.g., cord prolapse, cord compression between fetuses) seem to be the primary cause of fetal death, most management protocols for monoamniotic twins emphasize intensive fetal surveillance.^{155,156} Such surveillance should occur from the time of fetal viability, because intrauterine fetal demise has been documented in monoamniotic twins throughout gestation.^{151,152} Surveillance must be repeated frequently, because fetal compromise and death have been documented despite twice-weekly fetal testing.¹⁵¹ The only intervention proposed to reduce the likelihood of cord accidents in monoamniotic twins is maternal administration of sulindac, a prostaglandin inhibitor that results in decreased amniotic fluid volume, which may, in turn, stabilize fetal lie and theoretically reduce the risk for cord entanglement.¹⁵⁷ Because evidence to support its safety and efficacy is lacking, sulindac treatment is considered experimental.

Because umbilical cord accidents are not predictable by current methods of fetal surveillance and continuous fetal heart monitoring is not feasible,¹⁵⁸ we have managed monoamniotic twin gestations with daily NSTs beginning at 24 to 26 weeks' gestation to determine the frequency of variable decelerations.^{154,156} If variable decelerations increase in frequency, we begin continuous fetal heart monitoring and intervene with cesarean delivery if fetal heart testing becomes non-reassuring.

In the absence of non-reassuring fetal heart rate test results, the timing and mode of delivery of monoamniotic twins are controversial. A report on 20 sets of monoamniotic twins found no fetal deaths after 32 weeks, suggesting that prophylactic early delivery was not needed.¹⁵⁹ However, a subsequent addendum to that series reported a double fetal death at 35 weeks, calling into question the safety of expectant management beyond a gestational age at which neonatal morbidity is likely to be low. Although vaginal delivery of monoamniotic twins is clearly possible, the incidence of cesarean delivery is high when fetal testing is non-reassuring. In addition, there are case reports of cutting the nuchal cord of the second twin after delivery of the first twin's head.^{160,161}

In a series of 101 monoamniotic twin pregnancies from Japan, in which a gestational age of at least 22 weeks was

reached, the prospective risk for fetal death was 5% to 8% for each additional week between 30 and 36 weeks' gestation.¹⁶² Because of these concerns, we and others electively perform cesarean delivery at 32 to 34 weeks' gestation after administering betamethasone to the mother.^{101,154,156,163,164} It is difficult to recommend continuation of pregnancy beyond 34 weeks' gestation, given the ongoing risk for stillbirth and the high rates of infant survival beyond this gestational age. Whereas the majority of recent studies have suggested scheduled cesarean section, vaginal delivery may be acceptable if the fetal heart rates are continuously monitored and the mother has been informed that an emergent cesarean delivery may be necessary.

TWIN REVERSED ARTERIAL PERFUSION SEQUENCE

Twin reversed arterial perfusion (TRAP) sequence, or acardiac twinning, is a unique abnormality of monochorionic multiple gestations in which one twin has an absent, rudimentary, or nonfunctioning heart. The incidence is estimated to occur in 1% of monozygotic twin pregnancies, with a birth estimate of approximately 1 in 35,000 births. The condition occurs because of early first-trimester circulatory failure of one fetus in a monochorionic twin pregnancy, together with the development of arterioarterial and venovenous anastomoses between the umbilical arteries of both fetuses.¹⁶⁵ This results in a profoundly abnormal twin mass that is perfused directly from the other, usually normal, twin.

The donor, or "pump twin," provides circulation for itself and for the recipient (the "perfused twin") through a direct umbilical arterial-to-umbilical arterial anastomosis at the placental surface. There is reversal of blood flow in the umbilical artery of the acardiac twin, with the artery bringing deoxygenated blood from the co-twin to the acardiac twin. This perfusion is usually asymmetric in the recipient twin, with relative hypoperfusion of the upper part of the body, leading to significant structural anomalies. A bizarre range of anomalies can be seen in the acardiac twin, including anencephaly, holoprosencephaly, absent limbs, absent lungs or heart, intestinal atresias, abdominal wall defects, and absent liver, spleen, or kidneys.¹⁶⁶ Up to one third of the fetuses also have an abnormal karyotype.¹⁶⁷

Prenatal diagnosis of TRAP is based on the recognition of one normal-appearing fetus and an additional, profoundly abnormal appearing fetus or amorphous mass of tissue. The

pregnancy should be clearly monochorionic. Two thirds of cases demonstrate a single umbilical artery. The acardiac fetus may be unrecognizable as a fetus or may have an abnormal-appearing head or trunk with no obvious heart. Sonographic signs of cardiac failure may be visible in the pump twin, including polyhydramnios, cardiomegaly, and tricuspid regurgitation. The differential diagnosis of TRAP includes intrauterine fetal demise of one fetus and anencephaly. Doppler velocimetry of the umbilical cords demonstrating reversed direction of flow in the umbilical artery and vein may be helpful in confirming the diagnosis.¹⁶⁸

The goal of antepartum management of TRAP pregnancies is to maximize outcome for the structurally normal pump twin. The pump twin is at risk for development of hydrops or congestive cardiac failure. In one of the earliest published series, of 49 cases of TRAP, the overall perinatal mortality rate for the pump twin was 55%, with polyhydramnios leading to prematurity as the major factor determining prognosis.¹⁶⁹ Other series have suggested a perinatal mortality rate for the pump twin as low as 35%.¹⁷⁰ Prediction of prognosis for the pump twin depends on the ratio of the weight of the perfused twin to the weight of the pump twin, with a 30% chance of congestive cardiac failure when the ratio is greater than 0.70, compared with 10% when the ratio is less than 0.70.¹⁶⁹ Other criteria that may suggest the need for intervention include an abdominal circumference measurement in the acardiac twin greater than or equal to that of the pump twin, polyhydramnios with maximum vertical fluid pocket greater than 8 cm, abnormal Doppler indices, hydrops in the pump twin, or TRAP in the setting of monoamniocity.¹⁷¹

In the absence of such poor prognostic features, expectant management with serial sonographic evaluation may be reasonable.^{172,173} Serial weekly echocardiographic surveillance of the pump twin is recommended for early signs of cardiac failure, such as atrial or ventricular enlargement, tricuspid regurgitation, or decreased ventricular fractional shortening capacity. Rapid growth of the acardiac fetus may also be a sign of poor outcome.¹⁷⁴ Antenatal corticosteroid administration should be given if delivery is expected to occur between 24 and 34 weeks' gestation. Signs of cardiac decompensation after 32 to 34 weeks' gestation should prompt consideration for delivery. Antenatal intervention on behalf of the pump twin should be considered if poor prognostic criteria, as summarized earlier, are noted before 32 to 34 weeks' gestation.

If features suggestive of impending cardiac failure are present at an early gestational age, consideration should be given to an invasive procedure to interrupt the vascular supply to the acardiac mass. Percutaneous approaches for interrupting blood flow to the acardiac twin include fetoscopy (with bipolar cord coagulation or laser ablation), or, alternatively, radiofrequency thermoablation, thermocoagulation, or harmonic ultrasound scalpel to the acardiac twin's cord.^{170,171} Typical survival rates for cord coagulation range from 70% to 80%, and those for radiofrequency ablation are similar, with some series as high as 86%.^{170,175} One suggested advantage of the radiofrequency ablation technique is use of a relatively small, 17-gauge needle, compared with the typical 2- to 3-mm fetoscope for cord ligation approaches. However, in a comparison of both approaches in 53 cases of TRAP, perinatal survival was similar with 92% survival for cord ligation and 78% for radiofrequency ablation.¹⁷⁶ In practice, it may be optimal to have access to different surgical approaches. For example, radiofrequency ablation may be useful if there is significant oligohydramnios that may limit fetoscopic access or visualization.

Recently, a more aggressive approach to TRAP has evolved as more centers become experienced with fetoscopic surgery in the setting of TTTS. As first-trimester diagnosis of TRAP is now commonplace, it may be reasonable to offer definitive cord interruption prophylactically at 16 to 18 weeks' gestation, before features of cardiac decompensation develop. In a series of 24 TRAP cases followed at one center, there was 90% survival of the pump twin in 10 cases that underwent prophylactic intervention by 18 weeks, whereas in eight other cases there was spontaneous demise of the pump twin after first-trimester diagnosis but before intervention could be performed at 18 weeks.¹⁷⁷ However, in that series, there were another five cases of TRAP in which perfusion of the acardiac mass spontaneously stopped without the need for intervention. In another series of 18 TRAP cases managed at a single center, seven underwent radiofrequency ablation and 11 were managed conservatively (provided the acardiac twin was less than 50% of the size of the pump twin).¹⁷⁸ Pump twin survival was similar in both groups (100% and 91%, respectively), leading the authors to conclude that conservative management in carefully selected cases is a reasonable management strategy. Therefore, with the current available data, it is difficult to conclude whether prophylactic intervention early in the second trimester is a better approach than delaying intervention until features of cardiac decompensation begin. Both approaches currently appear reasonable.

CONJOINED TWINS

Conjoined twins are a subset of monozygotic twin gestations in which incomplete embryonic division occurs 13 to 15 days after conception, resulting in varying degrees of fusion of the two fetuses. The estimated frequency of conjoined twinning is 1.5 in 100,000 births.¹⁷⁹ The prenatal diagnosis should be straightforward and is confirmed by failure to visualize two fetuses separately in what appears to be a single amniotic sac. Other sonographic features that assist in making the diagnosis include bifid appearance of the first-trimester fetal pole, more than three umbilical cord vessels, heads persistently at the same level and body plane, and failure of the fetuses to change position relative to each other over time.¹⁸⁰ Prenatal diagnosis of conjoined twins has been made in the first trimester with the aid of three-dimensional sonography.¹⁸¹ However, caution should be exercised in making a definite diagnosis of conjoined twins at less than 10 weeks' gestation, because false-positive diagnoses have been documented.¹⁸²

By careful sonographic survey of the shared anatomy, it should be possible to classify conjoined twins into one of the following five types:

1. Thoracopagus, in which the two fetuses face each other, accounts for 75% of conjoined twins (Fig. 38-4). The fetuses usually have common sternum, diaphragm, upper abdominal wall, liver, pericardium, and gastrointestinal tract. Because 75% of thoracopagus twins have joined hearts, prognosis for surgical division is extremely poor.
2. Omphalopagus (or xiphopagus) is a rare subgroup of thoracopagus in which there is an abdominal wall connection, often also with a common liver. Because joined hearts are rare in omphalopagus, twins in this subgroup have a much better surgical prognosis than twins with other forms of thoracopagus.
3. Pygopagus accounts for 20% of cases; the twins share a common sacrum and face away from each other. There is

Figure 38-4 Conjoined twins. Thoracopagus conjoined twins at 20 weeks' gestation, demonstrating a single trunk containing two parallel spines (A) and leading to two separate heads (B).

a single rectum and bladder, and prognosis for surgical separation is usually good.

4. Ischiopagus, in which the twins share a single common bony pelvis, accounts for 5% of conjoined twins. Surgical prognosis is good, although the remaining lower spines are often abnormal.
5. Craniopagus accounts for 1% of cases and is marked by partial or complete fusion of skull, meninges, and vascular structures. Surgical prognosis depends on the degree of fusion of vascular structures, in particular the presence of a superior sagittal sinus adequate to allow venous drainage.¹⁸⁰

Termination of pregnancy is commonly requested by parents of conjoined twins, especially in cases of thoracopagus with joined hearts. If expectant management is selected by the parents, fetal echocardiography and possibly magnetic resonance imaging should be used to delineate the exact extent of union and assist in neonatal surgical planning.¹⁸³ In addition, a careful search must be made to exclude other anomalies that commonly coexist with conjoined twins. In one series of 36 sets of prenatally diagnosed conjoined twin pregnancies from a

single center, 30 sets of twins were considered to have lethal conditions, because it was not feasible to separate them.¹⁸⁴ Pregnancy termination was performed in 12 cases, and the remaining 18 cases were delivered by cesarean section. Five sets of twins underwent surgical separation, and, in total, six children survived, giving an overall survival rate of only 8.3%. When expectant management is selected, cesarean section (usually through a classic incision) is the delivery method of choice to minimize maternal and fetal trauma. Vaginal delivery is reasonable only in cases of extreme prematurity, when fetal survival is not an issue and maternal trauma is deemed to be less than with a cesarean section.

The surgical separation of conjoined twins, although beyond the scope of this chapter, has been summarized in the surgical literature.¹⁸⁵ One of the largest series of conjoined twins managed at a single center was reported from South Africa, where 46 pairs of conjoined twins were seen over 40 years. In total, 17 sets underwent surgical separation, with 22 children (65%) surviving.¹⁸⁶ A survival rate of 85% was reported from another series of 10 sets of conjoined twins treated by surgical separation.¹⁸³ Tremendously complex moral and ethical issues occur in the neonatal period regarding appropriate surgical options in conjoined twins when only one twin has the potential of survival.¹⁸⁷

INTRAUTERINE DEMISE OF ONE FETUS

Intrauterine demise of one fetus in a multiple gestation during the first trimester is common and was originally thought to have no effect on the prognosis for the surviving fetus or fetuses. Such a "vanishing twin" has been reported to occur in 21% of twin pregnancies, with no obvious detrimental effect on the remaining fetus.¹⁸⁸ However, it now appears that intrauterine demise of one fetus in a monochorionic twin pregnancy at as early as 12 weeks' gestation can result in profound neurologic injury to the surviving fetus.¹⁸⁹ In a series of 642 surviving fetuses from vanishing twin pregnancies, an increased risk of being small for gestational age was noted, with the risk being inversely related to the gestational age at time of the demise of the co-twin.¹⁹⁰ Intrauterine demise of one fetus in the second or third trimester is rarer (2% to 5% of twin pregnancies; 14% to 17% of triplet pregnancies) and probably has far greater potential for significant morbidity to the surviving fetus or fetuses. After the death of one twin in a monochorionic gestation, approximately 15% of remaining fetuses also die, compared with approximately 3% of remaining fetuses in a dichorionic gestation.¹³⁹

The risk for significant neurologic morbidity is increased after intrauterine death of one fetus in a monochorionic, but not in a dichorionic, gestation. Abnormal neonatal cranial imaging is noted in 34% of monochorionic twin survivors compared with 16% of dichorionic twin survivors after single intrauterine fetal demise.¹³⁹ Serious neurologic abnormality, such as multicystic encephalomalacia leading to significant neurologic handicap, occurs in 26% of surviving fetuses after the death of a co-twin in a monochorionic gestation, compared with only 2% in dichorionic pregnancies.¹³⁹ Importantly, there does not appear to be an early gestational age cutoff before which neurologic morbidity can confidently be avoided in the case of monochorionic single fetal demise, with severe morbidity being reported after the death of a co-twin at as early as 12 weeks of gestation.¹⁸⁹ Additionally, in a recent meta-analysis, it was noted

that the risk for neurologic injury in monochorionic pregnancies is higher if single fetal demise occurs between 28 and 33 weeks, compared with demise at more than 34 weeks' gestation.¹³⁹

Neurologic injury in the surviving fetus probably occurs because of significant hypotension at the time of death of the co-twin. In a series of fetal blood sampling studies performed immediately before and after intrauterine death of one twin, primarily in the setting of evaluation of TTTS, no evidence of fetal anemia was noted before fetal death, but all surviving fetuses were found to be anemic after death of the co-twin.¹⁹¹ This study suggested that acute blood loss from the surviving fetus into the dead fetus occurs proximate to fetal demise, and that subsequent obstetric intervention may be too late to influence the outcome for the surviving twin.

Because the risk for neurologic morbidity is present from the moment one twin dies, expectant management may not be appropriate for monochorionic gestations in which one fetus appears to be in a premorbid condition. This 26% risk for profound neurologic injury after demise of a co-twin must be weighed against the risk for complications of prematurity with a premorbid fetus in a monochorionic multiple gestation. If fetal demise has already occurred, close surveillance of the surviving fetuses is recommended, although this may not prevent neurologic injury, which may already have occurred. Antenatal neurologic injury (e.g., multicystic encephalomalacia) may not be predictable by ultrasound or cardiotocographic monitoring. Delivery at 37 weeks, or after lung indices suggest maturity, is reasonable in such situations.

The maternal risks after intrauterine death of one fetus have probably been overestimated. The risk for maternal disseminated intravascular coagulopathy was once estimated at 25%, but in recent reviews of spontaneous fetal deaths and selective terminations in multiple gestations, no clinical cases of disseminated intravascular coagulopathy were noted.

SELECTIVE TERMINATION OF AN ANOMALOUS FETUS

When a multiple gestation is complicated by the discovery of a significant anomaly in one fetus, counseling of the parents and management decisions are difficult. Factors to incorporate into the decision-making analysis include the following:

- Severity of the anomaly
- Chorionicity of the pregnancy
- Effect of the anomalous fetus on the normal co-twin or co-triplets
- Ethical beliefs of the parents

Three main choices are available: expectant management, termination of the entire pregnancy, and selective termination of the anomalous fetus.

The phrase "selective termination" refers specifically to deliberate termination of an anomalous fetus in a multiple gestation, typically in the second trimester. Selective termination is performed to optimize outcome for the normal fetus and to prevent delivery of an abnormal fetus. This differs from "multifetal reduction," which refers to a nonspecific reduction in the number of fetuses present in a higher-order multiple gestation, almost always in the first trimester, to lower the risk for prematurity for the remaining fetuses.¹⁹²

Expectant management of a multiple gestation complicated by a single anomalous fetus leads to a 20% increase in the

risk for preterm delivery attributable to the presence of an anomalous fetus, a correspondingly lower birth weight, and a higher cesarean delivery rate than is reported in normal twin gestations.¹⁹³ In addition, expectant management of twins discordant for anencephaly is associated with an increased rate of intrauterine death of the normal co-twin in monochorionic gestations, as well as an increased rate of premature delivery, probably secondary to polyhydramnios, in both monochorionic and dichorionic gestations.¹⁹⁴ Amnioreduction to reduce the incidence of prematurity may be considered if significant polyhydramnios develops in twins discordant for anencephaly.

The method of selective termination depends on the chorionicity.¹⁹⁵ In dichorionic gestations, ultrasound-guided intracardiac injection of potassium chloride is the most common technique; in monochorionic gestations, complete ablation of the umbilical cord of the anomalous fetus is required to avoid death or neurologic injury in the normal fetus. When selective termination in a monochorionic gestation is considered in contemporary obstetric practice, ultrasound-guided cord occlusion, fetoscopic cord occlusion, or laser ablation is most commonly used.^{196,197}

These selective termination procedures for monochorionic gestations are significantly more complicated than the potassium chloride injection procedure used for dichorionic gestations. Few data are available to counsel patients about the safety and efficacy of these monochorionic techniques. Fetoscopic cord ligation may be associated with a 10% procedure failure rate and up to a 30% risk for pPROM.¹⁹⁶ In one series of 80 consecutive monochorionic cord coagulation procedures, the overall perinatal survival rate was 83%. There was a 10% rate of unexpected intrauterine fetal death, most of which was related to pPROM before viability.¹⁹⁸ Reports of mistaken fetoscopic ligation of the cord of the normal fetus have also been described.¹⁹⁹ Bipolar cautery and aortic thermocoagulation using single fetoscopic ports or single spinal needle access with sonographic guidance may be safer, but there are insufficient data to recommend an optimal choice for selective termination in monochorionic gestations.

Before performing the procedure, the physician must confirm that the targeted fetus has the anomaly in question. If the abnormal fetus has a structural anomaly, correct fetal identification is straightforward. If a chromosomal abnormality exists without structural markers and there is doubt about the position of the target fetus, repeated chromosomal analysis using rapid techniques (PCR or FISH) is required immediately before termination. The physician must be certain of the chorionicity of the pregnancy. Potassium chloride injection is contraindicated if dichorionicity cannot be confirmed with certainty.

Results of selective termination from a large multicenter study of 402 cases of twins, triplets, quadruplets, and quintuplets demonstrated a 100% technical success rate, with an 8% rate of pregnancy loss before 24 weeks (5% if the procedure was performed before 12 weeks, 9% if performed between 13 and 18 weeks, and 7% if performed between 19 and 24 weeks).²⁰⁰ All procedures used intracardiac potassium chloride injection. In addition, another 6% of patients delivered between 25 and 28 weeks, 8% between 29 and 32 weeks, and 17% between 33 and 36 weeks. There were no cases of laboratory or clinical coagulopathies or other complications in the mothers.²⁰⁰

A series of 200 cases of twins, triplets, and quadruplets at one center demonstrated increased risks for preterm delivery if the presenting twin was terminated, and an increased risk for

pregnancy loss among triplet pregnancies.²⁰¹ The overall rate of unintended pregnancy loss before 24 weeks' gestation at this center was 4%, but the rate increased to 11% for selective termination in triplet gestations. The pregnancy loss rate may increase to as high as 43% with the termination of more than one anomalous fetus in a pregnancy. There does not appear to be a significant difference in pregnancy loss rates at various gestational ages.^{67,201}

Selective termination of a single anomalous fetus in a multiple gestation therefore seems to be a reasonable management option. These data should be used to counsel patients according to the unique circumstances of each case.

MULTIFETAL PREGNANCY REDUCTION

The goal of first-trimester MFPR is to reduce the number of fetuses in a higher-order multiple gestation so as to decrease the chance of premature delivery and thereby to improve the outcome for the remaining fetuses. Higher-order multiple gestations are associated with a significant risk for delivery before viability. Fetuses that reach viability have a significant risk for birth before 28 weeks, when serious long-term neonatal morbidity is likely.

The natural history of triplet gestation suggests a 7% to 8% risk for delivery between 24 and 28 weeks' gestation.^{8,67,202} The natural history of quadruplet gestation suggests a 14% risk for delivery before 28 weeks' gestation.^{67,202} The risk for spontaneous loss of a triplet pregnancy before 24 weeks' gestation is approximately 11%.²⁰² The risk of losing the entire pregnancy before 20 or 24 weeks in quadruplet or higher gestations is unknown, because, in general, only pregnancies that successfully reach 20 weeks' gestation have been reported in the literature. In addition, the risks to maternal health of expectantly managed higher-order multiple gestations are significant. The risks just described should be carefully discussed with each couple during counseling before a management plan is selected in all cases of higher-order multiple gestations.

The technique of transabdominal MFPR, as typically performed between 10 and 13 weeks' gestation, is straightforward.²⁰³ Prophylactic antibiotics are generally not given, as they would typically not be used prior to CVS or amniocentesis procedures. Ultrasonography is used to map the location of all gestations precisely in the uterus, and measurements are taken of crown-rump length and nuchal translucency thickness. If an abnormality is found or these measurements are abnormal in a particular fetus, that fetus is selected for reduction. Otherwise, the fetus or fetuses that are technically easiest to access are chosen, with the exception of the fetus overlying the internal os, which is rarely selected. If a monochorionic pair of fetuses exists in a higher-order multiple gestation, that pair is usually selected for reduction.⁶⁷ Potassium chloride injection must not be used for MFPR in a single fetus of a monochorionic pair because of the risk for co-fetal demise or neurologic injury in the fetus that shares the placenta. Under continuous ultrasound guidance and with sterile technique, a 22-gauge needle is placed into the thorax of the targeted fetus, 2 to 3 mL of potassium chloride is injected, and asystole is observed for at least 3 minutes. The procedure is then repeated for additional fetuses as required, with a different needle, or occasionally with the same needle puncture. Another ultrasound study is performed 1 hour after the procedure and again 1 week later to confirm demise of the targeted fetuses and viability of the remaining fetuses.

Transvaginal MFPR is typically reserved for the rare situation in which target fetuses cannot be safely approached transabdominally, because this technique is associated with significantly higher loss rates when compared with the transabdominal approach (12% versus 5%).²⁰⁴

A current area of debate with MFPR is the role of prenatal diagnosis before or after the procedure. Options include amniocentesis for surviving fetuses 4 weeks after MFPR, and CVS for some or all fetuses before MFPR. Amniocentesis after MFPR does not appear to further increase the risk for pregnancy loss.¹⁸³ The main drawback of amniocentesis is that, if an abnormality is discovered, patients may have to consider yet another reduction procedure. The main goal of CVS before MFPR is to confirm normal karyotype in fetuses that are destined to be retained, rather than confirming abnormal karyotype in fetuses that are about to be reduced. By focusing the CVS procedure solely on those fetuses destined to be retained, the overall risk for pregnancy loss should be minimized. CVS has also been shown to be safe when it is performed before MFPR, with no obvious increase in the risk for pregnancy loss.²⁰⁶ Decisions regarding which placentas to sample are made on the basis of starting fetal number, finishing fetal number, likely target fetuses, and ease of access to particular placentas. Fetuses that are chromosomally abnormal or untested are preferentially selected for reduction.⁶⁷ For example, in a quadruplet pregnancy to be reduced to twins, it is reasonable to perform CVS only for the two fetuses being retained; if these fetuses are confirmed to be chromosomally normal, the remaining two fetuses can then be reduced.

The overall pregnancy loss rate before 24 weeks for transabdominal MFPR procedures has fallen from 8% to 5%, reflecting a procedure-related learning curve.²⁰⁴ The relative contribution to the overall loss rate of procedure-related loss, as opposed to the spontaneous loss typical of multiple gestations, is uncertain. International collaborative MFPR data from more than 3500 pregnancies documented a loss rate before 24 weeks that was directly related to both the starting and the finishing number of fetuses.²⁰⁴ This loss rate decreased from 22% to 15%, 12%, 6%, and 6%, respectively, with six, five, four, three, and two fetuses present at the start of the procedure. In addition, the risk for very premature delivery at 25 to 28 weeks decreased from 6% to 6%, 4%, 3%, and 1%, respectively. The optimal finishing number of fetuses appeared to be twins, with a loss rate before 24 weeks of 9%, compared with 20% for triplets. Reflecting the importance of the learning curve, these authors reported that the pregnancy loss rates for MFPR procedures performed most recently (1995 to 1998) were 4% for triplets reduced to twins and 7% for quadruplets reduced to twins.²⁰⁴ A single-center series of MFPR described 1000 cases, with a pregnancy loss rate of 5% before 24 weeks' gestation.²⁰⁷ This group subsequently updated their experience from 2000 consecutive MFPR cases and noted an increase in the number of patients choosing to reduce to a singleton.²⁰⁸ These authors also noted a significant increase in the number of patients undergoing CVS before the MFPR procedure (1.5% in the first 1000 cases, and 44% in the second 1000 cases). The documented safety of CVS, as well as the increasing desire of patients to be more selective about which fetuses to reduce and to be confident of not leaving viable fetuses with chromosomal abnormalities, appear to underlie these changing trends.²⁰⁸

For fetuses that reach viability after MFPR, 85% to 90% can be expected to be born at 32 weeks' gestation or later, with only

TABLE 38-4 Meta-Analysis of Studies Comparing Outcome of Expectantly Managed Triplet Gestations with That of Triplets Reduced to Twins

Management	Number of Pregnancies	Pregnancy Loss (<24 wk)	Preterm Delivery (24-31 wk)
Expectant management	411	18/411 (4%)	105/393 (27%)
Reduction to twins	482	39/482 (8%)	46/443 (10%)

From Papageorgiou AT, Avgidou K, Bakoulas V, et al: Risk of miscarriage and early preterm birth in trichorionic triplet pregnancies with embryo reduction versus expectant management: new data and systematic review. *Hum Reprod* 21:1912, 2006.

3% to 5% born between 25 and 28 weeks.^{203,209} It is now clear that MFPR is associated with better outcomes for patients with quadruplet and higher gestations. When counseling such patients, the option of MFPR should be presented, and patients should be informed that their best chance of delivering healthy, surviving infants is by undergoing MFPR. Debate still exists, however, on the role of MFPR for triplet gestation. The FIGO Committee for the Ethical Aspects of Human Reproduction and Women's Health has recommended that for triplet pregnancies and higher "it may be considered ethically preferable to reduce the number of fetuses rather than to do nothing."²¹⁰ The American Society of Reproductive Medicine has taken a more neutral view on the role of MFPR, stating that "MFPR appears to be associated with a reduced risk for prematurity, although the true benefit of this intervention is difficult to enumerate owing to potential bias in interpreting the data."²¹¹

Table 38-4 summarizes studies of expectantly managed triplet gestations compared with outcome after reduction of triplets to twins, and it compares outcome to nonreduced twin pregnancies.¹¹ Reduction of triplets to twins yields a significant prolongation of gestation, but at the expense of an increased rate of earlier miscarriage. From a total of 893 triplet pregnancies reviewed, 411 were expectantly managed and 482 underwent MFPR to twins. The rate of miscarriage before 24 weeks was 4% in the expectantly managed group but 8% in the MFPR group. This worse outcome with MFPR was offset by a reduction in the rate of preterm delivery between 24 and 32 weeks, from 27% in the expectantly managed group to 10% in the MFPR group.¹¹ Maternal complications may also be decreased when triplets are reduced to twins; one study reported a 22% incidence of gestational diabetes among non-reduced triplet pregnancies, compared with 6% among triplets reduced to twins.²¹²

The data in Table 38-4 may be a little misleading, however, particularly with reference to perinatal mortality. MFPR involves the obligate death of one fetus in a triplet gestation, so the overall fetal mortality rate for triplets reduced to twins must be at least 333 per 1000. This may not be clear to families if only perinatal mortality rates focusing on survivors of the MFPR procedure are presented. No long-term outcome data for the survivors of reduced triplet pregnancies are available. We believe

the available information makes a convincing argument to include MFPR in the counseling of all patients with triplet gestations. For an individual woman with triplets to select MFPR, she must decide whether the obligate death of one fetus, together with an increased risk for procedure-related pregnancy loss, justifies a 50% reduction in the risk for delivery before 32 weeks' gestation. This decision should be individualized in all cases.

After the MFPR procedure, women should be observed closely for the usual complications of multiple gestation. Surveillance for appropriate fetal growth is recommended, because there may be an increased risk for intrauterine growth restriction after MFPR.²¹³ In addition, the psychological implications for mothers who have undergone MFPR can be significant. Seventy percent of these women demonstrate grief reactions, and 84% describe the procedure as very stressful.²¹⁴

PREVENTION OF HIGHER-ORDER MULTIFETAL GESTATION

In view of the complex issues involved, MFPR should not be considered a simple solution to the problems of higher-order multiple gestations in this era of assisted reproductive technologies.²⁰³ Instead, attention should be focused on prevention of the problem, which may be alleviated at least in part through careful supervision of assisted reproductive practices. The American College of Obstetricians and Gynecologists recommends that it is preferable to terminate an ovulation induction cycle if a higher-order multiple gestation appears to be likely, and to limit the number of embryos transferred in an in vitro fertilization, rather than to allow a situation to develop in which patients have to consider the option of MFPR.²¹⁵ The ethical challenges associated with MFPR decision making are complex and are different from those concerning elective abortion. In the latter situation, the patient's intent is to avoid the birth of a child, whereas in the former, the opposite scenario exists: the patient is considering MFPR precisely because she wants to maximize her chance of having a healthy child.²¹⁵

**Disorders at the
Maternal-Fetal Interface**

Pathogenesis of Spontaneous Preterm Birth

CATALIN S. BUHIMSCHI, MD | JANE E. NORMAN, MD

Preterm Birth Syndrome: New Phenotypic Classification

Preterm birth (PTB) occurs between fetal viability and 37 completed weeks of gestation.¹ The definition of *viability* is controversial because of the increasing frequency of survival at progressively lower gestational ages. Most countries define it as a lower limit of 20 to 22 weeks, but this varies, preventing straightforward comparison of reported rates of neonatal mortality and morbidity.² A recent influential report has suggested that a less arbitrary definition of PTB would include all births (including live births, stillbirths, and pregnancy terminations) occurring from 16 weeks 0 days to 38 weeks 6 days (i.e., 112 to 272 days).³ The rationale for the latter limit is that births between 37 and 39 weeks are associated with greater short- and long-term morbidity than those after 39 weeks,⁴ whereas the rationale for the early limit is that the pathologies inducing spontaneous abortion between 16 and 20 weeks are similar to those inducing PTB at a later gestation. Where accurate recording of gestational age is not possible—for example, in resource-poor countries—a birth weight of 500 g has historically been used to define the lower limit of viability. However, this approach leads to inaccuracies, because viable neonates born after 24 weeks may be affected by intrauterine growth restriction (IUGR), and some pre-viable infants may weigh more than 500 g.

Worldwide, approximately 1.1 million neonates die from prematurity-related complications.⁵ Rates of PTB vary around the world, with the United States having among the highest incidences.⁶ In 2010, the PTB rate in the United States was around 12.0%, representing a progressive decline over the past 4 years.⁷ Its decline from 2008 to 2010 was most noticeable among infants born at 34 to 36 weeks (late preterm). However, the percentage of infants born at less than 34 weeks also dropped, from 3.56% to 3.50%. A reduction in PTB rates was seen for most age, race, and ethnic groupings. By contrast, the birth rate for infants having low birth weight (LBW; <2500 g) was unchanged from 2008 to 2010, at 8.15%. Regrettably, the percentage of newborns delivered at very low birth weight (1500 g) declined only minimally, from 1.46% in 2008 to 1.45% in 2010. This is significant, as very-low-birth-weight premature newborns are at the highest risk for early death or disability.⁸

Traditional classification systems categorize PTBs as either spontaneous or indicated. Spontaneous preterm labor can occur either with intact membranes or with prelabor (premature) rupture of the fetal membranes (PROM). Indicated PTBs

can result from induction of preterm labor or from preterm cesarean delivery for maternal or fetal indications (e.g., pre-eclampsia, IUGR).⁹ The Global Alliance to Prevent Prematurity and Stillbirth (GAPPS) has recently proposed an alternative classification system that is likely to be very influential.¹⁰ Under this paradigm, PTB is categorized according to the clinical phenotype consisting of (1) one or more conditions of the mother, placenta, or fetus; (2) the presence or absence of signs of parturition; and (3) the pathway to delivery (spontaneous or caregiver initiated) (Fig. 39-1). There is some overlap between the GAPPS classification system and the traditional criteria—for example, *indicated* preterm delivery in the previous system corresponds to *caregiver-initiated* parturition in the new system, and it normally occurs in the absence of parturition. In this chapter, we address PTB under the new classification system, and we describe it according to the maternal, placental, and fetal phenotype.¹⁰ Under the new classification system, PTB rates include infants born between 37 + 0 and 38 + 6 weeks of pregnancy, and thus these rates are about 28% higher than previously. Unless otherwise indicated, it is assumed that for the conditions described in this chapter, there is evidence of parturition, and the pathway to delivery is spontaneous. The mechanisms of disease responsible for indicated preterm deliveries with caregiver-initiated parturition are discussed in other chapters. About 75% all PTBs have a spontaneous pathway to delivery: About 45% (23.2% to 64.1%) are from preterm labor with intact membranes, and about 30% (7.1% to 51.2%) are from preterm labor after PROM.¹¹⁻¹⁴

Mechanisms of Spontaneous Preterm Birth

THE COMMON PATHWAY

Term and preterm labor share common pathways, which include increased uterine contractility, cervical ripening, and membrane rupture leading to fetal prematurity and damage.¹⁵ However, whereas term birth results from physiologic activation of these common pathways, PTB results from a disease process (or pathologic activation) (Fig. 39-2) that activates one or more of the components of the common pathway via similar or alternative mechanisms.^{16,17}

The *common pathway of parturition* includes anatomic, biochemical, immunologic, endocrinologic, and clinical changes.¹⁶ Although the anatomic and clinical events have been studied in detail, the biochemical, immunologic, and endocrine events are

still incompletely understood. In the peripheral circulation, an increase in unbound corticotropin-releasing hormone and, in the uterus, increased nuclear factor kappa B (NF- κ B) activity (associated with functional progesterone withdrawal, prostaglandin production, and leukocytic influx) are consistently demonstrated in association with parturition.¹⁸ There is continuing debate about which (if any) of these events is the master regulator that controls the timing of parturition, and which (if any) is the *sine qua non*, without which parturition cannot occur. Evidence for each of these processes is briefly reviewed below.

Prostaglandins as Key Activators of the Common Pathway of Parturition

Prostaglandins are viewed as crucial mediators for the onset of labor,¹⁹⁻³⁴ because they can induce myometrial contractility,^{19,23,32,34} promote proteolysis of cervical and fetal membrane extracellular matrices to cause cervical ripening and fetal membrane rupture,^{21,22,26,27,31} and stimulate decidual/membrane activation.³⁵ Evidence of a role for prostaglandins in the initiation of human parturition includes the following: (1) Administration of prostaglandins induces termination of pregnancy^{30,36-46}; (2) indomethacin or aspirin therapy delays spontaneous onset of parturition in animals⁴⁷⁻⁵⁰; (3) concentrations of prostaglandins in plasma and amniotic fluid increase during labor⁵¹⁻⁵⁹; (4) intra-amniotic injection of the prostaglandin precursor arachidonic acid induces abortion²⁸; (5) expression of myometrial prostaglandin receptors increases in labor^{60,61}; and (6) labor is associated with increased expression of prostaglandin endoperoxide synthase 2 (PTGS-2) messenger RNA and increased activity of this enzyme in the amnion (a rate-limiting step in the production of prostaglandins). This increase in amniotic PTGS-2 activity is accompanied by decreased expression of the prostaglandin-metabolizing enzyme 15-hydroxyprostaglandin dehydrogenase (PGDH) in the chorion. This would allow prostaglandins produced in the amnion to traverse the chorion and

decidua to reach the myometrium, where they can stimulate smooth muscle contractions.⁶² The increase in PTGS-2 activity is induced by an increase in NF- κ B activity in both amnion⁶³ and myometrium.⁶⁴ The importance of NF- κ B in the induction of PTB is further underscored by the demonstration that an NF- κ B inhibitor can reduce lipopolysaccharide (LPS)-induced PTB in a mouse model.⁶⁵

NF- κ B and prostaglandins activate common pathways of parturition by the following biochemical mechanisms: (1) Prostaglandins directly promote uterine contractions by increasing sarcoplasmic and transmembrane calcium fluxes and through increased transcription of oxytocin receptors, connexin-43 (gap junctions), and the prostaglandin E₂ (PGE₂) receptors EP₁ through EP₄ (although EP₃ appears to be the predominant receptor subtype⁶⁶) and the PGF_{2 α} receptor FP⁶⁷⁻⁷⁰; (2) prostaglandins induce synthesis of matrix metalloproteinases (MMPs) by fetal membranes and cells in the uterine cervix to promote membrane rupture and cervical ripening^{71,72}; (3) PGE₂ and PGF_{2 α} increase the ratio of expression of the progesterone receptor (PR) isoforms PR-A and PR-B to induce functional progesterone withdrawal⁷³; and (4) NF- κ B activation induces activation of a cassette of inflammatory genes, which may also induce a functional progesterone withdrawal.⁶⁴ Figure 39-3 describes the molecular mechanisms implicated in the common pathway of parturition.

INFLAMMATION, STRESS, AND TERM AND PRETERM PARTURITION

Inflammation is a highly orchestrated process designed to ensure survival of the host.⁷⁴ The inflammatory process has a physiologic component intended to ensure maintenance of homeostasis. Increasing evidence suggests that parturition at term is such a process. Liggins first proposed that cervical ripening was an inflammatory event, and this hypothesis is supported by data showing a profound leukocytic (neutrophilic

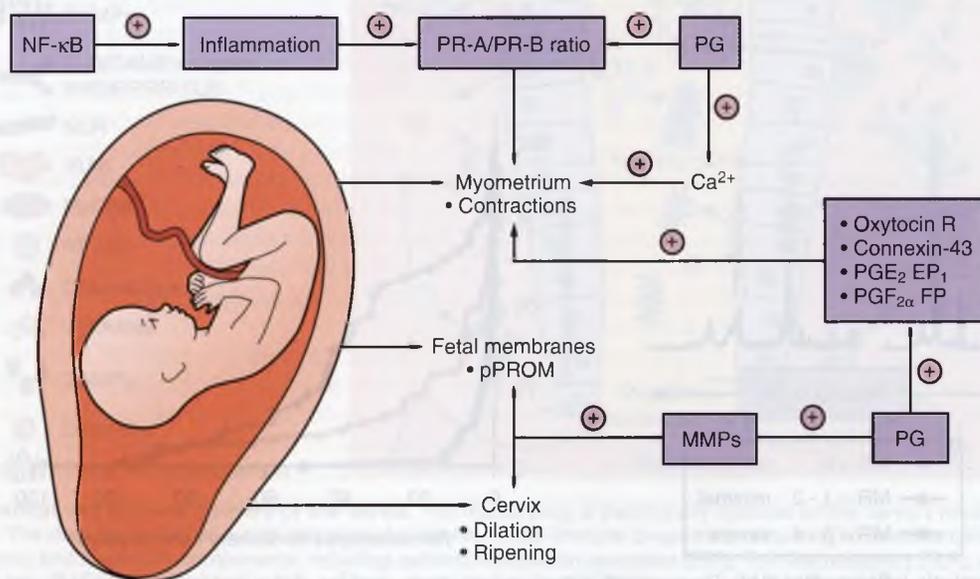

Figure 39-3 Prostaglandins as key activators of the common pathway of parturition. and macrophage) invasion into the cervix during normal parturition.⁷⁵ Similar processes appear to operate in the myometrium,⁷⁶ where labor is accompanied by increased expression of cell adhesion molecules, chemotactic agents such as interleukin (IL)-8, and proinflammatory cytokines,^{75,77} as well as by leukocyte activation in peripheral blood.⁷⁸ Whether these events are crucial to the initiation of labor or merely an epiphenomenon remains uncertain. Although these events may be physiologic at term, they can be activated pathologically before term, with major damaging consequences. For example, proinflammatory agents such as LPS and IL-1 β can stimulate preterm labor in animal models, and preterm labor in women is often accompanied by infection or inflammation, so a causal role for inflammation in the pathophysiology of preterm labor remains likely.

Complex biochemical and neurohormonal interactions among maternal, fetal, and placental compartments are required during normal term parturition in humans.⁷⁹ In term labor, these processes reflect the normal maturation of the fetal hypothalamic-pituitary-adrenal-placental axis. A series of physiologic adaptive responses in each of these compartments can also be triggered by stress subsequent to malnutrition, infection, ischemia, vascular damage, and psychosocial factors.⁸⁰ However, the nature of the stimulus whereby stress induces premature activation of the mechanisms involved in PTB remains unknown. In early pregnancy, the villous trophoblast produces a variety of growth factors, cytokines, neuropeptides, and hormones. There is substantial evidence that the placenta plays a central role in controlling the length of gestation and the onset of parturition in humans.⁸¹ Placental histologic changes consistent with infection and ischemia-induced fetal stress are far more common in patients with spontaneous preterm delivery than in controls with idiopathic preterm and term birth.^{82,83} Maternal-fetal trafficking of numerous hormones is highly dependent on various enzymatic pathways. The 11 β -hydroxysteroid dehydrogenase (11 β -HSD) regulates placental transfer of cortisol, which is a glucocorticosteroid with a key role in the activation of the hypothalamic-pituitary-adrenal (HPA) axis. Interestingly, hyperactivity of the maternal HPA axis

has been involved in the occurrence of maternal depression.⁸⁴ Carriers of a polymorphism in the gene encoding for the 11 β -HSD type-1 have a higher level of HPA activity and susceptibility to depression.⁸⁵ Collectively, these and other data⁸⁶ appear to indicate a genetic predisposition toward maternal mood disorders and may implicate various placental polymorphisms in the occurrence of maternal mood disorders linked to PTB.⁸⁷

Preterm Birth Resulting from Intra-amniotic Infection

Preterm delivery is often associated with intra-amniotic infection. Infection may not be obvious (see Clinical Chorioamnionitis, later). That intrauterine infection may induce PTB is suggested by at least three lines of evidence. First and most compellingly, intrauterine infection or systemic administration of microbial products (e.g., bacterial endotoxin) to pregnant animals results in spontaneous preterm labor and birth.⁸⁸⁻¹⁰⁰ Second, subclinical intrauterine infections are consistently associated with preterm labor and PTB in humans.^{101,102} Third, pregnant women with intra-amniotic infection¹⁰³⁻¹⁰⁵ or intra-amniotic inflammation (defined as an elevation of amniotic fluid concentrations of proinflammatory cytokines,^{106,107} matrix-degrading enzymes,¹⁰⁸ and a specific set of antimicrobial peptides [e.g., defensins, calgranulins¹⁰⁹] in the mid-trimester) are at increased risk for spontaneous PTB later in that pregnancy (Fig. 39-4).¹¹⁰

Culture-based data suggest that a large number of intra-amniotic infections are polymicrobial.^{110,111} Based on microbial cultures alone, the most common microorganisms identified in the fetal membranes and amniotic fluid of patients with infection-associated PTB are *Ureaplasma urealyticum*, *Mycoplasma hominis*, *Gardnerella vaginalis*, *Streptococcus* group B (GBS), *Bacteroides* species, and *Escherichia coli*.^{110,112-114} *Listeria monocytogenes* is a much rarer participant.¹¹⁵ However, it is increasingly clear that culture techniques are extremely limited as a diagnostic test for infection in the amniotic cavity and elsewhere.¹¹⁶ Cultures underestimate the frequency with which microbial pathogens are involved in the process. Metagenomics, which uses genomics techniques to study communities of

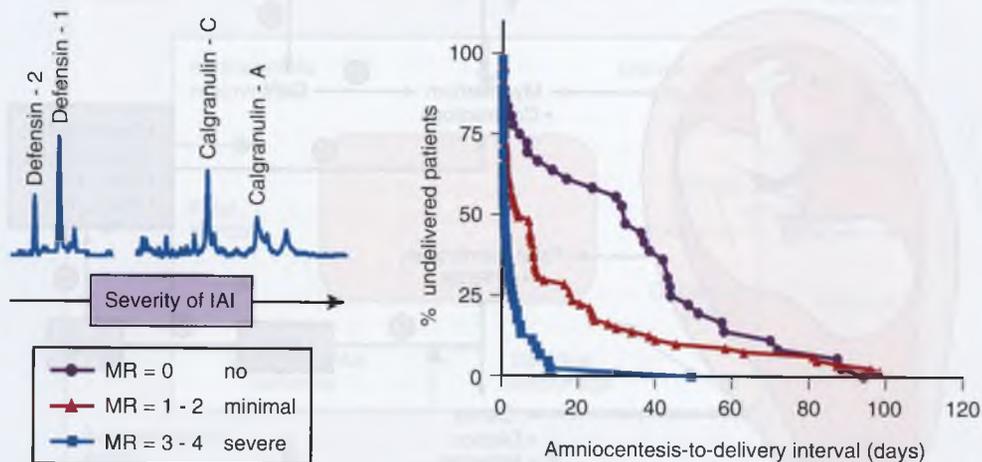

Figure 39-4 Intra-amniotic inflammation (IAI). Representative mass spectrometry profiles of the amniotic fluid based on the severity of inflammation (MR = 0 ["no" inflammation]; MR = 1 to 2 ["minimal" inflammation]; MR = 3 to 4 ["severe" inflammation]). The proteomic mass restricted (MR) score is the result of the presence in the amniotic fluid of four protein biomarkers: neutrophil defensins 2 and 1, and calgranulins C and A. Women with severe inflammation (3 to 4 biomarkers present in the amniotic fluid) had shorter amniocentesis-to-delivery intervals (i.e., were less likely to carry the pregnancy to term) than women with MR = 0 (absent biomarkers) or MR = 1 to 2 (1 to 2 biomarkers present).

microbial organisms without the need to isolate and culture them, has shown that many environmental and human microbial species cannot be cultured.^{117,118} Reasons for this include the low prevalence of these organisms, their slow growth or resistance to being cultured in conventional media, and their specialized growth requirements.¹¹⁹ The cornerstone of genomics-based detection methods are sequencing of full-length or variable regions of the bacterial 16S ribosomal RNA (16S-rRNA) gene.¹²⁰ This gene is characterized by a high degree of conservation and a clustering of the variable regions of the 16S-rRNA gene into discrete taxonomic units; the latter allows an in-depth characterization of species richness and the diversity of complex microbial communities.¹²¹ Metagenomic studies of amniotic fluid show that the bacterial diversity of the amniotic fluid microbiome is rich and is characterized by the presence of “uncultivated” and difficult-to-cultivate species, such as *Sneathia*, *Fusobacterium nucleatum*, *Bergeyella*, Clostridiales, *Peptostreptococcus*, and *Bacteroides*.^{122,123}

Currently, the Human Microbiome Project is characterizing the microbial communities found at several different sites on the human body (see website commonfund.nih.gov/hmp). Recent studies on the vaginal microbiome in women of reproductive age have revealed the complexity of vaginal flora, including major differences between ethnic groups.¹²⁴

Comprehensive metagenomic studies of the amniotic fluid microbiome in health and disease will surely emerge in the next few years.

The mechanism by which microorganisms gain access to the amniotic cavity is incompletely understood. Because most intra-amniotic bacteria are genital tract microorganisms, and the amniotic fluid is normally sterile, the current paradigm of intrauterine infection implies that bacteria most often originate from the lower genital tract and invade the pregnant uterus via an ascending mechanism.¹²⁵ Once the mechanical barrier and the complex innate immune barrier of the cervix are bypassed (Fig. 39-5), microorganisms infect the decidua and penetrate the fetal membranes to invade the amniotic fluid.^{126,127} Finally, microorganisms gain access to and infect the fetus.¹²⁶ This biologically plausible conceptual framework is based on studies that demonstrated that (1) microorganisms frequently implicated in intra-amniotic infection (e.g., GBS, *Mycoplasma*, *E. coli*) are common constituents of the vaginal microbiome¹²⁸ and cohabitants of the amniochorionic space¹²⁹; (2) the presence of *Ureaplasma* and *Mycoplasma* in the amniochorion incites polymorphonuclear tissue infiltration and a higher degree of histologic chorioamnionitis in pregnancies complicated by PTB¹³⁰; (3) in vitro, GBS and *E. coli* have the capacity to attach to the chorioamniotic membranes¹³¹; (4) in animal models of

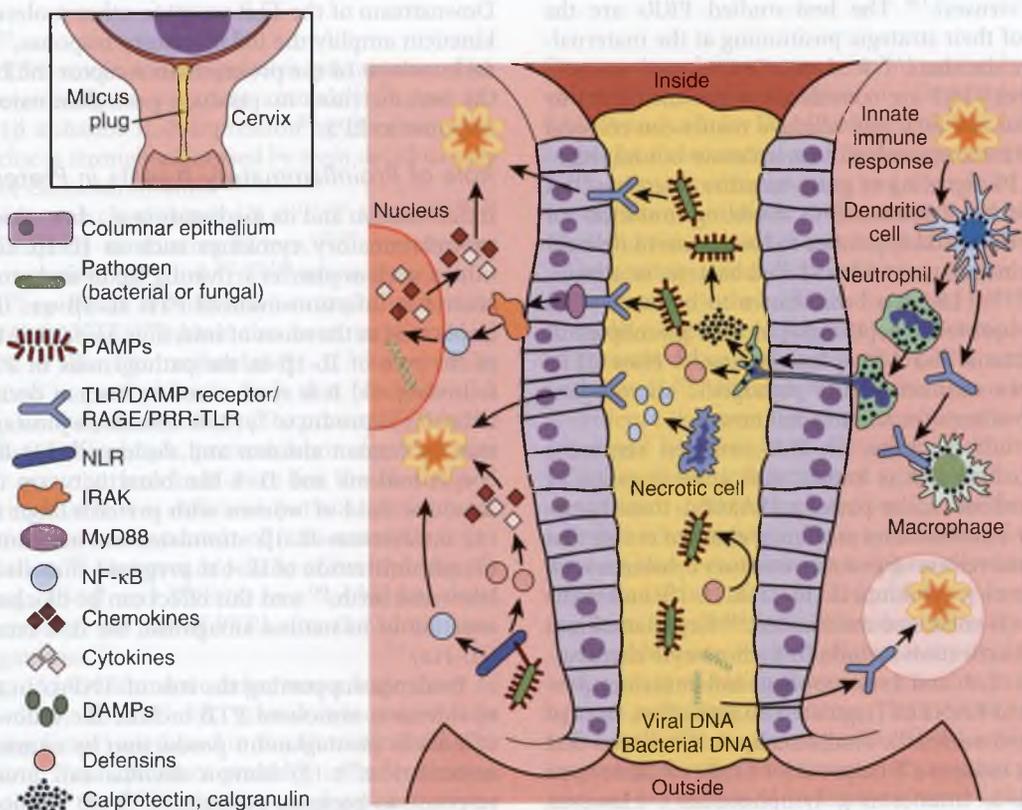

Figure 39-5 Mechanical and immune barriers of the cervix. The mucus plug is traditionally considered the cervix's mechanical barrier against ascending infection. The data suggest that the mucus plug also carries innate immune properties, consisting of immune cells (dendritic cells, neutrophils, macrophages), and molecular components including pattern recognition receptors (PRR); Toll-like receptors (TLR); receptor for advanced glycation end products (RAGE); nucleotide-binding, oligomerization domain (NOD)-like receptor (NLR); cytokines and chemokines; damage-associated molecular patterns (DAMPs); pathogen-associated molecular patterns (PAMPs); and antimicrobial peptides (defensins, calgranulins). The microbe-specific molecules that are recognized by a given PRR (NOD, TLR) trigger an innate immune response via specific signaling pathways that include tumor necrosis factor- α (TNF- α); myeloid differentiation primary response gene (88) protein (MyD88); and interleukin (IL)-1 receptor-associated kinases (IRAK).

infection-induced PTB, transcervical and choriodecidual inoculation of GBS is followed by transmigration of bacteria from the choriodecidual space to the amniotic fluid cavity, a graded amniotic-fluid leukocyte infiltration response, and levels of proinflammatory cytokines (tumor necrosis factor- α [TNF- α], IL-6, IL-1 β), prostaglandins (PGE₂, PGF_{2 α}), and uterine activity.^{132,133}

A secondary route of intra-amniotic infection is probably hematogenous transplacental seeding of the fetus, with the infectious organisms, in particular *Haemophilus influenzae* or *F. nucleatum*, originating from other parts of the body including the mouth.^{134,135} Iatrogenic infections during invasive procedures such as chorionic villous sampling, amniocentesis, and cordocentesis are also possible.¹³⁶ Retrograde microbial seeding of the amniotic fluid through the fallopian tubes or colonization of the uterine endometrium before implantation has also been proposed.¹²⁶ Compelling evidence in support of these pathways remains to be provided.

Emerging evidence suggests that microorganisms are "sensed" by the innate components of the immune system,¹³⁷ leading to a cascade of events that culminate in PTB. These sensing components include soluble pattern-recognition receptors (PRRs), lectin, and C-reactive protein. The transmembrane PRRs include scavenger receptors, C-type lectins, and Toll-like receptors (TLRs). Intracellular PRRs include NOD1 and NOD2, retinoic acid–induced gene type 1, and melanoma differentiation-associated protein 5, which mediate recognition of intracellular pathogens (e.g., viruses).¹³⁸ The best-studied PRRs are the TLRs.¹³⁷ Because of their strategic positioning at the maternal-fetal interface (the decidua),¹³⁹ fetal membranes, and myometrium,¹⁴⁰ TLR4 and TLR2 are considered major mediators by which the maternal and fetal reproductive tissues can respond to infection. TLR4 is recognized as the membrane-bound receptor that triggers LPS signaling of gram-negative microbes.¹⁴¹ A strain of mice bearing a spontaneous disabling mutation for TLR4 is less likely than wild-type mice to have preterm delivery after intrauterine inoculation of heat-killed bacteria or administration of LPS.^{98,142} TLR2 has been shown to be involved in recognition of lipoproteins, peptidoglycan, and glycolipids of gram-positive bacteria and Mycoplastmataceae.¹⁴³ How TLRs distinguish between commensal and pathogenic microorganisms in vaginal or other sites remains unknown.

Although the full spectrum of TLR-mediated responses remains to be elucidated, it is known that, once engaged by pathogen-associated molecular patterns (PAMPs), these bacterial sensors trigger a downstream molecular chain of events that lead to synthesis and release of proinflammatory cytokines such as TNF- α ; interferon- γ ; cytokines IL-12, IL-6, IL-1 β ; and many others via an NF- κ B–mediated mechanism.¹⁴⁴ Key chemokines secreted after TLR activation include IL-8; monocyte chemoattractant proteins 1, 2, 3, and 4; macrophage inflammatory proteins 1 α and 1 β ; and RANTES (regulated on activation, normal T cell expressed and secreted). Traditionally, it is believed that activation of TLRs induces a T helper cell 1 (T_H1) cytokine-type response (i.e., IL-2, interferon- γ , lymphotoxins). However, using genetically engineered animal models and a variety of in vitro cell culture systems, Pulendran and colleagues showed that TLR4 engagement can also trigger a T_H2 cytokine reaction consistent with the release of IL-4, IL-5, IL-6, and the anti-inflammatory cytokine IL-10, depending on bacterial type.¹⁴⁵ The significance of this observation during human pregnancy remains to be clarified, but these results underline the concept

that the balance among proinflammatory and anti-inflammatory cytokine responses can dictate the intensity and possible resolution of an infectious process.

The biologic activity of the TLRs depends not only on the presence of bacterial pathogen-associated molecular patterns but on a palette of intracellular signaling adaptors (e.g., MyD88) and co-receptor molecules (e.g., CD14) that associate with TLRs in complex supramolecular arrangements.¹⁴⁶ Equally important is that TLR signaling can be elicited by endogenous damage-associated molecular patterns (DAMPs).¹⁴⁷ Like cytokines, DAMPs (i.e., high-mobility group box-1 [HMGB1, or amphoterin], S100 β proteins) are endogenous proinflammatory and pro-oxidative stress molecules. Acting through TLR2, TLR4, and the receptor for advanced glycation end products (RAGE), DAMPs recruit inflammatory cells, which in turn amplify innate immune responses and enhance levels of cytokine activation.¹⁴⁷ It was reported that the RAGE-DAMP system is present in women with PTB and intra-amniotic infection.¹⁴⁸ Activation of the RAGE-DAMP system correlates with the degree of inflammation and oxidative stress damage in amnion epithelial, decidual, and extravillous trophoblast cells (Fig. 39-6).¹⁴⁹ PAMPs and DAMPs may continue to keep active the processes that lead to fetal cellular damage.

Last, the roles of soluble receptor modulators (soluble TLR2, soluble TNF receptor-1, soluble IL-6 receptor, soluble glycoprotein (gp)130, and soluble RAGE) in fine-tuning human TLR-mediated signaling have just begun to be elucidated.¹⁵⁰⁻¹⁵³ Downstream of the TLR receptor, other molecules such as prokineticin amplify the inflammatory response,¹⁵⁴ so that lentiviral knockout of the prokineticin receptor inhibits the ability of the myometrium to produce proinflammatory cytokines in response to LPS.¹⁵⁵

Role of Proinflammatory Agents in Preterm Birth

Inflammation and its mediators (e.g., chemokines such as IL-8; proinflammatory cytokines such as IL-1 β and TNF- α ; and others, such as platelet activating factor and prostaglandins) are central to infection-induced PTB. IL-1 β was the first cytokine implicated in the onset of infection-associated PTB.¹⁵⁶ Evidence of the role of IL-1 β in the pathogenesis of PTB includes the following: (1) It is synthesized by human decidua in response to bacterial products¹⁵⁷; (2) it stimulates prostaglandin production by human amnion and decidua¹⁵⁸; (3) IL-1 α and IL-1 β concentrations and IL-1-like bioactivity are increased in the amniotic fluid of women with preterm labor and infection¹⁵⁹; (4) intravenous IL-1 β stimulates uterine contractions¹⁶⁰; and (5) administration of IL-1 to pregnant animals induces preterm labor and birth,¹⁶¹ and this effect can be blocked by the administration of its natural antagonist, the IL-1 receptor antagonist (IL-1ra).¹⁶²

Evidence supporting the role of TNF- α in the mechanisms of infection-associated PTB include the following: (1) TNF- α stimulates prostaglandin production by amnion, decidua, and myometrium⁹⁵; (2) human decidua can produce TNF- α in response to bacterial products^{163,164}; (3) amniotic fluid TNF- α bioactivity and immunoreactive concentrations are elevated in women with preterm labor and intra-amniotic infection¹⁶⁵; (4) in women with preterm PROM and intra-amniotic infection, TNF- α concentrations are higher in the presence of labor¹⁶⁵; (5) TNF- α can stimulate the production of MMPs,^{166,167} which have been implicated in membrane rupture¹⁶⁸⁻¹⁷⁰; (6) application of TNF- α to the cervix induces changes that resemble cervical

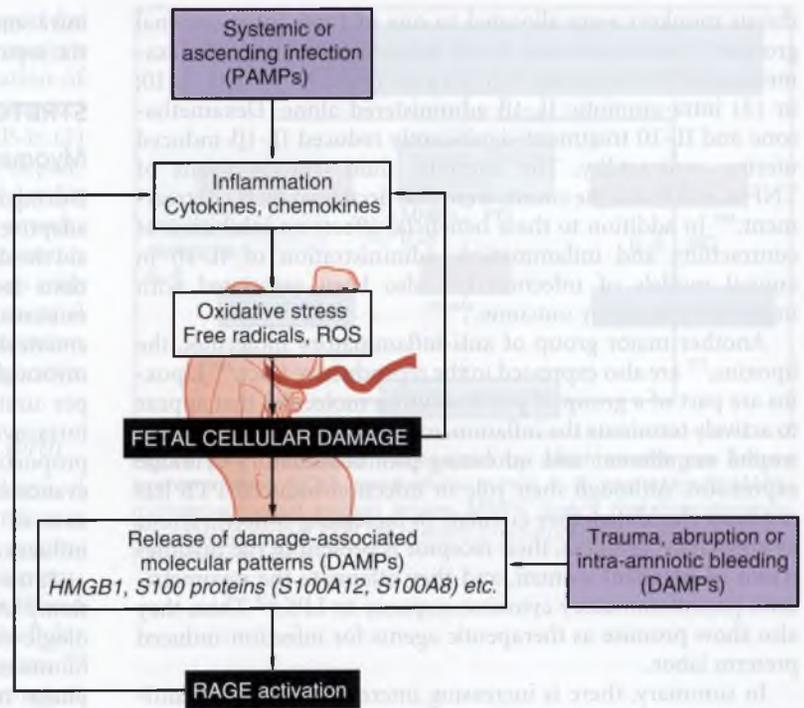

Figure 39-6 Working model for the potential role of the RAGE-DAMP system leading to inflammation, oxidative stress, and fetal damage. DAMPs, damage-associated molecular patterns; HMGB1, high-mobility group box-1; PAMPs, pathogen-associated molecular patterns; RAGE, receptor for advanced glycation end products; ROS, reactive oxygen species; S100A8, calgranulin A; S100A12, calgranulin C.

ripening¹⁷¹; (7) TNF- α can induce preterm parturition when administered systemically to pregnant animals^{172,173}; and (8) TNF- α and IL-1 β enhance IL-8 expression by decidual cells, and this chemokine is strongly expressed by term decidual cells in the presence of chorioamnionitis.¹⁷⁴

Other cytokines and chemokines (IL-6,¹⁷⁵⁻¹⁸⁰ IL-10,^{160,181,182} IL-16,¹⁸³ IL-18,¹⁸⁴ colony-stimulating factors,¹⁸⁵⁻¹⁸⁷ macrophage migration inhibitory factor,¹⁸⁸ IL-8,^{187,189-193} monocyte chemoattractant protein-1,¹⁹⁴ epithelial cell-derived neutrophil-activating peptide-78,¹⁹⁵ and RANTES¹⁹⁶) have also been implicated in infection-induced PTB. The redundancy of the cytokine network implicated in parturition is such that blockade of a single cytokine is unlikely to be sufficient to prevent PTB in the setting of infection. For example, preterm labor after exposure to infection can occur in knockout mice for the IL-1 type I receptor, suggesting that IL-1 is sufficient, but not necessary, for the onset of parturition in the context of intra-amniotic infection or inflammation.¹⁹⁷ However, blockade of multiple signaling pathways (e.g., IL-1 β and TNF- α) in a double-knockout mouse model decreased the rate of PTBs after the administration of microorganisms.¹⁷³

In the setting of intra-amniotic infection, a large array of cytokines (e.g., IL-6, IL-8, IL-1 β , granulocyte-macrophage colony-stimulating factor) are found in the amniotic fluid. The sources of amniotic fluid cytokines probably include decidua, fetal membranes, and the fetus. However, independent of the source, amniotic fluid IL-6 and many other cytokines induce recruitment of fetal neutrophils.¹⁹⁸ Cytokines also induce degranulation of neutrophilic granulocytes with release of MMP-1 (collagenase). With the exception of TLR3, human leukocytes express the mRNAs of TLR1 through TLR10.¹⁹⁹ Expression of TLR2 is higher in circulating leukocytes obtained from women in labor than from pregnant women not in labor.⁷⁸

Thus, neutrophil secretion of cytokines and chemokines probably follows their recognition of a large repertoire of bacterial PAMPs and cellular DAMPs. Taken together, these observations highlight the maternal and fetal involvement in the process of intra-amniotic inflammation and the role of mother and fetus in amplification of the inflammatory status of the amniotic fluid and tissue damage in a forward loop fashion.²⁰⁰

Increasing evidence points to a role for complement in inflammation-induced PTB. Increased cervical deposition of the split complement product C3 was noted in mouse models of preterm labor induced both by LPS and by progesterone withdrawal.²⁰¹ Although work in this area is in its infancy, there is evidence that complement activation is restricted to preterm labor and is absent from physiologic parturition at term.^{202,203} Whether these inflammatory agents truly operate independently from intrauterine infection (i.e., sterile inflammation) or whether intrauterine infection mediates all of these effects is unclear, and reexamination using modern techniques to identify intrauterine infection is required (see Preterm Birth Resulting from Intra-amniotic Infection, earlier).

In addition to the proinflammatory events just described, a wide variety of anti-inflammatory mediators are now known to operate in the pregnant uterus. The most widely known of these is the anti-inflammatory cytokine IL-10, which is thought to be important for the maintenance of pregnancy.²⁰⁴⁻²⁰⁶ Its concentrations are increased in intra-amniotic inflammation,²⁰⁷ suggesting that IL-10 may play a role in damping the inflammatory response²⁰⁸⁻²¹³ and may have therapeutic value.²¹⁴⁻²¹⁹ IL-10 knockout mice are more sensitive to LPS-induced preterm labor than wild-type mice—a defect that is ameliorated by external IL-10 administration.²²⁰ In wild-type animals, exogenous IL-10 also attenuates the preterm labor phenotype. For example, in a nonhuman primate model of intrauterine infection, pregnant

rhesus monkeys were allocated to one of three interventional groups: (1) intra-amniotic IL-1 β infusion with maternal dexamethasone intravenously; (2) intra-amniotic IL-1 β and IL-10; or (3) intra-amniotic IL-1 β administered alone. Dexamethasone and IL-10 treatment significantly reduced IL-1 β -induced uterine contractility. The amniotic fluid concentrations of TNF- α and leukocyte counts were also decreased by IL-10 treatment.¹⁶⁰ In addition to these beneficial effects on inhibition of contractility and inflammation, administration of IL-10 in animal models of infection has also been associated with improved pregnancy outcome.^{214,221}

Another major group of anti-inflammatory molecules, the lipoxins,²²² are also expressed in the reproductive tract.²²³ Lipoxins are part of a group of pro-resolution molecules that appear to actively terminate the inflammatory process, promoting neutrophil engulfment and inhibiting proinflammatory cytokine expression. Although their role in infection-induced PTB has not been elucidated, they circulate in increasing concentrations as pregnancy advances, their receptor is present in the myometrium of pregnant women, and they attenuate the myometrium's proinflammatory cytokine response to LPS.²²³ Thus, they also show promise as therapeutic agents for infection-induced preterm labor.

In summary, there is increasing interest in the use of anti-inflammatory strategies—either for upregulating endogenously produced molecules or for external application of anti-inflammatory agents to treat preterm labor.²²⁴ These issues will be discussed further in the chapter on treatment of preterm labor.

Bacterial Species and the Intensity of Intra-amniotic Inflammatory Responses

Once present in the amniotic fluid, microorganisms can stimulate the production of proinflammatory cytokines through activation of fetal membrane TLR receptors.²²⁵ Several microorganisms (e.g., *Ureaplasma*, *Mycoplasma*) are traditionally considered to have low virulence.^{113,226} Studies describing the presence of *Ureaplasma parvum* and *M. hominis* in the amniotic fluid of second-trimester asymptomatic women are in support of this concept.¹⁰³ Menon and coworkers demonstrated in vitro that in comparison with gram-positive and other gram-negative bacteria, *Ureaplasma* has a lower proinflammatory effect on fetal membranes.²²⁵ However, isolation of *Ureaplasma* and *Mycoplasma* in the amniotic fluid has been consistently associated with a wide range of adverse outcomes, such as early abortion, stillbirth, prematurity, and neonatal morbidity and mortality.²²⁷ Although an intense intra-amniotic inflammatory response is often encountered at the time of clinical onset of PTB, these studies prove association, not causation.²²⁸ Evidence that these so called silent microorganisms are capable of triggering an inflammatory response in vivo that can induce PTB was recently provided by Novy and coworkers.²²⁹ They inoculated *U. urealyticum* and *M. hominis* into the amniotic fluid of rhesus monkeys, which resulted in an increase in a myometrial contractile activity that was preceded by an intense proinflammatory cytokine response and prostaglandin synthesis.²²⁹

Invasion of the amniotic fluid with gram-positive anaerobes, *E. coli*, and GBS results in intra-amniotic inflammation and fetal sepsis.¹¹⁴ However, intra-amniotic inflammation can also occur in the absence of positive amniotic-fluid culture results.¹¹⁰ As previously mentioned, "uncultivated" or difficult-to-cultivate bacteria may play an important role. The extent of

intra-amniotic inflammatory response triggered by such bacteria, separately or as a group, remains to be determined.

STRETCH AND PARTURITION

Myometrial Stretch and Term and Preterm Birth

During human pregnancy, significant physical and biochemical adaptive transformations of the myometrium are required to aid the development and growth of the fetus. These transformations facilitate conversion of the uterus into a thin-walled muscular organ and maintain myometrial quiescence.²³⁰ Mathematical models derived from studies aimed to understand myocardial contractility indicate that wall stress (applied force per unit of cross-sectional area) is directly proportional to intracavitary pressure and radius of the curve, but inversely proportional to the thickness of the muscular wall.²³¹ The relevance of this model for the pregnant uterus is that the thickness of the myometrium and intra-amniotic pressure both influence uterine wall stress.²³²

Intra-amniotic pressure remains low through human gestation.²³³ A low pressure is achieved through various electrophysiologic (e.g., by decreased number of gap junctions)²³⁴ and biomolecular (e.g., by hormonal signals that stimulate macrophage migration, by release of cytokines, by activation of inflammatory transcription factors) processes that maintain a state of uterine quiescence in the setting of progressive myometrial stretch.²³⁵ The mechanisms that signal conversion of the myometrium from a quiescent to a highly contractile state are unknown. However, it is reasonable to propose that several of these mechanisms are mechanically activated.²³⁵

A large body of clinical data implicates excessive myometrial stretch in the genesis of PTB. For example, a high amniotic fluid index (AFI ≥ 25 cm) is associated with a significantly increased incidence of PTB.²³⁶ Polyhydramnios and multiple gestations are the most relevant examples.^{236,237} There has been increased interest in identifying the molecular mechanisms responsible for the onset of uterine contractility.²³⁸ Progesterone receptor transcriptional activity has been proposed as critical for the preservation of myometrial relaxation.²³⁸ This inhibitory effect seems to be mediated by repressing the expression of genes that encode contraction-associated proteins.^{238,239} Two such genes are connexin-43 and oxytocin receptor. The connexin-43 gene encodes a protein with critical roles in synchronizing myometrial contractile activity,²³⁴ and oxytocin receptor gene controls responsiveness of myometrial cells to oxytocin.²⁴⁰ Mechanical stretch, however, upregulates expression of connexin-43, an effect that is inhibited by progesterone.²⁴¹ In vitro data demonstrated that the upregulation of the expression of oxytocin-receptor mRNA that occurs as a result of myometrial stretching is controlled via DNA binding to various transcription factors, including activator protein-1 (AP-1) and CCAAT/enhancer binding protein (C/EBP)- β .²⁴² Interestingly, the transcription factor NF- κ B did not increase the promoter activity of the oxytocin receptor gene.²⁴² That mechanical stimulation of the uterine wall promotes expression of oxytocin receptor mRNA, and that this effect is favored by progesterone withdrawal, was confirmed in vivo.²⁴³

Myometrial elongation stimulates the expression of a variety of cytokines and chemokines (e.g., CCL2, CXCL8, CXCL1, CCL2) with a characteristic proinflammatory profile for preterm labor tissues.^{244,245} In various experimental models, the primary mediator of myometrial stretch-induced inflammation

appears to be NF- κ B.²⁴⁴ These experiments provide support for the concept that uterine distention carries an inflammatory component. Other mechanisms that can lead to activation of myometrial contractility subsequent to excessive mechanical stretch are (1) increases in the transcription factor AP-1; (2) activation of mitogen-activated protein kinase (MAPK)-dependent and cyclooxygenase (COX)-2-mediated prostaglandin synthesis^{246,247}; (3) downregulation in the expression of stretch-dependent K⁺ (SDK) channels²⁴⁸; (4) changes in the expression of transient receptor potential canonical (TRPC) proteins with a role in store-operated calcium entry in human myometrial smooth muscle cells²⁴⁹; and (5) upregulation in the expression pattern of gastrin-releasing peptide, a molecule with agonistic contractile properties.²⁵⁰

Fetal Membrane Stretch and Term and Preterm Birth

Fetal membranes carry important protective and biochemical functions. In physiologic pregnancy, the fetal membranes undergo progressive mechanical stretch, allowing their accommodation to the growing uterus.²⁵¹ The human fetal membranes are complex tissues composed of highly specialized epithelial and mesenchymal cells embedded in an extracellular matrix composed primarily of collagen and proteoglycans.²⁵² Interstitial types I and III collagens predominate and represent the main structural components that maintain the mechanical integrity of the membranes.²⁵² Collagen can be stretched but it is not elastic, whereas other structural components (e.g., elastin) of the extracellular matrix are both stretchable and elastic.

By comparing the surface area of the fetal membranes with that of the uterine cavity, Parry-Jones and Priya demonstrated that after 28 weeks of gestation, the intact fetal membranes are under tension and in a state of active stretch.²⁵³ A significant decrease in the elasticity of membranes that ruptured before labor was observed independent of gestational age. In a study conducted by Millar and coworkers, the investigators confirmed marked differences in elasticity between individual membranes and a diminished ability of the membranes that rupture before term to stretch.²⁵⁴

Traditionally, rupture of the fetal membranes was viewed as a mechanical event.²⁵⁵ However, although this might hold true for specific clinical cases, maintenance of the tensile strength of fetal membranes appears to involve a highly coordinated balance between synthesis and degradation of various components of the extracellular matrix.²⁵⁶ It has been proposed that changes in the membranes, including decreased collagen content, altered collagen structure, and increased collagenolytic and proinflammatory activity, are associated with preterm PROM and PTB.²⁵³ In vitro, stretching of the fetal membranes induces collagenase activity.²⁵⁷ Thus, it is possible that, in vivo, a loaded state of the fetal membranes might facilitate their susceptibility to enzymatic degradation. Mechanical stimulation of the amnion cells results in increased expression of COX-2 and PGE₂ production, suggesting a feed-forward loop under which stimulation of uterine contractions magnifies the degree of stretching to the point of rupture and preterm delivery.²⁵⁸ Because this phenomenon is mediated through members of the AP-1 family of transcription factors (i.e., Fos and Jun) and NF- κ B, involvement of various inflammatory pathways has also been also proposed. Synthesis and expression of the proinflammatory cytokines IL-8 and IL-1 β are increased after exposure of the whole membranes and amnion cells to mechanical stretch.²⁵⁷⁻²⁵⁹ Interestingly, expression of IL-8 was upregulated in both amnion

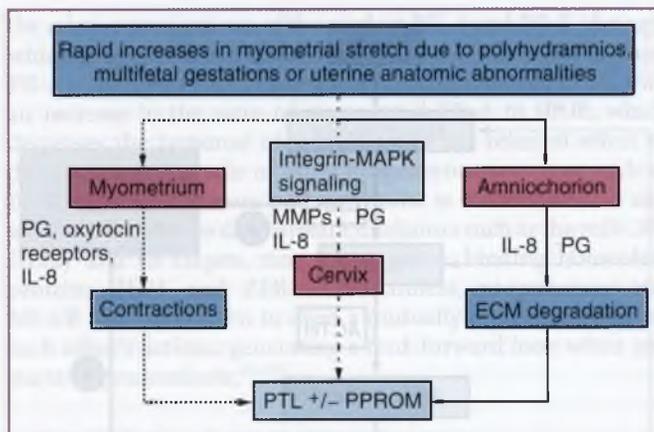

Figure 39-7 Proposed mechanisms by which stretch can induce preterm labor. ECM, extracellular matrix; IL-8, interleukin-8; MAPK, mitogen-activated protein kinase; MMPs, matrix metalloproteinases; PG, prostaglandins; PPROM, preterm premature rupture of membranes; PTL, preterm labor.

and chorion, but not in decidua.²⁵⁹ Studies using an in vitro cell culture model for fetal membrane distention demonstrated upregulation of proinflammatory genes, including those for IL-8 and pre-B-cell colony-enhancing factor (visfatin).²⁶⁰ Stretching of the fetal membrane in vitro results in overexpression of various genes, specifically those for IL-8, interleukin-enhancer binding factor 2, huntingtin-interacting protein 2, and interferon-stimulated gene encoding a 54-kDa transcript.²⁶¹

These molecular mechanisms, schematically represented in Figure 39-7, highlight that myometrial and excessive mechanical stretch of the fetal membranes could lead to PTB through integration of multiple cellular and extracellular signaling pathways. Each of these mechanisms can be linked to various phenotypic components of the PTB syndrome: polyhydramnios, multiple fetuses, and twin-twin transfusion syndrome.

ACTIVATION OF THE MATERNAL-FETAL HPA AXIS IN TERM AND PRETERM BIRTH

Considerable and well-deserved attention has been paid to glucocorticoid physiology during human pregnancy. Substantial research data indicate the existence of a positive feedback loop involving glucocorticoids, proinflammatory cytokines, prostaglandins, surfactant protein-A, and 11 β -HSD type-1 in human fetal membranes in women who are going to have a preterm delivery.²⁶² There is evidence to support the hypothesis that this mechanism is active in human preterm parturition in the setting of infection-induced histologic chorioamnionitis.²⁶³ Additionally, in the model of preterm parturition, stress may be involved in the production of abundant biologically active glucocorticoids and prostaglandins, which might promote accelerated fetal maturation and initiation of parturition.²⁶²

A schematic representation of the physiology of the fetal hypothalamic-pituitary-adrenal-placental axis in pregnancy is presented in Figure 39-8. Corticotropin-releasing hormone (CRH; a 41-amino-acid peptide) appears to be the mediator of stress-associated preterm deliveries.²⁶⁴ The glucocorticosteroid

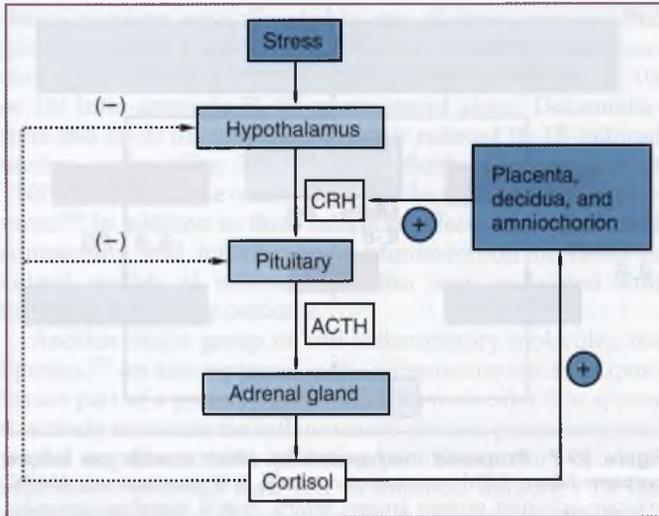

Figure 39-8 The fetal hypothalamic-pituitary-adrenal-placental axis in pregnancy. ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.

hormone cortisol displays an inhibitory effect on the hypothalamic CRH production.²⁶⁴ On the other hand, cortisol stimulates the placental production of CRH.²⁶⁴ A positive, feed-forward system of CRH is a unique biologic feature of the placenta, causing progressive increases in placental CRH production as pregnancy advances to term. The effect of CRH seems to be broad, based on its expression by various placental, chorionic, amniotic, and decidual cells.²⁶⁵ In uncomplicated pregnancies, maternal plasma free CRH levels rise exponentially during the second half of pregnancy and peak during labor.⁸¹ The exponential rise in maternal plasma CRH concentration is associated with a concomitant fall in levels of CRH binding protein, leading to a rapid increase in maternal circulating levels of bioavailable CRH. This suggests that CRH may act directly as a trigger for parturition in humans. The CRH concentration across the gestation curve in women with subsequent PTB runs parallel but to the left of the CRH curve for term pregnancy.²⁶⁶ Despite these findings, it is unclear whether precocious elevation of maternal plasma CRH levels is an epiphenomenon or a trigger for preterm delivery mechanisms.²⁶⁷ Because CRH maternal plasma concentrations are elevated in both term and preterm parturition, it appears that CRH is part of a common pathway of labor.

Several effector mechanisms have been proposed as being involved in activation of the common pathway of labor by CRH. First, the output of $\text{PGF}_{2\alpha}$ and PGE_2 production and synthesis is stimulated by CRH in amniotic, chorionic, decidual, and placental cells.^{268,269} Cortisol synthesized in response to CRH can increase amnion COX-2 expression while inhibiting chorionic PGDH expression.²⁷⁰⁻²⁷² The net result would be an increase in the bioavailability of prostaglandins. Prenatal stress increases not only prostaglandin levels but also that of maternal circulating inflammatory markers (e.g., IL-6, IL-8, TNF- α) that are associated with prematurity.²⁷³ The link between stress hormones and various inflammatory signaling pathways in pregnancies complicated by infection and histologic chorioamnionitis has been demonstrated.²⁷⁴ Torricelli and associates showed that

expression of the mRNAs of CRH and its receptor CRH-R1 was higher in pregnancies complicated by preterm PROM and chorioamnionitis.²⁷⁴ In their experimental setup, endotoxin increased trophoblast CRH, urocortin-2, and CRH-R1 mRNA expression in a dosage-dependent manner. Moreover, prostaglandins increase cervical expression of IL-8, which recruits and activates neutrophils, releasing additional MMPs and collagenases, which can promote cervical extracellular matrix disorganization and weakening of the fetal membranes.⁷¹ The secretion of IL-8 and MMP-1 was significantly higher, and MMP-3 secretion was lower, in preterm cervical fibroblasts. In summary, cervical ripening seems to have an inflammatory component, with CRH possibly contributing to its initiation. However, preterm and term cervical fibroblasts might have different phenotypes based on different secretion patterns of IL-8, MMP-1, and MMP-3.⁷¹

Progesterone is a hormone with key roles in human parturition. Data published by several groups suggest that CRH directly modulates the endocrine function of placental trophoblasts, including production of progesterone²⁷⁵ and estrogens.²⁷⁶ Keeping in mind the common pathway to parturition, it is plausible that CRH-induced PGE_2 , and $\text{PGF}_{2\alpha}$ increase the expression of the PR-A isoform and decrease that of the PR-B isoform in myometrium, cervix, and decidua.^{73,277,278} Because PR-A antagonizes many of the classic PR-mediated genomic effects of PR-B, prostaglandins appear to induce a functional progesterone withdrawal. Decidual cells, and not amnion and chorion cells, seem to be the direct target of progesterone during human pregnancy.²⁷⁹ This assertion is supported by Merlino and colleagues, who reported that in contrast to the intense nuclear PR mRNA and protein expression observed in decidual cells, PR expression is barely detectable in amnion and chorion.²⁷⁹

Experimental data also suggest that a functional increase in myometrial CRH signaling may lead to activation of myometrial contractility and labor. A direct CRH signaling effect is possible based on the observation that both CRH-R1 and CRH-R2 are expressed in pregnant upper- and lower-segment human myometrium.²⁸⁰ Placing these observations in the context of labor is difficult because the protein level of CRH-R1 in the upper contractile segment was significantly downregulated in pregnancy, with a further decrease at the onset of labor. No significant changes in CRH-R2 expression were observed in either upper- or lower-segment myometrium. There is evidence for a myometrial relaxing effect of CRH, favoring uterine quiescence.²⁸¹ Therefore, the role of CRH in controlling activation of myometrial contractility, both term and preterm, continues to be an enigma.

Fetal Control of the Onset of Parturition

Using matched maternal and fetal pairs samples, Lockwood and coworkers evaluated activation of the maternal-fetal HPA axis in patients undergoing cordocentesis during the second half of gestation.²⁸² The authors noted that in physiologic pregnancy, placenta-derived maternal serum CRH values correlated better with fetal ($r = 0.40$) but only modestly with maternal ($r = 0.28$) cortisol levels. Based on these findings, it is possible that placental-derived CRH stimulates the release of fetal pituitary adrenocorticotropic to enhance fetal adrenal cortisol production, which further stimulates placental CRH release. At term, cortisol released into the amniotic fluid can directly stimulate fetal membrane prostaglandin production by increasing

amniotic COX-2 expression and inhibiting the chorionic prostaglandin-metabolizing enzyme PGDH.^{271,283} This suggests that a local amniotic-fluid positive feedback loop exists to tie fetal HPA axis maturation to parturition.

Compelling data indicate that the fetus actively participates in controlling the timing of labor via production of adrenal hormonal precursors.²⁸⁴ This argument is supported by the evidence that at term, before the onset of labor, the weight and volume of the fetal adrenal gland equals that of the adult.²⁸⁵ An important role of the fetus in stress-induced PTB has been proposed.²⁸⁶⁻²⁸⁸ By using volume analysis—virtual organ computer-aided analysis (VOCAL)—of three-dimensional (3D) ultrasonographic images, Turan and colleagues demonstrated that a birth-weight-corrected fetal adrenal gland volume of greater than 422 mm³/kg was a significant predictor of PTB.²⁸⁹ Development of the fetal adrenal zone of the fetal adrenal gland after 28 to 30 weeks' gestation creates the context of a stress-induced activation of the placental-fetal HPA axis and enhancement of placental estrogen production. This is because a unique adaptation evolved in primates: placental expression of CRH.²⁹⁰ Placental CRH stimulates the fetal adrenal zone, an adrenal structure unique to primates, to produce dehydroepiandrosterone sulfate (DHEAS), which is converted to estrogen by the placenta. In addition, CRH can directly augment fetal adrenal DHEAS synthesis.²⁹¹ Remarkably, fetuses exposed to intra-amniotic inflammation also have higher adrenal gland volumes and lower cortisol-to-DHEAS ratios.²⁹² Placental sulfatases facilitate conversion of fetal adrenal gland DHEAS to estradiol, estrone, and estriol. These estrogens increase myometrial expression of contraction-associated proteins such as oxytocin receptor and connexin-43.^{293,294} Because reductions in PR-B expression lead to increased expression of the estrogen receptor- β (ER- β), placental estrogen production would act synergistically to prostaglandin-induced increases in myometrial ER- β expression.²⁹⁵

PROGESTERONE WITHDRAWAL AND PARTURITION

The role of progesterone in the timing of the onset of human parturition has long puzzled reproductive biologists. Progesterone—literally, “in favor of carrying [a baby]”—is secreted initially by the corpus luteum and then by the placenta in large amounts during pregnancy. It maintains uterine quiescence by inhibiting myometrial contractions.²⁹⁶ In many species, including most mammals, the onset of parturition is triggered (in part) by an increase in circulating estrogen and a decrease in circulating progesterone levels.²⁹⁷ Although there is no acute change in progesterone levels at the time of parturition,²⁹⁸ the importance of progesterone in human pregnancy is shown by the efficacy of the antiprogestone mifepristone as an abortion-inducing agent in early pregnancy²⁹⁹ and its actions in inducing labor in later pregnancy³⁰⁰ (although its side-effect profile is such that it should be used only in the scenario of intrauterine fetal death). Additionally, progesterone administration reduces the rate of spontaneous PTB by around 50% in women at high risk because of a history of a previous PTB and in those who are at risk because of a short cervix.³⁰¹

Although progesterone levels do not change as human labor starts, increasing evidence suggests that labor is associated with a functional progesterone withdrawal (see Mesiano and coworkers for a review³⁰²). Briefly, although circulating progesterone levels do not change, parturition is associated with changes in

the relative proportions of the nuclear PR-A and PR-B, through which progesterone is thought to exert the bulk of its actions. PR-A is thought to act as an endogenous repressor of PR-B, with an increase in the ratio of myometrial PR-A to PR-B, which decreases the response of the uterus to the relaxant effect of progesterone. The role of other progesterone receptors such as PR-C and PR cofactors and repressors is still debated,³⁰³ and work continues into downstream mediators such as the miR-200 family and its targets, zinc finger E-box binding homeobox proteins ZEB1 and ZEB2.²³⁹ Regardless, progesterone and NF- κ B (see later) seem to exert a mutually repressive effect on each other's actions, generating a feed-forward loop when one starts to predominate.^{63,304}

GENE-ENVIRONMENT INTERACTION

A gene-environment interaction is said to be present when the risk for a disease (occurrence or severity) among individuals exposed to both the genotype and environmental triggers is either more severe or less severe than that predicted from the presence of either the genotype or the environmental exposure alone.^{305,306} There is evidence for a gene-environment interaction in infection-related PTB.³⁰⁷ In a case-control study, patients who had a spontaneous preterm delivery (>37 weeks) were compared with controls delivered after 37 weeks. The environmental exposure was bacterial vaginosis diagnosed by symptomatic vaginal discharge, a positive whiff test, and clue cells on a wet preparation. The genotype of interest was TNF- α allele 2.³⁰⁸ The authors found that patients with both bacterial vaginosis and the TNF- α allele 2 had an odds ratio (OR) of 6.1 (95% confidence interval [CI], 1.9 to 21) for spontaneous PTB, and that this OR was higher than for patients with either bacterial vaginosis or carriage of the TNF- α allele alone, suggesting that a gene-environment interaction predisposes to PTB.^{307,309}

A schematic representation of the principal molecular and biochemical mechanisms responsible for the main pathways of preterm parturition is presented in Figure 39-9.

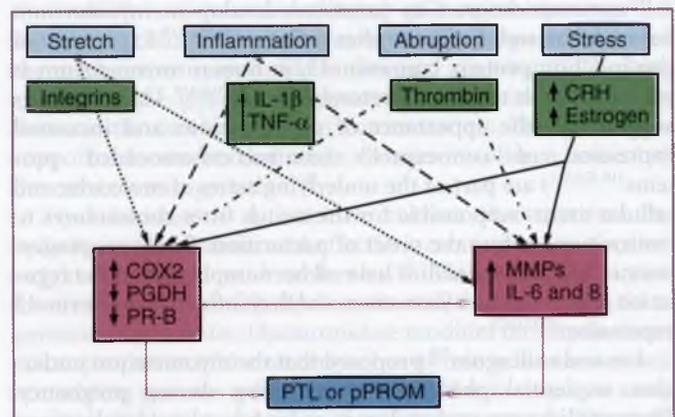

Figure 39-9 Principal biochemical mechanisms responsible for the main pathways of preterm parturition. Spontaneous Preterm Parturition as a Syndrome

It is increasingly clear that preterm labor is not a single disease, but a syndrome with multiple causes. The classification system used in this chapter is the system proposed by a project funded by the Global Alliance to Prevent Prematurity and Stillbirth.¹⁰ Because the etiology of preterm labor is often not known, this system has deliberately avoided classification based on cause and has chosen a system based on phenotype. The phenotypes are based on the following: (1) significant maternal conditions (e.g., extrauterine infection, clinical chorioamnionitis, maternal trauma, worsening maternal disease, uterine rupture, preeclampsia/eclampsia), significant fetal conditions (e.g., fetal demise, IUGR, abnormal fetal heart rate or biophysical profile, infection or fetal inflammatory response syndrome, fetal anomaly, alloimmune fetal anemia, polyhydramnios, multiple fetuses), and pathologic placental conditions (e.g., histologic chorioamnionitis, placental abruption, placenta previa); (2) the presence or absence of signs of initiation of parturition; and (3) whether the pathway to delivery is caregiver initiated or spontaneous. The aim is to provide a classification system to “use in both population surveillance and research, so that when specific types of PTBs are discussed, studied, or compared across populations or over time, categories have consistent definitions that are widely understood and accepted.”¹⁰ Such an aim is laudable, and this is the classification system followed here, but before it is widely adopted and used, a paradigm shift will have to occur in many clinicians’ approach to and understanding of PTB (see Fig. 39-1).

MYOMETRIAL CONTRACTILITY

Myometrial contractions are a hallmark of parturition, both at term and before term. The biochemistry of myometrial contractility has been extensively reviewed.^{310,311} Contraction of individual myocytes is achieved by increasing intracellular calcium levels, which ultimately promotes phosphorylation of myosin, and hence increased actin-myosin cross-links and contraction. During labor, the individual myocytes contract together as a functional syncytium. This increased coordination is induced by gap junction formation, which increases cell-to-cell communication. Gap junctions develop in myometrium before labor and disappear after delivery.^{234,312-315} Expression of gap junction protein, connexin-43, in human myometrium is similar in both term and preterm labor.^{241,316-319} These findings suggest that the appearance of gap junctions and increased expression of connexin-43 (contraction-associated proteins^{318,320,321}) are part of the underlying series of molecular and cellular events responsible for the switch from contractures to contractions before the onset of parturition. Estrogen, progesterone, and prostaglandins have all been implicated in the regulation of gap junction formation, and they influence connexin-43 expression.^{67,322,323}

Lye and colleagues³²⁴ proposed that the myometrium undergoes sequential phenotypic remodeling during pregnancy. Their studies were undertaken in rodents but have implications for humans. Three distinct stages of rat gestational myometrial development were recognized:

1. *Proliferative*, in which the number of myocytes increased, as demonstrated by greater levels of cell nuclear antigen labeling and protein expression in early pregnancy. This

phenotype coincided with a higher myometrial expression of antiapoptotic proteins (BCL2 and BCL2L1 [formerly BCL-xL]).

2. *Synthetic*, in which the myometrial cells underwent hypertrophy, as demonstrated by a higher protein-to-DNA ratio in the second half of pregnancy. This stage coincided with a higher secretion of extracellular matrix proteins from the myocytes, in particular collagen I and collagen III, as well as a high concentration of caldesmon (a marker of synthetic phenotype).
3. *Contractile*, which occurred at the end of pregnancy and coincided with low myometrial expression of interstitial matrix proteins and high expression of components of the basement membrane (laminin and collagen IV).

In humans, restrictions on tissue access mean that comparisons are largely limited to those between pregnant women delivered in labor at term and women delivered before the onset of labor. Gene microarray studies suggest that various cellular processes, including inflammation, transcriptional regulation, and intracellular signaling, are upregulated in laboring compared with nonlaboring myometrium, with these processes overlapping but being slightly different from those occurring in the cervix and fetal membranes.^{325,326} Notwithstanding the important contribution that arrays made to understanding of myometrial physiology, it is increasingly recognized that computerized modeling has much to contribute to the understanding of uterine contractions. A model would integrate state-of-the-art knowledge in cardiac electrophysiology, biochemistry/gene expression, and anatomy, and it would provide an *in silico* arena for testing of novel therapies. This approach, already well advanced in cardiac pathophysiology,³²⁷ is at a much earlier stage for pregnant uterine physiology.³²⁸

CERVICAL ADAPTATION AND REMODELING DURING HUMAN PREGNANCY

Traditionally, it was held that the closed cervix holds the fetus inside the uterus, and that progressively more forceful myometrial contractions lead to cervical effacement and dilation.³²⁹ However, 2D and 3D ultrasound evaluation of the cervix established that during human gestation, cervical shortening and decreases in cervical volume often occur at an “asymptomatic” stage, before the onset of uterine contractions.^{330,331}

As noted, it was recently proposed that classification of the preterm parturition syndrome based on phenotype, rather than on clinical signs or symptoms, may facilitate a better understanding of the etiology of PTB.¹⁰ From this perspective, a short or a dilated cervix may be the first clinical manifestation of a parturition process triggered as a result of decidual activation³³² or uterine contractility.³³⁰ The complexity of the issue is emphasized by the observation that in the Preterm Prediction Study, a short cervix (≤ 2.0 , ≤ 2.5 , ≤ 3.0 cm), as seen by sonography, had a low sensitivity but a high specificity for prediction of PTB before 35 weeks.^{330,333} A cervical length of 2.5 cm or less at 22 to 24 weeks was associated with spontaneous PTB in only 18% and 27% of women prior to 35 and 37 weeks, respectively. This suggests that the majority of women with a short cervix by sonography will not deliver prematurely. On the basis of these observations, Iams and colleagues proposed that a short cervical length may represent a spontaneous preterm parturition phenotype characterized by asymptomatic shortening of the cervix, but not decidual and myometrial activation.³³⁰

Understanding the process of cervical functional adaptation to pregnancy has become critical for a better comprehension of the mechanisms responsible for initiation of human parturition, cervical insufficiency, and spontaneous preterm labor. Today, it is recognized that cervical biology undergoes major enzymatic and biomechanical transformations that differ from those of the myometrium.^{334,335} Thus, although anatomically part of the uterus, the cervix should be viewed as a separate, complex, and heterogeneous organ.³³⁶

For most of a normal human gestation, the cervix remains closed and firm. The current working model of parturition indicates that the cervix must undergo a multistep adaptive process: (1) softening (chronic, slow, progressive); (2) ripening (precedes labor); (3) effacement and dilation (acute, occurs within hours); and (4) repair (occurs after delivery for several weeks).^{336,337} Each of these phases involves distinct biochemical, biomechanical, and molecular events, which could be phenotype dependent. This assertion is supported by studies conducted in animals with various genetic backgrounds (high-regenerative repair versus low-regenerative high-fibrotic repair).³³⁸

The cervix is a composite viscoelastic material consisting of elastic (collagen and elastin) and viscous macromolecular components (sulfated glycosaminoglycans and proteoglycans).³³⁹ The ratios of constitutive elements of the cervix vary by the region of the cervix they occupy.^{340,341} During each phase of the adaptive process, the complex interaction between connective tissue, extracellular matrix (collagen, elastin, macromolecular proteoglycans), smooth muscle, and fibroblasts dictates the mechanical behavior of the uterine cervix.³⁴²

Collagen makes up almost 90% of the cervix³⁴³ and is believed to be the most critical element responsible for maintenance of tissue structural integrity.^{339,344} Major cervical collagens are types I and III.³⁴⁵ Interestingly, interstitial collagens types I and III also predominate and maintain the mechanical integrity of the amnion.²⁵² This observation implies that various factors (e.g., inflammation) may modify the biology of the cervical and fetal membrane tissues in parallel. Collagen is actively synthesized during pregnancy, and it is remodeled by the interplay of neutrophils, fibroblasts, and various enzymatic pathways.³⁴⁶⁻³⁴⁸ The role of MMPs in cervical ripening remains incompletely understood.³³⁷ A possible role of MMPs in the process of adaptation and collagen remodeling was supported by data showing that in pregnant rabbits the antiprogesterone onapristone (ZK 98.299) augmented the cervical mRNA expression levels of MMP-3 (or stromelysin-1).³⁴⁹ In addition, studies conducted in rodents revealed that systemically administered PGE₂ elevated the cervical tissue levels of MMP-2 and MMP-9.³⁵⁰ This effect was predominantly seen at term, not before term. However, the role of collagenases during the process of cervical ripening has been challenged.³⁵¹ Incubation of the cervical tissue with MMP-1 altered neither the stiffness nor the extensibility of the rat cervix. Biomechanical experimentation revealed that the changes in physical properties of the rat cervix during physiologic ripening are similar to those induced by PGE₂ and anti-progesterin, and they consist of increased extensibility, compliance, and strength. They cannot be attributed to increased collagenase activity, which decreases tissue compliance and strength.³⁵¹ Studies conducted in healthy pregnant women suggest that the functional relevance of MMPs is probably minimal.^{352,353} This assertion is based on the observation that cervicovaginal MMP-9 did not change with spontaneous labor or rupture of membranes at term and did not predict success of labor induction.³⁵²

The net enzymatic activity of MMPs, if there is any, is modulated by their interaction with tissue inhibitors of MMP (TIMPs) and various cytokines.³⁵⁴ Peptidyl lysine oxidase, copper, and vitamins C and E are also important regulators of collagen metabolism, directly involved in its synthesis and degradation.^{355,356}

Animal studies have generated a large body of knowledge about processes involved in pregnancy-related changes to the cervix.³³⁷ From this research we have learned that before cervical ripening, the collagen is dense, organized, rigid, and not extensible.³³⁹ Collagen's 3D structure, which limits access of degrading collagenases and permits cross-linking between fibrils, might play a role. By the end of the first trimester, collagen becomes less tightly packed.³³⁷ As a result, the cervix becomes softer but retains its tensile strength. Cross-links between collagen molecules are essential for providing strength. Several investigators have focused their attention on decorin (dermatan sulfate proteoglycan), which seems to be implicated in the process of collagen reorganization and cross-linking.^{357,358} Animal studies revealed that an increase in the decorin-to-collagen ratio was associated with disorganization and rearrangement of collagen fibrils, followed by a marked decrease in mechanical strength.³⁵⁹

Orientation of the collagen fibrils is not the only element involved in regulating the preparative process of the cervix for labor. For example, a decline in the collagen type I mRNA expression was observed in human gestation, suggesting that a decreased synthesis of this collagen could be involved in the process of uterine cervical ripening.³⁶⁰ This finding was in agreement with light-induced autofluorescence measurements of the human cervix.³⁶¹ By using this noninvasive technology, Maul and coworkers provided evidence that a gradual decrease in cervical collagen concentration occurs with advancing gestation.³⁶¹

Other elements of the extracellular matrix, such as proteoglycans, elastin, and its hydration status, reliant on negatively charged glycosaminoglycans and levels of vascular endothelial growth factor (VEGF), are also considered important determinants of cervical biomechanics.^{362,363} Glycosaminoglycans such as hyaluronic acid are distributed widely throughout connective tissues, including the uterine cervix.³⁶⁴ These molecules have a high affinity for water and therefore may control tissue hydration, which is an essential element of cervical ripening.³⁶⁵ A decrease in collagen content was repeatedly proposed as one of the mechanisms responsible for cervical ripening.³³⁹ The high affinity of the glycosaminoglycans for water may artificially decrease the cervical collagen concentration. This premise is supported by studies that refute changes in collagen content of the cervix across gestation.³⁴²

Hyaluronidase is an intrinsic enzyme that catalyzes the hydrolysis of hyaluronic acid, effectively creating low-molecular-weight hyaluronic acid molecules.³⁶⁴ This catalyzing action lowers the viscosity of the hyaluronic acid, thus increasing tissue permeability to water. Hyaluronidase modifies the tensile viscoelastic properties of the rat cervix, but its role in human cervical remodeling remains to be determined.³⁶⁶ Elastin may have a role in cervical dilation and tissue compliance to stretch. This conclusion is mostly supported by histologic data demonstrating fragmentation of the elastin fibers in women with an incompetent cervix.³⁶⁷

Relaxin is a two-chain peptide hormone that serves an important role in cervical growth and remodeling associated

with pregnancy.^{368,369} Specifically, relaxin-deficient mice display difficult parturition, an event also observed in relaxin leucine-rich repeat containing G protein-coupled receptors (LGR) knockout mice.³⁶⁹ In humans, relaxin may manifest its effect via an increase in collagenase activity and increased glycosaminoglycan synthesis.³⁶⁸ Other collagen accessory proteins such as thrombospondin-2, tenascin-C and lysyl-hydroxylase, with an important role in collagen cross-linking, seem to be also involved.^{370,371}

Significant gestational changes also occur in the cellular compartment of the cervix.³⁴¹ Human studies demonstrated that apoptosis of stromal cells may be involved in cervical remodeling.³⁷² A higher number of apoptotic nuclei were seen in laboring than in nonlaboring cervix, suggesting an increased rate of apoptosis as pregnancy progresses to term. Based on animal studies, it was proposed that relaxin, estrogens, and progesterone are important regulators of apoptosis.³⁷³ Interestingly, all of these three hormones promoted cell proliferation and repressed apoptosis by unknown mechanisms. Availability of co-regulatory proteins (nuclear receptor co-repressor transcriptional factor) at different stages of pregnancy, or the local ratios of various hormones may contribute to the process.³⁷⁴ Apoptosis is followed by infiltration of macrophages and neutrophils that add to disorganization and dispersion of the collagen and elastin fibers.³⁴³ The increase in decorin expression and the resulting collagen disorganization promote the influx of water, enhancing the ability of the cervix to dilate during labor.³⁴⁴

At the end of pregnancy, changes in the mechanical behavior of the cervical tissue are the result of various biochemical transformations.³⁷⁵ What remains incompletely understood is the nature of the signals responsible for coordination of the process of cervical ripening, softening, and dilation. Chief candidate regulatory molecules are hormones (e.g., prostaglandins, progesterone), cytokines, and decorin.³⁷⁶ Prostaglandins induce a marked increase in the decorin-to-collagen ratio,³⁷⁷ which in turn may provoke collagen disorganization and rearrangement of its 3D conformation. In various studies, prostaglandin-induced cervical ripening was characterized by extracellular matrix transformations similar to physiologic ripening such as diminished collagen concentration, increased synthesis of hydrophilic proteoglycans, and increased collagen solubility.³⁷⁸ The mechanisms are extremely complex and may involve augmentation of glycosaminoglycan synthesis by IL-1 β , and the neutrophil chemoattractant IL-8.⁷¹ IL-8 is also thought to initiate cervical ripening by promoting neutrophil chemotaxis to and activation in cervical stroma.⁷¹ Interestingly, prostaglandins had no effect on hyaluronic acid synthesis, so tissue hydration most probably entails other mechanisms. Additional factors involved may include relationships among prostaglandins and the receptors for estrogen (EP₄), androgens, and progesterone (PR-A, PR-B).³⁷⁹

The important role of progesterone for maintenance of cervical competency has long been postulated.³⁸⁰ Today, the attention is even more focused on progesterone because of the results of randomized clinical trials that pointed to its potential role in prevention of premature birth.^{381,382} In an animal model, Stys and colleagues demonstrated that progesterone has different effects in the myometrium and in the cervix, supporting the hypothesis that it prevents term and PTB by acting on both myometrium and cervix.³⁸³ In humans, the contribution of progesterone to the process of cervical remodeling is supported by

the clinical data demonstrating that administration of the anti-progesterone RU486 increases the likelihood of a favorable cervix.³⁰⁰ However, RU486 alone is not sufficient to induce labor, implying that factors involved in controlling the activation of myometrial contractility play a decisive role. Understanding the molecular mechanism by which progesterone maintains a state of cervical competency proved to be a challenge.³⁸⁴ It has been postulated that alterations in the expression of PR isoforms and changes in the metabolism of estrogen and progesterone are associated with cervical changes in human parturition.^{337,385} Data generated using mice deficient in steroid 5 α -reductase type-1, an enzyme with an essential role in cervical progesterone catabolism, indicate that at least part of progesterone's effect on cervical remodeling is controlled by this enzyme.³⁸⁶ It has been also proposed that in the cervix, progesterone is an important regulator of hyaluronic acid and MMP metabolism, and it affects the intensity of an inflammatory response after activation of various inflammatory pathways.^{201,387,388}

The laboring cervix is histologically characterized by an abundance of neutrophils and macrophages, and by an outpouring of proinflammatory cytokines.^{389,390} Young and collaborators reported that in the human cervix, IL-6, IL-8, and TNF- α were localized to leukocytes, glandular and surface epithelium, and stromal cells.³⁹¹ Although these data might argue that the cervical biology is heavily dependent on various inflammatory processes, especially at term, it is important to recognize that during ripening, the influx of monocytes into the cervix depends on the loss of progesterone function.³⁹² Furthermore, the timing of inflammatory cell migration and activation in the pregnant cervix of mice deficient in 5 α -reductase type-1 (Srd5a1-/-) suggests a role for the inflammatory cells and activation of downstream signaling pathways of various cytokines, in postpartum remodeling rather than in the cervical ripening phase.³⁹³ As animal and human labor begins and the cervix dilates, there is increased activity of inflammatory mediators such as IL-1 β and IL-8 that can activate various NF- κ B-dependent signaling pathways.^{394,395} Expression of proinflammatory cytokines stimulates synthesis and activation of collagenases, elastases, MMPs, and possibly nitric oxide synthases.³⁹⁶ The increase in IL-6 stimulates prostaglandin and leukotriene production, potentially causing dilation of cervical vessels and promoting extravasation of various inflammatory cells.¹⁷⁶ Proteases released by degranulating neutrophils encounter an already destabilized collagenous fiber network. In this context, collagen disorganization can be further augmented by collagenases, even in the absence of a significant change in their level of expression. If true, the process should be strictly time limited, because the sustained action of proteases may cause severe tissue damage. Differential expression of nitric oxide synthase in the uterus and cervix during pregnancy has been described.³³⁴ Nitric oxide production is upregulated in the cervix during labor, an effect that is opposite from that in the myometrium (i.e., anti-contractile).³³⁵ This increase is accompanied by softening of the cervix, and blockade of nitric oxide reduces cervical distensibility.³³⁵ The mechanism of nitric oxide-induced cervical ripening during pregnancy may be mediated in part by increased PGF_{2 α} ,³⁹⁷ but not by cytokine synthesis.³⁹⁸

What can be concluded from the large body of published research is that cervical adaptation to pregnancy cannot be the result of a single factor, and that various pathways should be involved simultaneously. Indeed, various genes, with roles in

cell adhesion, regulation of extracellular matrix, and inflammation, were found to be differentially expressed in the ripened cervix.^{326,399} Current data reveal that cervical shortening at term was associated with downregulation of bone morphogenetic protein-7, claudin-1, β_6 integrin, and endometrial progesterone-induced protein mRNA. The clinical significance of these discoveries remains to be determined.⁴⁰⁰

CERVICAL ADAPTATION AND REMODELING DURING PRETERM BIRTH

Cervical adaptation and remodeling is a complex process. However, a relevant question is whether cervical ripening and dilation at term and preterm are driven by the same molecular mechanisms. A study by Akins and colleagues demonstrated that collagen morphology in premature cervical remodeling is different from that in physiologic term ripening.⁴⁰¹

Because the processes of term and preterm cervical ripening and dilation have been associated with various inflammatory events, inflammation was consistently presented as the final common pathway of parturition.³²⁶ This hypothesis was supported by data that demonstrated that in the absence of infection, IL-8, IL-6, and monocyte chemoattractant protein-1 (MCP-1) were significantly elevated in human term and preterm cervical tissues.⁴⁰² As shown, asymptomatic women with intra-amniotic infection or inflammation had higher degrees of cervical shortening and dilation.^{110,403-405} Thus, it is reasonable to assume that in some clinical circumstances, a short or a dilated cervix favors microbial invasion of the gestational sac via an ascending mechanism.¹²⁵ In such cases, processes involved in premature cervical shortening and dilation might represent the first event leading toward premature birth. However, the reverse is possible—that is, intra-amniotic infection may induce an outpouring of inflammatory mediators that in turn might persuade ripening and opening of the cervix.

The clinical implication is that presence in the cervicovaginal fluid of specific biomarkers may reflect activation of signaling pathways involved in premature ripening, cervical dilation, and premature birth. Additional nuances concerning the involved molecular networks have been described with the recent advances in genomic and proteomic technology.^{406,407} Comprehensive survey of the cervicovaginal fluid proteome showed that calgranulin-A, calgranulin-B, azurocidin, insulin-like growth factor-binding protein-1, and defensins were found upregulated in the cervicovaginal fluids of women at risk for PTB.^{406,407} Most of these biomarkers are part of the innate immunity defense mechanism of the cervix and are constitutively expressed in the cervical mucus.⁴⁰⁷ Their differential expression⁴⁰⁸ may mediate the process of leukocyte infiltration, shown previously to be involved in cervical remodeling.³⁹⁰

To understand the process of cervical ripening and dilation in the setting of intra-amniotic infection-induced PTB, several investigators have used animal models of intrauterine infection. With respect to the profile of cervical inflammatory infiltrate, Holt and coworkers suggested that there might be differences between various mechanisms involved in triggering PTB.⁴⁰⁹ The monocyte population dominated the progesterone withdrawal mechanism, whereas neutrophils governed the process of endotoxin-induced PTB. A comparison of the genes differentially expressed in the cervix of animals in which PTB was induced by mifepristone or endotoxin showed that genes involved in immunity and inflammation were upregulated in

the cervix of inflammation-induced PTB.⁴¹⁰ On the other hand, term labor was not associated with a differential expression of immune pathways. Genes responsible for the expression of various cytokines (TNF- α , IL-6, IL-1 β) and MMPs (MMP-2, MMP-9) were upregulated in the cervix of animals with intrauterine infection.⁴¹⁰ Notably, expression of cytokines was not increased in term cervixes but was amplified in the postpartum period. These findings argue that, in the postpartum period, cytokines may play an important cervical reparative role or may confer immune protection.

Premature cervical ripening is a feature of patients with multiple gestations, and is rarely seen in diethylstilbestrol-exposed women.^{411,412} IL-8,^{413,414} MMPs,^{31,348} prostaglandins,^{71,337,415} and nitric oxide³³⁵ have been implicated in the control of cervical ripening. These mediators may be synthesized in response to amniochorion stretch and may exercise part of their biologic effects in parturition by degradation of the cervical extracellular matrix.

It has been suggested that cervical insufficiency is characterized by a “muscular cervix,” with low collagen and high smooth muscle content.⁴¹⁶ However, cervical insufficiency does not appear to be associated with a constitutionally low collagen content or collagen of inferior mechanical quality. Therefore, the hypothesis that a muscular cervix with an abundance of smooth muscle cells contributes to the development of cervical insufficiency is not supported by the present studies aimed to address this problem.

Collectively, the data presented here support the view that PTB is not an accelerated form of physiologic cervical ripening.

DECIDUAL ACTIVATION AND BLEEDING

Decidual activation refers to a complex set of pathophysiologic events that lead to separation of the fetal amniochorionic membranes from the decidua, bleeding, spontaneous rupture of the membranes, activation of myometrial contractility, and expulsion of the placenta. The relative contributions of the decidual activation and bleeding process to PTB vary.

During gestation, the chorioamniotic membranes gradually fuse with the decidua. Before delivery, biochemical and molecular occur that allow separation and expulsion of the fetal membranes. Fibronectins have multiple binding sites to permit cell binding and interaction with cytoskeletal organization to effect cell migration, adhesion, and decidual cell differentiation.⁴¹⁷⁻⁴¹⁹ Elastase-induced release and degradation of the glycosylated cellular fibronectin (i.e., fetal fibronectin) diminishes the binding ability of this glycoprotein for components of the extracellular matrix, thereby facilitating separation of the fetal membranes from the decidua.⁴²⁰ Detection of fetal fibronectin into cervical and vaginal secretions before preterm parturition⁴²¹⁻⁴²³ is one of the most clinically useful biomarkers of PTB.⁴²⁴⁻⁴²⁶

Placental abruption can be viewed as a binary event in which molecular signals involved in decidual bleeding arise as a consequence of either inflammation or aberrant coagulation (Fig. 39-10). Although relatively distinct from other causes of prematurity, it is believed that many of the molecular events responsible for decidual activation and abruption are inflammatory. The acute lesions of chorioamnionitis and funisitis (e.g., hematoma, fibrin deposition, compressed villi, hemosiderin-laden histiocytes) are frequently associated with

of clinical manifestations of the disease.^{428,429} Various processes that lead to vascular disruption and the interaction of circulating factor VIIa with decidual cell membrane-bound tissue factor generate thrombin, explaining the strong association between abruption and disseminated intravascular coagulation.⁴⁴⁴ The mechanisms responsible for the stimulation of myometrial contractions in the presence of intrauterine hemorrhage and the specific role played by the thrombin have been defined.⁴⁴⁵⁻⁴⁴⁷ Elovitz and coworkers demonstrated that intrauterine inoculation of whole blood stimulated rat myometrial contractility.⁴⁴⁵ Furthermore, fresh whole blood stimulated myometrial contractility in vitro, and this effect was partially blunted by hirudin, a thrombin inhibitor.⁴⁴⁵ In vitro, thrombin induced cytosolic calcium concentration oscillations that were similar to those produced by oxytocin.⁴⁴⁵ These studies confirmed that membrane receptor-Gq protein and protease-activated receptor-1 (PAR1) coupling events play an important role in modulating thrombin stimulation of myometrial smooth muscle.^{445,447}

Thrombin may exert pleiotropic effects on decidual cells. Genomic studies have provided a better understanding of the process of endometrial decidualization.⁴⁴⁸ Among the genes responsible for the normal phenotypic and morphologic remodeling processes of the human decidua, the homeobox (HOX) gene family appears to be critical.⁴⁴⁹ In vitro, thrombin decreased gene expression of HOXA9, HOXA10, and HOXA11. Furthermore, thrombin decreased HOXA10 mRNA and protein levels. IL-1 β , a cytokine with important regulatory roles in prostaglandin production,⁴⁵⁰ mimicked the effect of thrombin on HOXA10 gene expression. These observations provide proof of the concept that two recognized mediators of decidual inflammation and PTB, thrombin and IL-1 β , may operate by reducing the expression of HOXA10 gene.

The inflammatory events that follow abruption can occur dependent on or independent of progesterone.^{451,452} Coincident with activation of the coagulation cascade, decidual injury causes release of cytokines.⁴⁵³ Cytokines act in an autocrine or paracrine manner to elicit and increase the synthesis of MMPs⁴⁵⁴ and VEGF.⁴⁵¹ It has been proposed that TNF- α , IL-1 β , IL-6, IL-8, and IL-11 are involved.⁴⁵³ Other cytokines, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), monocyte chemoattractant protein-1 (CCL2), and colony-stimulating factor-1 (CSF1), may be implicated in the regulatory process of decidual activation and bleeding.^{438,455}

Progesterone appears to create both a hemostatic and an antiproteolytic milieu in the decidua. Using a primary cell culture experimental setup, Schatz and colleagues demonstrated that first-trimester decidua expresses tissue factor and plasminogen activator inhibitor-1 (PAI-1), which is considered a fast inhibitor of the primary fibrinolytic agent tissue plasminogen activator (tPA).⁴⁵⁶ There is experimental evidence that progestins are exercising a similar effect in cultured term decidual cells.⁴⁵⁷ The molecular mechanisms through which progestins promote decidual hemostasis via enhanced expression of tissue factor, the primary initiator of hemostasis, and PAI-1, the primary antifibrinolytic compound, involve epidermal growth factor receptor (EGFR) and induction of transcription factors Sp-1 and Sp-3.⁴⁵⁸

In addition to controlling the decidual hemostasis, progestins inhibit the proteolytic activity of collagenase MMP-1 and MMP-3.^{459,460} Because antiprogestins (e.g., RU486) reverse the progestin-inhibited expression of MMPs, an attractive

hypothesis is that progesterone withdrawal may induce an increase in the decidual expression of MMP-1 and MMP-3, which would promote extracellular matrix and fibrillar collagen degradation, preceding bleeding, premature separation of the placenta, and preterm PROM.

Taken together, the results of these studies may explain at least partially the potential role of progesterone in preventing decidual activation and bleeding, by inhibiting the general proteolytic and inflammatory activity at the maternal-fetal interface. The mechanism by which progesterone function is balanced in the setting of high maternal circulatory levels is unknown. Abruption-associated PTB is accompanied by reduced immunostaining for PR, and thrombin inhibits PR protein and mRNA expression in cultured term decidual cells.^{460a}

Epidemiologic studies suggest that for some women, the recurrence risk for placental abruption is higher than the general background risk, and that thromboembolic events occur more commonly among female relatives of women with placental abruption.⁴⁶¹⁻⁴⁶³ However, genetic studies involving candidate genes dispute this association.^{464,465} Zdoukopoulos and Zintzaras tried to identify the most frequent gene polymorphisms associated with placental abruption.⁴⁶⁶ A positive association was identified for Arg506Gln (OR = 3.4; 95% CI, 1.4 to 8.3) and G20210A (OR = 6.7; 95% CI, 3.2 to 13.0) polymorphisms. The positive correlation between placental abruption and prothrombin gene mutation (G20210A) was confirmed in nulliparous women (OR = 12.1; 95% CI, 2.4 to 60.4).⁴⁶⁷ On the other hand, a study conducted by the Maternal-Fetal Medicine Units Network argues against this association, suggesting that the practice of screening women without a history of thrombosis or adverse pregnancy outcomes for the G20210A prothrombin gene mutation polymorphism is not necessary.⁴⁶⁸

PRETERM PREMATURE RUPTURE OF MEMBRANES

Preterm PROM (pPROM) is one of the leading risk factors for PTB. The amniochorion has a unique biology characterized by distinctive molecular, enzymatic, and biomechanical transformations.²³⁵ Multiple pPROM risk factors have been identified.^{11,469} Whatever the cause, the final common pathway must be weakness of the amniochorion membrane that allows rupture. Clinicians and scientists have traditionally attributed rupture of the membranes to mechanical stress, particularly that associated with uterine contractions. The molecular mechanisms that could trigger pPROM after excessive mechanical stretch were presented earlier.

Fetal membranes are pluristratified structures whose composition ensures their cohesion, elasticity, and mechanical strength. The strength of the fetal membranes is derived from both synthesis- and protease-induced degradation of the components of the extracellular matrix. The mechanisms responsible for degradation of the extracellular matrix are tightly regulated by several MMPs (MMP-1, 2, 3, and 9) and TIMP-1 and TIMP-2.¹¹ A marked decidual infiltrate of neutrophils, which are a rich source of the extracellular matrix-degrading proteases elastase and MMPs, are associated with abruption-induced pPROM.^{428,429} This phenomenon occurs in the presence or in the absence of infection. Predominant activities for MMP-1,⁴⁷⁰ MMP-8,⁴⁷¹ and MMP-9,⁴⁷² and a low concentration of TIMP-1 and TIMP-2,⁴⁷³ have been demonstrated in the amniotic fluid of women with pPROM. This implies that at least part of the MMPs' bioavailability at the site of

amniochorion injury and rupture is the result of activation and degranulation of fetal neutrophils.^{198,474} In addition to collagen, gelatinases cleave fibronectin and proteoglycans, facilitating detachment of fetal membranes from the lower uterine segment, disruption of the extracellular matrix, and rupture.^{11,475}

Activation of MMPs and other proteases may occur dependent on or independent of inflammation and infection.⁴⁷² The existence of a focal defective area, rather than generally weakened fetal membranes, has been proposed.⁴⁷⁶ This theory is based on the observation that an excessive matrix remodeling process occurs in the region of fetal membranes overlying the internal os of the cervix.^{477,478} Histologic examination of the "restricted zone of extreme altered morphology" reveals marked swelling and disruption of the fibrillar collagen network in the compact, fibroblast, and spongy layers of the fetal membranes.⁴⁷⁸ Observations by Bell and colleagues suggest that changes in the zone of altered morphology are more extensive in the setting of pPROM.⁴⁷⁹ A significant decrease in the amount of collagen type I, III, or V has been reported in the zone of altered morphology, and studies conducted by Lappas and associates demonstrate that remodeling of the extracellular matrix in the supracervical area is probably related to activation of MAPK/AP-1, and NF- κ B-dependent signaling pathways.^{480,481} Enhanced expression of tenascin, an extracellular matrix protein expressed during tissue remodeling and wound healing, may also be involved.^{479,482} Identification of tenascin in the fetal membranes signifies the presence of injury and a wound healing-like response that may precede pPROM. Studies conducted by George and colleagues suggest that apoptosis is accelerated in the chorion of pPROM women, and that this phenomenon is of higher intensity in the setting of chorioamnionitis.⁴⁸³

Although the precise mechanism responsible for programmed cell death in the fetal membranes is unknown, it is conceivable that cytokines play a role.⁴⁸⁴ Kumar and coworkers showed that TNF- α and IL-1 β incubated amniochorion exhibited a dosage-dependent decrease in the mechanical force required to reach the breaking point of the tissue.⁴⁸⁵ Both TNF- α and IL-1 β stimulated the production of immunoreactive MMP-9 and a decrease in TIMP-3, suggesting collagen remodeling and apoptosis in fetal membranes exposed to increased cytokine levels. The observation that α -lipoic acid inhibits cytokine-induced fetal membrane weakening suggests that this mechanism is NF- κ B mediated.⁴⁸⁶ Fortunato and Menon showed that IL-1 β increased caspase 2, 3, 8, and 9 activities, whereas IL-6-treated membranes did not exhibit a significant change.⁴⁸⁴ However, the role of IL-6 and its alternative trans-signaling pathway remains to be determined, especially when the levels of this cytokine and that of soluble gp130 molecule were found to be significantly decreased in women with pPROM and intra-amniotic infection compared with women with intra-amniotic infection and intact membranes.¹⁵³ A possible explanation for the low cytokine levels in the amniotic fluid of women with pPROM could be fetuin-mediated aggregation of amniotic fluid cytokines and proteins into calcifying nanoparticles that may play an important pathophysiologic role in rupture of the amniochorion (increasing necrosis and apoptosis).⁴⁸⁷

The observed reduced antioxidant glutathione peroxidase and superoxide dismutase enzyme activity in the supracervical area of the fetal membranes implies that local oxidative stress is an important factor predisposing to pPROM.⁴⁸⁸ Compelling evidence suggests that MMP activity in the human fetal

membranes is reduction-oxidation (redox) regulated.⁴⁸⁹ By using an in vitro amniochorion explant model, it was shown that MMP-9 activity was directly increased by superoxide anion, a byproduct of macrophages and neutrophils that are abundantly present in both amniochorion and decidua of pregnancies complicated by infection and decidual hemorrhage. *N*-Acetylcysteine decreased the amniochorionic MMP-9 activity, suggesting that this glutathione precursor may have therapeutic value.⁴⁸⁹

Vaginal bleeding is a well-recognized risk factor for PTB. Women who are experiencing vaginal bleeding during the first trimester have an increased risk for PTB (adjusted relative risk [RR] = 2; 95% CI, 1.6 to 2.5).⁴⁹⁰ Moreover, the risk for pPROM is increased if vaginal bleeding persists more than one trimester during gestation (OR = 7.4; 95% CI, 2.2 to 25.6).⁴⁹¹ Much interest has been shown about understanding the relationship between decidual bleeding, activation of MMPs, and pPROM. It was hypothesized that in abruptio thrombin generated from decidual cell-expressed tissue factor can indirectly promote pPROM via enhanced expressed MMP-1 and stromelysin-1 (MMP-3).^{441,492} Furthermore, in vitro, thrombin enhances the expression of MMP-9 in fetal membranes at term.⁴⁹³ Along with data confirming that the maternal coagulation system is activated in women with ruptured membranes,⁴⁴¹ the results of these experiments support the premise that thrombin is central to the pathophysiology of pPROM. Kumar and colleagues demonstrated that thrombin and TRAP (specific agonist for thrombin receptor PAR1) weaken the fetal membranes in a dosage-dependent manner.⁴⁹⁴ Thrombin appears to exercise this effect in a direct fashion, whereas cytokines such as TNF- α and IL-1 β require the presence of choriodecidua.⁴⁹⁴ Interestingly, thrombin, but not TNF- α and IL-1 β , exhibited protein MMP-9 and decreased TIMP-3 production in isolated amniochorion cells. Because thrombin-induced decreases in biomechanical strength of the amniochorion are reversed by α -lipoic acid, it is probable that PKB/Akt, NF- κ B, or nuclear factor-erythroid 2-related factor 2 (Nrf2) signal transduction pathways, or more than one of these, are directly involved.^{494,495}

Phenotypic Components of the Preterm Birth Syndrome

MATERNAL CONDITIONS

Extrauterine Infection

Given the very close link between intrauterine infection and preterm labor (reviewed later), it is not surprising that there is also a strong association between maternal extrauterine infection and PTB.

Globally, maternal infections with human immunodeficiency virus (HIV) and malaria are important contributors to PTB. In a large population-based study, women infected with HIV were more likely than uninfected women to give birth before term.⁴⁹⁶ In this study, antiretroviral treatment of HIV reduced rates of adverse outcomes, including PTB, but the specific antiretroviral agents used were not reported. Although this study did not differentiate between spontaneous and caregiver-initiated PTB, others have shown that both are increased in women infected with HIV.⁴⁹⁷ Accumulating evidence now suggests that the use of modern highly active antiretroviral therapy (HAART, which involves multiple drugs and clearly reduces

vertical transmission of HIV) is itself a risk factor for spontaneous and caregiver-induced PTB, even after adjustment for confounders.⁴⁹⁸ The mechanisms of the increase in preterm labor associated with HIV infection and with HAART are unknown.

Malarial infection increases the risk for both stillbirth and PTB,⁴⁹⁹ probably by a combination of mechanisms including placental dysfunction, anemia, and maternal sepsis. In endemic areas, intermittent presumptive treatment for malaria is recommended during pregnancy to reduce perinatal mortality and low birth weight,⁵⁰⁰ although the evidence that such a strategy also prevents prematurity is weak.

More localized maternal extrauterine infections, whether symptomatic or asymptomatic, also increase the risk for preterm labor. The link between asymptomatic bacteriuria and PTB is well established.⁵⁰¹ Women hospitalized with appendicitis are also more likely to give birth before term.⁵⁰² These links also appear to hold true for emerging infections—for example, the risk for spontaneous preterm labor is some two to three times higher in women infected with the H1N1 influenza virus, with a significant increase in the risk for stillbirth and perinatal mortality compared with uninfected women.⁵⁰³ The pathophysiology linking extrauterine infection to preterm labor is uncertain. For some infections, such as periodontitis, a mechanism by which mouth microorganisms induce bacteremia and hence reach the uterine has been postulated,⁵⁰⁴ although evidence to support this claim is weak.

Clinical Chorioamnionitis

Larsen and coworkers provided one of the first pieces of evidence that intrauterine infection is an important trigger for PTB.⁵⁰⁵ There is now compelling microbiologic evidence to suggest that intrauterine infection may contribute to about 25% of PTBs, with bacterial involvement as high as 80% for early gestation, declining to about 10% toward term (ascertainment of intrauterine infection notwithstanding).^{200,506,507}

Clinically, intrauterine infection can manifest with obvious signs of maternal and/or fetal infection (maternal fever, tachycardia, uterine tenderness, leukocytosis, and foul odor of the amniotic fluid). Multiple studies confirmed the non-overlapping nature of histologic and clinical chorioamnionitis.^{200,508,509} Clinical chorioamnionitis occurs in just 20% of pregnancies complicated by intra-amniotic inflammation and histologic chorioamnionitis. Because previous studies had associated short- and long-term follow-up characteristics to distinct placental lesions,⁵¹⁰⁻⁵¹³ the results of histologic examination of the placenta (as performed by a perinatal pathologist) was used as an intermediate-outcome variable when evaluating performance of new diagnostic tests.⁵¹⁴ Recognition of clinical chorioamnionitis is also a challenge in the setting of maternal systemic inflammatory conditions unrelated to obstetric causes (e.g., pyelonephritis, appendicitis, pneumonia).

In the newly proposed classification system, *clinical chorioamnionitis* is defined as “clinically suspected intrauterine infection, manifest by maternal fever and rupture of the membranes plus two features from maternal tachycardia, uterine tenderness, purulent amniotic fluid, fetal tachycardia and maternal leukocytosis.”^{7,10} It is acknowledged that this somewhat strict definition would not include many women presenting in spontaneous preterm labor and subsequently found, on careful testing, to have microorganisms in the uterine cavity. However, for the purposes of this chapter, we will describe all the links

between intrauterine infection and inflammation (whether clinically apparent or not) and preterm labor under this heading of clinical chorioamnionitis (because of the consistency in pathophysiology), while acknowledging that subclinical infection or inflammation may not strictly fulfill the recently proposed clinical phenotype of clinical chorioamnionitis.

Maternal Trauma and Uterine Rupture

Although major maternal trauma is uncommon during pregnancy, it is associated with an increased risk for immediate or delayed PTB. Population-based studies suggest that the rate of trauma sufficient to require hospitalization is around 2 to 3.5 per 1000 pregnancies.^{515,516} In some women, the trauma is so severe that immediate PTB occurs either as a result of maternal injury, or as a result of fetal or maternal death, or to facilitate maternal resuscitation, although the absolute risk for immediate delivery is small. Women with major injuries who survive, and women with minor trauma, have about double the odds of either spontaneous preterm labor or placental abruption during the remainder of the pregnancy.⁵¹⁵⁻⁵¹⁷

Other forms of maternal trauma that make important contributions to PTB include treatment for preinvasive cervical carcinoma⁵¹⁸ (see Cervical Disorders, later) and previous cesarean delivery, which leads to an increased risk for stillbirth in the subsequent pregnancy after around 34 weeks' gestation (hazard ratio, about 2) compared with those with a previous vaginal delivery.⁵¹⁹ Although previous cesarean delivery is a common antecedent of uterine rupture during labor, it is possible for uterine rupture to occur de novo. Regardless of the setting of the uterine rupture, PTB is commonly associated.⁵²⁰

Worsening Maternal Disease, Including Preeclampsia

The final maternal phenotypic components of the PTB syndrome include worsening maternal disease, preeclampsia, and eclampsia. These conditions are risk factors for caregiver-initiated pathways to PTB (typical OR = 3 to 5),¹⁴ although a recent population-based study demonstrated that maternal diabetes and preeclampsia were also associated with increased odds of spontaneous preterm labor.¹⁴

Maternal Stress and Anxiety

A large number of epidemiologic studies confirmed that maternal psychosocial stress is, worldwide, an independent factor for PTB.⁵²¹⁻⁵²⁵ Although there is no universally accepted definition of stress, it is generally the result of an interaction between a person and the environment in which there is a divergence between environmental demand and the individual's psychological, social, and biologic resources. From this perspective, the nature and timing of the stressful events may vary from a heavy workload to anxiety and depression.^{526,527} Population-based research conducted with pregnant women of different sociodemographic backgrounds and races showed that periconception stress and anxiety are independently associated with increased rates of spontaneous PTB.^{528,529} Stress during pregnancy also has adverse consequences, with the risk for PTB apparently being higher when the stress exposure occurs during the second half of gestation (months 5 to 6) (OR = 1.24; 99% CI, 1.08 to 1.42).⁵²⁴ Because of the large heterogeneity of study designs, populations, and the associated behavioral risk factors, the magnitude of the effect is often difficult to determine. However, the general consensus is that the overall impact is modest.^{529,530}

Data derived from registry-linked births have noted slightly higher odds of PTB in women with post-traumatic stress disorder, with an OR that varies from 2.5 (95% CI, 1.05 to 5.84)⁵³¹ to 2.3 (95% CI, 0.82 to 6.38).⁵³² Exposure to specific severe disaster events and the intensity of the disaster experience are considered predictors of poor pregnancy outcomes.⁵³² Antenatal depressive symptoms affect approximately 18% of pregnant women.⁵³³ What can be concluded from the large body of literature is that during pregnancy, women with depression are at increased risk for PTB.⁵³⁴ The extent of the effect varies depending on the method of ascertainment of depression, socioeconomic status, and race.⁵³⁵ For example, depression among African-American women is associated with an adjusted OR for PTB of 1.96 (95% CI, 1.04 to 3.72).⁵³⁶ Absence of similar findings in Hispanic and non-Hispanic white populations suggests ethnic disparity in the effect of stress in the United States.

The clinical relevance of the impact of various maternal stressors on the occurrence of PTB is multidimensional. First, comorbidity of depression and anxiety creates the context for the worst pregnancy outcome.⁵³⁷ Second, women with significant psychosocial stress factors and psychiatric conditions (depression, anxiety, bipolar disease) are frequently prescribed medications that may affect the growth and development of the fetus.⁵³⁸ However, data on the use of antidepressant medication during pregnancy is reassuring overall—treatment can be recommended in view of the risks associated with absence of treatment.⁵³⁹⁻⁵⁴¹ In a large study, exposure to selective serotonin reuptake inhibitors (SSRIs) during the first trimester was not associated with increased risk for congenital malformations in general (OR = 1.22; 95% CI, 0.81 to 1.84) or increased risk for PTB (OR = 1.21; 95% CI, 0.87 to 1.69). Others have shown a modest impact on PTB. Yonkers and colleagues⁵⁴² found that use of an SSRI, both with (OR = 2.1; 95% CI, 1.0 to 4.6) and without (OR = 1.6; 95% CI, 1.0 to 2.5) a major depressive episode, was associated with PTB. A major depressive episode without SSRI use (OR = 1.2; 95% CI, 0.68 to 2.1) had no clear effect on PTB risk. Use of SSRIs in pregnancy was associated with increases in spontaneous but not medically indicated PTB.⁵⁴² Third, early recognition of maternal stress and

implementation of behavioral interventions reduces the occurrence of PTB (OR = 0.42; 95% CI, 0.19 to 0.93).⁵⁴³ Fourth, fetal exposure to maternal stress may have sustained programming effects on the HPA axis responsiveness and sympathetic nervous system functionality later in life, which seems to be sex (male) dependent.⁵⁴⁴

Complex biochemical and neurohormonal interactions between maternal, fetal, and placental compartments are required during normal and premature human parturition.⁷⁹ A series of physiologic adaptive responses in each of these compartments can be triggered by stress subsequent to malnutrition, infection, ischemia, vascular damage, and psychosocial factors.⁸⁰ However, the nature of the stimulus whereby stress induces premature activation of the mechanisms involved in PTB remains unknown. The pathways by which stress can induce preterm labor are represented in Figure 39-11. There is substantial evidence that the placenta plays a central role in controlling the length of gestation and the onset of parturition in humans.⁸¹ Thus, placental histologic changes consistent with infection- and ischemia-induced fetal stress are far more common in patients with spontaneous PTB than in idiopathic preterm and term birth controls.^{82,83} Maternal-fetal trafficking of numerous hormones is highly dependent on various enzymatic pathways. For example, 11 β -HSD regulates placental transfer of cortisol, which is a glucocorticosteroid with a key role in activation of the HPA axis. Interestingly, hyperactivity of the maternal HPA axis has been involved in the occurrence of maternal depression.⁸⁴ Carriers of a polymorphism in the gene encoding for 11 β -HSD type-1 have a higher level of HPA activity and susceptibility to depression.⁸⁵ Collectively, these and other data⁸⁶ appear to indicate a genetic predisposition toward maternal mood disorders and may implicate various placental polymorphisms in the occurrence of maternal mood disorders linked to PTB.⁸⁷

Cervical Disorders

Cervical insufficiency can produce a wide spectrum of diseases,⁵⁴⁵ including recurrent pregnancy loss in the mid-trimester and spontaneous PTB later in gestation. The latter often appears with

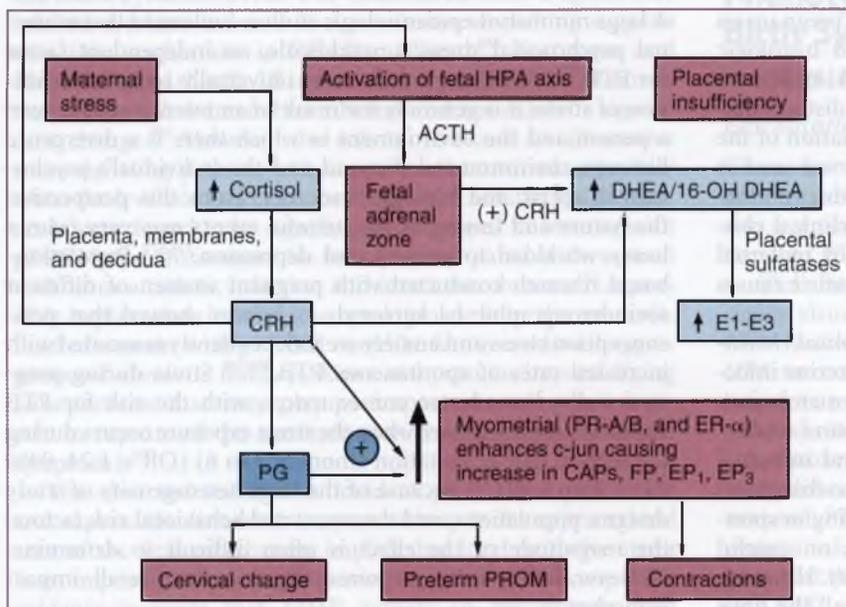

Figure 39-11 Proposed pathways by which stress can induce preterm labor. ACTH, adrenocorticotropic hormone; CAPs, contraction-associated proteins; CRH, corticotropin-releasing hormone; DHEA, dehydroepiandrosterone; E1-E3, estrone, estradiol, and estriol; EP₁ and EP₃, prostaglandin E receptors types 1 and 3; ER- α , estrogen receptor- α ; FP, prostaglandin F receptor; HPA, hypothalamic-pituitary-adrenal; PG, prostaglandins; PR, prostaglandin receptor; PROM, premature rupture of membranes.

bulging membranes in the absence of significant uterine contractility or rupture of the membrane, as well as with precipitous labor at term. Cervical insufficiency may be the result of a congenital disorder (e.g., hypoplastic cervix or diethylstilbestrol exposure in utero), surgical trauma (e.g., conization resulting in substantial loss of connective tissue), or traumatic damage of the structural integrity of the cervix (e.g., by repeated cervical dilation).⁵⁴⁶

Most cases of cervical insufficiency reflect not primary cervical disease leading to premature remodeling but other pathologic processes such as infection, which has been reported in 50% of patients presenting with acute cervical insufficiency,⁵⁴⁷ or recurrent decidual hemorrhage. The reader is referred to a detailed review of this condition and the role of cervical cerclage in the prevention of PTB.⁵⁴⁸

Increasing evidence implicates treatment for pre-invasive cervical carcinoma as a risk factor for PTB. Treatments associated with an increased risk for PTB include cold knife conization (RR = 2.59; 95% CI, 1.80 to 3.72) and large loop excision (RR = 1.70; 95% CI, 1.24 to 2.35).⁵⁴⁹ There is a greater effect on delivery before 30 weeks, with cold knife conization associated with an RR of 5.33 (95% CI, 1.63 to 17.40).⁵⁵⁰ Cold knife conization is also associated with an increase in perinatal mortality.⁵⁵⁰ These data are important because the large number of women treated means that treatment for pre-invasive cervical disease could become a major contributor to rates of PTB.

The mechanisms by which treatment for pre-invasive disease increases the risk for prematurity are unclear.⁵⁵¹ One hypothesis is simply that mechanical disruption of the cervix weakens the cervix. In support of this hypothesis, there is evidence that the depth of the excision correlates with the risk for prematurity, with an estimated 6% increase in risk for each additional 1 mm of tissue excised (OR = 1.06; 95% CI, 1.03 to 1.09).⁵⁵² More recent data suggest that cervical pre-invasive disease and spontaneous preterm labor may share common risk factors but are not directly linked. These common risk factors may include human papilloma viruses and other microbial infections in the cervix, or defects in the immune response.^{551,553} For example, in a study of more than 170,000 women, the increased risk for PTB applied to both women undergoing colposcopy only and women undergoing a single excisional treatment, with both having an increased risk compared with women with normal Pap smears.⁵⁵⁴ A meta-analysis suggested that, when all the relevant studies were combined, an increased risk for PTB remains for women having excisional (but not ablative) treatment, compared with an untreated comparison group, although the relative risk is less than when an external comparison group (presumably not subjected to the same common risk factors) is used.⁵¹⁸

FETAL CONDITIONS

Intrauterine Fetal Demise

A variety of definitions and gestational age cutoff levels are used for reporting stillbirth.⁵⁵⁵ The ages range from 20 to 28 weeks, and birth weights range from 350 to 1000 g.⁵⁵⁵ The World Health Organization defines stillbirth as death before expulsion or extraction from the mother of a product of conception, independent of gestational age, showing no signs of life as indicated by the absence of breathing, heartbeat, pulsation of the umbilical cord, or movements of voluntary muscles. The U.S. fetal mortality rate declined for the past few decades, reaching an all-time low level of approximately 6 per 1000 live births.⁵⁵⁶

A steady decline in fetal mortality at 28 weeks of gestation or more has paralleled the increase in late PTBs. It is reasonable to propose that better screening for syphilis, anemia, diabetes, IUGR, preeclampsia, and PTB, and the development of rigorous clinical protocols for evaluation of fetal heart rate, contributed to the observed reduced rate of stillbirth, at the expense of caregiver-initiated PTB. However, despite implementation of various clinical strategies, fetal deaths at 20 to 27 weeks of gestation did not decline, thereby implying increased vulnerability of the fetus at this gestational age.

Among the major risk factors for stillbirth worldwide are uteroplacental vascular insufficiency, abruption, smoking, maternal medical conditions (e.g., lupus, chronic hypertension, antiphospholipid syndrome, thyroid disease, cholestasis, thrombophilia), African-American race, maternal nutritional deficiencies, obesity, congenital and aneuploidy preeclampsia, infections (e.g., parvovirus, cytomegalovirus, syphilis, malaria, *Listeria monocytogenes*), chorioamnionitis, multiple gestations, and umbilical cord complications.⁵⁵⁷ Many of these are well-recognized risk factors for either spontaneous or caregiver-initiated PTB (with the latter resulting from nonreassuring fetal status in utero or a gestational age at which the risk for stillbirth outweighs the risk for prematurity-related complications).⁵⁵⁸

The existence of various common factors that underlie both stillbirth and PTB is supported by large epidemiologic studies. Gordon and coworkers found that the risk for stillbirth in a subsequent pregnancy was significantly increased if the initial pregnancy was complicated by delivery of a small-for-gestational-age (SGA) preterm neonate (7/1000 live births).⁵⁵⁹ These findings are consistent with the work of Surkan and colleagues, who found a similar association between PTB and stillbirth (19/1000 live births).⁵⁶⁰ These concepts are incorporated in the PTB classification system proposed by the Global Alliance on Prematurity and Stillbirth, which suggested that PTBs should be classified using a single system, regardless of whether the infant is alive or dead at birth.¹⁰

A reasonable hypothesis is that the health of the placenta is a common denominator in the two conditions.⁵⁶¹ The following evidence supports this concept: (1) In animal models of LPS-induced PTB, cytotoxic natural killer cells infiltrate the placenta and are associated with placental cell death, a phenomenon similar to that observed in inflammation-induced fetal demise^{562,563}; (2) medical conditions associated with stillbirth (e.g., severe thrombophilia) and spontaneous PTB share a common constellation of placental histologic features (e.g., thrombosis, infarction, perivillous fibrin deposition, inflammation)^{428,564-566}; (3) failure to modify spiral arteries resulting from defective endovascular trophoblast invasion is associated with stillbirth⁵⁶⁷; and (4) pregnancy loss rate is significantly higher in patients with confined placental mosaicism than in the cytogenetically normal cohort.⁵⁶⁸ As whole exomic and genomic sequencing becomes readily available, a common set of genes that perturb the normal physiology of the placenta and uterus in pregnancies complicated by stillbirth and PTB may be found. Maternal stress⁵²¹⁻⁵²⁴ and socioeconomic status⁵⁶⁹ have been linked to PTB as well as stillbirth. Therefore, residual confounding related to social factors linked to stillbirth may be important determinants of the PTB syndrome phenotype.

Intrauterine Growth Restriction

Diagnosis and management of IUGR is one of the most common and challenging problems in modern obstetrics. Confusion in

terminology and lack of uniform diagnostic criteria play an important role. For example, the terms SGA and IUGR are frequently used interchangeably, but some suggest that SGA is more appropriate for the newborn⁵⁷⁰ and that IUGR should refer to the fetus.⁵⁷¹ The American College of Obstetricians and Gynecologists favors a sonographic estimated fetal weight of less than the 10th percentile for IUGR.⁵⁷² There is evidence demonstrating that most of the adverse perinatal outcomes are primarily confined to infants below the fifth or third percentile at birth.⁵⁷³

The underlying etiology of IUGR is important and frequently assists with determination of the timing of delivery. Overall fetal growth and development in utero is highly dependent on maternal, fetal, or placental factors, and perturbations occurring in any of these compartments can lead to IUGR. A detailed list of various maternal, fetal, and placental conditions linked to IUGR is presented in Chapter 47. However, the risk factors for IUGR, stillbirth, and PTB overlap.

The relationship between IUGR and prematurity is complex. Traditionally, the etiology of IUGR is unknown in approximately 60% of cases.⁵⁷⁴ In such cases, gestational age may play a considerable role because major complications of prematurity wane considerably after 34 weeks of gestation.⁵⁷⁵ Therefore, after 34 weeks of gestation, a caregiver-initiated premature delivery of the idiopathic IUGR fetus is indicated to avoid stillbirth.⁵⁷⁵ In other clinical situations (e.g., preeclampsia) maternal status is the primary indication for premature delivery of an IUGR fetus. However, several lines of epidemiologic evidence suggest a link between spontaneous PTB and fetal growth restriction.^{559,560,576}

Placental association with IUGR is unique because it can be the primary cause (e.g., in the case of mosaicism) of fetal growth restriction.⁵⁷⁷ However, placental mosaicism does not appear to be associated with an increased risk for spontaneous PTB.⁵⁶⁸ IUGR is often related to placental abnormalities, including partial abruptions, previa, infarcts, and hematomas. Salafia and colleagues described histologic changes of the placenta in pregnancies complicated by IUGR.⁵⁷⁸ Placental lesions were infarction, chronic villitis, hemorrhagic endovasculitis, and placental vascular thromboses. One or more of these lesions were present in 55% of IUGR cases. The spectrum of placental lesions was not uniform across cases. These observations suggest that in some cases of IUGR, decidual hemorrhage is the primary mechanism of disease, whereas in others, inflammation is responsible for commencement of myometrial contractility or pPROM. In some other IUGR cases, chronic villitis and hemorrhagic endovasculitis tend to occur together, implying that the two pathways can also act in parallel.⁵⁷⁸⁻⁵⁸⁰

Abnormal Fetal Heart Rate or Biophysical Profile

A number of methods for assessing fetal well-being, including the nonstress test (NST) and the biophysical profile (BPP), are routinely used to assess fetal behavioral response to intrauterine stress.^{581,582} Maturation and maintenance of the structural and functional integrity of the fetal autonomic nervous system is responsible for the changes in fetal heart and biophysical activity (movements, breathing, tonus) observed in utero at various gestational ages.⁵⁸³ Approximately 80% of normally developed fetuses at 28 to 32 weeks demonstrate BPP test scores and fetal heart rate reactivity appreciated as normal (using the criteria of 8/8 or 8/10, and 10-beat, respectively).^{584,585}

Many studies assessed the relationship between prematurity, NST, and BPP.⁵⁸⁶⁻⁵⁹³ The purpose of this large body of research

was to assess whether appropriate clinical decisions (i.e., continuation of pregnancy or caregiver-initiated PTB) can be made on the basis of these two tests to avoid neurologic morbidity and stillbirth in preterm infants delivered in the setting of IUGR or intrauterine infection. Although the original studies were encouraging,⁵⁹⁴ the overall consensus was that neither the NST nor the BPP had good sensitivity for predicting poor neurodevelopment (e.g., cerebral palsy) or infectious complications (e.g., neonatal sepsis).^{589,592,595} Steroids that are universally recommended to avoid prematurity-related complications might add to the complexity of the clinical decision process because they can alter both fetal heart rate⁵⁹⁶ and BPP scores.⁵⁹⁷ Therefore, other tests such as umbilical artery and venous Doppler velocimetry were proposed to be incorporated in the clinical algorithms to indicate the appropriate time of delivery for fetuses at risk.⁵⁹⁸

The fetus relies on the placenta to ensure adequate oxygen and nutritional transfer from the mother.⁵⁹⁹ However, in the context of an acutely or chronically impaired oxygen transfer or placental inflammatory dysfunction, abnormal BPP scores and fetal heart rate monitoring patterns may become the first clinical manifestation of such an intrauterine process.^{600,601} This paradigm is supported by the histopathologic evidence that abnormal fetal heart rates and BPP scores are more frequently present in association with thrombotic vasculopathy, villous endothelial necrosis, placental infarcts, acute umbilical cord vasculitis (funisitis), and histologic chorioamnionitis.^{589,593,602} Thus, an abnormal fetal heart rate or BPP is not the cause but rather a symptom of an underlying etiology leading to spontaneous PTB or caregiver-initiated prematurity.

Infection and the Fetal Inflammatory Response Syndrome

Infection and the inflammatory response syndrome are defined as a fetal phenotype leading to preterm labor in the new classification system.¹⁰ Although there is extensive overlap between these conditions and clinical chorioamnionitis, increasing evidence suggests that the fetal inflammatory response syndrome (FIRS), which is almost always associated with fetal infection, is a distinct entity.

FIRS was initially described in pregnancies complicated by preterm labor and pPROM.^{176,396} It was defined as a fetal plasma concentration of IL-6 greater than 11 pg/mL.³⁹⁶ There are close parallels with the adult systemic inflammatory response syndrome, with similar peripheral blood leukocyte transcriptomic responses.⁶⁰³ Fetuses with elevated plasma IL-6 concentrations have higher rates of severe neonatal morbidity and a shorter cordocentesis-to-delivery interval than those with IL-6 concentrations lower than 11 pg/mL.^{176,335,397,398} The histopathologic landmarks of FIRS are funisitis and chorionic vasculitis.³⁹⁹ The disorder can also be diagnosed by measurement of C-reactive protein concentrations in umbilical cord blood.³²⁶ Fetuses with FIRS have more systemic derangements, including hematologic abnormalities (neutrophilia), and a higher median nucleated red blood cell count, than those without elevated IL-6.⁴⁰⁰ In addition, they have biochemical evidence of fetal stress, as manifested by a fetal plasma ratio of cortisol to DHEAS,⁴⁰¹ congenital fetal dermatitis,⁴⁰² fetal cardiac dysfunction,¹¹⁰ involution of the thymus,⁴⁰³ and abnormalities of the fetal lung^{125,371,373,398,404-407} and brain.^{31,71,83,408-433,335} FIRS was initially described in the context of fetal infection, and it is more common in infants with demonstrable microorganisms (such as *Mycoplasma* and

Ureaplasma) in their cord blood.⁵¹⁰ However, FIRS can be triggered by other fetal stressors such as hypoxemia.⁶⁰⁴

Fetal Anomaly

About 2% to 3% of all pregnancies are complicated by a fetal anomaly.^{605,606} The incidence of fetal anomalies in monozygotic twins, compared with those in singletons or dizygotic twins, is increased by 5% to 6%.⁶⁰⁷ Overall, the antenatal detection rate of fetal structural anomalies is approximately 45%, with a range of 15% to 85%.⁶⁰⁸ Recognition of fetal structural anomalies varies based on severity or whether the antenatal screening is performed on a low- or a high-risk population.⁶⁰⁸ Approximately 18% of fetal structural anomalies are associated with chromosomal aneuploidy, but in about 50% of the cases, no cause is identified.⁶⁰⁹ Congenital heart defects are the most common nonchromosomal anomalies (6.5/1000 births), followed by limb defects (3.8/1000 births), anomalies of the urinary system (3.1/1000 births), and nervous system defects (2.3/1000 births).⁶¹⁰

Most fetal anomalies carry no risk in utero. However, approximately 2% of cases of fetal anomalies, and 25% to 28% of fetuses with aneuploidy, end as stillbirth.^{611,612} To avoid death in utero, antenatal testing is often recommended for fetuses with anomalies or chromosomal abnormalities appreciated as nonlethal. This approach significantly increases the chance of caregiver-initiated prematurity to facilitate immediate direct care of the newborn.⁶⁰⁹

Fetal surgery consists of in utero treatment of various congenital malformations. Implementation of various forms of in utero fetal surgical reparative techniques (e.g., meningomyelocele, spina bifida, congenital diaphragmatic hernia) is associated with potential benefits that must be weighed against the increased likelihood of maternal and fetal complications, such as induced PTB, pPROM, infection, and placental abruption.⁶¹³⁻⁶¹⁵

An increased risk for spontaneous PTB was reported in pregnancies complicated by multiple anomalies,⁶¹⁶ gastroschisis,⁶¹⁷ and twin pregnancies with one anomalous fetus.⁶¹⁸ The underlying etiology remains unknown, but anomalies associated with polyhydramnios remain at highest risk. In such cases, excessive myometrial stretch may play a role.^{236,237}

Polyhydramnios

During human gestation, amniotic fluid is of great importance. In the gestational sac, it protects the fetus from trauma and favors fetal musculoskeletal and lung development. As noted in Chapter 3, the complex nature of the amniotic fluid dynamics reflects contributions from maternal and multiple fetal systems (cutaneous, renal, respiratory, digestive, placental, fetal membrane).⁶¹⁹ Volume-regulatory mechanisms that are involved during the second half of pregnancy in controlling the amount of amniotic fluid are fetal (urine, lung, swallowing) and amnio-chorion absorption dependent.

Polyhydramnios, or excess amniotic fluid, complicates approximately 1% to 2% of pregnancies and has been associated with a variety of adverse pregnancy outcomes, including PTB.⁶²⁰ Traditionally, polyhydramnios was diagnosed when the AFI of the deepest pool was greater than 8 cm, or when the sum of the AFIs of four quadrants was greater than 24 cm.⁶²¹ Maternal, fetal, and placental conditions associated with polyhydramnios include maternal diabetes mellitus⁶²² and insipidus,⁶²³ rhesus iso-immunization,⁶²⁴ congenital and chromosomal abnormalities,⁶²⁵ multiple gestation,⁶²⁶ and placental tumors.⁶²⁷

However, 50% to 60% of polyhydramnios cases are classified as idiopathic.⁶²⁸ In such situations, reduction of the physiologic amniotic fluid turnover may result from aberrant expression of members of the transmembrane channel family of aquaporins.⁶²⁹

Perturbation of the amniotic fluid flow resulting from fetal conditions can lead to volume abnormalities such as polyhydramnios. Irregular swallowing (from obstruction, or neurologic)^{630,631} and gastrointestinal tract anomalies (tracheoesophageal fistula, congenital diaphragmatic hernia)^{632,633} may yield hydramnios in anomalous fetuses. In such clinical scenarios, it is reasonable to propose that excessive myometrial and fetal membrane stretch leads to premature activation of uterine contractility, cervical ripening, and dilation. However, clinical studies estimate that PTB occurs in 18.5% of cases with mild (AFI, 25 to 30 cm), 21.8% with moderate (AFI, 30.1 to 35 cm), and 14.3% with severe (AFI > 35.1 cm) polyhydramnios.⁶²⁰ Fetuses with congenital malformations and those of diabetic mothers have a significantly higher incidence of PTB than fetuses with unexplained polyhydramnios. Thus, the underlying cause of polyhydramnios, rather than the relative excess of amniotic fluid, may determine the occurrence of PTB.⁶²⁰

Multiple Pregnancies

Premature birth in multiple pregnancies is seven times greater than in singletons.⁶³⁴ The gestational age at delivery decreases with increasing numbers of fetuses. The average gestational age of delivery with twins is 35 weeks, compared with 30 weeks for quadruplets.⁶³⁵ Overall, 52.2% of multiple births deliver before 37 weeks and 10.7% before 32 weeks.⁶³⁶ These observations implicate extreme mechanical stretching in the pathophysiology of multiple pregnancy-related PTB.

Sfakianaki and coworkers explored whether the higher uterine volume of multiple gestation could lead to a thinner uterine wall and increased myometrial wall stress, and therefore perhaps explain the tendency for twin gestations to deliver earlier than singletons.⁶³⁷ However, there was no significant ultrasonographic change in the myometrial thickness of the uterine body across pregnancy in women who deliver twins term or preterm, even though there is a substantial increase in the uterine volume in the multiple pregnancies. However, thinning of the lower uterine segment occurred earlier in twin pregnancies destined to deliver before term. Based on these findings, it was proposed that the uterus of the women who deliver preterm twins have a natural limitation of adaptation to the increased length, volume, or weight, and that this limit may be reached at an earlier point in gestation than with twins delivering at term.

Structural and functional differences in the myometrium in twin versus singleton pregnancies might be anticipated, as the myometrium in a multiple pregnancy is exposed to a greater degree of stretch. However, studies comparing myometrium of singleton and multiple pregnancies found no difference in the expression of G-protein (G α , which mediates cyclic AMP synthesis and relaxation), gap junction proteins (connexin-43, connexin-26), and prostaglandins (EP₁, EP₃, and EP₄).⁶³⁸ Turton and coworkers reported preliminary data that oxytocin augments contractions to a greater extent in myometrium from twin pregnancies than myometrium from singletons in vitro.⁶³⁹ Further studies are required to determine whether this effect is stretch dependent.

There is much heterogeneity among patients with multiple gestations. In some, infection plays a central role.⁶⁴⁰⁻⁶⁴² In others,

cervical shortening and dilation, coupled with acute inflammatory lesions of the placenta, may cause stress and decidual hemorrhage-induced PTB.^{643,644} Assisted reproductive technology, which is responsible for approximately 15% to 20% of multiple births,⁶⁴⁵ demonstrates increased rates of perinatal complications—preterm delivery as well as maternal complications, such as preeclampsia, gestational diabetes, placenta previa, and placental abruption.⁶⁴⁶ It is not possible to separate risks related to assisted reproductive technology from those caused by underlying reproductive pathology, or from the medical condition requiring delivery. These separate mechanisms of disease may operate alone or in conjunction with uterine overdistention to activate the components of the common pathway.⁶⁴⁷

PLACENTAL PATHOLOGIC CONDITIONS

Histologic Chorioamnionitis

A large body of research points toward the choriodecidua as a major site of inflammatory processes linked to PTB.^{139,514,648,649} In the setting of silent chorioamnionitis, inflammatory cytokines and chemokines, released as a result of engagement of TLRs, lead to recruitment of inflammatory cells such as macrophages, dendritic cells, and neutrophils, with the final purpose of killing the invading pathogens and halting their spread into the amniotic fluid and to the fetus.^{438,648} The leukocytes invading the chorion and amnion are maternal in origin.⁶⁵⁰ The process of inflammatory cell migration into the decidual and fetal membrane tissue is tightly controlled and involves chemotactic factors (chemokines) and cell adhesion molecules (e.g., selectins, integrins). The resultant microenvironment is rich in inflammatory mediators that induce tissue damage and result in cytokine and chemokine translocation in the amniotic fluid. Nitric oxide, vascular endothelium growth factor, and angiopoietins seem to be involved in the process of cytokine transfer across fetal membranes.^{648,651}

The inflammatory events occurring in the choriodecidua and fetal membranes are important because they could lead to premature activation of myometrial contractility and PTB through synthesis and release of free radicals, prostaglandins, and metalloprotease.^{489,652,653} Based on these observations, it is reasonable to assume that the development of a maternal inflammatory response (deciduitis) has some diagnostic potential, even if the process at the time of evaluation is subclinical.

Examination of the placenta has been the first step in pathologically classifying the wide range of clinical phenotypes linked to PTB (e.g., infection, abruption, hypoxia) and poor neurodevelopmental outcome of the neonate. A significant focus has been on antenatal inflammatory processes.⁶⁵⁴⁻⁶⁵⁶ The proximity of the placenta to the fetus, and their common embryologic origin have facilitated a significant number of studies that linked placental inflammatory lesions to short- and long-term neonatal outcomes such as cerebral palsy.⁶⁵⁷ The major drawback is that pathologic examination of the placenta is possible only after birth. As a result, histologic biomarkers are irrelevant during the antenatal period, because they do not allow initiation of therapies meant to prevent either PTB or adverse neonatal outcomes. Their overall usefulness is for postnatal counseling and research purposes.

Pathologic examination of the placenta has a further limitation: the relatively large subjectivity in interpretation of

histologic findings. First, the inflammatory lesions responsible for similar outcomes are characterized by a high degree of heterogeneity and poor to moderate intraoperator and interoperator variability.⁶⁵⁸ Second, the intricacy and redundancy of biologic processes responsible for cellular and tissue injury might lead to identical pathologic footprints in the context of distinctive triggers. Third, a mild degree of histologic chorioamnionitis may occur after normal labor at term, without pathologic consequences for the newborn.^{656,659}

Placental Abruption

Placental abruption represents hemorrhage into the decidua basalis, with complete or partial separation of the placenta from its implantation site.⁴³² The incidence of placental abruption varies from 0.5% to 2%, based on the clinical definition and the criteria applied to characterize its intensity.^{427,660} The peak rate of abruption is at 24 to 27 weeks of gestation,⁶⁶¹ with an occurrence of PTB as high as 40% (RR = 3.9; 95% CI, 3.5 to 4.4). The high rate of abruption-related perinatal mortality, calculated to be approximately 119 in 1000 births, is heavily confounded by prematurity.⁶⁶² In addition, the abruption-derived prematurity may have long-term consequences for the surviving infants (e.g., hypoxic ischemic encephalopathy, intraventricular hemorrhage, bronchopulmonary dysplasia, cerebral palsy).

The classic clinical presentation of abruption manifests as vaginal bleeding, uterine contractions, or abnormal fetal heart rate, or a combination of these. A challenging situation is a *concealed* abruption, when bleeding is not clinically observable. In this situation, a diagnosis of placental abruption can be established on the basis of fresh macroscopic or histologic examination of the placenta.⁴²⁸ The converging point between abruption and intra-amniotic infection is histologic chorioamnionitis. The acute lesions of histologic chorioamnionitis are frequently associated with evidence of abruption (hematoma, fibrin deposition, compressed villi, hemosiderin-laden histiocytes).⁴²⁷ The key histologic finding in placental abruption is hemorrhage in the decidua basalis,⁴³² which is thought to result from pathologic processes damaging the vascular endothelium at the maternal-fetal interface.⁴³³ Important to understanding the relationship between placental abruption and PTB is that decidual hemorrhage is a risk factor for preterm contractions and pPROM.⁶⁶³ This could be the consequence of bleeding-induced neutrophil infiltration, activation of MMPs, and prostaglandin synthesis.⁶⁶⁴ A comprehensive description of the molecular mechanisms and pathways governing the process of placental abruption-induced PTB was presented earlier.

Placenta Previa

A diagnosis of placenta previa is established when the placenta is inserted into the lower uterine segment and partially or entirely covers the cervix.⁶⁶⁵ Placenta previa complicates about 0.3% to 0.8% of pregnancies and is one of the most frequent causes of painless bleeding during the second half of gestation.^{665,666} Risk factors for placenta previa include a history of prior cesarean delivery, uterine surgery, termination of pregnancy, smoking, advanced maternal age, multiparity, drug abuse, and multiple gestations.⁶⁶⁵ Antepartum bleeding is a strong predictive risk factor for PTB. In such clinical scenarios, over 50% of the women are delivered before term.⁶⁶⁷ The median gestational age of the first episode of bleeding is approximately 30 weeks, with a median interval of 20 days between the first bleeding episode and delivery.⁶⁶⁷

The pathophysiology of bleeding in placenta previa includes tearing of the placental attachment over the lower uterine segment or the internal os of the cervix. Bleeding is augmented by the inability of the myometrial fibers of the lower uterine segment to contract and thereby close the bleeding vessels. A variety of regulatory molecules play functional roles in controlling the process of trophoblast invasion during implantation and placentation.⁶⁶⁸⁻⁶⁷⁰ These include vasoactive and cell surface proteins, proteases, cytokines, chemokines, and growth factors.⁶⁷⁰ The underlying cause of the excessive myometrial penetration that characterizes placenta accreta, increta, or percreta accompanying placenta previa remains largely unknown.⁶⁶⁵ Excessive trophoblast invasion can trigger profound vaginal or intraperitoneal bleeding. Recent data suggest that a lower systemic level of free VEGF and a switch of the interstitial extravillous trophoblasts to a metastable cell phenotype characterize placenta previa with excessive myometrial invasion and bleeding.⁶⁷¹ The local hemostatic milieu of the human decidua plays an important role in generating uterine contractions and amplification of bleeding through mechanisms that are similar to those involved in placental abruption.

Other Placental Abnormalities

Umbilical cord abnormalities, such as single umbilical artery, varices and aneurysms, thrombosis of umbilical vessels, hematoma, abnormal insertion of the blood vessels, and excessive coiling, knots, and entanglement of the cords, in monoamniotic twin pregnancies can be associated with abnormal fetal growth, development, and behavior that can contribute to premature delivery.⁶⁷²⁻⁶⁷⁶ Placental pathologic conditions previously associated with PTB include gestational trophoblastic diseases,

vascular tumors (chorangioma, teratoma), accessory lobes, and vasa previa.⁶⁷⁷⁻⁶⁷⁹ The vast majority of the literature describing these umbilical cord and placental abnormalities is descriptive. Many cord and placental abnormalities occur in association with complex congenital anomalies, chromosomal aneuploidy, IUGR, hydrops, histologic chorioamnionitis, or abruption, or as complications of multifetal gestation. On the basis of existing knowledge, it is difficult to determine if pathophysiologic events characteristic for each abnormality are independently responsible for triggering PTB, or if premature delivery is the result of several overlapping factors.

Summary

Preterm labor, pPROM, and cervical insufficiency are syndromes caused by various pathologic processes leading to decidual activation, increased myometrial contractility, cervical remodeling, and membrane rupture. The clinical presentation depends on the nature and timing of the insults affecting the various components of the uterine common pathway of parturition. The revised classification system for PTB depends largely on clinical phenotype. Although it requires a paradigm shift to think of preterm parturition as a syndrome, it should facilitate a more accurate comparison of causes of PTB in various populations and with regard to trends over time. The revised classification system has important implications for understanding the biology of preterm parturition, as well as its diagnosis, treatment, and prevention.

Preterm Labor and Birth

HYAGRIV N. SIMHAN, MD, MS | VINCENZO BERGHELLA, MD | JAY D. IAMS, MD

Preterm birth is the principal unsolved problem in perinatal medicine. Nearly 15 million infants were born prematurely in 2010¹—more than one in 10 of all births. The majority of premature births—60%—occur in south Asia and sub-Saharan Africa. In 2010, the United States ranked sixth in the world for the number of babies (517,443) born preterm. Advances in care have improved outcomes for preterm infants, but prematurity is still the most common underlying cause of perinatal² and infant morbidity and mortality³ in developed nations. Consequences of preterm birth for surviving infants extend across the life course and include neurodevelopmental, respiratory, gastrointestinal, and other morbidities. The rate of preterm birth in the United States rose by more than one third between 1980 and 2006, even as the perinatal and infant mortality rates decreased.

Preterm birth is a unique condition, defined by time rather than a distinct phenotype or pathology. The duration of pregnancy at birth reflects two major correlates of maternal and fetal health: (1) whether the birth was occasioned by a normal or an aberrant pathway, and (2) whether the infant has reached maturity at birth. Infants born at full term after the spontaneous onset of normally progressive labor are most likely to be healthy and mature. A process that leads to birth before the fetus has fully matured suggests that continued pregnancy may carry some health risk for the mother or the fetus, or both. Thus, premature parturition may provide a health advantage over continued pregnancy for the mother and infant and yet also compromise an immature infant's health.

Classifications of preterm birth may advance biologic understanding, define clinical phenotypes, and aid in designing trials and interpreting their data. The most commonly used categories are based on clinical presentation as either a *spontaneous* or an *indicated* preterm birth. Spontaneous preterm births are preceded by activation of one or more steps of the parturitional process (cervical ripening, membrane and decidual activation, and coordinated uterine contractility [see Chapter 5]). Clinical presentations of spontaneous preterm delivery include preterm labor with intact membranes, preterm premature rupture of membranes (pPROM), preterm cervical effacement or insufficiency, early stillbirth, and some instances of uterine bleeding of uncertain origin. Indicated preterm births are medically caused or initiated and are actively undertaken in response to maternal or fetal compromise. This categorization scheme has fallen under scrutiny in recent years. In this chapter, we will address some limitations to this approach and alternative classification systems that reflect a modern understanding of clinical presentation and biology. The physiology and pathophysiology of preterm parturition are discussed in Chapters 5 and 39. This chapter addresses the overall problem of preterm

birth, including the epidemiology and burden of disease for all preterm neonates and specific care for the clinical syndrome of preterm labor. Cervical insufficiency, pPROM, and stillbirth are discussed in Chapters 41, 42, and 45, respectively. Newborn and childhood complications of preterm birth are discussed in Chapter 72.

The Problem of Preterm Birth

DEFINITIONS

A birth at less than 245 days after conception, or, by menstrual dating, at or after 20 and before 37 weeks (259 days) of gestation from the first day of the last normal menstrual period, is commonly defined as *preterm* or *premature*. Births at or after 37 0/7 weeks are considered to be term. Infants who weigh less than 2500 g at birth, regardless of gestational age, are designated as low birth weight (LBW). Infants who weigh less than 1500 g are called very low birth weight (VLBW), and those below 1000 g are extremely low birth weight (ELBW). Preterm and LBW infants have in the past been considered together, but advances in the accuracy of pregnancy dating increasingly allow outcomes related to gestational age to be distinguished from outcomes related to birth weight. This is important, because perinatal and infant morbidities vary substantially according to age and maturity as well as weight.⁴ Obstetric data are reported by gestational age. Traditionally reported by birth weight, newborn and infant data are increasingly described by gestational age as well.⁵

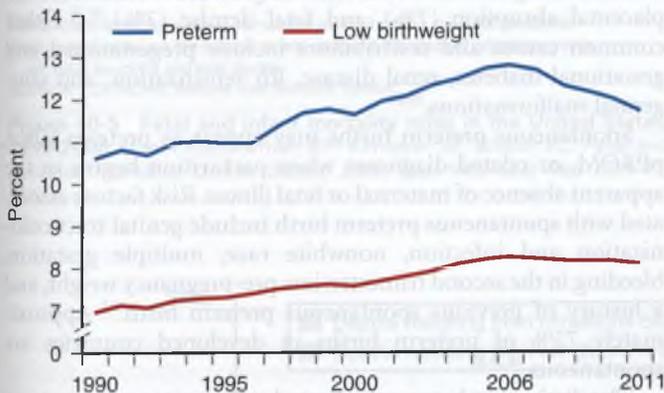

Both lower and upper boundaries of preterm are currently under scrutiny. The lower boundary between preterm birth and spontaneous abortion was historically based on maternal perception of fetal movement, and it is commonly defined as 20 weeks in the United States, but it varies between states² and between countries. The 20-week boundary is challenged by data showing that pregnancies ending between 16 and 20 weeks have a pathophysiology similar to that of births at 20 to 26 weeks, and that that pathophysiology confers a similarly increased risk for preterm birth between 16 and 36 weeks in future pregnancies, regardless of whether the fetus was liveborn or stillborn.^{6,7}

Similarly, the disadvantages of an upper boundary based on age rather than maturity have become increasingly apparent. Fetal and neonatal maturation are not complete at 37 weeks. Infants born at 37 and even 38 weeks display clinical features of immaturity more commonly than those born at 39 weeks, and they often suffer related short- and long-term morbidity.^{8,10} Current practice acknowledges the less-than-complete maturity of 37- to 38-week infants by adoption of the categories shown in Table 40-1.

TABLE 40-1 Gestational Age Terminology

Description	Gestational Age (wk)
Preterm	<37
Late preterm	34 0/7 to 36 6/7
Term	37 0/7 to 41 6/7
Early term	37 0/7 to 38 6/7
Full term	39 0/7 to 41 6/7
Post-term	≥42

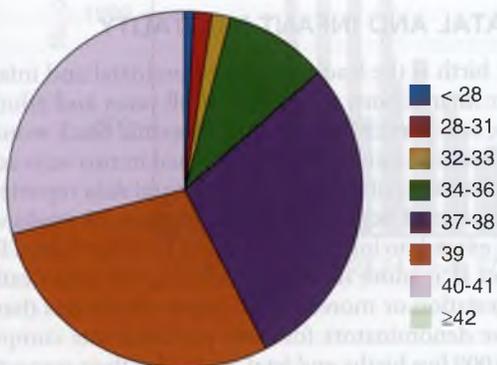

Figure 40-2 Chart showing relative frequency of births by gestational age intervals in weeks. (Data from Martin JA, Hamilton BE, Ventura SJ, et al: *Births: final data for 2010*, Natl Vital Stat Rep 61:1–72, 2012.)

Incidence of Preterm Birth

Births before 37 weeks in the United States increased annually from 9.4% in 1980 to a peak of 12.8% in 2006. The rate has since fallen each year to just under 11.99% in 2010.¹¹ Preliminary data from 2011 show a further decline to 11.72% (Fig. 40-1).¹²

More than 70% of preterm births occur between 34 and 36 weeks (Fig. 40-2). Although these late preterm infants

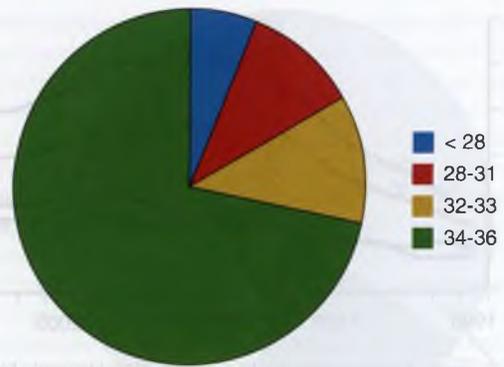

Figure 40-3 Gestational age distribution of all preterm births (PTBs).

- 16% of preterm births before 32 weeks
- 13% of PTBs at 32 to 33 weeks
- 71% of PTBs at 34 to 36 weeks

(Data from Martin JA, Hamilton BE, Ventura SJ, et al: *Births: final data for 2010*, Natl Vital Stat Rep 61:1–72, 2012.)

experience significant morbidity, most perinatal mortality and serious morbidity occurs among the 16% of preterm infants (<3.5% of all births) who are born before 32 weeks' gestation, commonly called *very preterm births* (Fig. 40-3).

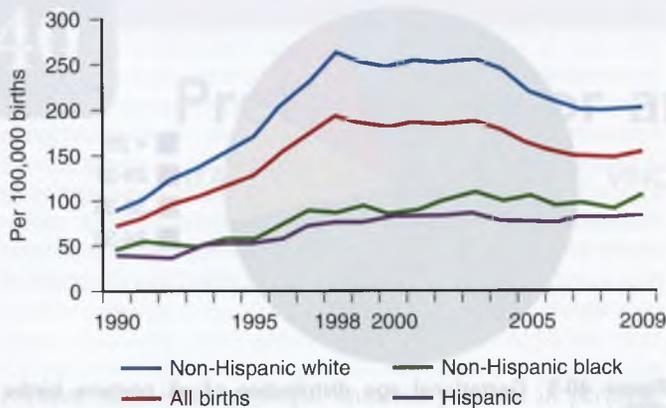

Ascertainment of Preterm Birth and Low Birth Weight

Reported rates of preterm birth vary according to the gestational age boundaries chosen and whether and when prenatal ultrasound was employed. Definitions of preterm birth vary internationally and within the United States.² The lower boundary of gestational age is 20 weeks in most of the United States, but it varies from 20 to 24 weeks in reports from other countries.^{13,14} The definition of LBW is universally accepted as a birth weight of less than 2500 g, but the lower boundary ranges from 350 to 500 g, is variably applied, and is often affected by cultural and religious beliefs and whether the infant shows signs of life. Low birth weight is no longer considered an appropriate surrogate for preterm birth in developed countries.

Determination of gestational age by ultrasound measurement of fetal structures has greater accuracy than other methods when used in the first 12 to 20 weeks of pregnancy. As access to and quality of prenatal ultrasound services has increased, the distribution of gestational age has shifted earlier, reducing the number of post-term births and providing a corresponding increase in births before 37 weeks of gestation.

Changes in the Incidence of Preterm Birth

Regardless of the definitions chosen and methods used to determine gestational age, the incidence of preterm birth increased in developed countries between 1990 and 2006. The rise was caused by the rising number of multifetal pregnancies resulting from fertility care, and by practice changes favoring delivery over expectant management in the care of complicated late preterm singleton births. The U.S. preterm birth rate rose in singleton pregnancies from 7.3% in 1990 to a peak of 9.2% in 2006,¹¹ but it has since declined annually as perinatal and infant morbidities associated with late preterm birth were recognized and reported.¹⁵ The frequency of higher-order multifetal gestations related to fertility therapies has also declined significantly since 1998, but only in non-Hispanic white women.^{11,16} The rate of twin pregnancies has continued to increase (Fig. 40-4).

NOTE: Triplet/+ births are births in triplet and higher order multiple deliveries.
SOURCE: CDC/NCHS, National Vital Statistics System.

Figure 40-4 Triplet and higher-order birth rates by race and Hispanic origin of mother, United States, 1990-2009. (From Martin JA, Hamilton BE, Ventura SJ, et al: *Births: final data for 2010*, Natl Vital Stat Rep 61(1):1-72, 2012.)

BOX 40-1 AMERICAN SOCIETY OF REPRODUCTIVE MEDICINE RECOMMENDATIONS TO LIMIT HIGHER-ORDER MULTIFETAL GESTATIONS

- Use of single-embryo transfer (SET) in in vitro fertilization (IVF) cycles to reduce twinning
- Use of low-dosage gonadotropins in ovulation-induction insemination cycles
- Moving from low-dosage ovulation-induction drugs directly to IVF cycles rather than to higher-dosage induction cycles
- Extensive education and counseling on the risks of multifetal pregnancies and prematurity for families, professionals, and the public

In response to the increased number of preterm infants born from multifetal pregnancies after fertility treatments, the American Society of Reproductive Medicine (ASRM) issued guidelines that curbed the rise. In 2011, the ASRM issued recommendations to achieve successful pregnancies while reducing the risk for preterm birth (Box 40-1).¹⁷ The rise in preterm births related to fertility therapies is also discussed in Chapter 39.

Clinical Presentations of Preterm Birth

Preterm birth has been called multifactorial because of the numerous obstetric and medical conditions that accompany it. Traditional obstetric taxonomy has not distinguished the clinical presentations of preterm parturition (e.g., preterm labor, pPROM, cervical insufficiency) from causative mechanisms such as infection, hemorrhage, uterine distention, trauma, or fetal compromise, or from risk factors (e.g., multiple gestation, prior preterm birth, preeclampsia, abruptio placentae, placenta previa, fetal growth restriction, maternal diabetes, hypertension, pyelonephritis). Designation of clinical presentations (e.g., preterm labor and pPROM) as separate pathogenic entities has impaired understanding of the pathways leading to preterm

birth. It is more useful to consider preterm birth as preterm pathologic initiation of one or more steps in the parturitional process, or as a means to resolve maternal or fetal risk (or both) related to continuing the pregnancy.

The concept of *spontaneous* versus *indicated* preterm birth offered by Meis and colleagues is consistent with this distinction.¹⁸ Indicated preterm deliveries account for about 25% of preterm births in the United States, and they follow medical or obstetric conditions that could create undue risk for the mother (e.g., maternal sepsis, hypoxia), the fetus (e.g., poorly controlled maternal diabetes, intrauterine growth restriction), or both (e.g., maternal hypertension, placenta previa or abruption) if the pregnancy were to continue. The most common diagnoses leading to indicated preterm birth are preeclampsia (40%), nonreassuring fetal status (25%), fetal growth restriction (10%), placental abruption (7%), and fetal demise (7%).^{18,19} Other common causes and contributors include pregestational and gestational diabetes, renal disease, Rh sensitization, and congenital malformations.^{20,21}

Spontaneous preterm births may appear as preterm labor, pPROM, or related diagnoses when parturition begins in the apparent absence of maternal or fetal illness. Risk factors associated with spontaneous preterm birth include genital tract colonization and infection, nonwhite race, multiple gestation, bleeding in the second trimester, low pre-pregnancy weight, and a history of previous spontaneous preterm birth.²² Approximately 75% of preterm births in developed countries are spontaneous.^{18,23,24}

The distinction between indicated and spontaneous preterm births is not always clear, but the terms are useful as a framework for evaluation of trends and causes of preterm delivery.

Consequences of Preterm Birth

(See also Chapter 72.)

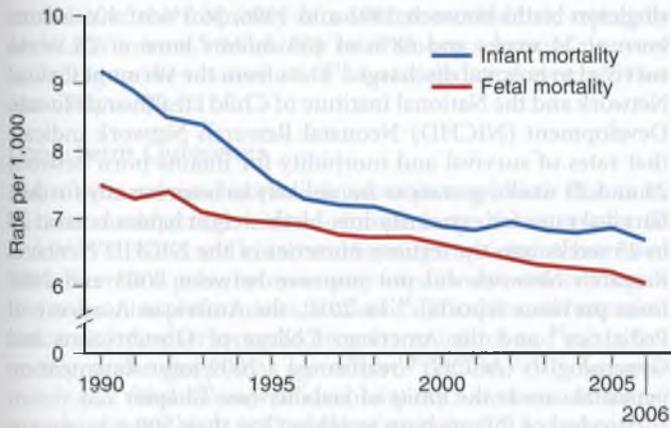

PERINATAL AND INFANT MORTALITY

Preterm birth is the leading cause of perinatal and infant mortality for infants born to women of all races and ethnic backgrounds, and particularly for non-Hispanic black women.^{3,25}

The *perinatal* mortality rate is defined in two ways according to the boundaries of the fetal and neonatal data reported.² Perinatal definition **I** begins with fetal deaths at 28 weeks of gestation and extends to infant deaths at less than age 7 days. Perinatal definition **II** is more inclusive, including all fetal deaths at 20 weeks' gestation or more, and all infant deaths less than age 28 days. The denominators for both perinatal rate computations are per 1000 live births and fetal deaths for their respective time periods.

Perinatal definition **I** is most useful when data are compared between states, whereas definition **II** more accurately represents the combined effects of prenatal, intrapartum, and neonatal care. The *infant* mortality rate is the number of deaths of live-born infants before 1 year of age per 1000 live births; stillbirths are not included in the denominator. Rates of fetal, perinatal, and infant mortalities have declined since 1990² (Fig. 40-5).

Fetal deaths account for more than half of perinatal deaths and are almost as frequent as infant deaths. In 2005, there were 25,894 fetal deaths (51.6% between 20 and 27 weeks, and 48.7% after 28 weeks), and 18,782 neonatal deaths (79.9% before 7 days, and 20.1% between 7 and 28 days after birth) (Fig. 40-6).²⁶

NOTE: Infant mortality rates are the number of infant deaths per 1,000 live births. Fetal mortality rates are the number of fetal deaths at 20 weeks of gestation or more per 1,000 live births and fetal deaths. SOURCE: CDC/NCHS, National Vital Statistics System.

Figure 40-5 Fetal and infant mortality rates in the United States, 1990-2006. (From MacDorman MF, Kirmeyer SE, Wilson EC: *Fetal and perinatal mortality, United States, 2006*, Natl Vital Stat Rep 60:1-11, 2012.)

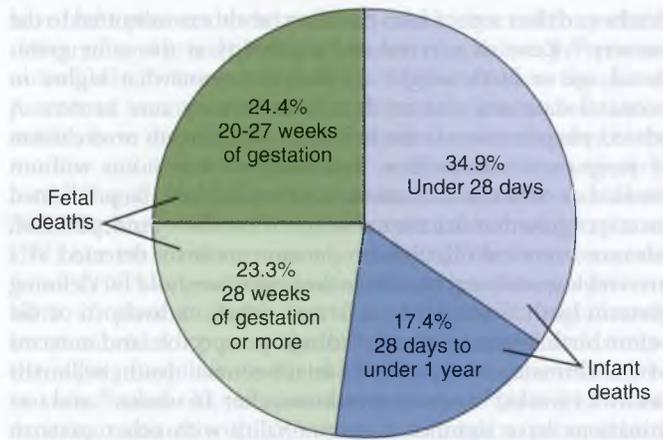

Figure 40-6 Relative magnitudes of fetal deaths at 20 weeks of gestation or more, and of infant deaths: United States, 2005. (From MacDorman M, Kirmeyer S: *The challenge of fetal mortality*, NCHS Data Brief (16):1-8, 2009.)

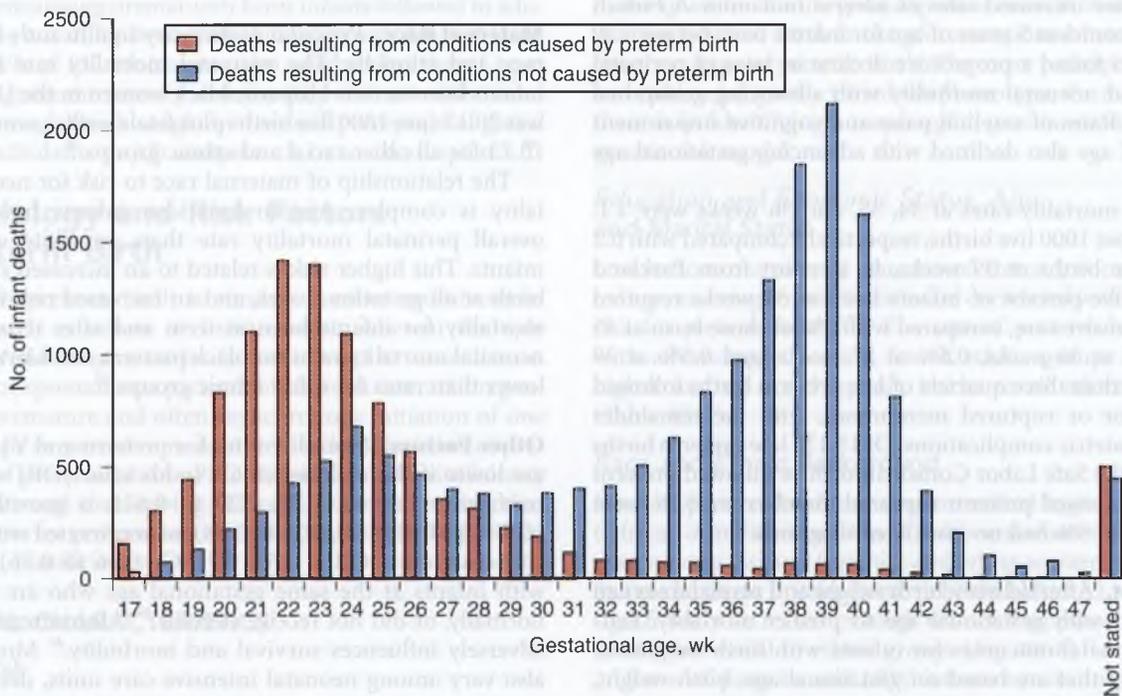

Figure 40-7 Relative contribution of prematurity-related conditions to overall infant mortality in 2004. Infant mortality increases markedly as gestational age declines. (From Callaghan WM, MacDorman MF, Rasmussen SA, et al: *The contribution of preterm birth to infant mortality rates in the United States*, Pediatrics 118:1566-1573, 2006.)

Preterm birth is the most frequent cause of infant mortality, accounting for at least a third of infant deaths (Fig. 40-7).

Despite a rising rate of preterm birth, fetal and infant mortality rates declined between 1990 and 2004. The decline in perinatal mortality was related primarily to a decrease in fetal deaths after 28 weeks' gestation, primarily because of a substantial decline in births and stillbirths after 40 weeks and because of an increase in indicated preterm births during this time.

Factors Affecting Perinatal, Infant, and Childhood Mortality and Morbidity

(See also Chapter 72.)

Data Collection. Reports of survival and morbidity vary according to the denominator employed. Obstetric data sets include all living fetuses at entry to the obstetric suite,²⁷ whereas neonatal data sets exclude intrapartum and delivery room

deaths and thus report rates based on newborns admitted to the nursery.²⁸ Rates of survival and morbidity at the same gestational age or birth weight are therefore somewhat higher in neonatal data sets and in data from tertiary care centers. A related phenomenon is the influence of inclusion or exclusion of pregnancy terminations. Terminations may occur without medical or obstetric indication, but they may also be predicated on severe growth restriction, absence of amniotic fluid, pPROM, advanced cervical dilation, or a major anomaly detected at a pre-viable gestational age above the lower threshold for defining preterm birth. Some of these fetuses either are liveborn or die before birth. From a pathophysiologic perspective, and in terms of the ultimate consequence of fetal/neonatal death, stillbirths before 24 weeks,²⁹ spontaneous losses after 16 weeks,³⁰ and terminations have significant commonality with other preterm births.⁷ Inclusion of stillbirths and pregnancy terminations will have a major influence on preterm birth frequency estimates and preterm birth-attributable mortality.

Gestational Age. Gestational age is the strongest pre-delivery predictor of survival and morbidity for the infant. The perinatal mortality rate is strongly related to gestational age at birth, especially between 22 and 32 weeks.³¹ Although mortality declines sharply after 32 weeks, infants born between 32 and 37 weeks still have increased rates of adverse outcomes. A French study of outcomes at 5 years of age for infants born between 30 and 34 weeks found a progressive decline in rates of perinatal mortality and neonatal morbidity with advancing gestational age at birth. Rates of cerebral palsy and cognitive impairment at 5 years of age also declined with advancing gestational age at birth.³¹

Neonatal mortality rates at 34, 35, and 36 weeks were 1.1, 1.5, and 0.5 per 1000 live births, respectively, compared with 0.2 per 1000 live births at 39 weeks, in a report from Parkland Hospital.¹⁵ Five percent of infants born at 34 weeks required neonatal intensive care, compared with 2% of those born at 35 weeks, 1.1% at 36 weeks, 0.6% at 37 weeks, and 0.5% at 39 weeks. More than three quarters of late preterm births followed preterm labor or ruptured membranes, with the remainder caused by obstetric complications. Of 15,136 late preterm births reported by the Safe Labor Consortium, 30% followed preterm labor, 32% followed preterm ruptured membranes, 32% were iatrogenic, and 6% had no associated diagnosis.³²

Birth Weight. After delivery, birth weight and neonatal sex can be combined with gestational age to predict mortality. Estimates of neonatal outcomes for infants with birth weights of 400 to 1000 g that are based on gestational age, birth weight, sex, treatment with antenatal steroids, and multiple versus singleton gestation are available from the NICHD website (www.nichd.nih.gov/about/org/der/branches/ppb/programs/epbo/Pages/epbo_case.aspx).³³

Very-Low-Birth-Weight Infants. Regionalized care for high-risk mothers and infants, antenatal fetal treatment with glucocorticoids, neonatal administration of exogenous pulmonary surfactant, and improved ventilator technology have produced survival rates that now exceed 90%, and survival without major morbidity in more than 80% of infants born at 28 weeks' gestation or weighing 1000 g at birth.

Extremely-Low-Birth-Weight Infants. Increasing attention has been paid to infants born at the peri-viable thresholds of age (22 to 25 weeks) and weight (400 to 600 g). In a study of

singleton births between 1991 and 1996, 56.1% of 406 infants born at 24 weeks and 68% of 454 infants born at 25 weeks survived to hospital discharge.³¹ Data from the Vermont Oxford Network and the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network indicate that rates of survival and morbidity for infants born between 23 and 25 weeks' gestation are unlikely to improve any further. Survival rates for extremely-low-birth-weight babies born at 23 to 25 weeks into the tertiary nurseries of the NICHD Neonatal Research Network did not improve between 2003 and 2007 from previous reports.³⁴ In 2010, the American Academy of Pediatrics³⁵ and the American College of Obstetricians and Gynecologists (ACOG)³⁶ reaffirmed a 2002 joint statement on perinatal care at the limits of viability (see Chapter 72).

Survival of infants born weighing less than 500 g is uncommon. A Vermont Oxford Network study reported that 48% of 4172 infants with birth weights between 401 and 500 g and a mean gestational age of 23.3 weeks died in the delivery room.³⁷ Among 17% who survived to hospital discharge, the mean gestational age was more than 25 weeks, and significant morbidity was universal. Notably, the risk for neonatal mortality does not exceed 50% for babies of any ethnicity or race until the gestational age at birth is less than 24 weeks and birth weight is less than 500 g.

Maternal Race. Perinatal deaths vary significantly by maternal race and ethnicity. The perinatal mortality rate in 2004 for infants born to non-Hispanic black women in the United States was 20.17 (per 1000 live births plus fetal deaths), compared with 10.73 for all other racial and ethnic groups.²⁶

The relationship of maternal race to risk for neonatal mortality is complex. African-American infants have a greater overall perinatal mortality rate than do white or Hispanic infants. This higher risk is related to an increased risk for stillbirth at all gestational ages, and an increased risk for neonatal mortality for infants born at term and after term. However, neonatal mortality rates for black preterm and LBW infants are lower than rates for other ethnic groups.³⁸

Other Factors. Mortality rates for preterm and VLBW infants are lower if the child is female (odds ratio [OR] = 0.42; 95% confidence interval [CI], 0.29 to 0.61), is growth restricted (OR = 0.58; 95% CI, 0.38 to 0.88), or was treated with antenatal corticosteroids (OR = 0.52; 95% CI, 0.36 to 0.76), compared with infants at the same gestational age who are male, grew normally, or did not receive steroids.^{39,40} Intrauterine infection adversely influences survival and morbidity.⁴⁰ Mortality rates also vary among neonatal intensive care units, despite similar care practices and patient demographics.⁴¹ Therefore, local statistics should be combined with data from the NICHD website³³ when counseling patients.

Perinatal Morbidity

Preterm infants are at risk for specific diseases related to the immaturity of various organ systems and the cause and circumstances of preterm birth. Common complications in premature infants include respiratory distress syndrome, intraventricular hemorrhage (IVH), bronchopulmonary dysplasia, patent ductus arteriosus, necrotizing enterocolitis (NEC), sepsis, apnea, and retinopathy of prematurity.

The frequency of major morbidity rises as gestational age decreases, especially before 32 weeks. There is wide geographic

variation in the frequency of neonatal morbidities, especially for VLBW infants.⁴¹ Morbidity rates among survivors also vary according to the occurrence of adverse neonatal events.⁴² (See also Chapter 72.)

Long-Term Outcomes

Major neonatal morbidities related to preterm birth that carry lifetime consequences include chronic lung disease, grades III and IV IVH, NEC, and vision and hearing impairment. Increased rates of cerebral palsy, neurosensory impairment, reduced cognition and motor performance, academic difficulties, and attention deficit disorders are reported for preterm infants and rise in frequency as the gestational age at birth declines.^{27,43-45} Approximately one third of cases of cerebral palsy have been attributed to early preterm birth (<32 weeks of gestation).⁴⁶ A study of 308 surviving infants born before 25 weeks found that almost all had some disability at age 6 years: 22% had severe neurocognitive disabilities (cerebral palsy, IQ > 3 standard deviations below the mean, blindness, or deafness), 24% had moderate disability, 34% had mild disability, and 20% had no neurocognitive disability.⁴⁵

Health care workers regularly overestimate the likelihood and severity of neurologic morbidity in infants born before term.⁴⁷ This is important, because these expectations may adversely influence outcomes.⁴⁸

Self-esteem among prematurely born infants followed to adolescence does not differ from that among persons born at term. Although 24% of 132 adolescents who weighed less than 1 kg at birth had significant sensory deficits, they did not differ from controls of normal birth weight in their self-perception of global self-worth, scholastic or job competence, or social acceptance.⁴⁹

Epidemiology and Risk Factors for Preterm Birth

Spontaneous preterm birth is similar to other multifactorial disorders, such as cancer or heart disease, wherein multiple endogenous and exogenous risk factors interact to cause disease. In the case of spontaneous preterm birth, such interaction generates the premature and often asynchronous initiation of one or more steps in parturition. As noted earlier, the clinical presentations of preterm labor, pPROM, and cervical insufficiency are indistinct and overlapping. Thus, it is not surprising that the risk factors for preterm labor are similar to those for pPROM and cervical insufficiency.

MATERNAL CHARACTERISTICS

Familial Risk

Studies showing familial risk patterns suggest that there is a heritable predisposition for preterm birth. Women whose sisters

have had a preterm birth have a 1.8-fold higher risk for preterm delivery,⁵⁰ and grandparents of women who deliver preterm are more likely to have been preterm themselves than the grandparents of women who deliver at term.⁵¹ Genetic association studies have discovered polymorphisms in several genes in the mother and the fetus associated with spontaneous preterm birth⁵²⁻⁵⁴ and LBW.⁵⁵ Gene-environment interaction was identified in a study wherein neither maternal bacterial vaginosis (BV) nor maternal carriage of an allele of the tumor necrosis factor (TNF)- α gene was associated with spontaneous preterm birth if present alone, but the combination significantly increased risk for preterm birth.⁵⁶ Another study demonstrated that a polymorphism in the interleukin (IL)-6 gene was related to an increased risk for spontaneous preterm birth in African-American women with BV but was not linked to preterm birth risk in African-American women who did not have BV or in white women regardless of BV status.⁵³ An interaction between maternal smoking and a genetic polymorphism that increases the likelihood of LBW has also been identified.⁵⁵ These studies support a role for gene-environment interactions in the pathogenesis of spontaneous preterm birth. Studies to date have employed both candidate-gene and whole-genome approaches to study DNA variants of biologically suspected genes, with limited insight into prematurity causation.⁵⁷ A major limitation in the quest to identify gene sequence variants that increase the risk for preterm birth is the aforementioned heterogeneity of the phenotype of preterm birth. The more pathophysiologically and epidemiologically varied the phenotype, the more difficulty there is in identifying a meaningful, parsimonious underlying genetic risk model.

Education and Economic Status, Age, and Marital Status

Low socioeconomic and educational status, low or high maternal age, and single marital status are correlated with an increased risk for preterm birth.^{58,59} The rate of preterm birth declines with advancing education for all ethnic groups but remains higher among non-Hispanic blacks at all educational levels (Table 40-2).

Race and Ethnic Background

Rates of preterm birth are almost twofold higher among black (African-American and Afro-Caribbean) women (16% to 18%) than among Asian, Hispanic, and white women in the United States and Great Britain. Preterm births before 32 weeks are also significantly increased in black women compared with women from other racial or ethnic groups (Fig. 40-8).¹¹

Rates of preterm and LBW infants remain higher for black women than for white, Asian, or Hispanic women, after controlling for social disadvantage⁶⁰ and education. Remarkably,

TABLE 40-2 Risk of Preterm Birth (%) by Maternal Race and Education

Years of Education	Non-Hispanic Black	Non-Hispanic White	Asian or Pacific Islander	Native American (American Indian and Eskimo)	Hispanic
<8	19.6	11.0	11.5	14.8	10.7
8-12	16.8	9.9	10.5	11.8	10.4
13-15	14.5	8.3	9.1	9.9	9.3
≥16	12.8	7.0	7.5	9.4	8.4

Data from Behrman RE, Stith Butler A, editors; Institute of Medicine Committee on Understanding Preterm Birth and Assuring Healthy Outcomes: Preterm birth: causes, consequences, and prevention, Washington, DC, 2007, National Academies Press.

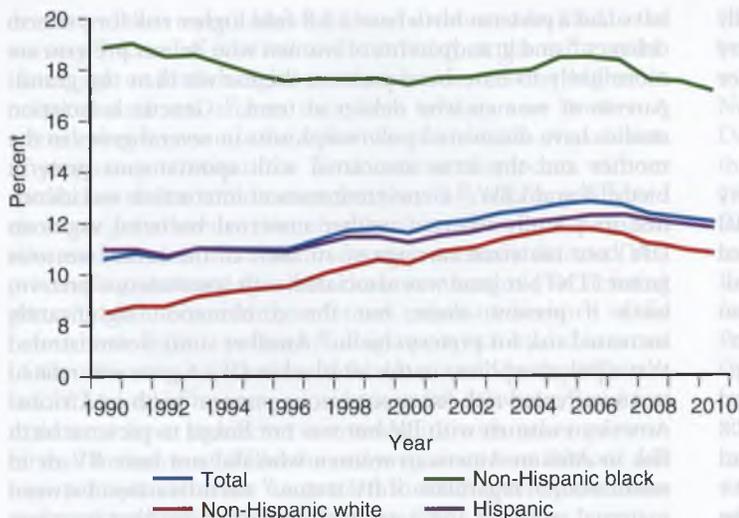

Figure 40-8 Preterm birth rates, by race and Hispanic origin: United States, 1990-2010. (From CDC/NCHS, National Vital Statistics System.)

preterm birth rates are higher for well-educated, non-Hispanic black women than for poorly educated, non-Hispanic white, Asian, or Hispanic women (see Table 40-2).

Rates of preterm birth among non-Hispanic white women are the same or lower than among non-Hispanic black women, despite increased socioeconomic risk.⁶¹ Rates of preterm delivery among black women born outside the United States are generally lower than among African-American women or among Afro-Caribbean women living in the United Kingdom,⁶² suggesting a risk that is somehow induced or enhanced by residence in the United States or Britain.

Maternal Behaviors and Environment

Maternal smoking is related to poor pregnancy outcomes such as growth restriction, placental abruption, infant mortality, and preterm birth.⁶³⁻⁶⁵ Smoking is important because of its high prevalence (20% to 25% of pregnant women smoke) and the potential for successful intervention.⁶⁶ The mechanisms by which smoking is related to preterm birth are unclear, but nicotine and carbon monoxide are vasoconstrictors that decrease uteroplacental blood flow. Smoking also affects the immune system. Neutrophil degranulation and superoxide production is increased in smokers.⁶⁷ Cytokine production after *in vivo* or *in vitro* stimulation is greater in smokers than in nonsmokers.⁶⁸ Smoking might promote preterm birth by altering the immunology of the reproductive tract. Cigarette smoking in pregnancy is associated with an increase of cervical anti-inflammatory cytokines without a commensurate increase of proinflammatory cytokines. This may have adverse effects on the host response to infection.⁶⁹ The biologic effects of smoking may differ by race. Blacks manifest a higher nicotine intake per cigarette and also a slower clearance of cotinine (the major nicotine metabolite) in response to cigarette smoking.⁷⁰

Substance abuse may be linked to preterm birth risk directly, as well as through concurrent exposure to lifestyle-related risk factors such as limited prenatal care, nutritional deficiencies, genital tract infections, and cigarette smoking. Marijuana use has not been independently related to preterm birth. Initial reports associating cocaine with preterm birth resulting from abruption may have been influenced by ascertainment bias; the

magnitude of the risk for preterm birth among cocaine users is now considered uncertain⁵ (see Chapter 67). Maternal alcohol consumption has a complex association with preterm birth, with some studies showing no relationship or even a modest reduction in the rate of preterm birth among light drinkers,^{19,71} and others confirming an increased risk related to regular and heavy alcohol intake.^{71,72}

Stress and Depression

Studies relating preterm birth risk to stress during pregnancy generally report a modest relationship, with relative risks (RR) of 1.3 to 1.4 for stressful life events such as death of a family member, loss of employment, or divorce.⁷³ Stress is often accompanied by other known risk factors, such as socioeconomic disadvantage, smoking, or African-American ethnicity. Lu and Chen found that adding stress to a statistical model of risk factors for preterm birth in 33,542 women had little effect on the observed relationship between race and preterm birth; they concluded that stressful life events, even events immediately preceding or during pregnancy, do not significantly contribute to racial and ethnic disparities in preterm birth.⁷⁴ Chronic stress may influence preterm birth risk by altering immunologic function.^{75,76} Chronic stress related to racism is a potential explanation for the disparity in preterm birth rates between African-American or Afro-Caribbean women and women of other ethnic backgrounds.⁷⁷

Depression before and during pregnancy is a risk factor for adverse pregnancy outcomes including preterm birth. Clinical depression occurs in as many as 15% to 35% of women. The reported relationship between depression and risk for preterm birth is modest (less than twofold).^{78,79} Risk factors for depression are similar to those related to preterm birth and include non-Hispanic black race, young age, limited education, and exposure to stressful life events.⁸⁰ (See also Chapter 66.)

Maternal Physical Activity

Work and physical activity have been studied in relationship to risk for preterm birth, with conflicting results. Although rates of preterm birth are lower in women who are employed than in those who are unemployed, the risk among employed women

may be increased by work that is physically demanding or stressful. In a European study, the risk for preterm birth was not related to employment per se but was increased among women who worked more than 42 hours per week (OR = 1.33; 95% CI, 1.1 to 1.6) or who were required to stand for more than 6 hours per day (OR = 1.26; 95% CI, 1.1 to 1.5).⁸¹ Work while standing was associated with preterm birth (OR = 1.56; 95% CI, 1.04 to 2.60) in a study from Guatemala,⁸² but this finding was not observed by researchers from North Carolina, where the risk for preterm birth was higher in women who worked nights than in those who worked days.⁸³ There are no data to relate specific work tasks to preterm birth risk.

Coitus during pregnancy commonly leads to a transient increase in uterine activity⁸⁴ and is an opportunity to acquire genital tract infections, but self-reported sexual activity was not related to the risk for preterm birth in a study of women with a prior preterm birth.⁸⁵ The practice of douching before or during pregnancy has been suggested to increase the risk for preterm birth, but the association is confounded by the higher prevalence of BV in African-American women, who are more likely to practice douching.^{86,87}

Nutritional Status

The risk for preterm birth has been related to maternal nutritional status during pregnancy, as measured by body mass index (BMI), nutritional intake, and serum markers of nutritional status.⁸⁸⁻⁹¹ Low maternal pre-pregnancy weight and BMI have consistently been associated with spontaneous preterm birth. After adjusting for confounders, Moutquin noted that women with a BMI of less than 20 were nearly four times as likely as heavier women to deliver a spontaneous preterm birth.⁹² Indeed, the relationship between low pre-pregnancy BMI and spontaneous preterm birth is consistent (OR = 1.7 to 3.9) among North American whites,⁹² African-Americans,⁹³ and urban Latinas.^{94,95} Low BMI also modifies the contribution of low pregnancy weight gain to the risk for preterm birth.⁹⁶ Compared with normal-weight women with adequate weight gain, the risk for spontaneous preterm birth at less than 37 weeks is sixfold greater for underweight women with poor gain and threefold greater for normal-weight women with poor gain.

Women with low serum iron, folate, or zinc levels have more preterm births than those with measurements in the normal range.⁹⁰ A relationship between folate deficiency and preterm birth was suggested originally in 1944 by Callender, who reported an increased incidence of prematurity in women with megaloblastic anemia in pregnancy.⁹⁷ Since that time, a number of studies have explored whether maternal folate status is linked with preterm birth. Investigations of dietary, supplemental, or biomarker folate in relationship to preterm birth have produced conflicting results, probably because of varying ranges and timing of folate assessment, ascertainment of gestational age, and population characteristics. Interestingly, among low-income women, low dietary folate has been shown to increase the risk for preterm birth threefold. The mechanisms by which maternal nutritional status might influence preterm birth risk are unclear but may involve effects on uterine blood flow or resistance to infection.^{98,99}

Infections

(See also Chapter 51.)

Genital Tract Infection and Colonization. The risk for preterm birth related to infection is sometimes considered to

be a risk that is acquired during pregnancy—an accurate concept for extragenital infections such as pyelonephritis or pneumonia, but one that does not fully apply to genital tract colonization and infection. Pre-pregnancy colonization of the upper and lower genital tract and the maternal immune response to that colonization are increasingly recognized as important aspects of infection-related risk for preterm birth. The correlation between genital tract infection and preterm birth has long been recognized,¹⁰⁰ but the pathways by which infection leads to preterm birth have not, until recently, been understood to involve activation of the innate immune system. Microorganisms are recognized by pattern-recognition receptors such as Toll-like receptors, which, in turn, elicit the release of inflammatory chemokines and cytokines such as IL-8, IL-1 β , and TNF- α . During intrauterine infection, microbial products and proinflammatory cytokines stimulate the production of prostaglandins and other inflammatory mediators as well as matrix-degrading enzymes. Prostaglandins stimulate uterine contractility, and degradation of extracellular matrix in the fetal membranes leads to pPROM.¹⁰¹ The contribution of infection to preterm birth has been estimated to be 25% to 40% on the basis of microbiologic studies, but this may be an underestimate, because intrauterine infection is difficult to detect with conventional culture techniques. For example, molecular microbiologic studies based on the polymerase chain reaction have revealed evidence of *Ureaplasma urealyticum* in amniotic fluid samples with negative cultures.^{102,103}

Intrauterine colonization and infection can occur in the decidua, the chorioamniotic space, or the amniotic cavity. Because microbial colonization is more common in the chorioamnion than in the amniotic cavity, amniotic fluid cultures underestimate the contribution of infection to preterm birth. However, bacteria are known to be present in the chorioamnion in women who deliver healthy infants at term,¹⁰⁴ indicating that bacteria in the chorioamnion do not always generate an inflammatory response that leads to preterm labor and birth. The most common pathway by which microorganisms gain access to the choriodecidual and amniotic cavity is probably ascent from the vagina and the cervix, but the timing of this spread is uncertain. It may occur before or during pregnancy.¹⁰⁵ Regardless of when colonization occurs, intrauterine inflammation is postulated to cause clinical symptoms, such as vaginal discharge, cervical effacement, ruptured membranes, or labor, only when microbial counts increase as the membranes try to adhere to the decidua in the second trimester.¹⁰¹ This phenomenon is consistent with the strong association between increased concentrations of fetal fibronectin, the choriodecidual “glue,” in vaginal fluid between 13 and 22 weeks’ gestation, with spontaneous preterm birth in the second trimester.¹⁰⁶ The microorganisms most commonly recovered from the amniotic cavity and chorioamnion are genital mycoplasma species, especially *U. urealyticum*, and other organisms of low virulence, consistent with the chronicity of intrauterine infections and the frequent lack of overt clinical signs of infection.¹⁰¹

Specific Infections. Bacterial vaginosis, an alteration in the microbial ecosystem of the vagina, is a clinical correlate of lower and upper tract infection. BV is diagnosed clinically by the presence of clue cells, a vaginal pH greater than 4.5, a profuse white discharge, and a fishy odor when the vaginal discharge is exposed to potassium hydroxide.¹⁰⁷ BV in pregnancy has been consistently associated with an increased risk for preterm birth, but apparently only as a marker, because eradication of BV from

the genital tract of pregnant women does not consistently reduce the likelihood of preterm birth.^{108,109} BV is more commonly detected in African-American women, and it is more strongly related to preterm birth in African-American women than in women of other racial or ethnic backgrounds.¹¹⁰ This association is unrelated to differences in sexual behaviors.¹¹¹ Moreover, eradication of BV does not reduce the risk for preterm birth in either African-American or white women.^{109,112}

Trichomonas vaginalis is present in 3.1% of women of reproductive age, and it is more common in African-American women (13%) than in other groups.¹¹³ It has been associated with a modest increase in the risk for preterm birth (RR = 1.3) in some studies¹¹⁴ but not in all.¹¹⁵

Sexually transmitted infections, including *Chlamydia trachomatis*, syphilis, and gonorrhea, confer an increased risk for preterm birth approaching twofold,¹¹⁶ but eradication of these organisms does not reduce that risk, suggesting involvement of host factors.

Clinical markers of genital tract infection that correlate with an increased risk for preterm birth include the detection of BV and an increased level of fetal fibronectin in cervicovaginal fluid after 22 weeks' gestation.¹¹⁷

Extragenital infections including pyelonephritis, asymptomatic bacteriuria, pneumonia, and appendicitis are also associated with preterm birth through mechanisms that are not well understood.^{118,119}

Periodontal Disease. Maternal periodontal disease has been linked to an increased risk for preterm birth,¹²⁰ but the basis for the association is uncertain.¹²¹ It most likely results from shared variations in the inflammatory response to microorganisms in the oral and genital tracts.¹²²⁻¹²⁵ Goepfert and colleagues demonstrated that, after adjusting for other factors, periodontal disease was not related to increased intrauterine bacterial colonization, histologic chorioamnionitis, or cord blood cytokine levels.¹²⁶

The biologic pathway explaining the relationship between periodontal disease and preterm birth is unknown. Variations in host response to microbial colonization related to genetic polymorphisms or concurrent environmental exposures, or both, have been proposed as contributors to the disparate rates of preterm birth among ethnic groups, particularly in relationship to infection-driven preterm birth,^{55,127} and may apply to other inflammation at extragenital sites, such as periodontal inflammation.

Uterine Abnormalities

Uterine Anomalies. Women with müllerian duct fusion anomalies have an increased risk for pregnancy loss, with clinical presentations that vary according to uterine anatomy, cervical involvement, and placental implantation site.^{128,129} Preterm births are reported in 25% to 50% of pregnancies among women with uterine malformations.^{130,131} Among 246 pregnancies in 130 women with uterine anomalies, 20.3% were delivered preterm, 8.5% delivered in the second trimester, and 25% were first-trimester losses.¹³¹ The preterm birth rate was particularly increased (approximately 35%) in women with bicornuate, didelphys, or arcuate uteri, compared with those who had septate or subseptate uteri (approximately 15%) in this report. Müllerian fusion anomalies may involve the cervix as well as the uterine cavity, so the clinical presentation may include cervical insufficiency, bleeding related to abnormal placental

implantation, and preterm labor. Clinical presentations leading to preterm birth in a study of 61 women with uterine anomalies included preterm labor in 39%, pPROM in 13.7%, and abruption in 5.9%.¹³² Prenatal exposure to diethylstilbestrol is associated with an increased risk for preterm labor and birth related to the typical T-shaped uterine anomaly.¹³³

Cervical Surgery. Women treated for cervical dysplasia with a loop electrosurgical excision procedure (LEEP), or with cervical conization using either laser or cold knife, have an increased risk for later preterm birth, but the basis of the association is uncertain. The largest studies of this relationship have come from Scandinavian registries in which long-term follow-up is possible.¹³⁴⁻¹³⁶ Among 8210 women treated surgically for dysplasia between 1986 and 2003, the risk for preterm birth before 37 weeks of gestation was increased after cervical conization (RR = 1.99; 95% CI, 1.81 to 2.20), as were the risks for birth between 28 and 31 weeks (RR = 2.86; 95% CI, 2.22 to 3.70) and before 28 weeks (RR = 2.10; 95% CI, 1.47 to 2.99). Risks of LBW and perinatal death were also increased after conization (RR = 2.06; 95% CI, 1.83 to 2.31, and RR = 1.74; 95% CI, 1.30 to 2.32, respectively). A Danish cohort of 11,088 women was monitored from 1991 through 2004; of 14,982 deliveries in the cohort, 542 occurred between 21 and 37 weeks. The rate of preterm birth was 3.5% in women with no previous LEEP and 6.6% in women previously treated with LEEP (OR = 1.8; 95% CI, 1.1 to 2.9). A meta-analysis and review of this topic found an increased risk for preterm birth in women with a history of treatment for precancerous lesions compared with controls with no history of cervical dysplasia, but there was no difference in preterm birth rates according to treatment procedures in women with dysplastic cytology.¹³⁷ This suggests that host factors may be more important than treatment in explaining the associations observed by others.

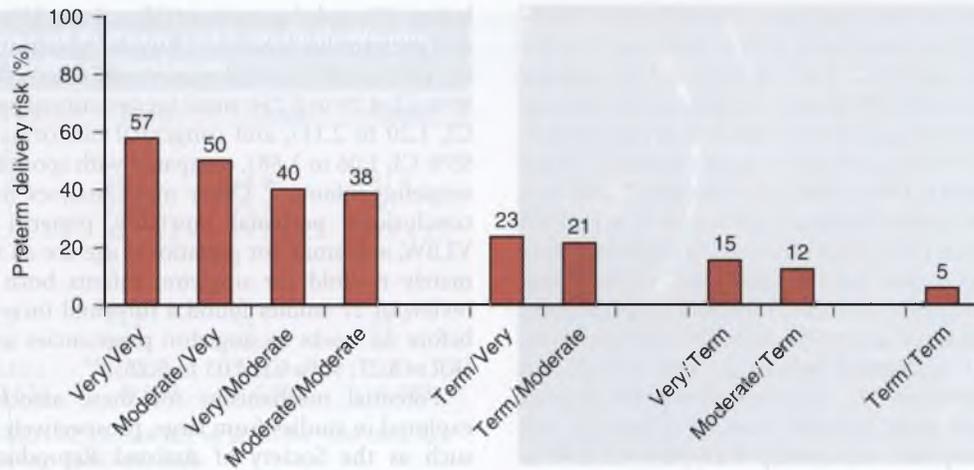

REPRODUCTIVE HISTORY

Prior Preterm Birth

Prior Spontaneous Preterm Birth. Although most women who experience a preterm birth will deliver at term in subsequent pregnancies, the recurrence risk for spontaneous preterm birth is twofold or higher. This yields an actual risk that ranges from 15% to 20% to more than 50% to 60% when maternal race, ethnicity, and the number and gestational age of prior preterm deliveries are considered.¹³⁸⁻¹⁴⁴ The recurrence risk rises in women of all races as the number of prior preterm births increases, with a nearly twofold rise for each prior preterm birth.²² The most recent birth is the most predictive (Fig. 40-9).¹⁴⁵

The risk increases further as the gestational age of the index preterm birth declines, especially with gestational age before 32 weeks.¹⁴⁶ A prior preterm birth as early as 16 to 18 weeks has been found to confer an increased risk in subsequent pregnancies.^{30,147}

The risk for recurrence is almost twofold higher for non-Hispanic black women than for any other group. Adams and colleagues related maternal race and gestational age of the initial preterm birth to recurrence risk.¹⁴⁴ If the first preterm birth occurred before 32 weeks, the risk for recurrent preterm birth was 28% for white women and 36% for African-American women.

Prior preterm delivery status by order and gestational age at delivery

Figure 40-9 Preterm delivery risk for third births according to gestational age at birth in previous pregnancies. (From McManemy J, Cooke E, Amon E, et al: Recurrence risk for preterm delivery, *Am J Obstet Gynecol* 196:576 e1–576 e7, 2007.)

When multiple risk factors occur in African-American women, recurrence rates exceeding 50% have been reported.^{148,149} In a placebo-controlled trial of 17 α -hydroxyprogesterone caproate (17OHP) to reduce the risk for recurrent preterm birth, 54% of women in the placebo arm delivered before 37 weeks, and 30.7% delivered before 35 weeks. The mean gestational age at delivery in the qualifying pregnancy was 31.3 \pm 4.2 weeks; 46% of subjects had more than one prior preterm birth, and 59% were African-American.¹⁴⁸ In another study of 611 women with one (75%) or more (25%) prior preterm births, 40% delivered before 37 weeks, and 25% delivered before 35 weeks of gestation. One quarter of the subjects in this trial were African Americans.¹⁴⁹ These rates are consistent with prior studies showing a 1.5-fold to twofold increased risk for each risk factor (African-American race, more than one prior preterm birth, and gestational age <32 weeks).^{5,30,138,142} and with prior observational studies.¹⁵⁰

The mechanisms of recurrence are not clear but have been related to short cervix,¹⁴² infection,¹⁵¹ and short interpregnancy interval. After adjusting for confounding variables, a short interval between pregnancies is associated with a twofold increased risk for preterm birth.^{152–154} A short interpregnancy interval is more common among women whose first birth was a preterm birth.

Prior Twin Preterm Birth. Prior preterm birth of twins confers an increased risk for preterm birth in a subsequent singleton pregnancy that is related to the gestational age at delivery of the index twin pregnancy,^{143,155,156} most recently in a study of 1957 women in the Netherlands Perinatal Registry with a twin birth followed by a subsequent singleton pregnancy.¹⁵⁷ The risk for singleton preterm birth was almost sevenfold higher (OR = 6.9; 95% CI, 3.1 to 15.2) in women whose twins were born before term, an increase similar to that reported by Facco and colleagues.¹⁵⁶ Menard and coworkers¹⁵⁵ found a 40% risk for preterm birth in a subsequent singleton gestation if the prior twin birth occurred before 30 weeks' gestation, a modestly increased risk when the twin birth was at 30 to 33 weeks, and no increased risk if the twin birth occurred between 34 and 37 weeks.

Prior Indicated Preterm Birth. Women with indicated preterm births also have an increased risk for another indicated preterm birth, because the underlying condition (e.g., maternal diabetes, hypertension) often persists.^{138,158} Unexplained fetal growth restriction can also be recurrent.^{159,160}

Prior Stillbirth. The risk for preterm birth is increased as the gestational age at birth of a prior preterm pregnancy falls. Recent data from the Stillbirth Collaborative Research Network demonstrated that this observation extends to include spontaneous births that occur before the threshold of viability, so that a history of stillbirth before 24 weeks or "late miscarriage" between 16 and 20 weeks also confers an increased risk for spontaneous preterm birth after 20 weeks in future pregnancies.¹⁶¹ This observation is important because these women may be candidates for progesterone prophylaxis, or at least for transvaginal screening of cervical length.⁷

Pregnancy Termination. A history of induced abortion is related to an increased risk for preterm birth in subsequent pregnancies.^{162–164} Women with more than one induced abortion have been found in several studies to have a higher risk for subsequent preterm birth, especially for births before 28 to 32 weeks' gestation.* A case-control survey of 2938 preterm and 4781 term births in 10 countries reported that women with a history of induced abortions were significantly more likely to have a subsequent spontaneous preterm delivery. A prior elective abortion did not affect the risk for subsequent indicated preterm birth. The risk for preterm birth increased with the number of abortions, and the strength of the association increased with decreasing gestational age at birth.¹⁶³ In another study of 12,432 women, rates of preterm delivery were compared according to the occurrence and number of previous

*Data to the contrary was published recently; see <http://www.plosmedicine.org/article/info%3Adoi%2F10.1371%2Fjournal.pmed.1001481;jsessionid=B1ACFC3B3308932598074552711EFFF5>.

induced abortions; other risk factors were controlled for. Previous induced abortion was associated with an increased risk for preterm birth (OR = 1.4; 95% CI, 1.1 to 1.8), and the risk for preterm delivery increased with the number of previous induced abortions (OR = 1.3; 95% CI, 1.0 to 1.7 for one previous abortion, and OR = 1.9; 95% CI, 1.2 to 2.8 for two or more).¹⁶⁵ These associations are supported by a 2009 meta-analysis,¹⁶⁶ and by a study of all first-time mothers with a singleton birth in Finland between 1996 and 2008 ($N = 300,858$) in which birth data were linked to an abortion register for 1983 to 2008.¹⁶⁷ Of first-time mothers, 10.3% ($n = 31,083$) had one, 1.5% had two, and 0.3% had three or more induced abortions. Most induced abortions were surgical (88%), performed before 12 weeks (91%), and carried out for social reasons (97%). Increased odds for preterm birth before 28 weeks were reported from all subgroups and exhibited a dosage-response relationship: 1.19 (95% CI, 0.98 to 1.44) after one, 1.69 (95% CI, 1.14 to 2.51) after two, and 2.78 (95% CI, 1.48 to 5.24) after three induced abortions. The cause of this association is unknown. Colonization of the upper genital tract was suggested as a possible explanation.¹⁶⁸ Women with two or more induced abortions may be candidates for cervical length screening.

CURRENT PREGNANCY CHARACTERISTICS

Bleeding

Vaginal bleeding related to placental abruption or previa are recognized causes of preterm delivery, but bleeding of uncertain origin has also been associated with spontaneous preterm birth, especially if the bleeding is recurrent or persistent.^{169,170} The mechanism by which bleeding is associated with preterm birth occurring weeks later is uncertain. A perhaps-related observation is the increased risk for preterm birth in pregnancies complicated by an elevated maternal serum α -fetoprotein not explained by structural fetal anomalies.¹⁷¹⁻¹⁷³ First-trimester bleeding in singleton pregnancies after assisted reproductive technology (ART) has been associated with an increased risk for preterm birth. In a review of 1432 singleton pregnancies conceived after ART, women with first-trimester bleeding had increased rates of pPROM (OR = 2.44; 95% CI, 1.38 to 4.31), birth before 37 weeks (OR = 1.64; 95% CI, 1.05 to 2.55), and birth before 32 weeks (OR = 3.05; 95% CI, 1.12 to 8.31).¹⁷⁴ The rate of preterm birth is also increased when one fetus in a multifetal gestation is lost, a finding noted among surviving singletons in multifetal gestation conceived by in vitro fertilization (IVF)¹⁷⁵ but not in spontaneously conceived pregnancies.¹⁷⁶ The risk for preterm birth is increased further in higher-order multiple gestations intentionally reduced to twins than in gestations of spontaneous twins.¹⁷⁷ These reports suggest that disturbance of the maternal-fetal interface in early pregnancy may be associated with risk for preterm parturition.

Assisted Reproductive Technologies

Preterm birth is more common in pregnancies conceived after ovulation induction and ART, including IVF and gamete and zygote intrafallopian transfer, frozen embryo transfer, and donor embryo transfer.¹⁷⁸ The increased rate of preterm birth after ART is observed in singleton as well as multifetal pregnancies. A review of pregnancy outcome of singletons conceived after in vitro fertilization found increased rates of perinatal mortality (OR = 2.40; 95% CI, 1.59 to 3.63), preterm birth

before 37 weeks' gestation (OR = 1.93; 95% CI, 1.36 to 2.74), and preterm birth before 33 weeks' gestation (OR = 2.99; 95% CI, 1.54 to 5.80), as well as increased rates of VLBW (OR = 3.78; 95% CI, 4.29 to 5.75), small for gestational age (OR = 1.59; 95% CI, 1.20 to 2.11), and congenital malformations (OR = 1.41; 95% CI, 1.06 to 1.88), compared with spontaneously conceived singleton infants.¹⁷⁹ Other meta-analyses have drawn similar conclusions: perinatal mortality, preterm birth, LBW and VLBW, and small for gestational age are all increased approximately twofold for singleton infants born after IVF.¹⁸⁰⁻¹⁸² A review of 27 studies found a threefold increased risk for birth before 32 weeks in singleton pregnancies conceived after IVF (RR = 3.27; 95% CI, 2.03 to 5.28).¹⁸³

Potential mechanisms for these associations have been explored in studies from large, prospectively collected data sets such as the Society of Assisted Reproductive Technologies (SART) database,^{184,185} the FaSTER Study¹⁸⁶ and elsewhere.¹⁸⁷ A study of FaSTER data found significant associations between ovulation induction and placental abruption, fetal loss after 24 weeks, and gestational diabetes, and between IVF and preeclampsia, gestational hypertension, and placental abruption. Low birth weight, but not preterm birth, was significantly higher in infants born after fresh, compared with frozen and thawed, embryo transfer.¹⁸⁵ Others have reported a threefold increase in preterm and LBW infants in singletons conceived after controlled stimulation of ovulation (e.g., with clomiphene as well as gonadotropins).¹⁸⁷ Notably, a SART study found that extended culture of embryos from cleavage stage to blastocyst stage was associated with an increased risk for preterm birth.¹⁸⁴ Singleton IVF births conceived after blastocyst transfer were at an increased risk for preterm delivery when compared with births after cleavage-stage transfer (18.6% versus 14.4%, respectively; adjusted OR = 1.39; $P < .001$) and very preterm delivery (2.8% versus 2.2%, respectively; adjusted OR = 1.35; $P < .001$).

Host factors linked to both subfertility and preterm birth, and medication effects, are other possible explanations for these associations.

Multiple Gestation

This topic is also discussed in Chapter 38.

Multifetal gestations have a sixfold increased risk for preterm delivery compared with singleton pregnancies. The risk increases with fetal number. In the United States, about 15% to 20% of all preterm infants are the product of the 3% of pregnancies that are multifetal. More than 50% of twins are born preterm, most often after spontaneous labor or pPROM before 37 weeks' gestation. The remainder deliver preterm because of maternal or fetal conditions such as preeclampsia or growth restriction. Almost all higher-order multiple gestations deliver before term. The risk for early birth rises with the number of fetuses, suggesting uterine overdistention and fetal signaling as potential pathways to early initiation of labor (Table 40-3). Nevertheless, nearly half of women with twins deliver after 37 weeks of gestation, suggesting that uterine stretch or distention is variably accommodated according to maternal characteristics including cervical length, physical activity, uterine tone, and other risk factors.¹⁸⁸⁻¹⁹¹

Uterine Factors

Uterine Volume. Increased uterine volume (e.g., polyhydramnios or multiple gestation) is a strong risk factor for preterm birth, conferring a relative risk of 6 or greater.¹⁹²

TABLE 40-3 Percentages of Preterm and Low-Birth-Weight Births by Order of Gestation

Births	Twin	Triplet	Quad	Quint
GESTATIONAL AGE				
<32 wk	11.8	35.9	64.9	81.4
<37 wk	59.7	93.0	95.9	100
Mean age (±SD)	35.2 ± 3.6	32.1 ± 3.9	29.7 ± 4.5	28.4 ± 2.7
BIRTH WEIGHT				
<1.5 kg	10.2	33.2	65.1	84.9
<2.5 kg	56.6	94.1	98.4	100
Mean weight (±SD)	2.333 ± 0.634	1.700 ± 0.559	1.276 ± 0.552	1.103 ± 0.383

From Martin JA, Hamilton BE, Sutton PD, et al: Births: final data for 2004, Natl Vital Stat Rep 55:80–81, 2006.

Uterine Contractions. Although uterine contraction frequency is related to the risk for preterm birth in singletons^{84,193,194} and twins,¹⁹¹ it has not been useful to predict preterm birth because of wide individual variation in normal pregnancies and the large overlap between women with contractions who do and do not deliver before term.¹⁹⁴

Cervical Length. As labor at term approaches, digital examination indicates that the cervix shortens, softens, rotates anteriorly, and begins to dilate. Softening and shortening are the features of the digital examination that most strongly correlate with preterm delivery.¹⁹⁵ A short cervix measured by transvaginal ultrasonography is a more reproducible risk factor for spontaneous preterm birth.^{196–199}

The predictive value of cervical length measurements is influenced by several factors, including the gestational age at measurement. Cervical effacement in normal parturition begins at about 32 weeks, limiting the usefulness of cervical length measurements thereafter to excluding preterm labor in women with symptoms. Cervical length measurements before 14 to 15 weeks have little relationship to risk for preterm birth.²⁰⁰ Cervical length in the second trimester has been most studied. The 50th, 10th, and 3rd percentiles between 16 and 22 weeks are approximately 40, 30, and 25 mm,^{198,201} respectively, when measured with a standardized transvaginal ultrasound technique²⁰² (Fig. 40-10). Between 22 and 32 weeks, these percentile values are 35, 25, and 15 mm, respectively.^{197,199} In an observational study of 2915 women,¹⁹⁷ a cervical length of 25 mm or less (the 10th percentile) at 22 to 24 weeks' gestation was associated with an RR of 6.5 (CI, 4.5 to 9.3) for preterm birth before 35 weeks, and an RR of 7.7 (CI, 4.5 to 13.4) for preterm birth before 32 weeks. Serial measurements improve predictive value, but additional observations of funneling and dynamic changes do not.^{203,204} "Short cervix" has been most often defined as below the 10th percentile (25 mm at 22 to 24 weeks), but the 5th percentile (20 mm) has been another useful threshold in clinical practice (see Medical and Surgical Interventions to Prevent Preterm Birth, later) (Fig. 40-11). The RR and positive predictive value of cervical length measurements below the 5th percentile are influenced only slightly by a prior history of preterm birth,^{205,206} but they are significantly influenced by the gestational age at measurement.²⁰⁷ Table 40-4 displays the likelihood

Figure 40-10 Endovaginal ultrasound image of a normal cervix at 24 weeks' gestation. The closed portion of the cervical canal is measured from the external os, identified as the most distal point at which anterior and posterior walls of the canal touch, to the internal os, identified as the most proximal point where the walls touch. The cervix in this image is measured in two segments because of the curved canal, a normal finding. The length is 40 mm, the 75th percentile. The internal os is closed, forming a "T" relationship to the canal.

Figure 40-11 Endovaginal ultrasound image of a cervix at 25 weeks' gestation, showing Y-shaped funneling at the internal os. The cervical length is 21.3 mm, approximately the 5th percentile.

of preterm birth before 35 weeks in women with a previous preterm birth according to cervical length and gestational age at measurement.²⁰⁸

Although short cervix is related to preterm birth, it is not diagnostic of cervical insufficiency (see Chapter 41). A short cervix can be viewed as evidence that the process of parturition has begun, but it gives no indication of the cause. Choriodecidual inflammation resulting from infection or hemorrhage, uterine overdistention, and acquired or congenital cervical insufficiency may all appear with short cervix.

Interventional Strategies

Efforts to prevent the morbidity and mortality associated with preterm birth may be categorized as tertiary (initiated after the process of parturition has begun, with a goal of preventing delivery or improving outcomes for preterm infants), secondary

TABLE 40-4 Probability of Preterm Delivery before Week 35, in Singleton Gestations with Prior Spontaneous Preterm Birth, as Predicted by Cervical Length

From Berghella V, Roman A, Daskalakis C, et al: Gestational age at cervical length measurement and incidence of preterm birth, *Obstet Gynecol* 110:311–317, 2007.

(aimed at eliminating or reducing risk in women with known risk factors), or primary (directed to all women before or during pregnancy to prevent and reduce risk).

Most obstetric care for preterm birth has been focused on tertiary interventions such as regionalized perinatal care, tocolysis, antenatal corticosteroids, antibiotics, and optimal timing of indicated preterm birth. These measures are intended to reduce the burden of prematurity-related illness and have minimal, if any, effect on the incidence of preterm birth. Chapter 34 describes appropriate use of antenatal glucocorticoids as a tertiary strategy to reduce perinatal morbidity and mortality regardless of the clinical presentation leading to preterm birth. This section describes clinical management of preterm labor. Chapters 41, 42, and 47 address clinical management of the related conditions of cervical insufficiency, preterm ruptured membranes, and fetal growth restriction, respectively.

Treatment of symptomatic preterm labor is directed at arresting labor long enough (1) to transfer the mother to an appropriate hospital for delivery and (2) to allow administration of corticosteroids; these two interventions have consistently been shown to reduce perinatal mortality and morbidity. Other interventions directed at reducing neonatal and infant morbidity and mortality include pre-delivery antibiotics and neuroprotectants.

Preterm Labor

DIAGNOSIS OF PRETERM LABOR

Symptoms and Signs

Diagnosis and treatment of preterm labor is challenging, because the sequence and timing of events that precede preterm labor are incompletely understood. Because the progression from subclinical preterm parturition to overt preterm labor is often gradual, the traditional criteria for the diagnosis of preterm labor (painful uterine contractions accompanied by cervical change) lack precision. The result is overdiagnosis in as many as 40% to 70% of women diagnosed with preterm labor

and enrollment of women who are not in labor into trials of agents to arrest preterm labor.²⁰⁹ Moreover, women who were treated to prevent or arrest preterm labor and were thought to have been treated successfully may not have required treatment at all; the true result of treatment is confidently known only for those whose treatment was unsuccessful. Reliable studies of methods to prevent or arrest preterm labor will not be possible until more accurate diagnostic criteria are established.

Preterm labor must be considered whenever abdominal or pelvic symptoms occur after 16 weeks' gestation. Symptoms including pelvic pressure, increased vaginal discharge, backache, and menstrual-like cramps occur commonly during normal pregnancy, and they suggest preterm labor more by their persistence than their severity. Contractions may be painful or painless, depending on the resistance offered by the cervix. Contractions against a closed, uneffaced cervix are likely to be painful, but recurrent pressure or tightening may be the only symptoms when cervical effacement precedes the onset of contractions.²¹⁰ The traditional criteria—persistent uterine contractions accompanied by dilation or effacement of the cervix (or both)—are reasonably accurate at identifying women at risk for imminent delivery if the contraction frequency is six or more per hour and cervical dilation is 3 cm or greater or effacement is 80% or greater, or if membranes rupture or bleeding occurs.^{211,212} When lower thresholds for contraction frequency and cervical change are used, false-positive diagnosis is common,^{209,211} but sensitivity does not necessarily increase.²¹³

Accurate diagnosis of early preterm labor is difficult, because the symptoms²¹⁴ and signs⁸⁴ of preterm labor occur commonly in normal women who do not deliver before term, and because digital examination of the cervix in early labor (at <3 cm dilation and <80% effacement) is not highly reproducible.²¹⁵⁻²¹⁷

Women with symptoms whose cervical dilation is less than 2 cm or whose effacement is less than 80% present a diagnostic challenge with respect to identifying risk for imminent delivery. In a clinical trial to identify women with true preterm labor, 179 women with preterm contractions and minimal cervical dilation were randomly assigned to receive either intravenous hydration and observation without intervention or observation

after a single dose of 0.25 mg subcutaneous terbutaline.²¹⁸ Intravenous hydration did not decrease preterm contractions.

Tests for Preterm Labor

Diagnostic accuracy can be improved by transvaginal sonographic measurement of cervical length or by testing for fetal fibronectin in cervicovaginal fluid.²¹⁹⁻²²⁴ Both tests improve diagnostic accuracy by reducing the number of false-positive diagnoses. Transabdominal sonography has poor reproducibility for cervical measurement and should not be used clinically without confirmation by a transvaginal ultrasound,²²⁵ but a cervical length of 30 mm or more by endovaginal sonography suggests, if the examination is properly performed, that preterm labor is unlikely despite symptoms. Similarly, a negative fibronectin test in women with symptoms before 34 weeks' gestation and cervical dilation of less than 3 cm can also reduce the rate of false-positive diagnosis if the result is returned promptly and the clinician is willing to act on a negative test result by not initiating treatment.^{217,220,224} A commonly used algorithm (Fig. 40-12) increased the efficiency of evaluation and reduced the incidence of spontaneous preterm birth.²²⁶

Clinical markers for high risk for imminent preterm delivery in women with symptoms include ruptured membranes, vaginal bleeding, and cervical dilation beyond 2 cm.²²⁷ Among women with intact membranes, no bleeding, and cervical dilation less than 3 cm, the combination of a positive fibronectin test and a sonographic cervical length of less than 30 mm predicted increased risk for delivery within 48 hours (26%); the risk was less than 7% if only one or neither test is positive.²²⁸ The presence of debris (or "sludge") in amniotic fluid near the internal

os on transvaginal sonography has also been associated with increased risk for delivery within 48 hours²²⁹ and with intra-amniotic infection²³⁰ in women with symptoms of preterm labor.

MANAGEMENT OF PRETERM LABOR

Strategies to Reduce Morbidity and Mortality

Regionalized Care. Many states have adopted systems of regionalized perinatal care in recognition of the advantages of concentrating care for preterm infants, especially those born before 32 weeks. Hospitals and birth centers caring for normal mothers and infants are designated level I. Larger hospitals that care for the majority of maternal and infant complications are designated level II centers; these hospitals have neonatal intensive care units staffed and equipped to care for most infants with birth weights greater than 1500 g. Level III centers typically provide care for the sickest and smallest infants, and for maternal complications requiring intensive care. This approach has been associated with improved outcomes for preterm infants.^{231,232}

Strategies to Reduce Morbidity

Antenatal Corticosteroids. Antenatal corticosteroids (see Chapter 34) promote maturation over growth of the developing fetus. In the lung, corticosteroids promote surfactant synthesis, increase lung compliance, reduce vascular permeability, and improve the postnatal surfactant response. Also, antenatal corticosteroids have similar maturational effects on other organs including the brain, kidneys, and gut.

Studies by Liggins and Grieves²³³ of mechanisms of parturition in sheep led to the serendipitous discovery of the beneficial effect of antenatal glucocorticoids on the maturation and performance of the lung in prematurely born infants. Subsequent studies have shown conclusively that antepartum administration of betamethasone or dexamethasone reduces the risk for neonatal death, respiratory distress syndrome, intraventricular hemorrhage, patent ductus arteriosus, and necrotizing enterocolitis. Guidelines for appropriate clinical use of antenatal corticosteroids have evolved from initial skepticism and selective use, through a period of broad and repeated treatment after the first NICHD panel report in 1994, to the practice of a single course of treatment recommended by the NICHD Consensus Panel in 2000. More recently, clinical trials support the notion that administration of a single rescue course of steroids before 33 weeks improves neonatal outcome (e.g., decreased respiratory distress syndrome, ventilator support, and surfactant use) without an apparent increase in short-term risk.²³⁴ A rescue course may be considered if the initial treatment was given more than 2 weeks before, and if the gestational age is less than 32 6/7 weeks, in a woman judged to be at risk for imminent delivery. However, regularly scheduled repeat courses or multiple courses (more than two) are not recommended.²³⁵ Betamethasone and dexamethasone, the only drugs found beneficial for this purpose, are potent glucocorticoids with limited if any mineralocorticoid effect. A course of treatment consists of two doses of 12 mg of betamethasone (a combination of 6 mg each of betamethasone acetate and betamethasone phosphate) administered intramuscularly 24 hours apart, or four doses of 6 mg of dexamethasone given intramuscularly every 12 hours. Other corticosteroids (prednisolone, prednisone) and routes of administration (oral) are not suitable alternatives because of reduced placental transfer, lack of demonstrated benefit, and, in

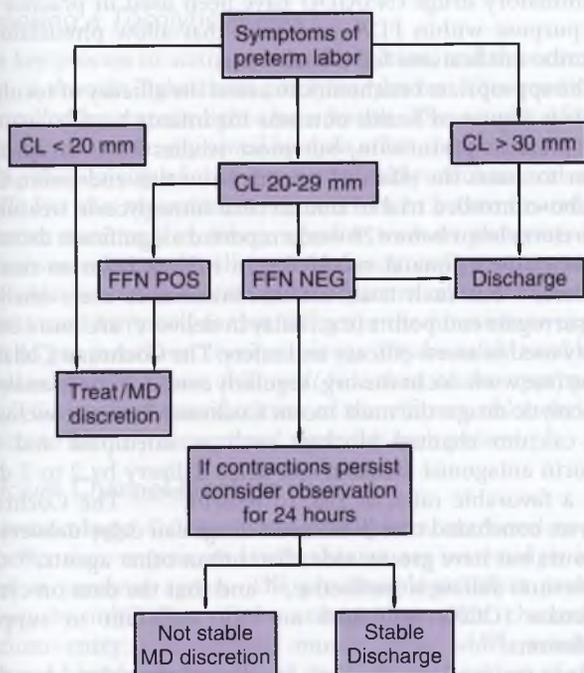

Figure 40-12 Preterm labor evaluation protocol. CL, cervical length; FFN, fetal fibronectin; NEG, negative (<50 ng/dL); POS, positive (≥ 50 ng/dL). (From Ness A, Visintine J, Ricci E, et al: Does knowledge of cervical length and fetal fibronectin affect management of women with threatened preterm labor? A randomized trial, *Am J Obstet Gynecol* 197:426 e1-426 e7, 2007.)

the case of oral dexamethasone, increased risk for adverse effects when compared with the intramuscular route. We do not administer steroids if the sole reason is the presence of a historical risk factor such as prior preterm birth, but we do consider giving steroids at the first evidence of preterm parturition after 24 weeks in the current pregnancy (e.g., bleeding, or cervical change demonstrated by digital or ultrasound examination, especially when accompanied by a positive test for fetal fibronectin) in women with a multiple gestation or a prior preterm birth. We believe that the advantage of ensured receipt of steroids outweighs the likelihood that the benefit of treatment will wane before delivery.

Antibiotics. Women with preterm labor should be treated with antibiotics to prevent neonatal group B streptococcal (GBS) infection (see Chapter 51). Because preterm infants have an increased risk for neonatal GBS infection, compared with infants born at term, intrapartum prophylaxis with penicillin or ampicillin is recommended.²³⁶ There is also evidence that infants born to women with pPROM have reduced perinatal morbidity when antepartum antibiotic prophylaxis has been administered (see Chapter 42).^{22,237} Antibiotic therapy for women with preterm labor and with intact membranes has not been effective in prolonging pregnancy or reducing morbidity²³⁸⁻²⁴² and should be limited to prophylaxis of GBS transmission or treatment of a specific pathogen (e.g., a urinary tract infection).²³⁶

Neuroprotectants. Because of the strong association of early preterm birth with neurodevelopmental morbidity, an antenatal or perinatal intervention to reduce this risk has been sought. Phenobarbital was the first such agent to be studied for this purpose, but it did not reduce intraventricular hemorrhage when given alone or in combination with vitamin K.²⁴³⁻²⁴⁵

Reports from observational studies of reduced rates of intraventricular hemorrhage, cerebral palsy, and perinatal mortality in premature infants whose mothers received antenatal magnesium sulfate prompted large, randomized, placebo-controlled trials of antenatal magnesium. The first trial enrolled 1062 women who delivered before 30 weeks' gestation.²⁴⁶ Gross motor dysfunction at age 2 years was significantly reduced, and mortality and cerebral palsy were less common among infants born to magnesium-treated mothers. No significant adverse effects were noted in infants exposed to antenatal magnesium sulfate. Two subsequent trials^{247,248} also reported reductions in neurologic morbidity and cerebral palsy among magnesium-treated infants. The available evidence suggests that magnesium sulfate given before anticipated early preterm birth reduces the risk for cerebral palsy in surviving infants.²⁴⁹

The neuroprotective effect of antenatally administered magnesium was assessed in a meta-analysis of five trials covering two gestational age groups (5235 fetuses at <32 to 34 weeks, and 3107 fetuses at <30 weeks).²⁴⁹ Major findings were similar for both gestational age groups:

- There were statistically significant reductions in the risk for “cerebral palsy” (RR = 0.7 for the <32- to 34-week group, and RR = 0.69 for the <30-week group) and in the risk for “death or moderate to severe cerebral palsy” (RR = 0.85 for the <32- to 34-week group, and RR = 0.84 for the <30-week group).
- The largest reduction in risk was for “moderate to severe cerebral palsy”:
 - <32 to 34 weeks: RR = 0.60 (95% CI, 0.43 to 0.84)
 - <30 weeks: RR = 0.54 (95% CI, 0.36 to 0.80)

- The numbers needed to treat to prevent one case of cerebral palsy in the <32- to 34-week group and in the <30-week group were 56 and 46 women, respectively.

The three trials reported slightly different administration regimens. All began with an intravenous bolus of MgSO₄ (4 or 6 g over 30 minutes), followed by 1 to 2 g per hour for 12 to 24 hours in two trials and without maintenance doses in the third. ACOG recommends that hospitals select and adhere to one of the reported regimens.

Neither the neuroprotective mechanism nor the response to magnesium sulfate is well understood. Although it seems likely that the neuroprotective effects of magnesium sulfate result from residual concentrations of the drug in the neonate's circulation, the data are insufficient to determine the maternal dosage that confers neonatal benefit.

TOCOLYTIC THERAPY

Goals of Tocolysis

Because the contracting uterus is the most easily recognized antecedent of preterm birth, stopping contractions has been the focus of therapeutic approaches. This strategy is based on the naive assumption that clinically apparent contractions are commensurate with the initiation of the process of parturition; by logical extension, successfully inhibiting contractions should prevent delivery. The failure of this approach to reduce preterm birth is evidence of the fallacy of the underlying assumption. The inhibition of myometrial contractions is called tocolysis, and an agent administered to that end is referred to as a tocolytic. Although no medications are currently approved for tocolysis by the U.S. Food and Drug Administration (FDA), calcium channel blockers, β -agonists, and nonsteroidal anti-inflammatory drugs (NSAIDs) have been used in practice for this purpose within FDA guidelines that allow physicians to prescribe medications for off-label use.

The appropriate benchmark to assess the efficacy of tocolytic agents is improved health outcome for infants born to women with preterm parturition, but most studies have insufficient power to assess the effect of treatment on this end point. One placebo-controlled trial of transdermal nitroglycerin treatment for preterm labor before 28 weeks reported a significant decrease in composite neonatal morbidity in infants born to treated mothers,²⁵⁰ but such trials are uncommon, so meta-analyses and surrogate end points (e.g., delay in delivery) are more commonly used to assess efficacy and safety. The Cochrane Collaboration (see www.cochrane.org) regularly conducts meta-analyses of tocolytic drugs; the most recent Cochrane Review concluded that calcium channel blockers such as nifedipine and the oxytocin antagonist atosiban can delay delivery by 2 to 7 days with a favorable ratio of risk to benefit.^{251,252} The Cochrane analyses concluded that β -mimetic drugs can delay delivery by 48 hours but have greater side effects than other agents,²⁵³ that magnesium sulfate is ineffective,²⁵⁴ and that the data on cyclooxygenase (COX) inhibitors are not sufficient to support conclusions.²⁵⁵

These reviews form the basis for clinical algorithms, but they are limited by the design and size of the original research studies. Because parturition is a gradual process with an accelerated phase of active labor that can be difficult to identify until well underway, it is extremely difficult for researchers to identify both the appropriate population and the appropriate moment

to use tocolysis. Selection of the best tocolytic drug is less important than selecting the patient for whom adjunctive therapies are appropriate and who would soon progress to delivery without tocolysis.

Contraindications to Arrest of Labor

Common maternal contraindications to tocolysis include severe preeclampsia or severe gestational hypertension, hemorrhage, and significant maternal cardiac disease. Preterm labor accompanied by maternal hypertension places both mother and fetus at risk for acute hypertensive crises, and it may occur in response to fetal stress or distress, uterine ischemia, or occult placental abruption. Although vaginal spotting may occur in women with preterm labor because of cervical effacement or dilation, any bleeding beyond light spotting is rarely due to labor alone. Placenta previa and abruption must be considered, because both may be accompanied by uterine contractions. In general, both diagnoses place a woman at greater risk for hemodynamic compromise in the setting of tocolytic treatment. However, tocolysis in women with these dangerous diagnoses may sometimes be considered to allow time for the administration of corticosteroids (e.g., in the setting of extreme prematurity when bleeding is believed to occur in response to contractions). Such treatment is fraught with difficulty, because even low dosages of some tocolytic agents can be hazardous in this situation. β -Mimetic agents and calcium channel blockers may hamper maternal cardiovascular response to hypotension, and prostaglandin inhibitors may impair platelet function. Cardiac disease is a contraindication because of the risks of tocolytic drug treatment reported in these patients. Fetal contraindications to tocolysis include gestational age of greater than 37 weeks, fetal demise or lethal anomaly, chorioamnionitis, and evidence of fetal compromise that requires prompt delivery.

Choosing a Tocolytic Agent

The key process in actin-myosin interaction, and thus contraction, is myosin light-chain phosphorylation. This reaction is controlled by myosin light-chain kinase. The activity of tocolytic agents can be explained by their effect on the factors regulating the activity of this enzyme, notably calcium and cyclic AMP. For the myometrium to contract in a coordinated and effective manner (i.e., labor, whether term or preterm), individual smooth muscle cells must be functionally interconnected and able to communicate with adjacent cells. There are no agents used for tocolysis that influence the function or expression of gap junctions. Tocolytic drugs may be safely used when standard protocols are followed. Selection of the appropriate tocolytic requires consideration of the efficacy, risks, and side effects to identify the optimal agent for each patient.

Calcium Channel Blockers

Pharmacology. Calcium channel blockers, marketed to treat hypertension, angina, and arrhythmias, are increasingly being used as tocolytic agents. The pharmacologic effect probably occurs by inhibition of the voltage-dependent channels of calcium entry into smooth muscle cells, which results in decreased intracellular calcium and decreased release of stored calcium from intracellular storage sites. Nifedipine is the calcium blocker most commonly used as a tocolytic agent. Calcium channel blockers are rapidly absorbed after oral administration. Pharmacokinetics in pregnancy are similar to those in the nonpregnant state. Nifedipine appears in plasma

within a few minutes after oral administration, reaches peak concentrations at 15 to 90 minutes, and has a half-life of 81 minutes.²⁵⁶ Placental transfer occurs within 2 to 3 hours after administration of oral nifedipine. In the mother, the duration of action of a single dose is up to 6 hours.

Effectiveness. There are no placebo-controlled trials of calcium channel blockers as tocolytics. The Cochrane Collaboration meta-analyses support the use of calcium channel blockers as short-term tocolytics over other available agents because they exhibit greater contraction suppression and fewer side effects than other agents in 12 reported trials.²⁵⁷ Rates of birth occurring within 7 days after treatment (RR = 0.76; 95% CI, 0.60 to 0.97) and before 34 weeks' gestation (RR = 0.83; 95% CI, 0.69 to 0.99) were significantly reduced with calcium channel blockers, as were the rates of neonatal morbidities, including respiratory distress (RR = 0.63; 95% CI, 0.46 to 0.88), NEC (RR = 0.21; 95% CI, 0.05 to 0.96), IVH (RR = 0.59; 95% CI, 0.36 to 0.98), and jaundice (RR = 0.73; 95% CI, 0.57 to 0.93), when compared with treatment with other tocolytic agents. Fewer women treated with calcium channel blockers ceased treatment due to adverse drug reactions (RR = 0.14; 95% CI, 0.05 to 0.36).

Maternal Effects. Hypotension and headache are the most common side effects of nifedipine. Pretreatment with fluids may reduce the incidence of maternal side effects such as headache (20%), flushing (8%), dizziness, and nausea (6%). Most side effects are mild, but myocardial infarction was documented in a healthy young woman 45 minutes after a second dose of nifedipine.²⁵⁸ Nifedipine is less likely to be discontinued because of maternal side effects than either magnesium sulfate or β -mimetic agents.^{251,259,260} Simultaneous or sequential use of calcium channel blockers with β -mimetics is not recommended because of effects on heart rate and blood pressure. Concurrent administration of magnesium with calcium channel blockers may cause skeletal muscle blockade.²⁶¹ As with other tocolytics, maternal pulmonary edema has been reported.²⁶²

Fetal Effects. Early studies in animals reported fetal hypotension, but a study in women treated with calcium channel blockers for preterm labor revealed no changes in the fetal middle cerebral artery, renal artery, ductus arteriosus, umbilical artery, or maternal vessels.²⁶³ There is one report of fetal death in a patient treated with nifedipine for tocolysis.²⁶⁴ Oei, in summarizing the European experience with nifedipine, advised the following precautions: "Calcium channel blockers should not be combined with intravenous β -agonists. Secondly, intravenous nicardipine or high oral doses of nifedipine (≥ 150 mg/day) should be avoided in cases of cardiovascular compromised pregnant women and/or multiple gestations. In all cases, blood pressure should be monitored and cardiotocography recorded during the administration of immediate release tablets, and patients should be advised to avoid chewing them."²⁶⁵

Treatment Protocol. When used as a tocolytic, nifedipine is commonly given orally with a 10- to 20-mg initial dose, repeated every 3 to 6 hours until contractions are rare, then followed by long-acting formulations of 30 or 60 mg every 8 to 12 hours for 48 hours while antenatal steroids are being administered. Serious maternal and fetal side effects are more likely with short-acting preparations when the drug is initiated, and they are more likely in women with hypertension or other

cardiovascular disorders. The long-acting preparations have fewer side effects, but headache and hypotension still occur. Adverse events are highest among women given more than 60 mg (total dosage) of nifedipine.²⁶⁶

Calcium Channel Blockers: Summary. Nifedipine has been used increasingly as a tocolytic because significant maternal and fetal side effects are uncommon and oral administration is convenient. However, efficacy is not established by placebo-controlled trials, and the ideal dosage regimen is not clear. In general, nifedipine should not be combined with magnesium or β -mimetics, and it should be avoided for women with hypertension or cardiac disease.

Cyclooxygenase Inhibitors

Pharmacology. Prostaglandin synthesis is reduced by inhibition of COX by NSAIDs. Prostaglandins mediate the final pathways of uterine muscle contraction, causing an increase in free intracellular calcium levels in myometrial cells and increased activation of myosin light-chain kinase. Gap junction formation is enhanced by prostaglandins. Prostaglandins given to pregnant women can ripen the cervix or induce labor, depending on the dosage and route of administration. COX, also known as prostaglandin synthase, converts arachidonic acid to prostaglandin G₂ (PGG₂). Prostaglandin synthesis is increased when the COX-2 form of this enzyme is induced by cytokines, bacterial products such as phospholipases and endotoxins, and corticosteroids. NSAIDs vary in activity, potency, and side effects. Indomethacin, the NSAID most often used as a tocolytic, crosses the placenta. Unlike aspirin, indomethacin binds reversibly to COX, so that inhibition lasts only until the drug is excreted. Umbilical artery serum concentrations equal maternal levels within 6 hours after oral administration. The half-life in the mother is 4 to 5 hours; it is 15 hours in a full-term infant but significantly longer in preterm infants.

Effectiveness. The Cochrane Review concluded that indomethacin administration was associated with a significant reduction in births before the 37th week, as well as with increased gestational age at birth and increased birth weight, but it noted that there were insufficient data to determine fetal safety.²⁵⁵

Maternal Effects. Prostaglandin inhibition has multiple side effects because of the abundance of prostaglandin-mediated physiologic functions. Serious maternal side effects are uncommon when the agent is used in a brief course of tocolysis. Gastrointestinal side effects such as nausea, heartburn, and vomiting are common but usually mild. Less common but more serious complications include gastrointestinal bleeding, prolonged bleeding time,²⁶⁷ thrombocytopenia, and asthma in aspirin-sensitive patients. Prolonged treatment with NSAIDs can lead to renal injury, especially if other nephrotoxic drugs are used. Hypertensive women uncommonly experience an acute increase in blood pressure after taking indomethacin. The antipyretic effect of an NSAID may obscure a clinically significant fever. Maternal contraindications to indomethacin tocolysis include renal or hepatic disease, active peptic ulcer disease, poorly controlled hypertension, asthma, and coagulation disorders.

Fetal and Neonatal Effects. Although the maternal side-effect profile is mostly benign, serious fetal and neonatal

complications can occur with COX inhibitors if the drugs are used outside established protocols. In actual practice, such complications are rare, but treatment guidelines must be followed carefully. The major fetal side effects are constriction of the ductus arteriosus, oligohydramnios, and neonatal pulmonary hypertension. Ductal constriction may occur because the formation of prostacyclin and PGE₂, which maintain ductal vasodilation, is inhibited by indomethacin.²⁶⁸ Transient ductal constriction has been reported in as many as 50% of fetuses of women treated with indomethacin before 32 weeks of pregnancy, usually after a week or more of therapy. This typically resolves within 24 hours after the medication is discontinued, without sequelae.^{269,270} However, persistent ductal constriction and irreversible right-sided heart failure have been reported with continued use.²⁷¹

Primary pulmonary hypertension in the neonate has been associated with fetal exposure to NSAIDs²⁷² including ibuprofen, naproxen, aspirin, and indomethacin. Although maternal indomethacin treatment within 16 hours of birth was blamed for a single case of neonatal pulmonary hypertension,²⁷³ neither a case-control series in which 75 exposed fetuses were matched with 150 controls²⁷⁴ nor a literature review and meta-analysis that compared outcomes in 1621 infants treated with indomethacin in utero with 4387 unexposed infants, found significant differences in neonatal morbidity when maternal indomethacin therapy was used in protocols that limited use to 48 hours or less taken before 32 weeks' gestation.^{275,276} This reassuring information does not mitigate the potential fetal risks of NSAID treatment for longer than 48 hours before 32 weeks, or for any duration after 32 weeks, nor the risks associated with prolonged or repeated maternal-fetal exposure to NSAIDs at any time during pregnancy.

Oligohydramnios may accompany indomethacin tocolysis, because indomethacin inhibits the normal prostaglandin inhibition of antidiuretic hormone and also exerts direct effects on fetal renal blood flow. These effects are dosage related and reversible, but they are not inconsequential: Neonatal renal insufficiency and death after several weeks of antenatal maternal treatment has been reported.²⁷⁷ Sulindac is an NSAID that has less placental transfer than indomethacin, but amniotic fluid index, hourly fetal urine production, and ductal blood flow were equally reduced in a randomized comparison of sulindac, indomethacin, and nimesulide.²⁷⁸

Other complications, including NEC, small-bowel perforation, patent ductus arteriosus, jaundice, and IVH, have been observed when indomethacin was used in a clinical setting only after other agents had failed and without limit on the duration or gestational age of treatment.²⁷⁹ No association with IVH has been reported in studies where standard protocols were used.^{274,275,280}

Because of the effect of NSAIDs on fetal urine production and amniotic fluid volume, indomethacin has been used when preterm labor is associated with polyhydramnios.²⁸¹ Uterine activity and pain associated with degenerating uterine fibroids in pregnancy also respond well to indomethacin.

Fetal contraindications to the use of indomethacin include renal anomalies, oligohydramnios, ductal-dependent cardiac defects, and twin-twin transfusion syndrome.

Treatment Protocol. Indomethacin is well absorbed orally. The usual regimen is a 50-mg oral loading dose followed by 25 to 50 mg by mouth every 6 hours. Therapy is generally limited

to 48 hours and to pregnancies before 32 weeks' gestation because of concern about the side effects described earlier.

Amniotic fluid volume and fetal renal anatomy should be assessed before indomethacin is used for tocolysis. Treatment beyond 48 hours may be considered in extraordinary circumstances but requires surveillance of amniotic fluid volume and ductal flow. Repeated courses should be avoided if possible. Treatment should be discontinued if delivery is imminent.

Indomethacin: Summary. Indomethacin is an effective tocolytic agent that is generally well tolerated by the mother. Concern about fetal side effects has appropriately limited the use of indomethacin to brief courses of therapy (48 hours, maximum) in patients with preterm labor before 32 weeks' gestation.

Oxytocin Antagonists

Pharmacology. Oxytocin stimulates contractions in labor at term by inducing conversion of phosphatidylinositol to inositol triphosphate, which binds to a protein in the sarcoplasmic reticulum, causing release of calcium into the cytoplasm. Oxytocin receptor antagonists compete with oxytocin for binding to receptors in the myometrium and decidua, to prevent or reduce calcium release. The oxytocin receptor antagonist, atosiban, inhibits spontaneous and oxytocin-induced contractions but does not affect prostaglandin-induced contractions.

Maternal and Fetal Effects. Maternal side effects are uncommon, because oxytocin receptors are located only in the uterus and breast. Oxytocin antagonists cross the placenta but do not affect fetal cardiovascular or acid-base status.

Effectiveness. Atosiban was evaluated in a randomized, placebo-controlled trial in which 531 women with preterm labor between 20 0/7 and 33 6/7 gestational weeks were treated with either intravenous and subcutaneous atosiban or intravenous and subcutaneous placebo.²⁸² Women in either study arm with persistent contractions and progressive cervical change 1 hour after entry were treated openly with a tocolytic agent of the clinician's choice. The interval from enrollment to delivery did not differ between the two groups (26 versus 21 days; $P = .6$). However, among 424 women who enrolled after 28 weeks' gestation, those treated with atosiban were more likely to remain undelivered without requiring an alternate tocolytic at 24 hours (73% versus 58%; OR = 1.93; 95% CI, 1.30 to 2.86), at 48 hours (67% versus 56%; OR = 1.62; 95% CI, 1.62 to 2.37), and at 7 days (62% versus 49%; OR = 1.70; 95% CI, 1.17 to 2.46). There were no differences in pregnancy prolongation for subjects enrolled between 20 and 28 weeks. The FDA did not approve atosiban because of an unexpected finding of more perinatal deaths among infants born to women enrolled into the atosiban arm before 26 weeks. It is not clear whether the difference in outcomes was related to the drug, or to the larger number of women with gestational age less than 26 weeks who were randomized to the atosiban arm. As in other placebo-controlled tocolytic trials, the rate of "successful" treatment in the placebo group was greater than 50%, indicating the difficulty in distinguishing active preterm labor from preterm parturition.

In another trial that compared subcutaneous infusions of atosiban with placebo infusion,²⁸³ there were no differences in the rates of preterm birth before 28, 32, or 37 weeks' gestation, but the interval from the start of maintenance infusion therapy to the first recurrence of preterm labor was longer for the

atosiban group. An international study group compared the efficacy and side-effect profile of atosiban with those of ritodrine.²⁸⁴ Efficacies in delaying delivery for 48 hours (about 85% for both drugs) and for 7 days (about 75% for both drugs) were similar, but cardiovascular side effects were much less common for atosiban (4%) than for ritodrine (84%).

A Cochrane Review noted that atosiban treatment was associated with an increased number of infants born weighing less than 1500 g in the treatment group, compared with the group receiving placebo (RR = 1.96; 95% CI, 1.15 to 3.35; two trials, 575 infants) but resulted in fewer maternal drug reactions requiring alternative treatment (RR = 0.04; 95% CI, 0.02 to 0.11; four trials, 1035 women). Evidence for the efficacy of atosiban to improve infant outcomes was deemed insufficient.²⁸⁵

In an open, randomized trial of atosiban compared with routinely used tocolytic agents conducted in 585 women, prolongation of pregnancy for 48 hours was equal in both groups, but significantly more women receiving atosiban remained undelivered at 48 hours without requiring an alternative tocolytic (77.6% versus 56.6%; $P < .001$). Maternal side effects were less common in women receiving atosiban.²⁸⁶

Atosiban: Summary. Atosiban has minimal maternal side effects and an efficacy that is comparable with that of other tocolytics. Although it is commonly used in Europe, it was not approved by the FDA because of concerns about fetal outcomes in women treated before 26 weeks, but those outcomes may not have been related to the drug.

Nitric Oxide Donors

Pharmacology. Nitric oxide (NO) acts to maintain normal smooth muscle tone. It is synthesized during the oxidation of L-arginine to L-citrulline, a reaction catalyzed by nitric oxide synthase (NOS). The interaction between NO and soluble guanylyl cyclase (sGC) links extracellular stimuli of NO formation to synthesis of cyclic guanosine 3',5'-monophosphate (cGMP) in target cells. The increase in cGMP content in smooth muscle cells activates myosin light-chain kinase, which causes smooth muscle relaxation. NO donors such as nitroglycerin inhibit spontaneous oxytocin- and prostaglandin-induced activity.

Glyceryl trinitrate (GTN) has been studied as an acute uterine relaxant to allow uterine manipulation for external cephalic version or ex utero fetal surgery and also as a tocolytic agent. Studies of GTN as a tocolytic have produced mixed results. Intravenous GTN was less effective in arresting contractions and had more side effects than magnesium sulfate in a study of 31 subjects.²⁸⁷

Maternal Effects. Headache and hypertension are the most commonly reported maternal side effects. In a randomized trial²⁸⁸ that compared transdermal GTN with ritodrine, treatment was discontinued in 25% of the GTN group because of maternal hypotension. Headache was frequent, occurring in 30% of GTN-treated women.

Fetal Side Effects. Fetal side effects are not commonly reported but might be expected because of the drug's effect on maternal blood pressure. Kahler and colleagues investigated maternal and fetal blood flow with Doppler ultrasound in women treated for preterm labor with GTN patches at a dosage of 0.8 mg/hr and found no effect on blood flow in any fetal organ.²⁸⁹

Effectiveness. In the trial that compared GTN to ritodrine, 26% of women in both arms delivered before 37 weeks.²⁸⁸ The Cochrane Review summarized four randomized trials that compared NO to placebo, no treatment, or other tocolytics and found that NO treatment of preterm labor was associated with fewer deliveries before 37 weeks, but the data were insufficient to assess newborn outcomes.²⁹⁰ A subsequent randomized trial compared β -mimetic tocolysis with GTN plus rescue β -mimetic tocolysis for persistent contractions in 235 women at 24 to 35 weeks' gestation in whom preterm parturition was confirmed by a positive finding of cervicovaginal fetal fibronectin or ruptured membranes. There was no significant difference in the time to delivery using Kaplan-Meier curves ($P = .451$).²⁹¹ In another placebo-controlled trial of NO tocolysis before 28 weeks, also published since the Cochrane Review, composite neonatal morbidity was significantly reduced in infants born to mothers treated with NO.²⁵⁰ This is one of the few studies to report improved neonatal outcome, but these studies are insufficient to recommend NO donors until additional, larger studies are reported.

Nitric Oxide: Summary. Nitric oxide donors have not been widely used for tocolysis but deserve further investigation. Current data do not support their use outside clinical trials.

Magnesium Sulfate

Pharmacology. Magnesium acts by competition with calcium either at the motor end plate (reducing excitation by affecting acetylcholine release and sensitivity at the motor end plate)²⁹² or at the cell membrane (reducing calcium influx into the cell at depolarization). Myometrial contractility is inhibited when maternal serum levels of magnesium are 5 to 8 mg/dL.²⁹³ Deep tendon reflexes may be lost when concentrations reach 9 to 13 mg/dL, and respiratory depression defects occur at 14 mg/dL. Magnesium is excreted almost entirely by the kidney, with at least 75% of the infused dose of magnesium (for the treatment of preeclampsia) excreted during the infusion and at least 90% excreted within 24 hours.²⁹⁴ As magnesium is reabsorbed in the loop of Henle by a transport-limited mechanism, the glomerular filtration rate affects excretion significantly. Increases in maternal serum magnesium also result in maternal hypocalcemia (the total calcium level falling by approximately 25%) and an increase in parathyroid hormone, but no change in maternal phosphate or calcitonin level. Hypocalcemia is usually asymptomatic. Magnesium ions cross the placenta rapidly, with fetal and newborn levels increasing proportionately with maternal levels.²⁹⁵ The mean half-life of neonatal hypermagnesemia secondary to maternal therapy may be as long as 40 hours.²⁹⁴

Maternal Effects. Magnesium has a low rate of serious maternal side effects, but flushing, nausea, vomiting, dry mouth, headache, blurred vision, generalized muscle weakness, diplopia, and shortness of breath occur, together with maternal sense of loss of control. Chest pain and pulmonary edema have been reported with a frequency similar to that seen with β -mimetics.²⁹⁶ If renal function is impaired (and magnesium excretion is thus reduced), hypermagnesemia leading to respiratory impairment is more likely. Theoretically, high serum magnesium concentrations could alter the amount of muscle relaxant needed during general anesthesia. Magnesium should not be used as a tocolytic in women with myasthenia gravis. Hypocalcemia may be asymptomatic, or it may manifest as hand contractures.²⁹⁷

Prolonged treatment has been associated with maternal osteoporosis.²⁹⁸ Neuromuscular blockade is possible if magnesium is used concurrently with nifedipine tocolysis.

Neonatal Effects. Magnesium crosses the placenta and achieves serum levels comparable to maternal levels, but serious short-term neonatal complications are uncommon if the duration of maternal therapy does not exceed 48 hours. Neonatal lethargy, hypotonia, and respiratory depression may occur. Prolonged magnesium tocolysis has also been associated with neonatal bone demineralization.²⁹⁹ Large studies (described earlier) that demonstrated the neuroprotectant benefits of magnesium sulfate have overcome an early report of possible adverse neonatal and infant effects of antenatal magnesium treatment.³⁰⁰ Subsequent randomized trials have enrolled more than 30 times as many subjects without evidence of increased neonatal or infant mortality related to magnesium and have demonstrated a reduction in moderate to severe cerebral palsy in surviving infants.^{246,299,301-305}

Effectiveness. Evidence to support magnesium sulfate as an effective tocolytic is weak.^{306,307} The Cochrane Library reviewers found no significant advantage regarding the rates of delivery within 48 hours or before 34 or 37 weeks in studies of women treated with magnesium.²⁵⁴ Two small randomized trials compared magnesium with nifedipine²⁵⁹ and celecoxib³⁰⁸, both found no difference in the percentage of women who delivered within 48 hours.

Despite the limited evidence of benefit, magnesium has been a common choice because of its familiarity and presumed safety relative to β -mimetics and other tocolytics. This rationale for choosing magnesium sulfate has been challenged by reviews that emphasized the paucity of data to support any benefit.³⁰⁹⁻³¹² Direct evidence of improved fetal, neonatal, or infant outcomes attributable to magnesium tocolysis is absent, and indirect support from comparative trials and secondary analyses is weak.^{254,306,309,311,312}

Treatment Protocol. Magnesium sulfate must be given parenterally to achieve serum levels above the normal range. Therapeutic dosage regimens are similar to those used for intravenous prophylaxis of seizures in women with preeclampsia. The customary clinical protocol for magnesium sulfate begins with a loading dose of 4 to 6 g MgSO₄ in a 10% to 20% solution (60 mL of 10% MgSO₄ in 5% dextrose in 0.9% normal saline) given over 30 minutes.²⁹⁶ This is followed by a maintenance dose of 2 g/hr (40 g of MgSO₄ added to 1 L 5% dextrose in 0.9% normal saline or Ringer lactate solution at 50 mL/hr). The intravenous rate is increased by 1 g/hr until the patient has less than one contraction per 10 minutes or until a maximal dose of 3 or 4 g/hr is reached. Intravenous fluids are restricted to 125 mL/hr. Fluid status should be followed closely. Deep tendon reflexes and vital signs, including respiratory rate, should be recorded hourly. Magnesium levels may be obtained to answer safety concerns, but the infusion should be reduced or stopped without waiting for drug level results if respiration or urine output declines. Calcium gluconate should be readily available to reverse the effects of magnesium.

Once contractions have decreased to less than one every 10 to 15 minutes, or once they have ceased, the infusion may be discontinued without first tapering the infusion rate. Magnesium is sometimes continued until an arbitrary end point is

reached (e.g., 12 hours after contractions cease) or until a steroid course is completed, but this approach is unsupported by data.

If renal function is normal, magnesium is excreted rapidly in the urine. Magnesium should be administered cautiously in women with evidence of renal impairment, such as oliguria or serum creatinine levels higher than 0.9 mg/dL. Magnesium sulfate should not be used in women with myasthenia gravis, because the magnesium ion competes with calcium.

Magnesium Sulfate: Summary. The tocolytic efficacy of magnesium sulfate is not supported by the literature.

β-Mimetic Tocolytics

Pharmacology. β -Sympathomimetic drugs, including terbutaline, ritodrine, and others, have been widely used for tocolysis. These agents act to relax smooth muscle in the bronchial tree, blood vessels, and myometrium through stimulation of the β -receptors. β -Receptors are divided into β_1 and β_2 subtypes. The β_1 -receptors are largely responsible for the cardiac effects, and β_2 -receptors mediate smooth muscle relaxation, hepatic glycogen production, and islet cell release of insulin. Variable ratios of β_2 - to β_1 -receptors occur in body tissues. Stimulation of β_1 -receptors in the heart, vascular system, and liver accounts for the side effects of these drugs. The most commonly used β -mimetic in the United States is terbutaline (marketed as a drug for asthma), but others, including albuterol, fenoterol, hexoprenaline, metaproterenol, nylidrin, orciprenaline, and salbutamol, are used in other countries. Although ritodrine was approved by the FDA for tocolysis in 1980, it did not achieve wide use because of frequent maternal side effects, and it is no longer marketed. Terbutaline has a rapid effect when given subcutaneously (3 to 5 minutes). Published protocols often employ subcutaneous administration, with a usual dosage of 0.25 mg (250 μ g) every 4 hours.³¹³

Maternal Side Effects. Maternal side effects of the β -mimetic drugs are common and diverse because of the abundance of β -receptors in the body. Maternal tachycardia, chest discomfort, palpitation, tremor, headache, nasal congestion, nausea and vomiting, hyperkalemia, and hyperglycemia are significantly more common in women treated with β -mimetics.²⁵³ Most side effects are mild and of limited duration, but serious maternal cardiopulmonary and metabolic complications have been reported. Terbutaline has been the subject of repeated FDA warnings: “*Terbutaline administered by injection or through an infusion pump should not be used in pregnant women for prevention or prolonged (beyond 48-72 hours) treatment of preterm labor due to the potential for serious maternal heart problems and death. In addition, oral terbutaline tablets should not be used for prevention or treatment of preterm labor*” (see www.fda.gov/Drugs/DrugSafety/ucm243539.htm).

Cardiopulmonary Complications of β -Mimetics. The β -mimetic agents can produce a mild (5 to 10 mm Hg) fall in diastolic blood pressure, and the extensive peripheral vasodilation may make it difficult for the patient to mount a normal response to hypovolemia. Exclusion of women with any history of heart disease or significant hemorrhage, and limitation of infusion rates to maintain maternal heart rate at less than 130 beats/min, are important steps to avoid cardiac complications. Symptomatic arrhythmias and myocardial ischemia have occurred during β -agonist tocolytic therapy; myocardial

infarction leading to death has been reported.³¹⁴ Tocolysis should be discontinued and oxygen administered whenever a woman reports chest pain during tocolytic therapy. Premature ventricular contractions, premature nodal contractions, and atrial fibrillation noted in association with β -mimetic therapy usually respond to discontinuation of the drug and oxygen administration. Baseline or routine electrocardiograms before or during treatment are not helpful. Nonetheless, an electrocardiogram is indicated if there is no response to oxygen and cessation of β -mimetic therapy. Pulmonary edema has been reported with all tocolytics, including β -mimetic therapy. Restriction of the duration of treatment to less than 24 hours, careful ongoing attention to fluid status, and detection of complicating conditions such as intrauterine infection may reduce this risk.

Metabolic Complications. β -Mimetic agents induce transient hyperglycemia and hypokalemia during treatment. Measurement of glucose and potassium before therapy is initiated, and, on occasion during the first 24 hours of treatment, may be appropriate to identify significant hyperglycemia (>180 mg/dL) or hypokalemia (<2.5 mEq/L). These metabolic changes are mild and transient, but prolonged treatment (>24 hours) may induce significant alterations in maternal blood sugar, insulin levels, and energy expenditure.³¹⁵ The risk for abnormal glucose metabolism is further increased by simultaneous treatment with corticosteroids. Other agents should be chosen for women with pregestational diabetes and gestational diabetes.

Neonatal Effects. Neonatal hypoglycemia, hypocalcemia, and ileus may occur after treatment with β -mimetics and can be clinically significant if the maternal infusion is not discontinued 2 hours or more before delivery.

Effectiveness. In a Cochrane Database analysis of 1332 women enrolled into 11 randomized, placebo-controlled trials of β -mimetic drugs, treated subjects were less likely to deliver within 48 hours (RR = 0.63; 95% CI, 0.53 to 0.75), but not less likely to deliver within 7 days.²⁵³ Perinatal and neonatal mortality and perinatal morbidity were not reduced by β -mimetic treatment in this analysis. Side effects requiring change or cessation of treatment were frequent. Other reviews have reported similar conclusions.³¹⁶

Because of their potential for clinically significant side effects and the availability of alternative choices, the β -sympathomimetic agents should not be used in women with known or suspected heart disease, severe preeclampsia or eclampsia, diabetes, or hyperthyroidism. These drugs are contraindicated if suspected preterm labor is complicated by maternal fever, fetal tachycardia, leukocytosis, or other signs of possible chorioamnionitis.

Long-term or maintenance use of β -mimetic drugs was once advocated to suppress contractions, but desensitization of the adrenergic receptor (tachyphylaxis) occurs after prolonged exposure to β -agonists, so that increasing dosages are required to maintain a response. Continuous subcutaneous infusion of terbutaline has fewer side effects at lower dosages than oral administration.³¹⁷ Although these protocols suppressed contractions, rates of preterm birth or perinatal morbidity were not reduced in randomized, placebo-controlled trials,^{318,319} and significant side effects were reported that led to the aforementioned FDA warning. Neither the Cochrane Review nor the most recent ACOG practice bulletin³²⁰ supports terbutaline infusion to prolong pregnancy.³²¹

β-Mimetic Tocolysis: Summary. β-Mimetic drugs were once commonly used as tocolytics, but they have been replaced by agents with better safety and side effect profiles. Long-term oral or subcutaneous treatment has not been shown in controlled trials to reduce either prematurity or neonatal morbidity, and it has notable patient safety concerns.

CLINICAL USE OF TOCOLYTIC DRUGS

Tocolytic therapy is used in several clinical circumstances. In caring for a woman with active contractions and advanced cervical effacement with the goal of arresting labor to allow time for maternal transfer, administration of antenatal steroids, and GBS prophylaxis, treatment with oral indomethacin or nifedipine may stop contractions promptly, after which the indomethacin or nifedipine can be continued. Treatment can be continued at least until contractions occur less frequently than four times per hour without additional cervical change. If labor has been difficult to stop in a patient with complete cervical effacement, acute treatment may be continued for 48 hours while steroid therapy is completed.

If contractions persist despite therapy, the wisdom of tocolytic treatment should be reevaluated. If cervical dilation has progressed beyond 4 cm, treatment should in most instances be discontinued. The presence of persistent contractions despite ongoing tocolysis raises the possibility of placental abruption or intra-amniotic infection. Amniocentesis should be considered.

If contractions persist without progressive cervical change, the risk for imminent preterm birth should be reevaluated, remembering that significant effacement, softness, and development of the lower uterine segment are the features of the digital examination that most reliably indicate preterm labor. If a fibronectin swab was collected before therapy was begun, it should be sent for analysis. A positive fibronectin test is not confirmatory, but a negative result, if collected before performance of a digital examination, suggests that preterm birth is unlikely (4%) within 2 weeks.^{220,228} Alternately, a transvaginal cervical ultrasound examination may be performed. A cervical length of 30 mm or more essentially excludes the diagnosis of preterm labor except in cases of acute abruption.²¹⁹

Initiating treatment with a second agent is often considered when contractions persist, but this is not supported by literature. Serum concentrations of tocolytic drugs are not helpful to guide treatment. A change to a second agent or combination therapy with multiple agents may slow contractions, but this approach often results in increased side effects and has not been shown to be efficacious. Sustained treatment with multiple tocolytics increases the risk for significant side effects and should be avoided.

CARE AFTER TREATMENT FOR PRETERM LABOR

Continued suppression of contractions after acute tocolysis does not reduce the rate of preterm birth.³²²⁻³²⁴ Meta-analyses of the relevant data found no evidence of prolongation of pregnancy or decline in the frequency of preterm birth.^{321,325} Out-patient monitoring of uterine contractions and associated care did not improve the rate of delivery before 37 weeks, birth weight, or gestational age at delivery.^{326,327}

The duration of hospitalization for preterm labor is influenced by the dilation, effacement, and sonographic length of

the cervix, ease of tocolysis, gestational age, obstetric history, distance from the hospital, and the availability of home and family supportive care. Risk factors that may complicate or increase the risk for recurrent preterm labor, such as a positive genital culture for chlamydia or gonorrhea, urinary tract infection, and anemia, should be addressed before the woman is discharged from hospital care. Social issues such as homelessness, availability of child care, or protection from an abusive partner are important determinants of a patient's ability to comply with medical care and must also be considered before the patient is released from the hospital.

Prevention of Preterm Birth

STRATEGIES

Primary prevention of the morbidity and mortality of preterm birth is an increasingly compelling strategy as the limitations of tertiary care are recognized. Public awareness of the importance of preterm birth as a leading cause of infant mortality remains low.³²⁸ Care aimed at reducing risk and amelioration of the consequences of preterm birth have advanced significantly in recent years, but primary prevention will require increased attention to social as well as biologic pathways that lead to prematurity. Systemic approaches to prevention of preterm birth and improved outcomes for preterm infants include quality improvement initiatives aimed at optimally structured prenatal care coordination,³²⁹ appropriate timing of scheduled births,^{330,331} optimal use of antenatal corticosteroids and progesterone prophylaxis, promotion of breastfeeding, and prolongation of the interval between conceptions. These efforts and others are reviewed in the March of Dimes' publication, *Toward Improving the Outcome of Pregnancy III*.³³²

Meanwhile, attempts to prevent preterm birth must recognize that prolongation of pregnancy intended to promote maturation might in some cases allow continued exposure to a suboptimal or even hazardous intrauterine environment. Indeed, gestational age at birth is only a surrogate end point for optimal fetal, infant, and lifelong health.^{5,333} Indicated preterm birth is by definition intended to improve maternal or fetal (or both) and neonatal health, in contrast to presumed fetal benefit by continuing the pregnancy in spontaneous preterm parturition. However, the distinction between indicated and spontaneous preterm birth can be artificial, because factors leading to labor and membrane rupture are understood to include intrauterine inflammation related to microbial infection, uterine vascular compromise, or decidual hemorrhage, all of which may contribute to neonatal and infant morbidity as much or more than fetal immaturity.

PREVENTION OF INDICATED PRETERM BIRTH

Strategies to prevent indicated preterm births target women with medical disorders and women with risk factors for preeclampsia, such as nulliparity, twin gestation, diabetes, chronic hypertension, and a history of preeclampsia or growth restriction. Numerous trials of various agents (low-dosage aspirin,^{334,335} antioxidant vitamins C and E,³³⁶ and fish oil^{337,338}) have been conducted to test their effects on the rates of preeclampsia, fetal growth restriction, and preterm birth. Cochrane Reviews³³⁹ have found modest benefit for antiplatelet drugs, chiefly low-dosage aspirin:

- An 8% reduction in the risk for preterm birth from a review of 29 trials that enrolled a total of 31,151 women (RR = 0.92; 95% CI, 0.88 to 0.97)
- A 10% reduction in small-for-gestational-age infants in a review of 36 trials that enrolled 23,638 women (RR = 0.90; 95% CI, 0.83 to 0.98)
- A 14% reduction in fetal or neonatal deaths in a review of 40 trials that enrolled 33,098 women (RR = 0.86; 95% CI, 0.76 to 0.98)

A Cochrane Review found a significant reduction in preeclampsia in women treated with supplemental calcium, with a concomitant reduction in preterm births,³⁴⁰ but there was no independent effect on the incidence of spontaneous preterm birth.³⁴¹ Similar reviews of the use of antioxidants to prevent preeclampsia found a slight decrease in preeclampsia but no evidence of a corresponding reduction in the risk for preterm birth.³⁴²

PREVENTION OF SPONTANEOUS PRETERM BIRTH IN PREGNANCY

Efforts to prevent preterm birth after conception have been difficult for two reasons. First, because more than half of preterm infants are born to women without apparent risk factors,^{142,343} prematurity prevention must be part of prenatal care for every woman. Second, because treatment of recognized risk factors (e.g., genitourinary tract infection) does not reduce the incidence of preterm birth, criteria for universal screening for preterm birth were not met: there were no effective interventions for women identified as being at risk. These limitations were eroded by studies demonstrating reduced risk for recurrent preterm birth in women with a prior spontaneous preterm birth treated with progestins, and they have now been further reduced by the recognition that short cervix is evidence of the early onset of parturition, that it can be detected by transvaginal ultrasound, and that it can be treated with some success with supplemental progesterone. These recent findings will require prenatal care providers to adopt locally appropriate strategies to identify women who are candidates for progesterone prophylaxis because of a prior preterm birth or short cervix, or both. Potential strategies are outlined in the following paragraphs. Regardless of the strategy chosen, limitations remain that relate to three unresolved factors:

- The percentage of preterm births that are preceded by cervical shortening, and how to find and treat those that are not
- The percentage of preterm births preceded by cervical shortening that are and are not amenable to progestin treatment and prophylaxis, and how to find and treat those that are not
- Issues related to training of personnel, ensuring the quality of cervical length measurement, cost, and efficient application in practice must be addressed to determine optimal strategies for screening for short cervical length.

Continued consideration of *risk assessment* as distinct from *treatment* remains relevant because risk factors associated with preterm birth may still contribute independently to adverse outcomes or contribute by accelerating preterm parturition, or both (e.g., maternal cigarette smoking). Risk factors may also serve as markers to identify candidates for cervical ultrasound screening for short cervix. Such strategies have not yet been tested, but they may appeal to those reluctant to adopt universal

cervical length screening. The following paragraphs will review strategies to reduce risk during pregnancy.

Prenatal Care

Preterm birth may be addressed by changes in the structure as well as the content of prenatal care. Removal of economic, transportation, and cultural barriers to a first prenatal visit, accelerated first visits for women with risk, geographic identification of risk zones, group prenatal care, alternative care providers, and alteration of the traditional preeclampsia-detection-based schedule of visits have been considered as potential pathways to reduce prematurity. The content and pace of prenatal care will probably require revision to incorporate historical and ultrasound screening, as well as prophylaxis for preterm birth.

Access. Early entry into care is associated with low rates of preterm birth, but the relationship is more likely related to the high rate of preterm birth among women who receive no prenatal care rather than to the content of early prenatal care. For example, early access to prenatal care did not influence the rate of preterm births among women enrolled in the First- and Second-Trimester Evaluation of Risk (FaSTER) study of prenatal diagnostic techniques in the first and second trimesters.³⁴⁴ Rates of preterm birth remained notably high among African-American women in this study despite early prenatal care. However, early care can create opportunities to identify risk factors and overcome obstacles to performing cervical sonography or beginning progesterone prophylaxis. Accelerated entry into care for women with risk factors for preterm birth is important.

Enhanced Care for Women with Risk. Enhanced prenatal care including social support, home visits, and education has not been an effective strategy to decrease preterm births.³⁴⁵⁻³⁴⁹ A Cochrane analysis found no benefit for enhanced prenatal care in women with increased risk.³⁵⁰ However, these efforts antedate application of cervical ultrasound, prophylactic progestins, and group prenatal care to women at risk.

Group prenatal care, in which traditional and enhanced prenatal care are provided in a supportive learning group of women with similar gestational age and demography led by a nurse or other health professional, has been associated with lower rates of preterm birth in studies of women who self-selected this approach³⁵¹ and in a randomized trial.³⁵² This is a subject of active investigation.

Preterm birth rates reported from prematurity prevention clinics have been inconclusive. A multicenter randomized trial that compared intensive patient education and frequent visits to routine care in more than 3000 high-risk women reported no significant differences in preterm birth rates³⁴⁷ but a single-site study reported a 19% reduction in preterm birth rates in high-risk women who received increased education and more frequent obstetric visits.³⁵³ Results from studies evaluating the effect of progestin supplementation in clinical practice are few and inconsistent. Manuck and colleagues reported a recurrent spontaneous preterm (<37 weeks) birth rate of 48.6% in 70 women seen in a prematurity clinic, compared with 63.4% in 153 women who received routine prenatal care.³⁵⁴ Composite neonatal morbidity was significantly reduced in infants born to women cared for in the prematurity clinic. Bastek and coworkers found no difference in the rates of spontaneous preterm birth at less than 37 weeks' gestation (16.7% versus 16.9%)

before and after progestin supplementation was introduced, but the mean gestational age at birth was more than a week longer after progesterone was adopted.³⁵⁵ Another prematurity prevention clinic reported a decline in preterm birth rates associated with progesterone use only after a policy change was made to identify progestin candidates among women with a prior preterm birth before 14 weeks' gestation, so as to overcome barriers to initiating treatment at 16 weeks.³⁵⁶

Modification of Maternal Activity

Restriction of physical activity, including bed rest, limited work, and reduced sexual activity, are frequently recommended to reduce the likelihood of preterm birth in pregnancies at risk for indicated and spontaneous birth, despite the absence of benefit and considerable evidence of maternal risk in the literature.³⁵⁷ Yost and colleagues found no relationship between coitus and risk for recurrent preterm birth.⁸⁵ However, limitation of sexual or physical activity has not been studied in women with short cervix.

Nutritional Supplements

Vitamins. Rates of spontaneous preterm birth before 37, 34, and 28 weeks' gestation were not improved by supplemental vitamin C and vitamin E given to prevent preeclampsia in a randomized trial conducted in 1877 healthy women.³⁵⁸ Another randomized trial in 9968 nulliparous women concluded that supplementation with vitamins C and E beginning at 9 to 16 weeks of gestation did not reduce spontaneous preterm births appearing with either preterm labor or ruptured membranes.³⁵⁹ There is insufficient evidence to determine the effect, if any, of supplemental vitamin D.³⁶⁰

Prolonged pre-conceptional folic acid supplementation was associated with a lower risk for preterm birth in a study based on maternal recall of prenatal vitamin intake over the preceding 2 years,³⁶¹ but this observation was made in a low-risk population and has not been confirmed in prospective studies.

Minerals. As noted, calcium supplementation reduces the incidence of preterm birth related to preeclampsia, but Cochrane Reviews discerned no effect on spontaneous preterm birth.^{340,341} Studies of other micronutrient minerals are limited but suggest that benefit, if any, of supplementation is limited to populations with dietary deficiencies.

Food Content. The preterm birth rate is low in populations with a high dietary intake of ω -3 polyunsaturated fatty acids (PUFAs), which reduce levels of proinflammatory cytokines. Dietary supplementation with PUFAs has been associated with reduced production of inflammatory mediators thought to participate in inflammation-driven parturition. A randomized trial of ω -3 supplements conducted in women at risk for preterm birth reported a 50% reduction in preterm births.³³⁷ A subsequent randomized trial of supplemental fish oil also reported a significant reduction in recurrent preterm birth (RR = 0.54; 95% CI, 0.30 to 0.98),³³⁸ but a randomized, placebo-controlled trial of supplemental ω -3 PUFAs in 852 women with a prior preterm birth found no effect of ω -3 supplementation on birth or spontaneous birth before 37 or 35 weeks (RR = 0.91; 95% CI, 0.77 to 1.07). The treatment groups did not differ when stratified by fish intake (RR = 0.92; 95% CI, 0.78 to 1.08). In this study, all participants in both arms were treated with 17OHPC.³⁶² In a secondary analysis of data from this study,

women who ate fish at least once a month had a significantly reduced rate of spontaneous preterm birth compared with women who consumed fish less than once a month (RR = 0.62; 95% CI, 0.45 to 0.86), regardless of their study assignment.

Proteins and Calories. The effects of protein and calorie supplementation during pregnancy are less clear.³⁶³ Although nutritional advice was associated with improved rates of preterm birth, energy and protein supplementation were not, and high-protein supplementation was linked to increased risk for small-for-gestational-age infants.

Smoking Cessation

Smoking cessation programs are more likely to be well received among pregnant than among nonpregnant women.³⁶⁴ A brief (<15 minutes) counseling session with a trained provider offering pregnancy-specific counseling was found to reduce smoking rates in pregnant women.³⁶⁵ The reduction was modest but clinically significant (RR = 1.7; 95% CI, 1.3 to 2.2). Smoking reduction and cessation in prenatal visits are persistently emphasized in most programs. Smoking cessation in pregnancy may be more successful when specific funding for this service is available.³⁶⁵ One program reported successful results in 3569 indigent women who received care coordination, nutritional counseling, or psychosocial counseling to address specific risks including smoking and inadequate weight gain.³⁶⁶ Women who stopped smoking had fewer LBW infants than women who continued to smoke (8.5% versus 13.7%). The rate of LBW infants was lower in women who achieved adequate weight gain than in those who did not (6.7% versus 17.2%). A Cochrane Review concluded that smoking cessation programs in pregnancy can produce moderate reductions in preterm birth (RR = 0.94; 95% CI, 0.93 to 0.96).³⁶⁷

Screening for Infection

Asymptomatic Bacteriuria. Screening and treatment for asymptomatic bacteriuria prevents pyelonephritis³⁶⁸ and has been reported to reduce the rate of preterm birth, but the optimal screening and treatment protocols to prevent preterm birth have not been studied recently.^{119,369}

Genital Infections. Genital tract colonization and infection are consistently associated with risk for preterm birth, but trials of screening and treatment for organisms including *U. urealyticum*,³⁷⁰ GBS,³⁷¹ and *T. vaginalis*^{115,372} have not demonstrated consistent reductions in the incidence of preterm birth despite eradication of the target organism. In some studies, antibiotic treatment of screen-positive women has increased the risk for preterm birth.^{115,372,373}

Routine screening of all pregnant women for BV, with treatment intended to reduce preterm birth, has been extensively studied, with mixed results.^{108,112,374,375} BV carriage has been associated with a positive screening test for fetal fibronectin.^{117,376} Although a secondary analysis suggested that antibiotic treatment might reduce the rate of preterm birth in women with BV who also have a positive fibronectin screen,³⁷⁷ the rate of preterm birth was not reduced by antibiotic treatment of women with a positive fetal fibronectin result who were treated with antibiotics in a randomized trial.³⁷⁸ Therefore, despite the consistent linkage of maternal BV to risk for preterm birth, and despite the ability of antimicrobial therapy to eradicate BV, screening and treatment for BV does not reliably reduce the

occurrence of preterm birth in low-risk women^{108,375} and is not recommended for these patients.^{221,379}

Antibiotic treatment for women with a prior preterm birth who also have BV was suggested by secondary analyses of data from two trials, one that enrolled women at risk for preterm birth,³⁸⁰ in which benefit was found only in women with BV, and another that enrolled women with BV,³⁸¹ in which benefit was limited to women with a prior preterm birth. Other trials of treatment for BV-positive women have produced conflicting results, perhaps because of variations in the timing, dosage, and antibiotic employed.^{373,382-384}

Lamont and colleagues^{385,386} argued that clindamycin used before 22 weeks' gestation to treat women with abnormal vaginal flora can reduce the incidence of preterm birth, but others express concern about higher rates of preterm birth in women treated with metronidazole^{115,373,378} and about the negative results of a Cochrane Review of 15 trials involving 5888 women.¹⁰⁸

The data produced by these trials suggest that the contribution to preterm birth of microorganisms colonizing and infecting the genital tract varies significantly between women, probably because of genetic and environmental exposures that must be further elucidated before antimicrobial agents can be used effectively and safely to prevent preterm birth. The appropriate role for antimicrobial therapy to reduce the risk for preterm birth cannot be determined until questions about the roles of concurrent exposures (e.g., smoking), host factors influencing immune defenses, and selection and timing of treatment are answered.^{127,387,388}

Screening to Assess Risk of Preterm Birth

Tests to assess risk for preterm birth may be useful when effective treatment is available for a positive test, or when a negative test result may safely avoid an intervention that has risk, inconvenience, high cost, or limited circumstances for use. Appropriate use of antenatal corticosteroids and tocolytic drugs are good examples. Assessment of the risk for imminent preterm birth may also be helpful when maternal transport to a tertiary care center is considered.

Scoring Systems and Biomarkers. Biologic markers of parturition have been studied as potential screening tests, alone and in combination with clinical risk factors, to create scoring systems that have had limited sensitivity, and, until recently, they did not identify women for whom an effective intervention was available. Clinical characteristics such as a maternal BMI of less than 19.6 kg/m², African-American ethnicity, social deprivation, and genitourinary colonization have been studied together with markers of parturition in maternal serum (α -fetoprotein, alkaline phosphatase, corticotropin-releasing hormone, relaxin) and cervical fluid (fetal fibronectin, granulocyte colony-stimulating factor, interleukins),^{142,376,389,390} but a clinical use has not been found.

Uterine contraction frequency was studied extensively as a screen for risk for preterm birth and as a marker of impending preterm labor.³⁹¹ Although contraction frequency is associated with preterm birth, it did not prove to be an efficient screening test because of the wide variation in contraction frequency in normal and complicated pregnancies.^{191,193,194}

Fetal Fibronectin. Fetal fibronectin, a glycoprotein thought to act as an adherent at the maternal-fetal interface, is uncommonly present in cervicovaginal secretions in the late second

and early third trimesters.^{376,392} Although the risk for preterm birth increases as the level of fetal fibronectin rises,³⁹³ it has been evaluated only as a qualitative test, with a value of 50 ng/dL or greater being called positive. A positive test is believed to indicate disruption of the maternal-fetal decidual attachment.³⁹⁴ Asymptomatic women with a positive fetal fibronectin test have an increased risk for preterm birth before 35 weeks, especially within 2 weeks of a positive result.^{376,395} Although the sensitivity of the fibronectin test at 22 to 24 weeks for all spontaneous births before 35 weeks was only 25%, sensitivity for births before 28 weeks was 65% in one study.³³² Placebo-controlled trials of antibiotics in women with a positive fibronectin result,³⁷⁸ and in women with historical risk and a positive fibronectin result,³⁷³ were disappointing. Preterm birth rates were not improved by antibiotic treatment in either trial, and in fact were slightly higher in women who received antibiotics. No other interventions for women with a positive fetal fibronectin test have been evaluated in controlled trials. Screening of low-risk women with fetal fibronectin testing is not recommended.³⁹⁶

Cervical Examination

Digital Examination of the Cervix. Recent emphasis on transvaginal ultrasound measurement of cervical length does not make digital assessment of the cervix obsolete but rather informs the digital examination by placing emphasis on the changes in cervical effacement, consistency, and position that precede dilation. Digital examination should document the position, consistency, length, and dilation of the cervix along the lateral fornix to generate a Bishop score,³⁹⁷ where a score of 4 or greater indicates cervical ripening has occurred. The cervical score (calculated by subtracting the cervical dilation in centimeters from the cervical length in centimeters, and ranging from +4 to -4), had a clinical usefulness similar to that of sonographic cervical length in judging risk for preterm birth.³⁹⁸

Cervical Ultrasound. Changes in the cervix preceding myometrial activation may be used to identify women in whom the parturitional process has begun. Evaluation of the cervix by transvaginal ultrasound measurement of cervical length (Boxes 40-2 and 40-3) identifies women with increased risk for preterm birth.^{196,199,217,399,402} However, because preterm cervical ripening occurs at variable rates over a period of weeks and does not always progress to early birth, the sensitivity of cervical length to predict preterm birth is modest—35% to 40%. In addition to measurement of cervical length, transvaginal sonography can detect other signs of pathologic parturition, such as the presence of debris (or sludge), a sign of intrauterine microbial colonization,⁴⁰³ and membrane edema or separation from the decidua.

Combined Testing. A comparison of digital examination, fetal fibronectin testing, and cervical sonography to predict birth before 35 weeks in nulliparous and low-risk multiparous women reported low sensitivity for all three tests: less than 25% each for digital examination and fibronectin, and 39% for cervical sonography.⁴⁰⁴ Sequential use of digital examination or fibronectin screening followed by cervical ultrasound had very low sensitivity. A study of women with greater a priori risk (254 women with and 52 women without a prior preterm birth)¹⁹⁴ found that tests of cervical change by digital examination or ultrasound had significantly greater sensitivity for subsequent preterm birth than tests for decidual or uterine activation, suggesting that cervical preparation typically precedes decidual

BOX 40-2 TRANSVAGINAL ULTRASOUND (TVU) MEASUREMENT OF CERVICAL LENGTH

TECHNIQUE OF TVU MEASUREMENT OF CERVICAL LENGTH

TVU is the most reproducible technique for cervical assessment. Its technical aspects are important. Ultrasound images of the cervix obtained with transabdominal and transperineal sonography are more difficult to obtain and are less reproducible than transvaginal images.³⁹⁹⁻⁴⁰¹ A standardized protocol is used to ensure reproducibility.¹⁹⁷

- First, the maternal bladder is emptied before initiating the examination. Ultrasound gel is placed on a transvaginal probe before covering it with a condom or specialized probe cover. Sterile ultrasound gel is then placed on the cover. If the membranes are ruptured, both the cover and the gel should be sterile.
- With the real-time image in view, the transducer is gently advanced into the anterior vaginal fornix until the amniotic fluid and cervix are visualized. It is important to avoid excessive pressure on the anterior cervical lip. The image is enlarged to fill at least two thirds of the ultrasound screen and oriented so that cephalad is to the left of the screen on a midsagittal image.
- The examiner first identifies the amniotic fluid and then the lowest edge of the empty maternal bladder. The internal cervical os is then located, often just below bladder edge. The appropriate sagittal view for measuring cervical length includes the usually T- or V-shaped appearance of the internal os, the triangular area of echodensity at the external os, and the endocervical canal, which appears as a faint line of echodensity or echolucency between the two, surrounded by a zone of cervical glands inside the cervical stroma (Fig. 40-13). Excess pressure on the cervix can artificially increase its apparent length. This can be avoided by first obtaining an apparently satisfactory image, withdrawing the probe until the image blurs, and then reapplying only enough pressure to restore the image. Cervical length is measured along the line made by the interface of the mucosal surfaces (the closed portion of the cervix). It is usually the distance between calipers placed at the notches made by the internal os and the external os. If the internal os is open, cervical length is measured from the tip of the funnel, where the mucosal surfaces touch, to the external os. Cervical length should be determined only from images in which the lower-most edge of the empty maternal bladder and the internal and external os are visible, and when the anterior and posterior lips of the cervix are of about equal thickness (Fig. 40-14). If the cervix appears asymmetric, thin anteriorly and thicker posteriorly, excessive probe pressure is likely.
- When the cervical canal is curved (Fig. 40-15), the length of the cervix should be measured by a single straight line from the internal to the external os, and also by the sum of two or more separate straight lines along each segment of the curved cervix. If the difference between the straight line and the point of maximal separation exceeds 3 mm, the sum of the segmental measurements is used.²⁰³ A curved cervix is usually long, whereas a short cervix is more often straight. Tracing the cervical canal should be avoided because it introduces unpredictable operator variation.
- Before a final determination of cervical length is recorded, gentle manual pressure should be applied by the sonographer to the fundus or suprapubic area to elicit the true cervical length.⁴⁰²
- The examination is performed over at least 3 to 5 minutes, allowing time after the application of fundal pressure to observe development of pressure-elicited changes in the cervix. After pressure has been applied, and three measurements that fully satisfy the criteria in the table have been obtained that vary by less than 10%, the shortest of these is chosen and recorded as the "shortest best." Reporting the average and the range of cervical length measurements is not useful and may be misleading. Choosing the shortest of three excellent images reduces interobserver and intraobserver variation.

Figure 40-13 Ultrasound image, sagittal view of cervix. The image used for measuring cervical length includes the usually T- or V-shaped appearance of the internal os, the triangular area of echodensity at the external os, and the endocervical canal.

Figure 40-14 Ultrasound image of normal cervix. When measuring cervical length, the relationship of the maternal bladder, the internal and the external os, and the anterior and posterior lips of the cervix should be visible. Ext os, external os; Int os, internal os.

Figure 40-15 Ultrasound image of a curved cervical canal.

BOX 40-3 PITFALLS TO AVOID WHEN MEASURING CERVICAL LENGTH WITH TRANSVAGINAL ULTRASOUND (TVU)

- Putting excess pressure on the cervix during the examination is a common error that creates an artificially longer cervix as a result of compression of the anterior cervical lip and lower uterine segment. This can be avoided by withdrawing the probe when the internal and external os are visualized, until slight blurring occurs, and then reinserting it slightly until a clear image returns.
- The anterior and posterior lips of the cervix should be of approximately equal thicknesses.
- If the lower uterine segment is underdeveloped, it can be difficult to identify the true internal os so that myometrium may be included in the cervical-length measurement. This should be suspected when the cervix appears longer than 50 mm, or when the internal os is cephalad above the bladder reflection.²⁵ A difference in echotexture between myometrium and true cervical stroma can often be appreciated during real-time scanning, and this provides a way to differentiate between the two structures. Before 14 weeks, it is particularly difficult to differentiate between the lower uterine segment and the cervix. Nonetheless, in some particularly high-risk pregnancies, such as those with prior second-trimester losses or large (or multiple) cone biopsies, cervical shortening has been seen as early as 10 to 13 weeks of gestation.¹⁹ Placenta previa may also create this same phenomenon, resulting in an apparent but artificially increased cervical length.
- Uneven placement of lubricant into the transducer cover may generate small air bubbles that create a poor image.
- Contractions during the examination can cause a false impression of a long cervix. If the internal os is not clearly visualized and a contraction is present, one needs to wait until the contraction resolves before the cervical length can accurately be measured.
- A common problem is measuring the cervical length too quickly, without allowing adequate time for any effects on the cervix to resolve.
- If the image remains suboptimal, the cervix is often easier to locate sonographically if a digital examination is performed, as gel from the examiner's glove left in the cervical canal makes the external os more echogenic. In addition, digital examination aids in the assessment of risk for premature delivery by determining dilation, position, and consistency, features not optimally assessed by ultrasound.

To obtain adequate measurements of cervical length, TVU should be performed in accordance with these technical steps. At least 20 cervical ultrasound examinations performed under supervision are typically necessary before reproducible TVU cervical length images are obtained without supervision. The increased use of cervical sonography as a screening test will lead to standardized credentialing to perform this examination. Tutorials and credentials can be obtained from the Pregnancy Foundation's Cervical Length Education and Review (CLEAR) program (available at www.perinatalquality.org/CLEAR) and from the Fetal Medicine Foundation (www.fetalmedicine.com/fmf/training-certification/certificates-of-competence/cervical-assessment/).

activation and myometrial contractility in women with preterm parturition. Because preterm birth occurs in only 35% to 40% of all women with untreated short cervix¹⁹⁷ and in 25% to 30% of women with a positive fetal fibronectin in the second trimester,¹¹⁷ many women apparently experience the initial phases of preterm parturition but do not progress to preterm birth.

Medical and Surgical Interventions to Prevent Preterm Birth

Medical and surgical interventions to prevent preterm birth were, until recently, largely ineffective, but this is no longer true. Randomized trials have shown reduced rates of preterm birth in women treated medically with progestational agents (collectively referred to here as *progesterone*, recognizing the different pharmacologic properties of the agents studied)^{148,405-407} and surgically with cerclage.^{408,409} Women who benefit from either treatment share one common characteristic: short cervical length demonstrated by transvaginal sonography. Progesterone treatment does not reduce the risk for preterm birth in women with a prior preterm birth who do not have short cervix,¹⁴⁹ or in nulliparous women with a moderately short cervix.⁴¹⁰ Similarly, cervical cerclage for women with a prior preterm birth reduces the risk for recurrent preterm birth in women whose cervix is short (<25 mm), and it is especially effective in women with a very short cervix (≤15 mm) (see Chapter 41).⁴⁰⁹ In contrast, the risk for preterm birth in women with multifetal gestation is not reduced by progesterone supplementation^{411,412} or by cervical cerclage, suggesting a different pathway to preterm birth in multifetal pregnancies.

When considered together with ultrasound studies of cervical shortening in pregnancy,^{403,413,414} the results of these trials have advanced our understanding of the origins and progress of preterm parturition and have the potential to reduce the incidence and ultimately the morbidity and mortality of

preterm birth. Short cervix is now understood to represent evidence of preterm parturition in most instances rather than as a structural deficit (see Chapter 41). Progesterone is a medical prophylactic treatment that can be supplemented by cervical cerclage when progressive shortening occurs despite prophylaxis. The following paragraphs describe the basis for this strategy and outline the remaining uncertainties about its application.

Progestational Agents to Prevent Preterm Birth. Progesterone supplementation for women at risk for preterm birth was investigated with regard to several plausible mechanisms of action, including reduced gap junction formation and oxytocin antagonism leading to relaxation of smooth muscle, maintenance of cervical integrity, and anti-inflammatory effects.⁴¹⁵ Small trials performed in women with recurrent miscarriage and preterm birth were reviewed by Keirse, who concluded that 17OHPC does not protect against miscarriage but does reduce the occurrence of preterm birth.⁴¹⁶ This observation prompted two randomized trials of progestational agents in women with risk factors for preterm birth.^{148,407} In a trial that enrolled 142 women with a history of preterm birth or other risk factors to receive placebo or 100 mg progesterone suppositories daily beginning at 24 weeks of gestation, birth before 37 weeks occurred in 28.5% of women in the placebo arm as opposed to 13.5% in the progesterone arm.⁴⁰⁷ In a second, larger placebo-controlled trial, 459 women with a prior spontaneous preterm birth received weekly intramuscular injections of 250 mg 17OHPC or placebo.¹⁴⁸ Women treated with 17OHPC were significantly less likely to deliver before 37, 35, and 32 weeks. Secondary analyses of this study revealed a stronger beneficial effect for women whose qualifying preterm birth was less than 34 weeks⁴¹⁷ and for women with more than one prior preterm birth.⁴¹⁸ The rate of preterm birth before 37 weeks in the placebo

group was deemed by some to be higher than expected,⁴¹⁹ but the recurrence rate was not surprising given the demographics and obstetric history of the women enrolled: 59% of subjects in both groups were African Americans, the mean gestational age of the qualifying preterm birth was 31 weeks in both groups, and 32% of women enrolled had more than one prior preterm birth—all factors that increase the risk for recurrence beyond the usual twofold risk associated with a prior preterm birth. The groups differed in the mean number of previous preterm deliveries (1.6 in the placebo group versus 1.4 in the 17OHP group; $P = .007$), a difference that might have influenced the recurrence rate of 55%.

Subsequent trials that enrolled women with short cervix have reported significant reductions in preterm birth in women treated with vaginal progesterone compared with those treated with placebo, but only when short cervix was defined as less than the 3rd percentile.^{405,406} Fonseca and associates⁴⁰⁵ enrolled women with cervical length of less than 15 mm (1.7% of more than 24,000 women screened), and found significantly lower rates of preterm birth before 34 weeks (19% versus 44%; RR = 0.56; 95% CI, 0.36 to 0.86) in those treated with 200 mg vaginal progesterone suppositories daily. Hassan and colleagues⁴⁰⁶ enrolled women with cervical length measurements between 10 and 20 mm (2.3% of more than 32,000 women screened) and found similar results: Among 465 women randomized, those who received 90 mg vaginal progesterone gel daily until 36 6/7 weeks had lower rates of preterm birth before 28 weeks (5.1% versus 10.3%; RR = 0.50; 95% CI, 0.25 to 0.97), 33 weeks (8.9% versus 16.1%; RR = 0.55; 95% CI, 0.33 to 0.92), 35 weeks (14.5% versus 23.3%; RR = 0.62; 95% CI, 0.42 to 0.92). Neonatal morbidity or mortality was also significantly lower in treated patients (7.7% versus 13.5%; RR = 0.57; 95% CI, 0.33 to 0.99).⁴⁰⁶

In contrast, preterm birth rates were not reduced by progesterone supplementation in two other randomized, placebo-controlled trials that enrolled women with cervical length measurements well above the 3rd percentile.^{149,410} O'Brien and colleagues¹⁴⁹ found no effect of progesterone vaginal gel on the preterm birth rate in 659 women with a prior preterm birth (women likely to receive a cerclage were specifically excluded). Cervical length was measured at entry to characterize the a priori risk of women enrolled; mean cervical length of enrollees was 37 mm at 18 to 20 weeks, indicating a population with a low risk for preterm birth.³⁴⁰ Grobman and coworkers⁴¹⁰ enrolled nulliparous women with a singleton gestation between 16 and 22 3/7 weeks with cervical length less than 30 mm (the 10th percentile in this population) who were randomly assigned to receive weekly intramuscular injections of 17-OHP (250 mg) or placebo until 36 weeks. Birth before 37 weeks did not differ between women who received 17-OHP ($n = 327$) and those who received placebo ($n = 330$) (25.1% versus 24.2%; RR = 1.03; 95% CI, 0.79 to 1.35). Composite adverse neonatal outcome was not different (7.0% versus 9.1%; RR = 0.77; 95% CI, 0.46 to 0.30).

Progesterone supplementation is not effective as prophylaxis or as treatment in women with multiple gestations when multifetal gestation is the only risk factor. In randomized trials conducted in women with twin pregnancies, neither 17OHP^{412,420} nor vaginal progesterone⁴²¹ reduced the rate of preterm birth. Results in triplet gestations were no different.⁴¹¹ Uncertainty persists, however, about the effect of progesterone supplementation in three circumstances involving multifetal gestation that lack adequate literature: Care for women with

twins who also have a short cervix or a previous singleton preterm birth, as well as for women with a singleton pregnancy with a prior preterm birth of twins, is currently based on inadequate direct evidence, aided by interpretation of the literature in singletons. When the progesterone literature is considered in toto, progesterone prophylaxis is effective when a very short cervix represents the early onset of parturition, but it is not effective when short cervix is the result of other causes (e.g., uterine stretch), as might be the case for most women with multifetal pregnancies. Thus, women with twins and short cervix but with no other risk factors are unlikely to benefit from progesterone supplementation, as is suggested by the limited available literature.⁴²² We do not offer progesterone treatment to women with twins or triplets, regardless of cervical length, unless there is a documented history of a prior spontaneous preterm birth. Women with a previous spontaneous birth of twins before 32 weeks have an increased risk for spontaneous preterm birth in future singleton pregnancies¹⁵⁵⁻¹⁵⁷ as do women with a prior singleton preterm birth, regardless of fetal number in future pregnancies. We offer progesterone prophylaxis to these women. A history of preterm birth in a triplet pregnancy does not constitute an indication for progesterone prophylaxis.

A beneficial effect of supplemental progesterone is not universally observed in women with a prior preterm birth, indicating that some pathways to recurrent preterm birth are not affected by this therapy. The absence of effect in multiple gestations, coupled with the failure of progesterone to prevent preterm birth in all women with very short cervix,^{405,406} suggests that the effect may be related to modulation of inflammation or cervical ripening more than being an effect on uterine contractility.

There is growing evidence of neonatal benefit and safety for progesterone supplementation. In a meta-analysis of five high-quality trials that included a total of 775 women and 827 infants, treatment with vaginal progesterone was associated with a significant reduction in preterm birth before 33 weeks (RR = 0.58; 95% CI, 0.42 to 0.80), 35 weeks (RR = 0.69; 95% CI, 0.55 to 0.88), and 28 weeks (RR = 0.50; 95% CI, 0.30 to 0.81).⁴²³ Respiratory distress syndrome (RR = 0.48; 95% CI, 0.30 to 0.76), composite neonatal morbidity and mortality (RR = 0.57; 95% CI, 0.40 to 0.81), birth weight below 1500 g (RR = 0.55; 95% CI, 0.38 to 0.80), admission to neonatal intensive care unit (RR = 0.75; 95% CI, 0.59 to 0.94), and need for mechanical ventilation (RR = 0.66; 95% CI, 0.44 to 0.98) were all significantly less frequent in infants of treated women. There were no significant differences between the vaginal progesterone and placebo groups in the rate of adverse maternal events or congenital anomalies. The safety of progesterone supplementation is further supported by a review of outcomes of pregnancies treated before 1990,⁴²⁴ by a review of animal studies,⁴²⁵ and by a thorough neurodevelopmental evaluation of children at 4 years of age born to women treated in the NICHD trial.⁴²⁶ Studies to date have not shown increased rates of fetal growth restriction or stillbirth, but because progesterone prophylaxis may act through anti-inflammatory effects, potential risks related to that action will remain a concern.⁴²⁷

Current evidence supports offering 17OHP to women with a history of prior spontaneous preterm birth and vaginal progesterone to women with a cervical length of 20 mm or less before 25 weeks' gestation. Use of progesterone for indications other than prior preterm birth and short cervix is not supported

by the limited available evidence. Small studies have suggested that initiation of prophylaxis after 20 weeks may be beneficial,⁴²⁸ that discontinuation of prophylaxis may increase the risk for preterm birth,⁴²⁹ and that treatment after an episode of preterm labor for women with short cervix might be helpful.⁴³⁰ None of these studies have been large enough to influence current practice, but they do support further investigation to define the appropriate role for this treatment.

Whether the various progestational agents are similarly effective for either indication is not known, but is suggested by the results of the O'Brien trial,¹⁴⁹ in which progesterin treatment was ineffective in women with a history of preterm birth whose cervical length at entry averaged 37 mm, and by an analysis of data from women with a previous preterm birth in the Preterm Prediction Study that showed recurrent preterm birth rates of less than 10% when the cervical length was 35 mm or more at 22 to 24 weeks.

Although the benefit of progesterone supplementation has been observed in multiple research trials, the optimal clinical protocols for progesterone have not yet been developed. Wide clinical use of progesterone supplementation for women with a prior spontaneous preterm birth has been estimated to result in savings of more than \$2 billion annually in the United States.⁴³¹⁻⁴³³ Two cost-effectiveness studies support universal cervical length screening with transvaginal sonography for all pregnant women between 18 and 24 weeks, but they rely on assumptions that have not been tested in practice.^{434,435}

Discussions of how best to integrate comprehensive obstetric history and transvaginal cervical ultrasound into clinical practice to detect candidates for progesterone are underway, driven by recent practice guidelines from the Society for Maternal-Fetal Medicine⁴³⁶ and ACOG³⁹⁶ that support 17OHPC prophylaxis for women with a history of preterm birth, and vaginal progesterone for short cervix of 20 mm or less before 24 weeks. Both documents include care algorithms that are integrated in Figure 40-16.

Discussions of prevention strategies are currently focused on whether all women should undergo transvaginal cervical ultrasound examination to measure cervical length, or whether an algorithm can be devised that can identify women for whom it is unnecessary. The best care path is uncertain, but nevertheless, consideration of cervical ultrasound surveillance has entered routine prenatal care, and with it, some form of prematurity prevention screening may become standard for all pregnancies. It is likely that the optimal protocol or protocols will be identified by population-based observational reports, as was the case for GBS screening.

Cervical Cerclage to Prevent Preterm Birth. This topic is discussed in Chapter 41.

PREMATURITY PREVENTION BEFORE PREGNANCY

Pre-conceptual interventions are attractive because many risk factors are difficult to address successfully during pregnancy.

Public Educational Interventions

The public inaccurately perceives that the problems of preterm infants have been overcome by improved neonatal care.³²⁸ Increased awareness of preterm birth as the leading cause of infant mortality offers an opportunity to raise public awareness of avoidable risk factors.³ For example, greater public and

professional knowledge of evidence suggesting that repeated uterine instrumentation may confer an increased risk for subsequent preterm birth might affect decision making about these procedures.^{134,163,164,437} The use of laminaria has been reported to reduce the risk for subsequent preterm birth in women undergoing second-trimester dilation and evacuation.⁴³⁸

Similarly, broader public knowledge of the increased risk for preterm birth in singleton gestations conceived with ART might, if coupled with information about the consequences of prematurity, influence fertility care.⁴³⁹⁻⁴⁴¹ Such educational efforts could be modeled after successful efforts to reduce the prevalence of smoking.

Public and Professional Policies

In contrast to public education strategies, policies adopted by governmental or medical bodies can have a more immediate effect. Policies adopted to reduce the risk of higher-order multiple gestation have been successful in Europe, Australia, and the United States. Rates of triplet and higher-order multiple pregnancies were rising rapidly in the United States until 1998, when voluntary adoption of limitations on the number of embryos transferred was promoted by professional groups. The rate of higher-order multiples then fell by 50% between 1996 and 2003.^{442,443}

Social policies to improve pregnancy outcomes have been adopted by many European countries.⁴⁴⁴ Minimal paid pregnancy leave of 14 weeks, time off for prenatal visits, exemption from night shifts, and protection from workplace hazards, including complete work leave if necessary, are among the strategies used.

Systemic Interventions

Prenatal care can be considered as part of a continuum of care that begins long before women reach reproductive age. Prevention of risks associated with adverse pregnancy outcome can begin in the preadolescent period with attention to nutrition, sexually transmitted infection, timing of desired pregnancies, and general health education.³³²

Nutritional Supplements

Women considering a pregnancy are routinely advised to initiate supplementation with prenatal vitamins before conception, chiefly to reduce the risk for birth defects.⁴⁴⁵ A randomized, placebo-controlled trial of vitamin supplementation that enrolled women before conception and continued through the first 2 months of pregnancy found no effect of vitamins on the preterm birth rate.⁴⁴⁶

Smoking

The attributable risk of cigarette smoking exceeds 25% for preterm birth⁴⁴⁷ and approximates 5% for infant mortality.⁴⁴⁸ An overall decrease in maternal smoking before conception might be expected to reduce preterm births, but preterm birth rate in the United States rose from 11.6% to 12.5% between 2000 and 2004, a time when smoking among women aged 18 to 44 years declined from 25.5% to 21.7%.⁴⁴⁹ Reduced prevalence of smoking would nevertheless have multiple health benefits for pregnant women and infants.

Pre-Conceptual Care for Women with Risk

Pre-conceptual interventions to reduce risk for preterm birth typically target women with a previous preterm birth.⁴⁵⁰ The

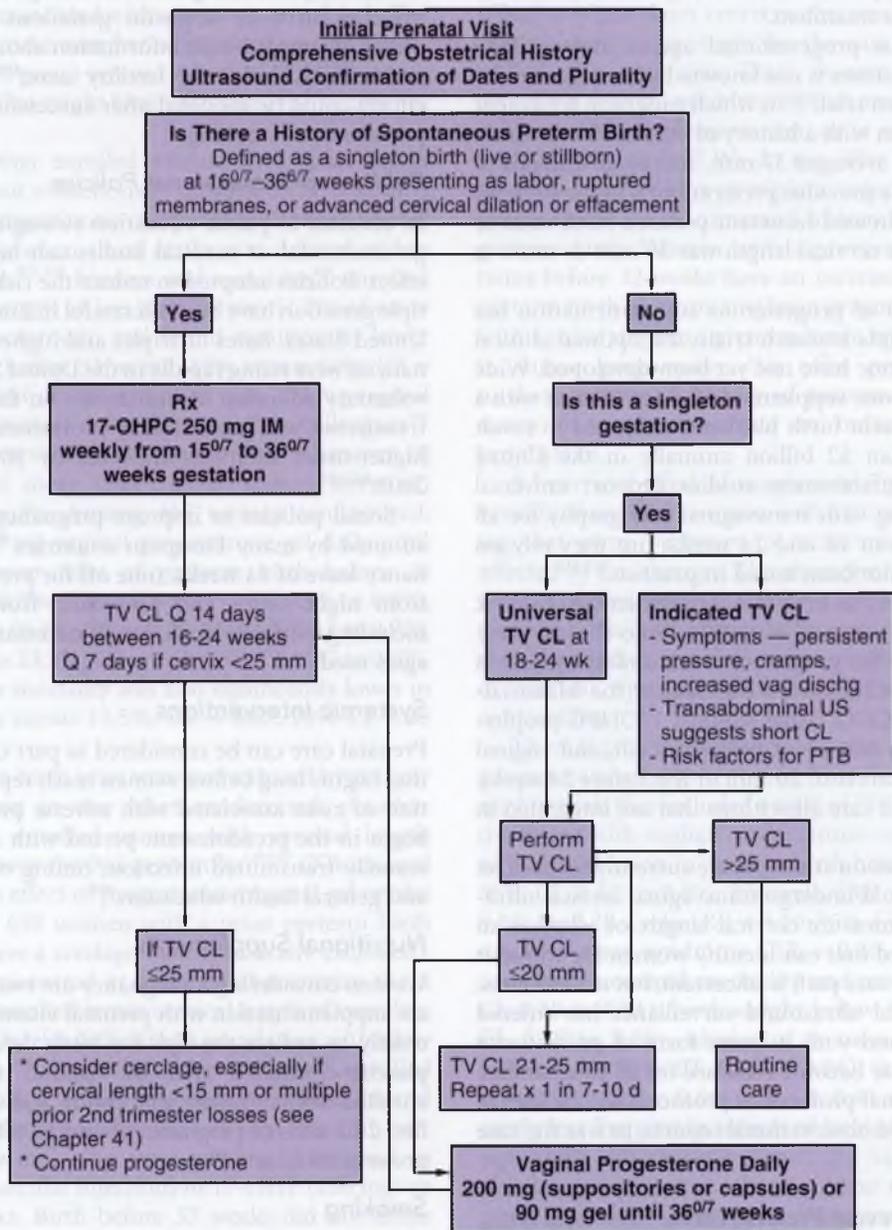

Figure 40-16 Algorithm for identification and treatment of candidates for progesterone supplementation. 17-OHPC, 17 α -hydroxyprogesterone caproate; IM, intramuscularly; PTB, preterm birth; Q, every; TV CL, transvaginal ultrasound measurement of cervical length; US, ultrasound; vag dischg, vaginal discharge. (Based on Practice Guidelines published by the Society for Maternal-Fetal Medicine and the American College of Obstetricians and Gynecologists Society for Maternal-Fetal Medicine Publications Committee: Progesterone and preterm birth prevention: translating clinical trials data into clinical practice, *Am J Obstet Gynecol* 206:376–386, 2012; and Committee on Practice Bulletins—Obstetrics, American College of Obstetricians and Gynecologists: Practice bulletin no. 130: prediction and prevention of preterm birth, *Obstet Gynecol* 120:964–973, 2012.)

upper gestational age boundary for a preterm birth is commonly 37 weeks, and the risk of recurrence declines as the gestational age of the index preterm birth approaches 37 weeks.¹³⁸ The lowest gestational age for which an increased risk for preterm birth is observed in subsequent pregnancies is optimal for clinical use and was determined to be 17 to 18 weeks for spontaneous preterm births in studies of data from the Preterm Prediction Study. Previous births before 17 weeks did not confer an increased risk for recurrent preterm delivery.^{138,147,450}

As noted earlier, the risk of recurrence is increased for both spontaneous and indicated preterm births.^{144,151,158} Risk increases as the gestational age of the previous preterm birth declines and as the number of preterm births increases.¹³⁸ Careful review of records from prior pregnancies may be helpful to establish the gestational age of the index birth, estimate the recurrence risk, and identify risks amenable to intervention, including some that may require pre-conceptional intervention (e.g., correction of müllerian anomalies)⁴⁵¹ and others that could determine care choices during pregnancy (e.g., prophylactic progesterone or cerclage). Pre-pregnancy medical risk factors have been identified in as many as 40% of preterm births,⁴⁵² suggesting that women with these risks might benefit from pre-conceptional control of diabetes, seizures, asthma, or hypertension.

Inter-conceptional care for women with prior preterm birth has been proposed,⁴⁵³ but evidence that these steps can actually influence the preterm birth rate is lacking. A randomized trial of inter-conceptional home visits and counseling by midwives did not reduce preterm birth and LBW infants in a study of

1579 women.⁴⁵⁴ On the basis of the hypothesis that pre-conceptional microbial colonization of the endometrium might increase the risk for preterm birth, a randomized, placebo-controlled trial of inter-conceptional antimicrobial treatment was performed in women with a prior early preterm birth.⁴⁵⁵ Study participants received metronidazole and azithromycin or placebo at 3-month intervals until their next pregnancy occurred. The rate of recurrent preterm birth was not influenced by antibiotic treatment. The proportion of women enrolled in this study whose qualifying preterm birth was related to infection is not known.³⁸⁷

Strategies to reduce the risk for preterm birth before conception may be applied to populations as well as to individuals. Population-based strategies include prevention of unplanned and potentially unwanted pregnancies because both are associated with increased rates of preterm birth. Such strategies include programs to promote continued school attendance through high school, education about contraception and sexually transmitted infection (e.g., use of condoms and long-acting contraceptives), and community efforts to promote social and economic security. Provision of long-acting reversible contraception among women at risk for unplanned pregnancy was successful in reducing unplanned births in a community program in St. Louis and could be expected to contribute to a reduction in preterm births as well.⁴⁵⁶

Cervical Insufficiency

VINCENZO BERGHELLA, MD | JAY D. IAMS, MD

Cervical Insufficiency versus Cervical Shortening

Traditionally, cervical insufficiency has been defined by four historical criteria: (1) *painless cervical dilation*, leading to (2) *recurrent*, (3) *second-trimester* births in the (4) *absence of other causes*, in the belief that these criteria identified women whose early births were caused solely by structural weakness of cervical tissue that could be corrected by surgical repair. However, it has become clear that these criteria do not distinguish women with structural cervical weakness from those in whom preterm parturition from other causes began in the second trimester. Studies of ultrasound images of cervical changes during pregnancy and related treatment trials have altered traditional concepts of cervical insufficiency and preterm parturition. Cervical shortening is now understood to occur often as an early step in parturition rather than being a hallmark of cervical insufficiency. This conclusion arises from evidence that progesterin supplementation rather than cerclage is the appropriate initial treatment for short cervix in women with singleton gestations without a prior spontaneous preterm birth (PTB).^{1,3} Long offered as treatment for cervical insufficiency and thus for short cervix as well, cerclage paradoxically confers greater benefit (i.e., lower relative risk) for women with a prior PTB whose cervical length (CL) by transvaginal ultrasound (TVU) is less than 15 mm than for those with a CL between 15 and 25 mm⁴; however, cerclage may increase the risk for PTB in women who have a short cervix and are carrying twins.⁵

The effects of a cerclage suture vary with the cause of the short cervix: It can repair and restore cervical strength in women with true cervical insufficiency; it can protect fetal membranes or prevent their prolapse through the cervix in women with preterm parturition; and, by mechanisms uncertain, it can increase the risk for PTB when the short cervix is the result of uterine distention or other mechanisms that are not related to cervical insufficiency or membrane prolapse. Thus, cervical insufficiency cannot be defined by short cervix alone or by a successful (i.e., term) pregnancy after cerclage placement. The current challenge is to identify women before conception or in early pregnancy who have impaired cervical strength that is best treated surgically, and to distinguish them from women who are best treated medically. The diagnosis of cervical insufficiency is thus one of exclusion, to be made in women with risk factors for, or evidence of, anatomic abnormalities, and in whom early parturitional cervical ripening is not present, recognizing that cervical cerclage may improve outcomes for the latter as well as the former.

Unfortunately, cervical insufficiency cannot be diagnosed or excluded by assessment of cervical function outside of

pregnancy. Evaluation with dilators, balloons, or hysteroscopy is not helpful.⁶ Ultrasound, magnetic resonance imaging, or hysterosalpingography may reveal a uterine or cervical abnormality, risk factors that support a diagnosis of cervical insufficiency but do not guarantee it.

Pathophysiology

The uterine cervix and corpus are derived from fusion of the distal müllerian ducts.⁷ The cervix is composed primarily of fibrous tissue; the proportion of smooth muscle varies from 6.4% in the lower third (near the external os) to 29% in the upper third (near the internal os).⁸ The histologic transition between the predominantly fibrous cervix to the predominantly muscular corpus varies from a narrow 1- to 2-mm zone to a relatively wide 5- to 10-mm zone.⁸

The cervix changes from a closed, rigid structure before pregnancy to a soft, distensible organ near parturition. Cervical remodeling begins soon after conception and continues throughout pregnancy and the puerperium. It consists of four overlapping phases: (1) softening alone, (2) ripening (softening with effacement [i.e., decrease in length], dilation, and change in position), (3) dilation in response to contractions, and (4) postpartum repair (Fig. 41-1).⁹

Images of the changing appearance and dimensions of the cervix obtained by TVU during pregnancy have informed our understanding of the onset and progression of preterm parturition. The incidence, onset, and rate of cervical shortening vary during pregnancy and relate to eventual pregnancy outcome. Women who deliver at term experience only minimal shortening in the second and early third trimester, at a rate of about 0.36 mm per week, until 32 to 34 weeks, after which progressive shortening occurs faster and effacement is common. CL measurements in women who deliver before term because of a medical indication such as preeclampsia or abruption are similar to those in women with term birth. However, women who later experience spontaneous PTB demonstrate a significantly earlier onset (as early as 16 to 24 weeks) and more rapid progression of cervical shortening. The rates of second-trimester cervical shortening are similar in women with spontaneous PTB, regardless of whether they present clinically with preterm labor (0.96 mm/week) or with preterm ruptured membranes (0.82 mm/week) (Fig. 41-2).¹⁰⁻¹²

Recognizing that the distinction between cervical insufficiency and early onset of spontaneous preterm parturition is uncertain, this chapter focuses on indications for cerclage in women with short cervix and on pregnancy outcomes and treatment of women with structural abnormalities (e.g., weakness) of the cervix. Often, such abnormalities are distinguished

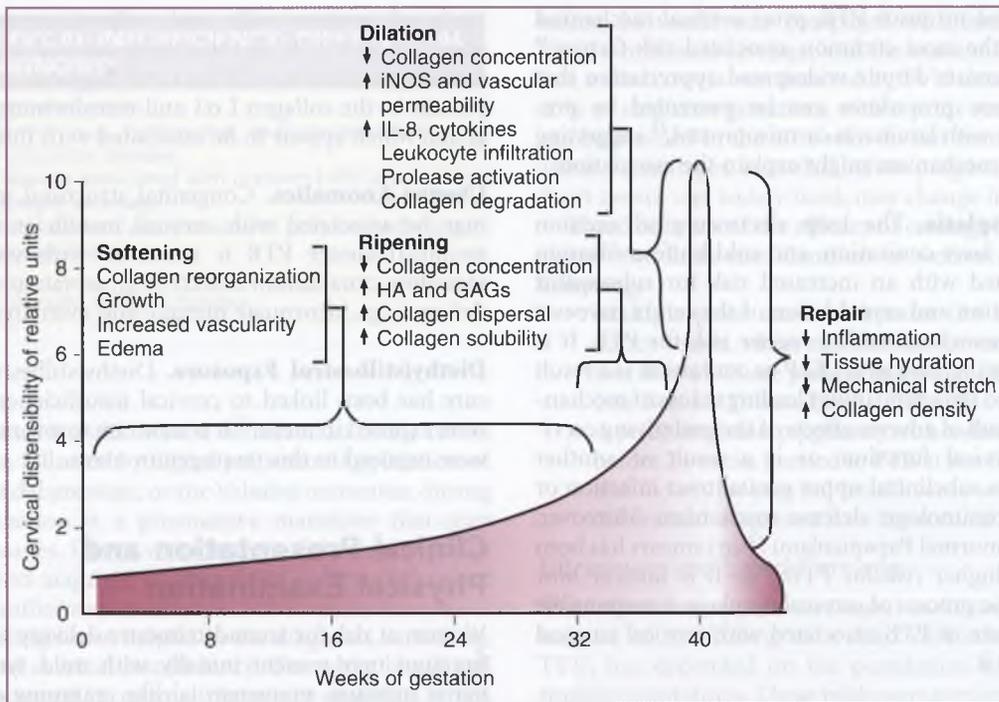

Figure 41-1 Stages of parturitional change in the cervix during pregnancy and the puerperium. Each stage is characterized by unique biochemical and cellular events. GAGs, glycosaminoglycans; HA, hyaluronic acid; IL-8, interleukin 8; iNOS, inducible nitric oxide synthase. (From Word RA, Li X-H, Hnat M, et al: *Dynamics of cervical remodeling during pregnancy and parturition: mechanisms and current concepts*, Semin Reprod Med 25:69–79, 2007.)

by historical risk factors suggesting cervical injury or congenital weakness.

RISK FACTORS FOR CERVICAL INSUFFICIENCY

Cervical insufficiency may be acquired or congenital, with the latter being less common (Box 41-1). Cervical insufficiency may be acquired via an injury to the cervix involving stretch,

BOX 41-1 CERVICAL INSUFFICIENCY: RISK FACTORS

ACQUIRED

- Cervical laceration or obstetric injury
- Cervical instrumentation
 - Dilatation and evacuation (D&E)
 - Dilatation and curettage (D&C)
 - Elective abortion
 - Loop electrosurgical excision procedure (LEEP)
 - Cold-knife conization
 - Laser conization
 - Hysteroscopy
- Prior second-trimester birth (at <28 wk)

CONGENITAL

- Collagen disorders (e.g., Ehlers-Danlos)
- Uterine anomalies
- In utero exposure to diethylstilbestrol (DES)

laceration, or removal of cervical tissue. Congenital deficiency in cervical tissue may arise from müllerian fusion abnormalities or from genetic collagen disorders.

Acquired Factors

Mechanical Dilatation. Cervical insufficiency has been associated with mechanical dilatation of the cervix during gynecologic procedures (e.g., dilatation and curettage [D&C], dilatation and evacuation [D&E], pregnancy termination, hysteroscopy).^{13,14} In fact, even just one voluntary pregnancy termination has been associated with a higher risk for spontaneous PTB.¹⁵ In women

with a short CL and no prior PTB, prior cervical mechanical dilation is one of the most common associated risk factors.¹⁶ This association persists despite widespread appreciation that trauma during these procedures can be prevented by pre-ripening the cervix with laminaria or misoprostol,¹⁵ suggesting that an alternative mechanism might explain the association.

Treatment of Dysplasia. The loop electrosurgical excision procedure (LEEP), laser conization, and cold knife conization have been associated with an increased risk for subsequent PTB.^{17,18} Laser ablation and cryoablation of the cervix have not been consistently associated with a higher risk for PTB. It is unclear whether the increase with LEEP or conization is a result of procedure-related structural injury leading to loss of mechanical support, is a result of adverse effects of the underlying cervical disease on cervical function, or is a result of another mechanism, such as subclinical upper genital tract infection or a change in the immunologic defense mechanism. Moreover, even a history of abnormal Papanicolaou (Pap) smears has been associated with a higher risk for PTB,¹⁹ so it is unclear how much the pathologic process of cervical dysplasia is responsible for the increased rate of PTB associated with cervical surgical procedures to treat it.

Obstetric Trauma. A cervical laceration may occur during labor or in the process of delivery, including spontaneous, forceps, vacuum, or cesarean birth,²⁰ that might weaken the cervix. Examples that suggest cervical trauma include a prior pregnancy concluded at term with a prolonged second stage of labor followed by a difficult vaginal birth, or by a cesarean birth with an extended uterine incision or laceration.

Congenital Factors

Other than collagen abnormalities and müllerian duct fusion anomalies, there is no evidence that cervical insufficiency is congenital. Sonography of the cervix in the first trimester rarely identifies a short cervix before 14 weeks except in women with prior cervical surgery.²¹

Collagen Abnormalities. Alterations in the regulation of type I collagen expression²² and genetic disorders affecting collagen (e.g., Ehlers-Danlos syndrome) have been associated with increased risk for PTB.²³ Familial collagen disorders may explain familial aggregation of cervical insufficiency.²⁴ As an example, a

study of women with and without cervical insufficiency observed that 27% of those with cervical insufficiency had a first-degree relative with the same diagnosis and had polymorphisms in the collagen I $\alpha 1$ and transforming growth factor- β genes, which appear to be associated with this condition.²⁵

Uterine Anomalies. Congenital structural uterine anomalies may be associated with cervical insufficiency.²⁶ The risk for second-trimester PTB is increased with uterine anomalies, including canalization defects (e.g., septate uterus), unification defects (e.g., bicornuate uterus), and even arcuate uterus.²⁷

Diethylstilbestrol Exposure. Diethylstilbestrol (DES) exposure has been linked to cervical insufficiency in women who were exposed in utero.²⁸ It is now rare to encounter women who were exposed to this teratogen in utero.

Clinical Presentation and Physical Examination

Women at risk for second-trimester delivery from cervical dysfunction may present initially with mild symptoms, such as pelvic pressure, premenstrual-like cramping or backache, and increased vaginal discharge, that have been present for several days or weeks, having usually begun at 14 to 20 weeks of gestation. These symptoms and slight changes in the color (from clear, white, or light yellow to pink, tan, or spotting) and consistency (thinner) of vaginal discharge are also consistent with cervical ripening from any cause. Detection of cervical insufficiency is particularly difficult in a first pregnancy. Initially, the symptoms may be dismissed as normal effects of pregnancy, so that the eventual reason for seeking care may be pelvic pressure from a prolapsed amniotic sac, ruptured membranes, spotting, or labor. Clinicians should consider the possibility of cervical insufficiency in symptomatic patients, especially those with risk factors (Table 41-1), and initiate a routine workup consisting of careful history, speculum and manual pelvic examination, and transvaginal sonography. Treatment delayed until membranes are visible is significantly less effective.

Physical examination is essential to visualize an opening at the internal os or prolapsed fetal membranes (or both), findings that are always abnormal in the first or second trimester. Examination of a woman with a history or symptoms suggestive of

TABLE 41-1 Indications for Cerclage

Accepted Cerclage Nomenclature	Definition of Indication*	Gestational Age at Placement (wk)	Former Nomenclature
History-indicated	Historical criteria (e.g., recurrent ≥ 3 early PTBs or second-trimester losses)	12-14	Prophylactic, elective
Ultrasound-indicated	Short CL (<25 mm) before 24 weeks in singleton gestations with prior SPTB	14-23	Therapeutic, salvage
Physical examination-indicated	Cervical changes (e.g., ≥ 1 cm dilated, or prolapsed membranes) detected on physical examination	16-23	Rescue, emergency, urgent
Transabdominal	Prior history-indicated cerclage that resulted in PTB at <33 weeks	11-12	—

*For singleton gestations only.

CL, cervical length; PTB, preterm birth; SPTB, spontaneous preterm birth.

BOX 41-2 CERVICAL INSUFFICIENCY: DIFFERENTIAL DIAGNOSIS*

- Maternal or fetal infection
- Uterine distention (e.g., hydramnios, multiple gestation)
- Bleeding or placental disease
- Other fetal disease associated with preterm birth (e.g., structural or karyotypic anomaly)
- Other maternal disease associated with preterm birth (e.g., poorly controlled diabetes)

*These disorders precede cervical changes.

cervical insufficiency should include visualization of the cervix using a speculum, followed by digital palpation. Application of suprapubic or fundal pressure, or the Valsalva maneuver, during speculum examination is a provocative maneuver that may reveal the membranes. Direct visualization of the cervix is also important to detect acquired or congenital defects that might cause cervical insufficiency.

Laboratory testing is not helpful in the diagnosis, screening, or management of cervical insufficiency. The white blood cell count may be increased in normal pregnancy and thus is not helpful unless markedly elevated. Cervicovaginal fetal fibronectin testing does not have a role in the diagnosis or management of cervical insufficiency. Intra-amniotic infection is a contraindication to cerclage and should be excluded by clinical examination whenever cerclage is considered. Infection may be suggested by the observation of debris in the amniotic fluid.^{29,30} When clinical suspicion for intra-amniotic infection is high but it cannot be confirmed by noninvasive means, amniocentesis can be performed to check the glucose concentration of the amniotic fluid, and to do a Gram stain and obtain a culture. Box 41-2 shows the differential diagnosis.

Treatment of Cervical Insufficiency

CERCLAGE

Cervical cerclage has been the treatment of choice for patients with presumed weakness of the cervix. When PTB is predicted, there are three main indications for cerclage (see Table 41-1). The first is based solely on poor obstetric history, which should include at least one prior early PTB. The second, ultrasound-indicated cerclage, is based on the TVU finding of a short (i.e., ≤ 25 mm) CL. The third indication for cerclage is the finding of an open cervix by manual or speculum examination. Transabdominal cerclage, a subset of history-indicated cerclage, may be indicated in women with a prior history-indicated transvaginal cerclage that resulted in PTB at less than 33 weeks.

In assessing the efficacy of cerclage, singleton gestations should be assessed separately from multiple gestations, as efficacies appear to differ in these populations.

History-Indicated Cerclage

The decision to perform cerclage is seldom based solely on a poor obstetric history because of the availability of TVU surveillance^{31,32} of CL and because of progesterone prophylaxis (see Chapter 40). In a meta-analysis of four trials involving singleton gestations with a prior spontaneous PTB, TVU screening of CL with the option of cerclage if the CL became less than 25 mm

before 24 weeks was compared with routine placement of history-indicated cerclage, and the outcomes were similar.³¹ In fact, a short cervix was detected by TVU screening in only about 40% of singleton gestations with a prior early PTB, so cerclage can be avoided in the 60% who do not manifest short cervix.³¹ These percentages, recorded before progesterone treatment for short cervix was widely used, may change in the future.

Based on trials of the efficacy of cerclage indicated by history alone,³³ we limit consideration to women with either of the following:

- Multiple prior second-trimester (14 to 28 weeks) pregnancy losses, when risk factors for cervical insufficiency (see Box 41-1) are present and other differential diagnoses (see Box 41-2) have been ruled out
- A prior singleton pregnancy with a short cervix (>25 mm) before 24 weeks that led to PTB at less than 32 weeks, when risk factors for cervical insufficiency are present and other differential diagnoses have been ruled out

Ultrasound-Indicated Cerclage

The effectiveness of ultrasound-indicated cerclage, placed because of the finding of a short cervix on second-trimester TVU, has depended on the population studied, even within singleton gestations. These trials were performed before progesterone therapy was employed.

Singletons without a Prior Preterm Birth. Ultrasound-indicated cerclage has not been shown to be beneficial in singleton gestations when a short cervix was identified before 24 weeks but there was no prior PTB. A meta-analysis of four trials of singleton pregnancies screened with cervical ultrasound, found to have a short (>25 -mm) cervix, and randomly assigned to cerclage or no cerclage showed a nonsignificant (24%) reduction in PTB at less than 35 weeks in the cerclage group if the patients had no risk factors for PTB—26%, compared with 33% in the group without cerclage (relative risk [RR] = 0.76; 95% confidence interval [CI], 0.52 to 1.15).⁵ This nonsignificant decrease in PTB deserves further study in women whose cervix shortens despite progesterone prophylaxis. Unfortunately, in women without a prior PTB, but with other risk factors such as prior cervical surgery, ultrasound-indicated cerclage has been insufficiently studied to make a recommendation.

The effect of cerclage in women with singleton gestations, no history of PTB, and a short cervix (≤ 20 mm) who are treated with progesterone has not been adequately investigated.

Singletons with Prior Preterm Birth. On the other hand, ultrasound-indicated cerclage has been associated with benefit when performed in women with a prior PTB who have a short cervix by TVU. Between 30% and 40% of women with singleton gestations who had a prior spontaneous PTB will develop a short cervix (<25 mm) before 24 weeks.^{4,31} In these cases, ultrasound-indicated cerclage has been shown to decrease the incidence of PTB, confirming the diagnosis of cervical insufficiency. In the largest trial, 302 women with a prior spontaneous PTB between 16 and 34 weeks (mean, 24 weeks) and a CL of less than 25 mm were randomly assigned to receive cerclage or no cerclage.⁴ Cerclage was associated with a significant reduction in perinatal deaths (8.8% versus 16%), and in births at less than 24 weeks (6.1% versus 14%) and less than 37 weeks (45% versus 60%).⁴ In a meta-analysis involving 504 singleton pregnancies with prior spontaneous PTB occurring at less than 34

weeks and having a CL of less than 25 mm before 24 weeks' gestation, cerclage was associated with a significant (30%) reduction in the risk for PTB at less than 35 weeks (28% versus 41%; RR = 0.70; 95% CI, 0.55 to 0.89) and a 36% reduction in composite perinatal mortality and morbidity (16% versus 25%; RR = 0.64; 95% CI, 0.45 to 0.91).³² Benefit from cerclage was seen at all CL cutoffs between 0 and 24 mm.⁴

Therefore, TVU screening for CL in women with singleton gestations who had prior spontaneous PTB, starting at about 16 weeks and then every 2 weeks until 23 weeks, is suggested so that cerclage can be offered to those who develop a CL of less than 25 mm despite progesterone prophylaxis (Fig. 41-3).³⁴⁻³⁶

According to current recommendations from the American College of Obstetricians and Gynecologists and the Society for

Maternal-Fetal Medicine, all women with a history of spontaneous PTB should be offered progesterone prophylaxis, regardless of CL.³⁵⁻³⁷ The data presented here show that cerclage is beneficial in these women, if short cervix (<25 mm) develops.^{4,32} A recent meta-analysis involving 169 singleton gestations with a prior PTB and a CL of 25 mm or less, most before 25 weeks, revealed that vaginal progesterone was associated with a significant reduction in PTB at less than 33 weeks (RR = 0.54; 95% CI, 0.30 to 0.98) and in composite neonatal morbidity and mortality (RR = 0.41; 95% CI, 0.17 to 0.98).³⁸

Interestingly, ultrasound-indicated cerclage was associated with the lowest risk ratios (i.e., the highest effectiveness) in prolonging pregnancy in women with a CL of less than 15 mm, suggesting that its benefit may come from prevention of exposed membranes. In fact, in the meta-analysis, the lowest risk ratio was for a CL of 15.9 mm or less: PTB occurred at less than 35 weeks with or without cerclage, 35.0% and 58.1%, respectively (RR = 0.59; 95% CI, 0.42 to 0.83).⁵

Physical Examination–Indicated Cerclage

Rarely, a woman presents before 24 weeks with minimal or no symptoms and speculum or digital examination reveals cervical dilation of 1 to 4 cm. Occasionally, such a finding follows the identification of a very short cervix (e.g., <5 mm) detected by TVU (see Ultrasound-Indicated Cerclage, earlier). If intra-amniotic infection, ruptured membranes, advanced labor, or significant hemorrhage is present, delivery is indicated. Intra-amniotic infection is diagnosed by the presence of an otherwise-unexplained fever or by uterine tenderness. In the absence of indications for delivery, the gestational age and degree of cervical dilation need to be determined. Prior to fetal viability, management is usually aimed at prolonging the pregnancy, but allowing or promoting delivery is appropriate in some circumstances, such as preterm premature rupture of membranes or advanced cervical dilation (>4 cm). If viability has been reached, the goal is to both prolong the pregnancy and improve neonatal outcome in the event of PTB.

Data from several studies^{39,40} suggest that a dilated cervix with visible membranes may be an appropriate criterion for cerclage placement in some cases. Placement of a cerclage when a dilated cervix and visible membranes are detected on digital examination at less than 24 weeks' gestation appeared to prolong pregnancy by about 1 month and to improve pregnancy outcome, compared with expectant management, in both a small trial³⁹ and retrospective cohort studies.⁴⁰

We suggest considering amniocentesis to check for infection in women with visible membranes and no clinical signs of infection, especially when the cervix is dilated 2 cm or more, or when there are ultrasound findings suggestive of inflammation: membrane edema, separation of membranes from the decidua, or debris in the amniotic fluid ("sludge"). Cerclage can be considered in these women only in the absence of infection, labor, and vaginal bleeding.

Prior Successful Outcome after Cerclage

Prolongation of pregnancy after cerclage placement does not prove a diagnosis of cervical insufficiency, because many pregnancies with premature cervical effacement have good outcomes in the absence of surgical intervention. In multiple randomized trials and controlled studies, about 60% to 70% of women with a history of early PTB or recurrent late miscarriage maintained a CL of greater than 25 mm in the second trimester

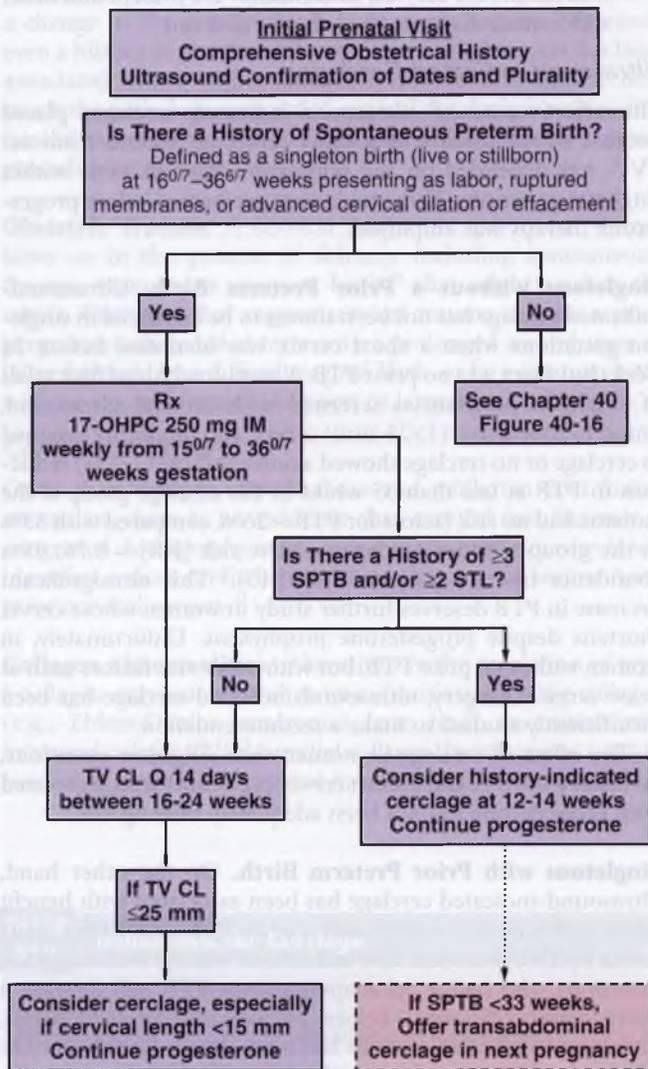

Figure 41-3 Suggested algorithm for women with prior spontaneous preterm birth (PTB), second-trimester losses, or early PTBs. 17-OHPC, 17-alpha hydroxyprogesterone caproate; CL, cervical length; IM, intramuscularly; SPTB, spontaneous preterm birth; STL, second-trimester loss; TV, transvaginal. (Modified from Iams JD, Berghella V: Care for women with prior preterm birth, *Am J Obstet Gynecol* 203:89-100, 2010; and Society for Maternal-Fetal Medicine Publications Committee, with assistance of Vincenzo Berghella: Progesterone and preterm birth prevention: translating clinical trials data into clinical practice, *Am J Obstet Gynecol* 206:376-386, 2012.)

and had low rates of recurrent PTB or loss without cerclage placement.^{4,31,41} Therefore, having had a cerclage does not mean that it is necessarily appropriate in a subsequent pregnancy. When women were treated with cerclage in a prior pregnancy without an appropriate indication, especially in the absence of a shortened cervix, a risk for PTB in a subsequent pregnancy does not warrant a history-indicated cerclage; TVU screening for CL and progesterone therapy for short cervix are more appropriate for these patients.⁴²

Women with a Prior Failed Cerclage

An extreme manifestation of cervical insufficiency occurs in women with multiple prior second-trimester losses or PTBs who receive a history-indicated cerclage at 12 to 14 weeks, but who deliver before 33 weeks despite this intervention. When these women have a subsequent pregnancy, transabdominal cerclage was associated with fewer recurrent PTBs than if they had received another history-indicated transvaginal cerclage.⁴³ We therefore recommend transabdominal cerclage and progesterone supplementation for these patients.

Multiple Gestations

The diagnosis of cervical insufficiency cannot be made reliably in women with multiple gestations. Cervical insufficiency implies a structural weakness in the cervix, which is usually not the cause of early PTB in women carrying more than one fetus. A second-trimester loss in a woman with a multiple gestation is unlikely to be caused by cervical insufficiency. The mechanism of early cervical shortening in women with a multiple gestation is rapid uterine overdistention, usually not cervical weakness. Data for triplets and higher-order multiple gestations are scant and limited to nonrandomized trials.

Twin-Indicated Cerclage. Cerclage based solely on the presence of a twin gestation has not been shown to be beneficial,⁴⁴ and in women with twins and a short cervix, it is potentially harmful. Thus, there is no reason to perform cerclage solely on the basis of the presence of a multiple gestation.

We recommend against placing a cerclage in women with multiple gestations for the TVU finding of a short cervix. Cerclage for a short cervix (<25 mm) before 24 weeks in women with twin gestations has been associated with harmful effects, with PTB increased more than twofold compared with no cerclage in the largest study, a meta-analysis that included 49 sets of twins.⁵

As no intervention has been definitively shown to be beneficial once the cervix is short in women with multiple gestations, we do not perform TVU screening for CL in this population.

Furthermore, there are no data related to the efficacy of cerclage in the rare women with a multiple gestation who also have a history of multiple prior early PTBs. Case-by-case decisions are required.

Management and Technical Considerations

Cervical cerclage is an invasive procedure that should be used only when indicated and shown to have beneficial effects. Contraindications to cerclage are shown in Box 41-3. There are several management and technical considerations.

Preoperative and Perioperative Management. An ultrasound should be performed before every cerclage placement to ensure fetal viability, to confirm gestational age, and to

BOX 41-3 CONTRAINDICATIONS TO CERCLAGE

- Severe fetal anomaly
- Intrauterine infection
- Active bleeding
- Active labor
- Preterm ruptured membranes
- Fetal death

assess fetal anatomy to rule out clinically significant structural abnormalities. An assessment of crown-rump length and nuchal translucency with analyte screening should be offered when cerclage is performed before 18 weeks (i.e., is history-indicated) and an anatomic survey performed when cerclage is planned later (i.e., is ultrasound-indicated or physical examination–indicated).

Subclinical intra-amniotic infection (IAI) occurs in about 1% to 2% of those undergoing ultrasound-indicated cerclage.²⁹ The incidence can be as high as 9% if *Ureaplasma* or *Mycoplasma* is cultured, but the clinical significance of this finding is unclear. The shorter the cervix, the higher the incidence of IAI is.³⁰ Unless membranes are prolapsed to, or past, the external os, amniocentesis is not indicated before the majority of ultrasound-indicated cerclages. Subclinical IAI occurs in about 20% or more in those undergoing physical examination–indicated cerclage.⁴⁵ Amniocentesis for women with cervical dilation of 2 cm or more, when cultured for *Ureaplasma* and *Mycoplasma*, reveals a greater than 50% incidence of IAI.⁴⁵ Therefore, amniocentesis should be discussed with and offered to women with cervical dilation on manual examination. Women with an amniotic fluid glucose level of less than 15 mg/dL, or whose Gram stain or culture is positive, should not undergo cerclage.

There is no good evidence that perioperative antibiotics are beneficial for women undergoing cerclage. There is also no study on the effect of progesterone used specifically around the time of cerclage.

The association of short cervix with uterine contractions raises the question of the usefulness of tocolytics (including anti-inflammatory agents) with (or without) cerclage for asymptomatic women with a short cervix. In a randomized controlled trial, women at high risk for PTB because of both a poor obstetric history and a short cervix by TVU received either indomethacin and an ultrasound-indicated cerclage, or bed rest alone.⁴⁶ The combination of indomethacin and cerclage was associated with a significantly decreased incidence of PTB compared with those who did not receive either. Thus the attributable effect of indomethacin could not be formally assessed, and the evidence is insufficient to make a clinical recommendation.

Spinal anesthesia is usually the preferred regional technique, as the procedure rarely takes more than 30 minutes.

Intraoperative Management. The cervix can be evaluated with ultrasound TVU before, during, and immediately after cerclage. After the patient is placed in the dorsal lithotomy position and the bladder is emptied to reduce the chance of bladder entry, surgical preparation of the perineum and vagina is performed, usually with povidone-iodine. This step is performed

gently in the vagina if the membranes are protruding from the cervix.

Exposure is aimed for optimal visualization of the cervix. We use a weighted speculum in the posterior vagina, Breisky retractors (Thomas Medical, Inc., Indianapolis) for lateral vaginal wall retraction, and Sims retractors (Thomas Medical) for anterior retraction. The primary surgeon performs the cerclage, and two assistants help with retraction aimed at optimal visualization. We use ring (or sponge) forceps on the cervix to optimize visualization of the cervix and its suture entry sites. Stay sutures may also be used in place of ring forceps when either access or secure grasp is difficult.

Technique. The transvaginal cerclage is usually performed using either the McDonald or the Shirodkar approach.⁴⁷ Several variations of these original techniques have been reported. In the McDonald technique, a purse-string suture is placed in four to six bites circumferentially around the cervix, just distal to the vesicocervical reflection (at the junction of the ectocervix and the anterior rugated vagina) and posteriorly, just distal to the vaginal-rectal reflection (Figs. 41-4, 41-5, and 41-6).⁴⁸ Less than 1 cm should be left between the exit of the last bite and the entry of the new bite of suture into the cervix. Each pass should be deep enough to capture sufficient cervical stroma to avoid pull-through and later displacement, but not so deep as to enter the endocervical canal (and risk rupture of the membranes, especially in women with cervical changes present). The suture is tied anteriorly after eliminating any slack with gentle traction

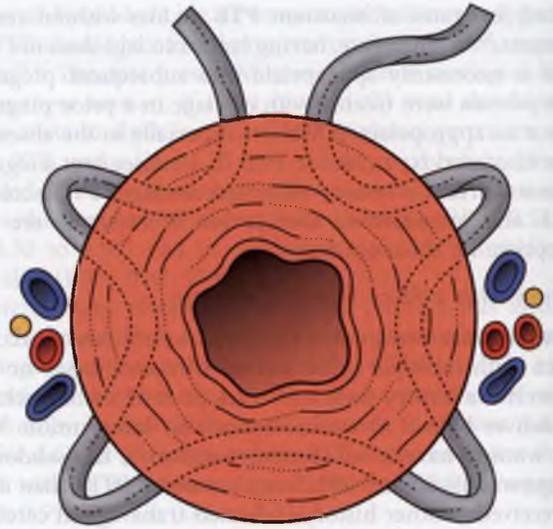

Figure 41-5 McDonald cerclage, coronal view. Each pass should be deep enough to contain sufficient cervical stroma to avoid pull-through, but not so deep as to enter the endocervical canal. The uterine vessels should be avoided laterally. Particular attention should be given to the placement of the posterior bite, as this is the most likely site of suture displacement. (Reproduced with permission from Berghella V, Baxter J, Berghella M: *Cervical insufficiency*. In Apuzzio JJ, Vintzileos AM, Iffy L, editors: *Operative obstetrics*, ed 3, United Kingdom, 2006, Taylor and Francis.)

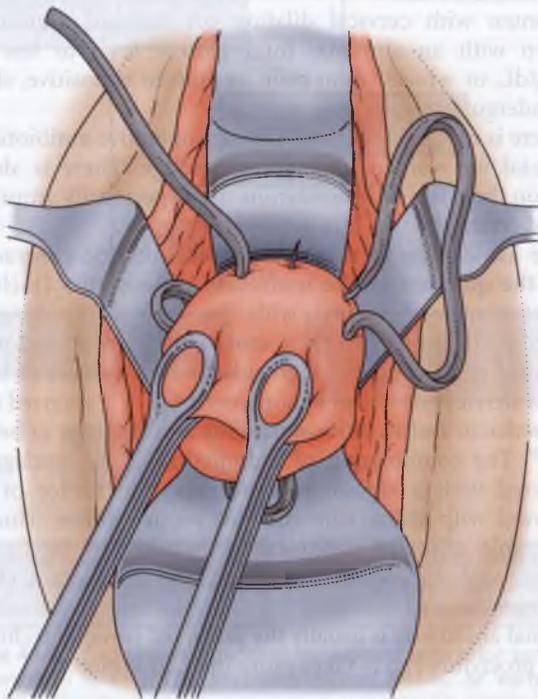

Figure 41-4 McDonald cerclage, in place before securing the knot. Just distal to the vesicocervical reflection, a purse-string suture is placed in four to six passes circumferentially around the cervix. The suture should be placed as high as possible. (Reproduced with permission from Berghella V, Baxter J, Berghella M: *Cervical insufficiency*. In Apuzzio JJ, Vintzileos AM, Iffy L, editors: *Operative obstetrics*, ed 3, United Kingdom, 2006, Taylor and Francis.)

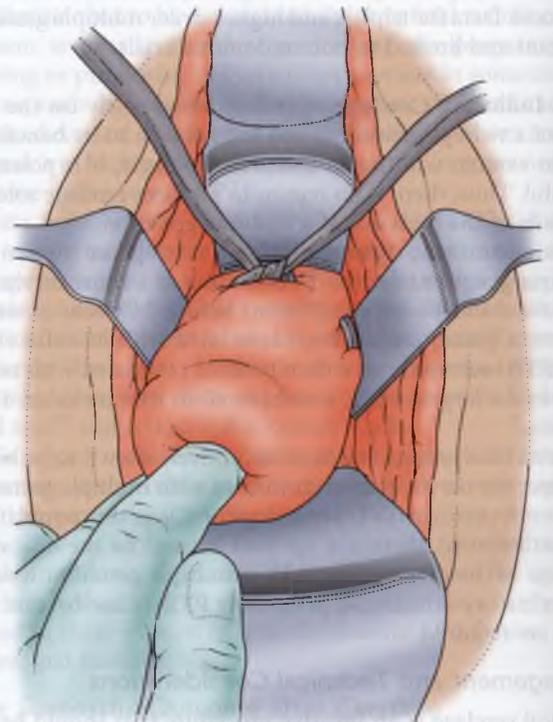

Figure 41-6 McDonald cerclage, tying the knot anteriorly. The suture is usually tied anteriorly, tight enough to admit a fingertip at the external os, but closed at the internal os. Successive knots (usually at least five) are placed, and the ends are left long enough (e.g., 2 cm) to facilitate later removal. (Reproduced with permission from Berghella V, Baxter J, Berghella M: *Cervical insufficiency*. In Apuzzio JJ, Vintzileos AM, Iffy L, editors: *Operative obstetrics*, ed 3, United Kingdom, 2006, Taylor and Francis.)

on the suture and counter-traction on the stroma. The suture ends are left long enough (2 to 3 cm) to allow easy removal.

The main difference between the McDonald and Shirodkar techniques is that the Shirodkar requires dissection of the vaginal mucosa off the bladder and rectum cephalad to facilitate placement of the suture as close as is safely possible to the internal os (i.e., as high as possible). It has not been proven that the Shirodkar technique reliably allows higher placement of the suture. McDonald also recommended placing the suture “as high as possible to approximate the level of the internal os.”⁴⁷ With proper technique, the McDonald suture can be placed close to the internal os (see Fig. 41-6).⁴⁹ The dissection and longer operating time for placement and removal of the Shirodkar cerclage could theoretically involve more complications than the McDonald technique. Placement of the cerclage can be assessed by postoperative cervical ultrasound, as shown in Figure 41-7 for a Shirodkar suture.

Analyzing only *history-indicated* cerclages, several series have shown McDonald and Shirodkar techniques to have similar efficacies.^{50,51} In a meta-analysis of four randomized controlled trials of only *ultrasound-indicated* cerclages for short cervix in singleton gestations, rates of PTB were similar for the McDonald and Shirodkar techniques.⁵² Analyzing only *physical examination-indicated* cerclages done for manually detected cervical dilation (usually of ≥ 1 cm), incidences of PTB were similar for the McDonald and Shirodkar techniques.⁵⁰ Most randomized trials^{4,33,46,53,54} and a meta-analysis³² of selected trials that confirmed ultrasound-indicated cerclage efficacy for prevention of PTB have used the McDonald cerclage, with no level 1 data showing efficacy when Shirodkar cerclage was used.⁵⁵ Thus, the McDonald technique is preferred over the Shirodkar, mainly because of its ease of placement and removal, and its proven comparative effectiveness.^{4,32,33,46,53,54}

Several types of material have been evaluated for cerclage, including human fascia lata; sutures such as Mersilene, silk, Prolene, and Tevdek; metal wire; and Mersilene tape. Today, the most commonly used are Mersilene 5-mm tape (Thicon RS-21

or D-8113; Ethicon Inc., Somerville, NJ)^{4,33,46} and large, nonabsorbable monofilament (e.g., Prolene, Ethicon).²⁹ In the absence of data suggesting the superiority of one suture type, the choice of suture should be investigated further and meanwhile left to the operator's preference. No study has compared different types of needles, such as Mayo, blunt, and cutting.

As one of the goals of cerclage is to reconstitute a closed endocervical canal, both Shirodkar and McDonald described placing the suture “as high as possible to approximate the level of the internal os.”⁴⁷ A cerclage height of at least 18 mm was associated with a lower incidence of PTB (4%) than placement at less than 18 mm (33%).⁵⁶ The stitch should therefore be placed as high as possible, close to the internal os, attempting to reach a cerclage height of more than 2 cm.

The evidence regarding the number of stitches to be placed is limited. We suggest placing a second stitch at the time of initial cerclage only if the initial stitch is evaluated to be too low in the cervix, and gentle pulling on this first stitch may allow placing a second stitch much closer to the internal os, at least 2 cm above the external os.

It can be particularly challenging to place a stitch if membrane prolapse or advanced cervical dilation is present. Several technical suggestions have been described. The Trendelenburg position can be used to harness the effect of gravity. Bladder filling can assist membrane replacement. A moist sponge on the ring forceps or a 16-French Foley balloon (with tip cut) has been used successfully to replace membranes mechanically.⁵⁷ Amniocentesis can also be used to reduce membrane prolapse and allow easier and safer physical examination–indicated cerclage.^{58,59} The amount removed is usually about 150 to 250 mL.^{58,59}

Cerclage seems to be effective up to 4 cm of cervical dilation,⁴⁰ but efficacy appears to diminish if the cervix is more than 4 cm dilated.⁶⁰

Postoperative Issues. It appears that cerclage can be safely performed in an outpatient setting. In women with cervical changes at higher risk for infection and preterm labor, especially if after 20 weeks, a 24-hour postoperative stay for observation can be considered.

No controlled study has evaluated activity restriction in association with cerclage. There is evidence that decreased activity such as bed rest, inpatient (as just described) or outpatient, does not prevent PTB.⁶¹ Women placed on decreased activity should be advised that there is no proven benefit associated with this intervention, and potential life-threatening risks such as thromboembolism exist.

TVU assessment of CL after cerclage predicts the incidence of PTB.⁶² However, no intervention has been shown to prevent PTB if the cervix further shortens after cerclage. Reinforcing cerclage, defined as a cerclage placed in a woman with a preexisting cerclage, has not been evaluated by randomized controlled trials. In women with a history-indicated cerclage who develop a short cervix by TVU (< 25 mm) at 14 to 23 6/7 weeks, reinforcing (second or repeat) cerclage is associated with a higher incidence of PTB.⁶³ We do not advocate serial TVUs for CL after placement of cerclage or reinforcing cerclage.

We suggest cerclage removal with preterm premature rupture of membranes, and with advanced preterm labor that puts tension on the stitch. We also suggest that, if the pregnancy's progression is uncomplicated to that point, with cerclage still in place, the cerclage should be removed at 36 weeks.

Figure 41-7 Transvaginal cerclage. Endovaginal ultrasound image of the cervix in a woman with a transvaginal Shirodkar cerclage. Arrows point to the 5-mm tape used for the procedure. Cervix measured in two segments: A = 2.23 cm from external os to the plane of the suture, and B = 1.17 cm from the suture to the internal cervical os.

OTHER INTERVENTIONS

Vaginal pessaries are intended to alter the axis of the cervical canal and displace the weight of the uterine contents away from the cervix. A review of the scant literature on this topic before 2010 concluded that the possibility of benefit could not be excluded.⁶⁴ A recent randomized trial reported an 82% reduction (6% versus 27%; odds ratio [OR] = 0.18; 95% CI, 0.08 to 0.37) in PTB before 34 weeks in women with singleton gestations who developed a short cervix assessed by TVU as being less than 25 mm before 24 weeks if they received an Arabin pessary, compared with controls who did not receive the pessary.⁶⁵ However, the rate of PTB in the control group was remarkably high. This report is very encouraging but insufficient to support routine clinical use.

A review of data from three randomized cerclage trials found that indomethacin therapy for asymptomatic women with a short cervix (<25 mm) at 14 to 27 weeks who did not receive a cerclage did not reduce the risk for spontaneous PTB at less than 35 weeks, but did appear to reduce the risk for PTB at less than 24 weeks.⁶⁶ Further research including larger numbers and a randomized trial design is necessary to further clarify the effectiveness, as well as the risks, of this therapy.

The evidence is insufficient to recommend antibiotics for women with cervical insufficiency, on the basis of poor obstetric history, short cervix by TVU, or dilated cervix on physical examination.

Lifestyle interventions (cessation of work and exercise, abstinence from coitus, bed rest, limited activity) have not been adequately evaluated by well-designed studies. Clinicians should consider the available evidence and the patient's individual circumstances when making lifestyle recommendations. We advise women with a prior PTB and a short cervix to avoid coitus.

Prevention of Cervical Insufficiency

As cervical insufficiency is primarily caused by acquired risk factors, prevention is the best cure. Interventions that prevent PTB (see Chapter 40) would also prevent cervical insufficiency. Operations requiring cervical dilation should seek to dilate the cervix as gently and slowly as possible, and as little as necessary. Ripening agents such as misoprostol and laminaria are preferred over mechanical dilators. Prevention of cervical dysplasia can be achieved with human papillomavirus vaccination and the use of condoms. When cervical surgery is necessary, only the diseased cervical tissue should be removed, making LEEP

the preferred method over cold knife or laser surgery. Cervical lacerations can be prevented with judicious use of forceps and vacuum. Removal of cerclage sutures before labor can reduce the incidence of cervical lacerations.⁶⁷

Management Considerations

The key to management is to screen for short cervix at the first opportunity, rather than waiting for symptoms to persist before evaluation. Unfortunately, no test performed in nonpregnant women reliably predicts cervical insufficiency in a future pregnancy.⁶ Risk factors for cervical insufficiency and PTB should be reviewed, and possible management in pregnancy should be discussed. Management depends mostly on the reproductive history and the results of TVU screening for CL (see Figs. 41-2 and 41-3). TVU knowledge of CL by itself does not prevent subsequent PTB.⁶⁸

Once a detailed review of historic risk factors is completed, a plan should be made regarding management. Only women with three or more early PTBs or second-trimester losses are candidates for history-indicated cerclage. All women with risk factors, except perhaps for those with multiple gestations, should be screened for short cervix with TVU. For women with early second-trimester losses, recurrent second-trimester losses, or large cold knife biopsies, in whom history-indicated cerclage is not performed, we suggest initiating TVU screening for CL at least at 14 weeks, if not at 12 weeks.^{21,69} Routine CL screening is favored by many and is endorsed as an option by both the Society for Maternal-Fetal Medicine³⁵ and the American College of Obstetricians and Gynecologists.³⁶ This topic is discussed in Chapter 40.

If a short CL (<25 mm) is detected before 24 weeks, we suggest counseling about risks, uterine monitoring, and physical examination before a definite plan (see Figs. 41-2 and 41-3) is made. As many as 80% of asymptomatic women with a short cervix in the second trimester will have some contractions on tocodynamometer monitoring.⁶⁹ These contractions are usually occasional, and not regular, but women with four or more contractions per hour have twice the risk for PTB that women with fewer than four contractions per hour have.⁶⁹ If contractions are frequent, cerclage should at least be postponed, and tocolysis and steroids for fetal maturation may be considered.

Premature Rupture of the Membranes

BRIAN M. MERCER, MD

Rupture of the fetal membranes is an integral part of normal parturition at term, and it is inevitable in the process of both term and spontaneous preterm birth. Spontaneous rupture of the membranes (SROM) at term and preterm can occur any time before or after the onset of contractions. When it occurs before the onset of contractions, it is referred to as premature rupture of the membranes (PROM). Whereas membrane rupture at term usually results from a physiologic process of progressive membrane weakening, the pathologic weakening associated with preterm PROM can result from several causes. Although delivery after PROM may be required by the presence of advanced labor, intrauterine infection, vaginal bleeding resulting from placental abruption, or non-reassuring fetal status, the physician often needs to decide whether to actively pursue delivery or conservatively manage the pregnancy. Management of PROM hinges on knowledge of gestational age, the neonatal risks related to immediate delivery, and an understanding of the anticipated clinical course and the relative risks involved with conservative management of intrauterine infection, abruptio placentae, and fetal distress (e.g., from umbilical cord accident or infection).

Physiology and Pathophysiology of Membrane Rupture

The fetal membranes consist of the amnion, which lines the amniotic cavity, and the chorion, which adheres to the maternal decidua. Initially, the amnion and chorion are separate layers. The amniotic sac is visible on ultrasound until it fuses with the chorion by the end of the 14th week of gestation. Subsequently, the amnion and chorion are connected by a collagen-rich connective tissue layer, with the amnion represented by a single cuboidal epithelial amnion layer and subjacent compact and spongy connective tissue layers, and the thicker chorion consisting of reticular and trophoblastic layers. Together, the amnion and chorion form a stronger unit than either layer individually. Physiologic membrane remodeling occurs with advancing gestational age, reflecting changes in collagen content and type, changes in intercellular matrix, and progressive cellular apoptosis. These changes lead to structural weakening of the membranes, which is more evident in the region of the internal cervical os.¹⁻⁶

Membrane weakening can be stimulated by exposure to local matrix metalloproteinases (e.g., MMP-1, MMP-2, MMP-9), decreased levels of membrane tissue inhibitors of matrix metalloproteinases (e.g., TIMP-1, TIMP-3), and increased poly(ADP-ribose) polymerase cleavage.^{4,7} Uterine contractions can also lead to membrane rupture through increased bursting pressure

from increased intra-amniotic pressure and from “strain hardening” with repeated contractions. If the fetal membranes do not rupture before labor, the work to cause membrane rupture at the internal cervical os decreases with advancing cervical dilation because of the lack of anchoring to the supportive decidua and the enhanced ability to stretch with contractions.

Preterm membrane rupture can arise through a number of pathways that ultimately result in accelerated membrane weakening. Bacterial collagenases and proteases can directly cause fetal membrane tissue weakening.⁸ An increase in local host cytokines or an imbalance in the interaction between MMPs and TIMPs in response to microbial colonization can have similar effects.⁹ There is specific evidence linking urogenital tract infection and colonization with preterm PROM. Amniotic fluid cultures after PROM are frequently positive (25% to 35%),¹⁰⁻¹⁵ and histologic evaluation in the setting of preterm birth has frequently demonstrated acute inflammation and bacterial contamination along the choriodecidual interface.¹⁶ Although these findings may reflect ascending infection after PROM, it is likely that ascending colonization and infection are directly involved in the pathogenesis of preterm PROM in many cases. Genital tract pathogens that have been associated with PROM include *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Trichomonas vaginalis*, and group B β -hemolytic streptococci (GBS).¹⁷⁻²¹ Although GBS bacteriuria has been associated with preterm PROM and low birth weight,²² and an association between cervical GBS colonization and preterm PROM is possible,²³ it does not appear that vaginal GBS carriage is associated with preterm PROM.^{24,25} Although the association between bacterial vaginosis and preterm birth, including that related to preterm PROM,^{26,27} is well established, it remains unclear whether bacterial vaginosis merely identifies those with a predisposition to abnormal genital tract colonization and inflammation, facilitates ascent of other bacteria to the upper genital tract, or is directly pathogenic and causative of membrane rupture. Physical effects related to preterm contractions and prolapsing membranes with premature cervical dilation can predispose the fetal membranes to rupture, as can the increased intrauterine pressure seen with polyhydramnios.^{2,28} It is likely that certain connective tissue disorders (e.g., Ehlers-Danlos syndrome) can result in intrinsic weakening of the membranes. Clinical associations with preterm PROM include low socioeconomic status, lean maternal body mass (<19.8 kg/m²), nutritional deficiencies (e.g., copper, ascorbic acid), and prior cervical conization. During pregnancy, maternal cigarette smoking, cervical cerclage, second- and third-trimester bleeding, acute pulmonary disease, prior episodes of preterm labor or contractions, and uterine overdistention with polyhydramnios or multiple gestations have also been linked to preterm PROM.^{2,28-39}

Although one or more factors may lead to membrane rupture, the ultimate clinical cause of PROM is often not evident at delivery.

In some cases, the factors leading to membrane rupture are subacute or chronic in nature. Women with a prior preterm birth have an increased risk for preterm birth due to PROM in subsequent pregnancies, especially if the prior preterm delivery resulted from PROM.⁴⁰ Asymptomatic women with a short cervical length (<25 mm) and remote from delivery are also at increased risk for subsequent preterm birth due to preterm labor or PROM. Some women may have polymorphisms for inflammatory proteins that alter their inflammatory response and increase the risk for preterm birth.^{41,42}

Prediction and Prevention

Because PROM at term is usually part of the normal parturition process, the focus of attention has been on the prediction and prevention of preterm birth due to PROM. Because delivery often occurs soon after membrane rupture, the optimal way to prevent complications from preterm PROM is to prevent its occurrence. Potentially modifiable risk factors for preterm PROM include cigarette smoking, poor nutrition, urinary tract and sexually transmitted infections, acute pulmonary diseases, and severe polyhydramnios. Other than treatment of infections, it is unknown whether correction of these factors can avert this complication. Although most other risk factors are fixed, in that they cannot be removed or remedied in a particular woman, knowledge of risk can help in counseling women about suspect symptoms and the importance of timely evaluation if preterm PROM occurs.

Perhaps the strongest risk factor for preterm PROM is a history of prematurity or PROM.⁴³ Those who have had an early preterm birth have the highest risk for a recurrence. A history of preterm birth after PROM confers a 3.3-fold increased risk for recurrent preterm birth from the same cause (13.5% versus 4.1%; $P < .01$) and a 13.5-fold higher risk for subsequent delivery before 28 weeks (1.8% versus 0.13%; $P < .01$). Identification of a short cervical length on transvaginal ultrasound also confers an increased risk for subsequent PROM in nulliparas and multiparas. In a study of preterm birth prediction, nulliparas with a cervix length less than 25 mm and a positive cervicovaginal fibronectin result at 22 to 24 weeks had a one-in-six (16.7%) chance of delivering a preterm infant because of PROM, and the combination of a prior preterm birth due to PROM, a short cervical length, and a positive fetal fibronectin value increased the risk for delivery before 35 weeks' gestation as a result of preterm PROM by 10.9-fold (25% versus 2.3%).⁴⁰ However, ancillary tests such as fetal fibronectin screening or transvaginal cervical sonography should be incorporated into routine practice only after effective interventions to prevent PROM have been identified for those with an abnormal test result.

Broad-based preventive strategies such as progesterone supplementation can be considered for those at risk as a result of less specific risk factors, such as a history of spontaneous preterm birth (see Chapter 40).^{44,45} Although one study suggested that vitamin C supplementation had value in preventing preterm PROM (7.6% versus 24.5%; $P = .02$), studies in which vitamin C was given alone or with other supplements to women without prior preterm birth as a risk factor indicated a trend toward *increased* preterm birth with such treatments (relative

risk [RR] = 1.38; 95% confidence interval [CI], 1.04 to 1.82).^{46,47} Vitamin C supplementation to prevent preterm birth resulting from PROM is thus not recommended.

Unfortunately, despite knowledge of a broad range of potential risk factors for preterm birth, we can predict only a small fraction of women destined to deliver preterm, and most preterm births resulting from preterm labor or PROM occur in women considered to be at low risk for these events. Because most cases of preterm PROM cannot be predicted or prevented, clinical efforts continue to be focused on evaluation and treatment of women who present with symptoms of preterm PROM.

Clinical Course

PROM affects approximately 8% of pregnancies at term, and 95% of these women deliver within 28 hours after membrane rupture.⁴⁸ Preterm PROM is also associated with brief latency from membrane rupture to delivery; delivery within 1 week is the most common outcome after preterm PROM at any gestational age. On average, latency increases with decreasing gestational age at membrane rupture. When PROM occurs before 34 weeks' gestation, 93% of women will deliver within 1 week, and 50% to 60% of those who are managed conservatively will deliver within 1 week.^{49,50} With PROM near the limit of viability, 60% to 70% deliver within 1 week, but 1 in 5 will have a latency of 4 or more weeks if they are managed conservatively.⁵⁰ Although the likelihood of spontaneous resealing of the membranes after preterm PROM is low (3% to 13%), the prognosis for those with PROM occurring after amniocentesis is much better, with 86% to 94% resealing spontaneously.^{38,51,52} In a study of women with PROM after second-trimester amniocentesis, leakage stopped in most cases with conservative management, although a normal fluid volume sometimes took time to reaccumulate (in a range of 8 to 51 days).⁵²

Complications after Premature Rupture of the Membranes

MATERNAL COMPLICATIONS

Chorioamnionitis complicates 9% of pregnancies with term PROM, a risk that increases to 24% with membrane rupture lasting longer than 24 hours.⁵³ The risk for intrauterine infection increases with the duration of membrane rupture and with declining gestational age.^{48,49,54-56} Chorioamnionitis can complicate 13% to 60% of cases when PROM occurs remote from term. Conservative management of PROM provides the opportunity for subclinical deciduitis to progress to overt infection, and for ascending infection to occur.^{16,48,49,56} Endometritis occurs in 2% to 13% of cases.^{56,57} Placental abruption is diagnosed in 4% to 12% of pregnancies complicated by PROM and can occur before or after the onset of membrane rupture.^{29,58,59} Maternal sepsis (0.8%) leading to death (0.14%) is an uncommon complication of preterm PROM occurring near the limit of viability.⁶⁰

FETAL COMPLICATIONS

The risks to the fetus are primarily those related to intrauterine infection, umbilical cord compression, and placental abruption. Fetal heart rate patterns consistent with umbilical cord compression resulting from oligohydramnios are commonly seen

after PROM.⁶¹ Umbilical cord prolapse can occur after membrane rupture, particularly with fetal malpresentation, which is more common with preterm gestations. Fetal death occurs in 1% to 2% of cases of conservatively managed PROM.⁶⁰ The reported incidence of fetal death after PROM at 16 to 28 weeks ranges from 3.8% to 22%.⁶²⁻⁶⁴ This particularly high risk for fetal loss may reflect increased susceptibility to umbilical cord compression and hypoxia, or intrauterine infection, but it may also reflect less aggressive obstetric interventions for fetal compromise before the limit of viability.

NEONATAL COMPLICATIONS

Gestational age at delivery is the primary determinant of the frequency and severity of neonatal complications after PROM. Respiratory distress syndrome (RDS), necrotizing enterocolitis, intraventricular hemorrhage (IVH), and sepsis are the most common serious acute morbidities, and they are common with early preterm birth. Neonatal sepsis is twice as common after preterm PROM than after preterm birth resulting from preterm labor. Neonatal infection can manifest as congenital pneumonia, sepsis, meningitis, and late-onset bacterial or fungal infection. Early preterm birth can lead to long-term complications, including chronic lung disease, visual or hearing difficulties, mental retardation, developmental and motor delay, and cerebral palsy. In general, these long-term morbidities are uncommon with delivery after about 32 weeks' gestation.^{65,66} Cerebral palsy and periventricular leukomalacia have been associated with amnionitis,⁶⁷ and increased amniotic fluid cytokines and fetal systemic inflammation have been associated with preterm PROM, periventricular leukomalacia, and cerebral palsy.⁶⁸⁻⁷⁰ This highlights that there needs to be the potential for neonatal benefit from delayed delivery if conservative management is to be attempted, because this delay offers the opportunity for intrauterine infection to develop. Alternatively, early gestational age at birth has been associated with neonatal white matter damage ($P < .001$) after controlling for other factors.⁷¹ Despite the described associations between PROM, intrauterine infection or inflammation, and adverse neurologic outcomes, it has not been shown that immediate delivery after PROM can prevent these morbidities.

In the past, mid-trimester PROM, which encompasses membrane rupture occurring at about 16 to 26 weeks' gestation, was considered to be a separate entity from preterm PROM because neonatal death could usually be anticipated with immediate delivery. With current survival rates of about 25% to 85% after delivery at 23 to 26 weeks' gestation, mid-trimester PROM is no longer a relevant clinical entity.^{65,66,72-74} Pre-viable PROM occurring before the limit of viability (i.e., before 23 weeks' gestation) is a special circumstance that places the fetus in particular jeopardy. Immediate delivery will result in neonatal death. Conservative management may result in fetal or neonatal loss before viability, and if viability is reached, delivery is likely to occur at an early gestational age, when the risks for long-term sequelae are highest. Neonatal survival after conservative management at 24 weeks or less is 44%, but survival varies with gestational age at PROM (14% percent for PROM occurring before 22 weeks, 58% for PROM at 22 to 24 weeks).⁷⁵ Stillbirth is common (23% to 53%) in this gestational age range, as are newborn morbidities such as RDS (66%), grade III to grade IV IVH (5%), sepsis (19%), and necrotizing enterocolitis (4%), as well as long-term complications such as bronchopulmonary dysplasia

(29%). However, estimation of individual outcomes before delivery is difficult, as the ultimate gestational age at delivery cannot be predicted.

Fetal lung growth and development can be especially adversely affected when PROM occurs in the early phases of development.⁷⁶⁻⁸¹ With PROM occurring during the late pseudoglandular or canalicular stage of pulmonary development, tracheobronchial collapse or loss of intrinsic factors in the tracheobronchial fluid, or both, may lead to failure of the terminal bronchioles and alveoli to develop, with resultant failure of lung growth.⁸²⁻⁸⁵ Pulmonary hypoplasia develops over weeks after membrane rupture occurs. The most accurate pathologic diagnosis is based on radial alveolar counts and lung weights.^{86,87} In surviving infants, pulmonary hypoplasia is suggested by a small chest circumference with severe respiratory distress, or by persistent pulmonary hypertension and radiographic findings such as small, well-aerated lungs with a bell-shaped chest and elevation of the diaphragm.^{77,82}

Overall, pulmonary hypoplasia becomes evident in 0% to 26.5% of infants (mean = 5.9%) delivering after PROM at 16 to 26 weeks' gestation. Early PROM before 20 weeks' gestation carries the highest potential for lethal pulmonary hypoplasia ($\approx 50\%$ with PROM before 19 weeks' gestation).^{77,80-82,88-90} With PROM at 15 to 16 weeks, an amniotic fluid index of 2 cm or less, and a latency of 28 days, the risk for pulmonary hypoplasia is estimated to be 74% to 82%.⁹¹ Lethal pulmonary hypoplasia is uncommon (0% to 1.4%) with PROM after 24 to 26 weeks' gestation, because there has been adequate alveolar development to support extrauterine life by this time.^{77,78,92} However, nonlethal pulmonary hypoplasia increases the likelihood of pulmonary barotrauma, including pneumothorax, pneumomediastinum, and the need for high ventilatory pressures because of poor pulmonary compliance.^{77,92,93} With prolonged oligohydramnios, restriction deformities can occur in up to 27% of fetuses.^{60,77,92-95}

Diagnosis

In more than 90% of cases, the diagnosis of PROM can be confirmed by clinical assessment, including the combination of history, clinical examination, and laboratory evaluation. Because optimal clinical care requires an accurate diagnosis, attention should be paid to confirming the diagnosis when a suspect history or ultrasound finding of oligohydramnios is identified. Other potentially confounding findings such as urine leakage, increased vaginal discharge with cervical dilation or membrane prolapse, cervical infection, passage of the mucus plug, and the presence of semen or vaginal douching should be considered.

A sterile speculum examination should be performed to provide confirmatory evidence of membrane rupture and to inspect for cervicitis and for umbilical cord or fetal prolapse, to assess cervical dilation and effacement, and to obtain cultures, including endocervical *N. gonorrhoeae* and *C. trachomatis*, and anovaginal GBS, as appropriate. Initially, digital cervical examination should be avoided unless imminent delivery is anticipated, because the needed information usually can be obtained with visualization of the cervix. Digital examination can shorten latency between membrane rupture and delivery, and some studies have shown that such examinations introduce vaginal organisms into the cervical canal and increase the risk for infection.⁹⁶⁻⁹⁹

Figure 42-1 Ferning. A typical ferning appearance is seen after the posterior vaginal fornix was swabbed, and the specimen was smeared on a glass slide and allowed to air dry. The sample was obtained from a patient with premature rupture of the membranes. (Courtesy of Thomas Garite, University of California at Irvine, Orange, CA.)

The diagnosis of membrane rupture is confirmed by visualization of fluid passing from the cervical canal. If the diagnosis is not confirmed on initial inspection, the pH of the vaginal side walls or pooled vaginal fluid can be evaluated using nitrazine paper, which turns blue at a pH higher than 6.0 to 6.5. Amniotic fluid usually has a pH of 7.1 to 7.3, whereas normal vaginal secretions have a pH of about 4.5 to 6.0. Blood or semen contamination, alkaline antiseptics, and bacterial vaginosis can cause false-positive nitrazine test results. If further clarification is needed, microscopic inspection can be performed for the presence of arborized crystals (i.e., ferning) (Fig. 42-1) in an air-dried sample collected from the vaginal side walls or pooled vaginal fluid. Ferning results from the interaction of amniotic fluid proteins and salts. Cervical mucus should be avoided during sampling because it can also yield a ferning pattern on microscopy. The fern test is unaffected by meconium and vaginal pH, but it can be falsely positive if there is heavy blood contamination.^{100,101} Prolonged leakage with minimal residual fluid can lead to false-negative clinical, nitrazine, and ferning test results. Reexamination after prolonged recumbency or alternative measures can be considered if initial testing is negative. Assessment of cervicovaginal secretions for fetal fibronectin, prolactin, human chorionic gonadotropin, placental α -microglobulin-1 (PAMG-1), and insulin-like growth factor-binding protein-1, and other markers may assist in the diagnosis of PROM. However, these tests have not generally been evaluated when the diagnosis of membrane rupture is unclear after clinical examination, so their additional diagnostic benefit is uncertain. Furthermore, a positive test result may reflect decidual disruption rather than membrane rupture in some cases, and a negative test result cannot exclude the diagnosis unequivocally. For example, PAMG-1 has been found in the cervicovaginal secretions of nearly one third of laboring women without suspected membrane rupture.^{102,103}

If the diagnosis remains unclear after initial evaluation, documentation of oligohydramnios by ultrasound, in the absence of fetal urinary tract malformations or significant growth restriction, is suggestive of membrane rupture. Ultrasonographically guided amniocentesis with infusion of indigo

carmin dye (1 mL of dye in 9 mL of sterile normal saline), followed by observation for passage of blue fluid from the vagina onto a perineal pad, can confirm or disprove the diagnosis of membrane rupture. Amniocentesis in the setting of oligohydramnios can be difficult, and particular attention should be paid to avoiding the umbilical cord vessels, which can have the appearance of a thin, linear fluid space in this circumstance.

Some women with a history of possible membrane rupture but a negative speculum examination result and a normal amniotic fluid volume on ultrasound subsequently return with gross membrane rupture. This pattern may reflect initial transudation of a small amount of fluid across a weakened membrane, or minimal leakage around a firmly applied presenting fetal part. Women with a suspect history and initially negative testing should be encouraged to return for reevaluation if symptoms are persistent or recurrent.

Management of Premature Rupture of the Membranes

Management of PROM is based primarily on the estimated risks for fetal and neonatal complications with immediate delivery weighed against the potential risks and benefits of conservative management to extend the pregnancy after membrane rupture (Fig. 42-2). The risks for maternal morbidity should also be considered, especially under the circumstance of pre-viable PROM.

INITIAL EVALUATION

After the diagnosis of membrane rupture is confirmed, the duration of membrane rupture should be estimated to assist the pediatric caregivers with subsequent management decisions. Gestational age is established on the basis of a combination of menstrual dates, clinical history, and ultrasound findings, as appropriate. Fetal presentation is assessed, and the patient is evaluated for labor, clinical findings of intrauterine infection, and significant vaginal bleeding. Fetal well-being is assessed by continuous heart rate monitoring if the limit of viability has been reached. After preterm PROM, it is important to evaluate fetal growth and residual amniotic fluid volume by ultrasound, and the potential for fetal abnormalities that can lead to polyhydramnios should be considered. Although narrowing of the biparietal diameter (i.e., dolichocephaly) as a result of oligohydramnios or breech presentation can result in underestimation of gestational age and fetal weight, ultrasound is usually as reliable after PROM as it is with intact membranes.¹⁰⁴ Tables using fetal head circumference rather than biparietal diameter can be consulted as needed. GBS carrier status should be ascertained if available from culture results within 6 weeks or if there has been a positive urine culture in the current pregnancy, and the need for intrapartum prophylaxis should be determined. In the absence of available culture results, a risk factor–based approach should be used for prevention of vertical transmission.¹⁰⁵

If conservative management is planned, the patient should be cared for in a facility that can provide emergent delivery for placental abruption, fetal malpresentation, or fetal distress. The facility should also have neonatal intensive care facilities and offer acute neonatal resuscitation, because conservative management is usually undertaken only if there is a significant risk

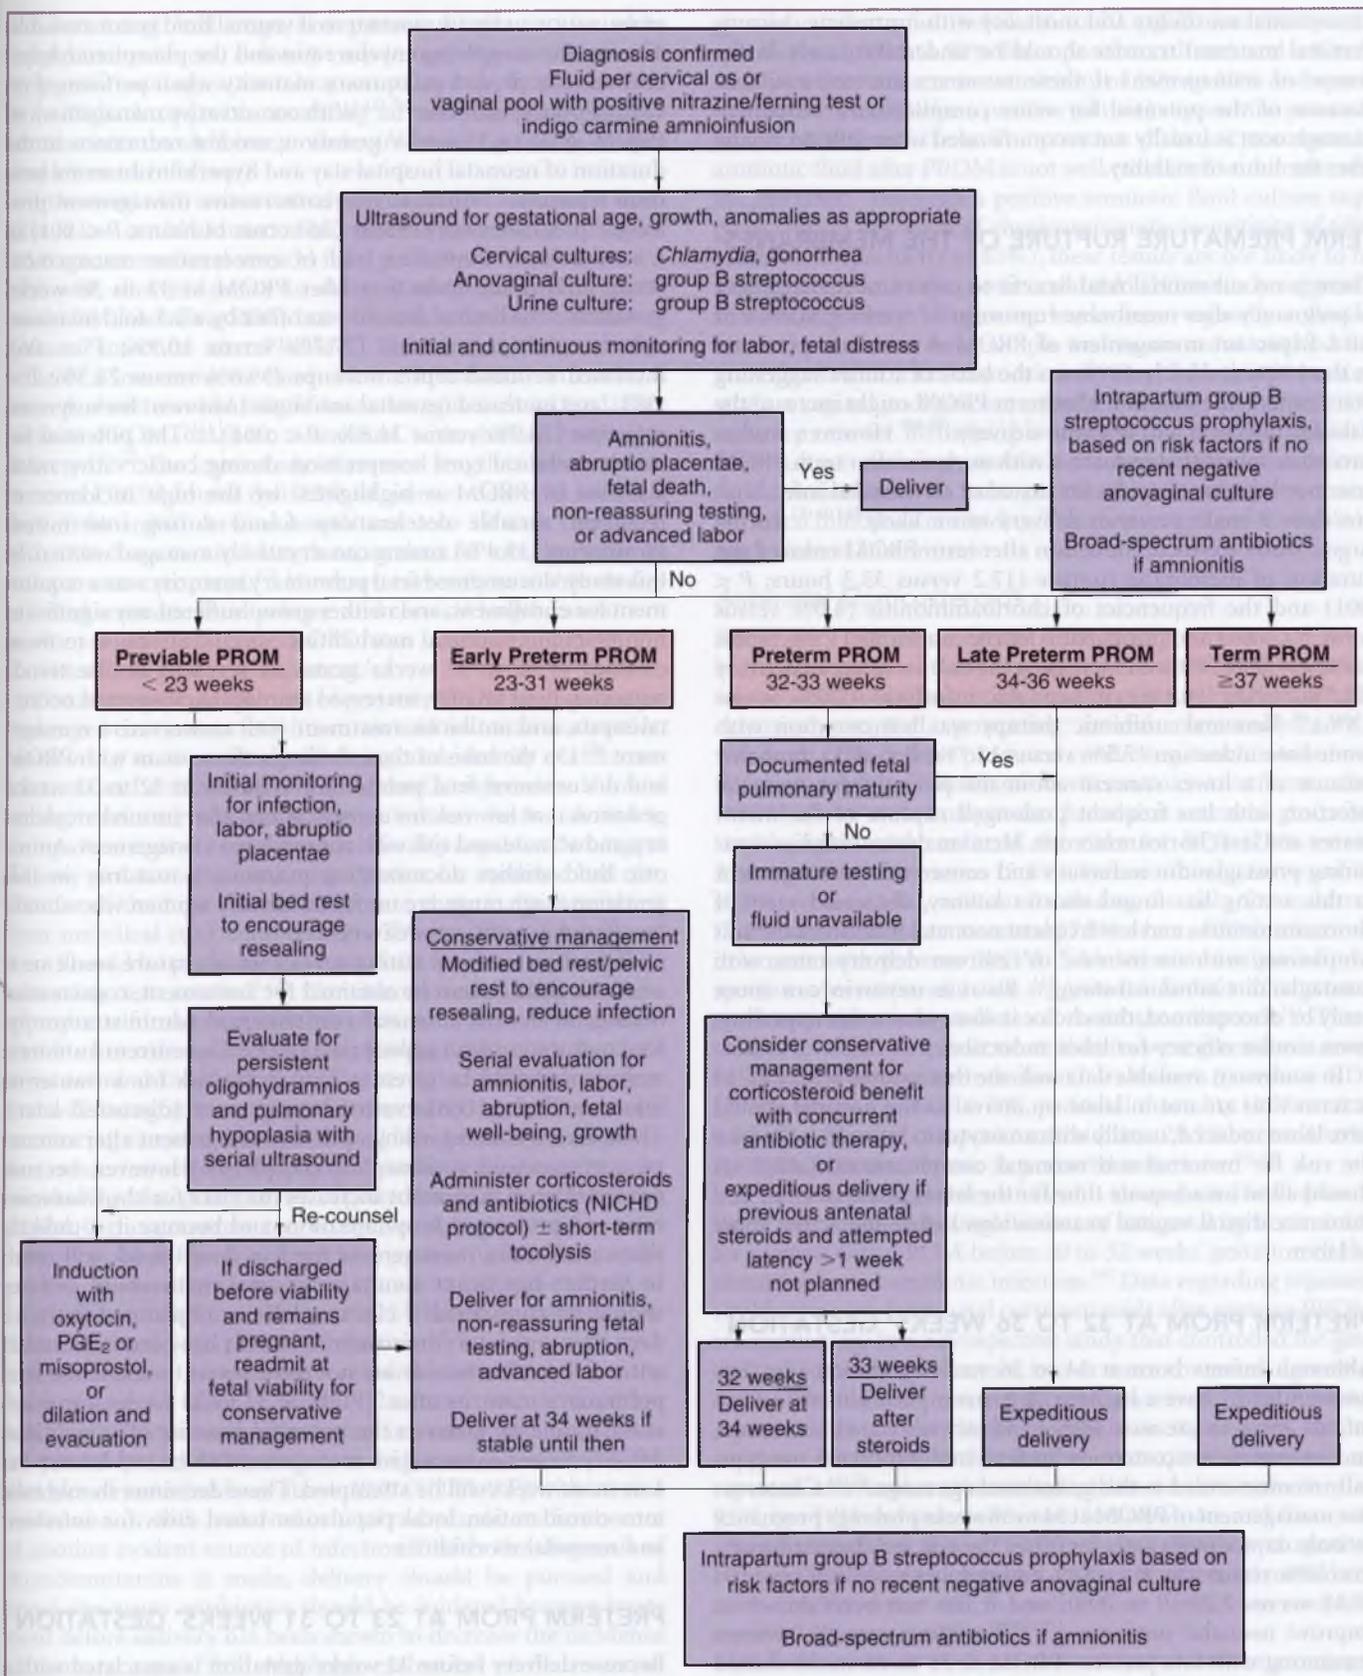

Figure 42-2 Algorithm for management of premature rupture of the membranes (PROM). The algorithm includes several alternatives for the approach to term and preterm PROM. NICHD, National Institute of Child Health and Human Development; PGE₂, prostaglandin E₂. (Adapted from Mercer BM: Preterm premature rupture of the membranes, *Obstet Gynecol* 101:178–193, 2003.)

for neonatal morbidity and mortality with immediate delivery. Prenatal maternal transfer should be undertaken early in the course of management if these resources are not available. Because of the potential for acute complications, outpatient management is usually not recommended when PROM occurs after the limit of viability.

TERM PREMATURE RUPTURE OF THE MEMBRANES

There is no substantial fetal benefit to expectant management of pregnancy after membrane rupture at 37 weeks' gestation or later. Expectant management of PROM at term was practiced in the 1980s and early 1990s on the basis of studies suggesting that immediate induction after term PROM might increase the risks for infection and cesarean delivery.¹⁰⁶⁻¹⁰⁹ However, studies have since found that induction with oxytocin after term PROM does not increase the risks for maternal or neonatal infections, nor does it make cesarean delivery more likely.^{48,110-112} In the largest study, oxytocin induction after term PROM reduced the duration of membrane rupture (17.2 versus 33.3 hours; $P < .001$) and the frequencies of chorioamnionitis (4.0% versus 8.6%; $P < .001$) and postpartum febrile morbidity (1.9% versus 3.6%; $P = .008$), without increasing the risk for cesarean delivery (13.7% versus 14.1%) or neonatal infections (2.0% versus 2.8%).⁴⁸ Neonatal antibiotic therapy was less common with immediate induction (7.5% versus 13.7%; $P < .001$), probably because of a lower concern about the potential for neonatal infection with less frequent prolonged rupture of the membranes and less chorioamnionitis. Meta-analysis of studies comparing prostaglandin induction and conservative management in this setting has found shorter latency, decreased rates of chorioamnionitis, and less frequent neonatal intensive care unit admissions, with no increase in cesarean delivery rates, with prostaglandin administration.¹¹³ Because oxytocin can more easily be discontinued, this choice is somewhat more appealing, given similar efficacy for labor induction.

In summary, available data indicate that women with PROM at term who are not in labor on arrival at the hospital should have labor induced, usually with an oxytocin infusion, to reduce the risk for maternal and neonatal complications. Caregivers should allow an adequate time for the latent phase of labor and minimize digital vaginal examinations before the active phase of labor.

PRETERM PROM AT 32 TO 36 WEEKS' GESTATION

Although infants born at 34 to 36 weeks' gestation (i.e., late preterm birth) have a higher risk for complications than term infants, severe acute morbidities and mortality are uncommon, and antenatal corticosteroids for fetal maturation are not typically recommended in this gestational age range.^{65,114} Conservative management of PROM at 34 to 36 weeks prolongs pregnancy by only days, significantly increases the risk for chorioamnionitis (16% versus 2%; $P = .001$), and reduces umbilical cord pH (7.35 versus 7.25; $P = .009$), and it has not been shown to improve neonatal outcomes.^{115,116} For these reasons, women presenting with late preterm PROM at 34 to 36 weeks should be actively delivered.

With delivery at 32 to 33 weeks' gestation, neonatal morbidities such as RDS can occur, but the likelihood of survival is high, and chronic morbidities are uncommon. Amniotic fluid can be collected from the vaginal pool at the initial sterile speculum

examination or by amniocentesis if vaginal fluid is not available. The lecithin-to-sphingomyelin ratio and the phosphatidylglycerol test can predict pulmonary maturity when performed on vaginal pool specimens.¹¹⁷⁻¹²¹ With conservative management of PROM at 32 to 33 weeks' gestation, modest reductions in the duration of neonatal hospital stay and hyperbilirubinemia have been reported.¹¹⁶ Alternatively, conservative management prolonged pregnancy only briefly (36 versus 14 hours; $P < .001$) in a randomized, controlled trial of conservative management versus immediate induction after PROM at 32 to 36 weeks' gestation. This limited benefit was offset by a 2.5-fold increased risk for chorioamnionitis (27.7% versus 10.9%; $P = .06$), increased neonatal sepsis workups (59.6% versus 28.3%; $P = .003$), and increased neonatal antibiotic treatment for suspected infection (78.7% versus 34.8%; $P < .001$).¹²² The potential for occult umbilical cord compression during conservative management of PROM is highlighted by the high incidence of recurrent variable decelerations found during intermittent monitoring (19.4%) among conservatively managed women. In this study, documented fetal pulmonary maturity was a requirement for enrollment, and neither group suffered any significant noninfectious neonatal morbidities. Specific attention to those enrolled at 32 to 33 weeks' gestation revealed similar trends regarding brief latency, increased amnionitis, suspected neonatal sepsis, and antibiotic treatment with conservative management.¹²³ On the basis of these findings, the woman with PROM and documented fetal pulmonary maturity at 32 to 33 weeks' gestation is at low risk for complications after immediate delivery, and at increased risk with conservative management. Amniotic fluid studies documenting pulmonary maturity in this gestational age range are useful to identify women who should be offered expeditious delivery.

If fetal pulmonary testing reveals an immature result or if amniotic fluid cannot be obtained for assessment, conservative management with antenatal corticosteroid administration for fetal maturation is an appropriate choice. Concurrent antibiotic treatment should be given to reduce the risk for intrauterine infection during conservative management (discussed later). There are no data regarding optimal management after antenatal corticosteroid treatment is completed. However, because conservative management increases the risks for chorioamnionitis and prolonged hospitalization, and because it is unlikely that conservative management for less than 1 week will result in further significant spontaneous fetal maturation, delivery should be considered if elective delivery is planned within 7 days after antenatal corticosteroid benefit has been achieved. If antenatal corticosteroids are not to be given to accelerate fetal pulmonary maturity after PROM at 32 to 33 weeks, consideration should be given to the potential benefits of expeditious delivery unless conservative management to extend latency for 1 or more weeks will be attempted. These decisions should take into consideration local population-based risks for infection and neonatal morbidities.

PRETERM PROM AT 23 TO 31 WEEKS' GESTATION

Because delivery before 32 weeks' gestation is associated with a high risk for perinatal death, severe neonatal morbidities, and long-term sequelae, women with PROM between 23 and 31 weeks' gestation should usually be managed expectantly to prolong pregnancy unless there is evidence of intrauterine infection, suspected placental abruption, advanced labor, or a

non-reassuring fetal heart rate pattern. Under certain additional circumstances, delivery may be appropriate despite an early gestational age at membrane rupture (e.g., fetal transverse lie [with back up] with coexisting advanced cervical dilation, human immunodeficiency virus infection, primary herpes simplex virus infection).

In women with conservatively managed PROM remote from term, a low initial amniotic fluid volume (amniotic fluid index < 5.0 cm, or maximal vertical fluid pocket < 2.0 cm) is associated with shorter latency to delivery and increased neonatal morbidity (including RDS) but not with increased maternal or neonatal infection after PROM.¹²⁴ Despite this, the predictive value of a low amniotic fluid volume for adverse outcomes is poor. A short cervical length on endovaginal ultrasound after preterm PROM has been associated with shorter latency to delivery.¹²⁵⁻¹²⁷ The latest study of cervical length in women with preterm PROM found that 83% of women delivered within 7 days if the initial cervical length was 1 to 10 mm, compared with 18% for a cervical length more than 30 mm, but only 41 women were compared.¹²⁵ However, currently available studies of initial amniotic fluid volume and cervical length assessment in women with preterm PROM have insufficient power and consistency to guide management.

Conservative management of preterm PROM includes initial prolonged continuous fetal heart rate and maternal contraction monitoring to assess fetal well-being and identify occult contractions and evidence of umbilical cord compression. If initial testing results are reassuring, the patient can be transferred to an inpatient unit or transferred to a facility capable of emergent delivery and acute neonatal resuscitation for modified bed rest. Because of the high risk for heart rate abnormalities resulting from umbilical cord compression (32% to 76%), fetal assessment should be performed at least daily for those with initially reassuring test results.^{61,128} Continuous monitoring may be appropriate for women with intermittent fetal heart rate decelerations but otherwise reassuring findings. Although the nonstress test and biophysical profile have the ability to confirm fetal well-being in the setting of preterm PROM, fetal heart rate monitoring can identify variable and late decelerations in addition to uterine activity. Biophysical profile testing may be confounded by the presence of oligohydramnios, but it can be helpful if the nonstress test is equivocal, particularly remote from term when the fetal heart rate pattern is less likely to be reactive. A nonreactive result for a nonstress test and a biophysical profile score of 6 or less within 24 hours of delivery have been associated with perinatal infection.^{129,130}

Conservative management requires surveillance for the development of labor, abruptio placentae, and intrauterine infection. Chorioamnionitis confers increased risks for perinatal mortality and IVH, and it is diagnosed clinically by the presence of maternal fever above 38.0°C (100.4°F) with uterine tenderness, or with maternal or fetal tachycardia in the absence of another evident source of infection.⁶¹ After the diagnosis of chorioamnionitis is made, delivery should be pursued and broad-spectrum antibiotics should be initiated because treatment before delivery has been shown to decrease the incidence of neonatal sepsis.¹³¹⁻¹³³ Although evaluation of the maternal white blood cell count can be helpful if clinical findings are equivocal, the counts can be artificially elevated within 5 to 7 days of antenatal corticosteroid administration. If the diagnosis of chorioamnionitis is suspected but additional confirmation is needed, amniocentesis may yield helpful results.^{11,134,135} A

glucose concentration below 16 to 20 mg/dL (sensitivity and specificity of 80% to 90% for a positive culture) and a Gram stain positive for bacteria (sensitivity of 36% to 80% and specificity of 80% to 97% for a positive culture) support the presence of intrauterine infection. The presence of leukocytes alone in amniotic fluid after PROM is not well correlated with intrauterine infection. Although a positive amniotic fluid culture supports clinical suspicion of chorioamnionitis (sensitivity of 65% to 85% and specificity of 85%), these results are not likely to be available before the diagnosis is clarified.¹³ One study suggested that determination of glucose levels from vaginally collected amniotic fluid may be a simple and noninvasive method for identification of intra-amniotic infection.¹³⁶ In this promising study, a vaginal pool glucose value below 5 mg/dL had a 74.2% accuracy rate for identifying women with a positive amniotic fluid culture. Although research has found elevated amniotic fluid interleukin levels to be associated with early delivery and perinatal infectious morbidity,¹³⁴ such testing is not available in most clinical laboratories.

Antenatal Corticosteroids

Respiratory distress syndrome is the most common acute morbidity after conservatively managed preterm PROM.¹³⁷ Antenatal corticosteroid administration after preterm PROM has been extensively studied, generating several meta-analyses.¹³⁸⁻¹⁴⁰ Although early reviews produced conflicting conclusions about the usefulness of antenatal corticosteroid treatment after PROM, a later meta-analysis concluded that antenatal glucocorticoids significantly reduced the risks for RDS (20% versus 35.4%), IVH (7.5% versus 15.9%), and necrotizing enterocolitis (0.8% versus 4.6%), without increasing the risks for maternal (9.2% versus 5.1%) or neonatal (7.0% versus 6.6%) infections in women with preterm PROM.¹⁴⁰ Multivariate analysis of prospective observational trials suggested a benefit of antenatal corticosteroid use regardless of membrane rupture.¹⁴¹ Three studies in which prophylactic antibiotics were given concurrent to antenatal corticosteroids found treatment to reduce RDS (18.4% versus 43.6%; $P = .03$), perinatal mortality (1.3% versus 8.3%; $P = .05$), and composite morbidities (29.3% versus 48.6%; $P < .05$), with no increase in perinatal infections.¹⁴²⁻¹⁴⁴

The National Institutes of Health Consensus Development Panel recommended a single course of antenatal corticosteroids for women with PROM before 30 to 32 weeks' gestation in the absence of intra-amniotic infection.¹⁴⁵ Data regarding repeated weekly courses of antenatal corticosteroids after preterm PROM are conflicting. In a retrospective study that controlled for gestational age and other factors, two or more courses of antenatal corticosteroids were associated with increased early neonatal sepsis (15.3% versus 2% for a single course, or 1.5% for no courses; $P < .001$).¹⁴⁶ In another retrospective analysis of repeated antenatal corticosteroids, there was no reduction in RDS, but IVH and amnionitis were less common, and there was a trend toward less sepsis.¹⁴⁷ RDS was less common in another retrospective review of repeated courses of antenatal corticosteroids (34.9% versus 45.2%) without an increase in neonatal sepsis (9.9% versus 6.2%).¹⁴⁸

Based on current evidence that antenatal corticosteroids are effective for induction of fetal pulmonary maturity without increasing the risk for infection, and that most women will remain pregnant for the 24 to 48 hours needed to achieve corticosteroid benefit after PROM, a single course of antenatal corticosteroids should be considered when PROM occurs before

32 weeks' gestation and for women with documented pulmonary immaturity at 32 to 33 weeks' gestation. Betamethasone (two doses of 12 mg IM, given 24 hours apart) or dexamethasone (four doses of 6 mg IM, given 12 hours apart) is considered appropriate. Repeated weekly antenatal corticosteroids are not recommended after preterm PROM. The benefits and risks of a single rescue course remote from the initial corticosteroid administration remain to be determined.

Adjunctive Antibiotics

Antibiotic therapy is given during conservative management of preterm PROM to treat or prevent ascending decidual infection to prolong pregnancy and to reduce gestational age-dependent morbidity while limiting the risk for neonatal infection. More than two dozen randomized clinical trials have been summarized in several meta-analyses.^{50,149,150} In the latest one, antibiotic treatment after preterm PROM significantly reduced chorioamnionitis (RR = 0.57); reduced delivery within 48 hours (RR = 0.71) and within 7 days (RR = 0.80); and reduced infant morbidities, including neonatal infection (RR = 0.68) and major cerebral abnormalities on ultrasound before discharge (RR = 0.82) compared with placebo therapy.¹⁵¹ The need for surfactant administration (RR = 0.83) and oxygen therapy (RR = 0.88) was also reduced. Antibiotics did not influence the risk for necrotizing enterocolitis (RR = 1.14; CI, 0.66 to 1.97). Oral amoxicillin-clavulanic acid treatment was associated with increased necrotizing enterocolitis (RR = 4.60; 95% CI, 1.98 to 10.72) in this analysis, but oral erythromycin therapy was not (RR = 1.00; CI, 0.56 to 1.80).¹⁵⁰ The study that dominated this meta-analysis included women with PROM up to 36 weeks' gestation and included a population at low risk for necrotizing enterocolitis overall (i.e., 0.5% among controls), and it was the only one of 10 studies that found a significant increase in necrotizing enterocolitis with antibiotic therapy.¹⁵² The meta-analysis found treatment with "all penicillins" (excluding amoxicillin-clavulanic acid) versus placebo to be associated with fewer births within 48 hours and 7 days of PROM, less overall maternal infection and chorioamnionitis, less neonatal infection, fewer positive neonatal blood cultures, and fewer major intracranial cerebral ultrasound abnormalities. Because of the increased risk for neonatal necrotizing enterocolitis with amoxicillin-clavulanate, the study authors recommended erythromycin as a better choice, even though benefits were limited to reduction in delivery at 48 hours, fewer positive neonatal blood cultures, and a reduced need for oxygen therapy.

In a clinical trial with adequate power to evaluate antibiotic therapy during conservative management of women with preterm PROM before 32 weeks' gestation, the National Institute of Child Health and Human Development Maternal-Fetal Medicine Units (NICHD-MFMU) Research Network assigned women with PROM to initial aggressive intravenous therapy for 48 hours (2 g of ampicillin intravenously [IV] every 6 hours, and 250 mg of erythromycin IV every 6 hours) followed by oral therapy for 5 days (250 mg of amoxicillin by mouth [PO] every 8 hours and 333 mg of enteric-coated erythromycin base PO every 8 hours) to provide limited-duration, broad-spectrum antimicrobial coverage before delivery.^{137,152} GBS screening was performed. GBS carriers were treated with ampicillin for 1 week and again in labor, and they were analyzed separately. Antibiotic treatment increased the likelihood of continued pregnancy after 7 days of treatment by twofold. Benefit persisted for 3 weeks after randomization despite

discontinuation of antibiotics at 7 days. Babies born to women treated with ampicillin plus erythromycin had a reduced incidence of one or more major infant morbidities (53% versus 44% rate of composite morbidity, including death, RDS, early sepsis, severe IVH, and severe necrotizing enterocolitis; $P < .05$). Antibiotic therapy also significantly reduced individual gestational age-dependent morbidities, including RDS (40.5% versus 48.7%), patent ductus arteriosus (11.7% versus 20.2%), chronic lung disease (bronchopulmonary dysplasia: 20.5% versus 13.0%), and stage 3 or 4 necrotizing enterocolitis (2.3% versus 5.8%), with P values of .05 or less for each. Chorioamnionitis was reduced with the study's antibiotics (23% versus 32.5%; $P = .01$), and neonatal sepsis (8.4% versus 15.6%; $P = .009$) and pneumonia (2.9% versus 7.0%; $P = .04$) were reduced for those who were not GBS carriers. The antibiotic study group had less neonatal GBS sepsis (0% versus 1.5%; $P = .03$). Two other studies have attempted to determine whether antibiotic therapy of shorter duration could provide similar benefit, but the studies lacked size and power to demonstrate equivalent effectiveness.^{153,154}

In summary, broad-spectrum antibiotic (ampicillin/amoxicillin plus erythromycin) therapy for women with preterm PROM before 32 weeks' gestation prolongs pregnancy sufficiently to reduce neonatal gestational age-dependent morbidities and reduce the frequencies of maternal and neonatal infections.¹³⁷ An alternative conclusion from the latest meta-analysis is that penicillins other than amoxicillin-clavulanic acid are an acceptable treatment for preterm PROM and that the benefits of erythromycin are limited to brief pregnancy prolongation, less need for oxygen therapy, and fewer positive neonatal blood cultures.¹⁵⁰ This is not inconsistent with the NICHD-MFMU approach. Up to a 7-day course of parenteral and oral therapy using ampicillin/amoxicillin and erythromycin is recommended for women undergoing conservative management of preterm PROM remote from term. Shortages in intravenous and oral antibiotics have led to the need for alternative antibiotic choices. Oral ampicillin, erythromycin, and azithromycin are probably appropriate alternatives if needed.

Adjunctive antibiotic administration to prolong latency must be distinguished from intrapartum prophylaxis to prevent vertical transmission of GBS from mother to baby.¹⁰⁵ Known GBS carriers and those who deliver before carrier status can be determined should receive intrapartum prophylaxis to prevent vertical transmission, regardless of prior antibiotic treatments. Women with a diagnosis of chorioamnionitis should receive broad-spectrum intrapartum antibiotic therapy.

Tocolysis

Evidence from prospective studies of tocolysis after PROM is similar to that from studies of tocolysis for preterm labor with intact membranes.¹⁵⁵⁻¹⁶⁰ After preterm PROM, prophylactic tocolysis with β -agonists before the onset of contractions can prolong pregnancy briefly. Therapeutic tocolysis administered only after contractions occur has not been shown to be effective in prolonging latency. In a retrospective comparison of aggressive tocolysis with limited treatment for contractions only during the first 48 hours, aggressive therapy was not associated with longer latency (3.8 versus 4.5 days; $P = .16$).¹⁶⁰ A report from the Collaborative Study on Antenatal Steroid Therapy suggested that tocolytic use after PROM was associated with subsequent neonatal RDS, but the biologic mechanism for this association is unclear.¹⁶¹

Overall, the available prospective studies have not found tocolytic treatment after PROM to increase or prevent neonatal morbidities after PROM. Tocolytic therapy has not been studied when antenatal corticosteroids and antibiotics were administered concurrently, and it remains plausible that prophylactic tocolysis could delay delivery long enough to allow antibiotic suppression of subclinical decidual infection and for corticosteroid effects on the fetus. Pending further study in this area, tocolytic therapy should not be considered an expected practice after preterm PROM, but it may be appropriate in pregnancies at high risk for neonatal complications with early preterm birth.

Cervical Cerclage

Preterm PROM complicates about one fourth of pregnancies with a cervical cerclage and one half of pregnancies requiring an emergent cerclage.^{37,162,163} Because no prospective studies have been performed regarding management of preterm PROM with a cerclage in situ, recommendations reflect the data available from retrospective cohorts. The risk for adverse perinatal outcomes does not appear to be different when PROM occurs with a cerclage or without one, provided the cerclage is removed on admission after PROM.^{164,165}

Several small studies comparing pregnancies of preterm PROM in which the cerclage was retained or removed have yielded consistent patterns.¹⁶⁶⁻¹⁷⁰ No study has found cerclage retention after PROM to reduce the frequency or severity of infant morbidities after preterm PROM, and each has demonstrated statistically insignificant trends toward increased maternal infectious morbidity with only brief pregnancy prolongation. One study found increased infant mortality and mortality resulting from sepsis with cerclage retention after PROM.¹⁶⁶ One study that compared different practices at two institutions found longer latencies with cerclage retention, but this finding could reflect population or practice differences at these institutions rather than the effect of cerclage retention.¹⁶⁷

Because cerclage retention after PROM has not been shown to improve perinatal outcomes and there are potential risks related to leaving the cerclage in situ, removal is recommended when PROM occurs, particularly if the indication for initial cerclage placement was not strong. Although deferred removal might enhance pregnancy prolongation for corticosteroid administration, the risks and benefits of this approach have not been determined.

Maternal Herpes Simplex Virus Infection

Neonatal herpes simplex infection most commonly results from direct maternal-fetal transmission at delivery, but hematogenous transmission can occur to the fetus in utero in some cases. Neonatal infection rates after primary and secondary maternal infections occur in 34% to 80% and in 1% to 5% of cases, respectively,^{169,170} and infection can result in mortality rates of 50% to 60% and serious sequelae in up to 50% of survivors.^{171,172}

Based on two case series including a total of 35 women with an active maternal genital herpesvirus infection, it has been generally accepted that increasing latency after membrane rupture of more than 4 to 6 hours increases risk for neonatal infection, and that cesarean delivery should be performed expeditiously to prevent fetal infection in this setting.¹⁷³⁻¹⁷⁵ However, a case series of women with conservatively managed PROM before 32 weeks' gestation coincident to active recurrent herpes simplex virus lesions suggests that conservative management may be considered.¹⁷⁶ Antenatal corticosteroids and antibiotics

were not administered, and antiviral therapy was inconsistent in this series. Cesarean delivery was performed for women with active lesions at the time of delivery. After latencies ranging from 1 to 35 days, none of the 26 infants developed neonatal herpes infection (CI, 0% to 10.4%).

Based on these data, conservative management of PROM complicated by recurrent maternal herpes simplex virus infection may be appropriate if membrane rupture occurs remote from term and the potential for mortality or serious sequelae with delivery is considered to be high. Antiviral therapy (e.g., acyclovir) during conservative management can reduce viral shedding and the frequency of recurrence.

PRE-VIABLE PROM BEFORE 23 WEEKS' GESTATION

Although the cause is often not apparent, clinical antecedents can be helpful in determining the likely outcomes in some cases of pre-viable PROM. Membrane rupture after amniocentesis is associated with cessation of leakage and subsequent successful pregnancy outcomes in most cases. Alternatively, pre-viable PROM in a pregnancy complicated by persistent second-trimester bleeding, oligohydramnios, or an elevated level of maternal serum α -fetoprotein more likely reflects an abnormality of placentation, which carries a poor prognosis.

The patient with pre-viable PROM and no other indication for immediate delivery should be counseled about the risks and benefits of expectant management, including a realistic appraisal of potential fetal and neonatal outcomes according to the available information for gestational age-appropriate outcomes.^{65,66,177} In addition to the maternal risks of conservative management previously delineated, muscle wasting, bone demineralization, and deep venous thrombosis can also occur with prolonged bed rest, and there are significant financial and social implications of prolonged hospitalization.

For women who decide that the risks of conservative management exceed the potential benefits, delivery can usually be accomplished with vaginal prostaglandin E₂, oral or vaginal prostaglandin E₁ (i.e., misoprostol), with a high-dosage oxytocin infusion, or by dilation and evacuation. The optimal approach depends on the patient's characteristics (e.g., gestational age, evident amnionitis, prior cesarean delivery) and preference, available facilities, and the physician's experience with these techniques.

Data to guide the management for women who choose conservative management of pre-viable PROM are lacking. There is no consensus about the advantages of inpatient versus outpatient management. Initial inpatient evaluation may include strict bed and pelvic rest to enhance the opportunity for resealing and for early identification of infection and placental abruption. Women who are discharged should be advised to abstain from intercourse and limit physical activity. They should return immediately in case of fever, abdominal pains, suspect vaginal discharge, or any vaginal bleeding. Hospitalization for the duration of amniotic fluid leakage may be appropriate in some circumstances. Discharged patients are typically readmitted to the hospital after the limit of viability has been reached to allow early intervention for infection, placental abruption, labor, and non-reassuring fetal heart rate patterns. Administration of antenatal corticosteroids for fetal maturation at this time is appropriate.

After an initial ultrasound assessment, repeated evaluation can be performed every 1 to 2 weeks to determine whether there is reaccumulation of amniotic fluid and to evaluate lung growth. Persistent, severe oligohydramnios after PROM before 20 weeks

is the strongest predictor of subsequent lethal pulmonary hypoplasia. Serial fetal biometric evaluation (e.g., lung length, chest circumference), ratios to adjust for overall fetal size (thoracic to abdominal circumference, thoracic circumference to femur length), and Doppler studies of fetal pulmonary artery and ductus arteriosus waveform modulation with fetal breathing movements can demonstrate whether fetal pulmonary growth has occurred over time. These results have a high predictive value for neonatal mortality resulting from pulmonary hypoplasia.^{82,90,178-183} If pulmonary hypoplasia becomes evident before the limit of viability, or if there is persistent, severe oligohydramnios, the patient may choose to reconsider her decision regarding ongoing expectant management.

Treatments to seal the membrane defect or restore normal amniotic fluid volume include transabdominal amnioinfusion and membrane sealing with fibrin, platelet, cryoprecipitate, or gel-foam plugs. The maternal risks and fetal benefits of these interventions have not been adequately evaluated, and there are inadequate data to recommend that any of these approaches be incorporated into routine clinical practice.¹⁸⁴

Summary

When term or preterm PROM occurs, there is the potential for significant perinatal morbidity and mortality, which can be reduced by considered and timely obstetric interventions. Expedient delivery of the patient with term and late preterm PROM can reduce the risk for perinatal infections without increasing the likelihood of operative delivery. Conservative management of PROM remote from term can reduce infectious and gestational age-dependent morbidities. Regardless of management approach, infants delivered after early preterm or pre-viable PROM are at high risk for perinatal complications, many of which cannot be avoided with current technologies and management algorithms. Attention to early diagnosis and management of complications that occur after PROM can lead to good perinatal outcomes in many cases.

Clinical Aspects of Normal and Abnormal Labor

JOHN M. THORP, Jr., MD | S. KATHERINE LAUGHON, MD, MS

Normal Labor and Its Limits

The proper management of labor and delivery depends on a thorough understanding of the biology of normal labor. Given the inherent limitations in our knowledge of human labor, the astute clinician must take care to not draw firm conclusions and be willing to change his or her practice as new evidence and insights arise. Moreover, effective recognition and management of labor abnormalities require knowledge of the limits of labor and of the physiologic response of both the mother and the fetus to the stresses of labor and delivery.

Uterine contractions occur throughout normal pregnancy. These contractions are irregular in timing and intensity, discoordinate in distribution, and, for the most part, entirely painless. Such uterine activity continues in normal pregnancy until late in the third trimester, when the contractions become more frequent, of greater and more consistent intensity, and more coordinated. Also, during the latter part of the third trimester, effacement (shortening) and dilation of the cervix begin. At the end of this largely painless phase, clinical labor begins, defined as the onset of painful uterine contractions associated with effacement and dilation of the cervix.

The precise onset of this combination of events frequently cannot be ascertained, and for practical purposes clinicians must rely on the patient's best estimate of when her labor contractions began or when they became regular in consistency and intensity. The specific onset of cervical effacement and dilation can rarely be documented in cases of spontaneous onset of labor; not uncommonly, both effacement and dilation occur late in the third trimester, before the onset of regular or noticeable uterine contractions. Therefore, the precise onset of labor is difficult to determine, and much of what is written about false labor, prodromal labor, and the latent phase of labor is influenced by this uncertainty.

Hendricks and colleagues,¹ who performed serial cervical examinations of 303 patients in the third trimester, studied these pre-labor changes of the cervix. Cervical dilation began earlier and was of greater magnitude in multiparas than in primiparas. Cervical effacement, on the other hand, began earlier and was of greater magnitude in primiparas. These authors introduced the concept of the "cervical coefficient," which is the product of cervical dilation (in centimeters) and the percentage of effacement. They found that, at any point in pre-labor, the cervical coefficient is relatively the same for all patients regardless of parity. The mean cervical dilation during the last 3 days before the onset of labor is 1.8 cm for nulliparas and 2.2 cm for multiparas. Their study stressed the importance

of the prelabor preparation of the cervix and its influence on the duration of labor. Their findings also demonstrated the difficulty of using a specific time for onset of labor if it is defined as the beginning of cervical dilation.

Categorization of Labor Events

By convention, labor is divided into three stages:

1. *First stage:* from onset of labor to full dilation of the cervix
2. *Second stage:* from full dilation of the cervix to delivery of the infant
3. *Third stage:* from delivery of the infant to delivery of the placenta

Pritchard and MacDonald² described a fourth stage of labor, comprising the hour immediately following delivery of the placenta.

One of the most thorough evaluations of the first stage of labor was that by Friedman,³ which has been conveniently summarized in a monograph. His graphostatistical analysis of labor in term patients^{3,4} depicted the relationship between duration of labor and dilation as a sigmoid curve, reflecting its exponential nature. He divided the first stage of labor into two major phases:

1. *Latent phase:* from the onset of regular uterine contractions to the beginning of the active phase
2. *Active phase:* from the time at which the rate of cervical dilation begins to change rapidly (at about 3 to 4 cm of dilation in the 1950s) to full dilation

Data from several thousand patients, in whom cervical dilation and the station of the presenting fetal part were documented throughout labor, were used to establish normal limits of labor for nulliparous and multiparous patients. A group of nulliparas and a group of multiparas were selected who had no apparent complications of labor and who delivered normal infants. From these cases, the norms for "ideal" labor were determined (Table 43-1). Descent of the fetal head in relationship to the ischial spines was found to begin well before the second stage. The rate of descent increased late in the first stage and continued linearly into the second stage of labor until the perineal floor was reached. Data for the maximum rate of descent and the length of the second stage of labor in all patients are also given in Table 43-1.

Friedman^{3,5} formulated a series of definitions that have been incorporated into routine obstetric care. For example, he defined no cervical dilation for 2 hours as an arrest of the active phase of labor and a rate of dilation in the active phase of less than 1.2 cm/hr in nulliparous women or less than 1.5 cm/hr in

TABLE 43-1 Characteristics of Labor in Nulliparas and Multiparas*

Characteristic	Nulliparas		Multiparas	
	All Patients	Ideal Labor	All Patients	Ideal Labor
Duration of first stage (hr)				
Latent phase	6.4 ± 5.1	6.10 ± 4.0	4.80 ± 4.9	4.50 ± 4.2
Active phase	4.6 ± 3.6	3.40 ± 1.5	2.40 ± 2.2	2.10 ± 2.0
TOTAL	11.0 ± 8.7	9.50 ± 5.5	7.20 ± 7.1	6.60 ± 6.2
Maximum rate of descent (cm/hr)	3.3 ± 2.3	3.60 ± 1.9	6.60 ± 4.0	7.00 ± 3.2
Duration of second stage (hr)	1.1 ± 0.8	0.76 ± 0.5	0.39 ± 0.3	0.32 ± 0.3

Data from Friedman EA: Labor: clinical evaluation and management, ed 2, New York, 1978, Appleton-Century-Crofts.

multiparous women as a protracted active phase. His work has helped generations of obstetricians conceptualize progress in labor and has provided a standardized model for intervention. Moreover, he demonstrated that labor is an exponential process with a slow rate of dilation at the outset, followed by a rapid rise in rate.

Are Friedman's labor curve and definitions applicable to populations a half-century later? Numerous studies done in the last decade indicate that the pattern of labor progression is different from what was observed in the 1950s⁶⁻¹⁰ and that the clinical cutoff points for intervention and the duration of those interventions derived from Friedman's work are no longer clinically useful.^{11,12} Zhang, Troendle, and Yancey,¹³ in a landmark paper using a statistical approach based on likelihood, demonstrated how different contemporary labor progression is from that described in earlier years. Differences include the following: (1) a gradual rather than an abrupt transition from latent to active-phase labor; (2) a length of active labor of 5.5 hours, rather than the 2.5 hours described by Friedman; (3) no deceleration phase; (4) the common occurrence of at least 2 hours elapsing in the active phase without cervical dilation; and (5) the 5th percentile for rate of dilation being less than 1 cm/hr.

The findings of Zhang's group¹³ appear in Table 43-2 and Figure 43-1. The figure allows comparison of Friedman's labor curves with those generated from contemporary practice. Rouse and colleagues^{12,14} incorporated this finding of slower rates of progression in modern labor into a demonstration that extending the minimum period of oxytocin augmentation for active-phase labor arrest, from 2 to at least 4 hours, was both effective and safe. The curves from both eras are plots of dilation against time and mimic an exponential mathematical equation. Like a compound interest curve, they begin slowly and rise more quickly as time elapses. The exponential nature of this biologic function can exasperate the patience of the laboring woman, her family, and caregivers. It lends biologic support to the age-old adage, "Patience is the virtue of the obstetrician."

Zhang and colleagues,¹⁵ using data from the National Collaborative Perinatal Project, extended their repeated-measured analysis techniques to women who spontaneously labored. In these 26,838 parturients, the abdominal delivery rate was 2.6% and the induction rate was 7.1%. Despite the fact that this cohort was assembled more than 50 years ago, the low rate of obstetric intervention makes it an ideal cohort in which to study the natural history of the first stage of labor with minimal obstetric intervention that would alter the normal progression.

TABLE 43-2 Expected Time Interval and Rate of Change at Each Stage of Cervical Dilation in Nulliparas*

Cervical Dilation (cm)	Time Interval (hr)	Rate of Cervical Dilation (cm/hr)
From 2 to 3	3.2 (0.6, 15.0)	0.3 (0.1, 1.8)
From 3 to 4	2.7 (0.6, 10.1)	0.4 (0.1, 1.8)
From 4 to 5	1.7 (0.4, 6.6)	0.6 (0.2, 2.8)
From 5 to 6	0.8 (0.2, 3.1)	1.2 (0.3, 5.0)
From 6 to 7	0.6 (0.2, 2.2)	1.7 (0.5, 6.3)
From 7 to 8	0.5 (0.1, 1.5)	2.2 (0.7, 7.1)
From 8 to 9	0.4 (0.1, 1.3)	2.4 (0.8, 7.7)
From 9 to 10	0.4 (0.1, 1.4)	2.4 (0.7, 8.3)

Data from Zhang J, Troendle J, Yancey MK: Reassessing the labor curve in nulliparous women, *Am J Obstet Gynecol* 187:824, 2002.

Figure 43-1 Changing patterns of cervical dilation in labor curves during the past half-century. The graph compares Friedman's labor curves with the modern-day pattern of cervical dilation over the course of labor. (Data from Zhang J, Troendle J, Yancey MK: Reassessing the labor curve in nulliparous women, *Am J Obstet Gynecol* 187:824, 2002.)

Among numerous, important findings, they discovered that the inflection points on the aggregate labor curves that are indicative of the onset of the active phase occurred later than the timepoint of 3 to 4 cm cervical dilation previously described by Friedman. The inflection point was much later and less

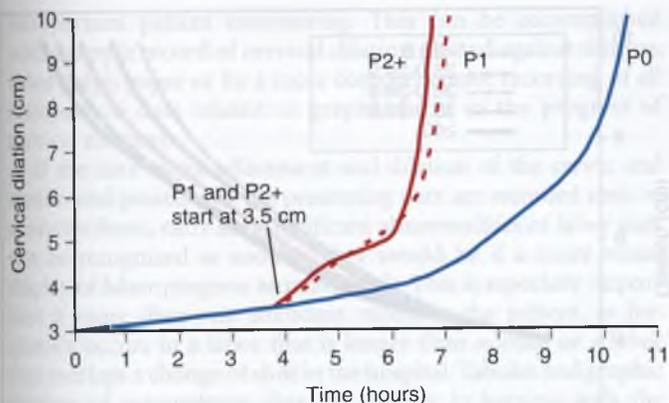

Figure 43-2 Average labor curves by parity. Labor curves are shown for women with singleton term pregnancies, spontaneous onset of labor, and vertex presentation who completed the first stage of labor and whose newborns had 5-minute Apgar scores of at least 7. Data are from The National Collaborative Perinatal Project, 1959-1966. P0, nulliparas; P1, parity 1; P2+, parity 2 or higher. obvious in nulliparous women (Fig. 43-2). Inflection points were at 5 to 5.5 cm in multiparous women, occurring slightly sooner in parity 2+ compared to parity 1.

Tables were constructed from these data that demonstrate median duration of labor in hours by parity and cervical dilation (Tables 43-3 and 43-4). Perusal of these tables shows that a parity 0 woman may require up to 4 hours to progress from 4 to 5 cm dilation. These tables suggest that boundaries for prolonged labor should be adjusted in clinical practice according to cervical dilation. A 2-hour cutoff is probably too short for women dilated less than 6 cm, and a 4-hour limit would be excessive after 6 cm.

Since the 1960s, both maternal characteristics and obstetric practices have changed considerably. Women are older and heavier, and both advancing maternal age and increasing body mass index (BMI) are associated with progressively longer labor.¹⁶⁻¹⁸ Zhang's group¹⁸ examined labor patterns in a more recent cohort of 62,415 low-risk parturients who achieved vaginal delivery in the Consortium on Safe Labor, a multicenter, retrospective, observational study in the United States from 2002 to 2008 (87% of the births occurred in 2005-2007). They found that progression of cervical dilation from 4 to 5 cm can

take longer than 6 hours, and that from 5 to 6 cm more than 3 hours. Another important finding was the "average" duration of labor was not necessarily applicable to an individual parturient; rather, an upper limit (e.g., the 95th percentile) may be more useful in clinical management. Zhang proposed the use of a partogram instead of average labor transition times as a better instrument for defining labor arrest.¹⁸

Characteristics of the Maternal Pelvis

The intelligent management of labor depends on an understanding of its mechanism as well as the norms and limits of its progress. One of the most important and helpful studies for understanding the mechanism of labor is that of Caldwell and associates.¹⁹ This report was the culmination of a study of more than 1000 radiographic examinations of the pelvis and fetal head, performed before, during, or after labor, in relation to the known details of delivery and the facts ascertained by vaginal examination. Many of the findings of this and later studies by the same authors²⁰ were incorporated in a monograph by Steer.²¹ Although a complete review of these important works is beyond the scope of this text, a study of their contributions will substantially increase the reader's understanding of the influence of the pelvic architecture on normal and abnormal labor. Several of the important findings are worth emphasizing in the remainder of this section.

With a gynecoid or android type of pelvis, the fetal head engages in the transverse position 60% to 70% of the time. The anthropoid pelvis predisposes to engagement in the occiput anterior or posterior position. After the fetal head enters the pelvis in the transverse position, it is carried downward and backward until it impinges on the sacrum low in the midpelvis. It is at this point that internal rotation begins.

Internal rotation usually occurs in the midpelvis. Anterior rotation of the fetal head is practically complete when the head makes contact with the lower aspects of the pubic rami.

The common occurrence of engagement and descent predominantly in the posterior pelvis is usually associated with a normal progress of labor and spontaneous delivery; when engagement and descent occur predominantly in the forepelvis, there is a higher incidence of abnormal progress of labor and a

higher rate of operative delivery. If the fetal head is descending in the posterior pelvis, the cervix usually is felt posteriorly in the vagina. If the cervix is palpated in a forward position, closer to the symphysis than to the sacrum, engagement and descent in the forepelvis must be suspected.

The increasing use of the vacuum extractor and the cesarean operation for delivery after second-stage arrest of labor has contributed to the lessening of emphasis on knowledge about pelvic types and their influence on descent and rotation of the fetal head. However, the relationship between pelvic architecture and the position of the fetal head often allows useful prediction or explanation of abnormal labor, especially in the descent phase.

A careful clinical examination frequently discloses the essential dimensions and shape of the pelvis. In general, the characteristics of the anterior segment of the inlet correspond to those of the anterior portion of the lower pelvis:

- A subpubic arch with a well-rounded apex and ample space between the ischial tuberosities is associated with a gynecoid anterior segment at the inlet.
- A subpubic arch with a narrow angle and straight rami, convergent sidewalls, and prominent spines is associated with a narrowed, android anterior segment at the inlet.
- A narrow subpubic arch with straight sidewalls is characteristic of an anthropoid anterior segment at the inlet.
- A wide subpubic arch with straight or divergent sidewalls and a wide interspinous diameter is associated with a flat anterior segment at the inlet.

The posterior segment can best be characterized by palpation of the sacrospinous ligament and the sacrosciatic notch. A narrow notch, associated with a short sacrosciatic ligament (<2 fingerbreadths), suggests an android posterior segment. A sacrosciatic ligament length of 2 to 3 fingerbreadths suggests a gynecoid posterior segment. If the ligament is directed backward and the spines are close together, the posterior segment of the inlet is probably anthropoid. If the ligament is directed laterally and the spines are far apart, the posterior segment of the inlet is likely to be flat.

The pelvic configuration can be assessed at the time of a pelvic examination when the patient is admitted to the labor unit, or it can be determined as part of the initial examination when the patient registers for prenatal care. The advantages of performing the assessment when the patient is hospitalized in labor are the increased relevance of the information at that time and the probability that the individual performing the examination will incorporate the results into a comprehensive assessment of the labor.

Role of Maternal Obesity

As maternal BMI rises in the developed world, there is a linear rise in the diagnosis of dystocia and the need for abdominal delivery.^{22,23} This is particularly pertinent to the American clinician: in the United States in 2008, 33.8% of adults were obese.²⁴ Kominiarek and colleagues, as part of the Consortium on Safe Labor, attempted to study how obesity affects labor progression.²² In 126,657 deliveries, the mean admission BMI was 30.5 kg/m² and more than 7% of the parturients had BMI greater than 40 kg/m². Figures 43-3 and 43-4 demonstrate the progression of dilation of parity 0 versus parity 1+ women. In both groups, labor was longer as obesity increased. The differences between normal-weight women and those with BMI

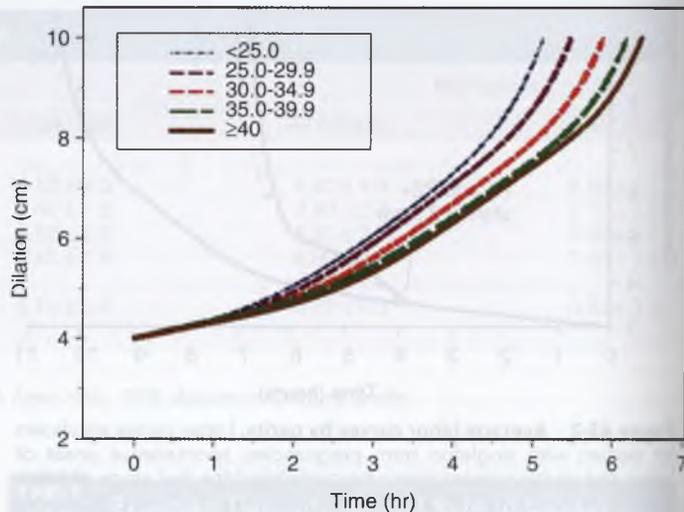

Figure 43-3 Predicted probability of cesarean delivery based on body mass index (BMI) as a continuum stratified by parity and prior cesarean status. (From Kominiarek MA, VanVeldhuisen P, Hibbard J, et al; for the Consortium on Safe Labor: The maternal body mass index: a strong association with delivery route, *Am J Obstet Gynecol* 203;264.e1, 2010.)

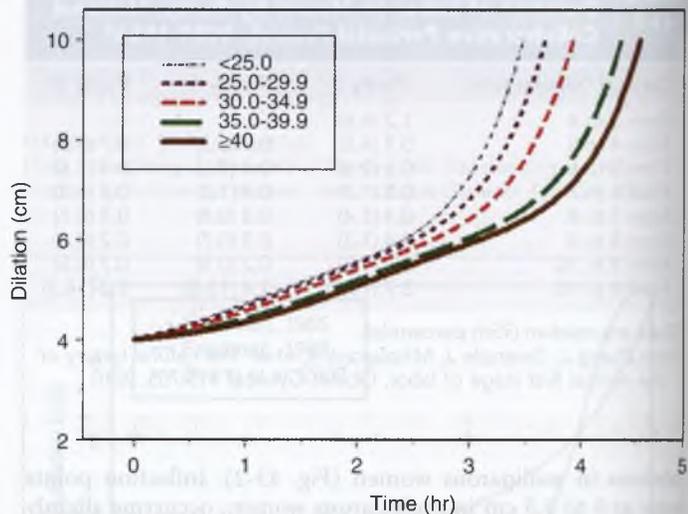

Figure 43-4 Cesarean section rate and pre-pregnancy maternal body mass index (BMI). (From Barau G, Robillard P, Julsey T, et al: Linear association between maternal pre-pregnancy body mass index and risk of cesarean section in term deliveries. *BJOG* 113:1173, 2006.)

greater than 40 kg/m² was more than 2 hours in nulliparous women and 1 hour in multiparous women. It is clear that maternal size has a significant impact on labor progression. Moreover, the risk for cesarean delivery increased by 5% in parity 0 women and by 2% in parity 1+ women for each 1 kg/m² increase in BMI.²²

Documentation of Labor Progression

One of the most important aspects of labor management is accurate and thorough documentation of the progress of labor or the lack thereof. Most authorities agree that a graphic display of intrapartum data that allows prompt visualization of the status and progress of cervical dilation and, in some cases, descent of the presenting part is an essential adjunct to

intrapartum patient monitoring. This can be accomplished with a simple record of cervical dilation plotted against time on ruled graph paper or by a more comprehensive recording of all intrapartum data related in graphic form to the progress of cervical dilation.

If the data about effacement and dilation of the cervix and station and position of the presenting part are recorded only in narrative form, early and significant abnormalities of labor may not be recognized as soon as they would be if a more visual display of labor progress were available. This is especially important if more than one attendant monitors the patient, as frequently occurs in a labor that is longer than normal or a labor that overlaps a change of shift in the hospital. Tabular and graphic displays of intrapartum data are entirely in keeping with the concept that labor and delivery are worthy of intensive surveillance, and they afford a convenient method of reviewing labor events in situations of an untoward fetal or maternal outcome.

The crucial factor in the evidence-based management of labor is the timing of interventions such as amniotomy, stimulation of contractions with oxytocin, operative delivery, or, in much of the world, transfer from home to a unit for those interventions. A World Health Organization trial performed in multiple labor units across the world, in which a graphical partogram was relied on to time interventions, demonstrated reductions in prolonged labors, in the frequency of emergency abdominal delivery, and in the use of oxytocin augmentation.²⁵ Therefore, visual representation of dilation versus time can help clinicians improve the care of patients in labor.

The compulsiveness, form, and orderliness of documentation of labor events need not interfere with compassionate, family-centered care of a woman in labor. In fact, the challenge of modern obstetrics is to manage a pregnancy with the least interference and yet maintain the capability of recognizing and correcting incipient complications at the earliest possible moment.

Management of Labor Abnormalities

ABNORMALITIES OF THE FIRST STAGE

In attempting to extend Friedman's work^{3,4} into contemporary practice, with its longer duration of normal labors, the modern obstetrician is faced with confusing definitions, the applicability of which in the individual case cannot be certain. Other than the recommendations of Rouse and colleagues^{12,14} to prolong augmentation in the face of second-stage arrest, we know of no new clinical guidelines for obstetricians to use. Moreover, Friedman's management suggestions were made without experimental verification of the hypotheses underlying his thinking. Friedman's framework³—in which he described labor abnormalities, identified associated problems, detailed the prognosis for the mother and fetus, and recommended a course of management—remains clinically useful, although the actual definitions of labor arrest and onset of active phase are outdated.

Friedman³ reported that abnormalities of the first stage of labor occurred in 8% of parturients, with a much higher incidence among primiparas than among nulliparas. Philpott and Castle²⁶ found that 11% of primiparas experienced abnormal labor progress in the first stage and required oxytocin augmentation. In a population-based study of 92,918 women, Sheiner and associates²⁷ found that failure to progress complicated 1.3%

TABLE 43-5 Factors Associated with Failure to Progress in the First Stage of Labor

Factor	Odds Ratio	95% Confidence Interval
Premature rupture of membranes	3.8	3.2-4.5
Nulliparity	3.8	3.3-4.3
Labor induction	3.3	2.9-3.7
Maternal age >35 yr	3.0	2.6-3.6
Fetal weight >4 kg	2.2	1.8-2.7
Hypertensive disorder	2.1	1.8-2.6
Hydramnios	1.9	1.5-2.3
Fertility treatment	1.8	1.4-2.4

Modified from Sheiner E, Levy A, Feinstein O, et al: Risk factors and outcomes of failure to progress during the first stage of labor: a population-based study, *Acta Obstet Gynecol Scand* 81:224, 2002. Printed with permission from Blackwell Munksgaard.

of all labors and resulted in abdominal deliveries. Independent risk factors are listed in Table 43-5.

Prolonged Latent Phase

On the basis of the 95th percentile limit of the distribution of latent-phase duration in the primiparous population, 20 hours is considered the definition of an abnormal latent phase. For multiparas, the corresponding definition of prolonged latent phase is 14 hours. Sometimes it is difficult to ascertain the difference between a prolonged latent phase and so-called "false" labor. Friedman³ found that prolongation of the latent phase was associated with excessive sedation, prematurely administered epidural anesthesia, unfavorable cervical status, or myometrial dysfunction.

Although early studies suggested that prolongation of the latent phase was not associated with increased perinatal mortality and was not the harbinger of other abnormalities of labor,²⁸ subsequent research showed otherwise. In a study of 10,979 patients in San Francisco, Chelmow and colleagues²⁹ found that prolonged latent phase of labor, defined as longer than 12 hours for nulliparous patients and longer than 6 hours for multiparous patients, was associated with an increased risk for subsequent labor abnormalities, cesarean delivery, low Apgar score, and need for neonatal resuscitation. These risks for adverse outcomes remained significantly elevated even when the data were controlled for other labor abnormalities, prolonged rupture of membranes, meconium-stained amniotic fluid, parity, and epidural use. In addition to the increased risk of cesarean delivery, a prolonged latent phase of labor in patients who delivered vaginally was associated with an approximately twofold increased incidence of third-degree and fourth-degree lacerations, febrile morbidity, and intrapartum blood loss.

One of the major problems with evaluation and management of the latent phase of labor is knowing at what hour labor began. Some authorities have used the time of admission to the hospital as a convenient starting point for judging when to intervene in the progress of labor.^{26,30,31} Friedman,³ however, regarded the onset of regular contractions as the beginning of labor and recommended intervention when the duration of the latent phase of labor reaches 20 hours in the primipara. He found that either adequate sedation ("therapeutic narcosis") or oxytocin augmentation resulted in the resumption of normal cervical dilation. Because most patients are exhausted after 20 hours of labor, Friedman preferred therapeutic narcosis over

oxytocin augmentation. For narcosis, he recommended morphine sulfate, 15 to 20 mg, with 10 to 15 mg more if the first dose has not made the patient somnolent and thereby inhibited uterine contractions. The obvious advantage of this therapy is that the patient awakens rested and refreshed and prepared for the active phase of labor.

Critics of this approach, especially O'Driscoll and Meagher,³¹ argued that waiting out 20 hours of latent phase before considering the labor to be abnormal only promotes exhaustion and discourages the patient. They advocated a protocol for active management of labor that has been practiced and evaluated at the National Maternity Hospital in Dublin. The protocol has several important features:

1. Patients are admitted to the labor unit only when they are experiencing painful uterine contractions as well as complete effacement of the cervix, ruptured membranes, or passage of blood-stained mucus.
2. Amniotomy is performed soon after admission for patients who have intact membranes.
3. Oxytocin augmentation of labor is performed if the progress of labor is less than 1 cm/hr over a 2-hour period. Oxytocin infusion is begun at 4 mU/min and is increased by 6 mU/min every 15 minutes until there are seven contractions per 15 minutes. The oxytocin infusion rate does not exceed 40 mU/min.
4. Continuous electronic fetal heart rate monitoring is used only if there is meconium-stained amniotic fluid and after the fetal scalp pH has been determined to rule out fetal acidosis.
5. A nurse-midwife is in constant attendance with the patient throughout labor.
6. The patient is assured that if her labor exceeds 12 hours, cesarean delivery will probably be performed.
7. The progress of labor is documented on a simple graphic form, and the senior obstetrician in charge of the unit reviews all cases daily. A partogram, as described earlier, is used to time interventions.
8. This approach to the management of labor is confined to nulliparas.

This active management protocol, with minor modifications, has also been evaluated in several obstetric services in the United States as well as other countries. These studies have consistently demonstrated a small but significant shortening of labor associated with active management. Although most have also demonstrated a decrease in the incidence of cesarean delivery for dystocia,³²⁻³⁵ the largest prospective and best-designed controlled trial showed no difference in the incidence of cesarean delivery for dystocia,³⁶ although it did show shortened labor and a decreased incidence of maternal infection with the active management protocol.

Holmes and associates³⁷ clearly demonstrated that women who present to the hospital with less than 3 cm dilation are more likely to undergo cesarean section or operative vaginal delivery than women presenting with more advanced dilation. Interestingly, they found that women presenting with less than 3 cm dilation had spent less time at home (2.0 versus 4.5 hours) since the onset of painful uterine contractions. Their results imply that women who present with reduced cervical dilation could have intrinsically different labors than those who present with more advanced dilation. Murphy and coworkers³⁸ and Falzone and colleagues³⁹ made similar observations, noting that nulliparous women presenting in labor with unengaged and

particularly floating (above $-3/3$ station) fetal heads had higher risks for obstetric intervention.

Protraction Disorders

Protraction disorders are those in which the progress of cervical dilation and descent of the fetal head occur at a slower than normal rate during the active phase of labor. The work by Friedman originally demonstrated that the rate of cervical dilation for nulliparas should be at least 1.2 cm/hr; for multiparas, it should be 1.5 cm/hr or faster.^{4,5} These criteria for minimum rates of cervical change represent the 95th percentiles for each parity category. More recently, the Consortium on Safe Labor found that nulliparous women who presented in spontaneous labor with vaginal delivery and normal perinatal outcome had longer 95th percentiles depending on the cervical dilation (Table 43-2).¹⁸ The 95th percentile for labor duration was 7 hours from 4 to 5 cm cervical dilation, and over 3 hours from 5 to 6 cm cervical dilation for multiparous women. In 2012, a joint summary was released by the Eunice Kennedy Shriver National Institute of Child Health and Human Development, Society for Maternal-Fetal Medicine, and American College of Obstetricians and Gynecologists.^{39a} After reviewing the available evidence, the workshop concluded, "These data suggest that the historical criteria defining normal labor progress—cervical change of 1.2 cm/hr for nulliparous women and 1.5 cm/hr for multiparous women—are no longer valid." For descent of the fetal head, the rate for nulliparas should be 1.0 cm/hr or faster; for multiparas, it should be 2.0 cm/hr.⁵

Friedman³ found protraction disorders in primiparas to be associated frequently with cephalopelvic disproportion (CPD), use of conduction anesthesia, and fetal malposition. Whether these factors are related in a cause-and-effect manner is not known. Moreover, he found oxytocin augmentation and therapeutic narcosis to be of little value in these cases. Friedman also noted unusually high neonatal mortality and morbidity rates when this labor abnormality was terminated by mid-forceps delivery; however, the diagnosis of a primary dysfunctional labor (i.e., persisting at a cervical dilation rate of <1.2 cm/hr) is usually made in retrospect, after oxytocin augmentation has been used and found not to increase the dilation rate.

The experiences of Beazley and Kurjak³⁰ and those of O'Driscoll and Meagher³¹ suggested that an early, more active use of oxytocin, as described in the active management of labor protocol, effectively corrects most protraction disorders, although these authors did not specifically separate protraction disorders from arrest disorders. Those who advocate the active management of labor explain that the use of x-ray pelvimetry is unnecessary in the nulliparous patient, because rupture of the uterus does not occur with the recommended oxytocin augmentation. Therefore, in nulliparous patients with suboptimal progress of labor from any cause, it is safe to use a trial of oxytocin to determine whether labor will progress to completion.

Ganström and associates⁴⁰ demonstrated significant differences in collagen content and collagen remodeling in the cervix and lower uterine segment in patients with protracted labors compared with those having normal labors. This finding may explain why some patients with protracted labor do not respond to oxytocin augmentation.

Arrest Disorders

Friedman³ originally defined an arrest disorder as the cessation of either cervical dilation or descent of the fetal head in the

active phase of labor for longer than 2 hours. In their pure form, arrest disorders differ from protraction abnormalities in that, before the arrest of progress, the rate of cervical dilation or descent of the fetal head is normal. Arrest of progress can also complicate a protraction disorder. In either situation, Friedman³ found that 45% of the cases of arrest disorder were associated with CPD. Philpott and Castle⁴¹ also found that patients whose labor progress crossed the "action line" (i.e., those with protraction or arrest disorders) had smaller pelvic measurements and more often required cesarean delivery for CPD.

Because of the frequent association between arrest disorders and CPD, Friedman³ recommended radiographic cephalopelvimetry followed by cesarean delivery for those with CPD and oxytocin augmentation for the remainder. He found that 80% of women with arrest disorders who did not have CPD delivered after oxytocin augmentation. Philpott and Castle⁴¹ and O'Driscoll and Meagher³¹ found that radiographic studies are not required, especially in primiparas, and that a trial of oxytocin augmentation is indicated in all protraction and arrest disorders. With careful monitoring of mother and fetus and discontinuation of augmentation if there is no progress after 4 to 6 hours, patients are not in danger. This is the approach of most, if not all, obstetric services in the United States; radiographic cephalopelvimetry is seldom used in the management of abnormal labor in vertex presentations.⁴²⁻⁴⁴

A notable exception is the use of the fetal-pelvic index by Morgan and Thurnau.⁴⁵ This technique combines ultrasound measurement of the fetal head circumference (HC) and abdominal circumference (AC) with radiographic measurement of the maternal pelvic inlet circumference (IC) and midpelvic circumference (MC). The fetal-pelvic index is the sum of the two greatest positive circumference differences (i.e., $HC - IC$, $HC - MC$, $AC - IC$, or $AC - MC$). A positive fetal-pelvic index value indicates the presence of fetal-pelvic disproportion, and a negative fetal-pelvic index value indicates the absence of fetal-pelvic disproportion. This index had a 94% positive predictive value for cesarean delivery of patients with abnormal labor patterns. These authors also found the fetal-pelvic index to be useful in predicting the success of induction of labor⁴⁶ and the success of attempted vaginal birth after previous cesarean delivery.⁴⁷ Ferguson and colleagues⁴⁸ were not able to confirm the efficacy of the fetal-pelvic index, and the method is not widely used.

Using labor progression guidelines based on the slower labor curves characteristic of modern parturients, Rouse and colleagues¹¹ demonstrated the effectiveness of a new protocol to treat arrest disorders. Their protocol had three principal elements:

- An intent to achieve a sustained uterine contraction pattern of greater than 200 Montevideo units as measured by an intrauterine pressure catheter
- A minimum of 4 hours of oxytocin-augmented labor arrest with a contraction pattern of greater than 200 Montevideo units before proceeding to abdominal delivery for active-phase arrest (more liberal than the original Friedman³ cutoff of 2 hours)
- For patients who cannot achieve a sustained uterine contraction pattern of greater than 200 Montevideo units, administration of a minimum of 6 hours of oxytocin augmentation before proceeding to cesarean delivery for active-phase labor arrest

The researchers demonstrated not only the effectiveness (92% vaginal delivery rate) but also the safety of this approach, with

no serious adverse maternal or perinatal effects. The only cost of liberalization of the minimums was an increased risk of maternal infection, with the risk proportional to the time elapsed.

These recommendations of Rouse and colleagues¹¹ raise the issue of whether intrauterine pressure catheters are useful tools for clinicians managing labor abnormalities. Lucidi and colleagues⁴⁹ reviewed the literature in 2001 and noted that there were no clinical trials testing the utility of this device. The technique is not included in the routines of the active management protocols described earlier. It would seem that partograms have a much stronger evidence basis than measurement of uterine contractility to guide the timing of obstetric interventions.

Zhang and colleagues, in the Consortium on Safe Labor, compared oxytocin augmentation protocols in 15,054 women.⁵⁰ Oxytocin regimen had no effect on cesarean delivery or other perinatal outcomes. Compared to regimens starting at 1 mU/min of oxytocin, those starting at 2 mU/min and 4 mU/min shortened duration of labor by 0.8 and 1.3 hours, respectively, in nulliparous women. Similar results were seen in parity 1+ women. Although the authors endorsed starting oxytocin augmentation protocols at higher doses, the reader should be mindful that these data were obtained within large, tertiary units. The findings may not be generalizable to smaller units with fewer resources to monitor mothers and their unborn babies. The small decreases in labor length must be weighed against any potential harms from higher-dose regimens.

Several authors have evaluated the effects of ambulation on the progress of labor. Flynn and coworkers⁵¹ found that patients who ambulated had more rapid labor with fewer instances of fetal distress than a similar number of patients who labored in bed. Williams and associates,⁵² studying 48 patients who ambulated, could find no differences in duration of labor or frequency of fetal distress compared with control patients. Read and colleagues⁵³ studied 14 patients whose labors were regarded as requiring augmentation because of lack of progress attributed to inadequate contractions. Progress of labor was as rapid in the eight patients who were randomized to an ambulation study protocol as in six control patients whose labors were augmented with oxytocin.

These studies suggest that ambulation is not detrimental to the progress of labor or the well-being of the fetus. However, it has not been established whether ambulation is clearly beneficial or whether it is a substitute for pharmacologic augmentation of labor in cases of abnormal progress.

ABNORMALITIES OF THE SECOND STAGE

Abnormalities of Rotation and Descent

Textbooks of obstetrics traditionally have discussed the first and second stages of labor as if they were separate clinical and biologic entities, which they are not. Descent and rotation of the fetal head frequently occur before complete dilation of the cervix, a phenomenon that is clear to most clinicians and that was confirmed by the studies of Friedman.³ In addition to showing slower rates of cervical dilation than did Friedman, the contemporary data of Zhang, Troendle, and Yancey¹³ showed a slower rate of fetal head descent. As demonstrated in Table 43-6 and Figure 43-5, it can take up to 3 hours to descend from +1/3 to +3/3 station and an additional 30 minutes for delivery. Again, there is a clear need for practice guidelines to incorporate these new data.

TABLE 43-6 Expected Time Interval and Rate of Descent at Each Stage of Station*

Station (in Thirds)		First and Second Stages		Second Stage Only	
From	To	Time Interval (hr)	Rate (cm/hr)	Time Interval (hr)	Rate (cm/hr)
-2	-1	7.9 (0.9, 65)	0.2 (0.03, 1.8)	—	—
-1	0	1.8 (0.1, 23)	0.9 (0.07, 12)	—	—
0	+1	1.4 (0.1, 13)	1.2 (0.12, 12)	—	—
+1	+2	0.4 (0.04, 3.8)	4.4 (0.44, 42)	0.27 (0.02, 2.93)	6.2 (0.57, 3.9)
+2	+3	0.1 (0.02, 0.9)	12.8 (1.9, 83)	0.11 (0.02, 0.63)	15.2 (2.6, 83)

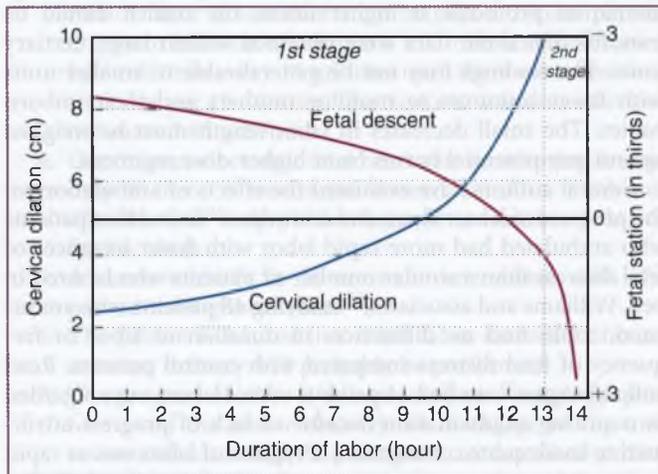

Figure 43-5 Patterns of cervical dilation and fetal descent in nulliparas. (From Zhang J, Troendle J, Yancey MK: Reassessing the labor curve in nulliparous women, *Am J Obstet Gynecol* 187:824, 2002.)

Arrest of descent and rotation, whether it occurs before or after complete dilation of the cervix, is a matter of concern and requires evaluation. Arbitrary limits on the duration of the second stage of labor probably resulted from misinterpretation of the data presented by Hellman and Prystowsky.⁵⁴ In their study, patients whose second stage of labor was longer than 2 hours were at increased risk for perinatal and maternal morbidity. This observation was interpreted by many clinicians to mean that delivery of the fetus should be accomplished, by whatever means, before 2 hours of the second stage had elapsed. This interpretation occasionally resulted in traumatic mid-forceps operations or unnecessary cesarean deliveries, not to mention overzealous use of the vacuum extractor. The reader should note that their recommendation of a 2-hour second stage limit antedates electronic fetal monitoring.

Cohen⁵⁵ demonstrated that when patients with fetal distress or traumatic delivery are excluded, the duration of the second stage bears no relationship to perinatal outcome. If there are no serious fetal heart rate abnormalities, the mother is well hydrated and reasonably comfortable, and there is some progress in descent or rotation of the fetal head (regardless of how slow),

there is no need for operative delivery. Similarly, Menticoglu and associates⁵⁶ confirmed that the duration of the second stage of labor is in itself not related to untoward outcomes. Hansen and coauthors,⁵⁷ in a trial of active versus passive pushing in the second stage, found that second-stage lengths as long as 4 to 9 hours had no harmful effects. Moreover, delayed pushing was better tolerated by patients and was associated with fewer fetal heart rate decelerations. Rouse and colleagues⁵⁸ performed a secondary analysis on 5341 participants in the fetal pulse oximetry trial and demonstrated that 55% of women with a second stage labor lasting 3 hours or longer had a successful vaginal delivery. There was an increased risk of maternal morbidity, including chorioamnionitis, severe perineal lacerations, uterine atony, and blood transfusions. Admission to a neonatal intensive care unit (NICU) and composite serious neonatal morbidity were also increased with a second stage lasting 3 hours or longer. More data are needed to help determine the optimal cutoff for second stage labor.

After the cervix is dilated more than 7 cm, descent or rotation of the fetal head can be expected. If this does not occur, uterine contractions, if they are not adequate, should be augmented with oxytocin. Manual examination to determine the position of the fetal head and the dimensions and shape of the pelvis often helps at this point. Posterior presentation, brow presentation, marked degrees of asynclitism, and very large infants are associated with longer labors, even with adequate contractions.

The Mueller-Hillis maneuver⁵⁹ also may help. The obstetrician applies pressure to the uterine fundus with one hand and detects descent of the fetal head with the examining finger in the vagina. If the fetal head descends 1 cm or more with fundal pressure, the prognosis for vaginal delivery is good; if no descent occurs, the prognosis for delivery is poor. This maneuver is not predictive of outcome if it is performed early in labor,⁶⁰ but it is helpful late in the first stage or in the second stage of labor.⁵⁹

Kominiarek and colleagues²² from the Consortium on Safe Labor showed that although obesity lengthened the first stage of labor in a linear fashion (i.e., with increases in BMI, the first stage was longer), there was no relationship between maternal weight and the length of the second stage. Robinson and coworkers studied this point further in 5341 nulliparous women from the fetal pulse oximetry trial.⁶¹ Obesity did not have any relationship with second-stage length and moreover was not related to need for abdominal delivery performed in the second stage. Therefore, obesity seems to affect labor by lengthening the first stage and to have no impact on the length of the second stage.

Shoulder Dystocia

Shoulder dystocia occurs in 0.24% to 2.00% of vaginal deliveries.⁶²⁻⁶⁵ This wide range of prevalence estimates highlights the lack of a standard definition. The cause is impingement of the biacromial diameter of the fetus against the symphysis pubis anteriorly and the sacral promontory posteriorly. Why the shoulders do not descend in the oblique diameters of the pelvis is unclear, although sometimes the fetus is simply too large. Although the risk of shoulder dystocia rises with increasing birth weight, 40% to 50% of cases occur in infants whose birth weight is less than 4000 g.

Risk factors for shoulder dystocia^{62,66-68} include fetal macrosomia, diabetes, a history of shoulder dystocia in a previous birth, and prolonged second stage of labor. Other factors that have been inconsistently reported as increasing the risk^{64,65,69} include a history of macrosomia or post-term pregnancy,

multiparity, obesity, and operative vaginal delivery from the midpelvis. In 50% of cases of shoulder dystocia, no risk factors are identified.

Maternal morbidity from shoulder dystocia includes postpartum hemorrhage and rectal injuries. The morbidity for the infant is attributable to asphyxia from delay in delivery or to trauma from the maneuvers used to deliver the fetus. Infant morbidity related to trauma includes brachial plexus and phrenic nerve injuries and fractures of the humerus and clavicle.⁷⁰ The most serious traumatic morbidity is brachial plexus injury (Erb palsy), which occurs in 10% to 20% of infants born after shoulder dystocia.^{64,70} If they are recognized early, 80% to 90% of brachial plexus injuries recover completely with proper physical therapy and, in some situations, neurosurgical management.⁷¹ For this reason, permanent neurologic injury is rare, occurring in 1 or 2 of every 10,000 births. This low prevalence greatly limits the ability to conduct prospective prevention studies.

Most brachial plexus injuries resulting from shoulder dystocia involve the arm and shoulder that are in the anterior pelvis at the time of delivery. The brachial plexus is believed to be injured when excessive downward traction and lateral extension of the fetal head and neck occur during the attempt to deliver the anterior shoulder⁶⁵; however, there are exceptions to this cause of brachial plexus injury.⁷² Some infants with brachial plexus injury were born by vaginal delivery in which there was no evidence of shoulder dystocia.⁷³ Also, brachial plexus palsy can involve the arm that was in the posterior pelvis at the time of delivery.⁷⁴ Furthermore, Erb palsy has occurred in infants born by cesarean delivery.^{75,76} Finally, several reports have described brachial plexus injuries in newborns that were confirmed by physical findings and electromyographic tests to have occurred before the onset of labor.^{77,78} It is postulated that these injuries resulted from chronic nerve compression due to malposition in utero.^{79,80} The presence of a permanent injury does not imply that the delivering clinician applied excessive force, despite the *res ipsa loquitur* argument seen in so many torts arising from these births.

Prevention of Shoulder Dystocia. Prevention of shoulder dystocia by prophylactic induction of labor is not effective.⁸¹ Primary cesarean delivery can prevent shoulder dystocia in a small proportion of patients when several predisposing factors are present, such as multiparity, gestational diabetes, and an estimated fetal weight in excess of 4500 g. Rouse and Owen,⁸² using decision analytic techniques, concluded that prophylactic cesarean delivery for sonographically detected fetal macrosomia to prevent shoulder dystocia is a Faustian bargain. Use of either 4000 or 4500 g as the cutoff point for abdominal delivery would require more than 1000 cesarean sections to prevent one permanent injury to the brachial plexus. Also, if arrest of descent of the fetal head occurs during labor along with other risk factors for shoulder dystocia, operative vaginal delivery should be avoided.

Management of Shoulder Dystocia. Conventional wisdom dictates that the most effective treatment includes prompt recognition that delivery of the shoulders will be difficult and avoidance of excessive downward traction on the fetal head when attempting to deliver the anterior shoulder. Retraction of the fetal head immediately on its delivery (turtle sign) is an early warning that delivery of the shoulders may be difficult. Studies using simulated models of the fetus and pelvis have

demonstrated that obstetricians frequently underestimate the amount of traction they apply to the fetal head.^{83,84}

Several maneuvers have been useful in resolving shoulder dystocia. Hyperflexion of the mother's thighs, known as the McRoberts maneuver, flattens the lumbosacral curve, thereby removing the sacral promontory as an obstruction to the inlet.^{85,86} The knee-chest position tends to accomplish the same end. Suprapubic pressure can be applied in conjunction with the McRoberts maneuver.

Rubin⁸⁷ described rotating the fetal shoulders into the oblique position by inserting the fingers of one hand vaginally behind the most accessible shoulder (usually the posterior) and pushing the shoulder toward the fetal chest. This is a substantial improvement on the commonly described Woods maneuver, which involves pushing the shoulder toward the fetal back.⁸⁸

If these maneuvers are not successful, the posterior arm of the fetus can be delivered if the obstetrician inserts one hand posteriorly, grasps the elbow, and draws the arm across the chest of the fetus.⁸⁹ This maneuver may result in fracture of the humerus or the clavicle, which is a consistently remediable injury and preferable to a brachial plexus injury of the opposite arm. Finally, replacement of the fetal head in the uterus followed by cesarean delivery—the Zavanelli maneuver—may be necessary in rare instances.⁹⁰

Although the soft tissue of the perineum does not contribute to shoulder dystocia, many protocols recommend a wide episiotomy to facilitate one or more of the described maneuvers.

The successful management of shoulder dystocia is a matter of considerable obstetric judgment and skill. There is an inverse relationship between the incidence of brachial plexus injuries from shoulder dystocia and the experience of the obstetrician.⁹¹ Shoulder dystocia culminating in an injury that is permanent (1 in 10,000 births) is so rare⁹² that all of the recommendations on prevention are based on accumulated wisdom and opinion rather than evidence-based medicine. Athukorala and coauthors demonstrated the paucity of evidence for interventions in their systematic review⁹³ and pointed to the flimsy foundation underlying any obstetrician's criticism of another's management of shoulder dystocia or suggestion that a particular approach in his or her own hands would have prevented an injury.

Hoffman and colleagues,⁹⁴ using data from the Consortium on Safe Labor, studied 132,098 deliveries, in which a total of 2018 cases of shoulder dystocia were reported, for an incidence of 1.5% (range among 12 centers, 0.2% to 3.0%). Among these cases, 101 babies (5.2%) had a birth injury, and 64 of those involved a nerve palsy. There were no neonatal deaths. The injury rates were the same whether the births were attended by residents, attending physicians, or midwives. Maneuvers performed are listed in Table 43-7. As the number of maneuvers needed to resolve the shoulder dystocia increased, so did the likelihood of temporary birth injury (Fig. 43-6). The McRoberts maneuver and suprapubic pressure were most often used as initial responses, and delivery of the posterior shoulder had the highest rate of success. However, because it is not known how many of the palsies were permanent, the conclusions of this study are applicable only to transient injuries.

Grobman and colleagues studied the impact of a shoulder dystocia protocol focused on team response in a large urban tertiary care hospital.⁹⁵ Informal training was concentrated on response to this event and not on specific maneuvers. Key elements were (1) an overt and unequivocal announcement of the

(From Hoffman MK, Bailit JL, Branch DW, et al; for the Consortium on Safe Labor: a comparison of obstetric maneuvers for the acute management of shoulder dystocia, *Obstet Gynecol* 117:1272, 2011.)

diagnosis, (2) a simplified approach to summoning the team through overhead notification and a paging tree, (3) declaration of the duration of shoulder dystocia to team members on their arrival, (4) role clarity for various team members, and (5) structured documentation. The “team” consisted of nurses, available attending obstetricians, anesthesia, pediatricians, and obstetric residents. During the three 6-month periods before, during, and after introduction of the protocol, documentation improved while the incidence of brachial plexus palsy diagnosed at delivery declined from 10.1% to 4.0% and then to 2.6%. The authors could not comment on the rate of permanent injury given the low prevalence of that phenomenon. Although these results may be generalizable to other tertiary care settings, implementation would not be possible in smaller community hospitals that lack the resources of academic health centers. This report does add evidence for the arguments that a coordinated team response and prearranged implementation process can reduce transient injury from shoulder dystocia.

ABNORMALITIES OF THE THIRD STAGE

Placental Separation and Control of Uterine Bleeding

The third stage of labor is defined as the time from delivery of the infant to delivery of the placenta. For all practical purposes, it should also include the hour after the delivery of the placenta, because it is during this time that the patient is at greatest risk for postpartum hemorrhage.

After the infant is born, the uterus contracts and placental separation occurs by cleavage along the plane of the decidua basalis. Placental separation usually is complete by the time two contractions have occurred, although several additional contractions may be necessary to accomplish expulsion of the placenta from the uterus. Large venous sinuses are exposed after separation of the placenta, and control of bleeding from these sinuses depends primarily on contraction of uterine muscle and only secondarily on coagulation and thrombus formation in the placental site. The average blood loss during a normal vaginal delivery is about 600 mL.⁹⁶ In the young, healthy parturient, acute blood loss is well tolerated because of the increased blood

volume of pregnancy and the decrease in vascular volume that occurs with the reduction of the uteroplacental circulation at the time of birth.

Management of the placenta in the third stage is a matter of debate among qualified obstetricians. Elective manual removal of the placenta, if performed promptly, has been associated with no increase in puerperal morbidity. Advantages include the immediate identification of retained placental fragments and intrauterine extensions of cervical lacerations and the shortened time of placental removal.^{97,98} However, manual removal is not a painless procedure in the unanesthetized patient, and it is unnecessarily invasive in most cases. Gentle massage of the uterine fundus encourages uterine contractions and helps one to detect changes in the shape of the uterus that signal placental separation. Vigorous fundal massage accomplishes nothing and is painful; if combined with excessive traction on the umbilical cord of a placenta implanted in the fundus of the uterus, it could promote uterine inversion.

The prophylactic administration of a uterotonic medication to reduce blood loss, either immediately after delivery of the infant or after delivery of the placenta, is a generally accepted practice, and prospective trials show that it decreases blood loss and reduces the need for therapeutic oxytocics.⁹⁹ These trials also found no difference in effectiveness of ergot preparations compared with oxytocin, although there were nonsignificant trends toward increased need for manual removal of the placenta, increased need for blood transfusions, and increased blood pressure associated with the use of ergot alkaloids. Intravenous oxytocin is the drug of choice on most obstetric services. Prophylactic administration of the thermostabile prostaglandin E₁ analogue, misoprostol, has been used to reduce bleeding in the third stage of labor.¹⁰⁰⁻¹⁰³

Retained Placenta

If the placenta has not been delivered with gentle umbilical cord traction and uterine massage after 30 minutes, it should be removed manually with the patient under general anesthesia or after a tocolytic drug has been given intravenously in combination with sufficient parenteral analgesia. Nitroglycerin is particularly useful in this situation as a tocolytic.¹⁰⁴ It may be given by translingual spray (400- μ g premeasured spray, 1 to 2 sprays repeated every 3 to 5 minutes for a maximum of three doses in 15 minutes) or by intravenous injection (50 to 150 μ g, repeated in 30 to 60 seconds if blood pressure is stable).

In rare instances, placental retention is caused by placenta accreta, the result of defective decidua basalis. It is characterized by the attachment and growth of chorionic villi directly into the myometrium. If the placenta cannot be removed manually and placenta accreta is suspected, hysterectomy is usually required to avoid catastrophic hemorrhage. The etiology of placenta accreta is not known, but there is a strong association with implantation of the placenta in the lower uterine segment, placenta previa, and prior cesarean delivery.

A report of 22 cases of placenta accreta by Read and coworkers¹⁰⁵ suggested that, in cases of focal or partial placenta accreta without excessive blood loss, conservative management may be successful. The conservative approach includes curettage of the retained placenta or suturing of the bleeding site (in cases of cesarean delivery); it should be considered only if preservation of fertility is of utmost importance and with the awareness that hysterectomy will be necessary if the conservative approach does not promptly control the blood loss. Descargues

and associates¹⁰⁶ described the role of prophylactic, selective embolization of the uterine arteries in cases of abnormal placental implantation diagnosed before delivery.

The episiotomy and vaginal or cervical lacerations are also sources of blood loss in the third stage of labor. Careful inspection of the vagina and cervix immediately after delivery allows one to identify lacerations of these structures so that they can be repaired promptly. Prompt repair also facilitates the management of an unexpected hemorrhage in the immediate recovery period by allowing the obstetrician to promptly attend to uterine atony.

Postpartum Hemorrhage

In the event of an immediate postpartum hemorrhage, the patient's vital signs should be monitored frequently, adequate intravenous lines should be established promptly, adequate fluid replacement should be started with infusion of lactated Ringer solution, and preparations should be made for blood transfusion. Thereafter, a prompt review should be made seeking possible sources of hemorrhage, including uterine atony; cervical, vaginal, or uterine lacerations; coagulopathies (spontaneous or iatrogenic); adherent placenta (accreta); and uterine inversion. Real-time ultrasound scanning is helpful in identifying retained portions of placenta or residual blood clots within the uterus.

Because the usual source of hemorrhage is uterine atony, intravenous oxytocin should be given in amounts adequate to compensate for the decreased sensitivity of the postpartum uterus to this drug.¹⁰⁷ Usually, 20 to 30 units of oxytocin in 1000 mL of fluid, given at an infusion rate not to exceed 100 mU/min, suffices. Because this amount of oxytocin far exceeds the threshold for its maximum antidiuretic effect,¹⁰⁸ fluid overloading is a potential danger in these patients. Bolus injections of oxytocin could cause hypotension and should be avoided, especially in patients who are at risk for volume depletion from hemorrhage.¹⁰⁹ Methylergonovine maleate (Methergine) or ergonovine maleate, given in doses of 0.2 mg intramuscularly, is often effective in maintaining uterine tone, but such drugs should not be given intravenously because of the danger of hypertension, central nervous system vasospasm, and hemorrhage.¹¹⁰

Increasingly, the 15-methyl analogue of prostaglandin $F_{2\alpha}$ (carboprost tromethamine) is being used to treat uterine atony if oxytocin infusion is not successful.¹¹¹ The recommended dose is 250 μ g intramuscularly, which can be repeated within a few minutes if the first injection does not suffice. Prostaglandin, particularly prostaglandin $F_{2\alpha}$, should be used with great caution, if at all, in patients with cardiovascular disease or asthma.

Based on its demonstrated effectiveness as a prophylactic measure against hemorrhage when given in the third stage of labor, equivalent to oxytocin or Methergine, misoprostol has been used to manage severe postpartum hemorrhage. Abdel-Aleem and colleagues¹¹² gave 1000 μ g of misoprostol rectally, and Adekanmi and associates¹¹³ administered 800 μ g of misoprostol into the uterus transvaginally to control hemorrhage. Both authors reported successes after failure of conventional pharmacotherapy. See Chapter 71, Table 71-13 for more information on pharmacologic agents that are useful for controlling uterine atony.

In some cases, uterine atony and uterine hemorrhage persist despite all measures taken to enhance uterine contractions and

after other possible sources of vaginal or cervical hemorrhage have been excluded. In these situations, exploratory laparotomy is often necessary (see Chapter 71).

During preparation for laparotomy, several measures can be taken that may adequately control the hemorrhage and avoid an operative procedure:

- Use of a large Foley catheter or Bakri balloon as a tamponade to halt bleeding from a low placental implantation site¹¹⁴
- Packing of the uterine cavity with sterile gauze (although no well-designed study has been undertaken to prove that packing is effective, retrospective evidence indicates that this measure can control hemorrhage resulting from atony in some cases¹¹⁵)
- For some patients, selective embolization of pelvic vessels to control hemorrhage adequately, in hospitals where the necessary facilities and personnel are available¹¹⁶

If all of these procedures have been tried in vain, laparotomy is performed with one or more of the following goals: (1) to identify any sources of occult intra-abdominal bleeding, such as unexpected uterine laceration; (2) to control the bleeding by appropriate arterial ligations; (3) in the most extreme and refractory cases, to perform hysterectomy.

When laparotomy is performed for postpartum hemorrhage, the patient should be placed in semilithotomy position. Sterile drapes should be applied in such a way that one observer can, with a sterile speculum, examine the vagina and cervix to determine when the bleeding has ceased. If major uterine lacerations are not found, the uterine arteries should be ligated by the method described by O'Leary and O'Leary (see Chapter 71).¹¹⁷ If this measure does not control uterine bleeding, the hypogastric arteries should be ligated. In 1997, B-Lynch and colleagues¹¹⁸ described a "brace" suturing technique that results in closure of the uterine blood supply. Other authors have confirmed the effectiveness of this uterine-conserving technique in small case series.^{119,120} The Hayman technique is a simpler way to "brace" suture the uterus.¹²⁰

Burchell¹²¹ described the pelvic vascular supply and demonstrated that the transient decreases in blood pressure and blood flow through regional vessels that occur at the time of internal iliac artery ligation are responsible for the control of hemorrhage. Because of the ample collateral circulation, there appear to be no long-term consequences of hypogastric artery ligation, and women have delivered normal infants in subsequent pregnancies after undergoing this procedure. Occasionally, a patient complains of mild bladder dysfunction and buttock pain in the immediate postoperative period, but these symptoms are transient.

In cases of extensive postpartum hemorrhage, the use of a central venous pressure line or a Swan-Ganz catheter facilitates more accurate monitoring of the cardiovascular status of the patient and avoids serious errors of hydration and pulmonary edema (see Chapter 71).^{122,123}

Inversion of the Uterus

Inversion of the uterus, a rare but dramatic complication of the third stage of labor and the immediate puerperium, must be recognized and corrected promptly to avoid serious long-term morbidity.¹²⁴ Uterine inversion is probably related to fundal implantation of the placenta, which results in thinning of the uterine wall in the area of implantation. Fundal implantation occurs in only 10% of all pregnancies but has been found in

virtually all reported cases of acute puerperal uterine inversion in which the site of placental implantation was recorded.^{124,125} The thin fundal area of the myometrium invaginates as the placenta separates, whereupon the inversion proceeds, with the uterus virtually delivering itself inside out. With this scenario in mind, one can easily imagine that vigorous fundal pressure or excessive cord traction could contribute to the tendency to inversion in a uterus predisposed by fundal implantation of the placenta.

Complete uterine inversion occurs when the inverted fundus extends beyond the cervix, usually looking like a beefy-red mass at the vaginal introitus. Incomplete inversions occur when the inverted fundus has not extended beyond the external cervical os. These cases are not as obvious and may be detected only by bimanual or visual examination of the cervix. In cases of postpartum hemorrhage in which the uterine fundus cannot be palpated abdominally, incomplete uterine inversion should be suspected.

Tocolytic drugs including magnesium sulfate,¹²⁶ β -mimetic compounds,¹²⁷ and nitroglycerin¹²⁸ have been used to assist in reinversion of the uterus. Because of the extensive blood loss and shock that often are associated with uterine inversion, an anesthesiologist should be summoned as soon as the diagnosis is recognized so that general anesthesia can be available if reinversion using tocolysis fails.

The technique of reinversion is the same whether it is accomplished with intravenous tocolysis or general anesthesia. The uterus is reinverted with gentle but firm and persistent pressure applied on the fundus to elevate it into the vagina.¹²⁹ In most cases, this technique, which presumably results in reinversion by indirect traction on the round ligaments when the uterus is elevated into the abdomen, is successful. Authorities disagree about whether the placenta, which is often attached to the inverted fundus, should be removed before attempts to reinvert the fundus are made. As a practical matter, the Johnson technique for reinversion¹²⁹ is easier if the placenta is not in place.

If the diagnosis is made and reinversion is accomplished promptly, there are no long-term sequelae. If the complication is unrecognized and reinversion is delayed, tissue edema magnifies the constriction of the cervix around the inverted fundus, making reinversion difficult. Tissue necrosis and damage to the bladder or urethra could ensue.

If the Johnson method of reinversion is not successful, laparotomy should be performed. The first step is to grasp the round ligaments about 1 inch into the inverted uterus and exert traction while an assistant elevates the uterus with a hand in the vagina. This procedure, described by Huntington,¹³⁰ may fail because the inverted fundus is too tightly trapped below the cervical ring, in which case the Haultain¹³¹ procedure may be performed. In the Haultain procedure, a longitudinal incision is made posteriorly through the inverted fundus, allowing ample room to reinvert the fundus. The incision is then closed, leaving the equivalent of a classic cesarean incision on the posterior surface of the uterus. If uterine inversion is recognized and treated promptly, an operative procedure is rarely necessary to accomplish reinversion.

The third stage of labor and the immediate puerperal recovery period are a crucial time for the parturient. Occasionally, uterine hemorrhage goes undetected or is recognized but treated inadequately. Acute tubular necrosis, pituitary necrosis, and adult respiratory distress syndrome—all recognized complications of puerperal shock and hypoxia—can be avoided by

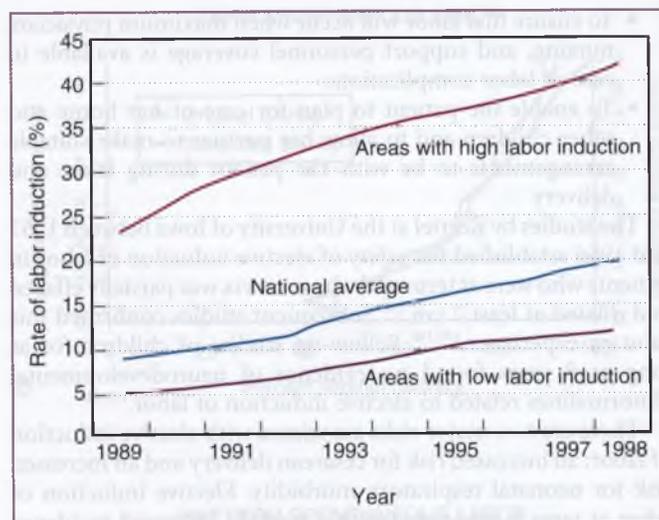

Figure 43-7 Rates of labor induction in the United States, 1989-1998. (From Zhang J, Yancey MK, Henderson CE: U.S. national trends in labor induction, 1989-1998, *J Reprod Med* 47:121, 2002. Printed with permission from the Journal of Reproductive Medicine.)

careful observation of all patients during this time and by deliberate and aggressive management of hemorrhage if it occurs.

Induction of Labor

Induction of labor may be elective (i.e., performed for the convenience of the patient or the professional staff), or it may be indicated for medical, obstetric, or fetal complications of pregnancy.

Between 1989 and 1998 in the United States, there was an increase in the incidence of induction of labor, from 9% to 19% of all births (Fig. 43-7).^{132,133} In 1998, the incidence of induction of labor varied widely by region, from 10.9% in Hawaii to 41.6% in Wisconsin. Also, the increase in the incidence of indicated induction was significantly smaller than the overall increase (70% to 100% increase), suggesting that the rate of elective induction increased more rapidly than did the rate of indicated induction.

Nicholson and colleagues¹³⁴ and Caughey and colleagues¹³⁵ questioned the conventional wisdom that induction is a risk factor for abdominal delivery. They pointed out that comparisons between women induced at a given gestational age and those in spontaneous labor at that age overestimate the risk of cesarean section, because the real comparison group for induced women should be the entire cohort awaiting spontaneous labor. Analysis of cohorts with their novel approach indicated that induction reduces the risk of abdominal delivery compared to expectant management, which is the real choice a woman and her obstetrician face. Verification of this inversion of conventional wisdom in prospective trials would radically change the practice of contemporary obstetrics.

ELECTIVE INDUCTION

Elective induction of labor is often justified on one or more of the following grounds:

- To assure the patient that the physician with whom she has good rapport will be present during delivery

- To ensure that labor will occur when maximum physician, nursing, and support personnel coverage is available in case of labor complications
- To enable the patient to plan for care of her home and other children and to allow her partner to make suitable arrangements to be with the patient during labor and delivery

The studies by Keettel at the University of Iowa between 1957 and 1966 established the safety of elective induction of labor in patients who were at term and whose cervix was partially effaced and dilated at least 2 cm.¹³⁶ Subsequent studies confirmed this salutary experience.^{137,138} Follow-up studies of children for as long as 8 years found no evidence of neurodevelopmental abnormalities related to elective induction of labor.^{139,140}

There are two major risks associated with elective induction of labor: an increased risk for cesarean delivery and an increased risk for neonatal respiratory morbidity. Elective induction of labor at term is associated with a twofold increased incidence of cesarean delivery compared with spontaneous labor.^{141,142} This increase is confined almost entirely to nulliparous women and, more specifically, to those in whom induction of labor is attempted when the cervix is not well effaced and somewhat dilated.^{143,144} This risk can be minimized by restricting elective induction of labor to patients with a favorable or ripe cervix.

An objective classification for selection of patients who are "favorable" for induction of labor¹⁴⁵ is shown in Table 43-8. Bishop found that a pelvic score of 9 or greater in the term multipara was associated with no failed inductions of labor in his series and that the average duration of labor was 4 hours. Although the criteria for successful induction of labor as described by Bishop applied only to multiparous women, subsequent studies showed the usefulness of Bishop's scoring system in nulliparous patients.¹⁴⁶ There is a 50% risk of failed induction of labor in nulliparous women at term for whom the Bishop pelvic score is 5 or less. Lange and colleagues,¹⁴⁷ in a study of induction of labor in 808 patients, found that dilation was the most important of the five components in the Bishop score and recommended that it be scored at twice the value given by Bishop. Most experienced obstetricians would agree with this. Transvaginal ultrasound examination of the cervix does not improve on the Bishop score in predicting the success of induction of labor.^{148,149} The presence of fetal fibronectin (fFN) in cervical and vaginal secretions is an additional means for predicting the success of induction of labor.^{150,151} The role that vaginal fFN can play in selecting patients for elective induction of labor has yet to be determined.¹⁵²

TABLE 43-8 Pelvic Scoring Table for Selection of Patients for Elective Induction*

Factor	Points Assigned			
	0	1	2	3
Dilation (cm)	0	1-2	3-4	5-6
Effacement (%)	0-30	40-50	60-70	80
Station	-3	-2	-1 or 0	+1 or +2
Consistency	Firm	Medium	Soft	—
Position	Posterior	Middle	Anterior	—

*The total pelvic score is obtained by adding the points scored for each factor.

Adapted from Bishop EH: *Pelvic scoring for elective induction*, *Obstet Gynecol* 24:266, 1964.

Laughon and colleagues¹⁵³ used data from the Consortium on Safe Labor to determine whether a simplified scoring system using only three components of the traditional Bishop score—dilation, effacement and station—could predict vaginal delivery as well as the traditional Bishop score with all five components. They studied 5610 women at parity 0 who were undergoing induction. A simplified nine-point scoring system had better positive and negative predictive values than the traditional method. Figure 43-8 displays the differences between traditional and simplified Bishop cervical assessment systems. The authors suggested that this simplified approach may prove useful in clinical decision making about labor induction and is easier for clinicians to calculate.

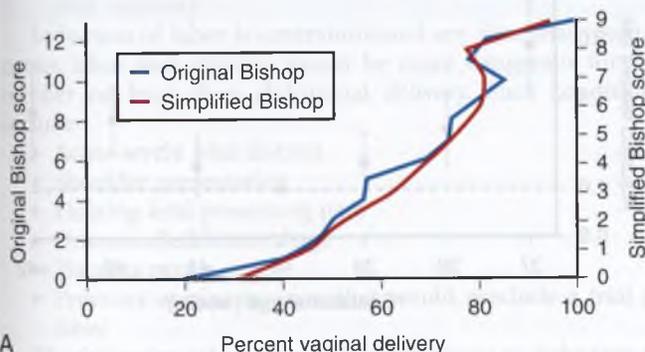

Amniotomy is often successful in inducing labor in patients who have a favorable cervix, although the mechanism of action is not entirely clear. Mitchell and associates¹⁵⁴ showed that artificial rupture of the membranes is followed by a substantial increase in plasma prostaglandins. In one of the largest studies of elective induction of labor, Keettel¹³⁶ found that, if the patient was at term with a vertex presentation, the fetal vertex was engaged in the pelvis, and the cervix was at least 2 cm dilated and partially effaced, only 3.4% of patients required oxytocin infusion after amniotomy to induce labor successfully. If the use of oxytocin is necessary, it should be given by intravenous infusion, preferably by constant infusion pump, with monitoring of the fetal heart rate, uterine contractions, and maternal vital signs. Whether induction is elective or indicated, adequate stimulation of uterine contractions is important in reducing the incidence of failed induction of labor. Rouse and associates¹² and Lin and Rouse¹⁵⁵ showed the effectiveness of requiring a minimum of 12 hours of oxytocin stimulation after membrane rupture before failed labor induction is diagnosed.

The second major risk of elective induction of labor is neonatal respiratory morbidity.^{156,157} This is caused, in part, by surfactant deficiency resulting from unexpected delivery of a premature infant. Consequently, scrupulous attention to confirmation of gestational age is necessary. The following criteria should be fulfilled before a patient is considered a candidate for induction:

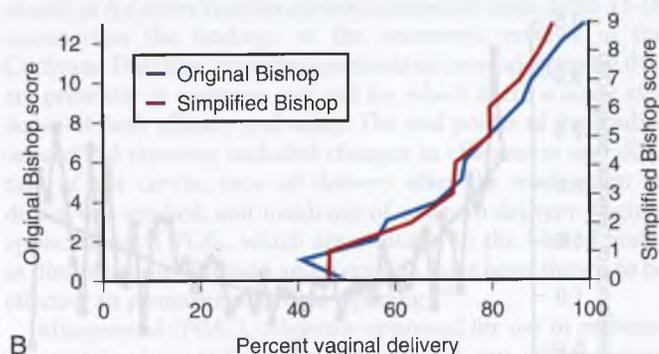

1. A well-established ovulation date, which can be determined by one of the following:
 - a. A regular menstrual history prior to the last menstrual period; the last menstrual period should not be considered normal if it occurred after cessation of oral contraceptive use
 - b. Basal body temperature chart demonstrating a biphasic rise
 - c. Clomiphene induction of ovulation followed by early confirmation of ovulation in pregnancy
 - d. Artificial insemination or in vitro fertilization and embryo transfer
2. Examination of the patient by the 14th week of pregnancy in which the uterine size was consistent with estimated gestational dates
3. Sonographic estimation of fetal weight performed before 20 weeks' gestation
4. Bishop pelvic score of 6 or greater

Based on criteria, the patient should be considered for elective induction of labor at 40 weeks (280 ± 3 days) after the last menstrual period, if the menstrual interval is 28 days, or at 266 days ± 3 days after the suspected ovulation date.

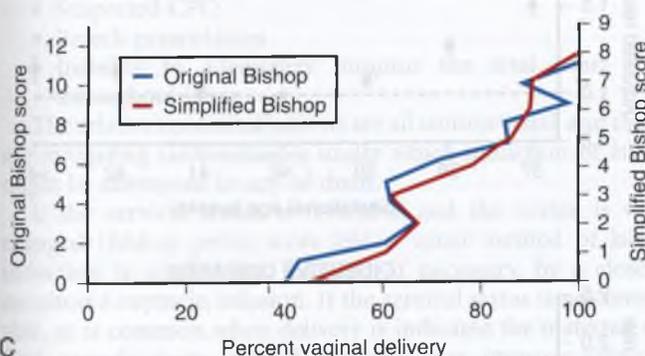

TERM INDICATED INDUCTION

TERM SPONTANEOUS LABOR

PRETERM INDICATED INDUCTION

PRETERM SPONTANEOUS LABOR

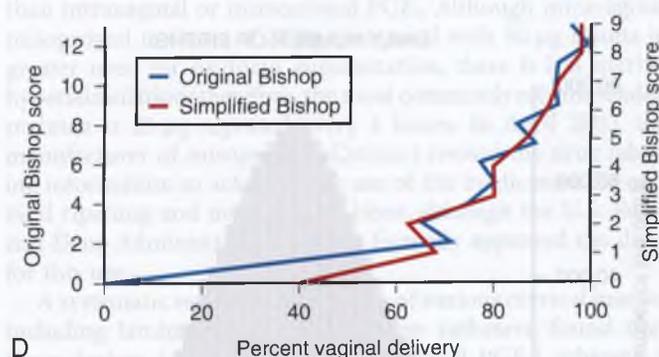

Figure 43-8 Comparison of the original and simplified Bishop scoring systems. The y axes show the traditional Bishop score (range 0 to 13) on the left and the simplified Bishop score using only dilation, station, and effacement (range 0 to 9) on the right. The x axes show the rate of vaginal delivery for the following separate populations of women: **A**, indicated induction at term (37 0/7 to 41 6/7 weeks' gestation); **B**, spontaneous labor at term; **C**, preterm (32 0/7 to 36 6/7 weeks' gestation) indicated induction; **D**, preterm spontaneous labor. (From Laughon SK, Zhang J, Troendle J, et al: Using a simplified Bishop score to predict vaginal delivery, *Obstet Gynecol* 117:805, 2011.)

The cause of respiratory morbidity in some infants after elective induction of labor is the fact that the birth took place before the occurrence of the normal events associated with parturition that prepare the fetus for the transition to extrauterine life.¹⁵⁸ One of the critical transition phenomena is a decrease in fetal lung fluid associated with the spontaneous onset of labor.^{159,160} If this does not occur, the most common manifestation in the newborn is "wet lung syndrome," which clears spontaneously in a few hours. In some infants, the respiratory morbidity is more serious, involving persistence of the fetal circulation and necessitating mechanical ventilation.¹⁶¹

Bailit and associates from the Consortium on Safe Labor¹⁶² showed that rates of NICU admission and sepsis actually declined for each week of gestation until 39 weeks and were lower when delivery was by spontaneous labor compared with electively induced labor. Whether these benefits are causally attributable to elective induction or a result of confounding from unmeasured factors cannot be ascertained from observational data. Elective induction was associated with improved neonatal outcomes, including less need for ventilation, sepsis, and NICU admission. The risk of hysterectomy was threefold higher with elective induction.

In a population-based follow-up study using the Medical Birth Registry of Norway, Moster and coworkers¹⁶³ explored the relationship between timing of delivery (between 37 and 44 weeks) and the prevalence of cerebral palsy in 1,682,441 infants. The risk was lowest with delivery at 40 weeks (Fig. 43-9), and delivery earlier or later increased that risk (Fig. 43-10). Although reverse causation is possible (i.e., infants destined to deliver with cerebral palsy may for that reason tend to be delivered early or late), this result does suggest the window between 39 and 40 weeks' gestation as the optimal interval for clinicians and patients choosing a time for a labor induction or cesarean delivery. In contrast, the congenital malformation risk curve in Figure 43-10 points to the likelihood of reverse causation, because birth defects are embryologic events that occur long before term.

Waiting until the pregnancy is at 40 weeks' gestation and the cervix is well effaced and partially dilated before induction of labor can minimize the risks of cesarean delivery and neonatal respiratory morbidity. If an obstetrics service concludes that elective induction of labor is permissible, the professional staff, including physicians and nurses from labor and delivery and the nursery, should collectively agree on criteria for patient selection and draw up a protocol for the labor induction

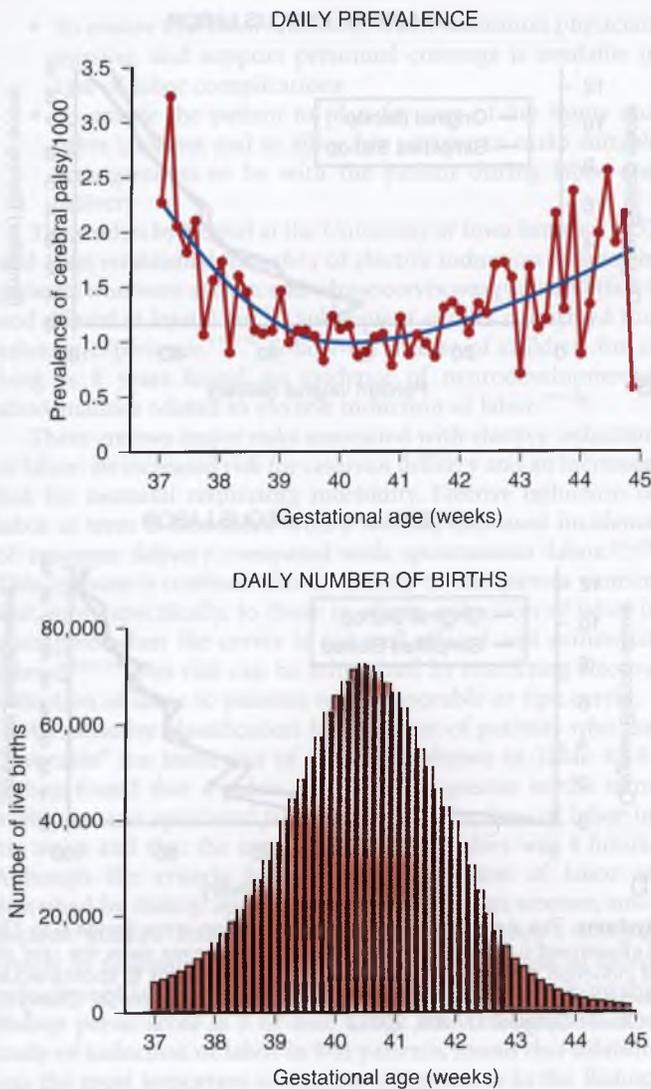

Figure 43-9 Prevalence of cerebral palsy by gestational age at birth. *Top panel:* Effect of gestational age on the prevalence of cerebral palsy in a cohort of 1,682,441 liveborn infants without congenital anomalies. The smoothed curve was fitted using the locally weighted scatterplot smoothing (LOESS) method. *Bottom panel:* Number of births each day from 37 to 44 weeks' gestation in the same cohort. (From *Moster D, Wilcox AJ, Vollset SE, et al: Cerebral palsy among term and postterm births, JAMA 304:976, 2010.*)

procedure. After such guidelines of care are established, elective induction of labor should undergo periodic review to determine the degree of compliance with the guidelines and to identify any related maternal or perinatal morbidity.

INDICATED INDUCTION

Induction of labor is indicated if prolongation of pregnancy is dangerous for either the mother or the fetus and there are no contraindications to amniotomy or the augmentation of uterine contractions. Maternal indications include the following:

- Pregnancy-induced hypertension
- Fetal death
- Chorioamnionitis

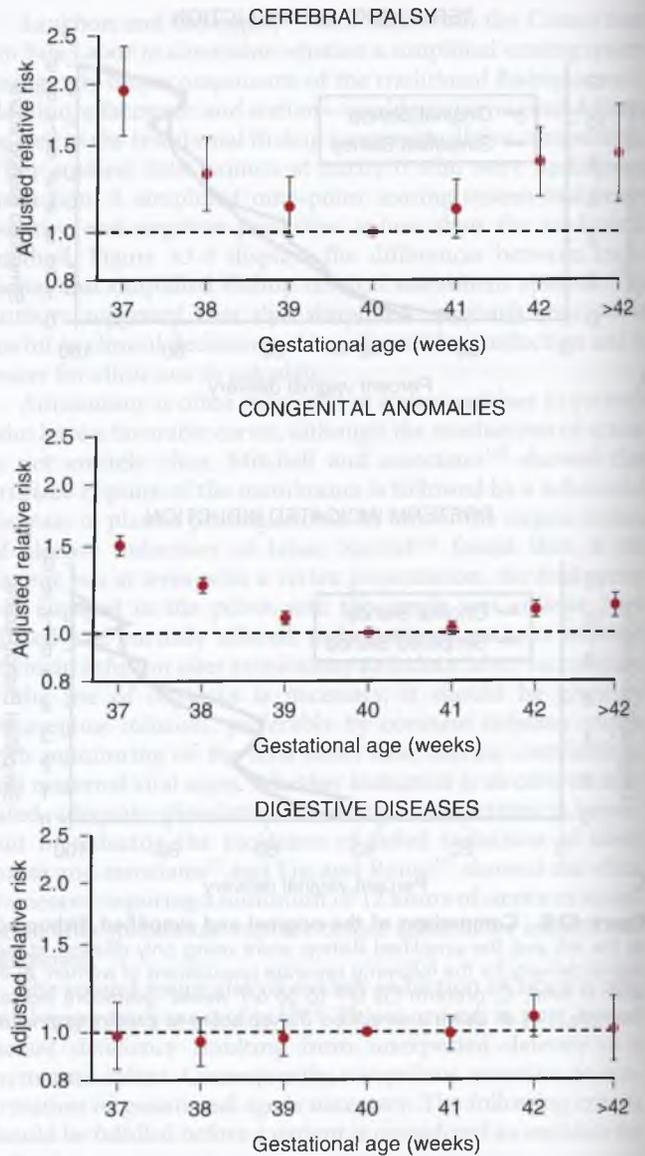

Figure 43-10 Relative risk of cerebral palsy, congenital anomalies, and digestive diseases by gestational age at birth. Information on cerebral palsy and digestive diseases from the study cohort of 1,682,441 liveborn infants without congenital anomalies. Digestive diseases are those coded by *International Classification of Diseases, Ninth Revision (ICD-9 codes 520-579)* and *Tenth Revision (ICD-10 codes K00-K93)*. Information on congenital anomalies is based on the original study cohort without exclusion of congenital anomalies ($N = 1,720,443$). Error bars indicate 95% confidence intervals. The reference category for all plots was 40 weeks. (From *Moster D, Wilcox AJ, Vollset SE, et al: Cerebral palsy among term and postterm births, JAMA 304:976, 2010.*)

Fetal indications for pregnancy termination include any condition in which a variety of fetal tests demonstrate significant fetal jeopardy in any of the following settings:

- Diabetes mellitus
- Post-term pregnancy, especially in association with oligohydramnios
- Hypertensive complications of pregnancy
- Intrauterine growth restriction
- Isoimmunization
- Chorioamnionitis

- Premature rupture of the membranes with established fetal maturity

Induction of labor is contraindicated any time that spontaneous labor and delivery would be more dangerous for the mother or fetus than abdominal delivery. Such conditions include

- Acute severe fetal distress
- Shoulder presentation
- Floating fetal presenting part
- Uncontrolled hemorrhage
- Placenta previa
- Previous uterine incision that would preclude a trial of labor

The following are relative contraindications to induction of labor:

- Grand multiparity (five or more previous pregnancies beyond 20 weeks' gestation)
- Multiple pregnancy
- Suspected CPD
- Breech presentation
- Inability to adequately monitor the fetal heart rate throughout labor

The relative contraindications are all controversial, and there are mitigating circumstances under which induction of labor might be attempted in any of them.

If the cervical status is favorable and the vertex is well engaged (Bishop pelvic score ≥ 6), a usual method of labor induction is amniotomy, followed, if necessary, by a closely monitored oxytocin infusion. If the cervical status is not favorable, as is common when delivery is indicated for maternal or fetal complications, several methods may improve cervical effacement and dilation.

Danforth¹⁶⁴ was among the first to study the effect of pregnancy on the cervix and to describe the histology of cervical softening and effacement. The cervix is composed largely of connective tissue, including types I, III, and IV collagen, and only 10% to 15% smooth muscle.¹⁶⁵ Before the onset of labor, the collagen content of the cervix decreases by 30% to 50% as the content of water and noncollagen and nonelastin proteins increases. The process of cervical ripening involves the production of cytokines (tumor necrosis factor- α , interleukin-1 β [IL-1 β], IL-6, IL-8) and the extravasation of neutrophils into the cervical stroma. Degranulation of the neutrophils releases proteases that are involved in the modification of cervical collagen.¹⁶⁶ The proteolytic enzymes are responsible for degrading cross-linked, newly synthesized collagen and thereby contribute to the rearrangement of collagen cells that is a hallmark of cervical softening. Apoptosis of smooth muscle cells in the cervix may also contribute to cervical ripening.¹⁶⁷ That this process is a genetically determined, timed event may explain the length of gestation. Although the specific endocrine and biomolecular mechanisms of cervical ripening (including the role of prostaglandins) are not fully understood, the result of this phenomenon is softening, thinning, and early dilation of the cervix.

Multiple drugs and devices have been used to enhance cervical ripening, including oxytocin, estrogen, corticosteroids, hyaluronidase, breast stimulation, sexual intercourse, relaxin, castor oil, prostaglandin E₁ (PGE₁) and PGE₂, mifepristone, hydrophilic cervical inserts, balloon catheters, and extra-amniotic saline infusion. Systematic reviews of the studies of most of these methods are included in the Cochrane Database. Table

43-9 lists methods that have been found to be ineffective or unsafe or for other reasons are not commonly used. Table 43-10 summarizes the findings of the systematic reviews in the Cochrane Database regarding methods of cervical ripening that are presently in common use and for which there is some evidence of both efficacy and safety. The end points of the studies on cervical ripening included changes in effacement and dilation of the cervix, time of delivery after the medication or device was applied, and incidence of cesarean delivery. Vaginal applications of PGE₂, which are available in the United States as dinoprostone (Prepidil and Cervidil), have been shown to be effective in promoting cervical ripening.¹⁶⁸

Misoprostol (PGE₁), originally approved for use in preventing gastric ulcers induced by nonsteroidal anti-inflammatory drugs, has proved to be an effective cervical ripening agent when applied intravaginally in doses of 25 or 50 μ g. A meta-analysis by Hofmeyr and Gulmezoglu¹⁶⁹ found that misoprostol was more effective in cervical ripening and induction of labor than intravaginal or intracervical PGE₂. Although intravaginal misoprostol in doses of 25 μ g compared with 50 μ g results in greater need for oxytocin augmentation, there is less uterine hyperstimulation; therefore, the most commonly recommended regimen is 25 μ g repeated every 4 hours. In April 2002, the manufacturer of misoprostol (Cytotec) revised the drug labeling information to acknowledge use of the medication for cervical ripening and induction of labor, although the U.S. Food and Drug Administration has not formally approved the drug for this use.

A systematic review of the studies of various cervical inserts, including laminaria tents and balloon catheters, found that these devices (compared with intravaginal PGE₂) achieved a lower rate of delivery within 24 hours, resulted in no difference in cesarean delivery rate, and were less likely to cause uterine hyperstimulation.¹⁷⁰ Small studies found that use of the Foley catheter compared favorably with intravaginal PGE₁ (misoprostol) for cervical ripening,¹⁷¹ but larger prospective trials are needed to confirm this impression.

Although randomized trials have shown that prostaglandins in general, and misoprostol specifically, result in cervical ripening as manifested in a significant increase in the Bishop pelvic score, they have not demonstrated a significant decrease in the incidence of failed induction of labor or a decrease in the risk of cesarean delivery after induction of labor in nulliparous patients. This suggests that failed induction of labor could be the result of several incomplete mechanisms of parturition, of which cervical ripening is but one manifestation.

Abnormal Presentation

BREECH PRESENTATION

Breech presentation occurs in approximately 3% to 4% of all deliveries. Its incidence decreases with advancing gestation. Weisman,¹⁷² using periodic radiographic examinations throughout pregnancy, found that 24% of fetuses were in breech presentation at 18 to 22 weeks of gestation, 8% at 28 to 30 weeks, 7% at 34 weeks, and 2.8% at 38 to 40 weeks. It is generally agreed that higher rates of neonatal morbidity and mortality are associated with breech presentation than with cephalic presentation at all gestational ages and birth weights.¹⁷³ There is less agreement about what can be done to eliminate the risk for the infant who is in breech presentation at the time of delivery.

TABLE 43-9 Cervical Ripening: Methods That Are Ineffective or Not in Common Use

Method of Cervical Ripening	Online Source	No. of Trials in Review	Major Findings
Oxytocin	Kelly & Tan, (3):CD003246, 2001	58	Less effective than intracervical or intravaginal PGE ₂
Estrogen	Thomas, Kelly, & Kavanagh, (4):CD003393, 2001	6	Insufficient data to determine efficacy
Corticosteroids	Kavanagh, Kelly, & Thomas, (2):CD003100, 2001 (updated 2006)	2	Insufficient data to determine efficacy; not recommended for clinical practice
Hyaluronidase	Kavanagh, Kelly, & Thomas, (2):CD003097, 2001 (updated 2005)	8	Insufficient data to determine efficacy
Breast stimulation	Kavanagh, Kelly, & Thomas, (4):CD003392, 2001 (updated 2005)	6	Effective in increasing incidence of women in labor within 72 hr, but safety issues not fully evaluated
Sexual intercourse	Kavanagh, Kelly, & Thomas, (2):CD003093, 2001	6	Insufficient data to determine efficacy
Castor oil	Kelly, Kavanagh, & Thomas, (2):CD003099, 2001	1	No reduction in cesarean delivery rate; high incidence of side effects
Relaxin	Kelly, Kavanagh, & Thomas, (2):CD003103, 2001	4	Improves cervical softening and effacement but does not increase success of induction of labor; not clinically useful
Extra-amniotic prostaglandin	Hutton & Mozurkewich, (2):CD003092, 2001	10	Compared with intravaginal or intracervical PGE ₂ or Foley catheter, no difference in outcomes
Intravenous prostaglandin	Luckas & Bricker, (4):CD002864, 2000	13	No more effective than IV oxytocin, with more side effects and uterine hyperstimulation
Stripping (sweeping) membranes	Boulvain, Stan, & Irion, (4):CD000451, 1997 (updated 2004)	22	Does not produce clinically important benefits; safe but associated with patient discomfort
Mifepristone	Neilson, (4):CD002865, 2000	7	Insufficient data to determine efficacy
Oral PGE ₁	Alfirevic & Weeks, (4):CD001338, 2000 (updated 2005)	41	No evidence for greater efficacy than intravaginal PGE ₁ ; doses ≥100 μg increase the incidence of side effects and uterine hyperstimulation
Oral PGE ₂	French, (2):CD003098, 2001	19	No more effective than IV oxytocin, with more side effects

Part of the problem could be inherent in the etiology of breech presentation itself. Term *breech presentation* is associated with fundal-cornual implantation of the placenta, which occurs in only 7% of all pregnancies.¹⁷⁴ This association suggests that breech presentation often is related to a space problem in the uterus: Given the fundal-placental implantation, an otherwise normal fetus finds it more comfortable to assume a breech position. Other studies have suggested that breech presentation could result from abnormal motor ability or diminished muscle tone in the fetus.

Braun and colleagues,¹⁷⁵ reporting from a dysmorphology clinic, showed that the expected incidence of breech

presentation (corrected for gestational age) was higher in fetuses with a variety of congenital disorders. Specifically, infants with neuromuscular disorders had an inordinately high rate of breech presentation at delivery.^{176,177} Furthermore, McBride and associates¹⁷⁸ found that 100 children delivered in a breech presentation at term and studied at 5 years of age scored less well on motor skills than children delivered in cephalic presentations, regardless of the method by which the breech delivery was accomplished. These results suggest that, at least in some cases, the fetus remains in a breech position because it is less capable of movement within the uterus. If these concepts are accurate, the outcome for the fetus in a breech presentation could depend

to a great extent on the reason for the breech position rather than the eventual mode of delivery.

Risks to the fetus inherent in breech presentation during labor and delivery include the following:

- Prolapse of the umbilical cord (especially in the footling breech)
- Trapping of the after-coming head by the incompletely dilated cervix (particularly in preterm infants weighing less than 1500 g and in CPD)
- Trauma resulting from extension of the head or nuchal position of the arms

Wright¹⁷⁹ was the first to suggest that a policy of cesarean delivery for all breech presentations would result in the lowest possible perinatal morbidity and mortality rates. Nevertheless, most patients with a term breech presentation were delivered vaginally until the mid-1970s, when the cesarean delivery rate began to increase as a result of the concern for fetal well-being. At one university center, the rate of cesarean delivery for term breech presentation abruptly increased, from 13% in the years 1970–1975 to 54% in 1976–1977.¹⁸⁰ In that center, a detailed analysis of the eight perinatal deaths that occurred among patients with a term breech presentation who delivered vaginally after having documented criteria for safe vaginal delivery found that six of the deaths would have been prevented by planned cesarean delivery. After 1975, the rate of cesarean delivery for breech presentation increased among most obstetric services in the United States. Data combined largely from retrospective cohort studies comparing vaginal with cesarean birth for patients with term breech presentations showed a small but statistically significant increase in risk of perinatal mortality and morbidity among patients who had vaginal deliveries.^{181–183}

In 2000, Hannah and colleagues¹⁸⁴ published the results of a large multicenter, randomized, controlled trial comparing planned vaginal delivery with planned cesarean delivery in patients with a breech presentation at term. This study of 2088 subjects was terminated when an independent data monitoring committee found statistically significant evidence that perinatal morbidity and mortality were greater with planned vaginal delivery, without any significant differences in maternal mortality or serious morbidity. There were several limitations to this study: (1) fewer than 10% of women underwent x-ray pelvimetry (thought by many authorities to be essential in screening patients for safe vaginal delivery); (2) the frequency and use of oxytocin for induction or augmentation of labor were not controlled for in the regression analyses; and most importantly, (3) 22% of patients who delivered vaginally were not attended by an obstetrician, whereas this was true for only one of the patients delivered by cesarean section.^{185–187} These and other limitations notwithstanding, the results of this study confirmed the mounting evidence from most of the retrospective studies that even with careful screening of patients with a breech presentation for a trial of labor, the risk of perinatal death and serious morbidity is slightly but significantly greater for planned vaginal delivery than for planned cesarean delivery.

In light of these findings, the American College of Obstetricians and Gynecologists (ACOG)¹⁸⁸ recommended that, if external version is not successful in a woman with a breech presentation at term, the patient should be advised to undergo a planned cesarean delivery. This recommendation does not apply to patients with breech presentation of a second twin.

Long-term developmental outcome (5 years) of surviving infants delivered vaginally in a breech presentation does not

differ significantly from that of infants delivered by cesarean section because of breech presentation.^{178,189,190}

Breech Vaginal Delivery

Some authorities still take the position that, in the presence of a qualified obstetrician, a patient who fulfills criteria for safe vaginal delivery of a breech presentation can be offered this option.^{185,191,192} Because of the declining frequency of breech delivery, however, fewer obstetricians are acquiring the requisite skills to safely allow a trial of labor and vaginal delivery for patients with breech presentations. Criteria for allowing a trial of labor in a breech presentation are as follows:

- Frank or complete breech presentation
- Estimated fetal weight of 2000 to 3800 g
- Normal gynecoid pelvis with adequate measurements
- Flexed fetal head

Safe vaginal delivery of a breech presentation depends, to a great extent, on the experience, judgment, and skill of the obstetrician. If an obstetrician is unsure about his or her skills for vaginal delivery with a breech presentation, cesarean delivery is preferred.

Most authorities agree that radiographic pelvimetry has a place in selecting patients for a trial of labor when there is a breech presentation. Potter and coworkers¹⁹³ studied 13 term infants without congenital defects who died from intracranial injury as a result of vaginal breech delivery. In 7 of the 13 mothers, pelvic radiographs (five of which were obtained in the puerperium) revealed diminished pelvic capacity. In the remaining six patients, radiographs were not obtained.

Beischer¹⁹⁴ reviewed the outcome of term breech deliveries when radiography was used to help decide the delivery method. Thirteen patients were delivered by cesarean section; all infants survived. Among the 51 infants delivered vaginally, there were 4 deaths, 3 of which were the result of tentorial tears. That study, together with the report of Todd and Steer¹⁹⁵ of 1006 term breech deliveries, suggested that vaginal delivery is not safe with radiographic pelvic measurements of less than the following:

- Anteroposterior diameter of the inlet, 11 cm
- Widest transverse of the inlet, 12 cm
- Interspinous diameter, 9 cm

Any other encroachment on the space below the inlet also contraindicates vaginal delivery. Pelvimetry performed with computed tomography exposes the fetus to substantially less radiation and is performed with greater facility in most hospitals than conventional x-ray pelvimetry.^{196,197} Also, pelvimetry by magnetic resonance imaging has been used for breech presentation, but the cost and the greater time required for this procedure make it less practical than pelvimetry by computed tomography.¹⁹⁸

Not uncommonly, patients are found to be in labor with an unexpected breech presentation. This will continue to occur despite the increasing practice of planned cesarean delivery for all patients with a term breech presentation. In a study by Zatuchni and Andros,¹⁹⁹ clinical screening of patients with breech presentations at term identified mothers who safely accomplished a vaginal delivery. Screening criteria did not include radiographic pelvimetry. On admission to the hospital in labor, patients were evaluated according to a “diagnostic index” (Table 43-11). In a prospective study of 139 patients with term breech presentations that excluded patients with a prolapsed umbilical cord, severe congenital anomaly, or uterine bleeding, the authors found that perinatal mortality and

Parity	0	>1	—
Gestational age (wk)	39	38	37
Estimated fetal weight	>8 lb (3630 g)	7 lb 1 oz to 7 lb 15 oz (3176-3629 g)	<7 lb (3175 g)
Previous breech deliveries (birth weight >2500 g)	0	1	2
Dilation (cm)	2	3	4
Station	-3 or higher	-2	-1 or lower

*The index is obtained by adding the points scored for each factor. Adapted from Zatzuchni GI, Andros GJ: Prognostic index for vaginal delivery in breech presentation at term: prospective study, *Am J Obstet Gynecol* 98:854, 1967.

morbidity occurred only in those patients with a diagnostic index of 3 or lower and that cesarean delivery for all patients with such an index would have resulted in an abdominal delivery rate of 21.5%.

The method of pain control for a vaginal breech delivery is another controversial issue. Conduction anesthesia has been used with good results,²⁰⁰ and a case can be made that it prevents the mother from pushing uncontrollably in the second stage and allows for an easier and more comfortable application of the Piper forceps to the after-coming head. However, in a study of 643 singleton term breech presentations, epidural analgesia was associated with longer duration of labor, increased need for augmentation of labor with oxytocin, and a significantly higher rate of cesarean delivery in the second stage of labor.²⁰¹ An anesthesiologist can be of great assistance if there is difficulty in the delivery of nuchal arms or the after-coming head.

Fetal monitoring is essential during labor with a breech presentation. Because the fetal abdomen and the insertion of the umbilical cord are in the lower uterine segment during the late first stage and the second stage of labor, significant variable decelerations are more likely to be encountered than with cephalic presentation. For this reason, membranes should be left intact as long as possible, to provide some hydraulic protection against umbilical cord compression. Vaginal breech deliveries are more often associated with significant fetal acidosis than cephalic presentations.²⁰² Therefore, one must exercise careful judgment as to when to intervene for "fetal distress." Fetal blood samples can be obtained from the buttock if there is a suspected or ominous fetal heart rate pattern; if the pH obtained between contractions is lower than 7.20 early in the second stage, abdominal delivery should be considered.

The use of oxytocin for induction of labor or augmentation of abnormal labor in a breech presentation is controversial. In the randomized, controlled trial by Hannah and associates,¹⁸⁴ a disproportionate number (64%) of the perinatal deaths in the intended vaginal delivery arm occurred in labors that were induced or augmented with oxytocin. If oxytocin is used, it must be administered with extraordinary caution.

Skillful, atraumatic delivery, regardless of the route of birth, is essential in keeping infant morbidity to a minimum. Milner²⁰³ showed that application of forceps to the after-coming head was associated with a reduced rate of neonatal mortality from breech delivery. The well-illustrated publication by Piper and Bachman,²⁰⁴ describing the use of the forceps designed by Piper and presenting in detail the method of breech delivery, should be standard reading for all physicians planning to assist in the vaginal delivery of a breech presentation. Even when the delivery is cesarean, forceps should be available (use of Piper forceps is not necessary), and they should be applied through the uterine incision to the after-coming head if there is any difficulty with its extraction. Calvert²⁰⁵ found that infants in breech presentation born by cesarean section had a higher incidence of birth asphyxia than a comparable group of infants in cephalic presentation born by cesarean. A uterine incision does not ensure an atraumatic delivery of an infant, especially one in a breech presentation.

External Version

External version substantially reduces the incidence of term breech presentation.^{206,207} If the procedure is performed at 36 weeks' gestation, the success rate is approximately 65%. Complications that require immediate delivery, including placental separation and umbilical cord compression, occur in 1% to 2% of patients. The procedure is performed late in gestation and with cesarean delivery capability available, so that prompt delivery can be accomplished if persistent umbilical cord compression or premature separation of the placenta occurs. Tocolytic medications have been used in most series to prevent uterine contractions during the procedure, and the evidence shows that their use improves the success rate of external version.²⁰⁸ Some have found that epidural analgesia, used either with the initial attempt or after a first attempt has failed, improves the success rate of external version, but the extant studies are not large enough to determine the safety of this practice or its cost-effectiveness.²⁰⁹⁻²¹¹

Overall, for patients who undergo external version of a breech presentation at 36 weeks' gestation, the risk of cesarean delivery is reduced by 50%. In addition to a reduced morbidity risk for mother and infant, the cost savings are substantial.²¹² Chan and coauthors²¹³ compared delivery outcomes in pregnancies that had undergone successful external cephalic version for breech presentation and pregnancies with singleton vertex presentations without external version. After successful external version, patients had significantly higher rates of instrumental delivery and emergency cesarean delivery. The higher risk of operative delivery was the result of an increase in several major indications: fetal heart rate abnormalities, failure of labor to progress, and failed induction of labor. It is apparent that external cephalic version, even when successful, does not eliminate all of the risks inherent in breech presentation.

Contraindications to external version include the following:

- Uterine anomalies
- Third-trimester bleeding
- Multiple gestation
- Oligohydramnios
- Evidence of uteroplacental insufficiency
- A nuchal cord identified by ultrasonography
- Previous cesarean delivery or other significant uterine surgery
- Obvious CPD

Primiparity, maternal obesity, advanced gestation, anterior implantation of the placenta, and excessive fetal weight have been associated with decreased success of external version but are not in themselves contraindications.

The procedure should be performed in a hospital in which cesarean delivery can be accomplished if unrelenting fetal distress occurs. A real-time ultrasonographic scan is performed to confirm the breech presentation; to detect multiple gestation, oligohydramnios, or fetal abnormalities; and to measure fetal dimensions.

After a reactive nonstress test, a tocolytic drug is administered (terbutaline sulfate, 0.25 mg subcutaneously). (Some obstetricians prefer to first attempt version without tocolysis, proceeding with external version under tocolysis if this is unsuccessful.) After the uterus relaxes, the version is attempted. One person can elevate and laterally displace the breech while a second person manipulates the fetal head in the opposite direction. Mineral oil on the abdomen facilitates movement of the hands during the procedure. A forward roll is attempted; if this is unsuccessful, a backward roll is tried. The fetal heart rate should be monitored intermittently with Doppler or real-time scanning. Fetal bradycardia occurs in about 20% of cases but almost always subsides after the manipulation ceases. External fetal heart rate monitoring is continued for 1 hour, after which the patient is discharged. Patients who are Rh-negative and who have a negative antibody titer should be given 1 unit (300 µg) of Rh immune globulin because of the risk of fetal-maternal transfusion associated with version (6% to 28%).^{214,215}

TRANSVERSE LIE

Transverse lie occurs in approximately 1 of every 300 deliveries.²¹⁶ Cruikshank and White,²¹⁷ reporting on 118 shoulder presentations, found that prematurity (38%) and high parity (87% of patients had already borne three or more infants) were the two most frequently associated conditions. Premature rupture of the membranes (30%) and placenta previa (10%) are also more common in transverse lie than in longitudinal presentation. The high perinatal mortality rates (3.9% to 24%) associated with transverse lie²¹⁶ are almost surely a result of the high prevalence of low-birth-weight infants in shoulder presentations, although prolapse of the umbilical cord occasionally results in perinatal death of a term infant in transverse lie. These accidents typically happen unexpectedly, when spontaneous rupture of the membranes occurs outside the hospital setting. In such cases, the patient is usually admitted to the hospital with a severely asphyxiated or dead fetus.

The diagnosis can usually be made by palpation of the abdomen. Not infrequently, the patient notices that the fetus is in an unusual position and draws this fact to the physician's attention. The fetal position can be confirmed by real-time ultrasonography.

Management of the patient with a confirmed diagnosis of transverse lie depends on the length of the gestation, the size of the fetus, the position of the placenta, and whether the membranes have ruptured. If the patient is in labor with a transverse lie and the expected fetal weight and gestational age are below those compatible with a reasonable (10%) chance of survival, no intervention is necessary beyond attempts to stop labor in the interest of increasing fetal weight and maturity before delivery. A fetus of this size (usually <600 g) eventually is delivered vaginally in shoulder presentation (*conduplicato corpore*)

without undue trauma to the mother. If the gestational age or expected fetal weight is such that the chance for neonatal survival, in the absence of severe asphyxia or trauma, is greater than 10%, cesarean delivery is usually necessary, especially if the membranes are ruptured or placenta previa is present.

The role of external version in the management of transverse lie is highly controversial. Before 36 to 37 weeks' gestation in patients who are not in labor, external version should not be attempted because of the danger of cord entanglement or placental trauma and the difficulty of maintaining the normal axial lie after version. Moreover, there is the possibility that spontaneous version to a longitudinal lie will occur with additional growth and maturity of the fetus or with the onset of contractions. However, if a transverse lie is identified at or beyond 36 to 37 weeks' gestation in a patient with intact membranes and CPD and placenta previa are not present, external version often results in a longitudinal lie and a normal vaginal delivery.

Edwards and Nicholson²¹⁸ demonstrated the benefits of a policy of admitting to the hospital all patients beyond 37 weeks' gestation in whom "unstable lie" is diagnosed. Their protocol in such patients was to search for etiologic factors and then, provided CPD and placenta previa were excluded, to perform external version followed by induction of labor after 38 weeks' gestation. In 102 cases so managed, 86 patients delivered vaginally, with only 1 case of cord prolapse and no perinatal deaths. In contrast, in 50 cases of unstable lie at or beyond 37 weeks' gestation in which the onset of spontaneous labor was awaited, there were 10 cases of prolapsed cord and 4 perinatal deaths. This experience suggests that, when a transverse or oblique lie is identified at or beyond 37 weeks' gestation, thorough etiologic evaluation and admission to the hospital should be considered.

If fetal mobility is restricted by well-advanced labor or the absence of amniotic fluid, or if placenta previa or CPD is detected, abdominal delivery in transverse lie is mandatory. Most authorities advise a low vertical or classic uterine incision in such cases, although Cruikshank and White²¹⁷ found an extraordinarily high maternal morbidity rate (severe intraperitoneal infection, 21%; maternal death, 8.3%) associated with classic incisions for delivery in shoulder presentations. The low transverse incision often suffices in cases of a back-up transverse lie, and the high transverse incision described by Durfee²¹⁹ can be used in cases of a back-down shoulder presentation.

Finally, a technique of intra-abdominal version to allow the use of a low transverse incision has been described.²²⁰ Use of a transverse rather than a vertical incision decreases the overall maternal morbidity of cesarean delivery by reducing acute puerperal complications associated with vertical incisions and by allowing the option of managing subsequent pregnancies with a trial of labor and vaginal delivery. However, uterine incision should always be chosen with the primary purpose of abdominal delivery in mind (i.e., to avoid fetal trauma and asphyxia).

DEFLECTION ABNORMALITIES

Brow and face presentations are manifestations of different degrees of deflection of a cephalic presentation and therefore can be considered together. Seeds and Cefalo²¹⁶ reviewed the literature regarding brow and face presentations. Each occurs with a frequency of about 1 in 500 deliveries, although the incidence probably would be higher if all fetal presentations

were assessed carefully early in labor. About 50% of such diagnoses are not made until the second stage of labor; many of the deflection problems detected early in labor correct themselves spontaneously as labor progresses.

With the exception of anencephaly, which almost always results in a face presentation, fetal anomalies do not seem to account for deflection problems in labor. Commonly reported etiologic factors in brow and face presentations include

- CPD
- Increased parity
- Prematurity
- Premature rupture of membranes

Apart from prematurity and anencephaly, the major problem associated with deflection presentations is dysfunctional labor in brow presentations. Friedman³ found that face presentation, contrary to generally held clinical impressions, did not appear to affect the course of labor significantly in either nulliparas or multiparas.

Brow presentation, in contrast, was associated with abnormalities of descent and longer second stage of labor compared with vertex presentation in matched controls. This is not surprising, because in brow presentation the largest dimension of the head, the mento-occipital diameter, must negotiate the inlet of the pelvis. Consequently, successful descent, rotation, and delivery of a brow presentation in the term infant depend on conversion to either a face or a vertex presentation. Moreover, it is often the delay in labor associated with this conversion that results in a more careful assessment of fetal position and the recognition of a brow presentation. Perinatal mortality rates for brow and face presentations are higher than for vertex presentations, but the differences can be accounted for by fetal anomalies (anencephaly), prematurity, and asphyxia and trauma associated with manipulation during vaginal delivery.

Management begins with recognition of the abnormality. Awareness and diagnosis of deflection problems are enhanced by an emphasis on careful vaginal examination and a description of the position and characteristics of the presenting fetal part as an essential element in labor monitoring. If, on vaginal examination, the lambdoid sutures and posterior fontanelle cannot easily be identified as occupying a central position in the pelvis, an abnormal presentation or deflection of a cephalic presentation must be suspected. Palpation of the anterior fontanelle or one of the orbits clearly identifies a deflection problem. Furthermore, in cases of abnormal descent or prolonged second stage of labor, deflection of the fetal head should be considered one of the possible causes, and the patient should be reevaluated with this in mind.

If deflection of the fetal head is identified in association with abnormal progression of labor, CPD must be suspected. Friedman³ found that 10.9% of patients with brow presentation had clinical and radiographic evidence of CPD, compared with 2.7% of controls with vertex presentations. If progress of labor is arrested and CPD is suspected, cesarean delivery is indicated. If labor progresses and there is evidence of resolution of a brow presentation to either a face or a vertex presentation, labor should be managed with the expectation of vaginal delivery. If labor is arrested and there are poor uterine contractions in the absence of CPD, the use of a carefully monitored course of oxytocin augmentation may be warranted. Seeds and Cefalo²¹⁶ suggested that radiographic pelvimetry be considered in these situations to exclude CPD.

Most brow presentations convert spontaneously to either a face or a vertex presentation, and 70% to 90% of face presentations result in spontaneous delivery. If the brow presentation fails to convert or the face presentation rotates to a persistent mentum posterior, cesarean delivery is required. If uncorrectable fetal distress occurs, labor should be terminated by abdominal delivery. It is generally agreed that rotating the fetal head or converting its deflection position either manually or with forceps is excessively dangerous to fetus and mother.

COMPOUND PRESENTATION

A compound presentation exists if an extremity is adjacent to the presenting part. This complication of labor occurs in approximately 1 of every 1000 deliveries and is associated with high rates of prematurity (31% to 61%) and fetal mortality (16% to 22%).^{217,221,222} Cord prolapse, which occurs in 11% to 20% of cases, is the most common intrapartum complication.²¹⁶ The vertex-arm combination is the most frequent compound presentation and has the best prognosis.

Management includes early diagnosis and fetal monitoring, with retraction of the presenting extremity and normal vaginal delivery occurring in most cases. If fetal distress or cord prolapse occurs or labor progress ceases, abdominal delivery should be accomplished promptly. Stimulation or manipulation of the presenting extremity to encourage retraction within the uterus is controversial.

Cruikshank and White²¹⁷ reported that, of 32 compound presentations, the presenting extremity could be manually replaced in 16 cases, resulting in uneventful vaginal delivery in 15 of the patients. On the other hand, Seeds and Cefalo,²¹⁶ in their review of the literature regarding compound presentation, advised against manipulation of the prolapsed part. Indeed, spontaneous retraction of the extremity occurs so frequently that attempts to replace it may not be necessary and may, in certain cases, encourage prolapse of the umbilical cord.

Operative Delivery

CESAREAN DELIVERY

The evolution of cesarean delivery as a safe procedure with extraordinarily low maternal and fetal mortality rates is one of the most important developments in modern perinatal medicine. Maternal mortality rates from cesarean operations in the 19th century were 85% or greater, with the operation being performed only in the most extraordinary circumstances to save the life of the mother.²²³ By the early decades of the 20th century, several important innovations in surgical care had occurred, including aseptic technique, reliable anesthesia, and the control of hemorrhage by proper suturing of tissue planes as well as ligation of severed blood vessels. Specifically for the cesarean operation, introduction of the low-segment incision, which allows exclusion of the uterine wound from the peritoneal cavity, dramatically decreased the risk of postoperative peritonitis as a complication of puerperal endometritis.²²⁴

The later additions of blood transfusion and antibiotic therapy further reduced the morbidity and mortality of cesarean delivery to the extent that, in 1950, D'Esopo published a remarkable study reporting 1000 consecutive cesarean deliveries without a single maternal death.²²⁵ The decrease in maternal morbidity associated with cesarean delivery made the operation

a reasonable alternative for delivery of fetuses at increased risk for asphyxia or trauma from labor and vaginal delivery. This decrease, together with more sophisticated methods of detecting chronic and acute fetal distress (e.g., ultrasonography, continuous fetal heart monitoring, fetal scalp blood sampling), changed the indications for and frequency of cesarean section for delivery.

Before 1960, cesarean deliveries comprised fewer than 5% of births and were performed primarily for maternal indications such as placenta previa, radiographically documented CPD, failure of induction of labor in severe preeclampsia, and repeat cesarean delivery.²²⁶ After 1960, with the emergence of fetal diagnostic and monitoring techniques, cesarean delivery rates gradually increased worldwide and were more commonly performed for fetal indications.^{227,228} The rate and duration of the increase varied; in the United States, the rate of cesarean delivery reached a peak of 23.5% in 1988.²²⁹ Four indications were found to account for 90% of the increase in the United States: dystocia, repeat cesarean delivery, breech presentation, and “fetal distress.”²³⁰ Although new indications for cesarean delivery, such as fetal spinal or abdominal wall abnormalities and prevention of vertical transmission of certain infectious diseases, played a small role in this increase, a more important effect was a lowered threshold for the standard indications.²³¹ Fear of litigation also played a role in the rise in cesarean delivery rates, not only in the United States but also in the United Kingdom.²³² Although it has been suggested that the rate of cesarean delivery is linked to physician reimbursement, the increase in cesarean delivery rates in countries that have global obstetric fees (e.g., Australia) suggests that financial incentive alone cannot account for the rise in cesarean delivery rates.²³³

In some countries, such as Brazil and Chile, the increase in the cesarean delivery rate has been well beyond that which could be accounted for by obstetric or medical indications.^{234,235} In these countries, the increase has occurred largely as a result of an increase in prelabor elective cesarean delivery, presumably for the convenience of patients or doctors. This phenomenon has occurred primarily, although not exclusively, among women in upper income levels. There is debate as to whether this has resulted from a patient population that is well educated in the risks and benefits of vaginal versus cesarean delivery and exercising their right of patient autonomy or a patient population that has been overly influenced and biased by health care providers to choose cesarean delivery.²³⁶

In the 1990s, interest emerged in the role of cesarean delivery to prevent pelvic floor dysfunction that has been attributed to vaginal birth. The risk of urinary incontinence at 6 months after delivery is twofold greater for women who have a spontaneous vaginal delivery than for those who have a cesarean delivery.²³⁷ In a large, multicenter, prospective, randomized, controlled trial of planned prelabor cesarean delivery compared with planned vaginal delivery in women with a term breech presentation, urinary incontinence was less common at 3 months after cesarean delivery (relative risk, 0.62; 95% confidence interval [CI], 0.41 to 0.93).²³⁸ The long-term effects of vaginal delivery on urinary continence are less clear-cut. Buchsbaum and colleagues²³⁹ found no significant difference in the incidence of urinary incontinence in nulliparous versus parous postmenopausal women. In a large, population-based study in Australia, MacLennan and associates²⁴⁰ found that the incidence of long-term pelvic floor dysfunction, including urinary incontinence, was greater in women who had operative vaginal deliveries than

in those who had cesarean deliveries. However, there was no difference in incidence of pelvic floor dysfunction with cesarean versus spontaneous vaginal delivery.

Sultan and colleagues²⁴¹ found that forceps delivery and episiotomy were risk factors for anal sphincter lacerations, whereas vacuum-assisted delivery and cesarean delivery were protective. Other studies found that cesarean delivery was associated with a reduced incidence of fecal incontinence if it was performed before onset of the second stage of labor.²⁴² Associations between the method of delivery and long-term anal sphincter function are less clear. Nygaard and associates,²⁴³ in a 30-year follow-up study of anal incompetence, found that the aging process was as important as obstetric events.

Notwithstanding the mounting evidence of an untoward effect of vaginal delivery (especially forceps delivery) on postpartum pelvic floor dysfunction, prospective randomized trials with adequate follow-up are necessary to adequately evaluate the effect of various methods of delivery on long-term pelvic floor function. There is currently insufficient evidence to recommend elective cesarean delivery to prevent long-term urinary or anal incontinence.

Finally, a number of the common risk factors for cesarean delivery—fetal macrosomia, advanced maternal age, increased maternal BMI, gestational diabetes, multiple pregnancy, and dystocia in nulliparous women—are increasing in frequency, especially in developed countries.

Cesarean delivery rates vary widely worldwide, from as low as 5% in Bolivia to as high as 40% in Chile.²³³ In the United States, the rate of cesarean deliveries declined 8% between 1991 and 1996 but has steadily increased thereafter, primarily because of a decline in vaginal births after previous cesarean deliveries,²⁴⁴ reaching 32.9% of all births in 2009 but remaining at that level since then.²⁴⁵

It seems unlikely that the cesarean delivery rate in the United States or in most developed countries will ever be as low as 15%, which is the goal of the World Health Organization.²⁴⁶ The cesarean delivery rate will not reach this level and is likely to increase gradually for the following reasons:

- There is a heightened sensitivity to, and lowered threshold for, using cesarean delivery for the traditional indications.
- There is an increased proportion of pregnant women whose pregnancies are complicated by the conditions for which cesarean delivery is necessary.
- There are evolving new indications for cesarean delivery, albeit indications that are variously supported by reliable evidence.
- Emphasis on patient autonomy in making decisions about method of delivery will result in women’s vulnerability to bias and non-evidence-based information about the relative risks and benefits of cesarean delivery.
- The benefits of a trial of labor for women with a previous cesarean delivery are equivocal.
- Fear of litigation will persist in the absence of tort reform.

Visco and colleagues from the University of North Carolina conducted a systematic evidence review on the topic of cesarean delivery on maternal request.²⁴⁷ After a review of 1406 articles, they concluded that the evidence about this approach to childbirth is “significantly limited” and that the literature is confounded by having studied *actual* route of delivery rather than the *planned* route. They could make no conclusions on the effectiveness and safety of cesarean delivery on maternal request

and called for the establishment of a CRT code that could document this indication. A 2006 NIH consensus conference came to similar conclusions. (The final statement and video from that event are available at <http://consensus.nih.gov/cesarean.htm> [accessed June 17, 2013]).

Another factor that tends to increase the rate of cesarean delivery is the waning enthusiasm for a trial of labor in women who have had a previous cesarean delivery. This has occurred as a result of an increase in the number, if not the incidence, of untoward fetal and maternal consequences of uterine rupture. In the 1980s, the incidence of vaginal birth after a previous cesarean (VBAC) increased in response to initiatives to control the rising cesarean delivery rate. Consequently, more physicians experienced one or more cases of uterine rupture, even though the incidence of symptomatic scar separation remained constant at about 0.5%. Relatively large population-based, retrospective studies have found the overall risk of serious maternal complications (e.g., uterine rupture, hysterectomy) to be twofold to threefold higher for a trial of labor after a previous cesarean compared with a repeat elective cesarean delivery.^{248,249} In a large, population-based study from Scotland comparing perinatal outcomes (not related to congenital abnormalities) for women who had a trial of labor after a previous cesarean delivery compared with those who had an elective repeat cesarean delivery, the risk of delivery-related perinatal death in the former group (12.9/10,000) was 11 times greater than with repeat cesarean.²⁵⁰

Zhang and coworkers²⁵¹ studied contemporary cesarean delivery practice in the U.S. Among 228,668 births in 19 U.S. hospitals, the overall abdominal delivery rate was 30.5%. Uterine scars resulted in pre-labor repeat cesarean delivery as the indication in 30.9% of abdominal deliveries. Only 28.8% of women who had a prior cesarean section attempted vaginal birth, and 57.1% were successful. More than 40% of women had their labor induced. Half of the cesarean sections for dystocia in induced labor occurred before 6 cm of dilation (Fig. 43-11).

The authors emphasized the need to prevent unnecessary primary cesarean deliveries and identified induction practice as an ideal place to start.

Complications of Cesarean Delivery

Maternal Complications. Although cesarean delivery is a reasonably safe surgical procedure, it is generally regarded as being associated with higher risks of morbidity and mortality than vaginal delivery. Data from the Professional Activities Survey of the Commission of Professional and Hospital Activities for the year 1978, which included about 1 million births and 100,000 cesarean deliveries, showed the rates of maternal death per 100,000 births to be 9.8 for vaginal deliveries, 40.0 for all cesarean deliveries, and 18.4 for “repeat” cesarean deliveries.²³⁰ Others have documented lower risks for cesarean delivery. Sachs and colleagues,²⁵² reviewing cesarean delivery–related mortality in Massachusetts in the period 1954–1985, found that the rate of death directly related to cesarean birth was 5.8 per 100,000 procedures. Frigoletto and coworkers²⁵³ reported on 10,231 consecutive cesarean deliveries at Boston Hospital for Women between 1968 and 1978 without a single maternal death. Varying definitions of maternal mortality and failure to control for the confounding influences of parity, maternal age, and medical and obstetric complications account for some of the differences in maternal mortality rates associated with cesarean delivery. In a study of 250,000 deliveries, Lilford and associates²⁵⁴ found a sevenfold relative risk of death associated with cesarean delivery compared with vaginal delivery when preexisting medical conditions were excluded. The same authors found that the relative risk of dying from a nonelective cesarean birth compared with an elective cesarean birth when preexisting medical conditions were excluded was 1.5. A population-based study in Washington State (1987–1997) that controlled for parity, maternal age, severe preeclampsia, and deaths unrelated to pregnancy found no significant increase in maternal mortality related to cesarean delivery.²⁵⁵

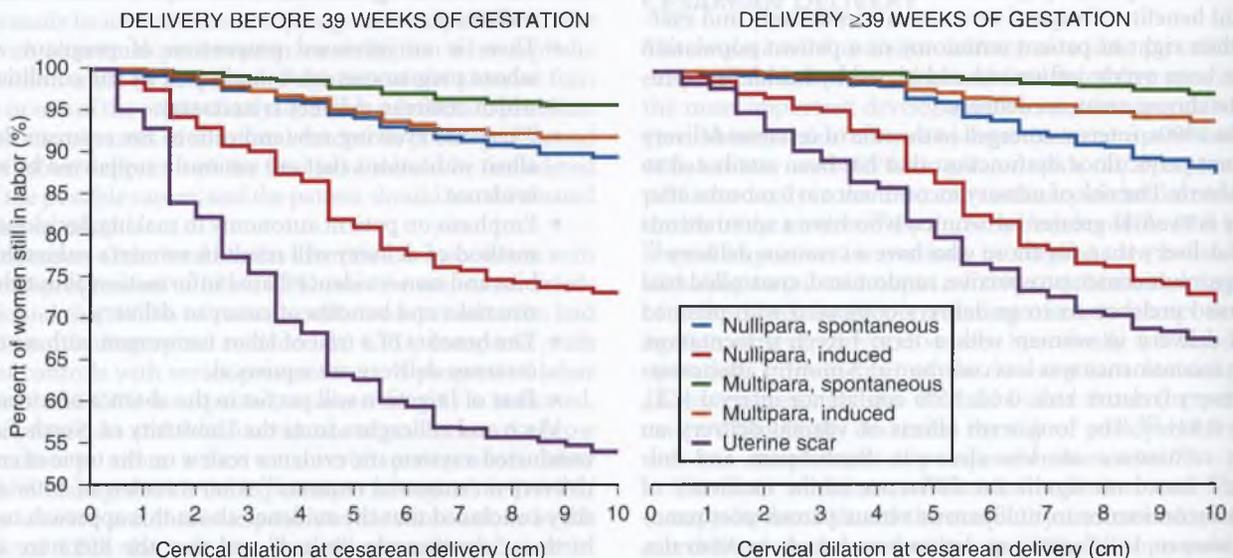

Figure 43-11 Cervical dilation at cesarean delivery. Cervical dilation at intrapartum cesarean delivery among women attempting vaginal delivery by parity, onset of labor (induced versus spontaneous onset), and previous uterine scar in singleton gestations. (From Zhang J, Troendle J, Reddy UM, et al; for the Consortium on Safe Labor: Contemporary cesarean delivery practice in the United States, *Am J Obstet Gynecol* 203:326.e1, 2010.)

It is apparent that the risks of morbidity and mortality of cesarean delivery are influenced by the associated medical complications in the patient requiring abdominal delivery and the skill of the medical team performing the procedure. Serious intraoperative complications occur in approximately 2% of cesarean deliveries and include anesthesia accidents (e.g., problems with intubation, drug reactions, aspiration pneumonitis), hemorrhage, bowel or bladder injury, amniotic fluid embolism, and air embolism.²⁵⁶

Frequently, cesarean delivery must be performed under emergency conditions soon after the patient is admitted to the hospital. Patient anxiety, obesity, an incompletely emptied stomach, acute hemorrhage from a placental accident, low blood volume and constricted vascular space in association with pregnancy-induced hypertension, and hypotension secondary to vena caval and aortic compression by the pregnant uterus are just a few of the problems frequently encountered in patients requiring emergency cesarean delivery. These problems challenge even the most skilled anesthesiologist. On some occasions, an emergency cesarean delivery must be performed with such haste that sterile and surgical techniques are compromised.

Urinary tract injuries, which occur in 1 or 2 per 1000 deliveries, are 10 times more common in cesarean deliveries than in operative vaginal deliveries.²⁵⁷ Most of the injuries that occur with cesarean delivery are simple bladder lacerations that are promptly identified and repaired without sequelae. Bowel injuries are often associated with intraabdominal adhesions from previous cesarean deliveries or other abdominal surgeries. Some intraoperative complications, such as amniotic fluid embolus syndrome and air embolus, are extremely rare and usually not preventable.

The following are postpartum maternal complications associated with cesarean delivery:

- Atelectasis
- Endomyometritis
- Urinary tract infection
- Abdominal wound hematoma formation, dehiscence, infection, or necrotizing fasciitis
- Thromboembolic disease
- Bowel dysfunction—adynamic ileus, pseudo-obstruction of the cecum (Ogilvie syndrome), and sigmoid volvulus

Duff²⁵⁸ found that, with the use of prophylactic antibiotics, the rate of febrile puerperal complications for cesarean delivery in a university obstetric service was 5% to 10% (see Chapter 51). Watson and colleagues²⁵⁹ found that febrile morbidity occurred in only 2.3% of high-risk private patients who underwent cesarean delivery. The rate of febrile morbidity in patients undergoing cesarean delivery without labor was only 0.5%. These studies emphasized the fact that low socioeconomic status and labor are important risk factors for postpartum febrile morbidity after cesarean delivery.

Postcesarean endomyometritis is a polymicrobial infection characterized by abdominal pain, malaise, anorexia, fever, uterine tenderness, and malodorous lochia. Prompt diagnosis and proper selection of antibiotic therapy for patients who become symptomatic with endomyometritis is important. In a systematic review of 47 trials comparing various antibiotic regimens for treatment of puerperal endometritis, French and Smaill²⁶⁰ found that the combination of clindamycin and gentamicin administered intravenously was more effective than other regimens. Regimens with activity against penicillin-resistant anaerobic bacteria were superior to those without this coverage.

Furthermore, they found that oral follow-up treatment was not necessary once the clinical signs indicated improvement.

Postcesarean bacteriuria occurs in approximately 11% of patients and is related largely to routine urethral catheterization.²⁶¹ Studies have shown that the risk of urinary tract infection after cesarean delivery can be reduced substantially by eliminating catheterization or by using intermittent rather than indwelling catheterization.^{262,263}

Wound hematomas are usually caused by faulty hemostasis and respond to drainage of the hematoma. The use of prophylactic antibiotics has substantially decreased the incidence of postcesarean abdominal wound infections, which now occur in no more than 3% of cesarean deliveries.^{264,265} Cesarean deliveries performed in the second stage of labor carry greater risk for wound infection, and obesity and the use of suprafascial drains are also risk factors. Obese women are at increased risk for development of necrotizing fasciitis, one of the most serious and potentially fatal consequences of wound infection.²⁶⁶ Between 25% and 30% of wound infections are caused by *Staphylococcus aureus*; these infections do not usually originate from wound contamination from the endometrium. For this reason, attention to sterile technique and proper wound care are essential for patients undergoing cesarean delivery.

Puerperal deep venous thrombosis occurs in 1% to 2% of patients delivered by cesarean section.²⁶⁷ Although pulmonary embolism is rare, it is one of the major causes of maternal mortality. Obesity, prolonged operative procedures, endometritis, and any inherited thrombophilia are risk factors. Treatment is intravenous heparinization followed by oral anticoagulants, the duration of which depends on the severity of the disease and whether the patient is found to have an inherited thrombophilia. Postoperative pelvic thrombophlebitis is a diagnosis made by exclusion when puerperal fever does not respond to antibiotic therapy but resolves with heparin treatment. Ovarian vein thrombosis can be recognized in patients with postoperative abdominal pain and a palpable tender mass extending from the lower quadrant into the flank, usually on the right side. Prophylactic heparinization is commonly used in the United Kingdom and Europe for both elective and emergency cesarean deliveries, but in the United States it is used only in patients at high risk for thromboembolism.^{268,269} There is no consensus as to whether an evaluation for inherited thrombophilia should be recommended for all patients with postcesarean deep venous thrombosis or pulmonary embolism. Clearly, such testing is in order if there is a family history of thromboembolism.

Postoperative adynamic ileus is not uncommon after cesarean section, especially if the bowel has been manipulated during the surgery. Kammen and colleagues,²⁷⁰ in a study of 21 patients who underwent abdominal radiography because of obstructive symptoms after cesarean delivery, found radiographic signs of distal colonic obstruction in 15. All 21 patients had rapid clinical and radiographic improvement on conservative management, confirming the eventual diagnosis of transient postoperative ileus. A more serious problem is postcesarean pseudocolonic obstruction with marked dilation of the cecum (Ogilvie syndrome). Although the etiology and pathogenesis of this syndrome are not clear, early recognition and surgical decompression are necessary to avoid rupture of the cecum.²⁷¹

Prophylactic antibiotics, regional anesthesia, early ambulation, and intermittent rather than indwelling urethral catheterization all have contributed to reducing the incidence of postcesarean febrile complications.

The incidence of long-term complications of cesarean delivery is more difficult to document. These complications include the following:

- Cesarean delivery in a subsequent pregnancy
- Uterine rupture in a subsequent pregnancy
- Placenta previa or placenta accreta in a subsequent pregnancy
- Ectopic pregnancy
- Infertility
- Bowel obstruction resulting from intraabdominal adhesions
- Decision to limit family size
- Fewer subsequent pregnancies

In the United States, the incidence of repeat cesarean delivery is greater than 75%. Among women who have a trial of labor after a previous cesarean delivery in which a low-transverse uterine incision was used, the risk of uterine rupture is 0.5% to 1.0%.²⁷² This risk has remained remarkably constant for decades. The risk is substantially increased after the classic (i.e., fundal) cesarean incision. Ananth and associates,²⁷³ in a systematic review of 36 studies published from 1950 through 1996, found that women who had a cesarean delivery were at twofold to threefold greater risk for placenta previa in the subsequent pregnancy compared with women who had a vaginal delivery, and the risk increased with the number of prior cesarean deliveries (see Chapter 46). A more recent, population-based, retrospective study of births in the state of Washington found a somewhat lower but statistically significant risk of placenta previa (odds ratio [OR] = 1.4; CI, 1.1 to 1.6) for the next pregnancy after a first-birth cesarean.²⁷⁴ Some authors also have found an association between previous cesarean delivery and placenta accreta in subsequent pregnancies,²⁷⁵ but this association is more difficult to document because of the rarity of placenta accreta (see Chapter 46). Although there is controversy as to whether there is an increased risk of ectopic pregnancy after cesarean delivery, there are a number of reports of ectopic pregnancies occurring in the uterine incision.²⁷⁶⁻²⁷⁸ Somewhat less controversial is the increased risk of infertility for patients delivered by cesarean.²⁷⁹ Postcesarean infertility is not explained by increased maternal age or by voluntary infertility, but it may be related to fallopian tube damage from postpartum infection.

Neonatal Complications. It appears that the safest, most atraumatic method of delivery for an infant is by cesarean section, and the increase in cesarean delivery rates after 1960 undoubtedly was fueled, in part, by concerns about the dangers to the fetus of labor and vaginal delivery in certain situations. Nevertheless, abdominal delivery is also associated with uncommon but significant dangers to the infant, including the following:

- Fetal asphyxia resulting from uteroplacental hypoperfusion induced by conduction anesthesia or maternal position
- Neonatal respiratory morbidity
- Scalpel lacerations

Maternal hypotension and its deleterious effect on uteroplacental perfusion are well-known dangers of the supine position. Conduction anesthesia, by blocking vasoconstriction in the lower extremities through the sympathetic nervous system, can further reduce cardiac output and further compromise uterine blood flow. Corke and associates²⁸⁰ demonstrated that even

brief (2-minute) episodes of hypotension result in umbilical blood gas values consistent with metabolic acidosis.

Cesarean delivery has long been recognized to be associated with an increase in neonatal respiratory morbidity at all gestational ages.²⁸¹⁻²⁸³ The frequency of this complication, its specific etiology and pathophysiology, and the mortality rate associated with it are all matters of dispute. The incidence of severe respiratory morbidity in infants born by elective cesarean delivery near term is inversely related to gestational age. Wax and colleagues¹⁶¹ found that infants born by elective cesarean delivery at 37 and 38 weeks' gestation had greatly increased risks of severe respiratory morbidity requiring mechanical ventilation (38-fold and 13-fold, respectively), compared with those born at 39 or 40 weeks' gestation. This syndrome could be related to a number of problems without a clear-cut and similar pathophysiology in each case, but the common denominator is cesarean delivery, especially when it is performed in the absence of labor. Morrison and coauthors,²⁸⁴ in a study of 33,289 deliveries at or after 37 weeks' gestation, found that the incidence of neonatal respiratory morbidity was significantly higher for the group delivered by cesarean section before labor (35.5/1000) compared with those delivered by cesarean section during labor (12.2/1000) (OR = 2.9; CI, 1.9 to 4.4).

Some cases of respiratory morbidity after cesarean delivery result from true iatrogenic prematurity, in which inaccurate gestational dates result unexpectedly in a premature infant. Even careful attention to the duration of pregnancy and use of amniotic fluid tests of fetal lung maturity have not completely eliminated this problem. Schreiner and colleagues²⁸⁵ and Heritage and Cunningham²⁸⁶ suggested that neonatal respiratory disease after elective repeat cesarean delivery—usually manifested as mild transient tachypnea of the newborn (wet lung syndrome)—is, in its most severe form, persistence of the fetal circulation. These observations, together with the studies of Boon and associates²⁸⁷ demonstrating the reduced air volume in the lungs of infants delivered by cesarean section compared with those delivered vaginally, suggest that neonatal respiratory disease after cesarean delivery is caused by incomplete adaptation of the fetal lung to extrauterine respiration. The specific sequence and timing for this adaptation to extrauterine cardiorespiratory status are unknown; nor is it known whether the physiologic and mechanical events of labor and delivery are necessary to complete pulmonary adaptation. The higher incidence of neonatal respiratory morbidity associated with repeat cesarean delivery in patients not in labor compared with those who are in labor suggests that labor is the signal that crucial physiologic changes have occurred to prepare a fetus for extrauterine life.

Accidental lacerations of the fetus occur in 1% to 2% of cesarean deliveries.^{288,289} The frequency of these accidents appears to be related to the experience of the surgeon, the most common situation being a well-thinned-out lower uterine segment in a patient who has ruptured membranes; in such cases, the uterus at the incision site may be only 2 or 3 mm thick. Usually, these inadvertent scalpel lacerations of the fetus are of only cosmetic importance, but we know of one infant who died as a result of a thrombosis of the sagittal sinus secondary to a scalpel incision incurred during cesarean delivery.

Cesarean delivery also imparts added risks for infants of future pregnancies, including fetal death resulting from antepartum rupture of uterine incisions and neonatal respiratory disease associated with subsequent elective cesarean delivery.²⁴⁷

Indications for Cesarean Delivery

Reducing the frequency of maternal and neonatal complications of cesarean delivery begins with a proper respect for the dangers of the procedure and careful selection of patients to be delivered in this manner. In general, cesarean delivery is indicated any time delivery must be accomplished and induction of labor, a trial of labor, additional labor, or vaginal delivery of the fetus is deemed to be of greater risk to the mother or the fetus than abdominal delivery. This straightforward generalization, although constituting a more rational approach than a simple list of absolute indications for the operation, does not do justice to the complexities of the decision in each case.

As the fetal indications for cesarean delivery have multiplied, so have the dilemmas of balancing the benefits and risks of operation for the mother and the fetus. For example, in placenta previa, vaginal delivery subjects both mother and fetus to unacceptable risks of exsanguination, and cesarean delivery is clearly in the best interests of both patients. In the case of a difficult mid-forceps delivery for fetal distress or failure of progress in the second stage of labor, the fetus will most certainly benefit from an expeditious abdominal delivery, but the mother's risks from cesarean versus vaginal delivery are a matter of serious debate. At the other end of the spectrum is the case of a footling breech presentation or genital herpes simplex infection, in which the operation is performed entirely for the benefit of the fetus, with no advantages to the mother apart from the reassurance that it may help her infant. Countless other situations could be used as examples of the difficult decision that faces both physician and patient when evaluating the proper method of delivery. One of the most recent examples, ironically, is the interest in nulliparous patients being considered as candidates for elective cesarean delivery in the absence of the usual indications for abdominal delivery. Studies that have linked postpartum urinary and anal incontinence to vaginal delivery have encouraged some women, especially nulliparas, and their obstetricians to consider elective cesarean delivery at term to reduce the risk of pelvic floor dysfunction. Harer²⁹⁰ summarized the arguments in support of such a practice. As noted earlier, however, there is insufficient evidence from adequate prospective trials to determine the long-term consequences of alternative methods of delivery on pelvic floor function or to support a recommendation for elective cesarean section to reduce the risks of urinary and anal sphincter incontinence.

The Consensus Development Statement on Cesarean Childbirth²³⁰ did much to clarify the indications for cesarean delivery and to draw attention to specific situations in which the need for cesarean delivery can be reduced by thorough evaluation of the patient and the facility.

The problem of dystocia, which includes both proven CPD and the less well-defined problem of "failure of labor to progress," was found to account for 30% of the increase in cesarean delivery rates in the United States. Studies by Silbar²⁹¹ and by Seitchik and colleagues²⁹² found that the increase in cesarean birth rate for dystocia resulted, in part, from an increased incidence of large infants and a consequent absolute increase in fetal-pelvic disproportion. Continuous electronic fetal heart rate monitoring contributed to the increase in cesarean delivery for "dystocia." Haverkamp and associates,²⁹³ in a prospective, controlled study, found that cesarean delivery was more often performed for dystocia when continuous labor and fetal monitoring data were available, compared with documentation of

uterine contractions and fetal heart rate data via palpation and auscultation by a nurse at the bedside. In the absence of data about absolute intrauterine pressure values and subtle fetal heart rate decelerations, it is tempting to speculate that there is longer and more vigorous oxytocin augmentation of desultory labors before cesarean section is considered in the group monitored by a bedside nurse. Or perhaps the nurse at the bedside allays anxiety and thereby contributes to a normal labor pattern and less fetal distress.

The diagnosis of fetal distress, which accounted for 10% to 15% of the increase in cesarean delivery rate in the studies described, is often made in the context of a labor that is not progressing normally. Zalar and Quilligan²⁹⁴ found that the use of fetal scalp blood sampling substantially reduced the number of cesarean deliveries performed for presumed fetal distress. Moreover, as experience is gained with reading fetal monitoring tracings, one is less likely to perform operative deliveries for abnormal but not necessarily ominous fetal heart rate changes. Consequently, judicious interpretation of continuous fetal heart rate monitoring data and persistent attention to factors that will improve the fetal environment often allow the additional time needed for successful labor and vaginal delivery. Garite and colleagues²⁹⁵ found that continuous fetal pulse oximetry in labor resulted in a 50% reduction in the number of cesarean deliveries for nonreassuring fetal status, compared with continuous electronic fetal heart rate monitoring in control subjects, but the overall rate of cesarean section was not reduced, because the number of abdominal deliveries for dystocia increased.

Bloom and coworkers²⁹⁶ randomly assigned 5341 nulliparous women in labor to either "open" or "masked" fetal pulse oximetry. Clinicians had access to oximetry data in the "open" arm and did not in the "masked" arm. There were no differences in the overall rate of cesarean delivery, nor in the rates of abdominal delivery for dystocia or fetal distress; a planned sub-analysis of cases with nonreassuring fetal heart rate tracings also demonstrated no differences. This trial called into question the value of fetal pulse oximetry in helping patients forego abdominal delivery or improving the health of newborns.

The waning enthusiasm for midpelvic forceps deliveries has contributed to the increased number of cesarean deliveries in the "dystocia" category.

Vaginal Birth after Cesarean Section

Before 1980, abdominal delivery after a previous cesarean section accounted for 25% to 30% of the increase in cesarean delivery rate.²³⁰ However, previous cesarean delivery performed through a low transverse uterine incision for a nonrecurring indication (presumed CPD not included) need not be an indication for a subsequent cesarean delivery. In hospitals with appropriate facilities (i.e., services and staff available for prompt emergency cesarean birth), a patient who has undergone previous cesarean delivery can be allowed a trial of labor.

In a meta-analysis of 31 studies that included 11,417 patients with a trial of labor after a previous low-transverse cesarean delivery, Rosen and associates²⁹⁷ found that maternal febrile morbidity was significantly lower after a trial of labor than after an elective repeat cesarean. Although the combined rate of rupture or dehiscence of the uterine wound was the same in the two groups, the OR for perinatal death in all patients with a trial of labor, compared with those who had undergone elective cesarean delivery, was 2.1 (CI, 1.3 to 3.4). The intended route of delivery, the presence of an unknown type of scar, and the

use of oxytocin made no difference in the rate of uterine wound dehiscence.

In a study of 6138 patients with one previous low-transverse cesarean birth, McMahon and colleagues²⁴⁸ found that major maternal complications (defined as need for hysterectomy, uterine rupture, or serious operative injury) occurred more often in women with a trial of labor than in those who delivered by repeat elective cesarean (OR = 1.8; CI, 1.1 to 3.0). All of the major complications occurred in women with unsuccessful vaginal birth.

Consequently, the overall risk associated with a trial of labor after a previous cesarean delivery will be decreased by selecting women who have a high probability (>80%) of successful vaginal delivery. Women who are likely to have a successful VBAC are those who are younger than 35 years of age, whose fetus weighs less than 4000 g, and whose previous cesarean delivery was performed for a reason other than failure of descent in the second stage of labor.

Small series have addressed the question of the safety of VBAC in patients with breech presentation,²⁹⁸ twin gestation,²⁹⁹ or post-term pregnancy.³⁰⁰ Although each of these reports noted no greater incidence of complications in those circumstances than for VBAC in singleton pregnancies with a vertex, term presentation, the small number of patients in each series demands continued caution in recommending VBAC for such patients.

Intrapartum rupture of a low-transverse uterine scar, which occurs in 0.5% to 1% of women who undertake a trial of labor after a cesarean delivery, is a serious emergency and can result in perinatal death.³⁰¹ Furthermore, serious puerperal morbidity is more common in women who undergo cesarean delivery after a trial of labor than in those who undergo a repeat elective abdominal delivery.²⁴⁸ After being fully informed about the risks and benefits of a trial of labor and VBAC, women are not universally enthusiastic. More than 25% choose to undergo another elective cesarean delivery if given the chance.³⁰²

Landon and associates³⁰³ reported on a cohort study of more than 30,000 women in which women with one prior cesarean delivery underwent either elective repeat cesarean delivery or a trial of labor. The prevalence of symptomatic uterine rupture was 0.7%. No infant in the repeat cesarean group but 12 of the infants in the trial of labor group suffered encephalopathy, and 7 of those 12 cases were associated with uterine rupture (for a rate of 0.46 per 1000 trials of labor). The rates of endometritis and of transfusion were higher in the trial of labor group, but there were no differences in the rates of hysterectomy or maternal death. This contemporary cohort is useful in counseling patients and demonstrates the low absolute risks associated with either approach.

Reducing the Morbidity of Cesarean Delivery

When cesarean delivery must be performed, the following measures ensure the lowest morbidity and mortality risks for mother and infant:

- Anesthesia administered by a skilled anesthesiologist
- Attention to maternal position and blood volume in the peripartum period
- Prophylactic antibiotics
- Use of a transverse uterine incision whenever possible
- Awaiting the onset of labor whenever possible in cases of repeat cesarean delivery
- Presence of a person skilled in newborn resuscitation

Equally good neonatal and maternal outcomes from cesarean delivery can be obtained with spinal, epidural, or general anesthesia or with local infiltration, provided that it is administered by a skilled person who is fully aware of the unique physiologic problems of the pregnant patient and her fetus.³⁰⁴ However, there are maternal and fetal risks associated with each method of anesthesia.

Spinal Anesthesia. Spinal anesthesia is associated with the highest incidence of hypotension and should always be accompanied by uterine displacement, maternal prehydration, and (more controversially) prophylactic ephedrine administration. Lindblad and associates³⁰⁷ used Doppler ultrasound to estimate fetal aortic and umbilical blood flow in women during cesarean delivery with intrathecal anesthesia. They found that if maternal blood pressure was maintained within the normal range with a preload infusion of lactated Ringer solution and ephedrine, fetal blood flow was unaffected for 30 minutes after induction. After this time, the pulsatility index in the fetal vessels decreased. Most important for the obstetrician is the awareness that, with spinal anesthesia, the time from onset of anesthesia to delivery of the infant is directly related to the degree of fetal metabolic acidosis resulting from uteroplacental hypoperfusion.³⁰⁸ Simply because the patient is alert is no reason to procrastinate in delivering the infant. There is perhaps as much, if not more, need for prompt delivery of the infant after spinal anesthesia as there is with general anesthesia.

Epidural Anesthesia. Epidural anesthesia is associated with maternal hypotension less often than is spinal anesthesia. Joupila and colleagues,³⁰⁹ however, found that epidural anesthesia was associated with a decreased clearance of xenon 133 (presumed to reflect decreased uteroplacental perfusion), especially when hypotension occurred. One major disadvantage of epidural block for cesarean delivery is the time required for the onset of operative anesthesia, which could preclude its use in many emergency situations. Quinn and Kilpatrick's study³¹⁰ of fetal outcomes in 212 consecutive cesarean deliveries demonstrated that regional anesthesia is satisfactory for urgent cesarean deliveries provided that delivery is not required within 20 minutes. Inhalation anesthesia was needed if the time interval from decision to delivery was less than 20 minutes.

General Anesthesia. General anesthesia, which has the advantage of rapid onset, is also associated with decreased uteroplacental perfusion during induction of the anesthesia.³¹¹ Pulmonary aspiration of gastric contents (Mendelson syndrome) is always a major threat with general anesthesia, and this risk is accentuated by the delayed gastric emptying in patients in labor; Cohen³¹² reviewed this subject. There is evidence that the particulate antacids, which are commonly used preoperatively to neutralize gastric acidity, may themselves cause pulmonary damage if aspirated, and their use has not eliminated Mendelson syndrome. A nonparticulate antacid such as sodium citrate, given 10 to 45 minutes before anesthesia, alone or in combination with a histamine₂ (H₂) receptor blocker such as ranitidine, should significantly decrease the risk of aspiration without contributing added hazard.³¹³ Perhaps the most important safeguard against the aspiration syndrome is skillful intubation while cricoid pressure is applied.

In patients given general anesthesia, as well as in those given conduction anesthesia, prompt delivery of the infant is

important, the crucial time being that from incision of the uterus to delivery.³¹⁴ Delivery of the infant within 90 seconds after making the uterine incision reduces the risk of fetal hypoxemia from altered uteroplacental and umbilical blood flow.

If regional anesthesia is used, adequate volume replacement is important in preventing hypotension. Prehydration with 1000 mL of saline or injection of lactated Ringer solution frequently compensates for vasodilation after onset of anesthesia. The supine position is a well known but frequently neglected danger in all pregnant women in the third trimester.³¹⁵ Often, during preparation for surgery and administration of the anesthetic agent, the patient is placed flat on her back. Appropriate wedges, left lateral tilt of the table, and even operating with the patient in the lateral position have been shown to prevent supine hypotension and reduce fetal asphyxia.

Bloom and colleagues,³¹⁶ using the previously described registry,³⁰³ demonstrated that more than 93% of abdominal deliveries could be accomplished by a regional technique, with a low failure rate (3.0%). Risk factors for needing general anesthesia included maternal size, increasing preoperative risk scores, and short interval from decision to incision. One maternal death was caused by an anesthetic complication (fluid intubation). This large series attests to the preferability and safety of regional anesthesia in contemporary obstetrics.

In addition to the use of regional anesthesia and early ambulation, the widespread use of prophylactic antibiotics for patients undergoing a cesarean delivery has reduced the risk of puerperal morbidity (see Chapter 51). The use of prophylactic antibiotics for cesarean delivery was the subject of two extensive systematic reviews. Smaill and Hofmeyr³¹⁷ reviewed 81 trials and found a significant reduction of puerperal endometritis and wound infection among women treated with prophylactic antibiotics for cesarean delivery, compared with women who did not receive such treatment. Hopkins and Smaill³¹⁸ reviewed 47 trials comparing various antibiotic regimens used for prophylaxis in women undergoing cesarean delivery. Ampicillin and first-generation cephalosporins were equally effective in reducing puerperal endometritis. Multiple-dose regimens were of no greater efficacy than single-dose treatments, and there was no significant difference in outcome with systemic versus lavage administration. Also, there was no advantage for the use of antibiotics with a broader range of activity. Although there is no conclusive evidence regarding optimal timing of administration, most obstetricians administer the medication after the umbilical cord has been clamped, in the interest of avoiding unnecessary exposure of the infant to an antibiotic. Finally, antibiotic prophylaxis reduces morbidity in elective cesarean delivery as well as in cesarean delivery performed during labor.

In the past, the extraperitoneal approach to cesarean delivery was used if chorioamnionitis was suspected.^{319,320} It appears that this operative technique is no longer widely taught or used, and the risks and benefits of this approach, compared with the standard intraperitoneal approach, have not been delineated.

The advantages of the transverse compared with the vertical uterine incision for cesarean delivery were first recognized by Kerr,³²¹ who showed that low vertical incisions almost always extended into the thicker muscle layers of the fundus and were more frequently complicated by improper healing and subsequent rupture. Also, if the entire uterine incision could be covered by bladder peritoneum, the risk of postoperative ileus, peritonitis, and subsequent adhesions and bowel obstruction was reduced.

The advantages of awaiting onset of labor before performing a subsequent cesarean delivery are the elimination of iatrogenic prematurity and reduction of the risk of neonatal respiratory illness. Awaiting the onset of labor also results in thinning of the lower uterine segment, which decreases blood loss and facilitates development of the bladder flap during the procedure.

Finally, the presence of a professional skilled in neonatal resuscitation is essential, especially when cesarean delivery is performed for fetal distress. It is not only courteous but also often vitally important to inform the pediatrician or nursery personnel as early as possible of an impending cesarean delivery. Special equipment, drugs, and blood products may need to be assembled for a sick neonate. It is a disservice to the mother to perform a major operation in the interest of fetal well-being and not follow up with the most expert care of the newborn.

Cesarean hysterectomy is occasionally lifesaving, especially in cases of uncontrolled hemorrhage from the site of a placenta previa, placenta accreta, or ruptured uterus. Cesarean hysterectomy could also be the treatment of choice in the woman with chorioamnionitis who desires sterilization and in whom cesarean delivery is indicated. For other indications, such as cervical intraepithelial neoplasia and a request for sterilization with a subsequent cesarean delivery, the operation is associated with sufficient morbidity to make its usefulness in these situations doubtful.

In a review of cesarean hysterectomy including 3913 operations, Park and Duff²² found the following complication rates: maternal mortality, 0.71%; bladder injury, 3%; vesicovaginal fistula, 0.4%; ureteral injury, 0.25%; and intraperitoneal bleeding requiring reoperation, 0.97%. Supracervical cesarean hysterectomy is justified in cases of life-threatening hemorrhage if the patient's vital signs are unstable. Complete removal of the cervix is one of the most difficult and time-consuming aspects of the cesarean hysterectomy procedure, especially if there has been substantial effacement and dilation of the cervix.

OBSTETRIC FORCEPS DELIVERY

Obstetric forceps were first used by members of the Chamberlen family in the 17th century but were not widely accepted until 100 years later.³²³ William Smellie was the first to systematically teach the principles of forceps deliveries. It is clear that he also was fully aware of the potential dangers of the instruments; in the introduction to volume II of *Treatise on the Theory and Practice of Midwifery*, he wrote, "If these expedients (forceps) are used prematurely when the nature of the case does not absolutely require such assistance, the mischief that may ensue will often over balance the service for which they were intended and this consideration is one of my principal motives for publishing this second volume."³²⁴

In 1988, the ACOG issued a Committee Opinion establishing new definitions for obstetric forceps.³²⁵ These definitions, which were incorporated in the 1991 ACOG Technical Bulletin entitled *Operative Vaginal Delivery*,³²⁶ were divided into three categories:

1. Outlet forceps
 - a. Scalp is visible at the introitus without separating labia
 - b. Fetal skull has reached pelvic floor
 - c. Sagittal suture is in anteroposterior diameter or right or left occiput anterior or posterior position
 - d. Fetal head is at or on perineum
 - e. Rotation does not exceed 45 degrees

2. Low forceps
 - a. Leading point of fetal skull is at station +2 cm or lower and not on the pelvic floor
 - b. Rotation is less than or equal to 45 degrees (left or right occiput anterior to occiput posterior or left or right occiput posterior to occiput posterior)
 - c. Rotation is greater than 45 degrees
3. Mid-forceps
 - a. Station is above +2 cm but head is engaged

This classification reflects what has been widely recognized among practicing obstetricians, that there are two types of forceps deliveries: low forceps deliveries, which are usually simple and uncomplicated for both mother and infant, and mid-forceps deliveries, which sometimes are difficult and can cause substantial trauma to either patient.

Hagadorn-Freathy and colleagues³²⁷ prospectively evaluated forceps deliveries, comparing outcomes as designated by the ACOG criteria published in 1965.³²⁸ When the older classification was used, there was no difference in outcome between outlet forceps and mid-forceps deliveries. When the deliveries were reclassified according to the more recent criteria, however, mid-forceps deliveries were associated with lower cord pH values and a higher incidence of fetal injury, compared with outlet or low forceps deliveries. In a review of operative vaginal deliveries, Bowes and Katz³²⁹ found that serious short-term maternal and perinatal morbidity are increased in forceps delivery if the vertex is above +2 cm station in the pelvis, compared with +2 station or lower.

A retrospective, population-based study of 583,340 liveborn singleton infants in California found that, among patients in labor for whom spontaneous vaginal delivery did not occur, there was no statistically significant difference in the incidence of neonatal intracranial hemorrhage between delivery by vacuum extraction, delivery by forceps, and cesarean delivery.³³⁰ Another important finding of this study was that the incidence of serious neonatal morbidity was significantly greater when cesarean delivery was performed after a failed attempt at vaginal delivery with either forceps or vacuum extractor, compared with cesarean delivery after a trial of operative vaginal delivery. There were multiple limitations to this study, including lack of information about the level of experience of those who performed the operative deliveries. Such limitations notwithstanding, the study suggested that, if spontaneous delivery cannot be accomplished safely for the mother or infant and the circumstances are not favorable for a relatively easy operative vaginal delivery, the patient should be delivered by cesarean. This contention is supported by evidence that many modern residency training programs in obstetrics and gynecology are not providing sufficient skill in the safe use of forceps.³³¹

Few studies with long-term follow-up of infants delivered with forceps have been published. Friedman and colleagues³³² published results from a collaborative perinatal project in which children delivered by mid-forceps demonstrated lower intelligence quotient (IQ) scores and a higher prevalence of suspected speech, language, and hearing abnormalities than did children born spontaneously. McBride and coworkers¹⁷⁸ studied 700 5-year-old children, all of whom were born at term, including 175 born by mid-forceps delivery. Using a variety of neurologic, hearing, visual acuity, and development tests, these authors found no differences related to method of delivery among the children who had been born in cephalic presentation. Dierker and associates³³³ compared 110 children 2 years of age or older

who had been delivered by mid-forceps with a similar number of children of the same age delivered by cesarean section. They found five cases of abnormal development among the children delivered by mid-forceps and seven cases among those delivered by cesarean section.

Seidman and coauthors³³⁴ related obstetric interventions to medical examinations and intelligence tests performed on more than 32,000 17-year-old men and women inducted into the Israeli Defense Forces. The mean intelligence scores for those delivered by forceps or vacuum extractor were not statistically different from those delivered spontaneously or by cesarean section.

In a retrospective study of 3417 children, Wesley and coworkers³³⁵ found no association of forceps delivery (versus spontaneous delivery) with decreased IQ score at 5 years of age. The studies that demonstrated a no-toward long-term effect of operative vaginal delivery are those in which the infants were born after 1970. A more conservative attitude about forceps, which has characterized the period since the late 1970s, may have been responsible for the salutary outcomes noted in recent studies of both short-term and long-term effects of operative vaginal delivery.

Mid-forceps deliveries, as defined by the 1991 ACOG criteria, should be undertaken with caution and with a willingness to abandon the procedure in favor of cesarean delivery if there is difficulty with proper application of the instrument or if the head does not easily descend or rotate. The use and teaching of mid-forceps delivery under the appropriate circumstances and by an adequately trained individual is in accord with current recommendations of the ACOG.³³⁶

Patel and Murphy³³⁷ reviewed the role of forceps in modern practice. Their 2004 review concluded that (1) most women prefer spontaneous delivery; (2) obstetricians increasingly choose cesarean section if problems arise during the second stage of labor; (3) injury to the pelvic floor and trauma to the baby are more common with forceps, whereas hemorrhage and maternal-infant separation occur more often after abdominal delivery; and (4) forceps delivery results in less morbidity in subsequent pregnancies. The authors bemoaned the decline in forceps skills among junior clinicians and advocated further research regarding the long-term sequelae of forceps operations.

VACUUM EXTRACTION

Malmström introduced the vacuum extractor into modern obstetrics in 1954.³³⁸ Since that time, it has largely replaced the use of obstetric forceps in Scandinavia and continental Europe, and it is used with increasing frequency in the United States.³³⁹ Bowes and Katz³²⁹ reviewed the use of the vacuum extractor for obstetric delivery. The indications for its use are virtually the same as those for the use of forceps:

- Arrest of labor in the second stage
- Maternal indication for shortening of the second stage of labor (e.g., cardiovascular or cerebrovascular disease, maternal exhaustion)
- Fetal distress
- Elective low-pelvic delivery

Contraindications for use of the vacuum extractor include the following:

- CPD
- Face or brow presentation

- Breech presentation
- Unengaged fetal head
- Premature infant
- Incompletely dilated cervix

Maternal complications of vacuum extractor delivery, including cervical and vaginal trauma, are generally less frequent and less severe than those of forceps delivery, and this is one of the major advantages of the instrument. Minor fetal complications include cephalhematomas and retinal hemorrhages, which are usually benign and self-limited. More serious complications, such as subgaleal hemorrhage (4%) and intracranial hemorrhage (2.5%), are usually associated with prolonged labor and fetal asphyxia but are probably less common than in forceps deliveries performed under the same circumstances.

Johanson and Menon³⁴⁰ performed a systematic review of nine randomized, controlled trials comparing the vacuum extractor with forceps for assisted vaginal delivery. They concluded that failure to deliver the infant occurred more often with the vacuum extractor than with the forceps. The vacuum extractor was associated with significantly less maternal pelvic trauma but with a greater risk for neonatal cephalhematomas and retinal hemorrhages. A 5-year follow-up study of 278 infants who were involved in a randomized, controlled trial of vacuum extraction versus forceps delivery found no statistical difference in long-term untoward effects between the two methods.³⁴¹ Almost all studies have found a substantial increase in risk of maternal and fetal morbidity when failure to deliver with the vacuum extractor is followed by an attempt to deliver with forceps. For example, Towner and colleagues³⁵⁰ found that use of both vacuum extraction and forceps resulted in a rate of intracranial hemorrhage that was 7.4 times greater than with spontaneous delivery and 3.4 times greater than with use of the vacuum extractor as the sole instrument. Also, Gardella and associates³⁴² compared 3741 combined vacuum and forceps deliveries with the same number of vacuum-only and forceps-only deliveries. There was a significant increase in both neonatal and maternal injury with sequential use of the instruments. A recommendation to avoid the combination of vacuum extractor followed by forceps is in accord with the current guidelines on operative vaginal delivery published by ACOG.³³⁶

Two major advantages of the vacuum extractor are the ease with which it can be applied and the need for less anesthesia than is required for forceps delivery. Moreover, it is far easier to teach and to learn the appropriate skill required to use the vacuum extractor safely than to acquire a similar level of skill with forceps delivery. Many of the studies that established the effectiveness and safety of the vacuum extractor compared with obstetric forceps were conducted with the Malmström metal cup or the Bird modification of the Malmström device. Currently, a variety of both rigid and soft polyethylene or silicone vacuum cups are the preferred instruments for vacuum extraction and the ones most commonly used in residency training programs in the United States.³³⁹ Randomized trials of soft versus rigid vacuum extractor cups have shown that soft cups have lower success rates than rigid cups but are less likely to cause maternal and fetal trauma.³⁴³

The collective evidence of the comparative efficacy and safety of vacuum extraction versus forceps has led some authorities to recommend the vacuum extractor as the instrument of first choice for operative vaginal delivery.³⁴⁴

Analgesia and Anesthesia for Low-Risk Labor and Vaginal Delivery

HISTORY

An interesting monograph by Caton³⁴⁵ and a shorter account by Caton and colleagues³⁴⁶ have chronicled the history of pain relief for childbirth during the past two centuries. It is safe to say that the plight of women in labor has improved dramatically since the 16th century, when Eufame MacLayne, a woman of some station, was tried by due process, convicted of an act contrary to divine law, chained to a stake atop Castle Hill, and burned. Her only crime was having received "a certain medicine for the relief of pain in childbirth."³⁴⁷ Until the 18th century, labor was conducted without the use of effective analgesia or anesthesia. The birth process was simply acknowledged to be a painful, traumatic, and often frightening experience that was to be endured with the aid of only crude and unproven potions. James Simpson, who held the Chair of Midwifery at the University of Edinburgh, was the first to administer chloroform to a woman in labor and became a champion of obstetric anesthesia.³⁴⁸ His work, and especially his care of Queen Victoria, who enjoyed the birth of one of her many children with the assistance of chloroform, changed both public and professional attitudes about the benefits of providing pain relief for women during labor. Modern obstetric units, many with the service of full-time obstetric anesthesiologists, provide a wide range of options for pain management, including psychophysiologic methods, parenteral analgesia, and regional analgesia.

One of the most important assets of a modern facility offering a full range of perinatal services is the presence of a qualified obstetric anesthesiologist. The physiologic changes that characterize pregnancy result in metabolic, respiratory, and cardiovascular phenomena not encountered in the nonpregnant state. These changes, together with the presence of the fetus in utero, are a challenge for the anesthesiologist. Furthermore, high-risk obstetric patients frequently have fetal or maternal problems that further complicate the already difficult task of administering anesthesia to two patients simultaneously (see Chapter 70).

The choice of drug and anesthetic technique for labor and delivery depends on the skill and experience of the person who performs the procedure, the progress of labor, other complications of pregnancy or labor, and the desires of the patient. With proper antenatal psychological preparation, many patients require minimal, if any, analgesia or anesthesia throughout labor, and healthy infants are born in most of these cases. Nothing should be done to discourage such a practice. Furthermore, everything should be done to facilitate birthing in quiet, pleasant, and friendly surroundings in which a friend or family members are allowed to accompany the parturient. There is considerable evidence that a supportive birth attendant (doula) reduces the need for analgesia and anesthesia and, in some populations, reduces the incidence of dystocia.^{206,349}

ANALGESIA

Sedatives and narcotic analgesics are frequently administered alone or in combination in the first stage of labor. There is increasing evidence that opioids given systemically do not relieve the pain of labor.^{350,351} These drugs do reduce anxiety and result in sedation. All drugs of this type rapidly appear in the fetal circulation when administered to the mother. Predictably,

there will be some sedation of the infant, depending on the specific drug given, the amount, the time, and the route of administration.

The drug most commonly used for pain is meperidine in doses of 50 to 100 mg intramuscularly or 25 to 50 mg intravenously. To enhance its effect, provide additional sedation, and prevent nausea, physicians may prescribe a phenothiazine such as promethazine, 25 mg, as well. The half-life of meperidine is increased and is more variable in pregnant women than in nonpregnant subjects. Furthermore, fetal hypoxia reduces the clearance of meperidine from fetal blood.³⁵² If the neonate appears depressed as the result of the administration of meperidine to the mother, injection of the narcotic antagonist naloxone may be indicated (0.1 mg/kg IV or IM). Other analgesics, such as butorphanol, nalbuphine, and fentanyl, all of which cause less respiratory depression, are used frequently for intrapartum pain control.³⁵³⁻³⁵⁵

Systematic reviews of parenteral opioids for relief of labor pain published by Elbourne and Wiseman³⁵⁶ and by Bricker and Lavender³⁵⁷ included 48 trials comparing a variety of parenteral opioids with placebo, with each other, and with regional analgesia. These reviews concluded that epidural analgesia provides more effective pain relief than does parenteral analgesia. However, there is no clear evidence that any one medication or one method of administration used for parenteral analgesia is superior to another. Long-term effects of parenteral opioids used during labor have not been studied extensively, although there is some concern about genetic imprinting at birth for later self-destructive behavior and drug addiction.³⁵⁸

Paracervical Block

Paracervical block was a popular form of anesthesia for the first stage of labor until it was implicated in several fetal deaths and was shown to be associated with fetal bradycardia in 25% to 35% of cases.³⁵⁹⁻³⁶¹ In some cases, death was related to direct injection of large doses of local anesthetic agents into the fetus, whereas the fetal bradycardia was probably a response to rapid uptake of the drug from the highly vascular paracervical space.

Although not advocated with enthusiasm by most authorities, this form of anesthesia is still used, especially in hospitals in which epidural anesthesia is not available. If paracervical block is used wisely in low-risk patients, it is safe and effective for the first stage of labor.³⁶² The anesthetic should be administered with great care to avoid direct fetal injection, and using the smallest amount of drug possible. Chloroprocaine (1% to 2%), rather than lidocaine or mepivacaine, should be used if repeated doses will be required.³⁶³ Anyone using paracervical block anesthesia should read the excellent account of this method published by Chestnut.³⁶⁴

Pudendal Block

Pudendal block is a common form of anesthesia used for vaginal delivery. When successful, it provides adequate pain relief for episiotomy, spontaneous delivery, forceps or vacuum extraction delivery from a low pelvic station, and repair of perineal, vaginal, or cervical lacerations. Because the local anesthetic agent is injected well away from the parauterine vasculature, uteroplacental blood flow and fetal heart rate are not affected to the same degree as in paracervical block. Occasionally, vaginal hematomas can be caused by pudendal nerve block, but the most dreaded complication is a retroperitoneal abscess.^{365,366} It is surprising that this complication does not occur more

frequently, inasmuch as the injection is made through a non-sterile field. The infrequency of infections in the Alcock canal is probably a consequence of the prolonged compression of the paravaginal tissues by the fetal head, which prevents hematoma formation.

The success of pudendal nerve block depends on a clear understanding of the anatomy of the pudendal nerve and surrounding structures. The anatomic study by Klink³⁶⁷ clarified the course of the pudendal nerve, described the variations of the nerve and its branches, and discussed the anatomy in relation to the performance of successful regional anesthesia. This article, with its helpful illustrations, is an excellent resource.

LOW SPINAL ANESTHESIA

Low spinal anesthesia, often called saddle block, is an effective means of anesthesia. It is relatively simple to perform and provides prompt, reliable pain relief that is adequate for spontaneous delivery or instrument delivery from the low pelvic or midpelvic station. It usually consists of 4 mg of tetracaine administered in a hyperbaric solution at the L4-L5 interspace with the patient sitting.

Although this technique is intended to anesthetize only the "saddle region," the level of anesthesia sometimes is as high as the T10 dermatome. Because of the ease of administration and the reliability of this form of anesthesia, it has been a favorite of obstetricians practicing in hospitals in which anesthesiologists are available only for cesarean delivery or other emergencies. As a result of the profound sympathetic block that occurs with spinal anesthesia, however, saddle block can be associated with profound hypotension and a decrease in uteroplacental perfusion. Furthermore, it can interfere with the voluntary abdominal pushing effort far more than epidural anesthesia does, frequently resulting in delivery of the infant by forceps. The popularity of this form of obstetric anesthesia is waning because it is being replaced by epidural anesthesia and because many patients insist on unmedicated, natural delivery.

EPIDURAL ANALGESIA AND ANESTHESIA

Epidural anesthesia is being used with increasing frequency, especially in hospitals where anesthesiologists are available to patients in labor 24 hours a day. In experienced hands, epidural anesthesia has an excellent safety record.³⁶⁸ Although it is the most difficult form of anesthesia to administer, it has the advantage of providing excellent pain relief for the first and second stages of labor and for delivery without altering the consciousness of the mother. Bupivacaine and chloroprocaine are the drugs most commonly used, the former providing more prolonged anesthesia but with a greater delay in onset. Combinations of local anesthetics and narcotics also provide excellent analgesia with less motor blockade.³⁶⁹

Continuous lumbar epidural anesthesia has been associated with late decelerations in fetal heart rate suggestive of decreased uteroplacental perfusion in as many as 20% of cases. This is more common with bupivacaine than with chloroprocaine or lidocaine.³⁷⁰ Also, the use of oxytocin to augment labor in women given continuous epidural anesthesia has been reported to increase the frequency of late decelerations noted on fetal monitoring.³⁷¹ When uterine hypertonus or maternal hypotension is associated with the augmentation of contractions in patients with epidural anesthesia, fetal heart rate patterns

indicating uteroplacental insufficiency occur in as many as 70% of cases.³⁷² Prehydration of the mother and avoidance of the supine position³⁷³ can reduce the incidence of uteroplacental insufficiency with epidural anesthesia. Drug mixtures of local anesthetics and analgesics results in less motor block; this allows women who have epidural anesthesia to be more mobile during labor, and they are less likely to be confined to the supine position.

Thorp and Breedlove³⁷⁴ reviewed the benefits and risks of epidural analgesia for labor and delivery. Both retrospective and prospective controlled trials have demonstrated that epidural analgesia results in longer labors and a higher incidence of operative vaginal delivery and cesarean delivery than intravenous analgesia. Some studies have suggested that the untoward effect of epidural analgesia on labor occurs primarily in patients in whom the epidural is placed when the cervix is dilated less than 5 cm³⁷⁵; however, controlled trials by Chestnut and coauthors^{376,377} established that the time of onset of epidural analgesia did not affect length of labor or method of delivery. In a retrospective, case-controlled study, Thompson and colleagues³⁷⁸ showed that those patients who had abnormal labor progress after epidural analgesia often had abnormal labor curves before placement of the epidural block.

Zhang and associates³⁷⁹ used a unique approach to determine whether epidural analgesia prolongs labor and increases the risk of cesarean delivery. A natural experiment occurred wherein the incidence of labor epidural anesthesia was suddenly increased from 1% to 84% in a brief period of time while other conditions remained unchanged. There was no resultant change in overall rate of abdominal delivery, rate of abdominal delivery for dystocia, rate of instrumental delivery, or length of the first stage of labor. The second stage of labor was prolonged by a mean of 25 minutes. Moreover, on-demand epidural analgesia did not increase the risk of fetal head malposition.³⁸⁰ The work of these authors confirmed the important studies of others³⁸¹⁻³⁸³ in finding that labor epidural analgesia does not increase the risk of cesarean delivery or the use of oxytocin or operative vaginal delivery. The only consistent effect of epidural analgesia is prolongation of the second stage of labor. Therefore, fear of increasing the risk of dystocia should not be used to limit patients' access to this effective analgesic technique.

The relationship between epidural analgesia for labor and delivery and chronic back pain after delivery is controversial. Retrospective studies found an association between epidural analgesia for labor and chronic back pain.³⁸⁴ However, a more recent prospective study, in which women were monitored for 1 year after delivery, found no statistically significant difference in the incidence of persistent back pain among those who did or did not receive epidural analgesia during labor.³⁸⁵

Another problem encountered with epidural analgesia or anesthesia for labor is an increased incidence of intrapartum fever.³⁸⁶ Fever occurs in approximately 30% of laboring patients after 4 to 5 hours of continuous epidural anesthesia. The specific cause of the febrile response is not known, although it could be related to the autonomic block that occurs with epidural anesthesia. Nevertheless, a clinical dilemma occurs in differentiating a "benign" febrile response to the epidural from intra-amniotic infection. As a consequence, most patients who develop a fever during labor are treated with antibiotics, and their infants are evaluated and treated for suspected sepsis.³⁸⁷ At present, there is no clear-cut way to avoid this problem.

An additional benefit of epidural anesthesia for patients undergoing cesarean delivery is that opioids can be injected into the epidural space to provide prolonged postoperative analgesia.³⁸⁸ The rare occurrence of serious respiratory depression (1 in 1200 cases) appears to be the only major complication. Transient nausea, urinary retention, and pruritus have also been reported in patients treated with epidural opioids.

Lieberman and O'Donoghue,³⁸⁹ in a comprehensive systematic review of the unintended effects of epidural analgesia during labor, drew attention to the many unanswered questions that remain despite the large number of studies that have been performed. Because many such studies lacked proper randomization to eliminate selection bias, there is a need for trials comparing epidural analgesia with other forms of analgesia in which randomization occurs during pregnancy rather than after labor begins. Nevertheless, Lieberman and O'Donoghue contended that current evidence supports the recommendation that women (especially nulliparous women) considering epidural analgesia for labor should be told the following:

- They are less likely to have a spontaneous vaginal delivery.
- The duration of their labor is likely to be longer.
- They will have an increased risk of instrument-assisted delivery, which is associated with an increased risk for serious perineal laceration.
- They are at greater risk of developing a fever during labor, which could lead to an evaluation and treatment of their infant for suspected sepsis.

There is evidence that the use of epidural anesthesia for pain control in labor is related to the size of the delivery service in hospitals in the United States.³⁹⁰ In 1997, the rate of use of epidural analgesia during labor was 50% among obstetric services with more than 1500 births per year, compared with 21% among obstetric units with fewer than 500 births per year. Clearly, this must reflect the more frequent availability of 24-hour coverage by anesthesiologists on the obstetric units of the larger hospitals. Proposed solutions to increase the availability of epidural anesthesia for women in labor include allowing certified registered nurse anesthetists (CRNAs) or adequately trained obstetricians to perform epidural anesthesia. Either of these innovations has economic and medicolegal ramifications that must be considered.

Labor Monitoring

The term "fetal monitoring" has become almost synonymous with continuous electronic fetal monitoring (see Chapter 33). The more comprehensive term, labor monitoring, refers to the conduct and management of the labor event from its onset to its completion. The primary goal of labor monitoring is to achieve delivery of a healthy infant from a healthy mother with as little trauma as possible. A secondary goal is to accomplish this delivery in a manner that is not degrading to the mother and that enhances and strengthens family relationships in a way that is consistent with the cultural and personal expectations of the patient. In a narrower context, this latter goal has been defined as "reducing bonding failure."³⁹¹ Certainly, a healthy and supportive family unit augments the growth and development of the newborn. To accomplish these goals requires attention to all the details of the labor and delivery process as they relate to a specific patient's medical, obstetric, and psychosocial situation.

One of the paradoxes of modern obstetric care is that the technologic advances that have contributed substantially to identification and correction of the pathophysiologic abnormalities of labor may depersonalize the labor event and even introduce phenomena that alter maternal and fetal physiology and create substantial maternal and family anxiety. The outcry against such depersonalization has come from many quarters and has resulted in reexamination of the management of labor and delivery. Indeed, it has been found that many of the traditional hospital obstetric practices, such as the perineal shave, enemas, and isolation of the patient from her family and friends, are not beneficial. More liberal use of ambulation and positions of comfort in labor and delivery have been found to be physiologically beneficial. Furthermore, the presence of family members or supportive friends may decrease anxiety, shorten the duration of labor, and reduce the need for medications.

Perhaps the most important figure in this entire scenario is the bedside nurse in the labor and delivery unit. The nurse's role is to bridge the gap between the most sophisticated obstetric technology and the expectations and needs of the patient and her family. The nurse must thoroughly understand the physiology and pathophysiology of labor; must be able to collect,

record, and interpret the data throughout the labor; and must anticipate both maternal and fetal problems. Furthermore, the nurse must provide timely communications to the physicians responsible for the patient's care and frequently must intelligently and compassionately help to interpret the course of labor to the patient and her family. This implies a one-to-one nurse-patient ratio for patients in active labor. All of these goals should be accomplished in a facility in which there can be an immediate response to a fetal or maternal emergency in the form of prompt delivery or resuscitation if necessary.

Recurrent Pregnancy Loss

BRITTON D. RINK, MD, MS | CHARLES J. LOCKWOOD, MD, MHCM

Miscarriage is the most common complication of pregnancy, affecting 50% of pregnancies when losses from conception through discernable embryonic development are included.¹ Approximately 5% of couples attempting pregnancy will experience two miscarriages, and 1% of couples will experience three or more losses.² The nomenclature of recurrent miscarriage is confusing, with a myriad of proposed definitions. The American Society for Reproductive Medicine defines recurrent pregnancy loss (RPL) as two or more failed pregnancies, not necessarily consecutive.² This definition will be used for the purpose of this chapter, focusing on losses before 20 weeks of gestation.

Classification schemas for miscarriage are not consistent and often do not reflect the different pathophysiologic processes that contribute to embryonic or fetal losses, and among the latter, the differences between losses occurring before and after 16 weeks' gestation. The historical choice of 20 weeks to separate early and late causes of fetal demise is arbitrary and imprecise. For example, some patients who experience multiple fetal losses between 16 and 20 weeks' gestation may be evaluated for RPL when in fact their process represents extreme preterm parturition.³ This lack of consistent terminology hinders much-needed analysis because of the variety of patient inclusion and exclusion criteria. In this chapter, we will concentrate on both early pregnancy loss (<10 weeks' gestation) and early fetal death (between 10 and 20 weeks' gestation).

That recurrent miscarriage is an actual disease process is evidenced by several distinct features. First, the observed frequency of RPL (1%) is greater than should occur by probability alone (0.4%) for miscarriage in three consecutive pregnancies.⁴ Second, a couple's prognosis depends on the outcomes of previous pregnancies. In general, a patient and her partner with unexplained RPL have a 75% chance of a successful future pregnancy, whereas the subsequent loss rate for a patient with antiphospholipid antibody syndrome, for example, may exceed 90% in an untreated pregnancy.⁵ Finally, RPL is more likely to occur in couples with similar reproductive histories, including a prior stillbirth, an anomalous fetus, a delayed conception, a family history of recurrent miscarriage, a preterm birth, or a previous child with growth restriction.⁶

Patients with RPL are among the most challenging to manage. Not only is the condition emotionally devastating for affected patients and their partners but also clinicians can be easily frustrated by a lack of sound clinical data to guide evaluation and management. The limited number of bona fide causes includes structural chromosome rearrangements and monogenic abnormalities, certain uterine anomalies, antiphospholipid antibody syndrome, and severe endocrine disorders. The medical literature is strewn with anecdotal reports of unproven causality and non-evidence-based management strategies.

Despite a comprehensive evaluation, a cause for RPL can be discerned in less than half of cases.¹ For many couples, evaluation and treatment recommendations are dictated by the research and clinical interest of the provider they encounter. This chapter provides a comprehensive review of RPL to guide providers in their care of patients with this challenging disease.

Genetic Abnormalities

MATERNAL AGE-RELATED ANEUPLOIDY

Cytogenetic alterations (Box 44-1) are identified in 50% to 60% of spontaneous abortion (SAB) specimens.¹ Common karyotypic abnormalities include autosomal trisomy (60%), monosomy X (20%), and polyploidy (20%).⁷ Maternal age is strongly associated with the risk for both SAB and aneuploidy. Most cases are derived from a nondisjunction event during meiosis I. However, a chromosome-specific influence of nondisjunction must exist to explain the predominance of cases of maternally derived trisomy 16, which results from errors in meiosis I, as opposed to trisomy 18, which arises during meiosis II.

There is a clear link between maternal age and both aneuploidy and SAB. The risk for trisomy in a clinically recognized pregnancy increases from about 2% to 3% for women in their twenties to 25% or more for women in their forties.⁸ A prospective cohort study, derived from the FASTER trial, assessed SAB rates in more than 36,000 women stratified into three age groups: less than 35 years, 35 to 39 years, and 40 years or older.⁹ Multivariable logistic regression noted that compared with women less than 35 years old, those of 35 to 39 years were at increased risk for SAB, with an adjusted odds ratio (adjusted OR) of 2.0 (95% confidence interval [CI], 1.5 to 2.6) whereas those 40 years or older had an adjusted OR for SAB of 2.4 (95% CI, 1.6 to 3.6). The association between conceptus chromosomal abnormalities and these two age groups was even higher, with adjusted ORs of 4.0 (95% CI, 2.5 to 6.3) for the younger group and 9.9 (95% CI, 5.8 to 17.0) for the older group. Moreover, a large prospective Danish cohort study tracking 634,272 women through 1,221,546 pregnancies found SAB rates of less than 12% for women 20 to 29 years old, 15% for those 30 to 34 years old, 24.6% for those 35 to 39 years old, 51% for those 40 to 44 years old, and 93.4% for those older than 44 years.¹⁰ Maternal age is the single strongest epidemiologic predictor of SAB, with the majority of losses linked to aneuploidy.

The increasing rate of aneuploidy observed as maternal age increases establishes a relationship between biologic aging and nondisjunction. Kline and colleagues compared the age of menopause in women with a euploid pregnancy with a group of women who had an aneuploid pregnancy loss.¹¹ Patients with trisomic pregnancies entered menopause earlier than those in

BOX 44-1 GENETIC FACTORS ASSOCIATED WITH RECURRENT PREGNANCY LOSS

- Aneuploidy
 - Maternal age
- Structural rearrangements
 - Robertsonian translocations
 - Reciprocal translocations
 - Other: inversions, duplications, deletions, etc.
- Single gene disorders
 - Copy number variants
 - Single nucleotide polymorphisms
 - Cytokine genes
 - Angiogenic factor genes
 - Hormone receptor genes
 - Male genetic factors

the group with no history of aneuploidy, supporting a theory of diminished ovarian reserve. Because aging is associated with an ever-shrinking oocyte pool, there is a progressive depletion of the number of oocytes available at the requisite stage of maturation for completion of normal meiosis. This is further supported by work suggesting that women who have had ovarian deficiency, either as a result of surgery or as a congenital abnormality, have an increased risk for trisomy 21.¹²

The basis for the maternal age-dependent increase in chromosomal malsegregation has been a long-standing mystery without definitive resolution. Several theories for nondisjunction have been proposed. Absent or reduced recombination events and abnormal chiasma position or function have been observed in human and animal models.⁸ In addition, premature separation of sister chromatids is postulated to be a result of pericentric recombination that disrupts cohesion.

Other possible causes of aneuploidy suggested in the literature include chronic oxidative stress, abnormalities in folate metabolism, and progressive shortening of oocyte telomere length.¹³ Since the original report in 1999, research has suggested a link between abnormal folate metabolism and risk for trisomy 21 resulting from genetic polymorphisms of metabolic enzymes.¹⁴ In addition, a meta-analysis suggested that fasting hyperhomocysteinemia is modestly associated with RPL (at <16 weeks).¹⁵ Thus, given its low cost and toxicity, it seems prudent to treat patients experiencing recurrent miscarriage with increased periconceptional folate supplementation (1 to 4 mg/day).

ROBERTSONIAN AND RECIPROCAL TRANSLOCATIONS

Approximately 3% to 5% of couples who experience RPL have a balanced structural chromosome rearrangement, as opposed to the rate of 0.2% in the general population.¹⁶ Tharpe and associates studied couples with RPL that resulted from parental chromosome abnormalities.¹⁷ In this population, 50% had balanced reciprocal translocations, 24% were robertsonian translocations, and 12% were mosaic for a female sex chromosome abnormality. The remaining 14% had other types of rearrangements including pericentric and paracentric inversions. Balanced rearrangements are known to predispose to errors in meiosis, resulting in abnormal offspring or RPL.

Stephenson and colleagues reported a cohort of almost 1900 couples with RPL.¹⁸ In that group, 51 carriers of a structural

chromosome rearrangement (2.7%) were identified who had 273 pregnancies documented before the evaluation. Chromosomal alterations included 28 parental carriers of a balanced reciprocal translocation and 12 carriers of a balanced robertsonian translocation, and the remaining 11 had inversion or complex rearrangements. Of the 273 pregnancies, 192 (70%) resulted in miscarriage. Of these losses, 148 (54%) occurred at less than 10 weeks' gestation and 44 (16%) occurred between 10 and 20 weeks. The mean maternal age at delivery was 29.8 years. Although only 36 miscarriage specimens were karyotyped, 36% were found to have an unbalanced rearrangement and 30% were aneuploid or polyploid. For these same 51 patients, after evaluation for RPL and without the use of assisted reproductive technologies (ART), the subsequent live birth rate for carriers of a reciprocal balanced translocation was 63% and 69% among those with a robertsonian translocation. Interestingly, there are conflicting data on whether carriers of reciprocal translocations have poorer pregnancy outcomes than those with a robertsonian translocation.¹⁹ There is no clear evidence to suggest a difference in risk for RPL between a maternal or paternal carrier, although men more often present with infertility.

SINGLE-GENE DISORDERS

Most examples of known single-gene causes of RPL are associated with second-trimester miscarriage, probably reflecting ascertainment biases. In many cases, a fetus is identified as having structural malformations either by ultrasound or at a postnatal evaluation. For example, lethal multiple pterygium syndromes are a collection of autosomal recessive and X-linked recessive disorders that are associated with fetal death at 14 to 20 weeks with variable features including arthrogryposis, hydrocephalus, hydrops, and cystic hygromas.²⁰ Incontinentia pigmenti is an X-linked disorder that is usually lethal in males. Affected males may also develop hydrops or cystic hygromas (or both), whereas affected females have dental anomalies and cutaneous manifestations.²¹ Other X-linked male in utero lethal disorders include chondrodysplasia punctata type 2, Rett syndrome, oral-facial-digital type 1, Aicardi syndrome, and Goltz syndrome.

The remarkable degree of heterogeneity in female X-chromosome inactivation (also called lyonization) may account for the phenotypic variability often observed in X-linked disorders among carrier females. Interestingly, skewed X-inactivation is a suggested mechanism for hemizygous X-linked mutations causing RPL in heterozygous women. In most women, one X chromosome is randomly inactivated so that in an individual, both copies of the X chromosome are inactivated in relatively equal proportions. However, skewed X-inactivation is the result of one X chromosome being preferentially inactivated. If the "normal" copy of an X-linked gene is preferentially inactivated, the mutated gene would be expressed in most cells, resulting in an abnormal phenotype. A study by Robinson and associates reported an increased incidence of extreme skewed X-inactivation (>90% skewing) among women with RPL (18%), compared with the incidence identified in the general population (6%).²² A meta-analysis of 24 case-control studies that compared 2750 patients who had RPL with 3123 controls showed that women with skewed X-chromosome inactivation (>90%) had a higher risk for RPL (OR = 2.43; 95% CI, 1.34 to 4.43).²³ Not all data support this association.²⁴ Further work is necessary to elucidate the role of X-chromosome inactivation in RPL.

Although most known examples of single-gene disorders result in fetal loss at 14 to 20 weeks, single-gene defects may also promote early recurrent miscarriage. These may be X-linked, autosomal recessive, or germ-line mutations involving loss of heterozygosity for developmentally lethal genes. For example, a study of heterozygous female carriers of glucose-6-phosphate dehydrogenase (G6PD) deficiency reported a 21.7% rate of pregnancy loss, compared with a control group with a miscarriage rate of 9.3%.²⁵ With advances in genomic technology, it may be feasible in the future to inexpensively sequence the genome of miscarriage samples to discover these putative single-gene causes, which will probably involve developmentally relevant genes such as those in the sonic hedgehog pathway. Evolving molecular and developmental biology technologies will expand our understanding of these complex pathways in normal and abnormal pregnancy.

COMPARATIVE GENOMIC HYBRIDIZATION, COPY NUMBER VARIATIONS, AND SINGLE NUCLEOTIDE POLYMORPHISMS

Conventional cytogenetics is rapidly being replaced by array-based comparative genomic hybridization techniques because of the latter's higher resolution in detecting genomic copy number variations (CNVs). In this technique, DNA from a tissue sample and from a normal reference sample are labeled with different fluorophores and then hybridized to several thousand probes for known genes and noncoding regions of the genome fixed to a glass slide. The ratio of fluorescent intensity between the test and reference DNA is then compared. The calculated ratio between them indicates the CNVs for a particular location in the genome. This technology identifies submicroscopic deletions and duplications that may be associated with human disease. It does not identify balanced rearrangements. Pathogenic CNVs are associated with *de novo* alterations (i.e., a change not identified in a clinically unaffected parent), larger size, and variation in a gene known to be associated with a disease phenotype.²⁶ Molecular technologies have rapidly advanced to increase the resolution, with applications now available to encompass the whole genome.

The suggestion that CNVs could be related to RPL arose in the past decade.²⁷ Approximately 500 spontaneous miscarriages have been studied with this technology. Up to 13% of products of conception studied identified a CNV.²⁸ The results are difficult to interpret because of variation in the level of resolution and DNA reference platforms used to detect variations. Many studies lack obstetric and family histories as well as information regarding the *de novo* or inherited nature of the variation. Candidate genes have been identified by this technique in animal models but have yet to be validated or confirmed in humans.²⁹ Further research is critical to establish a correlation between genotype and phenotype, and to better elucidate these alterations.

A single nucleotide polymorphism (SNP) is a DNA sequence variation that occurs when a single nucleotide varies at the same locus in the genomes of two individuals. SNPs may fall in a coding, noncoding, or intergenic region of a gene. This variation in genotype may (or may not) have a phenotypic consequence. In fact, although more than half of single-gene disorders are the result of a SNP, many such polymorphisms or variations are not pathogenic. A SNP must occur in 1% of the population to be categorized as such. They are conserved across evolution

and within a population, making SNPs important for anthropology research, but they also have increasing clinical applications. The mechanisms available to identify SNPs include DNA sequencing, mass spectrometry, and a SNP array. The basic principles of SNP array are the same as the DNA microarray. The SNP array contains known nucleic acid sequences from the genome and compares DNA sequences between the index case and a control.

SNPs have been described in cytokine genes, angiogenic genes, and hormone receptor genes. These mediators all have a plausible link to RPL because of the role they play in embryonic development. For example, a number of SNPs in functional cytokine genes such as the tumor necrosis factor (TNF)- α gene have been reported.³⁰ A study by Finan and coworkers evaluated tissue from couples with three or more idiopathic miscarriages occurring at less than 12 weeks' gestation.³⁰ The -1031T/C ($P = 1.02 \times 10^{-5}$), -376G/A ($P = .002$), and -238G/A ($P = .034$) polymorphisms were all found to be independently associated with the risk for early RPL. However, a meta-analysis of 16 genetic association studies of cytokine polymorphisms including TNF- α -308A and -238A did not identify a significant association between RPL and these gene alterations.³¹

Similar conflicting data have been reported for SNPs in genes related to angiogenesis and vasculogenesis. Because of the association between vascular endothelial growth factor (VEGF) and many adverse obstetric outcomes, including RPL and preeclampsia, researchers have studied the link between VEGF SNPs and RPL, and the findings have been conflicting.³² Investigators have also targeted p53 (specifically a codon 72 polymorphism) as a potential factor involved in RPL because of its role in cell apoptosis and estrogen- or progesterone-mediated activity. A case-control study comparing 60 women with spontaneous pregnancy loss and 64 women without a history of pregnancy loss did not identify a difference in genotype or allele frequencies between the two populations.³³ A recent meta-analysis including 523 women with RPL compared with 387 controls evaluated the p53 codon 72 polymorphism and did demonstrate a higher risk for RPL in those carrying this polymorphism (OR = 1.84; 95% CI, 1.07 to 3.16).³⁴ In addition, the study demonstrated that polymorphisms in other angiogenic and vasculogenic genes, including VEGF (-1154G/A) and endothelial nitric oxide synthase (Glu298Asp), were significantly and consistently associated with RPL (summary OR = 1.51; 95% CI, 1.13 to 2.03; and OR = 1.38; 95% CI, 1.09 to 1.74).

Because of the important role of hormones in pregnancy establishment and maintenance, polymorphisms in genes encoding hormones and hormone receptors have been evaluated. Many SNPs have been identified in the progesterone receptor gene (PROGINS) without any conclusive relationship.³² The literature on estrogen receptor polymorphisms is equally inconclusive. Meta-analysis of SNPs in PROGINS (741 women with RPL compared with 734 normal controls) and estrogen receptor gene- α (668 women with RPL and 765 normal controls) did not find a higher risk for recurrent miscarriage.²³ Further genetic and functional research on SNPs in all of these genes is necessary to clearly establish a mechanism or refute an association.

MALE GENETIC FACTORS

The paternal genome is equally important in fertilization, embryologic development, and placental function. Although

abnormalities on the Y chromosome were hypothesized as an origin of male-factor infertility in the 1970s, the Y chromosome contribution to RPL has been largely unexplored. The American Society for Reproductive Medicine patient information sheet on RPL identifies male factors as one of eight identified causes of RPL.³⁵ However, to date, available literature is scant, with small numbers of patients included. A study by Karaer and colleagues evaluated 43 men from couples with RPL and 43 men from couples with no history of pregnancy loss.³⁶ Using polymerase chain reaction techniques, DNA was tested for microdeletion in the Y chromosome azospermia factor region. Seven of 43 men with RPL demonstrated microdeletions in one of the four regions evaluated, whereas none of the men without a history of RPL were found to have similar alterations ($P = .006$). However, subsequent studies have failed to confirm these results.³⁷ Sperm oxidative stress and sperm DNA fragmentation have also been proposed as a cause of RPL, but reports in the literature have been conflicting.³⁸

USE OF ASSISTED REPRODUCTIVE TECHNOLOGIES

An argument has been proffered that patients with RPL could benefit from ART, including in vitro fertilization (IVF) with or without preimplantation genetic screening (PGS) for chromosomal abnormalities commonly found in abortus specimens. The basic thesis is that such losses are stochastic, and, thus, recruitment of large numbers of embryos with subsequent selection and transfer of those deemed putatively euploid after PGS will increase the likelihood of a live birth. Although the use of ART is appealing for couples with unexplained RPL who are desperate for a successful outcome, the prognosis for live birth in subsequent pregnancy without any intervention is approximately 75%.³⁹ Moreover, a number of randomized controlled trials have examined the outcomes of IVF with PGS for common aneuploidies in women of advanced reproductive age and have not shown clear benefit. Indeed, Hardarson and colleagues randomized 109 patients older than 37 years to PGS (56 patients) or to no PGS (53 patients) and observed a decreased clinical pregnancy rate in the PGS group: 8.9% (95% CI, 2.9% to 19.6%) versus 24.5% (95% CI, 13.8% to 38.3%), respectively.⁴⁰ Similarly, Mastenbroek and colleagues conducted a randomized, double-blind, controlled trial comparing three cycles of IVF with and without PGS in 408 women of ages 35 to 41 years.⁴¹ The primary outcome measure was ongoing pregnancy at 12 weeks of gestation, and these investigators also noted a lower ongoing-pregnancy rate in the PGS group than in the control group (25% [52/206] versus 37% [74/202]; rate ratio = 0.69; 95% CI, 0.51 to 0.93). Similarly the PGS group had a lower live birth rate (24% [49/206] versus 35% [71/202]; rate ratio = 0.68; 95% CI, 0.50 to 0.92). Although methodologic arguments have been presented to challenge the validity of these findings, there is no consensus that IVF with PGS improves live birth rates or reduces SAB rates in women of advanced reproductive age.

Two controversial studies have evaluated the use of IVF without PGS for couples with unexplained RPL.^{42,43} Although both reported a decrease in miscarriage rate after IVF, study sizes were small (57 and 20 couples) and confounding by adjuvant therapies occurred in both studies. To date, there have been no randomized controlled studies to assess miscarriage rates after PGS in couples with unexplained RPL. Four observational studies, including a total of 181 couples with unexplained RPL

undergoing IVF with PGS, together reported a live birth rate between 19% and 46% with a median miscarriage rate of 9%.⁴⁴ Maternal age varied between 35.4 and 37.6 years. A review of available evidence reveals a paucity of data on this topic, a poor quality of data, and a need for further investigation.

In vitro fertilization with preimplantation genetic diagnosis has been suggested for couples with a known structural chromosomal rearrangement. The reproductive risk varies with the nature of the balanced rearrangement and parent of origin. There are data to suggest that the live birth rate for couples with a balanced rearrangement is higher with spontaneous conception than with IVF and preimplantation genetic diagnosis (58% versus 29%, respectively, per oocyte retrieval), although this does not take into consideration the risk for unbalanced rearrangement in offspring with a poly-malformation, mental retardation condition.⁴⁵ Genetic counseling is important for this patient population to outline risks, benefits, and options for preconception and prenatal diagnostic testing.

Thrombophilias

There are two types of thrombophilia putatively associated with RPL (Box 44-2).

INHERITED THROMBOPHILIAS

The possible link between inherited thrombophilias and adverse obstetric outcomes, including miscarriage, has become a highly

contentious issue. Researchers and clinicians hypothesized that women or possibly fetuses with a genetic predisposition to thromboembolism could have thrombosis of the uteroplacental circulation and resultant complications such as preeclampsia, placental abruption, growth restriction, or fetal loss. Recommendations for screening and treatment were based on retrospective, generally small, case-control studies and meta-analyses.⁴⁶⁻⁴⁹ Subsequent prospective studies have not proven causality between inherited thrombophilia and miscarriage, so screening and treatment are no longer recommended.⁵⁰

The factor V Leiden (FVL) mutation is the most common heritable thrombophilia. It is present in about 5% of European-derived populations and 3% of African Americans, but it is very rare in nonwhite Africans and Asians.⁵¹ The mutation results in a substitution of glutamine for arginine at position 506 on the polypeptide, the site of cleavage by activated protein C. As a result, factor Va is resistant to degradation by activated protein C. This mutation accounts for the vast majority of cases of activated protein C resistance. The prothrombin *G20210A* gene mutation (PGM) is also a gain-of-function mutation resulting in a transition of guanine to adenine at nucleotide 20210 in the 3' untranslated region of the gene, resulting in a 30% increase in prothrombin levels in heterozygous states.⁵² This mutation is present in 2% to 5% in the general population.⁵³ Other inherited thrombophilias known to be significantly associated with venous thromboembolism include protein C and S and antithrombin deficiencies.

The early literature suggested a causal relationship between pregnancy loss and FVL. A meta-analysis of 31 studies reported a modest link between FVL and first-trimester SAB, with an OR of 2.01 (95% CI, 1.13 to 3.58) but a stronger association with late (>19 weeks) nonrecurrent fetal loss (OR = 3.26; 95% CI, 1.82 to 5.83).⁴⁶ A large case-control study of patients with recurrent stillbirths beyond 22 weeks showed an even stronger association with FVL (OR = 7.83; 95% CI, 2.83 to 21.67).⁵⁴ Moreover, Dudding and Attia conducted a meta-analysis of the link between FVL and adverse pregnancy events and noted no association with first-trimester miscarriage but a strong association with two or more second- or third-trimester fetal losses (OR = 10.7; 95% CI, 4.0 to 28.5).⁴⁷

A similar pattern holds for inherited thrombophilias in general. The European Prospective Cohort on Thrombophilia (EPCOT) retrospectively compared pregnancy outcomes among 571 women with thrombophilias having 1524 pregnancies, with 395 controls having 1019 pregnancies, and reported an association between inherited thrombophilias and stillbirth (OR = 3.6; 95% CI, 1.4 to 9.4) but not with SAB (OR = 1.27; 95% CI, 0.94 to 1.71).⁵⁵ Roque and colleagues assessed a cohort of 491 patients with a history of various adverse pregnancy outcomes and noted maternal thrombophilia was protective against recurrent SAB at less than 10 weeks (OR = 0.55; 95% CI, 0.33 to 0.92).⁵⁶ In contrast, these authors observed a weak association between maternal thrombophilias and losses at 10 weeks or more (OR = 1.76; 95% CI, 1.05 to 2.94) and a stronger association with fetal loss after 14 weeks (OR = 3.41; 95% CI, 1.90 to 6.10). Consistent with this protective effect of FVL on early pregnancy are the reports that IVF live birth and implantation rates were higher among FVL carriers than among noncarriers.⁵⁷ Indeed, extravillous endovascular trophoblasts occlude spiral arteries to minimize uteroplacental blood flow before 10 weeks' gestation, accounting for the low intervillous oxygen partial pressures prior to 10 weeks compared with after

12 weeks (17 ± 6.9 versus 60.7 ± 8.5 mm Hg, respectively).⁵⁸ Thus, there is no mechanistic explanation for how thrombophilias promote early pregnancy loss.

Recent prospective studies have cast further doubt on the association between inherited thrombophilias and many adverse pregnancy outcomes, including fetal loss. Dizon-Townson and associates assessed the prevalence and clinical significance of FVL among pregnant women with singleton gestations and no history of thromboembolism, who were at less than 14 weeks of gestation.⁵⁹ They noted the mutation was present in 2.7% of the 4885 women tested, and a nested case-control analysis found no differences in pregnancy loss, preeclampsia, placental abruption, or small-for-gestational-age births between FVL carriers and noncarriers. Similarly, Clark and coworkers found no association between FVL and fetal loss or other adverse pregnancy outcomes among 4250 pregnant women screened between 7 and 16 weeks' gestation.⁶⁰ Lindqvist and colleagues tested 2480 women for activated protein C resistance or FVL in early pregnancy and also observed no association between this condition and fetal loss, preeclampsia, or fetal growth restriction.⁶¹ Likewise, Silver and colleagues tested a pregnant cohort for the PGM and found that the 3.8% of women who were heterozygous for PGM had similar rates of pregnancy loss and other adverse pregnancy outcomes, compared with noncarriers.⁶² Prospective studies in low-risk populations do not suggest an association between inherited thrombophilias and fetal loss or other adverse pregnancy events. Routine testing for inherited thrombophilias in patients with RPL and no other risk factors is not recommended.⁵⁰

ANTIPHOSPHOLIPID ANTIBODY SYNDROME

The antiphospholipid antibody syndrome (APS) is defined by both clinical and laboratory criteria.⁶³ The clinical criteria include a history of deep venous or arterial thrombosis and characteristic obstetric complications including RPL. Laboratory criteria include the presence of medium to high titers of IgG/IgM anticardiolipin antibodies, IgG/IgM anti- β_2 -glycoprotein-1 antibodies at levels in the 99th percentile or higher, or a lupus anticoagulant on two or more occasions at least 12 weeks apart. At least one clinical criterion and one laboratory criterion must be present for definitive diagnosis. Obstetric complications include at least one fetal death at 10 weeks' gestation or older, at least one premature birth before 35 weeks resulting from severe preeclampsia or placental insufficiency, and at least three consecutive SABs before 10 weeks with other factors (genetics, anatomic, endocrine) excluded.

Antiphospholipid antibodies are immunoglobulins directed against proteins bound to negatively charged (anionic) phospholipids. There are approximately 20 such antibodies known.⁶⁴ They can be detected by screening for antibodies that bind directly to protein epitopes (e.g., β_2 -glycoprotein-1, prothrombin, annexin V), or by indirectly detecting antibodies that react to proteins present in an anionic phospholipid matrix (e.g., cardiolipin, phosphatidylserine), or by evaluating the downstream coagulation effects of these antibodies on *in vitro* prothrombin activation (e.g., lupus anticoagulants).⁶⁵ Suggested pathogenic mechanisms by which antiphospholipid antibodies (aPLs) induce fetal loss include impairment of the anticoagulant effects of placental anionic phospholipid-binding proteins β_2 -glycoprotein-1 and annexin V, and aPL induction of decidual and placental bed complement activation.⁶⁶⁻⁶⁸

There is ongoing debate about the clinical significance of other aPLs. Several investigators suggest testing for a panel of aPLs, including antiphosphatidylserine, although these are not included in the diagnostic guidelines. In vitro models demonstrate inhibition of trophoblast invasion in the presence of antiphosphatidylserine antibodies, and limited data suggest women with RPL and these antibodies may benefit from treatment.^{69,70} Further research is necessary to better clarify screening and treatment recommendations for alternative antibodies.

Persistently high levels of aPLs appear to be associated with obstetric complications, including fetal loss after 9 weeks' gestation, abruption, severe preeclampsia, and intrauterine growth restriction, in about 15% to 20% of affected patients. Between 5% and 15% of women with recurrent SAB have documented aPL, compared with 2% to 5% in the general obstetric population.⁷¹ In patients with strictly defined APS, the pregnancy failure rate in untreated pregnancies is up to 90%, with 52% of miscarriages occurring early (<10 weeks) and 38% occurring late (>10 weeks). Compared with patients having unexplained first-trimester losses without aPLs, those with antibodies more often have documented fetal cardiac activity prior to a loss (86% versus 43%; $P < .01$).⁷² The most consistent association with fetal loss is seen with lupus anticoagulant, which has reported ORs for pregnancy loss of 3.0 to 4.8; anticardiolipin antibodies display a wider range of reported ORs (0.86 to 20.0).⁶⁴

TREATMENT OF ANTIPHOSPHOLIPID ANTIBODY SYNDROME AND INHERITED THROMBOPHILIAS

The best rationale for treating thrombophilias to prevent RPL exists for APS, which remains the most treatable general cause of RPL. Proposed interventions include low-molecular-weight heparin (LMWH), unfractionated heparin, aspirin (81 and 325 mg), prednisone, and intravenous immunoglobulin (IVIG). Treatment with heparin and low-dosage aspirin is currently the standard recommendation. Mak and associates performed a meta-analysis of randomized clinical trials comparing the efficacy of heparin/LMWH plus aspirin and the efficacy of aspirin alone, in patients with APS and RPL.⁷³ Data were available from five trials involving 334 patients. Live birth rates were 74.3% (heparin plus aspirin) and 55.8% (aspirin alone). Thus, the combination of heparin and aspirin modestly increased the likelihood of a live birth compared with aspirin alone (RR = 1.3; 95% CI, 1.0 to 1.6; number needed to treat = 5.6 per live birth). No significant difference was noted in the prevalence of preeclampsia or preterm labor between the two groups.

Although LMWH is routinely substituted for unfractionated heparin in therapy for APS, its efficacy has not been thoroughly vetted in large, randomized trials. Stephenson and coworkers published a prospective randomized trial suggesting that unfractionated heparin and LMWH were equally efficacious in the treatment of patients with RPL.⁷⁴ Subsequently, a meta-analysis by Ziakas and associates suggested that treatment with unfractionated heparin and low-dosage aspirin may be superior to LMWH and low-dosage aspirin therapy.⁷⁵ The safety profiles, cost, and dosages must also be taken into consideration as further research is performed. Thus, on the basis of current data, either type of heparin appears acceptable for treating pregnant patients with APS.

There remains controversy about whether anticoagulation therapy prevents recurrent fetal loss among patients with an

inherited thrombophilia. Gris and colleagues conducted a clinical trial of enoxaparin (a LMWH) versus low-dosage aspirin in 160 women with one unexplained fetal loss at more than 10 weeks; the women were heterozygous for FVL or PGM, or had protein S deficiency.⁷⁶ They reported that enoxaparin therapy resulted in greater numbers of healthy live births (86.2%) than low-dosage aspirin alone (28.8%; $P < .0001$) (OR = 15.5; 95% CI, 7 to 34). However, this study has been criticized on methodologic grounds and because of the far lower than expected live birth rate in the aspirin-treated group. In contrast, Kaandorp and colleagues conducted a randomized, placebo-controlled clinical trial among 364 women with a history of unexplained recurrent SAB; they compared the efficacy of 80 mg of aspirin plus LMWH (nadroparin, at a dosage of 2850 IU), 80 mg of aspirin alone, or placebo and observed no difference in live birth rates among the three study groups (54.5%, 50.8%, and 57.0%, respectively).⁷⁷ They also found no significant benefits among the 16% of women who had an inherited thrombophilia. A second randomized controlled trial, the Scottish Pregnancy Intervention study, evaluated 294 women with a history of recurrent miscarriage to see whether LMWH (enoxaparin) plus low-dosage aspirin reduced the risk for pregnancy loss when compared with intensive surveillance.⁷⁸ The rate of miscarriage in the treatment groups versus surveillance group was 22% versus 20% (OR = 0.91; 95% CI, 0.52 to 1.59). Furthermore, the randomized clinical HepASA trial compared live birth rates among women with an inherited thrombophilia, APA syndrome, or antinuclear antibodies.⁷⁹ Patients were treated with LMWH (enoxaparin) plus aspirin or with aspirin alone. There was no additional benefit to treatment with LMWH in addition to aspirin ($P = .71$), and almost 80% of all women studied had a subsequent successful pregnancy outcome. Finally, the HABENOX study, a multicenter randomized control trial, compared aspirin or LMWH (enoxaparin) with a combination of the two, in women with recurrent miscarriage with or without thrombophilia.⁸⁰ No significant difference in live birth rate was found with enoxaparin treatment versus aspirin, or with a combination of LMWH and aspirin versus aspirin alone in women with recurrent miscarriage.

Thus, there appears to be no value to establishing the diagnosis of inherited thrombophilia in patients with recurrent early pregnancy loss. There is also no consensus on the usefulness of such evaluations among patients with later pregnancy losses and other adverse pregnancy outcomes. Furthermore, there appears to be no benefit to treatment. Moreover, in addition to the lack of evidence that treatment with anticoagulation improves pregnancy outcomes among patients with inherited thrombophilias and RPL, anticoagulation therapy is potentially harmful: Reported side effects include heparin-induced thrombocytopenia, heparin-induced osteoporosis, and possible fracture and injection-site complications.⁸¹

Endocrine Disorders

Three endocrine disorders are reported to be associated with RPL (see Box 44-2).

THYROID DISEASE

Autoimmune thyroid disease is the most common cause of hypothyroidism, with a reported prevalence of 5% to 20% among pregnant women.^{82,83} Normal maternal thyroid function

is important for trophoblast function and maintenance of early pregnancy.⁸⁴ Antibodies to thyroperoxidase and thyroglobulin are commonly identified in this disorder. Several studies have found antithyroid antibodies are more common in women with RPL.^{85,86} In contrast, Rushworth and coworkers studied 870 nonpregnant women with a history of three or more pregnancy losses.⁸⁷ They found that women with thyroid antibodies were as likely to achieve successful pregnancy as those without antibodies (58% versus 58%).

Nonrandomized studies have suggested that levothyroxine therapy may decrease SAB rates in euthyroid, thyroid-antibody-positive women and in those with subclinical hypothyroidism. De Vivo and coworkers evaluated 216 women with no history of thyroid disease and early pregnancy loss (<12 weeks' gestation).⁸⁸ They found that 85% had normal thyroid function, 11.5% had thyroid autoantibodies, and 3.8% had subclinical hypothyroidism. Thyroid-stimulating hormone (TSH) levels were higher in those with early miscarriage ($P = .04$) and in patients with subclinical hypothyroid disease as compared with euthyroid and thyroid-autoantibody-positive women ($P < .001$). Negro and colleagues reported that rates of early pregnancy loss were increased among thyroid-antibody-negative women with TSH levels between 2.5 mIU/mL and 5.0 mIU/mL, a level previously considered to lie in the normal range in most clinical laboratories.⁸⁹ A recent Cochrane Database Review recommends treating women with subclinical hypothyroidism to reduce the risk for miscarriage, although this does not directly address usefulness in patients with RPL.⁹⁰ Currently, the American College of Obstetricians and Gynecologists does not recommend universal screening for thyroid disease in pregnancy, but it suggests targeted testing for women with symptoms or history of disease.⁹¹

LUTEAL PHASE DEFECT

A luteal phase defect (LPD) is described as a failure to develop fully mature secretory endometrium. Progesterone plays a critical role in the maintenance of endometrial integrity and early pregnancy support.⁹² The antiprogesterin RU 486 can induce menstruation and early abortion by inhibiting these salutary effects of progesterone.⁹³ These observations provide biologic plausibility to the theory that LPDs could promote early pregnancy loss. The prevalence of LPDs among patients with early RPL is reported to be up to 35%.⁹⁴ However, among women with RPL, those with documented LPDs (defined by a mid-luteal phase single serum progesterone level of <10 ng/mL) actually had lower SAB rates in a subsequent pregnancy without any intervention, including progesterone supplementation, than those without such a defect.⁹⁵

Although in animal models the diagnosis of LPD has been described convincingly, it remains a contentious clinical entity. There is no clear method of diagnosis, whether by progesterone levels, endometrial biopsy, or basal body temperature charts.^{96,97} Studies of available treatments, including ovulation induction and progesterone supplementation, intended to reduce the rate of RPL, have conflicting results.⁹⁸ A Cochrane Review did show that progesterone supplementation was beneficial in women with a history of three or more consecutive pregnancy losses (OR = 0.38; 95% CI, 0.2 to 0.7).⁹⁹ For a patient with RPL and an LPD accompanied by hyperprolactinemia, bromocriptine is a treatment option that appears to improve live birth rates.¹⁰⁰

POLYCYSTIC OVARIAN SYNDROME

Initial reports suggested that polycystic ovarian syndrome (PCOS) was associated with recurrent miscarriage, but causal links between hyperandrogenism, hyperinsulinemia, and RPL have been difficult to establish.¹⁰¹ Further complicating matters, women with PCOS are reported to have a threefold increase in the prevalence of autoimmune thyroid disease when compared with unaffected healthy controls.¹⁰² In women with PCOS, treatment with metformin does not appear to reduce SAB rates. Legro and colleagues randomized 626 infertile women with PCOS to receive clomiphene citrate plus placebo, extended-release metformin plus placebo, or a combination of metformin and clomiphene for up to 6 months, and they observed live birth rates of 22.5%, 7.2%, and 26.8%, respectively.¹⁰³ The rate of first-trimester SAB did not differ significantly among the groups. This was corroborated by a second randomized clinical trial.¹⁰⁴ Many practitioners offer insulin-sensitizing agents to women with PCOS, particularly those with elevated androgens or insulin resistance, although there is a paucity of data to support this practice. Those patients with overt diabetes clearly have up to a threefold increased risk for spontaneous pregnancy loss, so women with risk factors should be screened by routine measures and treated accordingly.¹⁰⁵

Uterine Malformations and Endometrial Abnormalities

Women with müllerian tract anomalies appear to have an increased risk for RPL. Different studies vary significantly on the inclusion criteria and methods used to characterize congenital uterine anomalies (see Box 44-2), and prevalence rates range from 1.8% to 37.6%.¹⁰⁶ A review of the literature from 1950 to 2007 by Saravelos and colleagues reported the prevalence of congenital uterine anomalies to be 16.7% among women with three or more miscarriages (95% CI, 14.8 to 18.6).¹⁰⁷ However, in large studies (>500 women), when arcuate uterus is excluded, the prevalence of müllerian anomalies in women with RPL is between 3% and 7%.^{108,109} Sugiura-Osasawara and coworkers used a cohort design to study the pregnancy outcomes of a cohort of 42 patients with a bicornuate or septate uterus who had had two or more prior miscarriages and compare them with the outcomes of a cohort of 1528 women with RPL but a normal uterus.¹⁰⁸ No surgery was performed for those with müllerian anomalies, and 59.5% of those with an uncorrected septate or bicornuate uterus had a successful pregnancy, compared with 71.7% of controls. Interestingly, women without a uterine anomaly were more likely to have a miscarriage with aneuploidy than those with uterine anomalies ($P = .006$), which suggests confounding. There was no statistical difference in maternal age between the two groups.

The various theories proposed to account for the association between uterine anomalies and RPL include decreased vascularity in the septum, increased inflammation, and a reduction in sensitivity to steroid hormones.¹¹⁰ However, there is no substantive support for any of these putative etiologies. Although reductions in RPL with surgical correction have been reported in several large series, there have been no prospective randomized trials to validate this intervention.^{111,112} Open metroplasty is rarely recommended for bicornuate or didelphys uteri partly because of the attendant risks for infertility or uterine rupture

during pregnancy, and partly because of their generally more favorable associated pregnancy outcomes.

Although pregnancy outcomes are generally believed to be relatively unaffected by the presence of myomas, submucous myomas that distort the uterine cavity have been posited as causes of recurrent miscarriage and reduced IVF success rates. Saravelos and colleagues evaluated women with RPL and either cavity-distorting myomas or myomas that did not distort the uterine cavity and compared their pregnancy outcomes to those of a group of women without fibroids but with idiopathic RPL.¹¹³ Women with distorting submucous fibroids who underwent myomectomy had significantly lower rates of miscarriage after surgery (21.7% to 0%; $P < .01$), with a resultant increase in the live birth rate from 23.3% to 52.0% ($P < .05$). Women with fibroids that did not distort the uterine cavity (and who did not undergo myomectomy) had no difference in subsequent pregnancy rates when compared with women without uterine fibroids (70.4% versus 71.9%). Other uterine defects, such as Asherman syndrome and polyps, have been posited as causes of recurrent SAB, and descriptive series suggest improvement in pregnancy outcomes after hysteroscopic resection.¹¹⁴

Environmental Factors

A number of environmental factors have been reported to affect RPL (see Box 44-2).

CAFFEINE

Moderate caffeine consumption (defined as less than 200 mg daily by the American College of Obstetricians and Gynecologists) does not appear to increase risk for pregnancy loss.¹¹⁵ The older literature on caffeine intake and resultant miscarriage includes small numbers of patients, is largely retrospective, and is affected by recall bias. Two recent studies have attempted to overcome these methodologic challenges. Savitz and colleagues performed a longitudinal study enrolling women with 2407 clinically recognized pregnancies, of which 258 ended in miscarriage.¹¹⁶ Although RPL was not evaluated specifically in this study, 21% of the women reported having had a prior pregnancy loss. Data on ongoing caffeine consumption were collected, as was information on outcomes. Neither coffee nor caffeine consumption was related to overall risk for miscarriage (adjusted OR = 0.7 to 1.3). There was no relationship between time of intake (prior to pregnancy, 4 weeks after last menstrual period, or at 16 weeks' gestation) and outcomes. There was also no association between miscarriage and amount of caffeine consumed. A second prospective cohort study by Weng and coworkers included 1063 pregnant women who experienced 172 miscarriages.¹¹⁷ These authors did find an increased risk for miscarriage with caffeine consumption greater than 200 mg/day (adjusted hazard ratio = 2.23; 95% CI, 1.34 to 3.69). Further research is necessary to clarify the difference in outcomes between these two studies, which could be attributed to ascertainment bias or study design variation.

ALCOHOL

Alcohol consumption is not advised during pregnancy. The literature relating miscarriage risk to alcohol exposure dates to the 1980s and 1990s. Those studies show a modest effect on risk for

pregnancy loss, although the results must be interpreted cautiously given recall bias, the populations evaluated, and study design.¹¹⁸ Whether the pregnancy loss can be directly attributed to alcohol use or is a function of underlying maternal comorbidities associated with related behaviors remains a question. Armstrong and associates performed a retrospective study of 35,848 pregnancies and queried amount of alcohol consumed during a current or previous gestation.¹¹⁹ Alcohol consumption was associated with an increased miscarriage risk (OR = 1.26; 95% CI, 1.19 to 1.33) for each drink per day. In contrast, Halmesmaki and coworkers found no difference in miscarriage rates between women who reported three to four alcoholic drinks per week and those who denied alcohol exposure.¹²⁰ This null association has been reported in other studies.¹²¹ If any relationship exists, the overall effect appears to be small.

OBESITY

Obesity, defined as a body mass index (BMI) of 30 kg/m² or greater by the World Health Organization, is a nationwide epidemic, with a reported prevalence of 35.8% among adult women in the United States.¹²² Much of the data on miscarriage in obese women originates from populations who achieve pregnancy via ART or other infertility treatments. Metwally and colleagues published a meta-analysis of 16 studies and 5545 overweight or obese women who were compared with 11,151 women of normal body weight.¹²³ The rate of miscarriage regardless of the method of conception was increased among women with a BMI of 25 kg/m² or greater (OR = 1.67; 95% CI, 1.25 to 2.25). There are data to suggest that obesity increases risk for recurrent miscarriage in women who achieve pregnancy by spontaneous conception.¹²⁴ Lashen and colleagues performed a cohort study comparing obese women (BMI >30) with normal-BMI controls and their previous history of recurrent early miscarriage (defined as three or more pregnancy losses at <12 weeks' gestation).¹²⁵ The risk for recurrent early miscarriage was significantly higher for the obese cohort than for the normal weight cohort (OR = 3.5; 95% CI, 1.03 to 12.01). Proposed mechanisms include insulin resistance or abnormalities of endometrial receptivity. Further prospective work is necessary to better clarify an association.

Other Factors Associated with Recurrent Pregnancy Loss

IMMUNOLOGIC PROCESSES

There are conflicting data with regard to the role of immunologic mechanisms (see Box 44-2) in RPL. One hypothesis held that maternal antipaternal lymphocytotoxic antibodies (i.e., blocking antibodies) acted to shield the placenta from a maternal immune response. Researchers proposed that excessive human leukocyte antigen (HLA) sharing or an abnormally high HLA conformity by prospective parents would lead to the absence of such antibodies. This, in turn, would expose placental antigens to a more cytotoxic maternal immune response.¹²⁶ Proponents of this theory advocated treatment of couples with RPL but lacking these antibodies with infusions of the male partner's leukocytes or extracts of placental trophoblast to induce antibody production. However, meta-analyses of such approaches failed to support efficacy.¹²⁷ Thus, there appears to be no rationale for this line of therapy for RPL, and the U.S.

Food and Drug Administration ultimately moved to proscribe such treatment.

Another area of cellular immunology being investigated in women with RPL is the production of TNF- α and other CD4⁺ T-cell cytokines. Fukui and colleagues demonstrated higher CD4⁺ cell cytokine expression in women with RPL than in controls.¹²⁸ In a study of a cohort of 17 patients with RPL, Winger and Reed treated them with a TNF- α inhibitor in addition to LMWH and IVIG and suggested a higher live birth rate than for those treated with IVIG and LMWH alone.¹²⁹ The side effects of TNF- α inhibitors (e.g., granulomatous disease, lymphoma, lupus-like syndromes, demyelinating diseases) are major obstacles to further research and clinical usefulness of this intervention.

Other immunomodulatory therapies that have been proposed for the treatment of RPL include granulocyte colony-stimulating factor (G-CSF) and intravenous immunoglobulin. Scarpellini and colleagues randomized 68 patients with RPL who attended a private infertility practice to receive either recombinant human G-CSF or placebo starting 6 days after ovulation.¹³⁰ The live birth rate in the group treated with G-CSF was 82.8%, compared with 48.5% in the placebo group. The mechanism of action and biologic plausibility of this treatment are not readily apparent, and additional studies are needed to confirm this finding. Stephenson and associates conducted a multicenter, randomized, placebo-controlled trial comparing the use of IVIG (500 mg/kg every 4 weeks from documentation of pregnancy through 18 to 20 weeks' gestation) versus placebo in women with RPL.¹³¹ There was no difference in live birth rates between the two groups ($P = .76$). These findings have been corroborated by several other studies and a meta-analysis, and IVIG is not a recommended therapy for RPL.^{132,133}

CELIAC DISEASE

Celiac disease is a chronic enteropathy triggered by gluten exposure in the intestinal mucosa, resulting in atrophy of intestinal villi and causing malabsorption. It is an immune-mediated, inflammatory process that occurs in approximately 1% of the general population.¹³⁴ Affected individuals develop characteristic antibodies to the enzyme tissue transglutaminase (TTG). Celiac disease is also known to affect other target organs, including the liver, thyroid, skin, and reproductive tract. Epidemiologic studies suggest an association between celiac disease and adverse reproductive outcomes, including RPL, low birth weight, preterm birth, and infertility.^{135,136} Kumar and colleagues evaluated four groups of women (having either idiopathic RPL, stillbirth, unexplained infertility, or fetal growth restriction of unknown origin) and compared them with a control group who had a normal obstetric history.¹³⁷ TTG IgA antibodies as demonstrated by enzyme-linked immunosorbent assay (ELISA) were 5.43 times more likely to occur in the group with recurrent SAB, 4.61 times in the group with stillbirth, 7.75 times in the group with intrauterine growth restriction, and 4.51 times in the group with unexplained infertility, compared with controls. Bustos and coworkers compared the prevalence of various autoantibodies in 118 otherwise healthy women with three or more SABs with their prevalence in 125 fertile, multiparous control women who were without SABs.¹³⁸ The authors observed an increased prevalence of celiac disease-related antibodies for antigliadin-type IgA as well as of IgG and IgA anti-transglutaminase antibodies among cases versus controls (P

< .04). In contrast, Greco and associates observed antihuman IgA-class anti-TTG antibodies as well as endomysial antibodies (EMA) in 51 of 5055 pregnant women but found no higher rate of SAB among affected women.¹³⁹ Thus, celiac disease and the presence of related antibodies have been linked to recurrent miscarriage, and treatment with a gluten-free diet appears to improve live birth rates. However, in the absence of maternal symptoms, screening for occult celiac disease is not currently recommended in the workup of recurrent SAB.

OTHER INFECTIOUS AND INFLAMMATORY PROCESSES

Although *Chlamydia trachomatis*, *Ureaplasma urealyticum*, *Mycoplasma hominis*, human cytomegalovirus, adeno-associated virus, rubella, herpesviruses, and human papillomaviruses have been identified more frequently in genital tract cultures from women with RPL, there are no data establishing an association between chronic genital tract carriage of bacteria and recurrent SAB, or data indicating that empiric treatment offers benefit.^{140,141} There is inconsistent evidence to link the presence of bacterial vaginosis with early isolated SAB (adjusted OR = 2.67; 95% CI, 1.26 to 5.63).^{142,143} The presence of bacterial vaginosis during the first trimester of pregnancy has been repeatedly reported as a risk factor for second-trimester pregnancy loss.¹⁴⁴

Histopathologic evaluation of the placenta from first-trimester miscarriage specimens typically has a low yield in determining the etiology of RPL. However, exceptions include chronic intervillitis, chronic villitis, and plasma cell deciduitis, which are all associated with increased risk for recurrence.¹⁴⁵ Chronic intervillitis is characterized by dense infiltrate of histiocytes in the maternal intervillous space. This is a rare condition found in less than 1% of first-trimester placental specimens.¹⁴⁶ In addition to RPL, patients in whom this placental lesion is identified also have pregnancies complicated by severe fetal growth restriction and stillbirth. Similarly, chronic villitis is characterized by mononuclear cell infiltrate and fibrin deposition in the chorionic villi.¹⁴⁷ It is common in the third trimester and rarely identified in the first-trimester placenta. However, if progressive, it can result in RPL. Plasma cells detected in the decidua of a miscarriage specimen or by endometrial biopsy suggest chronic endometritis. Treatment with antibiotics is not proven to improve outcomes, and biopsy is not recommended in the evaluation of RPL.¹⁴⁵

Inherited Bleeding Disorders

Maintaining hemostatic balance is critical for implantation and pregnancy maintenance. Adverse reproductive outcomes including RPL have been reported in patients with bleeding disorders (see Box 44-2), including heritable and acquired deficiencies of fibrinogen or factor XIII deficiency.¹⁴⁸ Kadir and colleagues reported an increased rate of miscarriage (31%) after 72 pregnancies in 32 carriers of X-linked hemophilia A and B.¹⁴⁹ Similarly, Knol and colleagues reported a 21% miscarriage rate among 46 women who were carriers for either hemophilia A or B.¹⁵⁰ In contrast, the risk for miscarriage among women with von Willebrand disease is consistent with general population risk.¹⁵¹

An increased risk for miscarriage is reported in patients with deficient or defective fibrinogen, including diagnoses of

afibrinogenemia, hypofibrinogenemia, and dysfibrinogenemia. Abnormalities of fibrinogen can be inherited (typically autosomal recessive) or acquired and are rare, with a reported prevalence between 1 in 500,000 and 1 in 2,000,000.¹⁵² A review of pregnancies in six women with afibrinogenemia revealed nine miscarriages out of a total of 16 pregnancies (miscarriage rate, 56%).¹⁵³ Case reports of patients with autosomal recessive hereditary afibrinogenemia indicate a high miscarriage rate but with improved outcomes when fibrinogen replacement is used.^{154,155} The International Society of Thrombosis and Haemostasis conducted a study of 15 women with 64 pregnancies known to have familial dysfibrinogenemia and identified a miscarriage rate of 38%.¹⁵⁶ Losses linked with blood dyscrasias are generally associated with prolonged and excessive vaginal bleeding and frank abortion in the mid second trimester, and patients are treated by factor replacement therapy. Obtaining a three-generation pedigree and thorough medical history including questions on mucosal tract bleeding could suggest an underlying bleeding disorder.

Evaluation of Patients with Recurrent Pregnancy Loss

The evaluation of RPL is challenging for clinicians and requires a detailed history, construction of three-generation pedigree, physical examination, and laboratory assessment that can be costly with a remarkably low yield. Several authors and organizations have made recommendations for possible workups.^{157,158} Most experts identify a baseline assessment that includes genetic, anatomic, endocrine, and hematologic studies. Patients should be cautious of subsequent recommendations for evaluation and unorthodox treatment not supported by high-quality medical research.

The focus of the evaluation of a patient with two or more consecutive pregnancy losses should be on the identification of genetic factors. Thus, parental karyotypes, karyotyping of miscarriage specimens, and assessment of the placental pathology for trophoblast inclusions or chronic inflammatory processes appear to be reasonable diagnostic studies, although their cost-effectiveness is uncertain. Placental histology is particularly appropriate when no prior karyotypes were obtained from products of conception, and documented intermittent euploid losses occurring at around the same gestational age as the presence of trophoblast inclusions suggests genetic defects.¹⁵⁹ In the near future, whole genome sequencing or exome sequencing of specimens will probably be available. This process will undoubtedly identify many candidate genes of interest for translational research and potential clinical application.

For patients identified as having a structural chromosomal rearrangement, consideration may be given to ART, including preimplantation genetic testing. According to the American Society for Reproductive Medicine Practice Committee opinion, with support from research, there is no indication for ART with preimplantation genetic screening for couples with recurrent pregnancy loss, as there is no improvement in live birth rates or decrease in miscarriage rates. In addition, there is no role for preimplantation genetic screening when advanced maternal age is the sole indication for intervention.¹⁶⁰

A standard approach to search for uterine anatomic abnormalities should be conducted with sonohysterography and three-dimensional ultrasound. Remediable defects should be corrected before attempting a subsequent pregnancy. In

BOX 44-3 EVALUATION AND COUNSELING OF PATIENTS WITH RECURRENT PREGNANCY LOSS

GENETIC ASSESSMENT

1. Evaluate three-generation pedigree for suggestion of chromosomal rearrangement or other heritable disorders, including bleeding disorders or thrombophilia segregating in family.
 - a. Parental karyotype analysis
 - b. Specific testing for identified condition or referral for medical genetics evaluation
2. Review available medical records of prior pregnancy loss assessment
3. Parental karyotype analysis in couples with three or more miscarriages

ENDOCRINE ASSESSMENT

1. Screen for thyroid disease with thyroid-stimulating hormone (TSH), thyroperoxidase, and thyroglobulin antibodies.
 - a. Positive thyroid antibodies, with TSH <2.5 mIU/L (no treatment with repeat thyroid function testing in pregnancy)
 - b. Positive thyroid antibodies, with TSH >2.5 to 4 mIU/L (consider treating with levothyroxine tailored to TSH levels)
 - c. Overt hyperthyroid or hypothyroid disease (standard treatment)
2. Screen for prolactinoma
 - a. Treat elevated prolactin with bromocriptine.
 - b. Head imaging and referral for management as indicated
3. Consider empiric treatment for luteal phase defect with supplemental progesterone in women with three or more miscarriages of undetermined etiology.

THROMBOPHILIA ASSESSMENT

1. Personal or first-degree relative with venous thromboembolism
 - a. Consider testing for inherited forms of thrombophilia
2. Test for antiphospholipid antibody syndrome in those with one or more of the following clinical criteria (and treat with heparin and low-dosage aspirin if diagnostic laboratory criteria are met):
 - a. Vascular thrombosis
 - b. One demise or more of morphologically normal fetus older than 10 weeks' gestation
 - c. Preterm birth at less than 34 weeks' gestation resulting from preeclampsia or with evidence of placental insufficiency
 - d. Three or more unexplained miscarriages at less than 10 weeks' gestation, with anatomic, hormonal, and uterine abnormalities excluded

ASSESSMENT FOR UTERINE MALFORMATION

1. Evaluate müllerian structures with hysterosalpingogram, sonohystogram, hysteroscopy, or other approved modalities
 - a. Consider removal of cavity-distorting myoma or polyps.
 - b. Consider treatment of Asherman syndrome with hysteroscopic lysis of adhesions and postoperative prevention of adhesion reformation.

COUNSELING ON BENEFITS OF LIFESTYLE MODIFICATIONS

1. Moderate caffeine intake
2. Smoking cessation
3. Weight loss when applicable
4. Assess alcohol intake
5. Provide (or refer for) psychological support.

addition, a workup for aPL should be performed. If the patient meets the criteria for APS, treat with heparin and low-dosage aspirin. As anthropomorphic and social factors are modestly associated with the occurrence of isolated and recurrent miscarriage, prudent interventions for any patient include smoking cessation, reduction of caffeine and alcohol consumption, exercise, weight loss, and a healthy diet.

Patients may also be screened for abnormalities of prolactin and thyroid disease (TSH, anti-thyroperoxidase antibody, and anti-thyroglobulin antibodies) and treated accordingly (Box 44-3). The effect of thyroid autoimmunity on pregnancy and pregnancy-related complications continues to be an area of active research. There is no consensus among several national and international groups regarding normal serum TSH cutoff values, particularly in the obstetric patient. Recent research has focused on the role of anti-thyroid antibodies in the setting of normal TSH levels (2.5 to 5 mIU/L) in women with

unexplained early RPL. Several authors advocate screening and treatment for women with positive anti-thyroid antibodies and TSH levels in the range of 2.5 to 4 mIU/L.¹⁶¹

Any evaluation of patients who experience RPL should address the detrimental psychological response to this diagnosis. Patients report depression, anxiety, guilt, and deprivation and are at increased risk for post-traumatic stress disorder.¹⁶² As a consequence, they are often easily accepting of unconventional treatments. Several studies have reported the beneficial effect of psychological support for women who experience RPL.^{163,164} Thus, couples experiencing recurrent miscarriage should be screened for depression and post-traumatic stress disorder, and appropriate psychological support provided.

Stillbirth

UMA M. REDDY, MD, MPH | CATHERINE Y. SPONG, MD

Epidemiology

Stillbirth, defined as fetal death at 20 weeks or more of gestation, is one of the most common adverse pregnancy outcomes, with an estimated 3.2 million stillbirths at 28 weeks or more of gestation occurring worldwide annually.¹ It has been estimated that 98% of all stillbirths occur in low- and middle-income countries.² In the United States, stillbirth occurs in 1 of 160 pregnancies, and 26,000 stillbirths occur annually, which is equivalent to the number of infant deaths.³ The U.S. stillbirth rate is higher than in many developed countries.³ From 1990 to 2003, the stillbirth rate declined 1.4% per year, whereas the infant mortality rate declined by 2.8% per year.³ Between 1990 and 2003, the rate of fetal death occurring between 20 and 27 weeks' gestation remained stable at 3.2 per 1000 births, whereas the rate of fetal death at or after 28 weeks' gestation decreased from 4.3 to 3.0 per 1000 births.³ Since 2002, the overall stillbirth rate in the United States has remained relatively stable at 6.2 stillbirths per 1000 births. However, the most recently issued *National Vital Statistics Report* shows that from 2005 to 2006, there was a statistically significant decline of 3% for fetal deaths occurring at 20 to 27 weeks of gestation, resulting in a rate of 6.05 fetal deaths per 1000 live births and fetal deaths in 2006.⁴

There is a significant racial disparity in stillbirth rates in the United States, with a rate for non-Hispanic black women that is 2.2-fold higher than that for non-Hispanic white women (10.73 compared with 4.81 fetal deaths per 1000 live births and fetal deaths).⁴ The rate for Hispanic women is 10% higher than for non-Hispanic white women (5.29 per 1000 live births and fetal deaths).⁴ This difference is attributed in part to a higher risk for preterm delivery and in part to differences in maternal preconception health, infection, income, education, and access to quality health care.³ In an effort to better understand the racial disparity in stillbirth, the Stillbirth Collaborative Research Network (SCRN) conducted a multicenter, population-based, case-control study of stillbirths and live births enrolled at delivery, involving 59 tertiary-care and community hospitals, with access to at least 90% of deliveries in five catchment areas defined by state and county lines in the United States. The results suggested that much of the excess rate of stillbirth among non-Hispanic black women resulted from obstetric complications or infection, or both, with stillbirths often occurring intrapartum at less than 24 weeks' gestation, with a pathophysiology similar to that of spontaneous preterm birth.⁵

Maternal age and parity are significant risk factors for stillbirth. There is a U-shaped relationship between maternal age and stillbirth. The stillbirth rates (i.e., stillbirths per 1000 live births and stillbirths) for women younger than 15 years (13.12) and for women 45 and older (13.02) are 2.4 times the rate for 30- to 34-year-old women, who are in the lowest-risk group (5.4).⁴ Advanced maternal age (≥ 35 years) is also an

independent risk factor for stillbirth, even after controlling for factors that occur more often in older women, such as obesity, gestational diabetes, hypertension, and multiple gestations.³ The higher risk for stillbirth throughout gestation with advanced maternal age was studied in 5,458,735 singleton gestations without reported congenital anomalies from the 2001-02 U.S. National Center for Health Statistics data set.⁶ The peak risk period was 37 to 41 weeks. The risk for stillbirth at 37 to 41 weeks for women 35 to 39 years old was 1 in 382 ongoing pregnancies, and for women 40 years or older it was 1 in 267 ongoing pregnancies. Compared with women younger than 35 years, the relative risk (RR) for stillbirth was 1.32 (95% confidence interval [CI], 1.22 to 1.43) for women 35 to 39 years old, and 1.88 (95% CI, 1.64 to 2.16) for women 40 years or older at 37 to 41 weeks. This effect of maternal age persisted despite adjusting for medical disease, parity, and race/ethnicity, and it was subsequently confirmed in several other studies.^{7,8} Extremes of parity are also risk factors for stillbirth. Stillbirth rates are lowest for women with one prior pregnancy (4.87 per 1000 births). Compared with women who had one prior pregnancy, stillbirth rates were 21% higher for nulliparous women (5.88 per 1000 births), 18% higher for women with two prior pregnancies, 47% higher for women with three prior pregnancies, and 134% higher for women with four or more prior pregnancies.⁹ These patterns are consistent with data from other countries.

Multiple gestation and use of assisted reproductive technologies (ART) are also risk factors for stillbirth. The stillbirth rate is 2.8-fold higher for twins and 4.8-fold higher for triplet and higher-order pregnancies compared with singletons.⁴ The increased risk for multiple pregnancies is related in part to increased rates of preterm labor, fetal growth restriction, maternal hypertension, and placental and cord issues (especially with monochorionic twins). In addition, a high percentage of multiple gestations are the result of ART. The reason for the increased risk for stillbirth in ART pregnancies is unclear. In a recent study, compared with spontaneously conceived singleton pregnancies, singleton pregnancies from in vitro fertilization (IVF) or intracytoplasmic sperm injection (ICSI) procedures had more than four times the risk for stillbirth (odds ratio [OR] = 4.44; 95% CI, 2.38 to 8.28). Couples with a waiting time to pregnancy of 1 year or more and women who conceived after non-IVF ART had a risk for stillbirth similar to that of fertile couples and statistically significantly lower than women pregnant after IVF/ICSI, which indicates that the increased rate of stillbirth risk may be a result of the IVF/ICSI and not the underlying infertility.¹⁰

There is an association between previous adverse pregnancy outcomes and the risk for stillbirth. A previous preterm or small-for-gestational-age (SGA) birth appears to confer a significantly increased risk for stillbirth. In an analysis of 410,000 deliveries at 28 or more weeks' gestation in Sweden, previous

live birth of a growth-restricted infant before 32 weeks' gestation was associated with fivefold increased odds of stillbirth (OR = 5.0; 95% CI, 2.5 to 9.8).¹¹ This finding was confirmed in an Australian cohort in which preterm or SGA was associated with a stillbirth hazard ratio of 5.65 (95% CI, 1.76 to 18.12).¹² In a U.K. study, 364 women who had a stillbirth in their first pregnancy were compared with 33,715 women who had a live birth in their first pregnancy. Women with a previous stillbirth were at significantly increased risk for preeclampsia (OR = 3.1), placental abruption (OR = 9.4), induction of labor (OR = 3.2), instrumental delivery (OR = 2.0), elective (OR = 3.1) or emergency (OR = 2.1) cesarean delivery, prematurity (OR = 2.8), low birth weight (OR = 2.8), or malpresentation (OR = 2.8) compared with women with a previous live birth. There were significantly more stillbirths in the group of women with a previous stillbirth (1.4% compared with 0.5%); however, this was not significant when adjusted for confounders such as preeclampsia, abruption, preterm delivery, and low birth weight.¹³ This suggests that there may be an overall increased risk for stillbirth recurrence but not when the previous stillbirth is unexplained.

In most studies, previous stillbirth is associated with an increased recurrence rate of stillbirth. Using the Missouri maternally linked data containing births from 1978 to 1997, the risk for stillbirth recurrence among relatively low-risk women was studied. Of the 947 cases of stillbirth in the second pregnancy, 20 cases occurred in women with a history of stillbirth (stillbirth rate, 19.0 per 1000 births) and 927 in the comparison group of women with a previous live birth (stillbirth rate, 3.6 per 1000 births; $P < .001$). The adjusted risk for stillbirth was sixfold higher in women with a prior stillbirth. Analysis by stillbirth subtype in the second pregnancy showed that history of stillbirth conferred 10-fold increased risk for subsequent stillbirths between 20 and 28 weeks (95% CI, 6.1 to 17.2) and a 2.5-fold increased risk for stillbirths at greater than 29 weeks (95% CI, 1.0 to 6.0). There was also a 12-fold increased risk for intrapartum stillbirths (95% CI, 4.5 to 33.3) compared with a fourfold increased risk for antepartum stillbirths (95% CI, 2.3 to 7.7). Among low-risk women, who make up the majority of pregnant women, history of stillbirth was associated with an increased stillbirth recurrence for all subtypes of stillbirth except late stillbirths after 28 weeks.¹⁴ White women had a lower absolute risk for stillbirth recurrence than African Americans (19.1/1000 versus 35.9/1000; $P < .05$). After adjusting for potential confounders, there was a 2.6-fold increased risk for stillbirth recurrence in African Americans compared with whites.¹⁵

Previous cesarean delivery as a risk factor for stillbirth is controversial. An analysis of 11 million U.S. birth certificate and fetal death records between 1995 and 1997 found no association between previous cesarean delivery and stillbirth.¹⁶ However, the limitations of birth certificate data include under-reporting of repeat cesarean delivery with labor and vaginal birth after cesarean delivery.¹⁷ In addition, fetal death data have a higher percentage of nonstated responses for certain variables, such as method of delivery, than either live birth or infant death data.³ Studies with more details about subsequent pregnancies have indicated an increased risk for stillbirth. A study of 120,633 births in Scotland reported a 1.6-fold increased risk for unexplained stillbirth (95% CI, 1.2 to 2.3) in women with a previous cesarean delivery.¹⁸ Analysis of birth certificate data from almost 400,000 births in Missouri demonstrated a 1.4-fold increased risk for stillbirth (95% CI, 1.1 to 1.7) with previous cesarean delivery for African-American women but no association

among white women.¹⁹ In a U.S. cohort of 183,760 singleton pregnancies of 23 or more weeks' gestation, there was a 1.3-fold increased risk for antepartum stillbirth (95% CI, 1.0 to 1.6) for women with a previous cesarean delivery after controlling for important covariates such as maternal disease, race, prior preterm delivery, and body mass index (BMI).²⁰ As the overall rates of cesarean delivery remain high in the United States, this possible association between cesarean delivery and subsequent stillbirth risk is of concern.

An estimated 50% of reproductive-age women are classified as overweight (BMI > 25) and more than 30% are obese (BMI > 30).²¹ In pregnancy, obesity increases the risk for hypertension and diabetes and is an independent risk factor for stillbirth.²² In a meta-analysis, increased pre-pregnancy weight was associated with increased odds of stillbirth of 1.47 (95% CI, 1.08 to 1.94) and 2.07 (95% CI, 1.59 to 2.74) among overweight and obese pregnant women, respectively.²³ Pre-pregnancy obesity was associated with a 3.5- to 4.6-fold increased risk for stillbirth after 37 weeks' gestation.²⁴ In addition, in a cohort study of over 150,000 women who had two consecutive singleton pregnancies, an increase in BMI between the pregnancies was associated with significantly increased adverse outcomes including stillbirth.²² The reason for the increased stillbirth risk with high pre-pregnancy BMI and large interpregnancy weight gain is not well understood. The fetuses of obese women are at increased risk of congenital anomalies, death, and macrosomia, and, when there is maternal hypertension, intrauterine growth restriction.^{24a,24b} Furthermore, vascular and metabolic abnormalities as well as inflammation are theorized mechanisms underlying the relationship of obesity to stillbirth.^{25,26} As obesity is a modifiable risk factor, normalization of pre-pregnancy weight should be the goal.

A host of sociodemographic factors have been associated with an increased risk for stillbirth. Smoking, another modifiable risk factor, has been associated with a 36% increase in the odds of stillbirth (OR = 1.36; 95% CI, 1.27 to 1.46).²⁷ Women who quit smoking between their first and second pregnancies have been shown to reduce their risk for stillbirth to the same level as nonsmokers in the second pregnancy.²⁸ Alcohol use, illicit drug use, low maternal education level, and lack of or inadequate prenatal care have all been associated with increased stillbirth rates.²⁷

The roles of pre-pregnancy factors and racial disparity on stillbirth risk were studied by the SCRIN in 614 stillbirths and 1816 live births with detailed chart abstraction and maternal interview.²⁹ In multivariate analyses, pregnancy history was the strongest risk factor for stillbirth. When compared with multiparous women without previous pregnancy losses, there was a progressive increase in the risk for stillbirth for nulliparas (adjusted OR = 1.98; 95% CI, 1.51 to 2.60), then nulliparas with previous losses at less than 20 weeks' gestation (adjusted OR = 3.13; 95% CI, 2.06 to 4.75), and then multiparas with a previous stillbirth (adjusted OR = 5.91; 95% CI, 3.18 to 11.00). Having had at least one live birth, regardless of whether the woman had a pregnancy loss at less than 20 weeks, was somewhat protective. Other factors independently associated with stillbirth included non-Hispanic black race/ethnicity (adjusted OR = 2.12; 95% CI, 1.41 to 3.20), diabetes (adjusted OR = 2.50; 95% CI, 1.39 to 4.48), maternal age 40 years or older (adjusted OR = 2.41; 95% CI, 1.24 to 4.70), maternal AB blood type (adjusted OR = 1.96; 95% CI, 1.16 to 3.30), history of drug addiction (adjusted OR = 2.08; 95% CI, 1.12 to 3.88), smoking (10 cigarettes/day) during the 3 months before pregnancy (adjusted OR = 1.55;

95% CI, 1.02 to 2.35), obesity/overweight (adjusted OR = 1.72; 95% CI, 1.22 to 2.43), not living with a partner (adjusted OR = 1.62; 95% CI, 1.15 to 2.27), and multiple gestation (adjusted OR = 4.59; 95% CI, 2.63 to 8.00). Although multiple risk factors that were known at the time of pregnancy confirmation were associated with stillbirth, they accounted for only a small amount (19%) of the stillbirth risk.

Pathogenesis

INFECTION

Infection is believed to be associated with approximately 10% to 20% of stillbirths in developed countries^{5,50} and with a much greater percentage in developing countries. In developed countries, infection accounts for a greater percentage of preterm stillbirths than of term stillbirths.^{5,31} Infectious agents may result in stillbirth by producing direct fetal infection, placental dysfunction, or severe maternal illness.

Placental and fetal infections probably originate from either ascending or hematogenous spread. The most common is an ascending infection from the vagina into the space between the maternal decidua and the maternal chorion. Further spread may result in the organisms' reaching the amniotic fluid or the fetus. An immune response brings inflammatory cells into the chorioamnion (chorioamnionitis), the amniotic fluid (amnionitis), the umbilical cord (funisitis), or the fetus (usually pneumonia). Maternal systemic infections may also spread hematogenously and reach the fetus through the placental villi (villitis). These types of infections typically involve the fetal liver, as that is the first major fetal organ reached, but other organs are often involved.³²

Syphilis, which is increasingly uncommon in the United States, is still responsible for some stillbirths, especially in endemic areas. *Treponema pallidum*, the causative agent, can cross the placenta and infect the fetus after 14 weeks' gestation, with risk for fetal infection increasing with gestational age.³² About 50% of infected fetuses die in utero, and an additional 27% are born with congenital syphilis.³³ Other spirochetal diseases causing stillbirth include leptospirosis and Lyme disease. Bacterial pathogens implicated in stillbirth include *Escherichia coli*, group B streptococci, *Ureaplasma urealyticum*, *Mycoplasma hominus*, *Bacteroides* species, *Gardnerella*, *Mobiluncus* species, and various enterococci, which produce ascending infection.³² Malaria may be a cause of stillbirth in women who contract a first infection during pregnancy.³⁴ Other, less common organisms associated with fetal death include *Toxoplasma gondii* and *Listeria monocytogenes*.³²

Viral infection may also contribute to or cause fetal death. Parvovirus results in the clinical manifestation of fifth disease (or erythema infectiosum) in children but may be asymptomatic in adults. When parvovirus is responsible for stillbirth, the mechanism is most often destruction of erythropoietic tissue leading to severe anemia and hydrops. In a cohort of 1018 women with acute parvovirus B19 during pregnancy, fetal death occurred in 6.3% of cases, all observed when maternal B19 infection occurred before 20 weeks of gestation.³⁵ Parvovirus was implicated in up to 7.5% of fetal deaths in a Swedish study based on the identification of viral nucleic acid in the placenta.³⁶ None of the cases in this study had fetal hydrops, so direct myocardial damage was implicated as the cause. Other viral pathogens include enteroviruses, such as coxsackieviruses and

echoviruses, as well as cytomegalovirus (CMV). CMV is the most commonly acquired congenital viral infection, with a primary infection rate of about 1% during pregnancy. It is a known cause of fetal and placental damage, but its role in stillbirth remains unclear. Viruses for which vaccination is routine are rarely implicated in fetal death in developed countries. Recently, Ljungan virus, a picornavirus of bank voles, originally isolated in Sweden, has been reported to cause stillbirth in both Denmark and the United States.^{37,38}

MATERNAL MEDICAL CONDITIONS

Hypertensive Disorders

Hypertensive disorders of pregnancy complicate 10% to 16% of pregnancies and is a significant cause of stillbirth.³⁹ In the SCRN, 9.2% of stillbirths were associated with hypertensive disorders.⁵ The risk for stillbirth increases with the severity of hypertensive disorder. In a prospective cohort study of 1948 women with hypertension during pregnancy, the stillbirth rate for women with isolated chronic hypertension was relatively low and similar to the rate in the general population.⁴⁰ Women who developed preeclampsia with or without underlying chronic hypertension were at increased risk for perinatal mortality compared with women who had gestational hypertension.⁴⁰ The subgroup with the highest perinatal mortality rate (9.2%) in this cohort were women with chronic hypertension with superimposed preeclampsia.⁴⁰ In a Canadian cohort of more than 135,000 pregnancies, there was an increased risk for stillbirth among women with any hypertensive disorder (RR = 1.4; 95% CI, 1.1 to 1.8), which was further increased among women with pregnancies complicated by chronic hypertension (RR = 2.4; 95% CI, 1.2 to 5.1) or chronic hypertension with superimposed preeclampsia (RR = 4.4; 95% CI, 2.2 to 8.8).³⁹ The risk for stillbirth increases with multisystem disease: from 21 to 22 per 1000 with severe preeclampsia or eclampsia, to 70 per 1000 with the HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets).⁴¹

Diabetes Mellitus

Diabetes mellitus (DM) affects 2% to 5% of all pregnancies and is associated with about 4% of stillbirths.⁵ In women with poor glycemic control, stillbirths occur most commonly as a result of congenital abnormalities, placental insufficiency or fetal growth restriction, macrosomia or polyhydramnios, or obstructed labor (intrapartum stillbirth). The link between excessive fetal growth and stillbirth probably involves maternal hyperglycemia leading to fetal hyperglycemia, which in turn triggers excess fetal insulin production to maintain fetal plasma glucose levels in the physiologic range. In the fetus, insulin stimulates fetal growth, which may result in metabolic acidosis if excessive and if the placental oxygen supply is insufficient. The end point of this process may be a stillbirth. However, the relationship between quantitative measures of glycemic control and the risk for stillbirth is not well characterized.

Outcomes of pregnancies in type 1 diabetic women have improved over the past decades because of tighter glycemic control. However, the stillbirth risk remains elevated. In a prospective study comparing 5000 type 1 diabetics to nondiabetic controls, the rate of stillbirth was 1.5% in diabetic pregnancies, five times that seen in the nondiabetic population, with the majority occurring between 34 and 40 gestational weeks.⁴² Poor

maternal glycemic control was the most consistent finding in the women who had a stillbirth. Population-based studies confirm the increased risks for stillbirth among diabetic women. A study of U.S. birth certificate data showed a 2.5-fold increased risk for stillbirth,⁴³ and a national audit of pregnant women with diabetes in the United Kingdom reported a fourfold to fivefold increased risk (i.e., 25 to 30 per 10,000).⁴⁴

There have been conflicting reports regarding the difference in stillbirth rates between type 1 and type 2 diabetes. In one study, perinatal mortality in type 2 DM (46/1000) was significantly greater than that in type 1 DM (12.5/1000) or in gestational DM (GDM) (9/1000) ($P < .0001$). The excess in perinatal mortality in type 2 diabetics was greatest in the risk for stillbirth at 28 or more weeks' gestation, with a sevenfold increased risk compared with the general population. Women with type 2 diabetes were significantly older and more obese, and they presented later for care than women with type 1 diabetes.⁴⁵ However, a recent meta-analysis of 33 studies, comparing maternal and fetal outcomes in type 1 and type 2 diabetes, found type 2 diabetics had a higher risk for overall perinatal mortality (OR = 1.5; CI, 1.15 to 1.96) but no significant difference when analyzing stillbirth alone compared with type 1 diabetics.⁴⁶ Although the rate of GDM has also been increasing with the rise in maternal obesity, a cohort study of 3400 women with GDM found no differences in stillbirth or neonatal mortality rates compared with nondiabetics.⁴⁷

Thyroid Disease

Maternal hyperthyroidism in pregnancy is rare, occurring with a prevalence of 0.05% to 0.2%.⁴⁸ Graves disease, the most common cause of hyperthyroidism, results in fetal or neonatal thyrotoxicosis in about 1% of cases because of the transplacental passage of thyroid-stimulating immunoglobulins, and it is associated with an increased stillbirth rate of 7%.⁴⁸ Fetal thyrotoxicosis can result in stillbirth as a result of fetal growth restriction or fetal tachycardia resulting in nonimmune hydrops. On the other hand, hypothyroidism, both overt and subclinical, is relatively common, occurring in about 2.5% of pregnancies.^{49,50} Overt hypothyroidism places women at increased risk for pregnancy-induced hypertension,⁵¹ SGA infants,⁵¹ and stillbirth with a rate of 12/1000 to 20/1000.⁵² The risk for fetal or neonatal death increases by 1.6-fold for every doubling of the concentration of thyroid-stimulating hormone (TSH).⁵³ Results of studies are not consistent regarding an increased risk for stillbirth with subclinical hypothyroidism. The stillbirth rate was increased fourfold (OR = 4.4; 95% CI, 1.9 to 9.5) in one cohort of women with a TSH level of 6 mU/L or greater, compared with women with a TSH level of less than 6 mU/L, among 9403 women tested at 15 to 18 weeks' gestation.⁵⁰ In another study of 17,298 women, the stillbirth rate was not increased in women with subclinical hypothyroidism (defined as TSH values at the 97.5th percentile and normal free thyroxine) at 20 or fewer weeks' gestation.⁴⁹ In addition, an increased stillbirth rate has been noted in euthyroid women with high serum antithyroid peroxidase (TPO) antibody concentrations, as seen in Hashimoto thyroiditis. Women positive for TPO antibodies in the first trimester had more than a threefold increased risk for perinatal mortality when compared with TPO antibody-negative women.⁵⁴

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) has an overall prevalence of less than 1%, with a stillbirth rate of 40 to 150 per 1000.⁵²

Fetal prognosis appears to depend primarily on maternal disease activity and is increased with active renal disease. Another cause of stillbirth is neonatal lupus erythematosus with congenital atrioventricular (AV) block. This occurs in 1% to 5% of infants born to women with autoantibodies to SSA/Ro and SSB/La as a result of their transplacental passage, which can cause permanent destruction of the AV conduction system and scarring of the endocardium.⁵⁵ Congenital AV block has been associated with the development of hydrops in up to 40% of cases detected in utero, with a third resulting in stillbirth.⁵⁵

The presence of antiphospholipid antibodies and a prior fetal loss are also significant predictors of subsequent stillbirth in women with SLE. Antiphospholipid antibodies are present in over a third of patients with SLE and are associated with an increased risk for thrombosis and damage to the uteroplacental vasculature. A review of 554 women with SLE found that fetal death was more common in those with antiphospholipid antibodies (38%) than in those without antibodies (16%).⁵⁶

Renal Disease

The association of renal disease with stillbirth depends on the severity of renal impairment and the presence of hypertension. There is a positive linear relationship between maternal creatinine levels and stillbirth rates.⁵⁷ The overall stillbirth rate for women with mild (creatinine <1.4 mg/dL) and moderate (1.4 to 2.4 mg/dL) renal disease is 9%, whereas the stillbirth rate is 36% for women with severe renal disease (>2.4 mg/dL).⁵⁸ Furthermore, renal disease with hypertension carries a less favorable maternal and fetal prognosis, with a 10-fold increase in fetal death.⁵⁷ Preeclampsia occurs in 50% of women with pre-existing renal disease, and in 80% of those with associated chronic hypertension.⁵⁸ Although there have been reported cases of successful pregnancies in women with end-stage renal disease, dialysis during pregnancy generally carries a poor prognosis, with a live birth rate of only 52%.⁵⁸ However, if kidney transplantation is performed before the pregnancy and renal function normalizes, outcomes are significantly improved.⁵⁸

Intrahepatic Cholestasis of Pregnancy

Intrahepatic cholestasis of pregnancy (ICP), the most common form of noninfectious liver disease occurring in pregnancy, has been associated with an increased stillbirth rate of 12 to 30/1000 affected pregnancies.⁵² ICP is characterized by pruritus and an elevation in serum bile acid concentration, but the exact mechanism of the associated stillbirth is unknown. In a prospective study in Sweden, more than 45,000 pregnant women were screened for ICP, and the women with bile acid levels greater than 40 mol/L experienced significantly higher rates of fetal complications, such as asphyxia, spontaneous preterm delivery, and meconium staining of amniotic fluid, placenta, and membranes, compared with women with normal bile acid levels and women with mild ICP (bile acid levels of 40 mol/L or less).⁵⁹ Of note, stillbirth occurred in only 0.4% of patients, a rate similar to that expected for the general population. The authors postulated that the low incidence of stillbirth was caused by increased attention devoted to the women with ICP and earlier intervention, as evidenced by the high rates of induction of labor and planned cesarean delivery (25%). In general, stillbirth rarely occurs before the third trimester. However, there are no antenatal tests that reliably predict fetal well-being in this situation, with reports of stillbirth occurring within days of normal antenatal testing.

Thrombophilias

Antiphospholipid Antibody Syndrome. Antiphospholipid antibody syndrome (APS) is an autoimmune disorder characterized by the presence of antiphospholipid antibodies, thrombosis, and obstetric complications. Obstetric complications include at least one fetal death at 10 gestational weeks or more, or one preterm birth at 34 gestational weeks or less (resulting from severe preeclampsia, eclampsia, or placental insufficiency), or at least three consecutive spontaneous losses at less than 10 weeks' gestation, given normal parental karyotypes, maternal anatomy, and hormonal levels.⁶⁰ The three best-characterized antiphospholipid antibodies (APLAs) are lupus anticoagulant, anticardiolipin antibodies, and anti- β_2 -glycoprotein-I antibodies. The APLAs are found in 1% to 5% of young, healthy control subjects.⁶¹ The magnitude of the increased risk for stillbirth in women with APS is unclear. In a study of 366 high-risk women with a history of two pregnancy losses and no more than one live birth, more than 80% of APLA-positive women experienced at least one fetal death (at ≥ 10 weeks of gestation), whereas only 24% of APLA-negative women experienced a fetal death.⁶² The mechanism of pregnancy loss remains uncertain, but placental inflammation, thrombosis, and decidual vasculopathy are involved.⁶²

Heritable Thrombophilias. The role in stillbirth of heritable coagulopathies or thrombophilias that involve deficiencies or abnormalities in anticoagulant proteins or an increase in procoagulant proteins is unclear. Case series and retrospective studies have reported an increased stillbirth risk associated with the factor V Leiden mutation (FVL), which is associated with abnormal factor V resistance to cleavage by activated protein C (i.e., activated protein C resistance), the G20210A mutation in the prothrombin gene (PGM), and deficiencies of the anticoagulant proteins antithrombin and protein C and S.^{63,64} The histologic findings of placental infarction, necrosis, and vascular thrombosis observed in some cases of stillbirth have led to the hypothesis that thrombophilia (in somewhat the same way as APS) may also be associated with thrombosis in the uteroplacental circulation leading to stillbirth.

FVL is the most prevalent of inherited thrombophilias, and its association with stillbirth is one of the best studied in pregnancy. A meta-analysis of 27 stillbirths in 180 patients with FVL found that it was associated with late (>19 weeks), nonrecurrent fetal loss, with an OR of 3.26 (95% CI, 1.82 to 5.83).⁶³ In a preliminary retrospective case-control study by the European Prospective Cohort on Thrombophilia (EPCOT), 843 women with thrombophilia were compared with 541 unaffected women, and a significant association was observed between FVL and stillbirth at 28 or more weeks' gestation (OR = 3.6; 95% CI, 1.4 to 9.4).⁶⁴ A meta-analysis of FVL showed a graded increase in risk for second- or third-trimester fetal loss, with ORs of 2.4 (95% CI, 1.1 to 5.2) for isolated stillbirth and 10.7 (95% CI, 4.0 to 28.5) for two or more stillbirths.⁶⁵

Meta-analysis of five studies confirmed the link between the PGM and nonrecurrent loss at more than 20 weeks (OR = 2.3; 95% CI, 1.1 to 4.9).⁶³ Antithrombin (AT) deficiency, the most thrombogenic of the heritable coagulopathies, was found to be associated with a significantly increased risk for stillbirth at more than 28 weeks (OR = 5.2; 95% CI, 1.5 to 18.1).⁶⁴ The aforementioned meta-analysis also demonstrated that stillbirth (defined as losses at >22 weeks in three retrospective case-control studies) was associated with protein S deficiency, with an OR of 7.4 (95% CI, 1.3 to 43).⁶⁵

In a recent study of 750 stillbirths in The Netherlands, stillbirth was not observed to be associated with FVL, the PGM, or lupus anticoagulant.⁶⁶ There was a small association between both increased levels of maternal von Willebrand factor and decreased paternal protein S levels and stillbirth. However, because no other thrombophilias were associated with stillbirth, the authors concluded that routine thrombophilia testing after stillbirth is not warranted. The only exception may be the subset of stillbirths complicated by placental abruption or infarction, in which there was an increase in maternal thrombophilic defects.⁶⁶

Three large prospective cohort studies call into question any association between heritable thrombophilias and either stillbirth or obstetric complications characterized by placental insufficiency. In a large prospective observational cohort conducted by the National Institute of Child Health and Human Development (NICHD) Maternal-Fetal Medicine Units Network in over 4000 healthy American women, FVL⁶⁷ and PGM⁶⁸ were not associated with pregnancy loss, preeclampsia, SGA neonates, or abruption. A similar prospective observational Australian cohort evaluated 1707 nulliparous women for FVL, PGM, the methylene tetrahydrofolate reductase (MTHFR) polymorphisms, C677T and A1298C, and a thrombomodulin polymorphism.⁶⁹ Women with PGM had an OR of 3.6 (95% CI, 1.2 to 10.6) for the development of composite obstetric morbidity. None of the other thrombophilias were associated with individual or composite adverse outcomes.⁶⁹ Finally, in a prospective observational cohort of 6000 women in Sweden, there was no association between FVL and any adverse outcome including preeclampsia, stillbirth, abruption, or SGA fetuses.⁷⁰

The lack of an association between thrombophilias and pregnancy loss in these prospective cohorts raises questions about the robustness and validity of an association between thrombophilia and stillbirth. Thrombophilias are extremely common in healthy women with normal pregnancy outcomes. Furthermore, treatment of women with thrombophilias in subsequent pregnancies has not been proven to improve obstetric outcomes.⁷¹ Although stillbirth is not specifically addressed, testing for thrombophilias in patients with obstetric complications (and no personal or family history of thrombosis) is currently not recommended according to the recent American College of Obstetricians and Gynecologists (ACOG) practice bulletin on inherited thrombophilias and pregnancy.⁷² It remains unclear whether inherited thrombophilia is associated with stillbirth for the following: (1) women with a family history or a personal history of venous thromboembolism, or (2) women with clinical evidence of placental insufficiency such as fetal growth restriction or placental infarction or abruption.³² However, thrombophilia alone should be considered not as a cause of stillbirth but rather as a risk factor, and routine testing in all cases of stillbirth is not recommended.⁵²

CONDITIONS RELATED TO THE FETUS

Red Cell Alloimmunization

More than 50 different red cell antigens have been reported to be associated with hemolytic disease of the fetus and newborn. However, three antibodies, anti-Rhesus (RhD), anti-Rhc, and anti-Kell, account for the majority of fetuses with severe disease—that is, those requiring intrauterine transfusion for fetal anemia or resulting in hydropic stillbirth. The widespread

use of RhD immune globulin has resulted in a substantial reduction in the incidence of RhD alloimmunization in pregnancy. However, prophylactic immune globulins to prevent maternal antibody formation to other red cell antigens are not currently available. Therefore, maternal alloimmunization to non-RhD antigens continues to contribute to the occurrence of stillbirth.⁷³

Platelet Alloimmunization

Platelet alloimmunization may be a cause of stillbirth. Fetal or neonatal alloimmune thrombocytopenia results from maternal alloimmunization against fetal platelet antigens inherited from the father (and absent on maternal platelets). When severe, fetal alloimmune thrombocytopenia (platelet count $<50 \times 10^9/L$) results in intracranial hemorrhage and stillbirth.⁷⁴ Among whites, human platelet antigen (HPA)-1a is the most frequently implicated platelet antigen, followed by HPA-5a. In Asians, HPA-4 antigen is most commonly linked to fetal or neonatal alloimmune thrombocytopenia.⁷⁴

Chromosomal Abnormalities

Overall, fetal cytogenetic abnormalities account for 6% to 13% of all stillbirths,^{75,76} but the proportion is higher with macerated or malformed fetuses. In the SCRIN, a population-based study of all stillbirths occurring in five catchment areas, 7% of all stillbirths were found to be aneuploid.⁵ In a Dutch study of 750 stillbirths, 38% of stillbirths with morphologic abnormalities had chromosomal abnormalities, compared with 4.6% of those without morphologic abnormalities.⁷⁵ The distribution of chromosomal abnormalities associated with stillbirth was as follows: trisomy 21, 31%; monosomy X, 22%; trisomy 18, 22%; trisomy 13, 6%; and other chromosomal abnormalities, 19%.⁷⁵

Confined placental mosaicism (CPM), in which the karyotype of the fetus is euploid despite an abnormal cell line in the placenta, has only recently been appreciated as a cause of stillbirth. CPM occurs in approximately 1% to 2% of first-trimester chorionic villus samples.^{77,78} In most of these cases, the abnormal cell line has no phenotypic consequence. However, an increased risk for adverse pregnancy outcomes, such as spontaneous abortion, stillbirth, and fetal growth restriction, occurs in 15% to 20% of affected pregnancies.⁷⁸⁻⁸⁰ Factors that predict pregnancy outcome in patients with CPM include the specific chromosome involved (e.g., chromosomes 2, 3, 7, 8, 9, 16, and 22),⁸¹ the persistence of the abnormal cell line throughout pregnancy, the percentage of aneuploid cells in the placenta, the cell lineage containing the aneuploid cells, and the presence of uniparental disomy.⁷⁹ For example, CPM of trisomy 16 is associated with a particularly high probability of fetal death, preterm delivery, fetal growth restriction, and fetal anomalies, with less than one third of affected pregnancies delivering a full-term, normally grown infant.⁸²

Fetal single-gene and mendelian disorders may also result in stillbirth. Autosomal recessive disorders such as hemoglobinopathies (e.g., α -thalassemia); metabolic diseases such as Smith-Lemli-Opitz syndrome; glycogen storage diseases; peroxisomal disorders; and amino acid disorders have all been associated with stillbirth by different mechanisms.⁸³ X-linked dominant mutations may be lethal in male fetuses. Because of skewed X-inactivation, affected mothers are not as severely affected, and, unless examined by an experienced geneticist, their altered phenotype may be missed.⁸³ Lastly, autosomal dominant disorders caused by spontaneous mutations

(e.g., skeletal dysplasias) or inherited parental mutations (e.g., prolonged QT interval) may contribute to stillbirth.⁸⁴ Mutations leading to long QT syndrome (LQTS) are a known cause of unexpected death in infants, children, and young adults. Among 91 cases of fetal death after 13 weeks (average, 26.3 weeks), there were 8 cases (2 at <20 weeks and 6 at ≥ 20 weeks) with mutations associated with dysfunctional LQTS-associated ion channels (8.8% [95% CI, 3.9%-16.6%]).⁸⁴ This high frequency is in contrast to the reported frequency of LQTS in adults (1/5500 to 1/10,000),^{84a} suggesting that lethality might be greatly enhanced during fetal life. High levels of circulating progesterone, a hormone that prolongs the QT interval, may contribute to higher lethality of these mutations in affected fetuses.⁸⁴ Other factors that may contribute to lethality in an affected fetus include immaturity of the cardiac conduction system, volatility of the fetal autonomic nervous system with large physiologic swings in sympathetic tone, and cord compression leading to sequential parasympathetic and sympathetic stimulation.

Structural Anomalies

About 25% of stillborns have detectable structural anomalies as fetal causes of death.⁸⁵ There is heterogeneity in the diagnoses, with more than 90 associated disorders and no single diagnosis accounting for more than 1.5% of all occurrences.⁸⁵ Of particular note, amniotic band sequence is a sporadic condition of uncertain etiology that refers to the entrapment of fetal parts by disrupted amnion and often results in stillbirth. Findings are variable and include amputations, constrictions, clefts, and deformations.

Fetomaternal Hemorrhage

Fetomaternal hemorrhage, the transplacental passage of fetal blood cells to the maternal circulation, has been attributed as the cause of about 4% of stillbirths.^{86,87} Although fetal cells are detectable in about 50% of women after delivery, only 1% of all women experience massive transplacental hemorrhage.⁸⁸ The most consistent risk factors for fetomaternal hemorrhage are abruptio, abdominal trauma, cesarean delivery, operative vaginal delivery, manual removal of retained placenta, and multiple gestations.⁸⁹ The threshold for fetomaternal hemorrhage to cause stillbirth is unknown. The clinical impact is influenced by whether the hemorrhage is acute or chronic. Acute fetomaternal hemorrhage leads to severe fetal anemia, ultimately resulting in cardiovascular decompensation, stroke, disseminated intravascular coagulation, and stillbirth. In contrast, chronic bleeding is associated with chronic hypoxia leading to neurologic impairment or stillbirth. A large fetomaternal hemorrhage will cause severe fetal anemia and in some cases fetal death due to exsanguination. A transfusion of more than 25% of fetal blood volume (20 mL/kg or greater) has been associated with high rates of stillbirth (26%) as well as with neonatal anemia requiring transfusion (21.7%).⁹⁰

Fetal Growth Restriction

Fetal growth restriction (FGR) is not an actual cause of stillbirth; it occurs far more commonly among affected fetuses and can share common pathogenesis.⁹¹ Pathologic associations with FGR include fetal abnormalities (e.g., chromosomal and structural anomalies); multifetal pregnancy; maternal conditions such as infection (e.g., CMV), hypertensive disease, malnutrition, and smoking; uteroplacental vascular insufficiency; and

cord abnormalities such as velamentous cord insertion. It can be defined as the failure of the fetus to reach its growth potential. The definitions of FGR used in clinical practice differ widely: estimated fetal weight or the birth weight (e.g., below the 10th or the 5th percentile of the population, or <2 standard deviations below mean [about the 3rd percentile]). However, the use of population-based percentiles does not account for an individual baby's inherent growth potential.

Customized growth curves that adjust for physiologic maternal variations (e.g., height, weight, parity, ethnic origin) are better able to distinguish between normal-small and pathologically small babies. In a study of a large Swedish database,⁹² there was a sixfold increase in stillbirth rate when an SGA fetus was below the 10th percentile by customized growth charts, and such customization resulted in a larger proportion of babies being identified as at risk. However, there was no increase in the risk for stillbirth when a fetus was SGA by population-based curves alone—that is, the fetus was not SGA by customized standards. There was also a dosage-response effect, showing that the more profound the SGA was, the greater was the risk for fetal death. Fetuses dying at earlier gestational ages are also more severely growth restricted.⁹³ Most pregnancies complicated by FGR result in live births, so FGR is a risk factor rather than a cause of stillbirth. It is a clue that should prompt evaluation for associated conditions, such as preeclampsia or placental insufficiency, rather than being a diagnosis itself.

Placental Etiology

Beyond uteroplacental insufficiency associated with FGR, other placental causes of stillbirth include developmental abnormalities such as placenta previa, vasa previa, and neoplasms. Vasa previa occurs when submembranous fetal vessels cross the endocervical os, and it may cause stillbirth as a result of rupture of fetal vessels during labor or rupture of membranes, leading to fetal exsanguination. Fetal blood may pass through the vagina rather than entering the maternal circulation. Histologic evaluation of the placenta and cord confirms the diagnosis.

Acute circulatory disorders of the placenta associated with stillbirth may be on the maternal or fetal side. A major maternal-side circulatory disorder is abruptio placentae, which may be considered a cause of death when there are clinical signs of a large abruption or when histopathologic examination of the placenta shows extensive signs of abruption. The adjusted RR was 8.9 (95% CI, 6.0 to 13.0) for stillbirth in a cohort of women with abruption.⁹⁴ The subset of women with greater than 75% placental separation had an adjusted RR for stillbirth of 31.5 (95% CI, 17.0 to 58.4).⁹⁴

The diagnosis of abruption is often made on the basis of clinical parameters. The most common presentation is vaginal bleeding. However, some women have a concealed abruption, in which blood from premature placental separation remains trapped, never passing through the vagina. Other clinical signs of abruption include abdominal pain, abnormal fetal heart rate tracings indicative of hypoxia, and abnormal uterine contraction patterns with either tetanic contractions or tachysystole (or hyperstimulation). Risk factors include hypertension, trauma, preterm premature rupture of membranes (pPROM), chorioamnionitis, and illicit drug use. Clinicians often estimate the degree of placental detachment on the basis of gross evaluation of the placenta. However, it may be difficult to determine if the detachment occurred before or after death in cases of antepartum stillbirth. Placental abruption may be considered the cause

of death when there are clinical signs of a large abruption, or when histopathologic examination of the placenta shows extensive signs of abruption ($\geq 75\%$).

Histologic evaluation of the placenta can be helpful in documenting abruption. In cases of chronic abruption, there may be hemosiderin deposits in the placenta. In other cases, there may be evidence of abnormal placental vasculature, thrombosis, and reduced placental perfusion (e.g., infarction).

Umbilical Cord Pathology

Umbilical cord abnormalities account for 3% to 15% of stillbirths.^{5,95,96} Velamentous insertion of the umbilical cord occurs when vessels insert on the membranes rather than on the placenta. It may cause stillbirth if it leads to a vasa previa. With furcate insertion of the umbilical cord, the umbilical cord blood vessels lose the protective cover of Wharton's substance before entering the chorionic plate. Because of splaying of the vessels and their wide distribution, they are exposed to external trauma. During labor and delivery they may rupture and twist, consequently compromising the placental circulation and resulting in stillbirth.

Umbilical cord occlusion results in cessation of blood flow to the fetus. The mechanisms whereby cord accidents could lead to stillbirth include intermittent disruption of blood flow such as cord prolapse, fetal blood loss through cord hemorrhage, intrinsic cord abnormalities, and entanglement of the cords in the case of monochorionic twins.⁹⁶

Umbilical cord prolapse is an obstetric emergency that causes stillbirth and is defined as presentation of the cord in advance of the presenting fetal part. Cord prolapse is associated with abnormal presentation, prematurity, multiparity, obstetric manipulation, and abnormally long umbilical cords.^{97,98}

Umbilical cord torsion has been reported as a cause of fetal death and is seen most frequently at the fetal end of the cord. If the torsion occurred before the death, the cord should remain twisted after separation of the fetus from the placenta. The involved cord is congested and edematous, often with evidence of thrombosis of the cord vessels.⁹⁹ Other, uncommon causes of death include rupture, strictures, and hematomas of the umbilical cord.

Cord entanglement in the form of nuchal cords occurs in up to 30% of uncomplicated pregnancies. In a cohort-control study of almost 14,000 deliveries, single nuchal cords were present at birth in 23.6% of deliveries, and multiple nuchal cords in 3.7%.¹⁰⁰ Single or multiple nuchal cords were not associated with an increased risk for stillbirth in this cohort.¹⁰⁰ Similarly, true knots are also common in live births. Examination of a tight knot may show grooving of the cord and constriction of the umbilical vessels in long-standing cases, and edema, congestion, or thrombosis in more acute ones. It is difficult to attribute any adverse outcome to the presence of a knot in the absence of such changes. Thus, the isolated finding of a nuchal cord or a true knot at the time of birth is insufficient evidence that cord accident is the cause of the stillbirth.

In the SCRN study, umbilical cord abnormalities accounted for 10% of possible or probable causes of death and were more common in stillbirths of greater than 32 weeks' gestation. The criteria for considering a cord abnormality to be a cause of death were rigorous and included vasa previa, cord entrapment, and evidence of occlusion and fetal hypoxia, prolapse, or stricture with thrombi. Nuchal cord alone was not considered a cause of death.⁵

Complications of Multifetal Gestation

The eightfold- to 10-fold-higher stillbirth in multiple gestations is the result primarily of placental abnormalities, mostly with monochorionic placentation. The most common complication is twin-twin transfusion, which occurs in 9% of monochorionic diamniotic gestations as a result of arteriovenous anastomoses in the placenta.¹⁰¹ If severe, either twin may exhibit cardiac dysfunction, hydrops (often in the recipient), or death. The mortality rate may be as high as 90% in untreated cases.

Among monochorionic twins, 5% are monochorionic monoamniotic twins.¹⁰² There is a high stillbirth rate, in large part resulting from cord entanglement, as both fetuses and cords are in the same amniotic sac. Other potential contributors to fetal death include preterm birth, growth impairment, malformations, genetic abnormalities, and vascular anastomoses.

Twin reversed arterial perfusion (TRAP) sequence is a rare complication of monochorionic twins. It occurs in up to 1% of monochorionic pregnancies and results from artery-to-artery anastomoses with reversed perfusion in one of the twins. Reverse flow of deoxygenated blood leads to the abnormal development of one twin, so that the heart develops abnormally and cannot function. This “acardiac” twin cannot survive. However, the pump twin also is at risk for stillbirth because of the additional cardiac demands of perfusing the acardiac twin. Mortality in untreated cases has been reported to be as high as 55%.¹⁰³

Multiple gestations also increase the risk for preterm labor, pPROM, preeclampsia, and fetal growth restriction. Each of these disorders is independently associated with stillbirth.

Intrapartum Stillbirth

Intrapartum stillbirth rates are about 1/1000 births in developed countries compared with 7.3/1000 births in developing countries, and the rates are as high as 20 to 25/1000 births for some countries in southern Africa and Asia. About one tenth of stillbirths in high-income countries are intrapartum and are related to preterm labor, cervical insufficiency, pPROM, chorioamnionitis, and abruption, leading to labor at a pre-viable or peri-viable gestation.⁵ If the same condition occurs at a viable gestation (e.g., after 24 weeks' gestation), cesarean delivery may lead to preterm birth rather than stillbirth. In low-income countries, there are much higher overall stillbirth rates, with 50% or more of the stillbirths occurring intrapartum.¹⁰⁴ Causes of intrapartum stillbirth include shoulder dystocia, malpresentation, cord prolapse, severe birth trauma, or the fetal hypoxia that occurs with abruption or uterine rupture in these settings. In addition, there is an increased risk for intrapartum stillbirth for second twins regardless of chorionicity.¹⁰⁵

SCRN: CAUSES OF STILLBIRTH

To classify stillbirths in a population-based sample, SCRN developed the initial causes of fetal death (INCODE) research tool to systematically assign causes of death using a priori definitions based on the best available evidence on pathophysiology and on performance of an extensive stillbirth evaluation including postmortem examination and placental histology in 512 stillbirths.¹⁰⁶ A condition was considered to be a probable cause of stillbirth if it had a high likelihood of directly causing the fetal death; if a condition was not a direct cause of the stillbirth, but possibly involved in a pathophysiologic sequence that led to the fetal death, it was considered a possible cause of death;

and potentially important conditions that were present but did not meet criteria for probable or possible causes of death were recorded as present. A probable cause of death was found in 60.9% of stillbirths, and possible or probable cause was found in 76.2% when a complete evaluation was performed. The distribution of causes of death were as follows: obstetric conditions, 29.3%; placental abnormalities, 23.6%; fetal genetic/structural abnormalities, 13.7%; infection, 12.9%; umbilical cord abnormalities, 10.4%; hypertensive disorders, 9.2%; and other maternal medical conditions, 7.8%.⁵

Diagnosis and Evaluation

The most important initial evaluation of a stillbirth is a thorough medical and obstetric history (Box 45-1). Some testing is recommended in all cases of stillbirth, and the remainder of the

BOX 45-1 ESSENTIAL COMPONENTS OF MATERNAL-FETAL HISTORY

DETAILS OF THE PREGNANCY

- Gestational age at death (based on accurate dating criteria and determination of timing of death)
- Medical conditions complicating pregnancy
 - Hypertensive disorders
 - Gestational diabetes
 - Cholestasis of pregnancy
 - Viral illness
- Pregnancy complications
 - Multiple gestation
 - Preterm labor
 - Rupture of membranes
 - Fetal structural or chromosomal abnormalities
 - Infections
 - Trauma
 - Abruption
- Maternal serum marker screen, ultrasound findings

MATERNAL MEDICAL HISTORY

- Chronic disease
 - Diabetes
 - Hypertension
 - Autoimmune disease (systemic lupus erythematosus)
 - Cardiopulmonary disease
 - Thyroid disease
- History of pertinent acute conditions
 - Prior venous thromboembolism
- Cigarette, alcohol, or substance use
- Known genetic abnormalities
 - Balanced translocations
 - Single gene mutations

PREGNANCY HISTORY

- Pregnancy losses
- Previous stillbirth or neonatal death
- Previous pregnancy complicated by
 - Fetal growth restriction
 - Congenital anomalies
 - Abruption
 - Hypertension

FAMILY HISTORY

- Stillbirth or recurrent miscarriage
- Genetic syndromes
- Developmental delay or mental retardation
- Significant medical illnesses (pulmonary embolism, deep venous thrombosis)

BOX 45-2 EVALUATION OF STILLBIRTH**RECOMMENDED IN ALL CASES**

- Fetal postmortem examination
- Placental pathology
- Karyotype or microarray for congenital anomaly or karyotype failure
- Fetal-maternal hemorrhage testing: Kleihauer-Betke or flow cytometry

USEFUL IN SOME CASES

- Syphilis serology
- Indirect Coombs test (if not performed earlier in pregnancy)
- Toxicology screen
- Parvovirus B19, IgM and IgG
- Lupus anticoagulant, IgG and IgM anticardiolipin and anti- β_2 -glycoprotein antibodies
- Factor V Leiden, prothrombin gene mutation, antithrombin III, protein C and protein S levels (must be done at least 6 weeks after the birth)
- Glucose screening test
- Thyroid-stimulating hormone
- Serology or other testing for other infectious etiologies (cytomegalovirus, toxoplasmosis)
- Bile acids
- Sonohysterogram

NOT GENERALLY USEFUL

- Routine TORCH (toxoplasmosis, rubella, cytomegalovirus, herpes simplex) titers
- Antinuclear antibody testing

evaluation may be guided by the gestational age and clinical circumstances of the stillbirth. Maternal medical conditions, symptoms, or parts of the obstetric history will suggest possible risk factors and causes for the stillbirth and should guide a focused and cost-effective workup.

A complete postmortem evaluation is recommended in all cases of stillbirth (Box 45-2). Fetal autopsy is recognized by most experts as perhaps the single most useful diagnostic test in determining the cause of stillbirth.¹⁰⁷ It not only may identify gross anomalies and morphologic abnormalities but also may document more subtle findings that can determine or confirm other causes of stillbirth. Findings of the postmortem examination can confirm infection, anemia, hypoxia, and metabolic abnormalities as a cause of death. In fact, autopsy has been found to provide information on a cause of death in over 30% of cases.^{5,108} If families are uncomfortable with a complete autopsy, other options such as partial autopsy, gross examination by a trained pathologist, and other imaging modalities may be offered. Ultrasound and magnetic resonance imaging¹⁰⁹ have been found to be particularly useful in this setting. When a full autopsy is performed, published guidelines should be followed.¹¹⁰ These include measurements to establish gestational age, such as foot length and body weight. Recommendations also include an estimation of the interval between death and delivery, identification of intrinsic abnormalities and developmental disorders, and investigation for evidence of infection. In addition, it is preferable to use a pathologist experienced in perinatal autopsy, and to have a physician experienced in genetics and dysmorphology examine the fetus. The clinician should communicate the obstetric and pertinent medical history to the pathology team and request any tissue collection that may be needed for additional analysis. Families should be allowed

ample time to see and hold the baby and perform any religious or cultural activities prior to autopsy.

Gross and histologic evaluation of the placenta, umbilical cord, and fetal membranes by a trained pathologist is also considered an essential component of the evaluation. Placental weight should be documented and noted in relation to the norms for gestational age. Gross evaluation may reveal conditions such as abruption, umbilical cord thrombosis, velamentous cord insertion, and vasa previa. Placental evaluation can also provide information regarding infection, genetic abnormalities, anemia, and thrombophilias. Examination of the placental vasculature and membranes can be particularly revealing in stillbirths that occur as part of a multifetal gestation. Chorionicity should be established and vascular anastomoses identified.

Placental pathology may reveal an SGA placenta, defined as being less than 5% of the expected weight for the corresponding gestational age. This is usually associated with reduced uteroplacental blood flow and impaired villous growth and development. This finding is often associated with maternal vascular diseases such as preeclampsia or eclampsia, hypertension, and diabetes mellitus with renal disease. In chronic infections and aneuploidies, placental growth is also impaired. In maternal hypertensive conditions, the placentas often show multiple infarcts and decidual vasculopathy. A large-for-gestational-age placenta is defined as being greater than 95% of the expected weight for the corresponding gestational age and may be seen in hydrops fetalis as a result of immune or nonimmune causes, maternal diabetes mellitus, and specific infections such as syphilis.^{97,111}

Umbilical cord knots or tangling should be noted but interpreted with caution, as cord entanglement occurs in approximately 30% of normal pregnancies and most true knots are found after live births. Corroborating evidence should be sought before concluding that a cord accident is the likely cause of death (e.g., evidence of cord occlusion and hypoxia on perinatal postmortem examination and histologic examination of the placenta and umbilical cord). It has been proposed that the minimal histologic criteria for considering a diagnosis of cord accident should include vascular ectasia and thrombosis in the umbilical cord, chorionic plate, and stem villi. For a probable diagnosis, in addition to the previous findings, a regional distribution of avascular villi or villi showing stromal karyorrhexis is needed.¹¹²

Genetic evaluation should be offered in all cases of stillbirth. An abnormal fetal karyotype has been noted in 6% to 13% of all stillbirths tested,^{5,75,83} and in greater than 20% of those with structural anomalies or FGR.⁵² However, these numbers are probably an underestimate, because karyotyping is underused and because 25% to 60% of tissue cultures fail after contamination or maceration.^{75,76} Acceptable cytologic specimens include amniotic fluid, and a placental block taken from below the cord insertion site that includes the chorionic plate, an umbilical cord segment, or an internal fetal tissue specimen that thrives under low oxygen tension such as costochondral or patellar tissue. Fetal skin is suboptimal. Tissues should be placed in a sterile tissue culture medium of lactated Ringer solution at room temperature.⁵² Of these options, cultured amniocytes have the highest yield, so an amniocentesis should be considered before the delivery.^{52,75,113} In addition, tissue samples for karyotype may also be taken from the placenta to exclude confined placental mosaicism.

If karyotype is unsuccessful, molecular techniques are available that do not require live cells and can detect chromosomal imbalances that are below the resolution of conventional cytogenetic analysis, which identifies deletions and duplications that are greater than 5 megabases. Fluorescence in situ hybridization (FISH) can be used to test for the most common aneuploidies and to detect smaller abnormalities (<150 kilobases), but the number of probes that can be tested simultaneously is limited. Moreover, the choice of FISH probe is guided by the clinical phenotype, and when the molecular origins of a given phenotype are unknown, the clinical usefulness of FISH is significantly reduced.¹¹⁴

Microarray platforms are now available that provide coverage of the entire genome at a higher density, detecting deletions or duplications as small as 50 to 100 kilobases, known as copy number variants. Evidence that microarray platforms increase the diagnostic yield of clinically significant genetic abnormalities in the evaluation of stillbirth, beyond that available from karyotyping, was given in two small studies,^{115,116} as well as in the SCRN study.¹¹⁷ Array-based comparative genomic hybridization or absolute quantification arrays (typically called single nucleotide probe and copy number probe arrays) provide almost all of the same information provided by cytogenetic analysis. In addition, they may detect abnormalities in smaller regions of chromosomes that are missed by traditional karyotyping. Single nucleotide probe arrays can also detect uniparental disomy and consanguinity.¹¹⁸ In the SCRN study of 532 stillbirths, microarray analysis yielded results more often than did karyotype analysis (87.4% versus 70.5%; $P < .001$) and provided better detection of genetic abnormalities (e.g., aneuploidy or pathogenic copy-number variants) (8.3% versus 5.8%; $P = .007$). Microarray analysis also identified more genetic abnormalities among 443 antepartum stillbirths (8.8% versus 6.5%; $P = .02$) and 67 stillbirths with congenital anomalies (29.9% versus 19.4%; $P = .008$). Compared with karyotype analysis, microarray analysis provided relative increases in the diagnosis of genetic abnormalities (increases of 41.9% in all stillbirths, 34.5% in antepartum stillbirths, and 53.8% in stillbirths with anomalies). Microarray analysis was more likely than karyotype analysis to provide a genetic diagnosis, primarily because of its success with nonviable tissue, and it was especially valuable in analyses of stillbirths with congenital anomalies or when karyotype results could not be obtained.¹¹⁷ Limitations of microarray technology include cost, identification of copy number variants of uncertain clinical significance, and the attendant parental anxiety as a result of these findings and the additional counseling required before offering this test. Microarray technology does not detect certain genetic abnormalities such as balanced translocations or low-level mosaicism. Finally, it requires high-quality DNA that may be hard to obtain from macerated tissues.

Finally, genetic evaluation requires a detailed pedigree through third-degree relatives including stillborn infants. Recurrent pregnancy losses and the presence of liveborn individuals with developmental delay or structural anomalies may be clues to single-gene disorders. Consanguinity should be identified because of the increased possibility of severe autosomal recessive disorders. A detailed history of arrhythmias and sudden death (including sudden infant death syndrome) should be ascertained, because prolonged QT syndrome may be associated with stillbirth.⁸⁴ Finally, if the stillborn was male, the mother should be examined to assess subtle characteristics of an X-linked disorder that could be lethal in males.⁸³

Fetal-maternal hemorrhage testing requires identification and quantification of the extent of the hemorrhage, ideally before induction of labor. The results of such testing must be interpreted in the setting of the clinical and pathologic findings, as a small number of fetal cells may be detected in uncomplicated pregnancies. The Kleihauer-Betke test may have limited precision in quantifying hemorrhage, as it involves only the assessment of a small number of cells and may result in underestimation in cases of large hemorrhage. Flow cytometry is an alternative and can provide a more accurate quantification of fetal bleeding. Because only significant hemorrhage (e.g., $\geq 25\%$ of fetal blood volume) is likely to cause stillbirth, both tests are useful as part of the evaluation.⁹⁰ The usefulness of evaluating fetal-maternal hemorrhage testing after delivery is questionable because delivery itself can lead to fetal-maternal hemorrhage. However, because delivery is very unlikely to cause massive hemorrhage by itself and fetal cells persist for up to 2 to 3 weeks after delivery, testing soon after delivery is reasonable.⁸⁹

Indirect Coombs testing for maternal antibodies that may result in red cell alloimmunization during pregnancy is generally performed at the initial prenatal visit. Alloimmunization is a recognized cause of stillbirth and is usually associated with specific clinical and pathologic findings, such as fetal hydrops. As sensitization during the current pregnancy is very unlikely to result in stillbirth, repeat testing is not necessary if initial testing was normal. However, if an indirect Coombs test has not been performed during the current pregnancy, it should be part of the evaluation.⁵²

A maternal urine toxicology screen may be performed as part of the initial evaluation of stillbirth.⁵² In some populations, maternal substance use is associated with a proportion of stillbirths. As an alternative to a maternal urine screen, it is possible to measure stable metabolites of recreational drugs in certain fetal tissues such as meconium, hair, and homogenized umbilical cord.

Parvovirus serology and serologic testing for syphilis are commonly recommended because these agents have been consistently associated with stillbirth.⁵² Testing for other bacterial, viral, protozoal, and fungal pathogens should be guided by the clinical history, as well as by findings on pathology or imaging. If autopsy, pathology, or history is suggestive of an infectious etiology, an evaluation should be undertaken. This may include maternal or neonatal serology, special tissue stains, and testing for bacterial or viral nucleic acids. However, if clinical or histologic evidence is lacking, testing for infection produces a low yield.⁵² Although assessment of TORCH (*toxoplasmosis, rubella, CMV, herpes simplex*) titers has been traditionally advised for the evaluation of stillbirth, the usefulness of routine testing is unproven.⁵²

APS testing is recommended in stillbirths, especially when accompanied by growth restriction, severe preeclampsia, or other evidence of placental insufficiency.⁶⁰ Laboratory testing is performed by testing for lupus anticoagulant as well as IgG and IgM for both anticardiolipin and anti- β_2 -glycoprotein antibodies. A moderate to high IgG phospholipid (GPL) or IgM phospholipid (MPL) titer (>40 MPL or GPL, or >99 th percentile) is considered positive but must be confirmed with repeat testing after 12 weeks.⁶⁰

Testing for heritable thrombophilias is controversial and not routinely recommended.⁵² Most case-control studies show an association between heritable thrombophilias and stillbirth. However, prospective cohort studies have failed to show an

association. Testing may be most appropriate in cases with severe placental pathology, growth restriction, or a history of thrombosis.⁵² The thrombophilias most strongly linked to stillbirth include FVL, PGM, and deficiencies of antithrombin and protein S. However, many of these conditions are common in the general population, and most women with these conditions have uncomplicated pregnancies, making interpretation of a positive test difficult. In addition, thromboprophylaxis is of unproved efficacy. Therefore, in the absence of the previously mentioned complications, routine testing is not indicated and may lead to unnecessary interventions.⁵²

Testing for maternal medical conditions should be guided by history, physical examination, and clinical circumstances. For example, assessment of bile acids is appropriate in cases of pruritus or elevated liver function tests, and diabetes screening (oral glucose tolerance test, hemoglobin A_{1c}) is indicated if the baby is large for gestational age. A positive antinuclear antibody test in the absence of other findings of lupus is probably of no significance. Therefore, routine testing for subclinical maternal disease is not recommended.⁵²

Assessment of the uterine cavity should be considered when suspicion is raised for uterine malformations. Examples include stillbirths associated with cervical insufficiency, preterm labor, and pPROM. Stillbirths in these settings are often intrapartum and may occur at a pre-viable gestational age.⁵

Two recent large studies examined the yield of the various components of the stillbirth evaluation. In the SCRIN study, of the 512 stillbirths undergoing a complete evaluation, placental histology had the highest proportion of positive results (52.3%), defined as abnormalities contributing to a probable or possible cause of death.⁵ Perinatal postmortem examination yielded positive findings in 31.4% and karyotype in 9.0% of the stillbirth cases tested. Interestingly, 66.4% of all stillbirths had a positive result for at least one of these three tests. The remaining clinically indicated tests were positive in a much smaller proportion of stillbirths: anticardiolipin antibodies (4.8%), lupus anticoagulant (3.2%), fetal-maternal hemorrhage screen (4.6%), alloimmune antibody screen (3.6%), glucose screen, hemoglobin A_{1c}, or fructosamine (2.9%), parvovirus serology (IgM) (2.0%), and syphilis screen (0.4%).⁵ A recent Dutch study of 1025 stillbirths confirmed the SCRIN results regarding the yield of various tests. In this study, the most valuable tests for determination of cause were placental examination (95.7%), fetal postmortem examination (72.6%), and cytogenetic analysis (29.0%). Kleihauer-Betke testing, which is ideally performed before induction, was positive for fetal-to-maternal hemorrhage in 11.9% of women but was felt to be cause of death in only 1.3%.¹¹⁹ Thus, postmortem, placental examination, cytogenetic analysis, and fetal-to-maternal hemorrhage testing (at the time of induction) should be offered in all cases of stillbirths. In both the SCRIN and the Dutch studies, because the yield of the remainder of the stillbirth evaluation was relatively low, further sequential testing was indicated based on the results of the postmortem examination, placental histology, and cytogenetic testing, as well as on the specific clinical circumstances accompanying the stillbirth.

Management

The timing and mode of delivery of a stillbirth should be determined by gestational age, patient preferences, and clinical circumstances. There is no medical urgency for immediate delivery,

and for some women, expectant management or delayed delivery may be desirable. Consumptive coagulopathy and intrauterine infection are rarely associated with prolonged expectant management. Between 80% and 90% of women will enter spontaneous labor within 2 weeks of the fetal death; however, the latency period may be substantially longer.¹²⁰ Retention of a dead fetus can cause chronic consumptive coagulopathy due to gradual release of tissue factor from the decidua or placenta into the maternal circulation.¹²¹ This usually occurs after 4 weeks but may occur earlier. Coagulation abnormalities occur in about 3% to 4% of patients with uncomplicated fetal deaths over the following 4 to 8 weeks, and the percentage increases with abruption or uterine perforation.¹²¹ Another disadvantage of expectant management is that the long interval between fetal death and spontaneous labor limits the amount of information that can be obtained about the cause of death from a postmortem examination of the infant. In women opting for spontaneous labor (especially when the interval between fetal death and time of delivery is longer than 4 weeks), surveillance, such as weekly office visits, home assessment of maternal temperature, and patient reporting of abdominal pain, bleeding, or other concerning symptoms, is recommended. The usefulness of serial laboratory tests, such as fibrinogen or platelet count, is uncertain. Screening for coagulopathy (fibrinogen level, platelet count, prothrombin time, and activated partial thromboplastin time measurement) should be obtained before administration of neuraxial anesthesia as well as other invasive procedures.¹²¹

Several studies have examined induction of labor and dilation and evacuation (D&E) procedures during the second trimester. In a prospective cohort study, the grief response after induction of labor or D&E in women undergoing termination of pregnancy for fetal anomalies was assessed; there were no significant differences in grief resolution among patients who chose either method.¹²² However, D&E is associated with a lower complication rate than that seen with induction of labor, given experienced practitioners. One study found that patients undergoing surgical termination of pregnancy between 14 and 24 weeks of gestation had a lower overall rate of complications (4%) than women undergoing labor induction (29%).¹²³ Women who underwent surgical evacuation were less likely to have failure of the initial method for delivery and retained products of conception. However, the groups were similar with regard to the need for blood transfusion, infection, cervical laceration, maternal organ damage, or hospital readmission. Placement of laminaria was associated with a lower risk for complications from D&E, and misoprostol use was associated with a lower complication rate in women undergoing medical termination. A recent Cochrane Review concluded that D&E is superior to instillation of prostaglandin F_{2α} and also may be favored over mifepristone and misoprostol, although larger randomized studies are needed.¹²⁴ In a cost-effectiveness analysis, D&E was less expensive and more effective than misoprostol induction of labor for second-trimester delivery.¹²⁵ The rate of complications is not increased in subsequent pregnancies after D&E, although the studies are limited.^{126,127} Therefore, the mode of delivery should be based on the patient's wishes as long as provider experience and gestational age allow D&E to be a viable option (Box 45-3).

For induction of labor at less than 28 weeks' gestation, misoprostol is the most efficient method of induction, regardless of Bishop score, although high-dosage oxytocin infusion is an acceptable alternative.^{52,128} After 28 weeks' gestation, drugs such

BOX 45-3 PROTOCOL FOR STILLBIRTH DELIVERY**DILATION AND EVACUATION FOR UTERUS BETWEEN 13 AND 22 WEEKS' GESTATION SIZE**

- On admission, obtain hematocrit and type and screen.
 - Administer doxycycline (100 mg orally) 1 hour before procedure and 200 mg after procedure, or postoperative metronidazole (500 mg orally twice a day for 5 days).
 - To facilitate cervical dilation
 - Administer misoprostol (200 µg) in the posterior fornix 4 hours before procedure
- OR**
- Place laminaria in cervix.
 - Perform dilation and evacuation under ultrasound guidance.
 - Discharge to home after anesthesia has worn off and vaginal bleeding is minimal.
 - Administer RhD immune globulin if patient is Rh negative.
 - Schedule a follow-up visit in 2 weeks.
 - Prescribe nonsteroidal anti-inflammatory drugs or mild narcotics.

INDUCTION OF LABOR

- Upon admission to labor and delivery department, obtain complete blood count, type and screen. Consider fibrinogen level if fetus has been dead for more than 4 weeks.
 - Administer induction medications:
 - For uterus less than 28 weeks' size: misoprostol (200 to 400 µg) vaginally or orally every 4 hours until delivery of the fetus
 - For uterus greater than 28 weeks' size: misoprostol (25 to 50 µg) vaginally or orally every 4 hours
- OR** oxytocin infusion per usual protocol
- To minimize retained placenta, allow spontaneous placental delivery, avoid pulling on umbilical cord, and consider further doses of misoprostol at appropriate intervals.
 - Options for anesthesia include epidural, intravenous narcotics via patient-controlled-analgesia pump (PCA), or intermittent doses.
 - Parents should be encouraged to spend time with the infant and offered keepsake items (e.g., pictures, hand/footprints).
 - Administer RhD immune globulin to Rh-negative mothers.
 - Consider postpartum care on a nonmaternity ward.
 - Offer bereavement services.
 - Follow-up visit in 2 to 6 weeks

HISTORY OF PREVIOUS CESAREAN DELIVERY

- Previous low transverse incision and uterus less than 28 weeks' size, use misoprostol, dosing for induction at less than 28 weeks.
- Previous low transverse incision and a uterus greater than 28 weeks' size, use oxytocin protocols and cervical ripening with Foley bulb.
 - Repeat cesarean delivery is an option after discussing risks and benefits.
- Previous classic uterine incision, repeat cesarean delivery is appropriate.

as oxytocin or prostaglandins administered for induction of labor can be given according to standard obstetric protocols.^{52,128}

Women with a prior uterine scar are a unique group, and treatment must be individualized. For women with a previous low transverse incision and a uterus less than 28 weeks' size, the usual protocols for misoprostol induction at less than 28 weeks may be used.⁵² For women with a previous low transverse incision, and a uterus greater than 28 weeks' size, oxytocin protocols may be used, and cervical ripening with Foley balloon may be considered.^{52,128} Patients may choose a repeat cesarean delivery

in the setting of a fetal demise, but the risks and benefits must be carefully considered and discussed with the patient. Ideally, cesarean delivery is avoided. For women without a previous uterine incision, cesarean delivery should be limited to maternal indications.⁵² The data are limited for patients with a prior classic uterine incision,⁵² but given the risk of 1% to 12% for uterine rupture with labor¹²⁹ and the attendant maternal risks, repeat cesarean delivery is appropriate.¹²⁸

Clinicians should be sensitive to the emotional difficulties and needs of families suffering a stillbirth. Families should be offered the opportunity to see and hold their infant and be offered keepsake items such as photos, handprints or footprints, or special blankets or clothing.¹³⁰ All women should be offered bereavement services and psychological counseling and should receive close surveillance for development of depression. A visit to discuss all the results of the stillbirth evaluation and counseling regarding potential subsequent pregnancies is also recommended.

Prediction of Stillbirth

Prevention of stillbirth requires identification of women at highest risk. Biochemical markers have been found to be useful in modifying the risk for stillbirth. As part of the first-trimester screen, a low pregnancy-associated plasma protein A (PAPP-A) level has been associated with an increased risk for stillbirth. In a cohort of 7934 pregnancies, a PAPP-A level at less than the 5th percentile at 10 weeks was associated with a 9.2-fold increase in stillbirth from all causes, and a 46-fold increased risk for stillbirth specifically due to placental dysfunction (abruption or unexplained stillbirth associated with growth restriction independent of maternal characteristics). However, the positive predictive value of PAPP-A, even for placental causes of stillbirth, was still relatively low, at 1.8%.¹³¹ In second-trimester serum, unexplained elevated maternal serum α -fetoprotein (AFP) levels (in the absence of neural tube defect or ventral wall defect) are associated with stillbirth via a defect in placentation. A review of 21 studies found a consistent association of AFP levels greater than 2.5 multiples of the median (MoM) with stillbirth.¹³² Also, elevated β -human chorionic gonadotropin (β -hCG) has been associated with a 1.4-fold increased risk for stillbirth for every increase of 1 MoM.¹³³ In a study of 8483 births, low PAPP-A was not associated with high AFP, suggesting the two markers reflect different aspects of placental dysfunction. For women with a high AFP, the OR was 2.5 for antepartum stillbirth; for women with a low PAPP-A, the OR was 2.2; and for women with both a low PAPP-A and high AFP, the OR was 36.7. Thus, a low PAPP-A level and a high AFP level had a synergistic increase in stillbirth risk.¹³⁴

Doppler imaging of the uterine artery may have a role in the prediction of placenta-associated stillbirths when failure of trophoblastic invasion of the spiral arteries leads to increased impedance of flow in the uterine arteries. In pooled analyses of four Doppler studies performed in unselected populations, the likelihood of fetal or perinatal death with an abnormal uterine artery Doppler result at 22 to 24 weeks' gestation was 2.4 times higher (95% CI, 1.4 to 3.4) than the background rate of fetal or perinatal death in the general population, whereas for those with normal Doppler results the likelihood ratio was reduced to 0.8 (95% CI, 0.7 to 0.9).¹³⁵ In a subsequent study of 30,519 women with uterine artery Doppler imaging performed at 22 to 24 weeks' gestation, the RR for placental stillbirth (resulting

from preeclampsia, abruption, or SGA unexplained stillbirth) was increased 5.5-fold in women with a mean pulsatility index above the 90th percentile, and increased 3.9-fold in those with bilateral notching. As stillbirths resulting from placental causes occurred earlier in gestation (median, 30 weeks) compared with unexplained stillbirths (median, 38 weeks), uterine artery Doppler imaging was a moderate predictor of all-cause stillbirth up to 32 weeks (sensitivity, 58%, with a false-positive rate of 5%). On the other hand, the prediction of stillbirth at later gestations was poor, with a sensitivity of 7% at the same false-positive rate.¹³⁶

Improved antenatal detection of FGR is crucial to having a positive impact on stillbirth prevention. In up to a third of pregnancies, FGR may be missed, and it is incorrectly diagnosed about 50% of the time.¹³⁷ Without the correct diagnosis of FGR, antenatal surveillance may not be performed and timely delivery of the fetus at risk for stillbirth because of an unfavorable intrauterine environment will not occur.

Currently, there is no method of screening for stillbirth risk. Use of a priori (pre-pregnancy) risk factors such as race, parity, advanced maternal age (35 to 39 years old), and BMI, as well as individual biochemical markers to predict term stillbirth, is poor. Further research is needed to determine if a combination of maternal, biochemical, and ultrasound measures can predict women at highest risk for stillbirth.

Prevention of Stillbirth

Improved treatment of maternal medical disorders such as diabetes and hypertension has clearly decreased the risk for stillbirth in these situations. The risk for stillbirth associated with APS is decreased with treatment (prophylactic heparin or low-molecular-weight heparin and low-dosage aspirin).⁶⁰

There has been interest in the use of low-dosage aspirin to improve subsequent pregnancy after stillbirth. Low-dosage aspirin is an antiplatelet agent that irreversibly inhibits platelet cyclooxygenase, thereby decreasing the production of thromboxane A₂, a potent vasoconstrictor. Aspirin use was promoted by the recognition that thrombosis was central to the pathophysiology of APS, and its first use was to treat recurrent pregnancy loss in women with APS. Information on the use of low-dosage aspirin for prevention of stillbirth is limited. Three studies shed light on the possible impact of aspirin therapy; however, stillbirth was not the focus of these studies. In one study of 250 women with a history of at least one pregnancy loss at greater than 13 weeks' gestation and negative testing for lupus anticoagulant and anticardiolipin antibodies, there was almost a twofold increase in live births for those taking low-dosage aspirin (75 mg daily).¹³⁸ There were similar findings in a retrospective cohort of 230 women with previous intrauterine demise of a conceptus known to be alive at or beyond 10 weeks of gestation. In univariate analysis, low-dosage aspirin was associated with an OR of 0.41 (95% CI, 0.25 to 0.68) for subsequent pregnancy loss. After controlling for confounders, low-dosage aspirin was associated with an OR of 0.12 (95% CI, 0.05 to 0.32) in women 35 years of age or older. The authors speculated that low-dosage aspirin may improve the uteroplacental circulation by decreasing placental thrombosis, infarction, and insufficiency that is associated with fetal death.¹³⁹ However, in a more recent study, neither aspirin combined with nadroparin (low-molecular-weight heparin) nor aspirin alone improved the live birth rate, as compared with placebo, among women with

BOX 45-4 MANAGEMENT OF SUBSEQUENT PREGNANCY AFTER STILLBIRTH

PRECONCEPTION OR INITIAL PRENATAL VISIT

- Detailed medical and obstetrical history
- Evaluation/workup of previous stillbirth
- Determination of recurrence risk
- Discussion of increased risk for other obstetric complications
- Smoking, alcohol, and illicit substance cessation
- Weight loss in obese women
- Genetic counseling if a family genetic condition exists
- Support and reassurance

FIRST TRIMESTER

- Dating ultrasound by crown-rump length
- First-trimester screen: pregnancy-associated plasma protein A (PAPP-A), human chorionic gonadotropin (hCG), and nuchal translucency*
- Diabetes screen
- Antiphospholipid antibodies/thrombophilia workup: (only if specifically indicated)
- Support and reassurance

SECOND TRIMESTER

- Fetal anatomic survey at 18 to 20 weeks
- Quadruple screen: maternal serum α -fetoprotein, hCG, estriol, and inhibin-A*
- Uterine artery Doppler studies at 22 to 24 weeks*
- Support and reassurance

THIRD TRIMESTER

- Serial ultrasounds, starting at 28 weeks, to rule out fetal growth restriction
- Fetal movement counting starting at 28 weeks
- Antepartum fetal surveillance starting at 32 weeks, or 1 to 2 weeks earlier than the gestational age of a previous stillbirth if it occurred before 32 weeks
- Support and reassurance

DELIVERY

- Elective induction at 39 weeks, or before 39 weeks if desired by the couple and if fetal lung maturity is documented by amniocentesis

*Provides risk modification but does not alter management.

Adapted from Reddy UM: *Prediction and prevention of recurrent stillbirth*, *Obstet Gynecol* 110:1161, 2007, with permission from Lippincott Williams & Wilkins.

unexplained recurrent miscarriage.¹⁴⁰ Because the majority of previous fetal deaths reached less than 20 weeks of gestation and there was an increased proportion of women with recurrent pregnancy loss in these three studies, these results may not be directly applicable to women who have experienced a stillbirth that occurs at or later than 20 weeks of gestation. More research is necessary to determine if low-dosage aspirin administration in women with a previous stillbirth improves pregnancy outcome.

There is little evidence to inform recommendations for the management of subsequent pregnancy after stillbirth. Box 45-4 provides guidance based on the limited data available. Counseling should be individualized to the woman's particular circumstances. Smoking, alcohol, and illicit substance use should be discouraged. Because maternal obesity (BMI >30 kg/m²) has been associated with an increased risk of stillbirth, weight reduction to achieve a normal BMI (18.5 to 24.9 kg/m²) before

conception is recommended.^{24b} First- and second-trimester serum analyte screening for Down syndrome, and uterine artery Doppler studies may be performed, but they do not alter pregnancy management. Because nearly half of all stillbirths are associated with FGR, serial ultrasounds for fetal growth may be performed, starting at 28 weeks. If there is evidence of FGR, then the frequency of ultrasound to monitor fetal growth may be increased, usually to every 2 to 4 weeks, and Doppler studies and antepartum fetal testing can be performed. The ACOG technical bulletin on intrauterine growth restriction outlines management strategies.¹³⁷ In all women with a previous stillbirth, maternal assessment of fetal movement or fetal kick counts may be started at 28 weeks of gestation. Antepartum fetal testing, such as twice weekly nonstress tests and amniotic fluid index or biophysical profiles, may be initiated at 32 weeks or 1 to 2 weeks before the gestational age of the previous stillbirth. Weeks and colleagues reviewed the antepartum testing database, involving 70,000 tests on 15,000 women over a 12-year period.¹⁴¹ Results of fetal testing in 300 healthy women with previous stillbirth were evaluated to determine the optimal time to initiate testing. Out of these 300 women, there was one recurrent stillbirth and there were no neonatal deaths, for a perinatal mortality rate of 3.3/1000, less than half of the overall U.S. stillbirth rate of 7.5/1000 at the time. However, one stillbirth occurred despite normal antepartum testing, suggesting that in some instances, stillbirth cannot be predicted despite close antepartum surveillance. Women with earlier prior stillbirths (at <32 weeks) had more antepartum testing and more abnormal tests; however, the incidences of intervention for an abnormal

test, cesarean delivery for fetal distress, and FGR were similar to those for whom the prior stillbirth occurred at greater than 36 weeks. Therefore, the authors concluded that there was no relationship between the gestational age of the previous stillbirth and abnormal antepartum testing in subsequent pregnancies. The authors proposed initiating antepartum surveillance at 32 weeks or later, acknowledging that a rare patient with earlier fetal compromise may be missed.¹⁴¹ ACOG supports this conclusion and states that starting antepartum testing at 32 to 34 weeks is appropriate in healthy pregnant women with a history of stillbirth.¹⁴² (This ACOG statement was reaffirmed in 2009.) In pregnancies with multiple or particularly worrisome high-risk conditions (e.g., chronic hypertension with suspected FGR), testing may begin as early as at 26 to 28 weeks' gestation. In women with especially high-risk medical or obstetric conditions, testing should be initiated at 26 to 28 weeks.¹⁴² Caution should be used when interpreting the antepartum fetal surveillance of a fetus earlier than 32 weeks of gestation. The delivery plan should be discussed with the couple well in advance of the third trimester. The timing of the delivery depends on maternal anxiety, cervical ripeness, and the cause of the previous stillbirth. In most cases, if the pregnancy is uncomplicated, elective induction at 39 weeks' gestation may be appropriate. If earlier delivery is desired by the patient, amniocentesis should be performed to document fetal lung maturity.⁵²

DISCUSSION

The clinical history for a woman with a stillbirth is often unremarkable. The most common cause of stillbirth is placental abruption, which is a separation of the placenta from the uterine wall. This can occur at any time during pregnancy, but it is most common in the third trimester. Other causes include umbilical cord problems, such as cord entanglement or placental thrombosis. In some cases, the cause of the stillbirth is unknown. The management of a stillbirth depends on the gestational age of the fetus and the woman's wishes. Options include expectant management, induction of labor, or cesarean delivery. Counseling and emotional support are important for women who experience a stillbirth.

During the third trimester, the placenta provides a primary source of oxygen and nutrients to the fetus. If there is a problem with the placenta, the fetus may not receive enough oxygen and nutrients, which can lead to stillbirth. The most common cause of placental abruption is unknown, but it is more likely to occur in women with high blood pressure, trauma, or cigarette use. The symptoms of placental abruption include vaginal bleeding, abdominal pain, and a change in the shape of the uterus. If a woman experiences any of these symptoms, she should seek medical attention immediately. The management of placental abruption depends on the severity of the symptoms and the gestational age of the fetus. In some cases, the fetus may be delivered immediately, while in other cases, the pregnancy may be allowed to continue for a short period of time before delivery.

Placenta Previa, Placenta Accreta, Abruptio Placentae, and Vasa Previa

ANDREW D. HULL, BMedSci, BMBS | ROBERT RESNIK, MD

Bleeding in the later stages of pregnancy has been described as “third-trimester bleeding” or “antepartum hemorrhage.” Late pregnancy bleeding is a significant cause of maternal and fetal morbidity, fetal mortality, and preterm delivery. Traditional accounts of such bleeding have addressed placenta previa, abruptio placentae, and vasa previa, although in fact the only thing that these clinical problems have in common is that they all are concerned, to a greater or lesser extent, with hemorrhage. The etiology, management, and complications of each are quite distinct. In the past, uncertainty in precise diagnosis of the cause of late pregnancy bleeding has led to these conditions’ being considered together, but the universal availability of ultrasound technology has eliminated much of the diagnostic dilemma.

Bleeding during the second half of pregnancy complicates about 6% of all pregnancies. Placenta previa is ultimately documented in 7% of cases, and evidence of significant placental abruption is found in 13%. In the remaining 80% of cases, the bleeding can be ascribed to early labor or local lesions of the lower genital tract or no source can be identified.¹ Faced with a woman with late pregnancy bleeding, the clinician must rapidly reach a firm diagnosis and management plan to ensure the optimal outcome for mother and baby. Ultrasonography, electronic fetal monitoring, and, frequently, evaluation of the function of the maternal coagulation system make up the foundation on which both diagnosis and management are developed. Clinical assessment must occur simultaneously with imaging and fetal assessment.

In asymptomatic patients who are without antenatal bleeding but have been identified by prenatal ultrasonography as having risk factors (placenta previa, placenta accreta, or vasa previa), timing of delivery is the most important clinical decision that has to be made.

Placenta Previa

DEFINITION AND EPIDEMIOLOGY

Advances in the precision of sonographic diagnosis, particularly transvaginal ultrasound (TVUS) imaging, and increased understanding of the changing relationship between the placenta and the internal cervical os as pregnancy advances, have rendered traditional definitions and classifications of placenta previa obsolete. *Placenta previa* exists when the placenta covers the cervix either completely or partially or extends close enough to the cervix to cause bleeding when the cervix dilates or the lower

uterine segment effaces. The term “low-lying placenta” should be reserved for cases in which the placenta is seen on transabdominal ultrasound to extend into the lower uterine segment but its precise limits have not been defined and for cases identified before the third trimester. TVUS allows for localization of the placenta in relation to the internal cervical os with great precision. When such studies are performed, the placenta may be classified as a *complete previa* if it completely covers the internal os. The term *marginal placenta previa* should be used if the placental edge lies 2.5 cm or closer to the internal os. If the placenta is more than 2 to 3 cm from the cervix, there is no increased risk of bleeding.² A definitive diagnosis of placenta previa should be avoided in asymptomatic patients before the third trimester, because many cases of placenta previa identified early in pregnancy resolve as pregnancy advances.

Placenta previa affects about 1 (0.5%) of every 200 pregnancies at term.³ There is some evidence that the incidence of placenta previa is increasing.⁴ This increase may be related to the increasing rate of cesarean section observed in all developed countries. A single prior cesarean section or a prior pregnancy complicated by placenta previa increases the incidence of placenta previa in a subsequent pregnancy to as high as 5%,^{1,5,6} and the risk increases further with a history of more than one prior cesarean delivery.⁷ Advanced maternal age increases the incidence of placenta previa to 2% after 35 years of age and 5% after age 40.⁷ Multiparity, prior suction curettage, and smoking are all associated with higher risks of placenta previa.⁸⁻¹⁰ The relative risks for these associated factors are summarized in Table 46-1.

PATHOGENESIS

The underlying cause of placenta previa is unknown. There is a clear association between placental implantation in the lower uterine segment and prior endometrial damage and uterine scarring from curettage, surgical insult, prior placenta previa, or multiple prior pregnancies.

At least 90% of placentas identified as being “low lying” in early pregnancy ultimately resolve by the third trimester.¹¹ The term “placental migration” is widely used to describe this phenomenon. The placenta clearly does not move, however; rather, it is likely that the placenta grows toward the better blood supply at the fundus (a process known as trophotropism), leaving the distal portions of the placenta, closer to the relatively poor blood supply of the lower segment, to regress and atrophy. As the uterus grows and expands to accommodate the

developing fetus, there is differential growth of the lower segment, and this may further increase the distance between the lower edge of the placenta and the cervix.

Bleeding from placenta previa may occur before labor as a result of development of the lower uterine segment and effacement of the cervix with advancing gestation. Prelabor uterine contractions may also produce bleeding, as may intercourse or injudicious vaginal examination. Once labor begins, significant bleeding will occur as the cervix dilates and the placenta is forced to separate from the underlying decidua.

DIAGNOSIS

The classic history for placenta previa is that of painless third-trimester bleeding. Several small "herald bleeds" may occur in advance of major hemorrhage, but in up to 10% of cases there is no bleeding until the onset of labor. Some women experience pain secondary to uterine contractions. Bleeding may be provoked by labor, examination, or intercourse, but it usually has no identifiable precipitating cause. The patient is more likely to have a fetus with an abnormal lie, inasmuch as the placenta previa may prevent the fetus from establishing normal polarity. All women presenting with painless vaginal bleeding after 20 weeks' gestation should be assumed to have a placenta previa until proven otherwise. Transabdominal ultrasound should be quickly utilized to screen for placenta previa. Unless the placenta is clearly fundal and the lower segment is clear, TVUS should then be performed. Transabdominal ultrasound has

been shown to be inferior to TVUS for definitive placental localization.^{12,13} Concerns regarding the potential for TVUS to provoke bleeding are unfounded, and several studies have confirmed the safety of a careful TVUS approach (Fig. 46-1).^{7,13,14} The placement of the transvaginal probe should be observed continuously on the ultrasound monitor during insertion, to avoid placing the probe into a potentially dilated cervix. If a transvaginal probe is unavailable, translabial imaging using a regular abdominal probe can produce excellent results, with better visualization of the relationship between the cervix and placenta than is obtained from transabdominal scanning.¹⁵ A digital or speculum examination to inspect the cervix for local causes of bleeding should not be performed until placenta previa has been excluded by ultrasonography.

In the unusual setting of significant late pregnancy bleeding where ultrasound is not available and the diagnosis is not clear, there is still a place for the "double-setup" examination. The patient is taken to the operating room, and preparations are made for a cesarean delivery. A vaginal examination is then performed, beginning in the vaginal fornices and avoiding placing the fingers directly in the cervix. If a placenta previa is detected, cesarean section is performed. If no placenta previa is found, a search for other causes of third-trimester bleeding ensues.

Implications of Early Pregnancy Diagnosis

The routine use of ultrasonography in the first and second trimesters of pregnancy has led to the frequent observation of a low-lying placenta or a previa.

Transabdominal ultrasound tends to overdiagnose low-lying placenta, especially when the bladder is empty.¹⁶ Even with TVUS, the findings may not correlate with the placental position at term. Several reports confirm that up to 10 times as many women are found to have a placenta previa in the second or first trimester than at delivery.^{14,17-21} The earlier in pregnancy a diagnosis of placenta previa is made, the less likely it is that the finding will persist at delivery.²² The likelihood of persistence to term of a placenta previa found in the second trimester is also related to the degree to which the placenta overlies the cervix^{14,17-21} and the thickness of the placental edge.²³ It is recommended that a follow-up ultrasound study be performed between 28 and 32 weeks' gestation to further evaluate the placental position. If there appears to be a significant change in the position of the placental edge over time, a final study should be done at 36 weeks, before making a final decision as to the appropriate route of delivery.

MANAGEMENT

Any woman with vaginal bleeding after 20 weeks' gestation should be assessed on a labor and delivery unit. The primary focus should be on hemodynamic assessment of the mother and assessment of fetal well-being. Vital signs are obtained, and electronic fetal monitoring is initiated. One or two large-gauge intravenous lines should be placed, and maternal blood should be sent for determination of the hematocrit and type and screen. For substantial bleeding episodes, 2 to 4 units of blood should be cross-matched. Obstetric units might consider the use of an "Obstetric Hemorrhage Protocol" to facilitate access to the resources of the hospital blood bank for this and any other obstetric hemorrhage (Box 46-1). Rh immune globulin is administered, when appropriate, to Rh-negative, nonimmunized women.

Once the patient is stable and fetal condition has been assessed, the definitive cause of the bleeding can be addressed. If the diagnosis is clearly placenta previa and the patient is at or beyond 36 weeks' gestation, delivery is appropriate. If

bleeding is excessive or continues, or if there are concerns about the condition of the fetus, the patient should be delivered regardless of gestational age. In all other cases, management may be conservative and has been shown to be safe,^{24,25} with prolongation of pregnancy by an average of 4 weeks after the initial bleeding episode. The closer the gestational age to 36 weeks, the less likely it is that a significant prolongation of pregnancy will be gained.²⁶ Betamethasone to enhance fetal lung maturation should be administered to patients who are at less than 34 weeks' gestation if expectant management is planned.

There is controversy regarding the role of tocolytics in the setting of hemorrhage from placenta previa. Both β -mimetics and magnesium sulfate²⁷⁻²⁹ have been used in this setting and appear to be associated with significant prolongation of pregnancy without adverse effects.

After the initial presentation with bleeding, patients should remain in hospital until they have been free of bleeding for at least 48 hours. Some may then be considered for home management. Several studies have addressed the issue of safety of outpatient management in a controlled setting at home.^{25,30-33} With the exception of one report of an increase in perinatal mortality and morbidity and earlier gestational age at birth,³⁴ it appears to be a safe approach. Patients selected for home management should be asymptomatic with regard to bleeding and abdominal pain, should be able to remain at home with limited activity, and should have adequate support as well as adequate access to transport to a nearby hospital if bleeding recurs. A second significant bleeding episode usually results in readmission until delivery.

Several strategies have been proposed to reduce the risk of hemorrhage in women with a known placenta previa. Bed rest, reduced activity, and avoidance of intercourse are commonly mandated and seem logical, although there is no conclusive evidence to support these measures. Cervical cerclage was evaluated in two small, prospective studies^{35,36} without clear evidence of benefit and is not recommended.

All women whose placenta lies within 2 cm of the cervix, as documented by a late third-trimester TVUS scan, should be delivered by cesarean section.³⁷⁻³⁹ An asymptomatic woman whose placenta lies more than 2 cm from the cervical os can be allowed to labor safely.¹⁶ The presence of a low-lying placenta, even if it does not cause intrapartum bleeding, increases the risk of postpartum hemorrhage because of lower uterine segment atony.

Cesarean section for placenta previa should be performed by the most experienced team available because of the substantial risk of intraoperative hemorrhage.⁴⁰ In most instances, a lower uterine segment incision is appropriate. If the placenta is anterior, it is necessary to clamp the umbilical cord immediately to prevent excessive blood loss caused by disruption of the placenta during entry. A vertical incision is also reasonable in such cases and may be preferable if the fetus is premature or if a transverse lie exists.⁴¹ Postpartum hemorrhage may occur from the placental implantation site secondary to atony and may require the use of additional pharmacologic agents to control blood loss, such as methylergonovine maleate (Methergine), 15-methyl prostaglandin F_{2 α} (Hemabate), and high-dose oxytocin, used either singly or in combination. The B-Lynch suture⁴² or local suturing of the placental bed may be needed to control bleeding. In rare cases of refractory hemorrhage, hysterectomy may be required.

BOX 46-1 OBSTETRIC HEMORRHAGE PROTOCOL

- Blood is immediately drawn and set up for:
 - Type and cross-matching
 - Hematocrit
 - Coagulation studies (PT/PTT/fibrinogen)
 - Wall clot (blood is drawn into a plain tube and set aside; it should clot within 6 min)
- An ABG determination may be requested to assess acute blood loss (typically, every increment in base deficit of -1 to -2 requires 1 unit of PRBCs to correct it)
- Four units of type-specific or O-negative blood are made immediately available.
- The laboratory immediately starts to cross-match 4 units of blood and stays 4 units ahead of blood use.
- Two units of FFP are thawed and made available.
- One 10-pack of platelets is made available.
- The blood bank is alerted to provide further units of blood, FFP, and platelets as needed.
- Further samples for ABG and other laboratory studies are drawn as required.

ABG, arterial blood gases; FFP, fresh-frozen plasma; PRBCs, packed red blood cells; PT, prothrombin time; PTT, partial thromboplastin time.

Among women known to have a placenta previa who do not require very early delivery, elective delivery should be performed before significant bleeding has occurred. It is reasonable to plan on delivery at or just after 36 weeks' gestation, because there is little fetal advantage after that time, when weighed against the risk of a sudden and possibly excessive bleeding episode. The alternative is to perform an amniocentesis to confirm lung maturity before delivery, but the risk of hemorrhage with delayed delivery usually outweighs the risk of fetal lung immaturity at that gestational age.

The selection of anesthesia to be used for cesarean section in cases of placenta previa should be decided by the obstetrician and anesthesiologist involved with the delivery, in concert with the patient. In the United Kingdom, regional anesthesia was preferred by most obstetric anesthesiologists in a survey⁴³ and was used in 60% of cases in a retrospective series.⁴⁴ Regional anesthesia is associated with lower operative blood loss and less need for transfusion than general anesthesia,^{3,45} probably because many inhaled anesthetics cause uterine relaxation.

COMPLICATIONS

Placenta Accreta

One of the most serious complications of placenta previa is the development of *placenta accreta*. This condition involves trophoblastic invasion beyond the normal boundary established by the Nitabuch fibrinoid layer. If invasion extends into the myometrium, the term *placenta increta* is used; placental invasion beyond the uterine serosa (at times involving the bladder or other pelvic organs and vessels) is termed *placenta percreta*. Histologic examples of normal placental implantation and placenta accreta are shown in Figure 46-2.

Placenta accreta is associated positively with advanced maternal age, smoking, and parity, but its strongest recognized association is with placenta previa and prior uterine surgery.^{46,47} In patients with placenta previa, the risk of accreta is 10% to 25% with one prior cesarean section and exceeds 50% with two or more prior cesareans.⁴⁸⁻⁵⁰ Prevalence appears to be similar in women with these risk factors who are undergoing second-trimester pregnancy termination.⁵¹

The diagnosis of placental invasion of the myometrium usually can be made by ultrasound,^{52,53} with the reported sensitivity and specificity for the diagnosis of approximately 0.8 and 0.95, respectively.⁵³⁻⁵⁵ Magnetic resonance imaging (MRI) has also been used to confirm the diagnosis or to better delineate the presence or extent of accreta.⁵³ MRI is useful in the presence of a posterior placenta and in the assessment of deep myometrial, parametrial, and bladder involvement.^{32,56}

The ultrasound appearance of a normal placental implantation site is shown in Figure 46-3A. Normal attachment is characterized by a homogeneous appearance of the placenta and a hypoechoic boundary between the placenta and the bladder that represents the myometrium and the normal retroplacental myometrial vasculature. The bladder wall is intact throughout. In contrast, placenta accreta is associated with loss of the normal hypoechoic boundary, and there are usually intraplacental sonolucent spaces adjacent to the involved uterine wall (Fig. 46-3B). Color flow and power Doppler sonography have also been reported to facilitate the diagnosis.⁵⁷⁻⁵⁹ Chou and associates⁵⁸ evaluated 80 women with placenta previa to determine the accuracy of color flow Doppler ultrasonography in

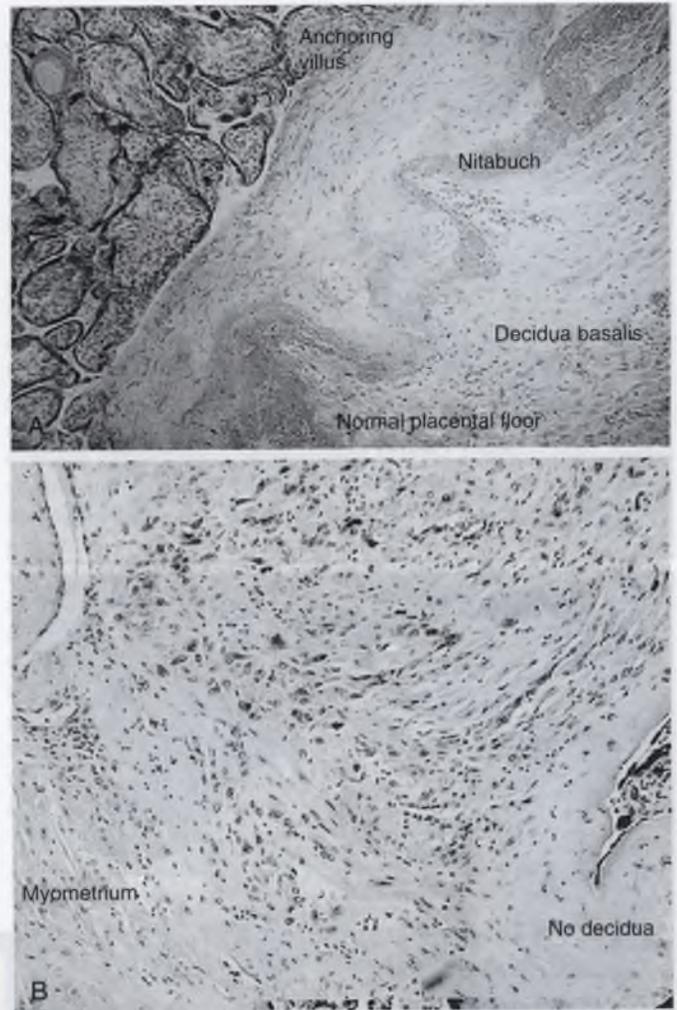

Figure 46-2 Histologic appearance of normal placental implantation and placenta accreta. **A**, Histologic section of a normal placental implantation site. distinguishing between uncomplicated placenta previa and placenta accreta. Using their criteria, the antepartum diagnosis of accreta was made in 16 of the 80 women studied and was confirmed histopathologically in 14. The sensitivity and specificity for diagnosis were 0.82 and 0.97, respectively. It is now clear that in most pregnancies at high risk for placenta accreta, an accurate determination regarding normal or abnormal implantation is now possible with the use of ultrasonography, MRI, or both. The preferred and generally recommended treatment for placenta accreta is a cesarean section and hysterectomy. It is important, if at all possible, to make the diagnosis before delivery, because intraoperative hemorrhage can be massive, and placenta accreta has been reported to be the most common indication for emergency peripartum hysterectomy.^{60,61} There is now ample evidence that predelivery diagnosis of placenta accreta, combined with elective delivery and care provided by a multidisciplinary team, markedly reduces maternal morbidity and intraoperative blood loss.⁶²⁻⁶⁵ The timing of elective delivery (34

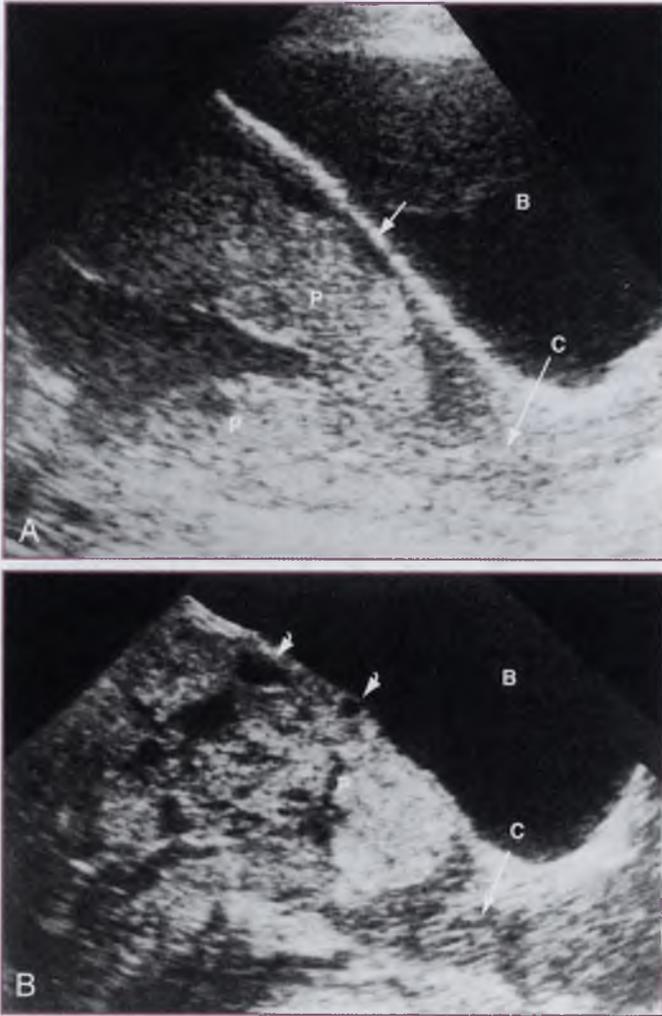

Figure 46-3 Ultrasound appearance of a normal placental implantation site and placenta accreta. **A**, Normal placental implantation in an anterior placenta previa. A hypoechoic area (arrow) separates the bladder wall and the placental tissue, representing myometrium and myometrial vasculature. **B**, Characteristic ultrasound appearance of placenta accreta. B, bladder; C, cervix; P, placenta.

to 37 weeks) has been somewhat controversial. We plan for delivery at 34 to 35 weeks after maternal corticosteroid administration. With this approach, our neonatal outcomes have been favorable.⁶³ Delivery is performed without amniotic fluid confirmation of fetal lung maturity. This strategy is supported by a decision analysis comparing various gestational ages with and without amniocentesis before delivery.⁶⁶

In an effort to diminish blood loss, it is recommended that delivery be accomplished through a fundal incision followed by clamping of the cord. The placenta is allowed to remain in situ while the surgeons proceed to a total abdominal hysterectomy. This may require very complex surgical technique and planning, and a pelvic surgeon capable of wide resection of the lower uterine segment and parametrial areas should be available, as well as ample transfusion capability.

Although published reports are not extensive, it has been suggested that balloon occlusion of the aorta or internal iliac vessels may help to prevent excessive blood loss during resection of the lower uterine segment. This involves preoperative placement of balloon-tipped catheters retrograde through the femoral arteries immediately before surgery. The catheters are guided under fluoroscopic direction into the internal iliac arteries and inflated during the dissection. However, the value and safety of this approach have been challenged since reports of no proven benefit and embolic complications were published.^{67,68} The utility of balloon-tipped catheters remains unclear because the timing of deployment during surgery has been highly variable and inconsistent.⁶⁹ A recent comprehensive literature review concluded that there is a need for larger studies, or preferably a randomized trial, to provide adequate answers to this controversial issue.⁷⁰ Nevertheless, the placement of catheters does provide the opportunity to manage potential postoperative bleeding with angiographic embolization rather than reexploration.

Conservative management may be an option if there is suspicion of a small focal accreta, if there is a fundal location after a myomectomy or classic cesarean section, or with a posteriorly implanted placenta. A few reports have suggested leaving the uterus and placenta in situ and using methotrexate postoperatively.⁷¹⁻⁷³ However, the numbers of reported cases are very few, and hemorrhagic and infectious complications have usually resulted. Sentilhes and colleagues reported on a cohort of 167 women with accreta in whom conservative management was planned before delivery. Eighteen required a primary hysterectomy for intraoperative bleeding, and 18 underwent a delayed hysterectomy. Severe morbidity occurred in 10 women, and there was one death due to complications of methotrexate therapy.⁷⁴ Follow-up was available for 35 women, of whom 14 desired a subsequent pregnancy. Of the 15 pregnancies achieved, there were 6 first-trimester losses, 4 preterm infants, and 2 recurrent placenta accretas.⁷⁵ Based on these reports, a definitive surgical approach to this serious obstetric complication is strongly recommended.

Neonatal Complications

It has been suggested that repetitive bleeding from placenta previa is associated with fetal growth impairment,⁷⁶ although this has been disputed.²⁶ Pregnancies complicated by placenta previa have also been reported to be associated with higher rates of fetal anomalies,⁷⁷ neurodevelopmental delay,⁷⁸ and sudden infant death syndrome (SIDS).⁷⁹ The reasons for these findings are unknown.

As might be expected, placenta previa and previa accreta are a cause of preterm birth due to the need for iatrogenic preterm delivery. Placenta accreta has also been reported to have a negative influence on fetal growth (odds ratio [OR] = 5.05 compared with controls).⁸⁰

Vasa Previa

DEFINITION AND EPIDEMIOLOGY

Vasa previa is a rare but potentially catastrophic complication in which fetal vessels run through the fetal membranes and are at risk of rupture with consequent fetal exsanguination. It is estimated that vasa previa affects between 1 in 1275 and 1 in 8333 pregnancies.^{81,82}

PATHOGENESIS

Vasa previa may occur because the insertion of the umbilical cord into the placenta is velamentous, with the umbilical vessels coursing through the fetal membranes before inserting into the placental disk and the unsupported vessels then overlying the cervix. It may also result from the presence of a bilobed or succenturiate placenta, with the connecting vessels similarly overlying the cervix.¹⁶ If the condition goes unrecognized, it is associated with a fetal mortality rate of almost 60%. In addition to a succenturiate placenta⁸³ and velamentous insertion, other risk factors include a low-lying placenta observed in the second trimester,⁸⁴ multiple gestation, and in vitro fertilization.⁸⁵

DIAGNOSIS

The key to reducing fetal loss from vasa previa is prenatal diagnosis.¹⁶ Many cases of vasa previa are identified only at the time of vessel rupture in labor. Vaginal bleeding is followed by fetal distress and death if emergent delivery cannot be effected in time. Because the entire fetal cardiac output passes through the cord, it can take less than 10 minutes for total exsanguination to occur. Electronic fetal monitoring may show an initial tachycardia, rapidly followed by decelerations, bradycardia, and a preterminal sinusoidal rhythm.⁸⁶ If a cesarean delivery can be accomplished immediately and with sufficient rapidity, good newborn outcome can be obtained with aggressive postnatal transfusion therapy.⁸⁷

It has been suggested that the blood from the vagina may be tested to confirm its fetal origin, using the Apt or Kleihauer-Betke test or electrophoresis.⁸⁸ In actual practice, such tests are unavailable or cannot be done quickly enough to be of any value. Occasionally, fetal vessels have reportedly been felt through the membranes during vaginal examination or visualized on amnioscopy; such observations are really only of historical interest in modern practice.

It is now well established that vasa previa may be diagnosed prenatally with the use of ultrasound.^{89,90} Routine obstetric ultrasound should include an assessment of the placental site and number of placental lobes and an evaluation of the placental cord insertion site. In all cases in which a multilobed or succenturiate placenta or a low-lying placenta or velamentous cord insertion is identified using transabdominal ultrasound, a detailed examination of the lower uterine segment and cervix should be performed using TVUS. Gray-scale ultrasound can identify placental cord insertion in most cases, but color or power Doppler makes the process easier and should be used (Figs. 46-4 and 46-5).^{89,92} There have been several studies evaluating this approach for prenatal detection of vasa previa,^{89,90,92,93} all of which showed high specificity and sensitivity of detection with little impact on the length of scan time. More importantly, in cases in which vasa previa was detected prenatally, there were no fetal deaths from the condition. A recent retrospective, multicenter study showed newborn survival rates of 97% in prenatally detected cases of vasa previa and a fetal loss rate of 56% in cases not identified before the commencement of labor.⁹⁴

B, A fetal arterial waveform using power and pulse-wave Doppler. C, Vasa previa in gray scale on transvaginal ultrasound. D, Confirmation of the vasa previa by color Doppler transvaginally.

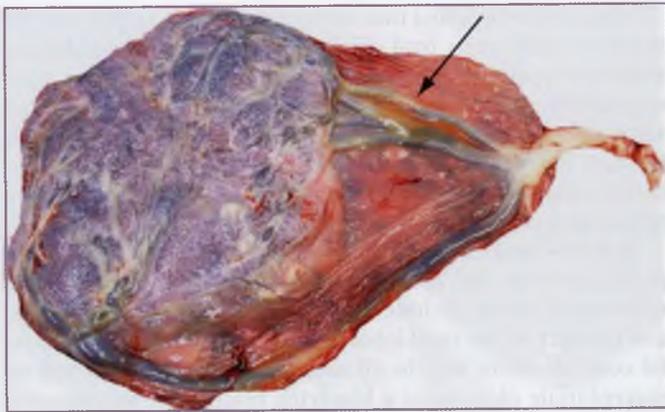

Figure 46-5 Vasa previa. The placenta from the case identified in Figure 46-4. The patient was delivered by elective cesarean section at 34 weeks' gestational age. Arrow shows velamentous cord insertion.

Newer imaging modalities such as MRI⁹⁵ and three-dimensional ultrasound have been described in the evaluation of vasa previa.^{96,97} MRI is of little practical use in routine cases. Although transvaginal three-dimensional power Doppler provides an excellent means of visualizing the entire lower uterine segment for the evaluation of vasa previa, similar information may be obtained by careful use of a two-dimensional vaginal probe. Such imaging combined with maternal positional change, the use of the Trendelenburg position, and gentle manual elevation of the fetal presenting part aid in visualizing the fetal vessels. The latter technique is particularly useful because the vessels may be compressed by the presenting part and therefore difficult to visualize.

MANAGEMENT

There is no uniformity of opinion as to the optimal management strategy for pregnancies with a prenatally diagnosed vasa previa, particularly in regard to the timing of elective delivery, although the Society of Obstetricians and Gynaecologists of Canada has published a guideline for management.⁹⁸ It has been suggested that patients be hospitalized at 30 to 32 weeks and delivered at 35 to 36 weeks' gestation without confirmation of lung maturity by amniocentesis.¹⁶ This approach is based on the 10% risk of membrane rupture before labor and the high associated fetal mortality rate. A decision analysis comparing 11 strategies for delivery timing concluded that delivery at 34 to 35 weeks best balanced the risk of prematurity with the risk of neonatal mortality.⁹⁹ Our approach has been to assess cervical length weekly from at least 30 weeks using TVUS. If the cervix is 2.5 cm in length or greater, out-of-hospital management continues. The patient is administered betamethasone just before 34 weeks' gestation and is delivered by cesarean section between 34 and 35 weeks, without additional testing for fetal lung maturity.

PREVENTION OF ADVERSE OUTCOMES

A significant reduction in fetal mortality should be possible with a diligent search as previously described. Public and professional awareness has been heightened by such organizations as The International Vasa Previa Foundation (<http://www.vasaprevia.com> [accessed January 7, 2013]). However, a

Figure 46-6 A large (6.5-cm) subchorionic hemorrhage at 12 weeks 6 days of gestation.

high index of suspicion by the attending physician and a meticulous approach to diagnosis provide the best opportunity for a favorable outcome.

Subchorionic Hemorrhage

Subchorionic hemorrhage is not generally considered to be part of the spectrum of placental abruption. It occurs in the first half of pregnancy and manifests with bleeding only, rather than the more dramatic clinical presentation seen with placental abruption. It usually presents with bleeding in the first or early second trimester, and a retroplacental blood clot is usually seen on TVUS. It is disconcerting to women who have the experience, and it is associated with increased risk of adverse pregnancy outcomes. A representative view of a typical subchorionic bleed is shown in Figure 46-6. In 2010, a retrospective review of 63,966 pregnancies revealed subchorionic hemorrhage in 1081 (1.7%). These women were at increased risk of abruption (OR = 2.6; 95% confidence interval [CI], 1.8 to 3.7) and preterm delivery.¹⁰⁰ A subsequent literature review and meta-analysis compared 1735 women with subchorionic hemorrhage to more than 70,000 controls. Those with subchorionic hemorrhage had greater risks of spontaneous abortion (OR = 2.18; CI, 1.29 to 3.68) and abruption (OR = 5.71; CI, 3.91 to 8.33). There was also a slightly higher risk of premature membrane rupture and preterm delivery, although the absolute risks remained low.¹⁰¹ These observations should help to provide counseling to women who experience early bleeding and retroplacental hematoma formation.

Abruptio Placentae

DEFINITION AND EPIDEMIOLOGY

Abruptio placentae is the premature separation of a normally sited placenta before birth, after 20 weeks' gestation. It is a particularly hazardous condition associated with significant maternal and fetal morbidity and mortality. About 1% of all pregnancies are complicated by clinically recognized abruption.¹⁰²⁻¹⁰⁵ The degree of abruption ranges across a broad clinical spectrum, from minor degrees of placental separation, with little effect on maternal or fetal outcome, to major

abruption associated with fetal death and maternal morbidity. Abruptio sufficient to cause fetal death occurs in about 1 of every 420 deliveries.¹⁰⁶ If placentas are routinely examined after delivery, evidence of abruption may be found in almost 4% of cases, most of which were unrecognized and of no apparent clinical consequence. There has been an increase of almost 25% in the rate of clinically detected abruption in the United States in recent decades, with a disproportionate increase seen among African-American women.¹⁰⁷

The incidence of abruption peaks between 24 and 26 weeks' gestation.¹⁰⁸ Approximately 10% of all preterm births occur because of abruption,¹⁰² and the infant outcomes are associated with increased rates of perinatal asphyxia,¹⁰⁹ intraventricular hemorrhage, periventricular leukomalacia,¹¹⁰ and cerebral palsy¹¹¹ when compared with gestational age–matched controls. Perinatal mortality in pregnancies complicated by abruption may be declining overall,^{105,112} but the rate continues to be higher than in gestational age–matched controls without abruption.¹⁰⁸ Placental separation is strongly associated with premature rupture of the membranes (pPROM), in both a causal and a consequential manner.¹¹³ Most pregnancies complicated by abruption result in the delivery of an infant weighing less than the 10th percentile for gestational age,^{114–116} suggesting a common pathway linking abruption to placental dysfunction and intrauterine growth retardation (IUGR).

PATHOGENESIS

Abruptio results from bleeding between the decidua and placenta (Fig. 46-7). The hemorrhage dissects the decidua apart, with loss of the corresponding placental area for gaseous exchange and provision of fetal nutrition. The process may be self-limited or ongoing with further dissection of the decidua. Dissection can lead to external bleeding if it reaches the placental edge and tracks down between the fetal membranes; circumferential dissection leading to near-total separation of the placenta can occur, particularly with concealed abruption. The underlying event in many cases of abruption is thought to be vasospasm of abnormal maternal arterioles. Some cases may result from venous hemorrhage into areas of the decidua that

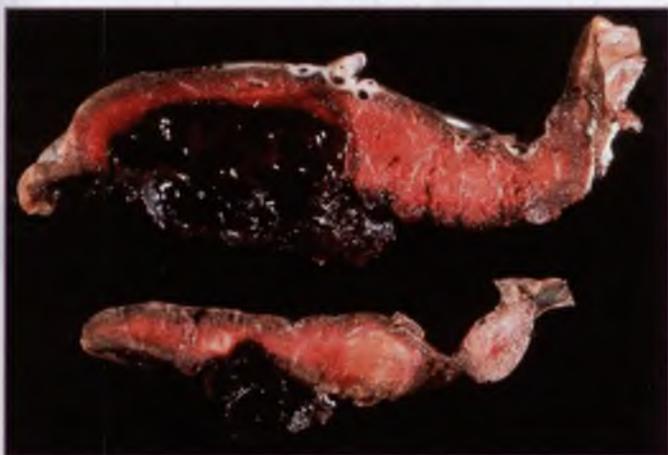

Figure 46-7 Abruptio placentae. A large retroplacental abruption at 30 weeks' gestation is shown.

have become necrotic secondary to thrombosis. Long-standing predisposition to abruption may be inferred from the finding that women destined to suffer abruption have low levels of pregnancy-associated plasma protein A (PAPP-A).¹¹⁷ Evidence of preexisting placental pathology in women with abruption includes poor trophoblastic invasion,¹¹⁸ inadequate remodeling of the uterine circulation as reflected by abnormal uterine artery Doppler flow,¹¹⁹ and the well-established associations among preeclampsia, IUGR, and abruption—all of which may be regarded as primary placental disorders. Abruptio may also occur secondary to acute shearing forces affecting the placenta-decidua interface, such as those that occur with trauma—particularly rapid deceleration injuries (motor vehicle accidents) and the sudden decompression of an overdistended uterus that occurs with membrane rupture in polyhydramnios or delivery of a multiple gestation.

As the abruption process continues, loss of placental function results in fetal hypoxia possibly ending in fetal death. The acute hemorrhage activates the coagulation cascade, and, with ongoing bleeding, disseminated intravascular coagulation (DIC) may result. Continued bleeding, with maternal hypovolemia and poor tissue perfusion, aggravates the DIC and results in a downward spiral into hemorrhagic shock. Bleeding into the myometrial tissue can lead to a Couvelaire uterus which becomes atonic and increases the risk of uterine hemorrhage after delivery.

Risk Factors and Associations for Abruptio

The most important risk factor for abruption is a history of abruption in a prior pregnancy.^{120,121} One meta-analysis showed an increase of up to 20-fold in the risk of abruption if a prior pregnancy had been similarly affected.¹²² With two prior pregnancies complicated by abruption, the risk of recurrence is 25%.¹⁰⁶

Maternal hypertension is also a significant risk factor for abruption. Chronic hypertension is associated with a fivefold increase in risk, which rises to eightfold with superimposed preeclampsia.¹⁰⁸ Preeclampsia alone is also strongly linked to abruption and to the severity of abruption.¹²³ It seems plausible that preeclampsia and abruption share many underlying pathologic mechanisms.

Perhaps the most readily preventable risk factor for abruption is cigarette smoking. Cigarette smokers are up to 2.5 times more likely to have an abruption than nonsmokers,^{124–128} and they have twice the perinatal mortality of nonsmokers.¹²⁹ There is a dose-response relationship between the number of cigarettes smoked and the risk of abruption.^{127,130,131} Even women who stop smoking before pregnancy are at increased risk. Substance abuse is closely linked to abruption: Any agent that causes vasospasm or transient severe hypertension may be causative.^{132,133} In the United States, as many as 10% of pregnant women who are cocaine or crack cocaine users will experience placental abruption.¹³⁴ Multiparity is also positively correlated with a small increase in the risk of abruption.^{1,114} The apparent association between maternal age and abruption is not significant when parity is taken into account.

There has been substantial interest in the possible association between thrombophilic disorders and abruption. Some retrospective studies of abruption have found increased rates of thrombophilia.^{135–137} However, both retrospective¹³⁷ and prospective case-control studies¹³⁸ of women with the factor V Leiden mutation showed no increase in abruption risk. It is

established that hyperhomocysteinemia is associated with abruption,¹³⁶ although, in the absence of this condition, the specific *MTHFR* gene mutations themselves do not appear to be associated with an increased risk.^{139,140}

Motor vehicle accidents are the most common traumatic event associated with abruption, and clinical evidence of abruption may not be apparent for 24 hours or longer after the trauma. Women with vaginal bleeding or contractions after a motor vehicle accident should be observed for at least 24 hours; those who are asymptomatic can safely be discharged after 6 hours of monitoring.^{141,142}

Membrane rupture may precede or follow chronic retroplacental bleeding or an acute abruption, and women with ruptured membranes should be monitored carefully for this possibility.^{122,143} Those with early pregnancy bleeding who have a subchorionic hematoma visible by ultrasound are also at increased risk for both pPROM and abruption.¹⁰¹

Screening tests performed for other indications may identify groups of women who are at increased risk for abruption but have no other high-risk factors. These tests include maternal first- and second-trimester serum screening for aneuploidy. Women with PAPP-A levels below the 5th percentile at the time of first-trimester serum screening for trisomy 21 have an increased risk of abruption,¹¹⁷ but low levels of human chorionic gonadotropin (hCG) in the first trimester are not similarly associated.¹⁴⁴ In one study of routine uterine artery Doppler velocimetry performed at 11 to 14 weeks' gestation as a screen for IUGR and preeclampsia, a pulsatility index higher than the 95th percentile or a PAPP-A value lower than the 10th percentile predicted 43% of pregnancies with a subsequent abruption.¹⁴⁵ In an earlier study of uterine artery Doppler ultrasound, persistent notching of the waveform after 24 weeks was associated with increased risk for abruption as well as IUGR and preeclampsia.¹¹⁹

Women with otherwise unexplained elevated serum levels (>2 multiples of the median [MoM]) of α -fetoprotein (AFP) on second-trimester serum screening for trisomy 21 have long been thought to be at increased risk for a wide range of adverse pregnancy outcomes, including abruption.^{146,147} However, a case-matched, prospective study found elevated AFP levels to be associated with an increased risk of abruption but no increase in the frequency of IUGR, preterm delivery, low birth weight, or fetal death.¹⁴⁸ An attempt to establish a critical cutoff value for elevated AFP and increased risk of abruption stressed the low specificity and high rate of false-positive results.¹⁴⁸

Elevated hCG values at the time of second-trimester serum screening have similarly been associated with adverse pregnancy outcome, including abruption.¹⁴⁹ Previously, a value greater than 2.0 MoM was thought to be significant in this context, but one case-control study showed that the threshold should be set at 3.0 MoM. Even at that level, a positive test had poor predictive value and was not associated with increased risk of abruption.¹⁵⁰ Abnormal inhibin values do not appear to be predictive of abruption.

DIAGNOSIS

The diagnosis of placental abruption is made based on clinical findings. The classic presentation is that of vaginal bleeding, usually accompanied by abdominal (uterine) pain. Examination often reveals uterine tenderness, and contractions may be present. About 10% of abruptions are concealed, with no

vaginal bleeding. If bleeding is present, the amount is often a poor guide to the degree of separation, because there is usually a mixed picture of apparent and concealed hemorrhage. Fetal compromise is a common finding, and if more than 50% of the placenta is involved, fetal death is likely. Massive concealed abruption often manifests with severe pain, a hard uterus, and a dead fetus; such a picture may occur in association with severe preeclampsia or recent use of a vasoactive drug such as cocaine.¹⁵¹ If abruption occurs in a posteriorly located placenta, severe back pain may be the only symptom; it may be worsened by abdominal palpation that pushes the fetus against the placenta. Abruption may precipitate preterm labor, and it should always be considered in the differential diagnosis for a patient in apparent idiopathic preterm labor.

Although ultrasonography is an integral part of the diagnostic approach to late pregnancy bleeding, its utility is primarily for the exclusion of placenta previa as the cause of hemorrhage. At least 50% of abruptions produce no findings on ultrasound.¹⁵²⁻¹⁵⁴ What is visualized by ultrasound depends on the site, scale, and timing of bleeding. In early acute abruptions, blood and clot retained within the uterus appear as hyperechoic or isoechoic collections relative to placental echogenicity.¹⁵⁵ In cases that remain undelivered, the hematomas resolve over several weeks, becoming hypoechoic and then sonolucent, usually by 2 weeks after the event.¹⁵⁵ Intrauterine clot may "jiggle" when bounced by the transducer (the "jello" sign). An acute abruption with obvious vaginal bleeding, in which little or no blood is retained within the uterus, may have no specific sonographic findings. Therefore, the absence of ultrasound findings never excludes an abruption.

Cardiotocography is an integral part of the evaluation for late pregnancy bleeding. Abruption is commonly accompanied by uterine contractions that may not be appreciated clinically, particularly after trauma.¹⁵⁶ Fetal heart rate tracings may exhibit a variety of abnormal patterns, including variable and late decelerations, poor variability, prolonged bradycardia, or a sinusoidal pattern; these are not specific to abruption and reflect underlying evolving fetal asphyxia.

Kleihauer-Betke testing is of no diagnostic value in abruption: It may be negative with proven abruption^{141,142,157} or positive when no abruption has occurred. Its only value in this setting is to guide Rh immune globulin dosing in Rh-negative women who are thought to have sustained an abruption.

Chronic abruption-oligohydramnios sequence (CAOS) is a term that was coined to describe women who present with bleeding attributed to abruption and go on to develop oligohydramnios without evidence of ruptured membranes.¹⁵⁸ Twenty-four patients were described, all of whom delivered preterm (average gestational age, 28 weeks). For the most part, the earlier the onset of bleeding, the earlier the delivery. More than half of the women went on to develop pPROM before delivery and after the development of oligohydramnios.

MANAGEMENT

The key to optimizing maternal and fetal outcomes in abruption is the individualization of care. Precise management depends on the extent of maternal and fetal compromise and the gestational age. Decision making should be rapid but methodical; delay in diagnosis and inappropriate triage lead to significantly increased perinatal mortality.¹⁵⁹ Twenty percent of all fetal deaths from abruption occur after presentation to the

hospital, and 30% of those deaths occur within 2 hours after admission.

Initial assessment should focus on maternal hemodynamic status (remembering that blood pressure may be elevated in the setting of preeclampsia) and fetal well-being. Maternal vital signs should be measured frequently, because they may change suddenly as the abruption evolves. Electronic fetal monitoring should begin immediately and be continuous throughout further assessment and management. A large-gauge intravenous line should be placed (two lines if the patient is hemodynamically unstable). Initial laboratory studies should include a baseline complete blood count and platelet count, type and screen and cross-match where appropriate, blood urea nitrogen and electrolytes, coagulation studies, and a wall clot. These studies serve as useful baseline references. An indwelling bladder catheter should be placed to allow urinary output to be closely monitored. In unstable or critically ill patients, management may be aided by placement of a central venous pressure line (preferably with a Cordis introducer) or an arterial line. The involvement of the obstetric anesthetic team should be sought early.

After these steps are taken, attention should be directed at excluding a placenta previa (by ultrasound examination) and deciding on the timing and route of delivery. Maternal or fetal compromise mandates immediate delivery, usually by cesarean

section unless the patient is in an advanced stage of labor. If the event occurs after 34 weeks' gestation, delivery should not be delayed, because the risks of conservative management outweigh any considerations of prematurity of the fetus. Between 20 and 34 weeks, if mother and fetus are stable, an attempt at conservative management may be considered.^{160,161} Betamethasone should be administered to enhance fetal lung maturity in all such cases. The patient should be monitored closely, because she continues to be at risk of an evolving process. The use of tocolytics is controversial; in most cases, they should not be used. Although studies addressing this issue have found no increase in adverse fetal or maternal events,^{27,160-162} no prospective trial has been performed.

If the patient has sustained a mild separation at a premature gestational age and is asymptomatic without evidence of bleeding, discharge home may be considered as an alternative to prolonged hospitalization. Either way, a clear management plan for delivery should be developed based on subsequent events or the reaching of an arbitrary gestational age (usually 37 weeks). The evaluation of patients undergoing expectant management should include regular assessment of fetal growth and tests of well-being, because these fetuses are at increased risk for IUGR.

If an abruption occurs after 34 weeks' gestation and maternal and fetal conditions permit, vaginal delivery is preferred. Amniotomy should be performed, and, if needed, an oxytocin

TABLE 45-2 Coagulation Tests Used in the Diagnosis of Abruptio Placentae

Test	What It Measures	Normal Value	Value in Abruption
Bleeding time	Vascular integrity and platelet function	1-5 min	Usually normal; test is of little clinical use in diagnosing abruption
Whole blood clotting time	Platelet function Fibrinolytic activity	Clot formation: 4-8 min Clot retraction: <1 hr Clot lysis: none in 24 hr	Clot formation abnormality indicates severe deficiency Abnormal retraction with thrombocytopenia
Fibrinogen	Fibrinogen level	400-650 mg/100 mL	Usually decreased
Platelet count	Number of platelets	>140,000/mm ³	Usually decreased
Fibrin degradation products	Fibrin and fibrinogen degradation products	<10 µg/mL	Almost always elevated; most sensitive test
Euglobulin clot lysis time	Fibrinolytic activity	None in 2 hr	Difficult to interpret with low fibrinogen levels
Prothrombin time	Factors II, V, VII, X	10-12 sec	Normal to prolonged
Partial thromboplastin time	Factors II, V, XIII, IX, X, XI	24-38 sec	Normal to prolonged
Thrombin time	Factors I, II Circulating split products Heparin effect	16-20 sec	Parallels fall in fibrinogen; good marker of abruption severity
Red blood cell morphology	Microangiopathic hemolysis	Absence of distortion or fragmentation	Presence of distortion or fragmentation is uncommon but indicates risk of renal cortical necrosis

TABLE 46-3 Blood Replacement Products

Component	Volume per Unit (mL)*	Factors Present	Effect of 1 Unit
Fresh whole blood	500	RBCs; all procoagulants	↑ Hematocrit 3%
Packed RBCs	200	RBCs only	↑ Hematocrit 3%
Fresh-frozen plasma	200-400	All procoagulants; no platelets	↑ Fibrinogen 25 mg/dL
Cryoprecipitate	20-50	Fibrinogen; factors VIII, XIII	↑ Fibrinogen 15%-25%
Platelet concentrate	35-60	Platelets; small amounts of fibrinogen; factors V, VIII	↑ Platelet count approximately 8000/mm ³

*Volume depends on individual blood bank.
RBCs, red blood cells.

Intrauterine Growth Restriction

ROBERT RESNIK, MD | ROBERT K. CREASY, MD

Human pregnancy, similar to pregnancy in other polytocous animal species, can be affected by conditions that restrict the normal growth of the fetus. The growth-restricted fetus is at higher risk for perinatal morbidity and mortality, the risk rising with the severity of the restriction. This chapter reviews the various causes of fetal growth restriction and considers the methods of antepartum recognition and diagnosis along with clinical management.

Definitions

At the beginning of the 20th century all small newborns were thought to be premature, but by the middle of the century the concept of the undernourished neonate arose, and newborns weighing less than 2500 g were then classified by the World Health Organization as low-birth-weight infants. In the 1960s, Lubchenco, Battaglia, and their colleagues, in a series of classic papers, published detailed graphs of birth weight as a function of gestational age and associated adverse outcomes.^{1,2} Three categories were used to define normal and abnormal fetal growth, utilizing percentiles of growth from a population-based reference of all newborn infants:

1. Those whose weights were lower than the 10th percentile were called *small for gestational age (SGA)*.
2. Those whose birth weights were between the 10th and 90th percentiles were labeled as *appropriate for gestational age (AGA)*.
3. Those larger than the 90th percentile were called *large for gestational age (LGA)*.

This classification of newborns by birth weight percentile has been extremely useful and of prognostic significance in that those of lower percentiles are at increased risk for immediate perinatal morbidity and mortality³ as well as subsequent adult disease. These Denver standards, however, do not reflect the increase in median birth weight that has occurred over the last 4 decades or the birth weight standards for babies born at sea level. More contemporary standards are available from large geographic regions, such as the state of California, based on data from more than 2 million singleton births between 1970 and 1976.⁴ Brenner and colleagues⁵ used data on black and white infants from Cleveland and aborted fetuses from North Carolina. Ott⁶ studied newborns from St. Louis. Arbuckle and associates⁷ based their study on more than 1 million singleton births and more than 10,000 twin gestations in Canada between 1986 and 1988, and Alexander and colleagues⁸ used information from 3.8 million births in the United States in 1991. A comparison of their 1991 U.S. national data with that of previous reports is shown in Figure 47-1.

Data collected between 1998 and 2006 reflect fetal weights in a modern American population of >391,000 infants from 33

states.⁹ Illustrated in Figure 47-2, they demonstrate dramatically the differences between the original Lubchenco growth curves and those generated from a large, ethnically diverse cross section of newborns in the United States.

However, these population-based growth curves that traditionally have been used in the United States define SGA as a birth weight below the 10th percentile for gestational age. Consequently, the term SGA has become synonymous with, and in fact a surrogate for, *fetal growth restriction (FGR)*, despite the fact that it has become increasingly apparent that many infants whose weights are below the 10th percentile are perfectly normal and simply “constitutionally” small. Conversely, the adverse perinatal outcome is increased for infants whose birth weights are between the 10th and 20th percentile but who have not achieved their growth potential. This has led investigators to recommend the use of customized rather than population-based fetal growth curves.^{10,11} This concept takes into account the ability of a fetus to achieve its growth potential, determined prospectively and independent of maternal pathology. The customized growth curve approach uses known variables affecting fetal weight, such as maternal height, weight, ethnicity, and parity at the beginning of pregnancy, in order to calculate fetal weight trajectories and optimal fetal weight at delivery. Several studies have shown that customized birth weight percentiles more accurately reflect the potential for adverse outcome.¹²⁻¹⁶ Customized growth charts may be downloaded at Gestation Network (<http://www.gestation.net> [accessed January 7, 2013]).

Not all epidemiologists are in agreement with the utility of customized growth curves,^{17,18} but regardless of the epidemiologic controversy, the clinician must be aware that maternal factors such as pre-pregnancy weight and ethnicity strongly influence fetal growth potential and size and that fetal growth velocity and function (as assessed by Doppler flow through fetal vessels and amniotic fluid volume) are superior to reliance on an isolated specific estimate of fetal weight in determining what represents normal and abnormal fetal growth. Zhang and associates have summarized these issues and framed the discussion for a much-needed internationally recognized, integrated definition of FGR.¹⁹

The challenges for the clinician include interpreting the significance of various research publications, when no uniform standard definition of FGR exists, and accurately distinguishing between the small normal fetus and one which is growth restricted.

Rate of Fetal Growth

Data obtained from study of induced abortions and spontaneous deliveries indicate that the rate of fetal growth increases from 5 g/day at 14 to 15 weeks' gestation, to 10 g/day at 20

weeks, and to 30 to 35 g/day at 32 to 34 weeks. The total substrate needs of the fetus are therefore relatively small during the first half of pregnancy, after which the rate of weight gain rises precipitously. The mean weekly weight gain peaks at approximately 230 to 285 g at 32 to 34 weeks' gestation, after which it decreases, possibly reaching zero weight gain, or even weight loss, at 41 to 42 weeks (Fig. 47-3).⁴ If the growth rate is expressed as the percentage of increase in weight over the previous week, however, the maximum is reached in the first trimester, and the rate decreases steadily thereafter.

Classification of Fetal Growth Restriction

Normal fetal growth occurs in three phases. The first phase is characterized by cellular hyperplasia and occurs in the first half

of pregnancy. During this period, most growth is the consequence of cell division. The second phase is that of both hyperplasia and cellular hypertrophy (increase in cell size). The final phase (the last 6 to 8 weeks of pregnancy) is that of hypertrophic growth.

With this pattern of growth in mind, a clinically useful method of classifying FGR takes into account fetal body size and length and the observation that there are two main types of FGR infants: (1) the infant of normal length for gestational

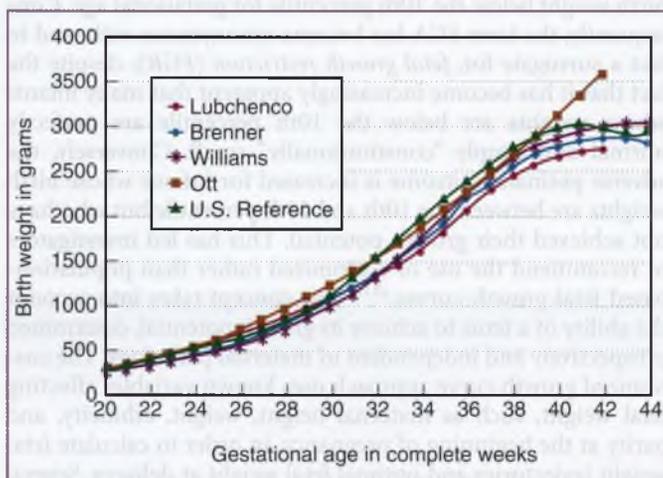

Figure 47-1 Fetal weight as a function of gestational age by selected references. Reprinted with permission from the American Academy of Pediatrics.)

age (biometry demonstrating normal skeletal dimensions and head size) whose weight is below normal due to decreased subcutaneous tissue and abdominal circumference (*asymmetrically small*), and (2) the infant whose weight and skeletal dimensions are both below normal (*symmetrically small*).

The symmetrically small fetus is usually the result of some factor that influences hyperplastic growth in early pregnancy, most often aneuploidy, malformations, or, less commonly, fetal infection. These fetuses account for 20% to 30% of those affected by FGR. More commonly, the FGR fetus demonstrates an asymmetric growth pattern. Most often, there is placental disease in which either the volume of placental tissue is inadequate to support growth or there is destruction of placental tissue resulting in impairment of nutrient and oxygen transfer. On occasion, long-standing placental disorders originating in early pregnancy may manifest with symmetric growth abnormalities, and asymmetric growth patterns first observed in the late second or early third trimester may develop a more symmetric appearance over a protracted period.

Cognizance of the mechanisms of fetal growth and both normal and abnormal fetal growth patterns helps to provide valuable clues regarding the etiology, management, and prognosis of the FGR fetus.

Incidence of Fetal Growth Restriction

Based on the previous discussion, it is apparent that the incidence of FGR varies according to the population under examination, the geographic location, the growth curves used as reference (population-based or customized), and the percentile chosen to indicate abnormal growth (i.e., the 3rd, 5th, 10th, or 15th).

Approximately one fourth to one third of all infants weighing less than 2500 g at birth have sustained intrauterine growth restriction (IUGR). Approximately 4% to 8% of all infants born in developed countries, and 6% to 30% of those born in developing countries, have been classified as growth restricted.²⁰

Perinatal Mortality and Morbidity

FGR is associated with an increase in fetal and neonatal mortality and morbidity rates. The perinatal mortality rates for fetuses and neonates weighing less than the 10th percentile but between 1500 and 2500 g were 5 to 30 times greater than those of newborns between the 10th and 90th percentiles; for those weighing less than 1500 g, the rates were 70 to 100 times greater.⁴ In addition, for birth weights below the 10th percentile, the fetal and neonatal mortality rates rise as gestation advances if birth weights do not increase.

As depicted in Figure 47-4, Manning showed that perinatal morbidity and mortality increase if the birth weight is below the 10th percentile, and markedly so if it is below the 6th percentile.²¹

In general, fetal mortality rates for growth-restricted fetuses are 50% higher than neonatal mortality rates, and male fetuses with FGR have a higher mortality rate than female fetuses. The 10% to 30% increase in incidence of minor and major congenital anomalies associated with FGR accounts for 30% to 60% of FGR-related perinatal deaths (50% of stillbirths and 20% of neonatal deaths).²² Deaths of infants with symmetric growth restriction are more likely to be associated with anomalous development or infection. However, in the absence of congenital abnormalities, chromosomal defects, and infection, neonates

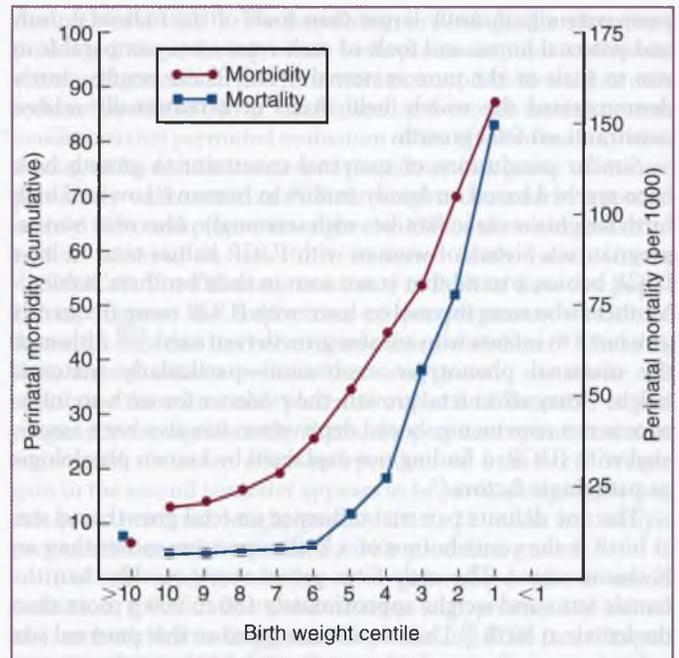

Figure 47-4 Morbidity and mortality in 1560 small-for-gestational-age fetuses. (From Manning FA: *Intrauterine growth retardation*. In Manning FA, editor: *Fetal medicine: principles and practice*, Norwalk, CT, 1995, Appleton & Lange.)

with symmetric growth aberration are probably not at increased risk of neonatal morbidity.²³ The incidence of mortality in the preterm newborn is higher if FGR is also present.²³ The incidence of intrapartum fetal stress with FGR approximates 25% to 50%.^{24,25}

In addition, FGR may contribute to perinatal morbidity and mortality by leading to both induced and spontaneous preterm births and the neonatal problems associated with preterm delivery.²⁶ Specific early and long-term morbidities related to FGR are discussed later in this chapter and in Chapter 72.

Etiology of Fetal Growth Restriction

IUGR encompasses many different maternal and fetal entities. Some can be detected before birth, whereas others can be found only at autopsy. It is important to discern the cause of FGR, because in many cases subsequent pregnancies may also be affected.

GENETIC FACTORS

There has been much interest in determining the relative contributions of factors that produce birth weight variation, namely the maternal and fetal genetic factors and the environment of the fetus. Approximately 40% of total birth weight variation is due to the genetic contributions from mother and fetus (approximately half from each), and the other 60% is due to contributions from the fetal environment.²⁷⁻³⁰

Although both parents' genes affect childhood growth and final adult size, the maternal genes have the main influence on birth weight. The classic horse-pony cross-breeding experiments by Walton and Hammond demonstrated the important role of the mother.³¹ Foals of the maternal horse and paternal

pony were significantly larger than foals of the maternal pony and paternal horse, and foals of each cross were comparable in size to foals of the pure maternal breed. These results clearly demonstrated the widely held thesis of a maternally related constraint on fetal growth.

Similar conclusions of maternal constraint to growth have been reached based on family studies in humans. Low and high birth weights recur in families with seemingly otherwise normal pregnancies. Sisters of women with IUGR babies tend to have IUGR babies, a trend that is not seen in their brothers' babies.³¹ Mothers who were themselves born with IUGR more frequently give birth to infants who are also growth restricted.^{32,33} Although the maternal phenotypic expression—particularly maternal height—may affect fetal growth, the evidence for such an influence is not convincing. Social deprivation has also been associated with IUGR, a finding not explained by known physiologic or pathologic factors.³⁴

The one definite paternal influence on fetal growth and size at birth is the contribution of a Y chromosome rather than an X chromosome. The male fetus grows more quickly than the female fetus and weighs approximately 150 to 200 g more than the female at birth.³⁵ There is also a suggestion that paternal size at birth can influence fetal growth, with birth weights potentially increased by 100 to 175 g.³⁶ Also, the greater the antigenic dissimilarity between the parents, the larger the fetus.

Specific maternal genotypic disorders can cause FGR, one example being phenylketonuria.³⁷ Infants born to homozygously affected mothers are almost always growth restricted, but whether the reason is an abnormal amount of metabolite crossing from mother to fetus or an inherent problem in the fetus is unknown.

There is a significant association between FGR and congenital malformations (see later discussion). Such abnormalities can be caused by established chromosomal disorders or by dysmorphic syndromes, such as various forms of dwarfism. Some of these malformations are the expression of a specific gene abnormality with a known inheritance pattern, whereas others are only presumed to be the result of a gene mutation or an adverse environmental influence.

Although in some reports only 2% to 5% of FGR infants have a chromosomal abnormality, the incidence rises to 20% if growth restriction is diagnosed in the first half of pregnancy or if mental retardation is present.³⁸ Birth weights in infants with trisomy 13, trisomy 18, or trisomy 21 are lower than normal,^{39,40} with the decrease in birth weight being less pronounced in those with trisomy 21. The frequency distribution of birth weights in infants with trisomy 21 is shifted to the left of the normal curve after 34 weeks' gestation, resulting in gestational ages 1 to 1.5 weeks less than normal, and birth weights and lengths are less than in control infants from 34 weeks until term. This effect is more marked after 37 weeks' gestation, but birth weights are still only approximately 1 standard deviation from mean weight. Birth weights in translocation trisomy 21 are comparable to those in primary trisomy 21. Newborns with other autosomal abnormalities, such as deletions (chromosomes 4, 5, 13, and 18) and ring chromosome structure alterations, also have had impaired fetal growth.

Although abnormalities of the female (X) and male (Y) sex chromosomes are frequently lethal (80% to 95% result in first-trimester spontaneous abortions), they could be a cause of growth restriction in a newborn.^{18,28} Infants with XO sex chromosomes have a lower mean birth weight than control infants

(approximately 85% of normal for gestational age) and are approximately 1.5 cm shorter at birth. Mosaics of 45,X and 46,XX cells are affected to a lesser degree. Although a paucity of reports prevents definite conclusions, it appears that the repressive effect on fetal growth is increased with the addition of X chromosomes, each of which results in a 200- to 300-g reduction in birth weight.⁴¹

FGR is associated with numerous other dysmorphic syndromes, particularly those causing abnormal brain development.

The overall contribution that chromosomal and other genetic disorders make to human IUGR is estimated to be 5% to 20%. Approximately 20% of fetuses with early-onset FGR have chromosomal abnormalities.

CONGENITAL ANOMALIES

In a study of more than 13,000 anomalous infants, 22% had FGR.⁴² Newborns with cardiac malformations are frequently of low birth weight and length for gestation, with the possible exception of those with tetralogy of Fallot and transposition of the great vessels. The subnormal size of many infants with cardiac anomalies (as low as 50% to 80% of normal weight in those with septal defects) is associated with a subnormal number of parenchymal cells in organs such as the spleen, liver, kidneys, adrenals, and pancreas.⁴³ The anencephalic fetus is also usually growth restricted.

Although infants with a single umbilical artery may be of lower birth weight, this is not generally a result of FGR.⁴⁴ Abnormal umbilical cord insertions into the placenta are also occasionally associated with poor fetal growth.⁴⁵

INFECTION

Infectious disease is known to cause FGR, but the number of organisms having this effect is poorly defined, and the extent of the growth restriction can be variable. There is sufficient evidence for a causal relationship between infectious disease and FGR for rubella and cytomegalovirus, and there is evidence for a possible relationship with varicella,⁴⁶ severe herpes zoster, and human immunodeficiency virus (HIV), although in the last case there may be complications related to other problems associated with HIV infection (see Chapter 51). With rubella infection, the incidence of FGR may be as high as 60%, and infected cells remain viable for many months.⁴⁷

Although there are no bacterial infections known to cause FGR, histologic chorioamnionitis is strongly associated with symmetric FGR between 28 and 36 weeks, and with asymmetric FGR after 36 weeks' gestation.⁴⁸

Although the incidence of maternal infections with various organisms may be as high as 15%, the incidence of congenital infections is estimated to be no more than 5%. It is believed that infectious disease can account for no more than 5% to 10% of human growth restriction.

MULTIPLE GESTATION

It has long been recognized that multiple pregnancies are associated with a progressive decrease in fetal and placental weight as the number of offspring increases in humans and in various animal species (see Chapters 4 and 38).^{49,50} In both singleton and twin gestations, there is a relationship between total fetal mass and maternal mass. The increase in fetal weight in

singleton gestations is linear from approximately 22 to 24 weeks until approximately 32 to 36 weeks' gestation.^{4,8} During the last weeks of pregnancy, the increase in fetal weight declines, actually becoming negative after 42 weeks in some cases.

If nutrition is adequate in the neonatal period, the slope of the increase in neonatal weight parallels the increase in fetal weight seen before 34 to 38 weeks. The decline in fetal weight increase occurs when the total fetal mass approximates 3000 to 3500 g for either singleton or twin gestations. When growth rate is expressed incrementally, the weekly gain in singletons peaks at approximately 230 to 285 g/wk between 32 and 34 weeks' gestation (see Fig. 47-3). In individual twin fetuses, the incremental weekly gain peaks at 160 to 170 g between 28 and 32 weeks' gestation.⁸ However, studies in triplets have indicated that the growth of individual triplets may continue in a linear fashion well beyond a total combined weight of 3500 g.⁵¹ Others have reported that before 35 weeks' gestation, triplets grow at about the 30th percentile for singletons, and by 38 weeks the average weight of each triplet is at the 10th percentile.⁵² Significant birth weight discordance also occurs if there is unequal sharing of the placental mass.⁵³ If multifetal reduction is performed, there is an increase in FGR in the surviving fetuses.⁵⁴

The decrease in weight of twin fetuses, frequently with mild IUGR, is usually the result of decreased cell size; the exception is severe IUGR associated with monozygosity and vascular anastomoses, wherein cell number also may be decreased.⁵⁵ These changes in twins are similar to those seen in IUGR secondary to poor uterine perfusion or maternal malnutrition. Twins with mild IUGR have an acceleration of growth after birth, so that their weight equals the median weight of singletons by 1 year of age. This observation supports the thesis that the cause of poor fetal growth in twin gestations is an inability of the environment to meet fetal needs rather than an inherent diminished growth capacity of the twin fetus. The example of twin fetuses supports the thesis derived from normal singleton pregnancies that the human fetus is seldom able to express its full potential for growth.

Many components of the environment can limit fetal growth (see later discussions). Twin-to-twin transfusion secondary to vascular anastomoses in monochorionic monozygotic twins frequently results in growth restriction of one twin, usually the donor (see Chapter 38). Maternal complications associated with FGR occur more frequently with twins, and the incidence of congenital anomalies is almost twice that of singletons, primarily among monozygotic twin gestations. The incidence of FGR in twins is 15% to 25%;^{7,56} because the incidence of spontaneous multiple gestations approximates 1%, these pregnancies probably account for fewer than 3% of all cases of human FGR. However, the actual incidence could be closer to 5% because of the increase in multiple gestations secondary to assisted reproductive techniques.

INADEQUATE MATERNAL NUTRITION

Numerous animal studies have demonstrated that undernutrition of the mother caused by protein or caloric restriction can affect fetal growth adversely. However, profound alterations in nutrition are required to have a significant effect in human pregnancies.

The important effects of maternal nutrition on fetal growth and birth weight were demonstrated by studies in Russia and Holland among women who suffered inadequate nutrition

during World War II. The population in Leningrad underwent a prolonged siege, during which both pre-conception nutritional status and gestational nutrition were poor, and birth weights were reduced by 400 to 600 g.⁵⁷ In Holland, a 6-month famine created conditions that permitted evaluation of the effect of malnutrition during each of the trimesters of pregnancy in a group of women previously well nourished.⁵⁸ Birth weights declined by approximately 10%, and placental weights by 15%, only when undernutrition occurred in the third trimester (daily caloric intake <1500 kcal). The difference in severity of FGR in these two populations suggests the importance of pre-pregnancy nutritional status, an idea that has been substantiated elsewhere.^{20,59} In addition, animal studies indicate that fetal growth, metabolic and endocrine function, and placental status and function in late pregnancy are significantly altered by peri-conception maternal nutritional status, an effect independent of fetal size.⁶⁰ Weight gain in the second trimester appears to be particularly important. Adequate maternal weight gain by 24 to 28 weeks in multiple pregnancies correlates positively with good fetal growth.⁶¹

It is still unclear whether it is generalized caloric intake reduction, specific substrate limitation (e.g., protein, key minerals), or both that is important in producing FGR (see Chapter 10). Glucose uptake by the fetus is critical, because there is the suggestion that little gluconeogenesis occurs in the normal fetus. In the FGR fetus, the maternal-fetal glucose concentration difference is increased as a function of the severity of the growth restriction,⁶² facilitating glucose transfer across the small placenta. Decreases in zinc content of peripheral blood leukocytes also correlate positively with FGR,⁶³ and serum zinc concentrations of less than 60 µg/dL in the third trimester are associated with a fivefold increase in the incidence of low birth weight.⁶⁴ Similarly, an association between low serum folate levels and FGR has been reported.⁶⁵ Although there have been numerous studies on supplementation, there is no convincing evidence that high protein intake or caloric supplementation has a beneficial effect on fetal weight. In addition, if a fetus is receiving decreased oxygen delivery as a result of decreased uteroplacental perfusion and has adapted by slowing metabolism and growth, it may not be advisable to increase substrate delivery. This important issue remains unresolved.

Another maternal nutrient that is important to fetal growth is oxygen. It is probably a primary determinant of fetal growth. FGR infants have a decrease in the partial pressure of oxygen and decreased oxygen saturation values in the umbilical vein and artery.⁶⁶ The median birth weight of infants of women living more than 10,000 feet above sea level is approximately 250 g less than that of infants of women living at sea level.⁶⁷ Pregnancies complicated by maternal cyanotic heart disease usually result in IUGR, but it is unclear whether abnormal maternal hemodynamics or the reduction in oxygen saturation (by approximately 40% in the umbilical vein) accounts for the poor fetal growth.⁶⁸ The association between hemoglobinopathies and IUGR could be due to decreased blood viscosity or decreased fetal oxygenation. Patients with chronic pulmonary disease (e.g., poorly controlled asthma, cystic fibrosis, bronchiectasis) and those with severe kyphoscoliosis may be at increased risk of FGR.

ENVIRONMENTAL TOXINS

Maternal cigarette smoking decreases birth weight by approximately 135 to 300 g; the fetus is symmetrically smaller.^{69,70} If

smoking is stopped before the third trimester, its adverse effect on birth weight is reduced.⁷¹ More disturbing is the reported dose-response relationship between maternal smoking and a smaller infant head size, specifically a circumference of less than 32 cm, as well as a head circumference more than 2 standard deviations below that expected for gestational age.⁷² The reason why not all women who smoke have FGR infants could be a function of maternal genetic susceptibility.⁷³

Reduction in birth weight also occurs with maternal alcohol ingestion of as little as one to two drinks per day.⁷⁴ Cocaine use in pregnancy similarly decreases birth weight, but there is also a reduction of head circumference that is more pronounced than the reduction in birth weight.⁷⁵ Use of other drugs, such as the anticonvulsants phenytoin and trimethadione, warfarin, and heroin, has also been implicated in FGR.

PLACENTAL FACTORS (THE MATERNAL-FETAL INTERFACE)

Although placental size does not necessarily equate with function, human placental function cannot be properly evaluated clinically, and this has led to studies of the interrelationships among size, morphometry, and clinical outcome. In general, birth weight increases with increasing placental weight in both animals and humans. FGR without other anomalies is usually associated with a small placenta. Chromosomally normal FGR newborns have a 24% smaller placenta for gestational age.⁷⁵ A small placenta is not always associated with an IUGR newborn, but a large infant from an otherwise normal pregnancy does not have a small placenta. Placental weight increases throughout normal gestation; with FGR, the placental weight plateaus after 36 weeks or earlier, and the placenta (after being trimmed of the membranes and cord) weighs less than 350 g.⁷⁶ As normal gestation advances, there is a greater increase in fetal weight than in placental weight, so that the ratio of fetal to placental weight increases in LGA, AGA, and SGA infants during the last half of gestation. In all three categories, when the fetal-placental weight ratio is greater than 10, there is an increased incidence of depressed newborns; this suggests that it is not only the FGR fetus that can outgrow the capacity of the placenta to bring about adequate transfer of necessary nutrients.⁷⁷

Adequate trophoblastic invasion of the uterine decidual bed, and the resultant alteration in uterine blood flow, is a vital necessity, not only for the initial establishment and adherence of the pregnancy but for also the adequate supply of nutrients to the fetus. The trophoblasts invade the decidua and myometrium to anchor the placenta, and a subpopulation of cytotrophoblasts invades the uterine blood vessels at the implantation site, resulting in extensive remodeling of the vessels.⁷⁷⁻⁸⁰ There is a replacement of endothelium and uterine smooth muscle cells that leads to a reduction in uterine arterial resistance and an increase in uteroplacental perfusion. Apoptosis plays an integral role in these vascular changes. It has also been suggested that the cytotrophoblast initiates lymphangiogenesis in the pregnant uterus; this is normally lacking in the nonpregnant state.

A number of reports have revealed that in many cases of FGR, particularly in early FGR, the depth of invasion by the cytotrophoblasts is shallow and the endovascular invasion rudimentary; these findings confirmed the early classic work of Brosens and colleagues,⁸¹ who described reduced trophoblastic invasion and decreased pregnancy-associated alterations in the placental bed of FGR pregnancies. The detailed morphologic

studies of Aherne and Dunnill⁸² also demonstrated that the mean surface area and, more importantly, the capillary surface area were reduced in the placentas of growth-restricted newborns. Apoptosis at the implantation site is increased with IUGR, and this has been suggested to be the mechanism limiting endovascular invasion.^{83,84} The levels of placental vascular endothelial growth factor and placental growth factor were reduced, and antagonists were increased, in studies of early FGR confirmed by Doppler imaging.⁸⁵ In summary, early abnormal implantation plays a key role in FGR, but the exact controlling mechanisms behind the impaired placentation remain to be delineated. There is considerable basic research interest in the role of angiogenic factors, implantation, and pregnancy disorders such as IUGR. This topic has been reviewed by Burton and colleagues.⁸⁶

The terminal villi are maldeveloped in FGR pregnancies when absent end-diastolic flow is demonstrated, indicating that these morphologic changes are associated with increased vascular impedance.⁸⁷ When end-diastolic flow is absent, there are more occlusive lesions of the intraplacental vasculature than when end-diastolic flow is present.⁸⁸ Information from cordocentesis studies has revealed fetal hypoxemia, hypercapnia, acidosis, and hypoglycemia in severe FGR.^{89,90} There is also a decrease in α -aminonitrogen, particularly branched-chain amino acids, in the plasma of the FGR fetus.⁹¹

Abnormal insertions of the cord, placental hemangiomas, abruptio placentae, and placenta previa are also associated with IUGR.⁹²⁻⁹⁴ There has been controversy in the past as to whether the presence of a velamentous cord insertion influences fetal growth. In a recent large cohort study of more than 529,000 singleton pregnancies, velamentous insertion was associated with an increase in the finding of SGA infants in 17% compared to 10.2% ($P = .001$) in controls with normal cord insertion.⁹⁵

MATERNAL VASCULAR DISEASE

Substantial evidence from experimental animal studies suggests that alterations in uteroplacental perfusion affect the growth and status of the placenta as well as the fetus. Ligation of the uterine artery of one horn of the pregnant rat results in IUGR of those fetuses nearest the constriction, and fetal and placental weights in guinea pigs, mice, and rabbits are lowest in the middle of each uterine horn, where arterial perfusion is lowest. Repetitive embolization of the uterine vascular bed during the last quarter of gestation in sheep gives rise to localized hyalinization and fibrinoid changes in the placenta⁹⁶ and results in a 40% reduction in placental weight and alterations in organ growth patterns similar to those observed in FGR fetuses from pregnancies complicated by maternal hypertensive disease. In addition, umbilical blood flow is reduced and fetal oxidative metabolism is decreased.^{97,98}

It has been strongly suggested in various studies that uteroplacental blood flow is decreased in pregnancies complicated by maternal hypertensive disease. Defective trophoblastic invasion of the uterine vascular bed results in relatively intact musculoelastic vessels that resist the normal decrease in uterine vascular resistance.⁹⁹ Clearance of radioactive tracers from the intervillous space is reduced in preeclamptic patients.^{100,101} Because maternal body mass and plasma volume are correlated, reduced plasma volume or prevention of plasma volume expansion could lead to decreased cardiac output and uterine perfusion and a resultant decrease in fetal growth.^{96,102} Alternatively, it may

be that abnormal placentation comes first. The current role of angiogenic factors in normal and abnormal trophoblastic invasion has been reviewed elsewhere.^{86,103}

The importance of normal trophoblastic invasion leading to normal maternal cardiovascular changes has been indicated by central maternal cardiovascular studies. IUGR below the 3rd percentile at 25 to 37 weeks of gestation is associated with reduced maternal systolic function, increased vascular resistance, and probable lack of volume expansion in otherwise normotensive patients.¹⁰⁴

Uteroplacental flow velocity waveform studies, using Doppler methods in pregnancies complicated by hypertension, have shown a higher incidence of IUGR in pregnancies in which abnormal waveforms were recorded. These abnormal waveforms are thought to reflect abnormally increased resistance to blood flow.^{105,106} High-resistance hypertension is associated with a marked decrease in fetal weight compared with low-resistance hypertension.¹⁰⁷ Increasing uteroplacental resistance, recorded with this methodology, has been positively correlated with fetal hypoxemia as determined by cordocentesis in FGR fetuses.⁸⁹

As discussed in Chapter 53, there has been conflicting evidence as to whether the congenital thrombophilias contribute to the clinical development of FGR, although the preponderance of evidence shows a lack of association.¹⁰⁸⁻¹¹¹

There are only fragmentary suggestions relating abnormal anatomic uterine vascular anatomy and FGR. FGR may occur at a higher frequency if the pregnancy is in a unicornuate uterus; vascular abnormalities are likely but not certain in such cases.¹¹² Patients with two (rather than the usual one) ascending uterine arteries on each side of the uterus also have a higher rate of FGR.¹¹³ However, pregnancy after bilateral ligation of the internal iliac and ovarian arteries, or after embolization of leiomyomata, is not associated with FGR.^{114,115}

Because exercise can affect uterine perfusion, this subject has been studied extensively. A moderate regimen of weight-bearing exercise in early pregnancy probably enhances fetal growth.¹¹⁶ However, high levels of exercise (>50% of pre-pregnancy levels) in middle and late pregnancy result mainly in a symmetric reduction in fetal growth and neonatal fat mass.¹¹⁷ In assessing levels of aerobic activity, neonates born to women in the highest quartile weighed 600 g less than those in the lowest quartile, an effect seen mainly in taller women.¹¹⁸

Clinical maternal vascular disease and the presumed decrease in uteroplacental perfusion can account for at least 25% to 30% of FGR. Undiagnosed decreased perfusion could also be the cause of FGR in an otherwise normal pregnancy, such as with recurrent idiopathic FGR. A history of a previous low-birth-weight infant is significantly associated with the subsequent birth of an infant with decreased weight, decreased ponderal index, and decreased head circumference.¹¹⁹ This finding of symmetric growth restriction is in contrast to the asymmetric FGR usually seen with maternal vascular disease.

Vascular disease becomes more prevalent with advancing age. In one large study, after controlling for confounding variables, the incidence of SGA births was increased more in nulliparous patients than in multiparous patients older than 30 years of age.¹²⁰

MATERNAL AND FETAL HORMONES

In general, there is limited transfer of the various circulating maternal hormones into the fetal compartments.

Although the effects of hypothyroidism or hyperthyroidism on fetal size are not striking, studies in subhuman primates indicate that, when the mother and fetus are athyroid, there is retarded osseous development and reduced protein synthesis in the fetal brain.¹²¹

Maternal diabetes without vascular disease is frequently associated with excessive fetal size (see Chapter 59). Although insulin does not cross the placenta, fetal hyperinsulinemia as well as hyperplasia of the pancreatic islet cells is seen frequently with maternal diabetes. These changes are thought to occur as a result of maternal hyperglycemia, which leads to fetal hyperglycemia and an increased response of the fetal pancreas. Fetal hypoinsulinemia produced experimentally in the rhesus monkey results in FGR; rarely, infants have been born with severe IUGR and requiring insulin treatment at birth, suggesting hypoinsulinemia in utero.^{122,123} If nutrient transfer becomes limited owing to placental disease secondary to maternal vascular disease, the fetus of the diabetic mother can sustain FGR.

Several small polypeptides with *in vitro* growth-promoting activity have been purified (e.g., insulin-like growth factor 1 [IGF-1], IGF-2), but the exact roles of these peptides and their binding proteins as fetal growth factors and their potential relationship to FGR are not well understood.

Leptin (from the Greek *leptos*, "thin") is a polypeptide hormone discovered in 1994. It has been shown to moderate feeding behavior and adipose stores. It is produced predominantly by adipocytes but can also be produced by the placenta, because neonatal levels fall dramatically after birth.¹²⁴ Reported concentrations in FGR have varied, and the exact role that this hormone plays in fetal growth remains to be clarified.

Diagnosis of Fetal Growth Restriction

DETERMINATION OF CAUSE

An attempt should be made to determine the cause of fetal aberrant growth before delivery in order to provide appropriate counseling, perform ultrasonographic evaluation to delineate fetal anatomy and monitor growth velocity, and obtain neonatal consultation.

The various disorders associated with suboptimal fetal growth have been addressed earlier in this chapter and are summarized in Box 47-1. Often, the cause is readily apparent. Among patients with significant chronic hypertensive disease, those who take prescribed medications known to be associated with prenatal growth deficiency, and those whose fetuses have congenital or chromosomal abnormalities, the diagnosis is easily established and management plans can be made. At times, however, the causal factors can be elusive. For example, growth restriction associated with preeclampsia may antedate the appearance of hypertension or proteinuria by several weeks. In many instances, a careful history, maternal examination, and ultrasound evaluation reveal the cause.

HISTORY AND PHYSICAL EXAMINATION

Clinical diagnosis of IUGR by physical examination alone is inaccurate; often, the diagnosis is not made until after delivery. Most clinical studies demonstrate that, with the use of physical examination alone, the diagnosis of IUGR is missed or incorrectly made almost half the time. Techniques such as measurement of the symphysis-fundal height are helpful in screening

Box 47-1 DISORDERS AND OTHER FACTORS ASSOCIATED WITH INTRAUTERINE GROWTH RESTRICTION*

MATERNAL FACTORS

- Hypertensive disease, chronic or preeclampsia
- Renal disease
- Severe nutritional deficiencies (e.g., inflammatory bowel disease, markedly inadequate pregnancy weight gain in the underweight woman, malnutrition)
- Pregnancy at high altitude
- Specific prescribed medications (e.g., antiepileptics)
- Smoking, alcohol use, illicit drug use

FETAL FACTORS

- Multiple gestations
- Placental abnormalities
- Infections
- Aneuploidy or structural abnormalities

*Growth is also strongly influenced by maternal pre-pregnancy weight and by ethnicity, which must be considered when evaluating overall growth (by use of customized versus population-based growth curves).

for abnormal fetal growth and documenting continued growth if they are performed repeatedly by the same observer, but they are not sensitive enough for accurate detection of most infants with growth restriction.^{125,126}

Despite the inaccuracy of such indicators, fetal assessment and specific aspects of the patient's risk factors can increase the clinician's index of suspicion about suboptimal fetal growth, without which more definitive laboratory investigation might not be considered. As discussed earlier, maternal disease entities such as hypertension, in particular severe preeclampsia and chronic hypertension with superimposed preeclampsia, carry a high incidence of IUGR. The diagnosis of a multiple gestation suggests the likelihood of diminished fetal growth relative to gestational age, particularly later in pregnancy and with monochorionic placentation. Additional maternal risk factors include documented rubella or cytomegalovirus infection, heavy smoking, heroin or cocaine addiction, alcoholism, and poor nutritional status both before conception and during pregnancy combined with inadequate weight gain during pregnancy.

ULTRASONOGRAPHY

Currently, ultrasonographic evaluation of the fetus is the preferred and accepted modality for the diagnosis of inadequate fetal growth. It offers the advantages of reasonably precise estimations of fetal weight, determination of interval fetal growth velocity, and measurement of several fetal dimensions to describe the pattern of growth abnormality. Use of these ultrasound measurements requires accurate knowledge of gestational age. Most women receiving early prenatal care undergo a first-trimester ultrasound study (crown-rump length), which helps to accurately establish gestational age.

Measurements of biparietal diameter, head circumference, abdominal circumferences, and femur length allow the clinician to use accepted formulas to estimate fetal weight and to determine whether a fetal growth aberration represents an asymmetric, symmetric, or mixed pattern (Fig. 47-5).¹²⁷ As discussed

previously, intrinsic fetal insults occurring early in pregnancy (e.g., infection, exposure to certain drugs or other chemical agents, chromosomal abnormalities, other congenital malformations) are likely to affect fetal growth at a time of development when cell division is the predominant mechanism of growth. Consequently, musculoskeletal dimensions and organ size may be adversely affected, and a symmetric pattern of aberrant growth is observed. Given this set of circumstances, one might expect to find that the femur length and head circumference are small for a given gestational age, as are the abdominal circumference and overall fetal weight, all of which are characterized as *symmetric* FGR. Symmetric FGR accounts for approximately 20% to 30% of all growth-restricted fetuses.

At the other end of the spectrum, an extrinsic insult occurring later in pregnancy, usually characterized by inadequate fetal nutrition due to placental insufficiency, is more likely to result in *asymmetric* growth restriction. In this type, femur length and head circumference are spared, but abdominal circumference is decreased because of subnormal hepatic growth, and there is a paucity of subcutaneous fat. The most common disorders that limit the availability of fetal substrates for metabolism are the hypertensive complications of pregnancy, which are associated with decreased uteroplacental perfusion, and placental infarcts, which limit the trophoblastic surface area available for substrate transfer. In fact, a fall-off in the interval growth of the abdominal circumference is one of the earliest findings in extrinsic or asymmetric FGR^{128,129}; conversely, the finding of an abdominal circumference in the normal range for gestational age markedly decreases the likelihood of FGR. Frequently, these patterns of growth abnormality merge, particularly after long-standing fetal nutritional deprivation.

Distinguishing between symmetric and asymmetric FGR is also of considerable clinical significance and may provide useful information for both diagnostic and counseling purposes. For example, a diagnosis of symmetric FGR in early pregnancy suggests a poor prognosis when the diagnostic possibilities are considered (e.g., fetal infection, aneuploidy, malformations); conversely, asymmetric FGR observed in the third trimester, particularly if it is associated with maternal hypertension or placental dysfunction, usually imparts a more favorable prognosis with careful fetal evaluation, appropriate and preferably delayed delivery timing, and skillful neonatal management.

Considerable attention has been directed at early ultrasound findings that may provide for the early prediction of FGR. In a study of 976 women whose pregnancies were the product of assisted reproductive technologies, the risk of delivering a growth-restricted fetus decreased as a function of increasing crown-rump length in the first trimester.¹³⁰ This confirmed previous findings suggesting that suboptimal growth in the first trimester is associated with IUGR.¹³¹

Efforts have also been made to correlate Doppler findings in the uterine artery with subsequent pregnancy complications, including FGR. Utilizing transvaginal color Doppler at 23 weeks' gestation, Papageorghiou and colleagues observed that increases in the uterine artery pulsatility index and "notching" were associated with subsequent development of IUGR, although the predictive value was low.¹³² In a more recent study of uterine artery pulsatility index at 11 to 14 weeks' gestation, a value greater than the 95th percentile predicted FGR with accuracy in 23% of the cases, and with increased sensitivity if the maternal serum concentration of plasma-associated pregnancy protein A (PAPP-A) was low. However, this parameter

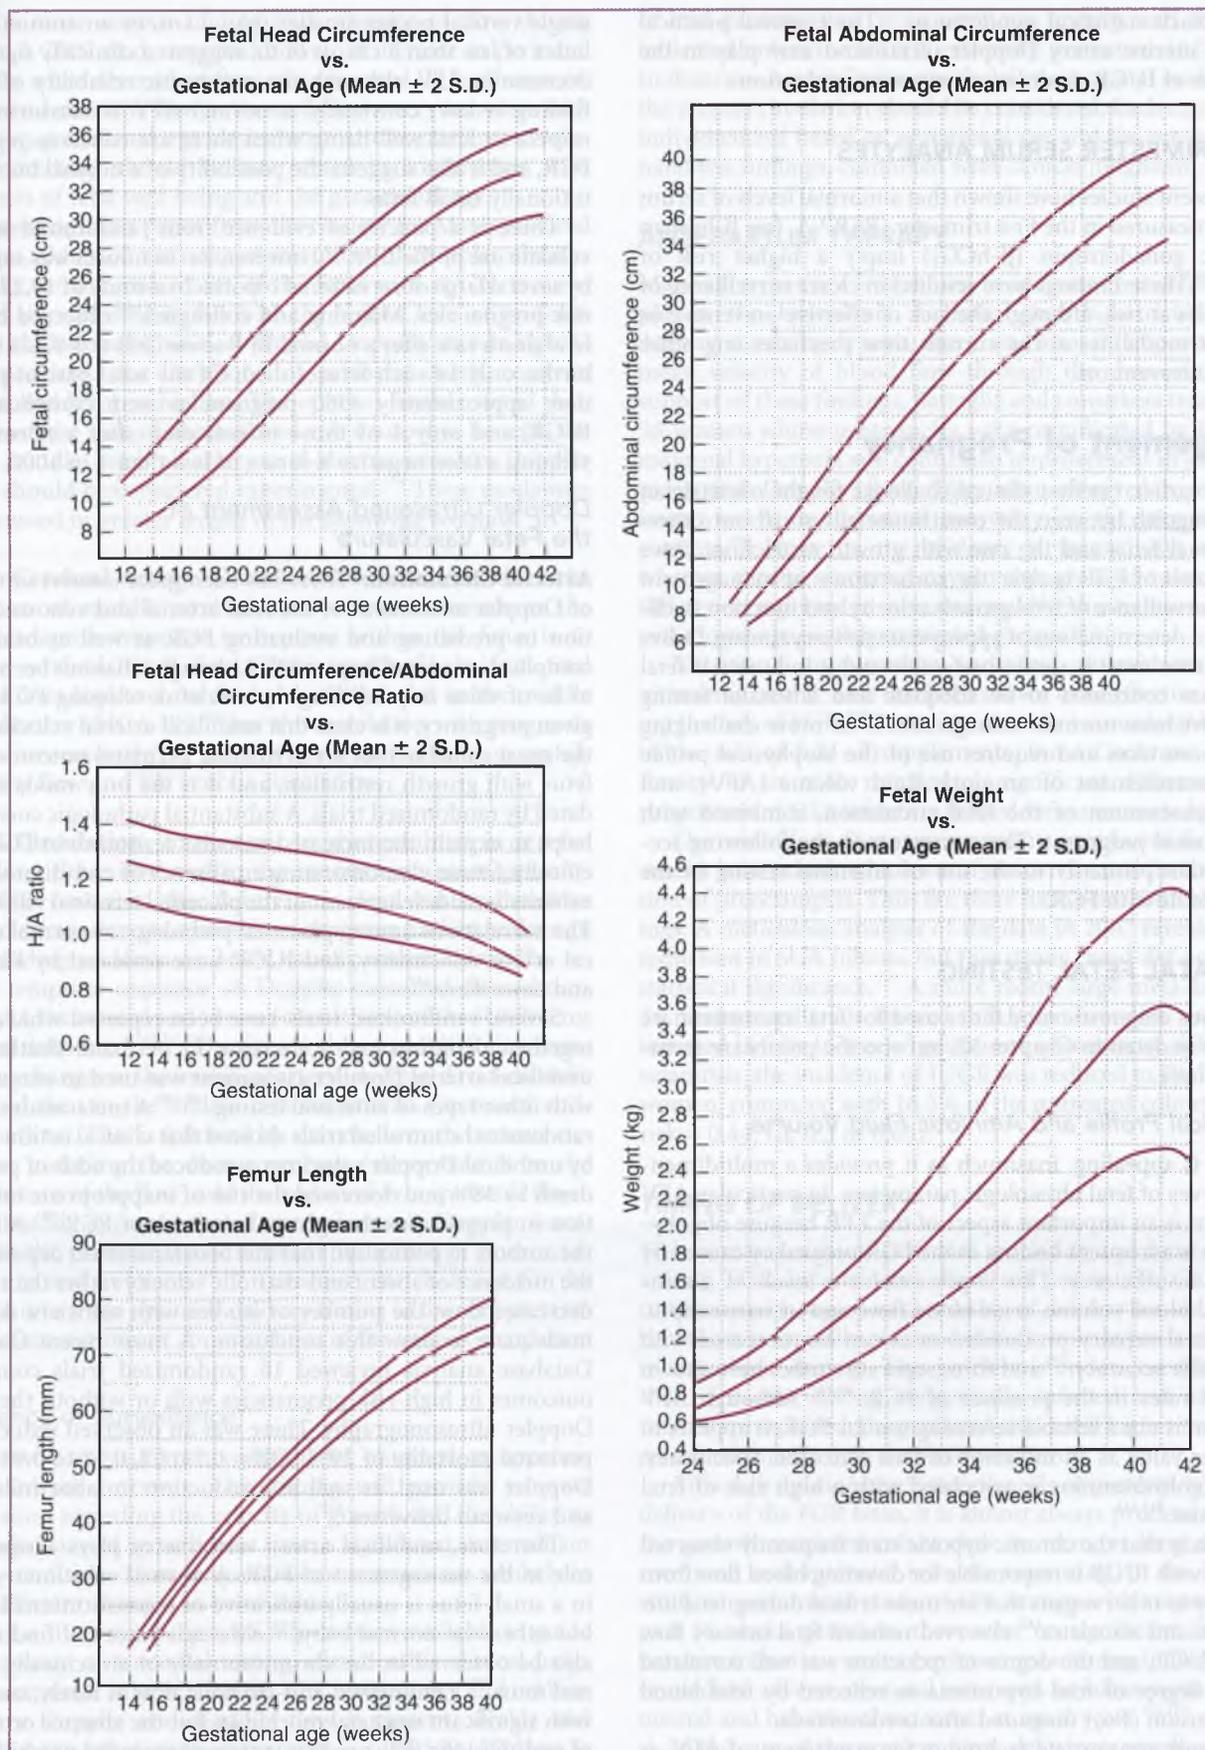

Figure 47-5 Composite of fetal body measurements used for serial evaluations of fetal growth. S.D., standard deviation.

did not reach statistical significance.¹³³ The eventual practical role that uterine artery Doppler ultrasound may play in the prediction of IUGR awaits more extensive evaluation.

FIRST-TRIMESTER SERUM ANALYTES

Several recent studies have shown that abnormal levels of serum analytes measured in the first trimester (PAPP-A, free β -human chorionic gonadotropin [β -hCG]) imply a higher risk of FGR.¹³⁴⁻¹³⁸ These findings have resulted in closer surveillance of pregnancies at risk, although the lack of effective preventive or treatment modalities at the current time precludes any other types of intervention.

Management of Pregnancy

As noted earlier, the first clinical challenge for the obstetrician is to distinguish between the constitutionally small but otherwise normal fetus and the one with growth restriction. Once the diagnosis of FGR is clear, the cornerstones of management include surveillance of fetal growth velocity and function (well-being) and determination of appropriate delivery timing. Delivery at or near term is always preferable and is indicated if fetal growth has continued to be adequate and antenatal testing results have been normal. Management is far more challenging remote from term and requires use of the biophysical profile (BPP), measurement of amniotic fluid volume (AFV), and Doppler assessment of the fetal circulation, combined with sound clinical judgment. The comments in the following sections pertain primarily to the use of antenatal testing in the preterm fetus with FGR.

ANTENATAL FETAL TESTING

The various diagnostic modalities used for fetal assessment are discussed in detail in Chapter 32, but specific points are reemphasized here.

Biophysical Profile and Amniotic Fluid Volume

The BPP is appealing, inasmuch as it provides a multidimensional survey of fetal physiologic parameters. In particular, AFV assessment is an important aspect of the BPP, because oligohydramnios is a frequent finding in the FGR pregnancy caused by placental insufficiency. This is presumably a result of diminished fetal blood volume, renal blood flow, and urinary output. Human fetal urinary production rates can be measured with considerable accuracy,¹³⁹ and three separate studies have shown decreased rates in the presence of FGR.¹⁴⁰⁻¹⁴² Although AFV assessment is not a reliable screening test for FGR, it appears to have some value as an indicator of fetal outcome. Specifically, severe oligohydramnios is associated with a high risk of fetal compromise.^{143,144}

It is likely that the chronic hypoxic state frequently observed in fetuses with IUGR is responsible for diverting blood flow from the kidney to other organs that are more critical during fetal life. Nicolaides and associates¹⁴² observed reduced fetal urinary flow rates in IUGR, and the degree of reduction was well correlated with the degree of fetal hypoxemia as reflected by fetal blood oxygen tension (P_{O_2}) measured after cordocentesis.

The most appropriate technique for assessment of AFV, as well as the arguments for and against each technique, are addressed in Chapter 32. It is reasonable to conclude that a

single vertical pocket smaller than 2 cm, or an amniotic fluid index of less than 5 cm, or both, suggests a clinically significant decrease in AFV, although the prognostic reliability of such a finding is low; conversely, a normal AFV is reassuring with respect to fetal well-being when there are concerns regarding FGR, and it also suggests the possibility of a normal but constitutionally small fetus.

There is a paucity of evidence from randomized trials to validate use of the BPP.¹⁴⁵ However, its usefulness was suggested by several large observational reports. In a study of 19,221 high-risk pregnancies, Manning and colleagues¹⁴⁶ observed that the fetal death rate after a normal BPP score (≥ 8) was 0.726 in 1000 births; only 14 such fetuses died. Of the total patient population, approximately 4380 pregnancies were complicated by IUGR, and only 4 of those infants died after a normal test, yielding a false-negative test rate of less than 1 in 1000.

Doppler Ultrasound Assessment of the Fetal Vasculature

Arterial Circulation. There has been great interest in the role of Doppler assessment of the fetal arterial and venous circulation in predicting and evaluating FGR as well as other fetal complications (see Chapter 32). Although it has not been shown to be of value in predicting the risk of developing FGR in any given pregnancy, it is clear that umbilical arterial velocimetry is the most valuable tool for predicting perinatal outcome in the fetus with growth restriction, and it is the only modality validated by randomized trials. A substantial pathologic correlation helps to explain the increased vascular resistance in FGR. Specifically, fetuses demonstrating an absence of end-diastolic flow exhibited maldevelopment of the placental terminal villous tree. The correlations among placental pathology, abnormal umbilical artery velocimetry, and IUGR were reviewed by Kingdom and coworkers.¹⁴⁷

Several randomized trials have been reported which, taken together, demonstrated a decrease in perinatal deaths when umbilical arterial Doppler assessment was used in conjunction with other types of antenatal testing.¹⁴⁸⁻¹⁵⁰ A meta-analysis of 12 randomized controlled trials showed that clinical action guided by umbilical Doppler velocimetry reduced the odds of perinatal death by 38% and decreased the risk of inappropriate intervention in pregnancies thought to be at risk of FGR.¹⁵¹ Although the authors hypothesized that this beneficial effect depended on the incidence of absent end-diastolic velocity rather than simply decreased flow, the number of studies with sufficient data was inadequate to draw this conclusion. A more recent Cochrane Database analysis reviewed 18 randomized trials comparing outcomes in high-risk pregnancies with or without the use of Doppler ultrasonography. There was an observed reduction in perinatal mortality of 29% (OR = 0.71; CI, 0.52 to 0.98) when Doppler was used, as well as a reduction in labor inductions and cesarean deliveries.¹⁵²

Therefore, umbilical artery velocimetry plays a significant role in the management of FGR. A normal velocimetry result in a small fetus is usually indicative of a constitutionally small but otherwise normal baby,¹⁵³ although a normal finding may also be observed in the chromosomally or structurally abnormal fetus.¹⁵⁴ Diminished end-diastolic flow is rarely associated with significant neonatal morbidity, but the absence or reversal of end-diastolic flow predicts increased perinatal morbidity and mortality and long-term poor neurologic outcome, compared with continuing diastolic flow.^{155,156} Not surprisingly, reversal of

flow is a more serious finding than absence of flow during diastole. A 2010 study reported a fivefold increase in perinatal mortality when reversal of flow was observed.¹⁵⁷ Furthermore, because end-diastolic flow in the umbilical artery increases with advancing gestational age under normal circumstances, velocimetry findings should be interpreted in conjunction with other tests of fetal well-being and the gestational age.

A recent opinion paper from the Society for Maternal-Fetal Medicine addressed the issue of the utility of Doppler ultrasonography for the assessment of the fetus with IUGR. It summarized all published studies with the highest level of evidence and concluded that umbilical arterial Doppler studies significantly decreased the likelihood of perinatal death, cesarean delivery, and labor induction. The opinion further stated that, because of the lack of randomized trials to prove benefit, the use of middle cerebral artery and ductus venosus Doppler studies should be considered experimental.¹⁵⁸ These modalities are discussed in greater length in the following sections.

Middle Cerebral Artery. There also has been interest in the evaluation of middle cerebral artery flow, inasmuch as the normal adaptive response to hypoxia within the fetus is to increase cerebral blood flow (“brain-sparing”). In fact, fetal hypoxia does lead to a reduced pulsatility index in the middle cerebral artery (MCA-PI),¹⁵⁹ but the correlation with prognosis is poor. Consequently, the focus of attention has been on umbilical artery flow and the venous circulation.

Venous Circulation. In contrast to abnormalities in arterial circulation, those observed in the venous circulation presumably reflect central cardiac failure. It is clear that an absent or reversed ductus venosus *a* wave is an ominous finding and a sign of impending acidemia or death, usually within 7 days.¹⁶⁰

The temporal sequence of Doppler-measured flow abnormalities in the arterial and venous circulations of the IUGR fetus has been delineated.^{161,162} The fetus with severe IUGR first demonstrates changes in the umbilical artery (decreased end-diastolic flow) and then in the middle cerebral arteries (increased end-diastolic flow). This is followed by alterations in the venous circulation, including the ductus venosus (abnormalities in the atrial portion of the flow) and the umbilical vein (pulsatile flow).

It is readily apparent that abnormal venous Doppler waveforms in the preterm IUGR fetus are indicative of poor acid-base status and outcome.^{163,164} Therefore, the challenge for the clinician is to try to optimize delivery timing in the very preterm fetus, before significant abnormalities in the venous circulation occur.

Frequency of Surveillance

Fetal growth measurements should be obtained at approximately 2-week intervals. This timing will provide accurate information regarding the velocity of growth and the ability to assess adequacy of growth over time, a significant determinant of fetal condition. More frequent measurements are unlikely to show sufficient changes to be of value.

Because there is a paucity of information available to guide the frequency of antenatal testing, considerable clinical judgment is required. In general, if the BPP is reassuring and umbilical artery Doppler end-diastolic flow is present, weekly and perhaps every-other-week evaluation is sufficient. If there is diminished flow in the umbilical artery, weekly testing should be complemented by a twice-weekly BPP. Absence or reversal

of end-diastolic flow is an ominous finding, and delivery is indicated unless the fetus is extremely premature (<32 weeks). In that case, hospitalization with daily testing and evaluation of the venous circulation should be considered. Each case must be individualized based on gestational age and the previous antenatal test findings, combined with clinical judgment.

ANTEPARTUM THERAPY

Maternal hyperoxia was shown to increase umbilical PO_2 and pH in the hypoxemic, acidotic, growth-restricted fetus.¹⁶⁵ Among surviving fetuses, there was also an improvement in mean velocity of blood flow through the thoracic aorta. In support of these findings, Battaglia and coworkers treated 17 of 36 women whose pregnancies were complicated by FGR with maternal hyperoxia and confirmed improvement in both blood gases and Doppler flow. They also observed a significant improvement in perinatal mortality in the oxygen-treated patients.¹⁶⁶ However, the evidence is inconclusive regarding whether chronic maternal oxygen therapy is of value, and any differences reported in outcome could be due to more advanced gestational age in oxygen-treated groups.¹⁶⁷

Nutritional supplements, including antioxidants such as vitamins C and E, have not been shown to be effective in reducing the risk of FGR.¹⁶⁸ There has also been considerable interest in the role of fish oil supplements, but a Cochrane Database Review of six trials revealed no significant difference in the proportion of SGA infants in treated versus untreated groups.¹⁶⁹

The role of low-dose aspirin remains controversial, and most studies have examined subsets of women treated for the prevention of preeclampsia. Thus far, there have been conflicting findings. A meticulous analysis of the data in 2007 revealed a 10% reduction in SGA infants, but this strong trend did not achieve statistical significance.¹⁷⁰ A more recent large meta-analysis of 34 randomized trials showed that when low-dose aspirin was initiated before 16 weeks' gestation in women at risk for preeclampsia, the incidence of IUGR was reduced to 7% in treated women, compared with 16.3% in the untreated cohort (relative risk = 0.44; CI, 0.3 to 0.65).¹⁷¹

TIMING OF DELIVERY

The increased risks of perinatal morbidity and mortality rates among FGR infants were discussed previously. Controversy continues with regard to the timing of delivery for such infants, because it is logically assumed that chronic hypoxia may result in neurologic damage. This problem is underscored by the fact that, if deaths among congenitally infected and anomalous infants are excluded, the perinatal risk is still higher for growth-restricted infants than for AGA newborns.

Although opinions vary as to the role of preterm versus term delivery of the FGR fetus, it is almost always prudent to deliver the growth-restricted infant close to term, as long as growth continues and antenatal tests are reassuring. In the DIGITAT study, a randomized study of 650 women with suspected FGR past 36 weeks' gestation, there were no significant differences between induction versus expectant monitoring in frequency of immediate adverse neonatal outcomes or subsequent developmental and behavioral outcomes at age 2 years.^{172,173}

In the case of the preterm fetus, delivery is usually indicated in the presence of worsening maternal hypertensive disease, failure of continuing fetal growth, reversal of umbilical artery

flow, or ductus venosus flow abnormalities. Based on current data, we would deliver any fetus past 32 weeks with reversed umbilical artery flow, and any past 34 weeks with absent umbilical artery flow, unless fetal growth velocity is sufficient and other antenatal tests are reassuring.

The preterm fetus (<34 weeks' gestation) should receive the benefit of corticosteroids for lung maturation if delivery is imminent.

The Growth Restriction Intervention Trial (GRIT) study underscored the difficulty in selecting the most appropriate delivery time to prevent morbidity.¹⁷⁴ In a randomized trial of 548 preterm FGR pregnancies (24 to 36 weeks' gestation) in which fetal compromise was identified but uncertainty regarding delivery timing persisted, approximately half of the pregnancies were delivered and the other half continued until the clinical course was clear. There was no difference in mortality between the two groups. However, among infants of less than 31 weeks' gestation, severe disabilities were observed at 2 years of age in 13% of the immediate deliveries, compared with 5% of those that were delayed, suggesting that prematurity-related complications were responsible. A follow-up study at 6 to 13 years of age was available in approximately one half of the cohort, and no differences were found in the immediate versus delayed delivery groups with respect to disability, cognition, or motor and behavioral scores.¹⁷⁵

Several methodologic concerns have been voiced regarding the GRIT studies, not the least of which is the lack of consistent and specific indications for delivery. Nevertheless, in a thoughtful editorial, Baschat and Odibo reemphasized that the important observed negative impact of prematurity carried a greater weight than that of deterioration in fetal status until the early third trimester, and they further implied that any deleterious neurodevelopmental effect might have occurred before FGR became clinically apparent.¹⁷⁶ Taken together, the findings suggest that delivery timing based on current antenatal testing is unlikely to influence outcome in the preterm fetus.

The overall findings and guidelines for evaluation and management of FGR are summarized in Table 47-1.

INTRAPARTUM MANAGEMENT

It has long been recognized that lower Apgar scores and meconium aspiration, as well as other manifestations of poor oxygenation during labor, occur with greater frequency among FGR infants. The problem of intrapartum asphyxia has been further elucidated by studies demonstrating the acid-base status of growth-restricted infants at the time of delivery. If moderate-to-severe metabolic acidosis is defined as an umbilical artery buffer base value of less than 37 mEq/L (normal, >40 mEq/L), almost 50% of FGR neonates show signs of acidosis at the time of delivery.¹⁷⁷ These findings document the problems of oxygenation during labor in such fetuses and emphasize that meticulous fetal surveillance is required during this critical period.

Consequently, the clinician should proceed to cesarean delivery if there is evidence of deteriorating fetal status, an unripe cervix, or any indication of additional fetal compromise during labor.

Prior to labor, the data suggest that there is no advantage of elective cesarean delivery over vaginal delivery even in the preterm fetus. A recent study of 2560 SGA infants between 25 and 34 weeks' gestation showed no significant differences in immediate adverse neonatal outcome and a slightly greater risk of respiratory distress in the cesarean delivery group.¹⁷⁸

Neonatal Complications and Long-term Sequelae

The growth-restricted fetus can experience numerous complications in the neonatal period related to the etiology of the growth insult as well as antepartum and intrapartum factors. These include neonatal asphyxia, meconium aspiration, hypoglycemia and other metabolic abnormalities, and polycythemia (see Chapter 72). After correction for gestational age, a large population-based outcomes analysis showed that the premature IUGR infant is at increased risk of mortality, necrotizing enterocolitis, and need for respiratory support at 28 days of age.¹⁷⁹

TABLE 47-1 Evaluation and Management of the Fetus with Intrauterine Growth Restriction

Parameter	Constitutionally Small Fetus	Fetus with Structural or Chromosome Abnormality or Fetal Infection	Substrate Deprivation or Uteroplacental Insufficiency
Growth rate and pattern	Usually below but parallel to normal; symmetric	Markedly below normal; symmetric	Variable; usually asymmetric
Anatomy	Normal	Usually abnormal	Normal
Amniotic fluid volume	Normal	Normal or hydramnios; decreased in the presence of renal agenesis or urethral obstruction	Low
Additional evaluation	None	Karyotype; specific testing for viral DNA in amniotic fluid as indicated	Fetal lung maturity testing as indicated
Additional laboratory evaluation of fetal well-being	Normal BPP/UA	BPP variable; normal UA	BPP variable; UA may show evidence of vascular resistance
Continued surveillance and timing of delivery	None; anticipate term delivery	Dependent on etiology	BPP and UA and DV; delivery timing requires balance of gestational age and BPP/UA and DV findings; fetal lung maturity testing may be helpful

BPP, biophysical profile; DV, ductus venosus Doppler findings; IUGR, intrauterine growth restriction; UA, umbilical artery Doppler findings. Adapted from Resnik R: *Intrauterine growth restriction*, *Obstet Gynecol* 99:490, 2002.

Pregnancy-Related Hypertension

KARA BETH MARKHAM, MD | EDMUND F. FUNAI, MD

Classification of Hypertensive Disorders

Interpretation of the literature regarding hypertension in pregnancy is difficult because of inconsistent terminology.¹ Although imperfect, the system prepared by the National Institutes of Health (NIH) Working Group on Hypertension in Pregnancy is straightforward and available worldwide.² The classification system includes the following diagnoses:

- Chronic hypertension
- Gestational hypertension
- Preeclampsia-eclampsia
- Preeclampsia superimposed on chronic hypertension

CHRONIC HYPERTENSION

Chronic hypertension is defined as persistent blood pressures greater than 140/90 mm Hg diagnosed before pregnancy or before 20 weeks' gestation. The diagnosis can also be based on hypertension that is observed for the first time during pregnancy and persists beyond the 84th day after birth.

GESTATIONAL HYPERTENSION

Gestational hypertension is defined as new-onset blood pressure elevations in the absence of proteinuria. This provisional diagnosis includes women without preeclampsia and those with preeclampsia who have not yet exhibited proteinuria, a distinction that ultimately cannot be made until after delivery.³ If preeclampsia has not developed and blood pressure values have returned to normal by 12 weeks after delivery, the diagnosis of transient hypertension in pregnancy can be assigned.

PREECLAMPSIA, ECLAMPSIA, AND HELLP

Preeclampsia is defined as new-onset blood pressure elevations accompanied by proteinuria in pregnancy. The diagnosis includes at least two measurements of systolic pressures greater than or equal to 140 mm Hg or diastolic pressures greater than or equal to 90 mm Hg.³ An incremental rise of blood pressure by 30 mm Hg systolic or 15 mm Hg diastolic is no longer included in the diagnostic criteria because the evidence does not show an increased risk for adverse outcomes in this cohort of patients.^{4,5} Proteinuria is defined by the presence of 300 mg of protein or more in a 24-hour urine specimen or 30 mg/dL (1+ dipstick) in a random urine specimen. A 24-hour urine specimen is preferable for diagnosis because of the discrepancy between random protein determinations and 24-hour urine protein measurements in preeclampsia.^{3,6-8} Alternatively, a timed collection corrected for creatinine excretion can be performed if a 24-hour urine collection is not feasible.³

Preeclampsia occurs as a spectrum that is arbitrarily divided into mild and severe forms. This terminology is useful for descriptive purposes but does not indicate different disease processes or cutoff points for therapy. The diagnosis of severe preeclampsia is made for any of the following criteria⁹:

- Blood pressure of 160 mm Hg systolic or higher or 110 mm Hg diastolic or higher on two occasions at least 6 hours apart while the patient is on bed rest
- Proteinuria level of 5 g or higher in a 24-hour urine specimen or a 3+ or greater value on two random urine samples collected at least 4 hours apart
- Oliguria of less than 500 mL in 24 hours
- Cerebral or visual disturbances
- Pulmonary edema or cyanosis
- Epigastric or right upper quadrant pain
- Impaired liver function
- Thrombocytopenia
- Fetal growth restriction

Eclampsia is the occurrence of seizures that cannot be attributed to other causes in a woman with preeclampsia. Edema occurs in too many normal pregnant women to be discriminant and has been abandoned as a marker for preeclampsia by most classification schemes.^{10,11} Edema of the hands and face occurs in 10% to 15% of normotensive women in pregnancy,¹² but this finding can be massive in severe preeclampsia (Fig. 48-1).

Although not included in the NIH Working Group on Hypertension in Pregnancy classification system, HELLP syndrome (*hemolysis, elevated liver enzymes, and low platelets*) is thought to be a variant of preeclampsia.¹³ Hypertension and proteinuria may not occur with this condition.¹⁴ Clinicians must therefore be alert to the possibility when managing women with signs and symptoms that could be explained by reduced organ perfusion. Although management for HELLP syndrome is similar to that for preeclampsia, some differences suggest that these two conditions may be separate entities. For example, women with HELLP syndrome tend to be older, white, and multiparous compared with preeclamptic women. The characteristic pathophysiologic changes in the renin-angiotensin system in women with preeclampsia does not occur in those with HELLP syndrome.¹⁵ In any case, the progression of HELLP syndrome and its termination with delivery argue for a management strategy similar to that for preeclampsia.

PREECLAMPSIA SUPERIMPOSED ON CHRONIC HYPERTENSION

Preeclampsia can occur in women with underlying chronic hypertension, a diagnosis that is associated with much worse maternal and fetal prognoses than either condition alone. The distinction between superimposed preeclampsia and worsening

Figure 48-1 Facial edema in severe preeclampsia. Markedly edematous facies of this severely preeclamptic woman (A) is especially evident when compared with her appearance 6 weeks after the birth (B).

chronic hypertension frequently tests the skills of the clinician. For clinical management, the principles of high sensitivity and unavoidable overdiagnosis are appropriate, especially with advancing gestational age. The diagnosis of superimposed preeclampsia is often suspected based on the new onset of proteinuria after 20 weeks' gestation. It is likely to occur in women with preexisting proteinuria who display a sudden increase in blood pressure or proteinuria. The diagnosis may be made when these women display objective evidence of involvement of other organ systems, including thrombocytopenia (platelet count $<100,000/\text{mm}^3$), elevated levels of liver transaminases, and worsening renal function.

PROBLEMS WITH CLASSIFICATION

The definition of gestational hypertension is somewhat controversial. Because the average blood pressure in women younger than 30 years old is 120/60 mm Hg, the standard definition of hypertension is judged by some to be too high.¹⁶ Some clinicians therefore recommend close observation of women with an incremental rise in blood pressure by 30 mm Hg systolic or 15 mm Hg diastolic even if absolute blood pressure does not exceed 140/90 mm Hg.³

The normal physiologic trends of blood pressure measurements during pregnancy also prove problematic for classification schemes. Blood pressure usually decreases early in pregnancy by an average of 7 mm Hg for systolic and diastolic readings, reaching a nadir at approximately 22 weeks' gestation (Fig. 48-2). Women who have chronic hypertension experience a greater decrease in blood pressure in early pregnancy than do normotensive women.¹⁷ The early decline and subsequent return of blood pressure to pre-pregnant levels in late

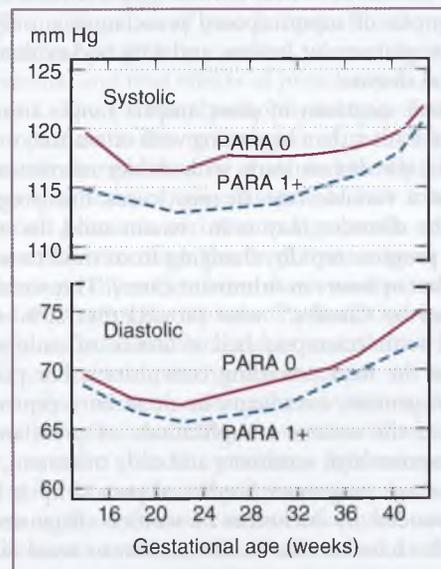

Figure 48-2 Blood pressure correlated with gestational age. Mean blood pressure is plotted against gestational age for 6000 white women between 25 and 34 years of age who delivered singleton term infants. (From Christianson R, Page EW: *Studies on blood pressure during pregnancy: influence of parity and age*, Am J Obstet Gynecol 125:509, 1976. Courtesy of the American College of Obstetricians and Gynecologists.)

gestation may erroneously satisfy criteria for a diagnosis of preeclampsia.

The diagnosis of chronic hypertension based on the failure of blood pressure to return to normal by 84 days after delivery can also be erroneous. For example, in a long-range prospective

TABLE 48-1 Renal Biopsy Findings in Patients with a Clinical Diagnosis of Preeclampsia

Biopsy Findings	Primigravidas n = 62	Multigravidas n = 152
Glomeruloendotheliosis ± nephrosclerosis	70%	14%
Normal histologic appearance	5%	53%
Chronic renal disease (chronic gestational trophoblastic neoplasia, chronic pyelonephritis)	25%	21%
Arteriolar nephrosclerosis	0%	12%

Adapted from McCartney CP: *Pathological anatomy of acute hypertension of pregnancy*, *Circulation* 30(Suppl II):37, 1964. By permission of the American Heart Association, Inc.

study, Chesley showed that many women who remained hypertensive 6 weeks after the birth were normotensive at long-term follow-up.¹⁸

Diagnosis of hypertensive disorders is further clouded by the fact that neither proteinuria nor hypertension is specific for preeclampsia. Renal biopsy specimens highlight these diagnostic difficulties (Table 48-1).¹⁹ Of 62 women with a diagnosis of preeclampsia, 70% had a glomerular lesion thought to be characteristic of the disorder, but 24% had evidence of chronic renal disease. Of 152 subjects with chronic hypertension and a presumed diagnosis of superimposed preeclampsia, only 3% had characteristic glomerular lesions, and 43% had evidence of pre-existing renal disease.

The clinical spectrum of preeclampsia ranges from mild to severe forms. Rather than beginning with eclampsia or the severe preeclampsia, the disease starts with milder manifestations and progresses at a variable rate. In most cases, this progression is slow, and the disorder may even remain mild. In others, the disease can progress rapidly, changing from mild to severe over days to weeks (or hours in fulminant cases). This variability was demonstrated by Chesley,²⁰ who showed that 25% of women hospitalized with eclampsia had evidence of only mild preeclampsia in the days preceding convulsions. For purposes of clinical management, overdiagnosis must be accepted because prevention of the serious complications of preeclampsia and eclampsia requires high sensitivity and early treatment, especially as gestational age progresses. Studies of preeclampsia are necessarily confounded by inclusion of women diagnosed as preeclamptic who have another cardiovascular or renal disorder.

Preeclampsia-Eclampsia

Despite the difficulties in clinical diagnosis, there clearly exists a disorder unique to pregnancy that is characterized by poor perfusion of many vital organs (including the fetoplacental unit) that is completely reversible with the termination of pregnancy. Pathologic, pathophysiologic, and prognostic findings indicate that preeclampsia is not merely an unmasking of pre-existing, underlying hypertension. Successful management of preeclampsia requires an understanding of the pathophysiologic changes and the recognition that the signs of preeclampsia are not the causal abnormalities.

EPIDEMIOLOGY OF PREECLAMPSIA AND ECLAMPSIA

Preeclampsia occurs in about 4% of pregnancies that extend beyond the first trimester. The most important risk factor is nulliparity; two thirds of all preeclampsia cases occur in nulliparous women. Other risk factors for preeclampsia, including age, race, and underlying medical conditions, are similar in nulliparous and parous women.²¹

The impression that preeclampsia is more common among women of lower socioeconomic status may be confounded by the relationship of preeclampsia to age, race, and parity. Several studies²²⁻²⁵ have shown no relationship between preeclampsia and socioeconomic status. In contrast, eclampsia is clearly more common in women of lower socioeconomic status,^{22,24,25} a finding that is likely related to the lack of availability of quality obstetric care for indigent women.

Preeclampsia has been linked to the extremes of childbearing age. This relationship has been demonstrated in older women regardless of parity,^{22,24,25} but the relation to young maternal age is lost when parity is considered. Because most first pregnancies occur in young women, most cases of preeclampsia occur in this age group.

The relationship between preeclampsia and race is complicated by the higher prevalence of chronic hypertension in African Americans. A modest association between preeclampsia and African-American race has been identified in some studies,²⁵⁻²⁸ with stronger associations often seen in studies that include the more severe forms of preeclampsia.²⁹ One study showed that black race was a significant risk factor only in nulliparous women (odds ratio (OR) = 12.3; 95% confidence interval [CI], 1.6 to 100.8),²⁹ but two large, prospective trials of medical prophylaxis in nulliparous women showed no association between race and preeclampsia after controlling for other risk factors.^{30,31} Maternal nonwhite race appears to be related more to the severity than the incidence of disease.

Several medical disorders may predispose women to preeclampsia. Chronic hypertension is a well-recognized risk factor, and 25% of women with this condition develop preeclampsia during pregnancy.^{32,33} Renal insufficiency with^{34,35} or without diabetes mellitus³⁶⁻³⁸ is another important risk factor.

The presence and severity of pregestational diabetes mellitus is independently associated with an increased risk for preeclampsia, particularly in the setting of diabetic microvascular disease.^{34,39} Historically, the incidence of preeclampsia in diabetic patients was estimated at 50%,²⁰ but later studies suggest a 20% to 21% risk of the disease overall in this population.^{34,39} The risk varies according to disease severity, with an 11% to 12% risk with class B diabetes, a 21% to 23% risk with class C and D diabetes, and a 36% to 54% risk with class F and R diabetes.^{34,39}

Connective tissue disorders such as systemic lupus erythematosus^{40,41} and antiphospholipid antibody syndrome⁴²⁻⁴⁴ have been described as predisposing risk factors for preeclampsia. In the former, the risk is particularly elevated in the setting of hypertension or lupus nephropathy.^{45,46} However, data regarding the latter are conflicting.^{44,47-49}

Obesity increases the risk of preeclampsia by approximately threefold, and the strength of this relationship increases with the magnitude of obesity.^{29,30,50} A linear relationship between pre-pregnancy body mass index (BMI) and the frequency of preeclampsia can be seen even in women of normal weight.⁵¹

This relationship is likely related to increased insulin resistance, a theory that is in concordance with the increased frequency of preeclampsia in women with gestational diabetes.⁵² In the United States, where 35% to 50% of women of reproductive age are obese, obesity is a major attributable risk factor for preeclampsia and is associated with one third of all cases of this disorder.

Certain conditions of pregnancy also increase the risk of preeclampsia. For example, the disease occurs in 70% of women with large, rapidly growing hydatidiform moles.⁵³ Preeclampsia often occurs at an early gestational age in these patients, and the diagnosis of a molar pregnancy should be suspected when preeclampsia is diagnosed before 24 weeks' gestation.

Preeclampsia is associated with multiple gestations, particularly in multiparous women.^{33,54} The incidence appears to increase with each additional fetus, occurring in 6.7% of twin, 12.7% of triplet, 20.0% of quadruplet, and 19.6% of quintuplet pregnancies.⁵⁵ The disease process may be initiated earlier and may be more severe in women with multiple gestations.⁵⁴

The mirror syndrome, an interesting variant of preeclampsia in which the mother's peripheral edema mirrors the fetal hydrops, occurs in almost 50% of pregnancies complicated by hydrops fetalis. Mirror syndrome can occur with alloimmunization processes, although only when fetal hydrops is present. It can be seen with nonimmune hydrops and occurred in 9 of 11 affected pregnancies in one small series.⁵⁶ This condition can manifest early in pregnancy with severe signs and symptoms of preeclampsia, including massive proteinuria and severe blood pressure elevations.⁵⁷⁻⁵⁹ Despite this severity, eclampsia is a rare complication, and the signs and symptoms of preeclampsia may resolve with treatment of the underlying disease process.⁵⁷⁻⁵⁹

CLINICAL PRESENTATION

Women with preeclampsia may present with a wide variety of signs and symptoms that range from mild findings to life-threatening abnormalities. The fetus may likewise be minimally affected or may be severely compromised. An understanding of the pathophysiology of the disorder provides insight into the diverse clinical presentations.

Symptoms

Most women with early preeclampsia are asymptomatic, an observation that serves as the rationale for frequent obstetric visits in late pregnancy. The symptoms that can occur—especially with preeclampsia of increasing severity—are listed in Box 48-1. Because preeclampsia is a disease of generalized poor perfusion, symptoms related to many organ systems may be observed. These symptoms elicit concern when they suggest involvement of the liver (e.g., epigastric pain, nausea and vomiting, stomach upset, pain penetrating to the back) or the central nervous system (e.g., headache, mental confusion, scotomata, blindness). Symptoms suggesting congestive heart failure or abruptio placentae are of great concern. Other complaints, such as tightness of hands and feet and paresthesias because of medial or ulnar nerve compression, may alarm the patient but have little prognostic significance.

Signs of Preeclampsia

Signs of preeclampsia usually antedate symptoms. The most common sequence is that of increased blood pressure followed by proteinuria.²⁰

BOX 48-1 SIGNS AND SYMPTOMS OF PREECLAMPSIA AND ECLAMPSIA

CEREBRAL FEATURES

- Headache
- Dizziness
- Tinnitus
- Drowsiness
- Change in respiratory rate
- Tachycardia
- Fever

VISUAL FEATURES

- Diplopia
- Scotomata
- Blurred vision
- Amaurosis

GASTROINTESTINAL FEATURES

- Nausea
- Vomiting
- Epigastric pain
- Hematemesis

RENAL FEATURES

- Oliguria
- Anuria
- Hematuria
- Hemoglobinuria

Blood Pressure Change. An increase in blood pressure is required for the diagnosis of preeclampsia. Blood pressure variations in normal pregnancy can lead to misdiagnosis, but the serious maternal and fetal effects of preeclampsia warrant such overdiagnosis. The primary pathophysiologic alteration (i.e., poor tissue perfusion due to vasospasm) is revealed more by blood pressure changes than by absolute blood pressure levels. Although a diagnosis of preeclampsia is not made without absolute blood pressures of 140 mm Hg systolic or 90 mm Hg diastolic, women who reach this level from a lower early pregnancy value typically suffer from more vasospasm than those for whom 140/90 mm Hg represents a lesser increase.

Although maternal and fetal risks rise with increasing blood pressure,⁶⁰ serious complications can occur in women who experience only modest blood pressure elevations. For example, studies have indicated that 20% of women with eclampsia have no prior systolic blood pressure measurements above 140 mm Hg.^{20,61} In another large, prospective study, 77% of the 383 patients with confirmed cases of eclampsia were hospitalized before seizure activity, 38% of whom had no documented proteinuria or hypertension beforehand.⁶² Others have observed similar findings.^{63,64}

Proteinuria. Proteinuria in the presence of hypertension is the most reliable indicator of fetal jeopardy. One study showed that the perinatal mortality rate tripled for women with proteinuria,⁶⁵ and another revealed a relationship between the amount of proteinuria and the perinatal mortality rate and number of growth-restricted infants.⁶⁶ These findings were corroborated in a study in which the risk for delivering a small-for-gestational-age fetus was higher for women with hypertension and proteinuria (52%) than for women with gestational (15%) or chronic (12%) hypertension.⁶⁷ The perinatal mortality rate in this study

was fourfold higher for cases with proteinuria than those with hypertension alone.⁶⁷ Despite these findings, eclampsia can occur in the absence of proteinuria.¹⁷

Retinal Changes. Fundoscopic examination reveals the presence of retinal vascular changes in at least 50% of women with preeclampsia, a finding that correlates well with renal biopsy changes.⁶⁸ Localized arteriolar narrowing is visualized as segmental spasm, and generalized narrowing is indicated by a decrease in the ratio of arteriolar-venous diameter from the usual 3:5 to 1:2 or even 1:3. These findings can occur diffusely or, in early stages, in single vessels.⁶⁹

Hyperreflexia. Although deep tendon reflexes are increased in many women before seizures, convulsions can occur in the absence of hyperreflexia,⁷⁰ and many pregnant women are consistently hyperreflexic without being preeclamptic. Changes in deep tendon reflexes or a lack of them is not part of the diagnosis of preeclampsia.

Other Signs. Other signs occur less commonly in preeclampsia but may indicate involvement of specific organ systems. Patients with marked edema may have ascites and hydrothorax, and those in congestive heart failure may display increased neck vein distention, a gallop rhythm, and pulmonary rales. Hepatic capsular distention, as manifested by hepatic enlargement and tenderness, is particularly concerning, as are petechiae or generalized bruising and bleeding due to disseminated intravascular coagulation (DIC).

Laboratory Findings

Laboratory studies may be markedly abnormal in severe preeclampsia and eclampsia, but these changes are often minimal or absent in mild disease.

Renal Function Studies

Serum Uric Acid Concentration and Urate Clearance. Uric acid is the most sensitive laboratory indicator of preeclampsia available. In one series, hypertension with hyperuricemia was as commonly associated with fetal growth restriction, as was hypertension with proteinuria.⁷¹ Hyperuricemia may be an early sign of disease, because uric acid clearance usually decreases before a measurable decrease in the glomerular filtration rate (GFR). Although increased serum levels of uric acid may be attributed to altered renal function, an alternative view favors increased production due to oxidative stress,⁷² and elevated uric acid may itself have pathogenic effects.⁷³ Tables 48-2 and 48-3 show normal uric acid levels during gestation and levels associated with preeclampsia.

Serum Creatinine Concentration and Creatinine Clearance. Unless a single value is markedly elevated, serum creatinine concentration is best interpreted serially. These concentrations vary as a geometric function of creatinine clearance, such that small changes in the GFR are best determined initially by measurements of creatinine clearance itself. Although often normal in women with mild disease, creatinine clearance is decreased in most patients with severe preeclampsia.

Liver Function Tests. Elevated levels of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) indicate a poor prognosis for the mother and baby.^{13,20,74} These findings usually correlate with severity of disease and, when associated

TABLE 48-2 Plasma Urate Concentrations in Normotensive Pregnant Women

Weeks' Gestation	Normotensive Patients		
	mmol/L	SD*	mg/dL
24-28	0.18	(20%)	3.02
29-32	0.18	(35%)	3.02
33-36	0.20	(30%)	3.36
37-40	0.26	(20%)	4.4
41-42	0.25	(24%)	4.2

*Numbers in parentheses are the standard deviation as a percentage of the mean values shown. Values for hypertensive and normotensive women are statistically different at all gestational ages ($P < .05$).

with hepatic enlargement, may be a sign of impending hepatic rupture.

Coagulation Factors. Although overt DIC is rare, many women with preeclampsia have subtle evidence of activation of the coagulation cascade. The average platelet count is similar to that seen in normal pregnancy,⁷⁵ but sequential measurements may reveal decreased platelet numbers in patients with preeclampsia.⁷⁶ Moreover, highly sensitive indicators of clotting system activation, such as reduced serum concentrations of antithrombin III,⁷⁷ decreased ratio of factor VIII bioactivity to factor VIII antigen,⁷⁸ and subtle indicators of platelet dysfunction (including alteration of turnover,⁷⁹ activation,⁸⁰ size,⁸¹ and content⁸²), are present in even mild preeclampsia and may antedate clinically evident disease.

Metabolic Changes of Preeclampsia. The increased insulin resistance of normal pregnancy is further exaggerated in preeclampsia. Evidence of this heightened insulin resistance syndrome includes elevations in circulating lipids, triglycerides, fatty acids, and low-density lipoprotein (LDL) levels and a reduction in high-density lipoprotein (HDL) cholesterol levels.⁸³⁻⁸⁹ These changes may antedate clinically evident disease and are observed to resolve after delivery. There is evidence that treatment of mice with pravastatin, an agent used to lower lipid levels, may improve vascular reactivity in preeclampsia.⁹⁰

Pathologic Changes in Preeclampsia

Pathologic changes provide strong evidence that preeclampsia is not merely an unmasking of essential hypertension or a variant of malignant hypertension. Evidence suggests that poor tissue perfusion, not blood pressure elevations, is the primary pathogenetic component driving the disease process.

Brain. Imaging with computed tomography (CT) demonstrates the presence of cerebral edema in some women with preeclampsia.⁹¹ Noninvasive studies of cerebral blood flow and resistance suggest that vascular barotrauma and loss of cerebral vascular autoregulation contribute to the pathogenesis of cerebral vascular pathology in this disease.⁹²

Liver. Gross lesions of the liver are visible in 60% of women with eclampsia, and one third of the remaining patients have evidence of microscopic abnormalities. Two temporally and etiologically distinct hepatic lesions have been described.⁹³ Initially, hemorrhage into the hepatic cellular columns occurs because of vasodilation of arterioles, with dislocation and deformation of the hepatocytes in their stromal sleeves (Fig. 48-3). Later, intense vasospasm causes hepatic infarction, ranging from small to large areas beginning near the sinusoids and extending toward the portal vessels (Fig. 48-4). Hemorrhagic changes are present in 66% and necrotic changes in 40% of eclamptic women and in about one half as many preeclamptic women. Hyalinization and thrombosis of hepatic vessels have been cited as evidence of DIC but could be the result of hemorrhage. Similar changes have been described in women with abruptio placentae.^{94,95}

Kidney. Unique glomerular, tubular, and arteriolar changes have been described with preeclampsia. The glomerular lesion is considered by some to be pathognomonic of preeclampsia, but identical changes may be seen in isolated placental abruption.⁹⁶

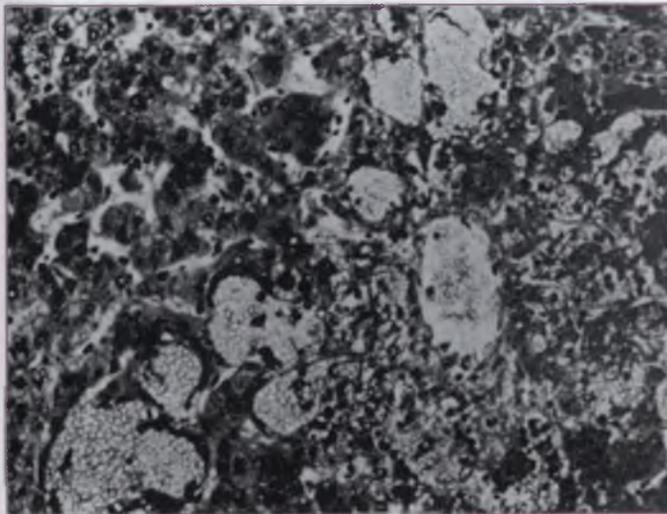

Figure 48-3 Hemorrhagic hepatic lesions in eclampsia. Hemorrhage into periportal area occurred with crescentic compression of liver cells. (From Sheehan HL, Lynch JB: Pathology of toxemia in pregnancy, London, 1973, Churchill Livingstone.)

Glomerular changes seen by light microscopy include decreased glomerular size, protrusion of the glomerular tuft into the proximal tubule, decreased diameter of the capillary lumen, and increased cytoplasmic volume within endothelial-mesangial cells (Fig. 48-5).⁶⁸ Electron microscopy suggests that the primary pathologic change occurs in endothelial cells, which are greatly increased in size and can occlude the capillary lumen, a phenomenon known as *glomerular capillary endotheliosis* (Fig. 48-6).⁹⁷

Characteristic glomerular changes occur in 70% of primiparas but in only 14% of multiparas who are diagnosed with preeclampsia.¹⁹ Glomerular lesions become increasingly common as certainty regarding the diagnosis of preeclampsia

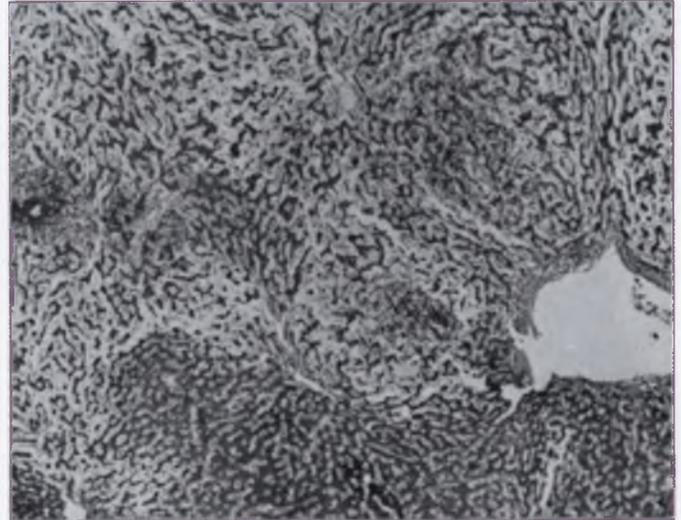

Figure 48-4 Hepatic infarction in eclampsia. Caused by intense vasospasm, hepatic infarction manifests as small to large areas of beginning near the sinusoids and extending into an area near the portal vessels. (Adapted from Sheehan HL, Lynch JB: Pathology of toxemia in pregnancy, London, 1973, Churchill Livingstone.)

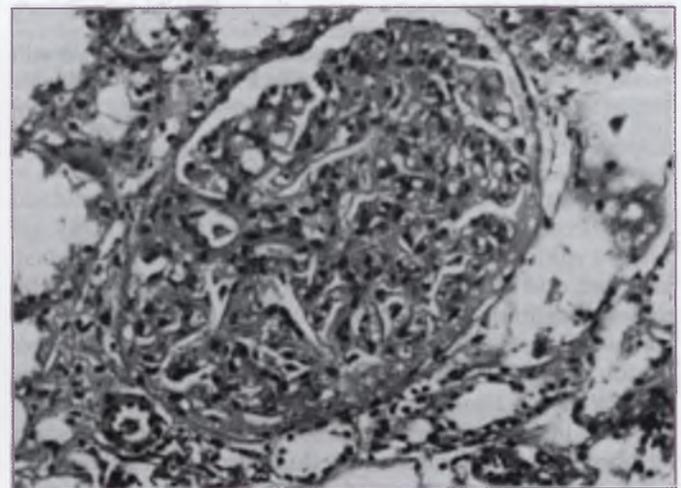

Figure 48-5 Glomerular changes in preeclampsia shown by light microscopy. The enlarged glomerulus completely fills the Bowman capsule. Diffuse edema of the glomerular wall is indicated by the vacuolated appearance. The visible capillary loops are extremely narrow, and there are virtually no red blood cells in the capillary tuft.

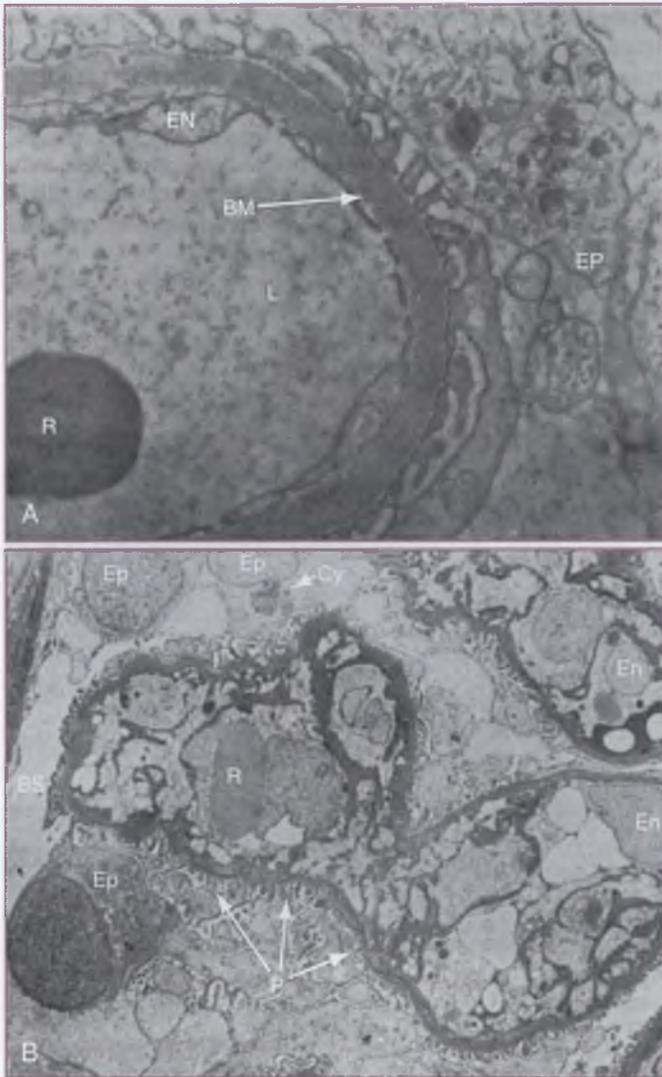

Figure 48-6 Electron photomicrographs of renal glomeruli. A, Normal anatomy, showing the basement membrane (BM), capillary endothelial cells (EN) that line the glomeruli, renal epithelial cells (EP), and the capillary lumen containing a red blood cell (R). B, In a biopsy specimen from a preeclamptic woman, the endothelial cells (En) are markedly enlarged, obstruct the capillary lumen, and contain electron-dense inclusions. The basement membrane is slightly thickened with inclusions, but the epithelial foot processes (P, arrows) are normal. BS, Bowman space; Cy, cytoplasmic inclusions; R, red blood cell. increases, and the magnitude of the lesions increases as the clinical condition becomes more severe. These changes are more consistently correlated with proteinuria than with hypertension. The glomerular alterations resolve within 5 to 10 weeks after delivery.⁶⁸

Nonglomerular changes occur with preeclampsia, including dilation of proximal tubules with thinning of the epithelium,⁹³ tubular necrosis,⁶⁸ enlargement of the juxtaglomerular apparatus,⁹⁸ and hyaline deposition in renal tubules.⁹³ Fat deposition has been associated with prolonged, heavy proteinuria,⁹³ and necrosis of the loop of Henle may be seen with hyperuricemia.⁹⁸ Thickening of renal arterioles may be visualized, particularly in

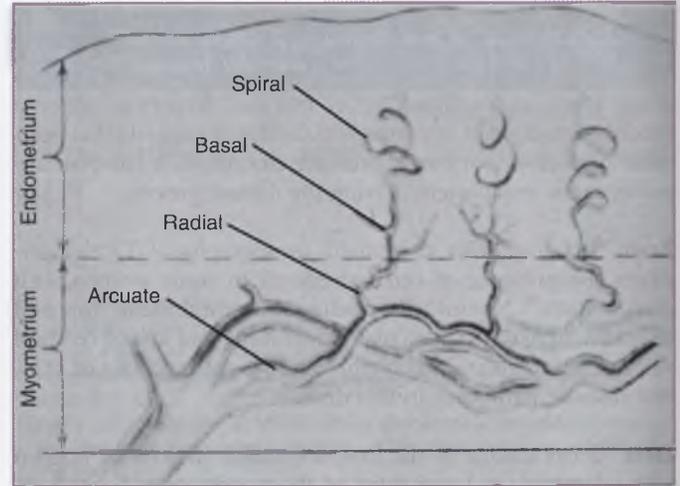

Figure 48-7 Schematic representation of uterine arteries. The characteristic changes occur in the decidual vessels supplying the placental site in a normal pregnancy. (From Okkels H, Engle ET: *Studies of the finer structure of the uterine vessels of the Macacus monkey*, *Acta Pathol Microbiol Scand* 15:150, 1938.)

women with preexisting hypertension, a finding that is likely related to the preexisting disease process because it does not regress after delivery.⁶⁸

Vascular Changes in the Placental Site. Figures 48-7 and 48-8 depict the characteristic changes seen in the placenta during normal pregnancy. Spiral arteries increase greatly in diameter,⁹⁹ endothelium is replaced by trophoblasts, and the internal elastic lamina and smooth muscle of the media are replaced by trophoblasts and an amorphous matrix containing fibrin (see Fig. 48-8).¹⁰⁰ These changes initially occur in the decidual portion of the spiral arteries and then extend into the myometrium as pregnancy advances, sometimes involving the distal portion of the uterine radial artery. The basal arteries are not affected. These morphologic changes in the vasculature are considered to be a direct or humoral reaction to trophoblasts that results in increased perfusion of the placental site.

In women with preeclampsia, these normal physiologic changes do not occur or are limited to the decidual portion of the spiral arteries. Myometrial segments of these vessels retain the nonpregnant component of intima and smooth muscle, and the diameter of these arteries is about 40% that of vessels in a normal pregnancy.¹⁰¹ Spiral arterioles may become necrotic, with components of the normal vessel wall replaced by amorphous material and foam cells, a change called *acute atherosclerosis* (Fig. 48-9).¹⁰² This lesion is best seen in basal arteries but is also present in the decidual and myometrial vessels. Acute atherosclerosis can progress to frank vessel obliteration, a finding that corresponds to areas of placental infarction. These changes may also be seen in other conditions of pregnancy, including fetal growth restriction, diabetes mellitus,¹⁰³ and preterm labor.¹⁰⁴ Abnormal invasion alone may not cause preeclampsia.

These placental changes are seen in one of seven primiparous women at the time of first-trimester abortion,^{105,106} suggesting that disordered placentation precedes the clinical presentation of preeclampsia. The disease process resembles that seen with rejection of transplanted kidneys, suggesting an immunologic cause. This immunologic theory is consistent with the finding of complement deposition within these decidual vessels.¹⁰⁷

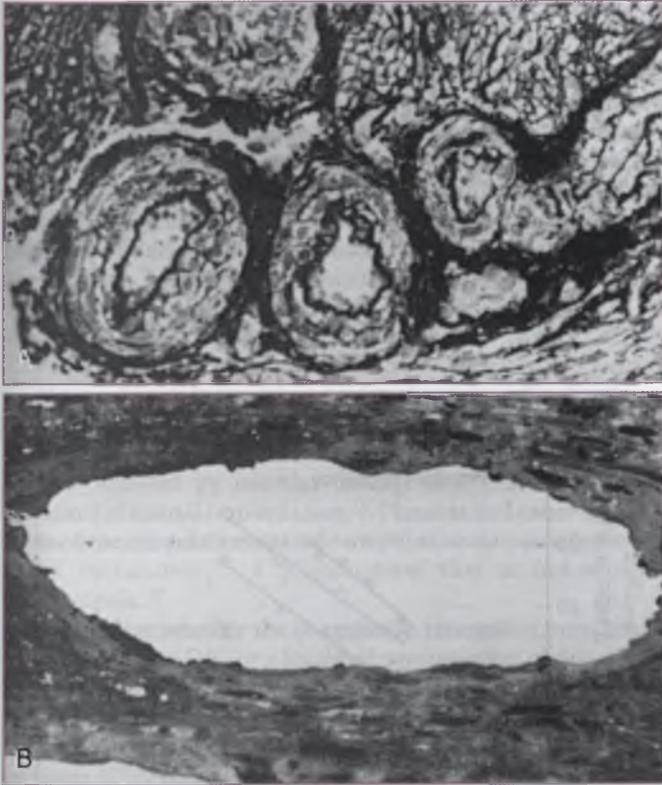

Figure 48-8 Spiral arterial changes in normal pregnancy. A, In a section of spiral arterioles at the junction of endometrium and myometrium in a nonpregnant woman, notice the inner elastic lamina and smooth muscle. B, In a section of spiral arteriole in the same scale and from the same location during pregnancy, notice the markedly increased diameter and absence of inner elastic lamina and smooth muscle. (Adapted from Sheppard BL, Bonnar J: *Uteroplacental arteries and hypertensive pregnancy*. In Bonnar J, MacGillivray I, Symonds G, editors: *Pregnancy hypertension*, Baltimore, 1980, University Park Press.)

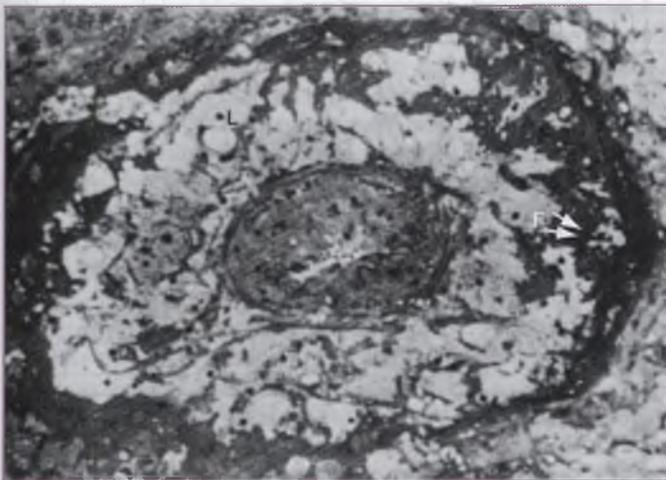

Figure 48-9 Atherosclerosis. Numerous lipid-laden cells (L) and fibrin deposition (F, arrows) can be seen in the media of this occluded decidual vessel. (Adapted from Sheppard BL, Bonnar J: *Uteroplacental arteries and hypertensive pregnancy*. In Bonnar J, MacGillivray I, Symonds G, editors: *Pregnancy hypertension*, Baltimore, 1980, University Park Press.)

Vascular remodeling of spiral arteries depends on normal trophoblastic invasion.¹⁰⁸ Expression of implantation-related adhesion molecules and receptors is abnormal in preeclampsia.¹⁰⁹ Although the trophoblasts lining decidual vessels normally begin to express molecules usually present only on endothelium,¹¹⁰ this phenomenon does not occur in preeclampsia.¹¹¹ These changes are potentially driven by decidually produced cytokines¹¹²⁻¹¹⁴ and local oxygen tension.^{115,116} Alterations in interactions between specific molecules on trophoblasts and maternal decidual cells may also contribute to abnormal invasion. One such example involves the interaction between the human leukocyte antigen type C (HLA-C) molecule on cytotrophoblasts and killer immunoglobulin receptors (KIRs) on maternal decidual cells. Certain fetal HLA-C and maternal KIR subtypes are associated with an increased frequency of preeclampsia, possibly related to inhibition of trophoblast invasion and vascular remodeling.¹¹⁶

Other Pathologic Changes of the Placenta. Placentas from women with preeclampsia demonstrate areas of cell death and degeneration within syncytiotrophoblasts. Even viable-appearing cells are abnormal, with decreased microvilli density, dilated endoplasmic reticulum, and reduced pinocytotic and secretory activity. The cells of the villous cytotrophoblasts are increased in number and have higher mitotic activity. The basement membrane of the trophoblast is irregularly thickened and has fine fibrillary inclusions.¹¹⁷ The cause of these changes may be related to local hypoxia, because similar syncytiotrophoblastic changes are present in placental segments maintained under hypoxic conditions *in vitro*.¹¹⁸

The placental trophoblasts in preeclampsia are characterized by increased apoptosis and necrosis,^{119,120} possibly due to hypoxia or hypoxia reperfusion injury.¹²¹ These changes may be the origin of the increased circulating syncytiotrophoblast microparticles seen in preeclampsia.¹²²

Pathophysiologic Changes in Preeclampsia

Preeclampsia can cause changes in virtually all organ systems, but several organ systems are consistently and characteristically involved.

Cardiovascular Changes

Blood pressure is the product of cardiac output and systemic vascular resistance (SVR). The cardiac output normally increases by up to 50% in pregnancy, but blood pressure remains largely unchanged, indicating that SVR must be decreased. A reduction in blood pressure is common in the first half of pregnancy, reaching a nadir at approximately 22 weeks' gestation (see Fig. 48-2). Some women who ultimately develop preeclampsia demonstrate a higher cardiac output before clinically evident disease, but output falls to pre-pregnancy levels with the onset of clinical preeclampsia.¹²³⁻¹²⁶ Increased SVR must therefore be the mechanism driving the increase in blood pressure seen with preeclampsia.

Arteriolar narrowing occurs in preeclampsia, a phenomenon that can be seen in vessels of the retina, kidney, nail bed, and conjunctiva.⁶⁸ Measurements of forearm blood flow indicate higher resistance in preeclampsia compared with normal pregnant women.^{127,128} The cause of this increased resistance remains unclear, but it is unlikely to be determined by the autonomic nervous system. Whereas normal pregnant women are exquisitely sensitive to interruption of autonomic neurotransmission

by ganglionic blockade and high spinal anesthesia, preeclamptic women are less sensitive.¹²⁹

Humoral factors have been implicated in the process of arteriolar narrowing (i.e., toxemia),¹³⁰ but later results are inconsistent with this theory, showing minimal changes in catecholamine levels.¹³¹ Although levels of endothelin 1, a vasoconstrictor produced by endothelial cells, are increased in the blood of preeclamptic women,¹³² they still occur in concentrations much lower than those necessary to stimulate vascular smooth muscle contraction *in vitro*.

A more compelling explanation for the vasospasm of preeclampsia is that of an increased response to normal concentrations of endogenous pressors. Women with preeclampsia have a higher sensitivity to all endogenous pressors tested, including vasopressin, epinephrine, norepinephrine, and angiotensin II.¹³³⁻¹³⁶ For example, administration of vasopressin can elicit marked blood pressure elevation, oliguria, and seizures in some preeclamptic patients.¹³⁴ The relationship between norepinephrine administration and blood pressure elevation is depicted in Fig. 48-10.

The most striking difference is seen in the sensitivity of the preeclamptic woman to angiotensin II. Normal pregnant women are less sensitive to angiotensin II than nonpregnant women, requiring approximately 2.5 times as much angiotensin II to raise blood pressure by a similar increment.¹³⁷ In contrast, preeclamptic women are much more sensitive to angiotensin II than are normal pregnant or nonpregnant women (Fig. 48-11),¹³⁶ a finding that may be observed weeks before the development of elevated blood pressure (Fig. 48-12).¹³⁸ Significant differences in sensitivity between women who later become hypertensive and those who remain normotensive have been observed as early as 14 weeks. However, a large British study did not confirm this classic finding,¹³⁹ perhaps reflecting the heterogeneity of preeclampsia.¹⁴⁰

Another theory suggests that arteriolar narrowing in preeclampsia is related to a decrease in circulating or local vasodilator substances, rather than an increase in circulating pressors. This attractive hypothesis, however, is not consistent with the unchanged sensitivities to norepinephrine, epinephrine, and vasopressin in normal pregnancy.¹³⁴⁻¹³⁶

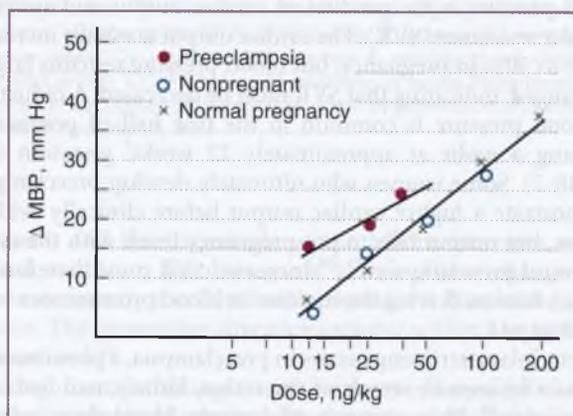

Figure 48-10 Mean dose-response graphs for norepinephrine. Women with preeclampsia have increased sensitivity to all endogenous pressors. MBP, mean blood pressure. (From Talledo OE, Chesley LC, Zuspan FP: Renin-angiotensin system in normal and toxemic pregnancies. III. Differential sensitivity to angiotensin II and norepinephrine in toxemia of pregnancy, *Am J Obstet Gynecol* 100:218, 1968.)

Coagulation Changes

DIC is diagnosed in 10% of women with severe preeclampsia or eclampsia,¹⁴¹ but even women with mild disease may demonstrate subtle changes in the coagulation system. With overt DIC, patients may develop end-organ damage due to the formation of microthrombi, with intravascular depletion of procoagulants and evidence of fibrin degradation.¹⁴² In the most advanced form of DIC, procoagulants (especially fibrinogen and platelets) decrease sufficiently to produce spontaneous

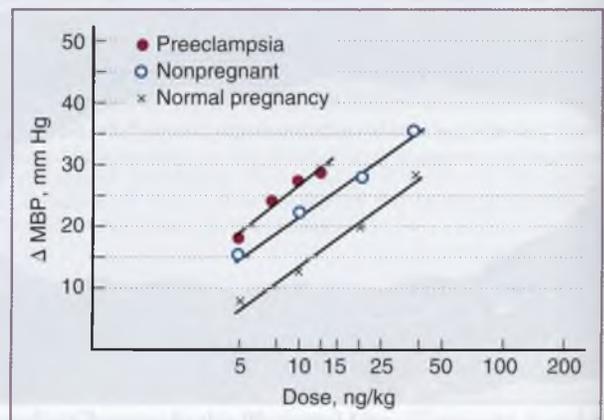

Figure 48-11 Mean dose-response graphs for angiotensin. Preeclamptic women are much more sensitive to angiotensin II than normal pregnant and nonpregnant women. MBP, mean blood pressure. (From Talledo OE, Chesley LC, Zuspan FP: Renin-angiotensin system in normal and toxemic pregnancies: III. Differential sensitivity to angiotensin II and norepinephrine in toxemia of pregnancy, *Am J Obstet Gynecol* 100:218, 1968.)

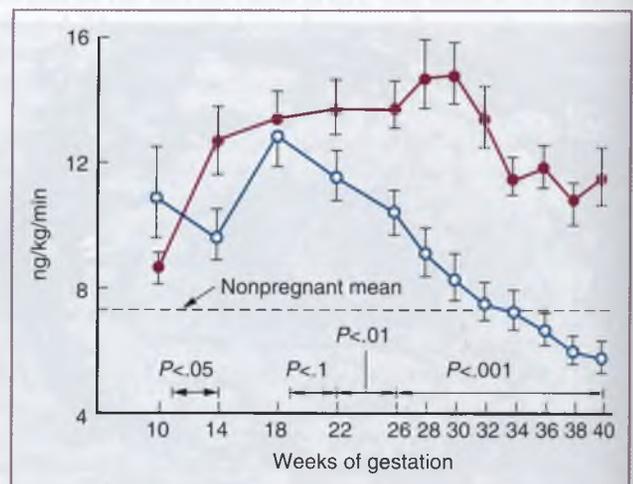

Figure 48-12 Angiotensin sensitivity throughout pregnancy. The dose of angiotensin II necessary to increase diastolic blood pressure (20 mm Hg) in women who developed elevated blood pressure in late pregnancy (blue line, open circles) was compared with the dose for those who remained normotensive (red line, filled circles). The resulting graph demonstrates that a significantly lower dose was required in the former group as early as 10 to 14 weeks' gestation. (Adapted from Gant NF, Daley GL, Chand S, et al: A study of angiotensin II pressor response throughout primigravid pregnancy, *J Clin Invest* 49:82, 1973. With permission of the American Society for Clinical Investigation.)

hemorrhage. In milder forms, only highly sensitive indicators of clotting system activation are present, including elevated levels of fibrin degradation products, increased platelet content in plasma,¹⁴³ reduced levels of antithrombin III,⁷⁷ a reduced ratio of factor VIII activity to factor VIII antigen,¹⁴⁴ and alterations in platelet appearance and function, including increased platelet turnover,⁷⁹ volume,⁸¹ and activation¹⁴⁵; reduced platelet content¹⁴⁶; and platelet dysfunction. Platelet concentrations may also diminish, but this may be evident only by serial observations.⁹⁶

These changes in the coagulation system are thought to be secondary rather than primary pathogenetic factors.¹⁴⁷ This idea is based on the fact that other signs of early preeclampsia (e.g., hyperuricemia) usually precede alterations in coagulation.⁷⁶

The cause of these hematologic changes is unknown. DIC may be initiated by vascular damage due to vasospasm or abnormal placental implantation.¹⁴⁷ Platelets and other components of the coagulation cascade may also be activated by endothelial dysfunction,¹⁴⁸ a phenomenon that is common in preeclampsia.¹⁴⁹

It is unclear whether the coagulation changes of preeclampsia represent true DIC or a localized consumption of procoagulants in the intervillous space. Microthrombi and fibrin antigen have been inconsistently observed systemically in the liver and kidney of preeclamptic women but may be increased in placental tissue.¹⁵⁰⁻¹⁵² Hematologic changes are often present in normotensive women with growth-restricted fetuses,¹⁵³ suggesting that localized coagulation in the intervillous space is important. Early alterations, including ratios of factor VIII activity and antigen and platelet counts, correlate better with fetal outcome than with clinical severity of preeclampsia.

Endothelial Cell Dysfunction

Evidence increasingly supports the theory that endothelial dysfunction plays an integral role in the pathophysiology of preeclampsia.^{149,154,155} Several products of injured endothelium, including cellular fibronectin,^{156,157} growth factors,¹⁵⁸ vascular cell adhesion molecule 1,¹⁵⁹ and factor VIII antigen, are increased in preeclamptic women before the appearance of clinical disease.⁷⁸ Vascular endothelium also displays evidence of impairment *in vitro* for women with preeclampsia.^{160,161}

The endothelium is a complex tissue with many important functions. Two of these, prevention of coagulation and modulation of vascular tone, have special relevance to preeclampsia. Intact vascular endothelium is resistant to thrombus formation.¹⁶² With vascular injury, endothelial cells can initiate coagulation by the intrinsic pathway (i.e., contact activation)¹⁶³ or by the extrinsic pathway (i.e., tissue factor).¹⁶⁴ Platelet adhesion can also occur with exposure of subendothelial components such as collagen¹⁶⁵ and microfibrils.

Endothelium profoundly influences the response of vascular smooth muscle to vasoactive agents.¹⁶⁶ In preeclampsia, vascular endothelium generates less prostacyclin, a highly potent vasodilator, than in normal pregnancies.¹⁶⁷⁻¹⁶⁹ In the setting of diffuse prostaglandin inhibition (including inhibition of prostacyclin), pregnant women are refractory to the normal vasoconstrictive properties of angiotensin II.¹⁷⁰ Preeclamptic women are usually more sensitive to angiotensin II than are normotensive pregnant women, but targeted inhibition of contractile prostanoids (e.g., thromboxane A₂) with aspirin leads to a reduction in this sensitivity.¹⁷¹

Nitric oxide (NO) is another bioactive material produced by normal endothelium.¹⁷² Its release is stimulated by several hormones and neurotransmitters and by hydrodynamic shear stress. NO is quite labile and acts synergistically with prostacyclin as a local vasodilator and an inhibitor of platelet aggregation. Current thinking favors NO as an endogenous vasodilator of pregnancy. Administration of inhibitors of NO synthesis reduces blood flow much more strikingly in pregnant than in nonpregnant women.¹⁷³ Production of NO is reduced with endothelial cell injury, leading to the hypothesis that NO levels in preeclampsia may be different from those of normotensive women. Data regarding this hypothesis are conflicting,¹⁷⁴⁻¹⁷⁹ with two studies showing reduced urinary NO excretion in preeclampsia^{177,180} and another finding increased excretion.¹⁸¹ Tissue concentrations of nitrotyrosine, the product of the interaction of NO and superoxide, are increased in the placenta¹⁸² and vasculature¹⁸³ of women with preeclampsia, indicating that the placenta directly or indirectly produces substances that alter endothelial function. Candidate substances include cytokines,^{184,185} placental fragments (i.e. syncytiotrophoblast microvillous membranes),¹⁸⁶ free radicals, and reactive oxygen species.¹⁸⁷ The theory of oxidative stress is especially interesting given the similarities between the lipid changes of preeclampsia and those of atherosclerosis,⁸⁴ an endothelial disorder in which oxidative stress is thought to play a key role.¹⁸⁸

A factor known as soluble FMS-like tyrosine kinase 1 (sFLT1) appears to play a role in endothelial cell dysfunction in preeclampsia. sFLT1 acts as an antagonist to vascular endothelial growth factor (VEGF), thereby impairing angiogenesis. Preeclamptic women possess increased levels of this factor, a finding that can be identified before the appearance of clinical signs of disease. Likewise, injection of sFLT1 in mice results in a constellation of signs similar to those seen with preeclampsia.

Information available today indicates that endothelial cell dysfunction can alter vascular responses and intravascular coagulation in a manner consistent with the pathophysiologic abnormalities in women with preeclampsia. Evidence is accumulating that endothelial injury can play a central role in the pathogenesis of preeclampsia.

Renal Function Changes

Renal function changes in preeclampsia include decreased glomerular filtration, proteinuria, reduced sodium excretion (resulting in fluid retention and edema), and alterations in the renin angiotensin aldosterone system.

Glomerular Functional Changes

Glomerular Filtration Rate. A decrease in the GFR frequently complicates preeclampsia, a finding only partially explained by decreased renal plasma flow (RPF). It appears that the filtration fraction, GFR/RPF, also is decreased,²⁰ perhaps due to intrarenal redistribution of blood flow.¹⁸⁹ More likely, the filtration fraction is decreased because of glomeruloendotheliosis, in which the occlusion of glomerular capillaries by swollen endothelial cells renders many glomeruli nonfunctional.

Protein Leakage. Proteinuria is primarily caused by glomerular changes in preeclampsia. Normally, protein is absent from urine because of a relative impermeability of glomeruli to large protein molecules with tubular resorption of smaller proteins. As glomerular damage occurs, permeability to proteins increases. As damage increases, so does the size of the protein

molecule that can cross the glomerular membrane, resulting in decreased selectivity. In women with preeclampsia, selectivity is low, indicating increased permeability due to glomerular damage.¹⁹⁰

The magnitude of proteinuria varies greatly over time in preeclamptic women, a finding that is not observed in patients with proteinuria due to other causes. Chesley quantitated this phenomenon,¹⁹¹ observing hourly variation in urinary creatinine/protein ratios. Because structural glomerular changes remain constant, proteinuria must at least partially depend on a varying functional cause, such as a variation in the intensity of renal vascular spasm. Vascular spasm has been shown to cause proteinuria, a finding demonstrated by the cold pressor test. In this test, immersing a patient's hand in ice water for 60 seconds increases blood pressure and protein excretion.¹⁹²

Renal Tubular Functional Changes

Uric Acid Clearance. Urate is not bound to plasma proteins under physiologic conditions¹⁹³ and is completely filtered at the glomerulus. Glomerular urate concentration is equal to renal arterial plasma concentration. Urate is then secreted and reabsorbed by renal tubules, predominantly in the proximal tubule. Most urate (98%) is reabsorbed, and about 80% of excreted urate is accounted for by urate secretion. Reabsorption occurs to a greater extent than secretion, and urate clearance is about 10% of creatinine clearance.¹⁹⁴

Abnormalities of uric acid clearance have long been recognized in preeclampsia.¹⁹⁵ This finding traditionally was attributed to decreased glomerular filtration,¹⁹⁶ but later studies have demonstrated a discrepancy between uric acid clearance and both inulin clearance and creatinine clearance.^{197,198} There is evidence that the decrease in uric acid clearance precedes decreases in GFR.¹⁹⁹

Urate clearance is decreased in the setting of hypovolemia, presumably due to nonspecific stimulation of proximal tubular reabsorption.²⁰⁰ Plasma volume depletion is coincident with these urate clearance changes,²⁰¹ but the correlation between the degree of volume depletion and the decrease in urate clearance is poor.²⁰¹

Angiotensin II infusion decreases urate clearance even in the presence of euolemia.²⁰² The increase in angiotensin II sensitivity seen in preeclampsia may therefore account for the change in urate clearance. Local effects of angiotensin II may also be important, because this substance can be produced in the kidney.²⁰³

In summary, uric acid clearance changes earlier in preeclamptic pregnancy than does GFR, suggesting a tubular rather than a glomerular functional explanation. Although the exact mechanism for the urate clearance change is not established, the common feature in the suggested mechanisms is that of decreased renal perfusion; however, increased production by poorly perfused tissue cannot be excluded.^{72,204}

Urinary Concentrating Capacity. There is evidence that tubular concentrating capacity is unchanged in pregnancy,²⁰⁵ but the studies suggesting this are notably confounded by a failure to correct for the increased GFR of pregnancy, which concomitantly increases concentrating capacity.²⁰⁶ However, both normotensive and hypertensive pregnant women appear to have a decreased capacity to concentrate urine in response to vasopressin.^{207,208}

Excretion of Phenolsulfonphthalein. Because phenolsulfonphthalein (PSP) is secreted by proximal tubular cells, its

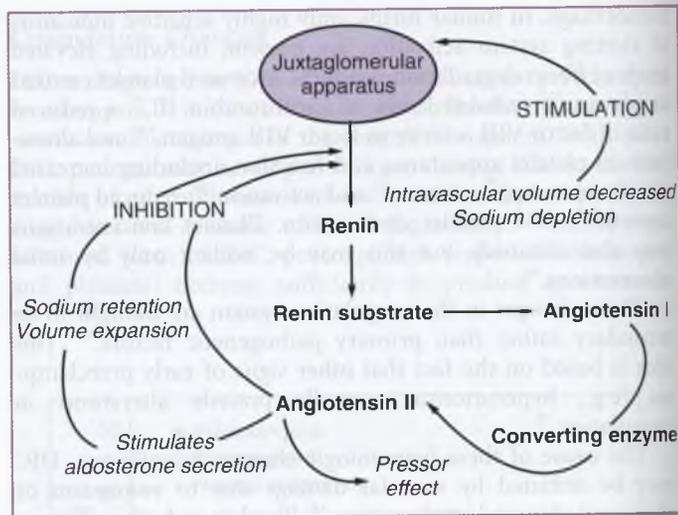

Figure 48-13 Schematic representation of the renin-angiotensin system. The system regulates pressure and volume in normal pregnancies, and abnormalities contribute to preeclampsia.

excretion can be used as an indicator of proximal tubular function.¹⁹⁹ PSP excretion varies independently of the changes in tubular secretory capacity seen with reduced GFR²⁰⁹ and altered renal plasma flow.^{210,211} Controlling for these factors, reduced PSP excretion precedes changes in GFR and clinically evident disease in women with preeclampsia.¹⁹⁹

Renin-Angiotensin-Aldosterone System. The renin-angiotensin-aldosterone system (RAAS) is important in blood pressure and volume regulation (Fig. 48-13).²¹² Dramatic changes occur in the RAAS during pregnancy,²¹³ including increased plasma renin activity,²¹⁴ decreased sensitivity to angiotensin II, and increases in the concentrations of angiotensinogen, renin,^{214,215} angiotensin II, and aldosterone.²¹⁶

RAAS abnormalities have been proposed as causal factors in preeclampsia.²¹⁷ The systemic concentrations of renin, angiotensinogen, angiotensin II, and aldosterone are decreased in preeclampsia compared with normotensive controls, but angiotensin II sensitivity is markedly increased. Women with preeclampsia may possess autoantibodies to angiotensin II receptors, resulting in increased activation of the RAAS.²¹⁸ Signaling through the angiotensin II receptor leads to other downstream effects,²¹⁹ such as activation of NADPH oxidase^{219,221} and hypoxia-inducing factors^{222,223} that may play a role in the pathophysiology of preeclampsia. Alterations have been identified in the localized RAAS of preeclamptic placentas, including increased renin synthesis in response to uterine ischemia.²²⁴

The reduced plasma renin activity and concentrations of preeclampsia compared with normotensive controls^{225,226} may reflect suppression of renin release from the kidneys. This is puzzling in view of the reduced plasma volume that is characteristic of the disease. There is no apparent nonphysiologic suppression of renin activity, because usual physiologic perturbations result in appropriately increased or decreased renin concentrations. For example, the renin level is increased with upright posture and head-up tilt²²⁷ and falls with volume expansion.²²⁸ Despite the intravascular depletion of preeclampsia, intense vasoconstriction results in a physiologic perception of overfill that suppresses renin release. The reduced renin

activity results in decreased aldosterone²²⁹ and angiotensin II¹³¹ concentrations compared with normal pregnancy. Despite these decreased concentrations, preeclamptic women are significantly more sensitive to these hormones, resulting in vasoconstriction systemically.

Studies of the RAAS indicate that no simple relationship exists between its components and preeclampsia. However, the significance of reduced plasma renin activity, plasma renin concentration, and angiotensin II concentration on blood pressure and sodium excretion in this group of women, who show apparent volume constriction and who are exquisitely sensitive to angiotensin II, deserves elucidation.

Atrial Natriuretic Factor. Atrial natriuretic factor (ANF), a peptide produced in response to atrial stretch with hypervolemia, regulates intravascular volume by several mechanisms, including increased sodium excretion and egress of fluid from the intravascular compartment. Although the reduced plasma volume of preeclampsia predicts reduced ANF concentration, the concentration is increased,²³⁰ a finding that precedes clinical disease.²³¹ The paradoxical findings of increased circulating ANF and reduced renin concentration with reduced plasma volume in preeclamptic women suggest that the reduced plasma volume is increased relative to the constricted vascular compartment.

Changes in Sodium Excretion. Sodium retention has long been associated with preeclampsia. Women with eclampsia and severe preeclampsia have very little urinary chloride and sodium.²³² Infusion of hypertonic saline into preeclamptic women results in excretion of the infused sodium at about one half the rate in normal pregnant women,¹³³ a finding that mimics that seen in women with glomeruloendotheliosis identified on renal biopsy.²³³ Most studies indicate that total body sodium is increased in preeclamptic patients.^{234,235}

The cause of sodium retention is difficult to determine because of the large number of factors that influence sodium excretion in normal pregnancy. Further complicating things, several anomalies of renal function exist in preeclampsia that could ultimately result in sodium retention (Box 48-2).

Several investigators have considered the increased sodium retention to be a primary factor inciting the pathogenetic changes in preeclampsia. Although this possibility cannot be definitively excluded, several reasons make it unlikely. Angiotensin sensitivity precedes obvious fluid retention by months, thiocyanate space (an indicator of sodium space) does not reliably predict preeclampsia,²³⁶ and neither dietary restriction of sodium intake nor diuretic-induced increased sodium excretion affects the occurrence of preeclampsia.²³⁷⁻²³⁹

Summary of Renal Function Changes. Renal function changes in preeclampsia are characteristic and consistent parts of the disease process. Prospective sequential studies of renal function indicate that some of these changes antedate the clinical diagnosis of preeclampsia but do not necessarily antedate other indicators of preeclampsia, such as changes in coagulation and plasma volume. They are unlikely to be causal abnormalities.

Immunologic Changes and Activation of Inflammatory Responses

Epidemiologic and laboratory observations suggest that fetal-maternal immunologic interactions may be etiologically important in the pathogenesis of preeclampsia. The increased incidence of preeclampsia in first pregnancies and the

BOX 48-2 FACTORS AFFECTING SODIUM BALANCE IN NORMAL PREGNANCY

FACTORS AFFECTING GLOMERULAR FILTRATION

- Blood pressure in critical areas of the kidney
- Relative tonus of afferent and efferent glomerular arterioles
- Plasma oncotic pressure
- Intrarenal redistribution of blood flow
- Central nervous system effects

FACTORS AFFECTING TUBULAR REABSORPTION

- Aldosterone
- Progesterone (an aldosterone antagonist)
- Renal vascular resistance
- Perfusion pressure in peritubular capillaries
- Oncotic pressure in peritubular capillaries
- Nonresorbable anions in the filtrate
- Velocity of flow in tubules
- Reabsorptive capacity of tubules
- Estrogens (stimulate sodium reabsorption, possibly indirectly, through effects on vascular permeability)
- Plasma sodium concentration
- Hematocrit (viscosity effects)
- Changes of plasma volume
- Angiotensin
- Sympathetic nervous system
- Possibly a natriuretic hormone ("third factor")

Adapted from Chesley LC: Hypertensive disorders in pregnancy, New York, 1978, Appleton-Century-Crofts.

protective effect even of miscarriage suggest that maternal exposure to fetal antigens may be protective, but this effect appears to be lost when subsequent pregnancies are fathered by a different individual.^{240,241} The increased risk of preeclampsia with a new father is compounded by the interpregnancy interval, which tends to be longer in pregnancies with new fathers. This finding is compatible with an immune-protective effect of antigen exposure, which is lost when antigen exposure is minimal for a prolonged period.²⁴² Exposure to paternal components of fetal antigens through sexual activity with the potential father before conception is also associated with reduced risk of disease.^{243,244}

Several immunologic mechanisms have been suggested.^{245,246} There is an efflux of fetal antigen into the maternal circulation during pregnancy. If the maternal antibody response is adequate, the complexes are cleared by the reticuloendothelial system. If the antibody response or clearance mechanisms are inadequate,²⁴⁷ pathologic immune complexes can cause vasculitis, glomerular damage, and activation of the coagulation system. Actual measurements of immune complexes in preeclampsia are inconsistent because of widely different methodologies and definitions of preeclampsia. Increased immune complexes are a feature of normal pregnancy, with further increases associated with mild preeclampsia and significant elevations with severe preeclampsia.²⁴⁸ An inadequate maternal antibody response is suggested by HLA typing, which demonstrates an increased concordance of the major histocompatibility antigens in maternal-paternal pairs that result in preeclamptic pregnancies.²⁴⁶ However, preeclampsia is less common in consanguineous marriages, a finding incompatible with this concept.²⁴⁹ Another theory proposes a simple excess of fetal antigens that overwhelms the maternal antibody system. This

idea is supported by the increased incidence of preeclampsia when trophoblastic tissue is increased, such as in twins, hydatidiform mole, and hydrotic placenta.

Another hypothesis holds that vascular changes in the spiral arterioles of the placental implantation site occur as the result of an allograft rejection between mother and fetus. The question is who is rejecting whom.²⁴⁶ Should the spiral arteries lined with trophoblast be thought of as fetal vessels, with the fetus rejecting the mother, or as maternal vessels, with the mother rejecting the fetus? If preeclampsia represents a rejection of the mother by the fetus, the preeclamptic mother would have to be deficient in the capacity to destroy fetal immune cells. However, if preeclampsia represents a rejection of the fetus by the mother, the protective effect of previous exposure to antigen would indicate that the preeclamptic mother has a deficit in blocking antibodies or suppressor cell function. For example, one theory implicates the HLA-G antigen on trophoblasts, with activation of the maternal immune system in response to abnormal antigen levels or certain polymorphisms.^{250,251} These alternative hypotheses—one requiring active intervention and the other passive intervention by the maternal immune system—should give disparate results in *in vitro* testing of maternal immune function. The experimental evidence available is not consistent enough to confirm or to contradict either hypothesis.

The innate immune response system may play a role.²⁵² Normal pregnancy is associated with an activation of an inflammatory response similar to that seen in sepsis. This inflammatory response is further exaggerated in preeclampsia.²⁵³ Placental substances (e.g., microvillus particles associated with apoptosis) interact with maternal immune cells, leading to activation of the inflammatory cascade.²⁵⁴ Increased release of these materials in preeclampsia is posited to further augment this immune response. The hypothesis of an immunologic cause of preeclampsia is consistent with much that is known about the disorder, and further delineation of immunologic alterations in preeclampsia could provide insight into the cause of this disease.

Oxidative Stress

Oxidative stress occurs when there is an excess of active oxygen products beyond the capacity of buffering mechanisms, antioxidants, and antioxidant enzymes. This phenomenon can occur with excess production of reactive oxygen products or with a deficiency of antioxidant mechanisms.²⁵⁵ Reactive oxygen products can damage proteins, lipids, and DNA, a harmful effect to which endothelium is particularly vulnerable. Lipid markers of oxidative stress are increased in women with preeclampsia.^{256,257} Lipid oxidation products, protein products of oxidation, protein carbonyls,²⁵⁸ and nitrotyrosine are present in the circulation, blood vessels,¹⁸³ and placenta¹⁸² of preeclamptic women and their infants. Reduced antioxidants^{259,260} and evidence of antibodies to oxidized LDL²⁶¹ are present in excess in women with preeclampsia. These changes occur in women before the development of clinical preeclampsia.^{262,263}

There are several origins of excess oxidative species relevant to preeclampsia. Transition metals such as iron catalyze the formation of reactive oxygen species, and free iron and redox active copper²⁶⁴ are increased in the blood of women with preeclampsia.²⁶⁵ Reduced tissue perfusion may result in hypoxia, with formation of reactive oxygen species on restoration of perfusion and reoxygenation.²⁶⁶ Uterine and placental blood flow is not privileged and is reduced when blood is shunted to other organs during exercise and other activities. In

late pregnancy, uterine and placental blood flow is reduced profoundly by postural effects on uterine perfusion. All of these changes are reversible and are followed by restored perfusion. Unlike in normal pregnancy, reduced placental perfusion in preeclampsia is sufficient to generate free radicals in the intervillous space,^{182,267} with systemic effects when these products of oxidative stress are released into the circulation.²⁶⁸

Genetics of Preeclampsia

Preeclampsia tends to occur in daughters and sisters of women with a history of the disease. In Aberdeen, the incidence of preeclampsia was increased fourfold among sisters of women who had preeclampsia in their first pregnancies compared with sisters of women who did not.²⁶⁹ Likewise, the incidence of preeclampsia was 15% among mothers but only 4% among mothers-in-law of preeclamptic women.²⁷⁰ Chesley²⁷¹ polled a group of women with a history of eclampsia and found that preeclampsia occurred in 37% of their sisters, 26% of their daughters, 16% of their granddaughters, and 6% of their daughters-in-law.

The fetal genome is related to the occurrence of preeclampsia. Men who have fathered preeclamptic pregnancies are more likely to father preeclamptic pregnancies with new partners than are men who have never been fathers in preeclamptic pregnancies.²⁷² Men born to preeclamptic mothers are more likely to be fathers of preeclamptic pregnancies than are men who are born of non-preeclamptic pregnancies.²⁷³

Possible causes of the inherited predisposition to preeclampsia include factors that affect the immune system, placental implantation, and the response to reduced placental perfusion. Potential candidates for this predisposition include certain HLA types,^{274,275} a variant of the angiotensinogen gene that appears to influence blood pressure and spiral artery remodeling,²⁷⁶⁻²⁷⁹ genes potentially associated with endothelial cell dysfunction,²⁸⁰⁻²⁸² and mutations in genes such as those for lipoprotein lipase²⁸³ and methylene tetrahydrofolate reductase²⁸¹ that may be associated with an increased risk of later-life cardiovascular disease.

In studies of genetic polymorphisms, the results vary according to the population studied.²⁸⁴ Although these and other studies²⁸⁵ support the genetic heterogeneity of preeclampsia,¹⁴⁰ this literature may be underpowered and subject to publication bias.²⁸⁶ In a study of 1000 paternal, maternal, and fetal triads of genetic influences, none of the usual gene polymorphisms was associated with preeclampsia.²⁸⁶ Overall, the results of linkage analyses to perform hypothesis-free testing of genetic associations have varied.²⁸⁶ The use of high-throughput genetic and gene expression and proteomic studies is just beginning to be applied to the study of preeclampsia.²⁸⁶

MANAGEMENT OF PREECLAMPSIA

General Considerations

Philosophy of Management. Three basic tenets should be considered when managing preeclamptic patients. First, *delivery is always an appropriate therapy for the mother but not always for the fetus.* Without an understanding of the cause, attempts to prevent or treat preeclampsia by conventional medical approaches have been unsuccessful. In terms of maternal health, the goal of therapy is to prevent maternal morbidity and mortality. Careful antepartum observation is necessary to achieve

this goal because the disease progresses at various rates. Preeclampsia is completely reversible and begins to abate with delivery. If only maternal well-being is considered, delivery of all preeclamptic women, regardless of disease severity or gestational age, is appropriate. When the fetus is considered, expectant management may be appropriate in some circumstances. Ultimately, any therapy for preeclampsia other than delivery must successfully lead to a reduction in perinatal mortality and morbidity.

Second, *the signs and symptoms of preeclampsia are not pathogenetically important*. Poor perfusion due at least in part to vasospasm is the major factor of preeclampsia leading to derangement of maternal physiologic function and ultimately to perinatal mortality and morbidity. This same process also causes increased total peripheral resistance, with subsequent elevation of blood pressure and decreased renal perfusion leading to proteinuria, sodium retention, and edema. Attempts to treat preeclampsia by natriuresis or blood pressure control do not alleviate the pathophysiologic changes. Natriuresis can be harmful, adversely affecting fetal outcome by further reducing the already restricted plasma volume of preeclampsia.

Third, *the pathogenetic changes of preeclampsia occur long before manifestation of clinical criteria leading to the diagnosis*. Changes in vascular reactivity, plasma volume, and renal function antedate (in some cases by months) the increases in blood pressure, protein excretion, and sodium retention. Irreversible changes affecting fetal well-being can exist before the clinical diagnosis is made. This likely explains the inability to reduce perinatal morbidity and mortality using dietary, pharmacologic, and postural therapy instituted after the recognition of clinical disease. The only justification for therapy other than immediate delivery is to palliate the maternal condition to allow fetal maturation, but even this rationale is controversial.

Delivery as Definitive Treatment for Preeclampsia

Delivery Remote from Term. Delivery in the setting of severe preeclampsia usually is chosen for the maternal and fetal indications described previously. Fetal indications for intervention include non-reassuring fetal testing, estimated fetal weight less than the 5th percentile for gestational age, oligohydramnios with an amniotic fluid index less than 5.0 cm or maximal vertical pocket less than 2.0 cm and persistently absent or reversed diastolic flow on umbilical artery Doppler velocimetry in a growth-restricted fetus. Delivery should be considered for all women with severe preeclampsia who have reached a favorable gestational age (>32 to 34 weeks' gestation).

Delivery at or Near Term. Expectant management may be considered when preeclampsia is diagnosed at less than 32 to 34 weeks' gestation, even if disease is severe. However, as gestational age approaches 34 weeks, short- and long-term neonatal outcomes are excellent, and the potential benefits of expectant management become less compelling. At 34 to 37 weeks, decisions regarding delivery are not guided by convincing evidence, and clinical judgment must consider the neonatal prognosis, severity of maternal disease, and the wishes of the patient.

At term, the treatment of choice for preeclampsia has traditionally been delivery. This approach has been affirmed by a multicenter, randomized clinical trial comparing induction of labor with expectant management for gestational hypertension and preeclampsia between 36 and 41 weeks' gestation.²⁸⁷ The study authors found that after subjects reached 37 weeks, there was a progressive reduction in the relative risk of maternal

composite morbidity (overall relative risk for 36 to 41 weeks = 0.71; 95% CI, 0.59 to 0.86; $P < .0001$), with no increase in the risk of cesarean delivery or neonatal morbidity with induction of labor.²⁸⁷ However, the principal maternal benefit of delivery was that of decreased risks of disease progression and severe hypertension, because the study was not designed to investigate more serious outcomes such as eclampsia, HELLP, and placental abruption.²⁸⁷

Route of Delivery. Delivery is typically done by the vaginal route, with cesarean delivery reserved for the usual obstetric indications. The decision to expedite delivery in the setting of severe preeclampsia does not mandate immediate cesarean birth.²⁸⁸ Cervical ripening agents may be used if the cervix is not favorable before induction,²⁸⁹ but it may be prudent to avoid a prolonged induction in the setting of intrauterine fetal growth restriction (IUGR) or oligohydramnios. The rate of vaginal delivery after labor induction decreases to about 33% at less than 28 weeks because of the high frequency of non-reassuring fetal heart rate tracings and failure to achieve cervical dilation.²⁹⁰ For this reason, some physicians recommend scheduled cesarean delivery for women with severe preeclampsia and a low Bishop score at less than 30 weeks' gestation.²⁹¹

After the decision for delivery is made, induction should be carried out aggressively and expeditiously. Because the probability of fetal compromise in preeclampsia is high, the fetus must be monitored adequately in all vaginal deliveries. Internal monitoring is preferable to allow determination of variability, but external monitoring may be adequate. Magnesium sulfate ($MgSO_4$) may decrease variability,²⁹² and further evaluation may be necessary to ensure that inadequate oxygenation is not responsible for the reduction. For the woman with marked hepatic capsular distention, cesarean delivery is indicated if vaginal delivery is not imminent. Even several extra hours could be life-threatening, and liver rupture is difficult to predict and to treat. In some cases of severe preeclampsia, rapidly worsening thrombocytopenia or other signs of maternal instability may preclude a trial of labor.

Regional anesthesia offers its usual advantages for vaginal and cesarean delivery. However, extensive sympathectomy may occur, resulting in decreased cardiac output, hypotension, and impairment of uteroplacental perfusion. This problem can be avoided by volume expansion and meticulous attention to anesthetic technique. Regional anesthesia is not a rational means of lowering blood pressure because it does so at the expense of cardiac output. Similarly, although analgesia with narcotics should be used when indicated, attempting to manage or prevent eclampsia with profound maternal sedation is dangerous and ineffective.

Basic Principles of Antepartum Management

When preeclampsia is suspected, careful evaluation of mother and fetus is essential, including assessment of blood pressures, laboratory values, and fetal well-being. If the diagnosis of preeclampsia is confirmed, maternal seizure prophylaxis and blood pressure control should be considered, and plans for delivery should be made according to the gestational age.

Assessment and Monitoring of Mother and Fetus

Maternal Monitoring. The primary goal of antepartum management is to gauge the rate of progression of the condition to prevent morbidity and mortality. Ideally, intervention should occur before the onset of clinical symptoms. Although many

hemodynamic and metabolic changes antedate the appearance of clinical signs in women destined to develop preeclampsia, none is sensitive enough to be clinically useful.^{78,133,199,293-295} The increased blood pressure response to angiotensin II^{138,296,297} was once the gold standard against which other predictors were judged, but a large study failed to confirm the predictive value of this test.^{78,139} Likewise, abnormal uterine artery Doppler velocimetry in the second trimester has been found to predict preeclampsia with a positive predictive value of only 20%, limiting the clinical use of this test.²⁹⁸ Other suggested markers include angiogenic and antiangiogenic factors, but additional evaluation is necessary before widespread use of these tests.²⁹⁹

Clinical management is dictated by the overt clinical signs of preeclampsia. Because proteinuria is often a late change that may even be preceded by seizures, it is not useful for early recognition. Likewise, although rapid weight gain and edema suggest fluid and sodium retention, they are neither universally present nor uniquely characteristic of preeclampsia. These signs are at most a reason for close observation of blood pressure and urinary protein. Early recognition of preeclampsia is based primarily on blood pressure elevations, although blood pressure changes without proteinuria undoubtedly occur in some normal women who do not have preeclampsia. Because the goal of early diagnosis is to identify patients requiring more careful observation, overdiagnosis is preferable to underdiagnosis.

After blood pressure elevations appear, evidence of multiorgan involvement should be sought through laboratory assessment, including measurement of platelets and liver enzymes.² A 24-hour or timed urine specimen should be collected,³⁰⁰ regardless of findings on urine dipstick evaluation.⁹ Because of the great variability in protein excretion over time,³⁰¹ 24-hour urine collections may reveal more than 300 mg of protein excretion despite only trace proteinuria on dipstick evaluation.⁸ To rule out fulminant progression, repeated examinations of blood pressure and laboratory studies are suggested within 24 hours. Frequency of subsequent observations is then determined by these initial observations and the ensuing clinical progression. If the condition appears stable, once- or twice-weekly observations may be appropriate. Any evidence of progression merits more frequent observations, perhaps in the hospital.

If deterioration in laboratory findings, symptoms, or clinical signs occurs, the decision to continue the pregnancy is determined on a daily basis. Subjective evidence of central nervous system involvement or hepatic distention is an important indicator of worsening preeclampsia.

Fetal Observation. Fetal well-being must be assessed when determining the safety of prolonging a pregnancy (see Chapter 32). With the diagnosis of gestational hypertension, nonstress testing is indicated, and fetal size should be assessed by ultrasonography. After the diagnosis of preeclampsia is made, it is even more important to monitor fetal well-being. Ultrasound evaluation of fetal weight and amniotic fluid volume should be performed, as should a nonstress test or, alternatively, a complete biophysical profile. Doppler velocimetry is not recommended unless fetal growth restriction is observed.

As long as the maternal condition is mild and stable, weekly monitoring of the fetus appears to be adequate. Unfortunately, no test of fetal well-being is satisfactory when the mother's condition is unstable, and testing should be repeated whenever maternal status changes. Management of fetal growth restriction, a common complication of preeclampsia, is

discussed in Chapter 47. Fetal jeopardy rather than lung maturity is the criterion to determine timing of delivery when preeclampsia occurs in the preterm period.

Expectant Management of Severe Preeclampsia Remote from Term

Prolonged expectant antepartum management of women with severe preeclampsia is not practiced in most centers. With improvements in neonatal care, many investigators regard delivery of women with severe preeclampsia beyond 32 to 34 weeks' gestation to be in the best interests of the mother and fetus. When gestational age is critical (<32 weeks), the physician may consider expectant management with control of maternal blood pressure and meticulous observation of maternal and fetal conditions.

Initial evaluation and management of a woman with suspected severe preeclampsia between 24 and 32 to 34 weeks' gestation includes the following:

1. The woman is admitted to the hospital
2. Barring rapid deterioration of the maternal or fetal status, reasonable efforts should be made to delay delivery for 48 hours to complete a full course of antenatal corticosteroids. Although there may be a reduced incidence of respiratory distress syndrome in neonates born to preeclamptic women, this does not justify withholding antenatal corticosteroid therapy.^{302,303}
3. Magnesium sulfate is used for seizure prophylaxis.
4. Blood pressure is monitored at least every 1 to 2 hours.
5. Fluid intake and urine output are strictly monitored.
6. Protein and creatinine clearance are monitored with a 24-hour urine collection.
7. Laboratory studies include a complete blood cell count with platelet count and smear, electrolytes, creatinine, ALT and AST, lactic acid dehydrogenase (LDH), uric acid, and albumin. A coagulopathy profile (i.e., prothrombin time, partial thromboplastin time, and fibrinogen) should be obtained if the ALT and AST values are more than twice normal or if the platelet count is less than 100,000 cells/ μ L.
8. Assessment of fetal well-being includes a nonstress test, amniotic fluid volume determination, and estimation of fetal size. If growth restriction is observed, umbilical artery Doppler velocimetry is suggested.

After complete assessment of the fetus and mother, the risks and benefits of expectant management must be reassessed daily. Several factors preclude a delay in delivery regardless of gestational age. Under these circumstances, the initial dose of antenatal steroids should be administered, but pregnancy should not be unnecessarily prolonged to administer the second dose.

Contraindications to Expectant Management. Immediate delivery should be considered for any of the following conditions:

1. Maternal hemodynamic instability (e.g., shock)
2. Non-reassuring fetal testing (e.g., persistently abnormal fetal heart rate testing, estimated fetal weight less than the 5th percentile for gestational age, oligohydramnios with an amniotic fluid index value less than 5.0 cm or maximal vertical pocket less than 2.0 cm, or persistent absent or reversed diastolic flow on umbilical artery Doppler velocimetry in a growth-restricted fetus)

3. Persistent, severe hypertension unresponsive to medical therapy
4. Persistent headache, visual aberrations, or epigastric or right upper quadrant pain
5. Eclampsia
6. Pulmonary edema
7. Renal failure with a marked rise in serum creatinine concentration by 1 mg/dL over baseline or urine output less than 0.5 mL/kg/hr for 2 hours that is unresponsive to hydration with two intravenous boluses of 500 mL of fluid
8. Laboratory abnormalities, including a rapid increase in aminotransferase values that exceed twice the upper limit of normal, a progressive decrease in platelet count to less than 100,000 cells/ μ L, or coagulopathy in the absence of an alternative explanation, which are worsening over 6 to 12 hours
9. Abruptio placentae
10. Gestational age of more than 34 weeks
11. Gestational age of less than 24 weeks, because there is little to no hope of survival if preeclampsia occurs before this gestational age,³⁰⁴ and without potential fetal benefit, delivery is indicated
12. Patient's desire to avoid the risks of expectant management

Some studies have reported that serious maternal complications with expectant management of HELLP syndrome are uncommon with careful maternal monitoring.^{305,306} However, the aim of expectant management is to improve neonatal morbidity and mortality. It has not been shown that overall perinatal outcome is improved with expectant management compared with pregnancies delivered after a course of corticosteroids, and expectant management therefore remains an investigational approach.^{307,308}

Candidates for Expectant Management. For women with severe preeclampsia remote from term, expectant management must involve continual review of the ongoing maternal and fetal risks versus the benefits of further fetal maturation. These women should be cared for in a hospitalized setting by or in consultation with a maternal-fetal medicine specialist. In this closely monitored environment, expectant management of severe preeclampsia remote from term may be considered, with particular attention to laboratory studies, fetal well-being, and blood pressures. In the absence of other features of severe preeclampsia, a proteinuria value greater than 5 g per 24 hours is not an indication for delivery. Several clinical studies have shown that neither the rate of increase nor the amount of proteinuria affects maternal or perinatal outcome in the setting of preeclampsia.^{309,310} For this reason, after the threshold of 300 mg per 24 hours for the diagnosis of preeclampsia has been exceeded, 24-hour urinary protein estimations do not bear repeating.

Asymptomatic women before 34 weeks' gestation with severe preeclampsia on the basis of laboratory abnormalities that improve or resolve within 24 to 48 hours after hospitalization may be managed expectantly.^{311,312} If initial laboratory abnormalities include elevated liver function test (ALT, AST) results less than twice the upper limit of normal, a platelet count of less than 100,000 cells/ μ L but greater than 75,000 cells/ μ L, or coagulopathy in the absence of an alternative explanation, it is reasonable to delay delivery, administer antenatal corticosteroids, and repeat

laboratory tests every 6 to 12 hours. If the laboratory values show a trend toward improvement or they resolve, expectant management may be continued until a more favorable gestational age. Delivery is warranted if liver function test results or platelet counts deteriorate or coagulopathy occurs.

Women with severe preeclampsia based only on the presence of IUGR in the setting of preeclampsia may be managed expectantly if the following criteria are met³¹³: mild IUGR only, defined as an estimated fetal weight between the 5th and 10th percentile for gestational age; gestational age less than 32 weeks; and reassuring fetal testing, defined as a reassuring nonstress test result, adequate amniotic fluid volume, and no persistent absent or reversed diastolic flow on umbilical artery Doppler velocimetry. Chapter 47 details the management of IUGR, and Chapter 32 discusses fetal surveillance. Daily fetal testing is indicated for monitoring of fetal well-being.³¹⁴ The admission-to-delivery interval in these cases averages only 3 days, and more than 85% of women require delivery within 1 week of presentation.^{308,313} Two studies have established a precedent for expectant management of patients with severe preeclampsia by blood pressure criteria alone in pregnancies less than 32 weeks' gestation with reassuring fetal testing.^{311,312}

Components of Expectant Management. Expectant management of severe preeclampsia is not associated with any direct maternal benefits. The mother is taking on a small but significant risk to her own health to delay delivery until a more favorable gestational age is reached for her child.

If the contraindications to expectant management described previously are absent, the following protocol may minimize the risk of maternal and fetal complications. Close supervision of mother and fetus is crucial because it is impossible to predict the clinical course the disease will take after admission.³⁰⁷

1. Hospitalize the woman until delivery.
2. Keep the patient on bed rest with bathroom privileges.
3. Monitor blood pressure every 2 to 4 hours while the patient is awake.
4. Assess maternal symptoms every 2 to 4 hours while awake.
5. Strictly record fluid intake and urine output.
6. Evaluations include a complete blood cell count, electrolyte determinations, and liver and renal function tests at least twice weekly, if not daily.
7. Administer antenatal corticosteroids, if not previously given.
8. Regularly assess fetal well-being at least daily with nonstress tests and with a biophysical profile if nonreactive.³
9. Delivery should occur after 32 to 34 weeks' gestation, depending on the clinical scenario.

Abnormal laboratory test values found on admission should prompt repeated tests every 6 to 12 hours. If there is no trend toward improvement within 12 hours, delivery should be strongly considered. Delivery should also be considered if laboratory abnormalities begin to worsen after an initial improvement.

There is no standardized protocol for fetal assessment in this setting. We suggest obtaining fetal kick counts and nonstress tests at least daily, ultrasound assessment of amniotic fluid volume once or twice per week, ultrasound estimation of fetal growth every 10 to 14 days, and weekly Doppler velocimetry of the umbilical artery if the fetus is growth restricted.

Several management strategies with no proven benefit in the setting of severe preeclampsia are often recommended but best

avoided. They include routine use of continuous fetal heart rate monitoring, routine initiation of antihypertensive therapy (which should be avoided except for women with chronic hypertension and those being managed according to standard protocols for severe preeclampsia by blood pressure criteria only remote from term),³¹² prolonged (>48 hours) antepartum administration of magnesium sulfate seizure prophylaxis, serial 24-hour urine collections for protein quantitation, and routine assessment of fetal lung maturity. However, the latter may be useful between 30 and 34 weeks when there is contradictory or equivocal evidence of maternal or fetal deterioration.

Postpartum administration of intravenous dexamethasone does not reduce the severity or duration of disease. The serendipitous observation that women who had received antepartum steroids appeared to evidence improvement in the HELLP syndrome³¹⁵ stimulated several retrospective and observational studies.³¹⁶⁻³²¹ These studies and a small, randomized, controlled trial³²² suggest improvement in laboratory findings and prolongation of pregnancy. The determinations of appropriate dosing and whether the benefit of therapy exceeds risks await larger, randomized, controlled trials. Its benefit for patients with HELLP syndrome remains controversial.³²³

Outcomes. Several studies have shown that with close monitoring, pregnancies complicated by severe preeclampsia can be managed expectantly, extending the pregnancy by 5 to 19 days on average and producing good maternal and neonatal outcomes.^{311,312,324,325}

Intrapartum Management

The patient with severe preeclampsia or eclampsia is acutely ill, with functional derangements of many organ systems,³²⁶ and she must be closely monitored in an effort to prevent morbidity and mortality. One U.K. study demonstrated a significant reduction in maternal death due to eclampsia, decreasing from 15.1% in the 1940s to less than 3.9% after 1950.³²⁶ Failure to recognize and appropriately manage this grave condition probably accounts for most deaths.

Baseline information should be obtained to determine renal function, coagulation status, and liver function. Some investigators advocate the use of cardiovascular monitoring with Swan-Ganz catheters or central venous pressure catheters in all women with severe preeclampsia and eclampsia, but others advocate for intensive monitoring only in oliguric patients whose urinary output does not improve with a modest fluid challenge (see Chapter 71). The major problems to be managed are those of high blood pressure, intravascular volume depletion, and convulsions. Less commonly, patients with DIC and myocardial dysfunction may be encountered.

Seizure Prophylaxis. Most seizures occur during the intrapartum and postpartum periods, when the preeclamptic process is most likely to accelerate. The Magpie study, in which 10,000 preeclamptic women were randomized to magnesium or placebo, demonstrated the efficacy of magnesium sulfate in preventing eclamptic seizures.³²⁷ Magnesium sulfate appears to be superior to phenytoin^{328,329} and diazepam^{330,331} for seizure prophylaxis.

In the Magpie study, treatment was effective and safe even in developing countries, but most of these women had significant disease; 25% had severe preeclampsia, and 75% required antihypertensive therapy. Despite the demonstrated efficacy of

magnesium sulfate, it can be challenging to determine when the risk of seizure occurrence is high enough to justify the use of magnesium. One large obstetric department observed a 50% increase in the incidence of eclampsia when magnesium prophylaxis was limited to women with severe disease.³³² It is difficult to rely on specific signs and symptoms of disease to decide on the need for prophylaxis.³³³⁻³³⁵ In one study, 17% of women with eclampsia did not have headaches, 80% did not have epigastric pain, and 20% had normal deep tendon reflexes (Table 48-4). This information adds to the data from Chesley, who showed that 24% of patients had no proteinuria before seizure activity.²³⁶

Most U.S. investigators recommend prophylactic anticonvulsant therapy for all women with a diagnosis of mild or severe preeclampsia. This approach includes women for whom the risks of treatment may exceed the risk of seizures. The anticonvulsant agent must be extremely safe for the mother, with safety of the fetus and neonate considered as the next criterion.

Magnesium Sulfate. Magnesium sulfate is the first-line agent for seizure prophylaxis in preeclampsia. Its pharmacokinetic processes during pregnancy are well established, as are its efficacy and its safety for the mother and fetus.

Pharmacokinetics, Mechanism of Action, and Maternal Side Effects. The volume of distribution of magnesium is greater than that of sucrose, indicating that the distribution of this ion goes beyond extracellular fluid and enters bones and cells.³³³ Magnesium circulates largely unbound to proteins and is almost exclusively excreted in urine. It is reabsorbed in the proximal tubule by a process limited by transport maximum (T_{max}), and its excretion increases as the filtered load increases above the T_{max} .³³⁴ In patients with normal renal function, the half-time for excretion is about 4 hours.³³³ Because excretion depends on delivery of a filtered load of magnesium that exceeds the T_{max} , the half-time of excretion is prolonged in women with a decreased GFR.

Elevated serum magnesium concentrations act on cell membranes to slow or block neuromuscular and cardiac conducting system transmission, decrease smooth muscle contractility, and depress central nervous system irritability. These actions produce the desired anticonvulsant effect but also cause decreased uterine and myocardial contractility, respiratory depression, and interference with cardiac conduction. These effects occur at different serum magnesium concentrations (Table 48-5). Blood pressures are not appreciably lowered by prophylactic magnesium doses.

TABLE 48-5 Effects Associated with Various Serum Magnesium Levels

Effect	Serum Level (mEq/L)
Anticonvulsant prophylaxis	4-6
Electrocardiographic changes	5-10
Loss of deep tendon reflexes	10
Respiratory paralysis	15
Cardiac arrest	>25

Depression of deep tendon reflexes occurs at serum concentrations lower than those associated with adverse cardiac and respiratory effects. The presence of deep tendon reflexes indicates that the serum magnesium concentration is not dangerously high. If deep tendon reflexes are lost, serum magnesium concentration may be greater than 10 mEq/L, but brisk deep tendon reflexes do not signify an inadequate magnesium dosage.

Dosage. In the United States, magnesium sulfate is routinely given intravenously rather than by more painful intramuscular injections. A typical loading dose is 4 to 6 g given intravenously over 15 to 30 minutes, followed by 1 to 2 g/hr as a continuous infusion. Magnesium is administered by continuous infusion because intermittent bolus infusions result in only transient elevations of magnesium levels. To ensure consistent infusion and to avoid inadvertent administration of large doses of magnesium, mechanically controlled infusion is mandatory. In all patients, deep tendon reflexes and respiratory status should be regularly monitored (at least every 2 hours).

Based on extensive experience, intravenous administration of magnesium at doses up to 2 g/hr appears to be safe if renal function is normal. The rate of infusion should be modified for patients with compromised renal function. If the maternal creatinine level is greater than 1.0 mg/dL, consideration should be given to limiting the infusion rate to 1 g/hr. Clinicians may need to use serum magnesium levels to monitor for overdosage in these cases.

If overdosage occurs (especially with apnea), calcium gluconate (10 mL of a 10% solution injected intravenously over 3 minutes) is an effective antidote. The therapeutic concentrations of magnesium are the doses that are usually effective and safe (Table 48-6). No study has compared magnesium concentrations in patients successfully or unsuccessfully treated with magnesium sulfate, and we do not recommend titrating levels to any specific therapeutic range. Unfortunately, magnesium is not a perfect anticonvulsant, and some women have convulsions despite high serum concentrations.³³⁵

Fetal and Neonatal Effects. Magnesium sulfate therapy at effective anticonvulsant doses is safe for the fetus and neonate. Neonatal serum magnesium concentrations are almost identical to those of the mother.³³⁶ Fetal serum magnesium levels do not increase with prolonged infusion, and there is no evidence of cumulative effects on the neonate with prolonged magnesium seizure prophylaxis.

In a study of 118 infants of mothers treated with magnesium sulfate, the average serum magnesium concentration was 3.7 mEq/L. The magnesium level did not correlate with Apgar scores.³³⁷ Administration of magnesium to the preterm fetus offers neuroprotection against cerebral palsy.³³⁸

Phenytoin. Phenytoin is an effective anticonvulsant, and several small studies have shown no obvious adverse fetal or

TABLE 48-6 Safety and Efficacy of Intravenous Magnesium Sulfate Therapy

Treated	1870
Seizures	11 (0.6%)
Seizure morbidity	1 (0.05%)
Treatment morbidity	0

maternal effects with the use of this agent.^{339,340} Although phenytoin is not as effective as magnesium for prophylaxis or treatment of eclampsia,^{328,329} it may be used when magnesium sulfate therapy is inappropriate, such as in cases of myasthenia gravis, compromised renal function, or significant pulmonary concerns.

Anticonvulsant Therapy Comparison. Magnesium is more effective than phenytoin or benzodiazepine to treat eclamptic seizures.³³⁰ If a patient already receiving magnesium has an eclamptic seizure, it is best to terminate it with another anticonvulsant agent, such as 5 to 10 mg of diazepam (Valium), 4 mg of lorazepam,³⁴¹ or a short-acting barbiturate such as 125 mg of intravenous pentobarbital. If these measures fail, general anesthesia may be necessary to terminate the seizure activity.

Because most seizures terminate spontaneously within 1 to 2 minutes, the most important therapy involves avoidance of injury and protection of the airway to prevent aspiration. These measures should be initiated before pharmacologic therapy.

Antihypertensive Therapy. Antihypertensive agents are not routinely administered to preeclamptic women. There are no proven fetal benefits to therapy and no clear evidence that lowering blood pressure reduces the risk of seizure activity. The goal of antihypertensive treatment is prevention of intracranial bleeding and stroke.

Therapy is reserved for women in whom blood pressure is persistently higher than 160 systolic mm Hg or higher than 105 to 110 mm Hg diastolic, the levels associated with intracranial bleeding and stroke, for more than 15 minutes.^{343,344} The goal of therapy is to reduce blood pressures to a level that provides a margin of maternal safety (i.e., 135 to 145 mm Hg systolic and 95 to 100 mm Hg diastolic) without compromising adequate uterine perfusion. Because these patients have elevated blood pressure with reduced plasma volume, overly aggressive treatment can lower maternal cardiac output and uterine perfusion, potentially resulting in fetal compromise.

The American College of Obstetricians and Gynecologists (ACOG) has outlined the need for rapid treatment of hypertensive emergency.³⁴⁵ The ACOG Committee created specific order sets for treatment with labetalol or hydralazine, and these specifications should be followed for appropriate intervention when faced with this potentially catastrophic complication of pregnancy.

Several agents available for reducing blood pressure rapidly are listed in Tables 48-7 and 48-8. Not listed are potent diuretic agents that lower blood pressure rapidly by depleting plasma volume, because the use of these agents in the plasma volume-depleted patient may reduce maternal cardiac output and uterine perfusion.

TABLE 48-7 Drugs for Treatment of Hypertensive Emergencies

Drug	Intramuscular Dosage	Intravenous Dosage	Interval between Doses	Mechanism of Action
Hydralazine	10-50 mg	5-20 mg	3-6 hr	Direct dilation of arterioles
Sodium nitroprusside	—	IV solution, 0.01 g/L; IV infusion rate, 0.25-8 µg/kg/min	—	Direct dilation of arterioles and veins
Labetalol	—	20-80 mg	3-6 hr	α- and β-Adrenergic blocker
Nifedipine	—	10 mg orally	4-8 hr	Calcium channel blocker

TABLE 48-8 Time Course of Action for Hypertensive Emergency Medications

Drug	Onset	Maximum	Duration
Hydralazine	10-20 min	20-40 min	3-8 hr
Sodium nitroprusside	0.5-2 min	1-2 min	3-5 min
Labetalol	1-2 min	10 min	6-16 hr
Nifedipine	5-10 min	10-20 min	4-8 hr

Hydralazine. As a direct vasodilator, hydralazine offers two major advantages. First, vasodilation results in a reflex increase in cardiac output and increased uterine blood flow even as blood pressure decreases. Second, the increase in cardiac output blunts the hypotensive effect and makes it difficult to overdose the patient. Two of the side effects of hydralazine, headache and epigastric pain, may be confused with worsening preeclampsia.

The pharmacokinetic profile of hydralazine is outlined in Tables 48-7 and 48-8. The onset of action is 10 to 20 minutes, with peak action 20 minutes after administration and a duration of action of 3 to 8 hours.

On the basis of the pharmacokinetics, the use of continuous intravenous infusions of hydralazine is not sensible because minute-to-minute control cannot be attained. An alternative approach is to administer the drug as a bolus infusion, which is repeated at 20-minute intervals until the desired control is attained and then repeated as necessary. A test dose of 1 mg is given over 1 minute with close blood pressure monitoring; 5 to 10 mg is then infused over 2 to 4 minutes. After 20 minutes, the blood pressure is determined and the following criteria for action are taken into account: The dose is repeated if no effect is obtained, a second smaller dose is administered if a suboptimal effect is noted, and further treatment is held if the diastolic blood pressure decreases to <100 mm Hg.

Labetalol. Labetalol is a mixed α-adrenergic and β-adrenergic antagonist that is useful for reducing blood pressure acutely. It is given intravenously as a bolus infusion beginning with 10 to 20 mg, followed by doses that may be doubled every 10 minutes as needed (up to 80 mg at a time with a maximum dose of 300 mg total) to achieve the desired effect.³⁴⁶ The major reservation with the use of labetalol is that it does not reduce afterload, unlike the vasodilators hydralazine and nifedipine.

Other Drugs. If hydralazine is ineffective, therapy with labetalol is usually initiated, or vice versa. However, if blood pressure control is not adequate after the administration of 20 mg of hydralazine and 80 mg of labetalol, other agents may be used, usually the calcium channel blocker nifedipine. Nifedipine may be used in doses of 10 mg orally, with repeat doses every 30 minutes as needed. For maintenance dosing, 10 to 20 mg can be given every 3 to 6 hours. It is quite effective

and well tolerated, and headache is the most common side effect.³⁴⁷

Management of Oliguria. In preeclamptic women, oliguria can have a prerenal or renal origin (see Chapters 57 and 71). Despite the fact that preeclamptic patients are plasma volume depleted, the use of fluids is controversial because excessive fluid infusion can lead to congestive heart failure and perhaps cerebral edema.³⁴⁸ Nevertheless, oliguria can be corrected in many patients by the use of intravenous fluids. To prevent complications, physicians should avoid the use of hypotonic fluids, which tend to worsen dilutional decreases in serum osmolality that may occur with oliguria from renal causes, elevated levels of antidiuretic hormone (ADH), or oxytocin treatment.

When oliguria is of renal origin, patients are at risk for fluid overloading. Because acute renal failure resulting in permanent renal damage is rare in pregnancy, whereas pulmonary edema is a relatively frequent complication, oliguria should be defined conservatively as urine output of less than 20 to 30 mL/hr for 2 hours.

If there are no clinical signs or history of congestive heart failure, 1000 mL of isotonic crystalloid can safely be infused in 1 hour. If urine output increases, fluid infusion is maintained at 100 mL/hour. If the oliguria does not resolve, further fluid infusion should be guided by central venous or preferably by pulmonary wedge pressures (see Chapter 71).

Relatively small amounts of intrapartum and postpartum blood loss can result in profound hypovolemia and shock in these patients, who already have compromised blood volumes. A large peripheral line should be in place at all times in the event that rapid replacement of blood volume becomes necessary.

Management of Less Common Problems

Disseminated Intravascular Coagulation. Evidence of DIC is an important indicator of severe, progressive preeclampsia. DIC is identified in 20% of severely preeclamptic and eclamptic women but is sufficient to cause overt coagulation problems in less than 10%.

The definitive therapy for DIC is removal of the inciting factor. In preeclampsia, the inciting factor is pregnancy related, and definitive therapy is termination of the pregnancy. Because long-term follow-up of women with preeclampsia indicates that all organ system functions return to normal, it is unlikely that occlusion of the microvasculature by thrombi in mild forms of DIC causes permanent damage.

Evidence of early DIC is not by itself an absolute indication for immediate delivery. With rapidly deteriorating renal or hepatic function or DIC complicated by spontaneous hemorrhage, delivery should be aggressively pursued. If procoagulants decrease to a level associated with spontaneous hemorrhage, appropriate procoagulant therapy should be given before

delivery, whether the anticipated mode of delivery is vaginal or cesarean section (see Chapter 53).

Pulmonary Edema. Pulmonary edema occurs in only a few women with preeclampsia, but it may be associated with high rates of maternal morbidity and mortality. Iatrogenic fluid overload is frequently to blame, but other causes are possible, including cardiogenic and noncardiogenic sources (e.g., decreased colloid oncotic pressure, pulmonary vascular leakage). Pulmonary edema is not uncommon as the patient enters a phase of postpartum diuresis, and clinicians must be cognizant of the possibility of this delayed complication arising even as the other concerns of preeclampsia are abating.

Management of pulmonary edema requires intensive monitoring, including accurate assessment of pulmonary and cardiac function and the ability to perform mechanical ventilation as needed (see Chapter 71). With these interventions, the mortality rate for pulmonary edema in preeclampsia has been greatly reduced.³⁴⁹

Postpartum Management in Preeclampsia. Delivery does not immediately reverse the pathophysiologic changes of preeclampsia, and it is necessary to continue palliative therapy for various periods. Approximately one third of convulsions occur in the postpartum period, most within 24 hours and almost all within 48 hours, although there are rare exceptions. Most physicians advocate continuing anticonvulsant therapy for 24 hours after delivery, but it may soon be possible to limit treatment as we become better at predicting maternal morbidity. In a prospective, multicenter study of women with preeclampsia, the fullPIERS (preeclampsia integrated estimate of risk) model was developed with the aim of identifying the risk of fatal or life-threatening complications within 48 hours of hospital admission.³⁵⁰ Predictors of adverse maternal outcome included gestational age, chest pain or dyspnea, oxygen saturation, platelet count, and creatinine and AST concentrations.³⁵⁰ This model holds the potential for identifying women at increased risk for adverse outcomes up to 7 days before such complications arise. It may permit a change in the setting of care, affect the timing of delivery, or pinpoint the patients in whom postpartum seizure prophylaxis is truly indicated.

Some of the constraints on therapy are eliminated by delivery of the fetus. For simplicity, magnesium sulfate therapy is usually continued, although any safe anticonvulsant regimen is reasonable at this time without consideration of fetal effects. Anticonvulsant efficacy rather than sedation is the goal, and barbiturate anticonvulsants in usual therapeutic doses require days to achieve effective levels. Similarly, phenytoin must be administered intravenously in large doses to achieve therapeutic levels within hours, with the attendant dangers of cardiac arrhythmia. Because serum magnesium concentrations decrease with increased urinary output, it is extremely unlikely that serum magnesium concentrations are therapeutic at usual doses in the setting of puerperal diuresis. However, convulsions rarely occur in the postpartum period, suggesting that rapid diuresis indicates resolution of the preeclamptic process.

On the basis of these considerations, it appears reasonable to discontinue magnesium sulfate therapy when diuresis occurs. Some physicians recommend continuing therapy for longer than 24 hours in selected patients, but it is difficult to determine the basis on which this selection can be made. In one randomized trial that was limited to subjects with mild preeclampsia, no difference in seizure risk was observed when magnesium was

discontinued after only 12 hours.³⁵¹ Unfortunately, this study was limited by a relatively small sample, and it is likely that any future studies will be similarly underpowered due to the rarity of the outcome.

Hypertension may take considerably longer than 24 to 48 hours to resolve. Women who are hypertensive 6 weeks after delivery may ultimately be normotensive at long-term follow-up.³⁵² Therapy is still indicated in patients with blood pressures greater than 160 mm Hg systolic or 105 mm Hg after the birth, but the fetus no longer influences therapeutic choices. If rapid blood pressure control is necessary, sodium nitroprusside is more effective and better tolerated than hydralazine. Conventional oral antihypertensive agents (e.g., angiotensin-converting enzyme [ACE] inhibitors, diuretics, metoprolol) can be started to achieve adequate control. The patient must be warned about the symptoms of hypotension, and she should be seen at weekly intervals because the need for therapy diminishes rapidly in some cases.

Therapies No Longer Recommended. Strict sodium restriction and diuretic therapy have no role in the prevention or treatment of preeclampsia. In particular, diuretics should not be given because plasma volume is already limited, and further volume depletion could adversely affect the fetus.

The antihypertensive agents sodium nitroprusside and diazoxide are likewise no longer recommended. With sodium nitroprusside, fetal concentrations of serum cyanide, sometimes to toxic levels, have been reported in animal studies.³⁵³ Diazoxide is rarely used because of its effects on maternal and fetal carbohydrate metabolism and its profound and slowly reversible effects on blood pressure.

There is little evidence that therapeutic efforts alter the underlying pathophysiology of preeclampsia. Therapeutic intervention for clinically evident preeclampsia is palliative. At best, it may slow the progression of the condition, enabling prolongation of the pregnancy. Bed rest is a usual and reasonable recommendation, although its efficacy is not clearly established.³⁵⁴ Anecdotal reports of clinical improvement with bed rest must be tempered by the recognition of the unpredictable course of preeclampsia.

PROGNOSIS FOR PREECLAMPSIA

Short-term Prognosis

Perinatal Mortality. The perinatal mortality rate is higher for infants of preeclamptic women regardless of the gestational age at delivery.³⁵⁵⁻³⁵⁷ In a study that reviewed 10,614,679 singleton pregnancies in the United States delivered after 24 weeks' gestation, the relative risk for fetal demise was 1.4 for gestational hypertensive disorders and 2.7 for chronic hypertensive disorders compared with normotensive controls. Causes of perinatal death include placental insufficiency and abruptio placentae³⁵⁸ (which cause intrauterine death before or during labor) and prematurity. Predictably, the mortality rate is higher for infants of women with more severe forms of the disorder. At any level of disease severity, the perinatal mortality rate is greatest for women with preeclampsia superimposed on preexisting vascular disease.

Over the past 35 years, the stillbirth rate attributable to preeclampsia has declined dramatically. However, infants born of preeclamptic pregnancies continue to have an approximately twofold increased risk of neonatal death.³⁵⁹

IUGR is more common in infants born to preeclamptic women (see Chapter 47), particularly with severe disease and early gestational age at diagnosis.³⁶⁰ As with perinatal mortality, IUGR is most common in infants of women with chronic hypertension with superimposed preeclampsia.³⁶¹

Improved medical and obstetric management and improved assessment of fetal well-being in the antepartum and intrapartum periods have contributed to the decreased stillbirth rate. The primary impact on perinatal mortality rate, however, comes from improvements in neonatal care.

Evidence suggests that the offspring of women with preeclampsia may have long-term effects beyond those related to prematurity. For example, in a mouse model, exposure to maternal obesity and sFLT1-induced preeclampsia led to alterations in blood pressure, metabolic, inflammatory, and atherosclerotic profiles in offspring at 6 months of age.³⁶²

Maternal Mortality. Maternal death associated with preeclampsia results predominantly from complications of abruptio placentae, hepatic rupture, and eclampsia. Historically, the mortality rate for eclampsia was 20% to 30% with expectant management only and 10% to 15% when profound maternal sedation was used for treatment. The change to magnesium as the exclusive therapeutic agent in the 1920s and 1930s resulted in a dramatic decrease in the maternal mortality rate to 5%, primarily due to reduced maternal sedation with this agent.²⁰ The current combination of magnesium sulfate and antihypertensive drugs followed by timely delivery has produced a maternal mortality rate of almost zero.^{70,363}

Long-term Prognosis

Preeclampsia and Later Life Cardiovascular Disease. There is evidence that preeclampsia is associated with long-term maternal health consequences. Although Chesley³⁵² found no increased risk of subsequent chronic hypertension for women with eclampsia in their first pregnancy, mortality was twofold to fivefold higher over the next 35 years among women with eclampsia in any pregnancy after the first (Fig. 48-14). Chesley's findings led to speculation that multiparous women with preeclampsia or eclampsia are more likely to have had unrecognized underlying chronic hypertension and that this, not preeclampsia, caused the subsequent increase in mortality. Similarly, Sibai and colleagues found that women with recurrent preeclampsia are more likely to develop chronic hypertension.³⁶⁴ These studies led to the statement by The National High Blood Pressure Education Program's Working Group on High Blood Pressure During Pregnancy that recurrent hypertension in pregnancy, preeclampsia in a multipara, and early-onset disease may all herald increased future health risks.²

Nulliparous women with preeclampsia alone were initially not thought to have increased risk of later vascular disease. This was refuted by a report from Norway³⁶⁵ that showed a modest (1.65-fold) increased cardiovascular mortality associated with preeclampsia at term and an eightfold increased risk when preeclampsia was severe enough to lead to preterm delivery. Scottish investigators likewise reported a fourfold increased risk (OR = 3.98; CI, 2.82 to 5.61) of subsequent hypertension for nulliparous women with preeclampsia,³⁶⁶ whereas Funai and colleagues described excess long-term mortality in this population largely due to a threefold increase in deaths from cardiovascular disease.³⁶⁷ Other reports also support a link between preeclampsia and maternal ischemic heart disease,^{368,369}

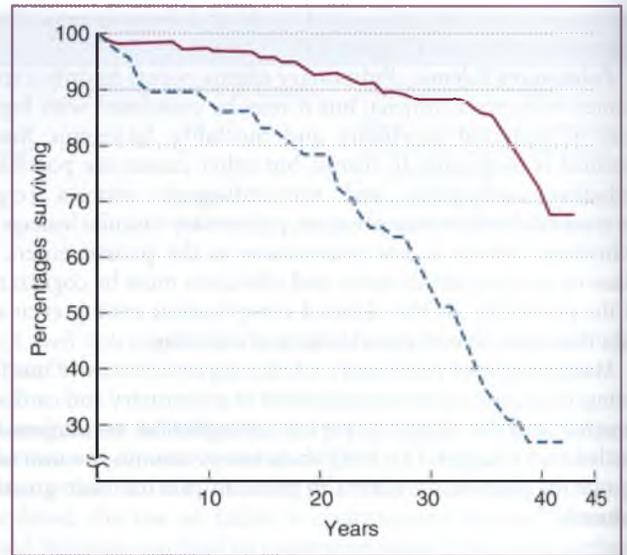

Figure 48-14 Eclampsia survivorship. Survivals are plotted for women with eclampsia in the first pregnancy (solid line) and those with eclampsia in a later pregnancy (dashed line). Survival of women with first-pregnancy eclampsia was not different from survival of those in a control group. (From Chesley LC, Annitto JE, Cosgrove RA: *The remote prognosis of eclamptic women: sixth periodic report*, Am J Obstet Gynecol 124:446, 1976.)

sometimes evident 20 years after the preeclamptic pregnancy and coincident with the onset of menopause.^{367,369} This relationship is particularly strong in women with a family history of cardiovascular disease.³⁷⁰

Obesity is a known risk factor for preeclampsia and cardiovascular disease. Although the increased risk of death for postmenopausal women is attenuated by controlling for obesity, this risk is not fully explained by obesity alone.³⁷¹ The findings linking obesity, insulin resistance, and preeclampsia are part of an interesting relationship between preeclampsia and the metabolic or insulin resistance syndrome.³⁷² This syndrome consists of obesity, hypertension, dyslipidemia (i.e., increased LDL cholesterol, decreased HDL cholesterol, and increased triglycerides), and increased uric acid levels, findings that are common among women with preeclampsia.³⁷² It has been well-established that this syndrome predisposes patients to cardiovascular disease in later life. An increased risk of preeclampsia is linked to other conditions with a similar predisposition, such as elevated homocysteine levels³⁷³; evidence of androgen excess, including polycystic ovarian syndrome³⁷⁴; elevated testosterone levels³⁷⁵; male fat distribution³⁷⁶; lipoprotein lipase mutations³⁸³; and elevations in sFLT1 levels.³⁷⁷

Women who are apparently healthy years after a preeclamptic pregnancy may nevertheless demonstrate subtle metabolic and cardiovascular abnormalities. Compared with women with uncomplicated pregnancies, formerly preeclamptic women have evidence of endothelial dysfunction,^{378,379} higher blood pressures,³⁷⁸ increased insulin resistance,³⁸⁰ dyslipidemia,³⁸¹ altered angiogenic factors,³⁸² and increased antibodies to the angiotensin 2 receptor.³⁸³ These data may explain the shared risk factors for preeclampsia and cardiovascular disease, but alternative explanations (e.g., preeclampsia causes vascular injury that

increases cardiovascular risk, normal pregnancies have a protective effect) are also plausible.

Follow-up in Preeclampsia. Because early recognition and treatment of significant blood pressure elevations reduce lifetime morbidity, all women with a clinical diagnosis of preeclampsia deserve long-range follow-up. The woman who is normotensive 12 weeks after delivery should be advised of her increased risk for hypertension in later life³⁶⁶ and should be counseled to have her blood pressure checked at least yearly. Because of the association between preeclampsia and later cardiovascular disease,³⁶⁷ formal assessment of cardiovascular risk factors in these patients is prudent.

Recurrence in Subsequent Pregnancies

The likelihood of recurrent preeclampsia is influenced by the certainty and severity of the clinical diagnosis in the first pregnancy. Of 225 women with hypertension during pregnancy, 70% experienced recurrence in their next pregnancy.³⁸⁴ In a study of primiparas diagnosed with severe preeclampsia, the recurrence rate was 45%.³⁶⁴ These groups probably included patients with unrecognized preexisting blood pressure elevation or underlying renal or cardiovascular disease.

Recurrence rates were reported in 2006 from a study of 896 parous women in Iceland according to standardized diagnostic criteria (National High Blood Pressure Criteria) in both pregnancies.³ The rates of recurrence differed substantially by the diagnosis in the first pregnancy (Table 48-9).³⁸⁵

Emerging evidence suggests that the earlier the gestational age of diagnosis, the more likely the risk of recurrence. Women with preeclampsia who delivered after 37 weeks' gestation had a 14.1% overall risk of developing preeclampsia in the second pregnancy. This risk increased to 37.9% for preeclamptic women who delivered before 28 weeks (OR = 3.90; 95% CI, 2.50 to 6.05).³⁸⁶

To determine the subsequent pregnancy outcomes of women with eclampsia, Chesley³⁸⁷ followed 270 women for more than 40 years (only 2 were lost to follow-up). Among 187 women who had eclampsia in their first pregnancies, 33% had some hypertensive disorder in a subsequent pregnancy. In most, the condition was not severe, but 5% had recurrent eclampsia. Of the 20 women with eclampsia as multiparas, recurrent hypertension occurred in 50% of subsequent pregnancies.

Women with a clinical diagnosis of preeclampsia have an increased risk of hypertensive disorders in subsequent pregnancies. The chance of recurrence decreases as the likelihood of true

preeclampsia increases and increases when the disease occurs in the late second or early third trimester.³⁸⁸ However, if the condition does recur, it usually will not be worse and, in most cases, will be less severe. The recurrence of severe preeclampsia or eclampsia in one pregnancy predicts its likely recurrence in subsequent pregnancies. There is also a risk of adverse outcomes in subsequent pregnancies even if preeclampsia does not recur. In a nationwide Swedish cohort ($N = 354,676$), women with prior preterm preeclampsia had more than doubled risks of stillbirth, placental abruption, and preterm births and had an even greater risk of giving birth to a small-for-gestational-age infant despite the absence of preeclampsia.³⁸⁹

PREVENTION OF PREECLAMPSIA

Since preeclampsia was first recognized, numerous approaches to prevention have been used. Sodium restriction and nutrient supplements have been unsuccessful.²⁰

To determine the benefit of aspirin, more than 35,000 women have been included in randomized, controlled trials of various sizes and quality.³⁹⁰ Small, single-center studies suggested benefit,³⁹¹⁻³⁹³ but larger, multicenter trials showed none.^{33,218} Meta-analyses of these trials indicated benefit of aspirin in reducing the frequency of preeclampsia diagnosis, preterm delivery, and growth-restricted infants.^{390,394} Seventy-two subjects needed to be treated to prevent one case of preeclampsia. There was a 14% reduction in fetal and neonatal deaths, with a number needed to treat of 243 to prevent one death. Using a meta-analysis of individual patient data, the PARIS Collaborative Group confirmed a reduction of preterm birth and the incidence of preeclampsia by a modest 10% with aspirin, but they showed no difference in perinatal death.³⁹⁵ The estimated number of women needed to treat to prevent one case of preterm birth in this study was 500 for low-risk pregnancies (incidence of 2%) and 50 for high-risk pregnancies (incidence of 20%).³⁹⁵ Given the lack of significant adverse effects evident with aspirin therapy, this degree of efficacy may warrant the therapy, especially in high-risk pregnancies.

Calcium supplementation was tested in a large, randomized, controlled trial in the United States.³⁹⁶ based on initial studies and a meta-analysis showing potential benefits.³⁹⁷ The conclusion of this study was unequivocal, showing no evidence that calcium reduces the incidence of preeclampsia, alters blood pressure, or affects fetal weight. The World Health Organization (WHO) carried out a subsequent trial of calcium supplementation in populations with low calcium intake. Treatment did not

TABLE 48-9 Types of Hypertensive Disorders of Pregnancy Occurring in Second Pregnancy Compared with Those in First Pregnancy

Disorder in Second Pregnancy*	Disorder in First Pregnancy				Total N = 896
	Gestational Hypertension n = 511	Preeclampsia or Eclampsia n = 151	Chronic Hypertension n = 200	Superimposed Preeclampsia n = 34	
Normal	153 (29.9%)	63 (41.7%)	24 (12%)	2 (5.9%)	242 (27%)
Gestational hypertension	239 (46.8%)	52 (34.4%)	69 (34.5%)	10 (29.4%)	370 (41.3%)
Preeclampsia	25 (4.9%)	17 (11.3%)	6 (3%)	4 (11.8%)	52 (5.8%)
Chronic hypertension	82 (16%)	16 (10.6%)	91 (45.5%)	14 (41.2%)	203 (22.7%)
Superimposed preeclampsia	12 (2.3%)	3 (2%)	10 (5%)	4 (11.8%)	29 (3.2%)
All recurrences	358 (70.1%)	88 (58.3%)	176 (88%)	32 (94%)	654 (73%)

*No women had eclampsia in their second pregnancy.

reduce the diagnosis of preeclampsia but did reduce other adverse outcomes.³⁹⁸ Calcium administration has therefore been proposed as a useful measure in populations consuming low levels of calcium.³⁹⁹

The results of antioxidant therapy are similar to those with calcium. An initial small trial of antioxidant vitamins C and E suggested benefit,⁴⁰⁰ but a subsequent larger trial did not.⁴⁰¹ Concerns regarding the safety of this therapy for the fetus were raised by an excess of low-birth-weight infants (but not IUGR or premature infants) in the antioxidant-treated group. The largest trial of low-risk women initiated antioxidant treatment far earlier in pregnancy than the other studies (start date at 9 to 16 weeks), with 40% of women enrolled before 12 weeks, whereas the other studies began at an average of 18 weeks.⁴⁰² This may be relevant because oxidative stress accompanies establishment of the intervillous circulation at 8 to 10 weeks' gestation.^{402,403} In this large trial, a total of 10,154 women underwent randomization, and outcome data were available for 9969 women.⁴⁰² There was no significant difference between the vitamin and placebo groups in the rates of preeclampsia (7.2% and 6.7%, respectively; relative risk = 1.07; 95% CI, 0.93 to 1.24),⁴⁰⁴ and rates of adverse perinatal outcomes were not significantly different between the groups.⁴⁰² In a later randomized trial, Vadillo-Ortega and colleagues added L-arginine to a food bar already containing antioxidants.⁴⁰⁵ The investigators hypothesized that by adding this amino acid, which is a substrate for nitric oxide synthase, endothelial function might be improved.⁴⁰⁵ Women at high risk for preeclampsia were randomized to one of three groups starting at about 20 weeks' gestation: daily food bars containing L-arginine and antioxidant vitamins, bars with only vitamins, or placebo bars.⁴⁰⁵ The proportion of women developing preeclampsia was 30.2% in the placebo group, 22.5% in the vitamin-only group (risk ratio = 0.74; 95% CI, 0.54 to 1.02), and 12.7% in the L-arginine plus vitamin group (risk ratio = 0.42; 95% CI, 0.28 to 0.62).⁴⁰⁵ The findings should be confirmed in a larger trial before this approach is attempted in practice, because overall effects of blood pressure were very modest, and the impact of L-arginine alone was not investigated.

The results of these studies raise several important points:

1. We should base clinical management on randomized clinical trials of appropriate populations and sizes to achieve sufficient power. Nonetheless, the success of management approaches in small trials but failure in large, multicenter trials may be related to the heterogeneity of preeclampsia.¹⁴⁰ Prophylaxis may be effective in a specific subset of women (e.g., calcium supplementation in women with low-average calcium intake).
2. Because the diagnosis of preeclampsia is based on signs that usually have minimal causal significance, prophylactic therapy should be aimed at the pathophysiologic abnormalities, with effects judged based on perinatal outcome.
3. The aspirin and calcium data suggest that initiation of therapy before disease is clinically evident may be successful in appropriately selected subjects.

Chronic Hypertension

Differentiation of chronic hypertension from preeclampsia can be difficult, and the discrimination between worsening chronic hypertension and the onset of superimposed preeclampsia is

even more complex. Accurate diagnosis is imperative because the rates of disease progression and effects on mother and infant of these conditions are very different. Management of the woman with hypertension in early pregnancy requires early recognition of blood pressure elevations, baseline testing to aid in the later diagnosis of superimposed preeclampsia, and meticulous maternal and fetal observation. If a decision is made to use antihypertensive therapy, drugs must be chosen on the basis of considerations specific to pregnancy.

EPIDEMIOLOGY

The prevalence of chronic hypertension increases with advancing age. For whites, the risk rises from 0.6% among women 18 to 29 years of age to 4.6% among those 30 to 39 years of age. African-American women have an even higher risk of chronic hypertension (2% and 22.3%, respectively).⁴⁰⁶ Hypertensive women are at an increased risk for preeclampsia, which occurs in 25% compared with 4% of previously normotensive women.

PATHOGENESIS

Effects of Chronic Hypertension on the Mother

Chronic hypertension in pregnancy has the same impact as blood pressure increases in any other 10-month period. Systolic and diastolic blood pressures that exceed 160 and 105 mm Hg, respectively, increase the risk of morbidity even in this short time period.

Maternal morbidity and mortality rates are greater in superimposed preeclampsia than in preeclampsia arising de novo. Blood pressure elevations with superimposed preeclampsia are also greater, increasing the possibility of intracranial bleeding. Two thirds of eclampsia cases occur in first pregnancies, but two thirds of maternal deaths due to eclampsia occur in pregnancies other than the first pregnancy, in which underlying hypertension is a more common disposing factor.⁴⁰⁷

In one review of 28 women with preeclampsia and stroke, systolic values ranged from 159 to 198 mm Hg. The range for diastolic values was even greater (81 to 133 mm Hg), but only five patients had diastolic values greater than 105 mm Hg.³⁴⁴ Morbidity is difficult to predict by blood pressures alone, although complications seem to be significantly more likely when systolic pressures exceed 160 mm Hg.³⁴⁴ The National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy recommended initiating therapy when systolic pressures exceed 150 to 160 mm Hg or diastolic pressures exceed 100 to 110 mm Hg.

Effects of Chronic Hypertension on the Fetus

The perinatal mortality rate for infants born to hypertensive mothers increases as maternal blood pressure rises.⁶⁶ Without antihypertensive therapy, a woman with a systolic pressure of 200 mm Hg or a diastolic pressure of 120 mm Hg has only a 50% chance of delivering a living infant. The perinatal mortality rate is even higher among hypertensive women with proteinuria, indicating the important effect of preexisting renal disease or superimposed preeclampsia on the fetus.

The perinatal mortality rate for infants of women with chronic hypertension and superimposed preeclampsia is greater than that for infants of women in whom the condition arises de novo.⁴⁰⁴ This difference has two explanations. First, the

decidual vessels of women with even mild preexisting hypertension demonstrate vascular changes similar to the changes in renal arterioles seen in women with long-standing hypertension.⁴⁰⁸ The resulting decrease in uteroplacental perfusion may be additive to and perhaps synergistic with the decidual vascular changes of preeclampsia, possibly explaining the higher incidence of abruptio placentae among women with superimposed preeclampsia. Second, preeclampsia frequently appears earlier in gestation in hypertensive women than in normotensive women, and fetal growth restriction is more common and frequently more severe in these infants.⁶⁶

Some investigators suggest that hypertension without preeclampsia has no adverse effect on the fetus,^{246,409} but this does not apply if the fetus is growth restricted. In a study of almost 300 pregnancies of women with chronic hypertension, perinatal death affected only growth-restricted babies.⁴¹⁰

MANAGEMENT

Antihypertensive Therapy to Reduce Maternal and Fetal Morbidity and Mortality

Antihypertensive therapy reduces maternal mortality as effectively during pregnancy as at any other time. Lowering of markedly elevated blood pressure (>160 mm Hg systolic pressure or 100 mm Hg diastolic pressure) can reduce morbidity over 10 months, and antihypertensive therapy in women with even mild to moderate hypertension can reduce the risk of severe hypertension in later pregnancy.⁴¹¹

Antihypertensive therapy could benefit mother and fetus if it resulted in a reduction in the incidence of superimposed preeclampsia. Unfortunately, such a reduction has not been evident in large studies. A Cochrane Review indicates no reduction of perinatal mortality by antihypertensive therapy, but only 2 of the 46 studies included therapy initiated in the first trimester.⁴¹¹ Because pathologic and pathophysiologic changes occur as early as 14 weeks' gestation, initiation of antihypertensive therapy after the first trimester may be too late to be effective. No clinical studies have shown increased perinatal mortality rates with antihypertensive therapy.^{412,413} If therapy is indicated for maternal considerations, it is safe for the fetus as long as the choice of drug is appropriate.⁴¹⁴ Some clinicians have suggested that antihypertensive therapy may be associated with an increased risk of small-for-gestational-age infants, but this risk is minimal and driven largely by therapy with β -blockers, specifically atenolol.⁴¹⁵

Antihypertensive medication is reserved for women with systolic pressures above 160 mm Hg and diastolic pressures above 90 to 100 mm Hg. Women using antihypertensive therapy when they become pregnant, regardless of pretreatment blood pressure, are best served by continuation of therapy. There is no evidence that antihypertensive therapy presents a substantial risk to the fetus, and discontinuation of therapy could adversely affect long-range compliance with drug therapy, increasing the risk to the mother.

Choice of Antihypertensive Agents

Effect on the Fetus. Fetal considerations, particularly teratogenic concerns, influence the choice of antihypertensive agents. Few of the available antihypertensive agents have been associated with morphologic teratogenic effects, but the ACE inhibitors are exceptions. Because development does not end after delivery, long-term follow-up of infants and children treated in

utero is required. This information is available only for α -methyl dopa. Children of mothers treated with this agent during pregnancy showed no signs of neurologic or somatic abnormalities when examined at age 7 years.⁴¹⁶

Maternal drug therapy has pharmacologic effects on the fetus. For example, maternal treatment with propranolol reduced fetal and maternal cardiac output in animal studies.⁴¹⁷ Because of the potential pharmacokinetic differences between mother and fetus, appropriate dosing for the mother may be excessive for the fetus.⁴¹⁸

Effect on Uterine Blood Flow. Maternal medication may affect fetal well-being by altering uterine blood flow. Antihypertensive drugs act by reducing cardiac output or systemic vascular resistance, both of which may affect blood flow to the uterus. Optimal drug choices in pregnancy require avoidance of agents that reduce uterine and uteroplacental blood flow. Agents that reduce cardiac output are therefore best avoided, but antihypertensive drugs that act on total peripheral resistance may increase, decrease, or have no effect on uterine perfusion, depending on the pattern of blood flow redistribution.

Reliable information regarding the effects of antihypertensive drugs on human uterine blood flow is scant. Studies of these drugs have involved pregnant animals, with an assumption that humans and sheep respond identically, or a comparison of blood flow to the kidney (an exquisitely autoregulated organ that usually receives 10% of cardiac output) with that of the uterus (an organ whose perfusion increases 500-fold over several months). With these limitations, Tables 48-10 and 48-11 outline the available information about antihypertensive agents used in pregnancy.

Specific Drugs

Diuretics. Diuretics are used frequently in nonpregnant patients as antihypertensive therapy, and their efficacy, safety, and tolerability are extensively documented.⁴¹⁹ The combination of diuretics with other antihypertensive drugs allows the use of lower doses of these agents. However, the indiscriminate use of diuretic agents during pregnancy has appropriately been condemned. In an epidemiologic assessment of 8000 pregnancies, a small but significant increase in the perinatal mortality rate was demonstrated for women receiving continued or intermittent diuretic therapy, especially when the drug was begun late in pregnancy.⁴²⁰ In women taking diuretics from early pregnancy onward, the plasma volume does not expand as much as in normal pregnancy,^{294,421} a phenomenon that may have adverse prognostic significance.^{422,423}

Some clinicians have recommended that diuretics be avoided entirely during pregnancy,^{246,424} although their concerns have only a theoretical basis. When continuous diuretic therapy is begun before 24 to 30 weeks' gestation, there is no evidence of an increased perinatal mortality rate or decreased neonatal weight.^{237,239} Despite the apparent safety, the theoretical concerns are enough to militate against the routine use of diuretics as initial therapy early in pregnancy. Perhaps more importantly, therapy should never be instituted if there is any evidence of reduced uteroplacental perfusion, such as with fetal growth restriction or preeclampsia. Diuretic therapy increases serum levels of uric acid, which renders uric acid determinations invalid for evaluation of superimposed preeclampsia.

β -Adrenergic Antagonists. β -Adrenergic antagonists are the initial antihypertensive agents for nonpregnant patients in

TABLE 48-10 Antihypertensive Agents Used in Pregnancy

Agent	Mechanism of Action	Cardiac Output	Renal Blood Flow
Thiazide	Initial: decreased plasma volume and cardiac output Later: decreased systemic vascular resistance	Decreased Unchanged	Decreased Unchanged or increased
Methyldopa	False neurotransmission, CNS effect	Unchanged	Unchanged
Hydralazine	Direct peripheral vasodilation	Increased	Unchanged or increased
Prazosin	Direct vasodilator and cardiac effects	Increased or unchanged	Unchanged
Clonidine	CNS effects	Unchanged or increased	Unchanged
Propranolol	β -Adrenergic blockade	Decreased	Decreased
Labetalol	α - and β -Adrenergic blockade	Unchanged blockade	Unchanged
Reserpine	Depletion of norepinephrine from sympathetic nerve endings	Unchanged	Unchanged
Enalapril	Angiotensin-converting enzyme inhibitor	Unchanged	Unchanged
Nifedipine	Calcium channel blocker	Unchanged	Unchanged

CNS, central nervous system.

TABLE 48-11 Side Effects of Antihypertensive Agents Used in Pregnancy

Agent	Maternal	Neonatal
Thiazide	Electrolyte depletion, serum uric acid increase, thrombocytopenia, hemorrhagic pancreatitis	Thrombocytopenia
Methyldopa	Lethargy, fever, hepatitis, hemolytic anemia, positive Coombs' test result	
Hydralazine	Flushing, headache, tachycardia, palpitations, lupus syndrome	
Prazosin	Hypotension with first dose; little information on use in pregnancy	
Clonidine	Rebound hypertension; little information on use in pregnancy	
Propranolol	Increased uterine tone with possible decrease in placental perfusion	Depressed respiration
Labetalol	Tremulousness, flushing, headache	Depressed respiration
Reserpine	Nasal stuffiness, depression, increased sensitivity to seizures	Nasal congestion, increased respiratory tract secretions, cyanosis, anorexia
Enalapril	Hyperkalemia, dry cough	Neonatal anuria
Nifedipine	Orthostatic hypotension, headache, tachycardia	None demonstrated in humans

many settings. These agents act by reducing cardiac output and perhaps by interfering with renin release.

Infants born to women treated with β -blockers in pregnancy have an increased risk of delivering growth-restricted infants compared with women treated with placebo or other antihypertensive agents.^{425,426} This adverse effect is primarily seen with the use of atenolol.⁴¹⁵ The β -adrenergic antagonists vary according to their β_1 -adrenergic subtype and lipid solubility. For example, atenolol more readily crosses the placenta than does metoprolol. Some of the β -adrenergic antagonists also have β -agonist effects. Theoretical and empirical decisions about the safety and efficacy of these drugs require evaluation of the pharmacologic characteristics of each agent rather than consideration of the drug class.

Labetalol. Unlike atenolol, labetalol possesses α -adrenergic and β -adrenergic antagonist activity. It is commonly used during pregnancy for acute treatment of elevated blood pressures and as therapy for chronic hypertension. Although some reports have suggested potential growth restriction,⁴²⁵ other studies have not.^{427,428} Experience has not identified any teratogenic concerns.

Hydralazine. Although hydralazine seems to be an ideal antihypertensive drug for pregnant women, side effects including headache and palpitations caused by a reflex increase in cardiac output usually prevent its use in effective dosages for chronic hypertension.

α -Methyldopa. α -Methyldopa is the drug used in the largest study and the only drug whose safety for infants has been

demonstrated in long-term follow-up assessments. It frequently causes drowsiness, occasionally to a degree that is incapacitating.⁴²⁹ In the original examination of infants whose mothers received α -methyldopa, there was a small but statistically significant decrease in head circumference, but this effect was not found in follow-up studies.⁴¹⁶

Other Antihypertensive Drugs. Several other antihypertensive drugs may offer theoretical advantages for use in pregnancy. More data are required about the efficacy and immediate and long-term safety of these drugs in pregnancy.

The ACE inhibitor enalapril is widely used in nonpregnant patients. Unexplained fetal deaths have been observed in pregnant ewes and rabbit does treated with another ACE inhibitor, and although, there are no reports specifically of fetal death, renal agenesis and neonatal renal dysfunction have been reported in humans.⁴³⁰ This class of drugs is now classified as pregnancy category X. Angiotensin II receptor blockers (ARBs) such as losartan and telmisartan have not been studied as extensively, but case reports suggest that they have problems similar to those of ACE inhibitors.⁴³¹⁻⁴³³ ACE inhibitors and ARBs should be discontinued during pregnancy.⁴³⁴

Pharmacologic Recommendations. ACE inhibitors and ARBs should be discontinued, but no other drugs are absolutely contraindicated during pregnancy. The drug regimens suggested here are preferred based on the data regarding efficacy, side effects, and long-term follow-up. However, if a woman has established excellent blood pressure control with another agent,

especially after unsuccessful trials of other drugs, she should continue the successful regimen during the pregnancy. However, women receiving atenolol should switch to another β -adrenergic antagonist of equivalent efficacy. It may be necessary to combine therapy for adequate effect, but if more than two drugs are needed, consultation with a cardiologist or nephrologist is prudent.

Suggested drug regimens are as follows:

- **Methyldopa:** The initial dose is 250 mg at night and then 250 mg twice daily, increasing to a maximum dose of 1 g twice daily. If the maximal dose is not tolerated or does not control blood pressures, another agent should be added (not substituted). The addition of a diuretic usually dramatically increases the efficacy of methyldopa.
- **Labetalol:** The initial dose is 100 mg twice daily, increasing to a maximum dose of 2.4 g/day in divided doses (usually 400 to 600 mg twice or three times daily).
- **Nifedipine:** Doses of 10 to 30 mg are given three times daily, or 30 to 60 mg of a sustained-release form is given once daily.

Obstetric Management in Chronic Hypertension

Antepartum management of the woman with chronic hypertension primarily involves recognizing superimposed preeclampsia as early as possible and monitoring fetal well-being.

Studies of renal function (i.e., creatinine clearance and 24-hour protein excretion), a serum uric acid determination, and a platelet count should be performed early in pregnancy. These baseline studies may aid in differentiating exaggeration of the usual blood pressure changes of pregnancy from superimposed preeclampsia. Because preeclampsia often occurs at earlier gestational ages in hypertensive women, these patients should be seen more frequently, particularly in the second and third trimesters.

Because precise knowledge of the gestational age may become critical if early delivery is needed, a first-trimester ultrasound is prudent to accurately establish the due date. Likewise, ultrasonographic evaluation of the fetus between 18 and 24 weeks' gestation provides a baseline to determine incremental growth in the event that growth restriction is suspected.

Most hypertensive pregnant women have essential hypertension. Thorough evaluation for most secondary forms of

hypertension is best reserved for the postpartum period because of obfuscation of many of these conditions by the physiologic changes of pregnancy and the risks of diagnostic procedures to mother and fetus. However, evaluation for pheochromocytoma and aortic coarctation should be considered. Pheochromocytoma is a potentially lethal complication, especially during the intrapartum period, that can be simply, accurately, and inexpensively diagnosed by determination of a serum or urinary catecholamine concentration. Coarctation of the aorta, a rare cause of hypertension in women of reproductive age, can be detected readily by determination of a lag between radial and femoral pulses, which should be measured as part of the physical examination of any hypertensive patient.

Extensive antenatal fetal surveillance should be employed for pregnancies with preeclampsia or growth-restricted infants.³ Because of the risk of placental insufficiency and subsequent fetal demise, many clinicians employ some form of antenatal surveillance in the third trimester.

Conclusions

Despite significant advances in medicine, preeclampsia continues to result in almost 75,000 deaths worldwide each year. Although discoveries such as aberrant angiogenic factors and endothelial cell dysfunction have shed light on the pathophysiology of this disorder, the ultimate cause remains elusive. Without a complete understanding of the disease process, clinicians continue to struggle to appropriately manage these patients. Ongoing research is imperative to prevent future maternal and neonatal morbidity and mortality.

ACKNOWLEDGEMENTS

We would like to thank James M. Roberts, MD, for drafting and maintaining this chapter over the course of the previous editions.

Patient Safety in Obstetrics

CHRISTIAN M. PETTKER, MD | EDMUND F. FUNAI, MD

Physicians have always strived to provide patients with the very best care and outcomes. However, in the past 40 years, health care has become progressively more complex, further dependent on technology, and increasingly reliant on more team members to provide care. The physician is still captain of the team, and yet, more than a dozen staff, including physicians, nurses, social workers, therapists, and trainees at various levels, may care for a patient on an obstetrics service through numerous work shifts. The opportunities for error have increased along with the complexity of care, and as we have improved our ability to deal with complex diseases, we have also increased the stakes for failure. At the same time, the expectations of federal and local regulatory bodies, employers, the insurance industry, the public as a whole, and individual patients have never been higher.

Although the idea of keeping patients safe and providing them with the best outcomes is certainly not new, turning these ideas into tangible practice has taken center stage in the health care industry. This chapter reviews the origins of the patient safety movement, discusses patient safety in obstetrics specifically, and outlines techniques to improve safety and cope with the aftermath of adverse events. Box 49-1 offers definitions for many of the terms in this chapter and in related literature.

The Patient Safety Movement

The origin of the patient safety movement can be traced to the Annenberg Conference, a 1996 meeting convened in the wake of a series of highly publicized medical mishaps, which brought together leaders from the American Association for the Advancement of Science, the American Medical Association (AMA), and The Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations, or JCAHO) to discuss errors in health care.¹ This meeting launched organizations, such as the National Patient Safety Foundation and the Institute for Healthcare Improvement (IHI), and other efforts, such as the Patient Safety Initiative of the Veterans Affairs (VA), the IHI's 5 Million Lives Campaign, and Sentinel Event reviews by The Joint Commission, all of which tackle the various issues that relate to unanticipated adverse outcomes and quality of care delivery in medicine.

Three years after the Annenberg Conference, the Institute of Medicine published a landmark report assessing the prevalence and impact of medical errors in the United States, estimating that a staggering 44,000 to 98,000 patients die each year as the result of medical errors.² Concluding that a majority of medical errors are caused by correctable faults, this report was a call to improve quality and deliver care more safely. A key foundation of the patient safety movement is the recognition of the ubiquity of human and system deficiencies that contribute to error. By understanding that error is nearly inevitable but mostly

preventable, patient safety efforts focus on human fallibility and seek to enhance communication, fail-safe measures, and barriers that decrease the likelihood that an error will manifest itself at the bedside.

A large proportion of patient safety work is based on techniques established in aviation. Recognizing the influence of human error and interpersonal interactions in airline accidents, the aviation industry took an early lead in adverse outcome reduction in the 1980s. Their two-pronged approach confronts human error by establishing guidelines, checklists, and drills to improve automation of processes, and it confronts imperfect interpersonal interactions by reducing hierarchies, teaching effective teamwork practices, and empowering individuals to speak up when they recognize an abnormal situation. Acknowledging that medicine is similarly stressful, time constrained, and teamwork dependent, patient safety leaders have adapted many of the principles and techniques of aviation to the health care environment.³

Computerized order entry and medication reconciliation, pre-procedure time-outs to ensure that the correct procedure is being performed on the intended patient, centralized management guidelines, and formalized handoffs are becoming routine measures in a number of hospitals in response to this approach. With the implementation of these techniques, the patient safety movement has shown great progress, and improvements in safety have been documented in cardiology,⁴ critical care,⁵ and anesthesia.⁶

Safety Challenges in Obstetrics

Patient safety in obstetrics seems to lag behind that in other specialties, despite the fact that childbirth is one of the most common reasons for hospital admission in the United States, accounting for more than 4 million hospitalizations each year and ranking second only to hospitalization for cardiovascular disease.⁷ Few published models exist for the reduction of obstetric adverse outcomes. One limited example is the IHI's "Idealized Design of Perinatal Care," which presents two perinatal care "bundles" proposed as policies for the induction and augmentation of labor.⁸ Moreover, there is no standard for assessing the rates of adverse events in perinatal care. Lack of traction in obstetrics is especially perplexing because the discipline is considered to be in a medical professional liability crisis. In fact, although obstetrician-gynecologists represent about 5% of physicians in the United States, they generate 15% of liability claims and 36% of total payments made by medical liability carriers.⁹

Good outcomes are mostly expected around the time of childbirth, although adverse events are estimated to occur in up to 16% of deliveries in the United States.¹⁰⁻¹² The expectation of a favorable outcome in a largely healthy and young patient population and the fact that two patients—mother and

child—can be affected make any adverse outcome particularly devastating and shocking. The profound impact of an obstetric adverse outcome on the family unit is one contributor to the liability crisis in obstetrics, in which the average payment for just one obstetric liability claim is approximately \$500,000 to \$1,900,000.¹³ Because 90.5% of obstetricians have experienced at least one liability claim during their career, with an average of 2.69 claims per physician, the liability crisis has a significant impact on the practice of obstetrics.¹⁴ In response, obstetricians

have changed their practice considerably, with 19.5% performing more cesarean deliveries, 19.5% eliminating attempts at vaginal birth after prior cesarean delivery, 21.4% reducing the number of high-risk obstetric patients they care for, 10.4% decreasing their number of deliveries, and 6.5% stopping practice altogether.¹⁴ Clearly, these are not direct ways of dealing with the liability and patient safety crisis in obstetrics; avoidance of the patients and procedures does not make them go away. The impact of these changes is so substantial that the

BOX 49-1 GLOSSARY

Term	Definition
Adverse event	A medical event or intervention that has an unexpected or undesired outcome.
After-action review	A debriefing after a notable event (e.g., code or other emergency) focusing on the processes that went well and those that could have gone better.
Callout	A communication tool used to convey critical information during an event such as a code. Allows everyone working on a problem to know what is going on and how to anticipate the next step, and it identifies who is in charge.
Chain of command (or of consultation)	An algorithm or flow diagram for the escalating involvement of leadership to aid in the resolution of disputes, differences, or questions.
Check-back	A communication tool used to verify accurate verbal or written information exchange, borrowed from the military and aviation. Usually takes the form of repeating what is heard to acknowledge receipt and verify accuracy.
Checklist	A list, usually written, of actions to be performed for a specific procedure. Team members will use a checklist to assist the staff in incorporating all necessary steps before or during a procedure. Checklists aim to implement evidence-based and best-practice strategies in a systematic fashion, making their use routine and universal. They also attempt to improve the function of a team by creating a shared set of standards and goals.
Crew resource management	A style of group training to confront imperfect interpersonal interactions by emphasizing communication and teamwork. Gives individuals examples of highly functioning teams. Often incorporates specific communication tools (chain of communication, CUS, check-back, or two-challenge rule) to reduce hierarchies and empower individuals to speak up when they recognize an abnormal situation. ^{75,78}
Cross-monitoring	The practice by which staff members observe each others' practice from a safety perspective. For example, one staff member may point out to another a hand-hygiene failure.
Culture of safety	The integration of safety thinking and practices into clinical activities, including development of systems for data collection and reporting, reducing blame, involving leadership, and focusing on systems. Recognizes the fallibility of human workers and aims to create a blame-free environment. ^{135,136}
CUS	The acronym for communication keywords (concerned, uncomfortable, scared) that demonstrate a level of alarm in regard to a clinical scenario. The words in the order listed indicate an escalation of worry. ⁸⁶
Four "whats"	An approach to ensure complete information is relayed during a handoff. What is the patient here for? What are the situation and major issues? What are you most concerned or worried about? What needs to be followed up on?
Handoff	The transfer of responsibility or accountability between caregivers or teams. A leading source of medical errors because each handoff is associated with a loss of information or a void in coverage. ¹³⁷ Structured handoff tools can be used to fill these gaps. (See also <i>Four "whats"</i> and SBAR.)
Huddle	A brief, regularly scheduled meeting of staff and providers to discuss short-term planning, problems, or workflow. ¹³⁸
Just culture	A model for a safety culture that balances no-blame with accountability in attributing the source of an error. In this model, human errors (slips, lapses, or mistakes) are distinguished from at-risk or reckless behaviors. Emphasis on accountability is placed on at-risk and reckless behavior. ¹²³
Mitigating speech	A manner of softening the tone of speech to be more acceptable to the receiver, often occurring when a subordinate does not want to assert his or her opinions or impressions. Structured communication tools aim to prevent the use of mitigating speech.
Near miss	An unplanned event deemed potentially harmful that does not result in an adverse outcome. The investigation of near misses can help prevent events leading to harm in the future. Often, harm is prevented in near misses because of chance or the presence of preventive measures resulting from individual conscientiousness or systemic barriers.
Normalization of deviance	The acceptance of events that are not supposed to happen. Can occur within an organization when recurrent system failures or near misses happen and do not lead to serious consequences. Over time, these failures are not recognized as unexpected deviations but rather become routine and normal. ²¹
Obstetric Adverse Outcome Index (AOI)	A set of indicators of significant adverse events related to pregnancy and childbirth. ¹¹ The AOI is expressed as the percentage of pregnancies affected by one or more indicators. May be used as a tool to compare quality and outcomes within a single institution or between multiple institutions. The occurrence of an AOI event may serve as a trigger for investigation of quality and safety practices.
Root-cause analysis	A systematic method of error analysis led by a trained facilitator and performed after a serious adverse event. Usually performed as a quality improvement tool to identify the various contributors (e.g., human factors, policy gaps, system latencies, environmental or equipment failures) to an adverse event. Mandated by The Joint Commission for use in the investigation of health care sentinel events. ¹³⁹ Usually results in a formal action plan calling for the implementation of tools for improvement.
Safety climate	The way safety concerns are perceived by a team and its individuals. Often assessed with quantitative tools such as the SAQ ⁶⁹ or the AHRQ Hospital Survey on Patient Safety Culture.
SBAR	Structured communication and debriefing technique for precise transfer of information. Acronym for situation, background, assessment, and recommendation. ⁸⁵

BOX 49-1 GLOSSARY—cont'd

Term	Definition
Sentinel event	As defined by The Joint Commission, "An unexpected occurrence involving death or serious physical or psychological injury, or the risk thereof. Serious injury specifically includes loss of limb or function. The phrase, 'or the risk thereof,' includes any process variation for which a recurrence would carry a significant chance of a serious adverse outcome. Such events are called 'sentinel' because they signal the need for immediate investigation and response." (www.premierinc.com/safety/topics/patient_safety/index_3.jsp . Accessed January 2013.)
Shared mental model	An organized way for team members to conceptualize how a team works and to predict and understand how their team members will behave to improve overall team performance, while sharing a joint vision of the desired outcome. ^{83,84}
Situational awareness	The extent to which team members are aware of the status of a situation, from detailed to the global. Includes the status of a team's patients and workload, and operational issues such as staffing, unit acuity, and bed availability. Inter-team and intra-team huddles can be effective for creating better situational awareness.
System failure	Adverse outcomes occur as a result of human errors or system failures. Most errors do involve a human element, but systems (e.g., infrastructure, protocols, equipment) are usually intentionally and unintentionally built to create barriers to harm. Systems are designed to be "fault tolerant," to prevent an individual error from causing harm. ¹²⁷ A system failure is a breach in one of these structures.
Time-out	A pre-procedure pause that includes all members of the involved team and is aimed at ensuring correct identification of patient and procedure. Often performed verbally and used to review key preparatory thoughts or actions. For example, a presurgical "time-out" will ensure the correct patient, the correct procedure, and the correct site.
Trigger	A signal that alerts a health care team to the possibility of an adverse event. An actual adverse event may serve as a trigger, but a trigger may simply be an event that is often connected with adverse events. For example, a blood transfusion is not necessarily adverse, but its occurrence can alert a team to investigate a case for possible errors or failures.
Two-challenge rule	A quick conflict-resolution technique in which one team member may question an action two times and if a sufficient answer is not provided, may halt that action. ⁸⁷

American College of Obstetricians and Gynecologists (ACOG) issued a Red Alert in 2004, naming 12 states in which the medical liability crisis is affecting the availability of obstetricians.¹⁵ Sadly, as obstetricians have struggled with how to deliver care more safely, they have limited their practices instead.

A more direct approach is to avert problems before they happen. There is little doubt that obstetric care can be delivered more safely in the future and that obstetricians can be guided by the work to enhance safety that has been successful in other industries and other medical disciplines. Both The Joint Commission and ACOG have issued statements addressing obstetric safety concerns, and ACOG has produced a monograph to help guide obstetric safety and quality projects.¹⁶⁻¹⁸ Admittedly, however, patient safety science is still rather nascent, especially in the obstetric realm, and in many areas, there is little guidance from the literature beyond retrospective studies and expert opinion.

Potential Strategies to Improve Patient Safety

There are many different strategies an obstetric practice or service may choose to employ to enhance patient safety. Although few have been subjected to the rigor of a randomized clinical trial, an increasing number of approaches, especially techniques that address suboptimal communication, have become mandated by regulatory bodies, such as The Joint Commission. Depending on its needs, a service may choose to employ some, most, or all of these strategies.

A Joint Commission Sentinel Event Alert provided an overview of the common approaches to preventing failures and latencies inherent in complex systems and human activities.¹⁹ This review investigated the root causes of 47 perinatal deaths reported to The Joint Commission. Although their review was limited to perinatal deaths, the root causes of other obstetric

adverse outcomes are likely to be similar. The most frequently cited root cause was poor communication (72%), with 55% of cases involving an organizational culture that prevented effective teamwork and communication (Fig. 49-1). Specific cultural factors included hierarchy and intimidation, lack of a structured chain of communication, and failure to function as a team. Other important root causes included staff competency (47%), orientation and training process (40%), and inadequate fetal monitoring (34%). Although the characteristics of individual settings may require different tools and approaches, knowledge of the common gaps should help any obstetric unit tactically move toward improving safety and quality.

OUTSIDE EXPERT REVIEW

At times, it is useful to bring a fresh pair of eyes to examine a service or practice. The potential benefits include an enhanced ability to recognize a gradual drift in practice away from accepted standards, also known as *normalization of deviance*,^{20,21} as well as greater credibility by virtue of being a disinterested party. A review may consist of a multiday visit to assess organizational risk and patient safety issues. The review team may interview staff from all professional categories (physicians, nursing, ancillary staff, administration) and use a triangulation method to resolve differences in perspectives, reporting only those findings repeated in at least two of the various domains.^{22,23} The team often reviews hospital policies and protocols and compares them with national standards. The review and recommendations—focused on principles of patient safety, evidence-based practice, and consistency with the standards of professional and governing bodies—provide an outline with specific observations and recommendations for improvement. There are several widely known consultants in the field, and ACOG offers a similar service via the Voluntary Review of Quality of Care program.^{24,25}

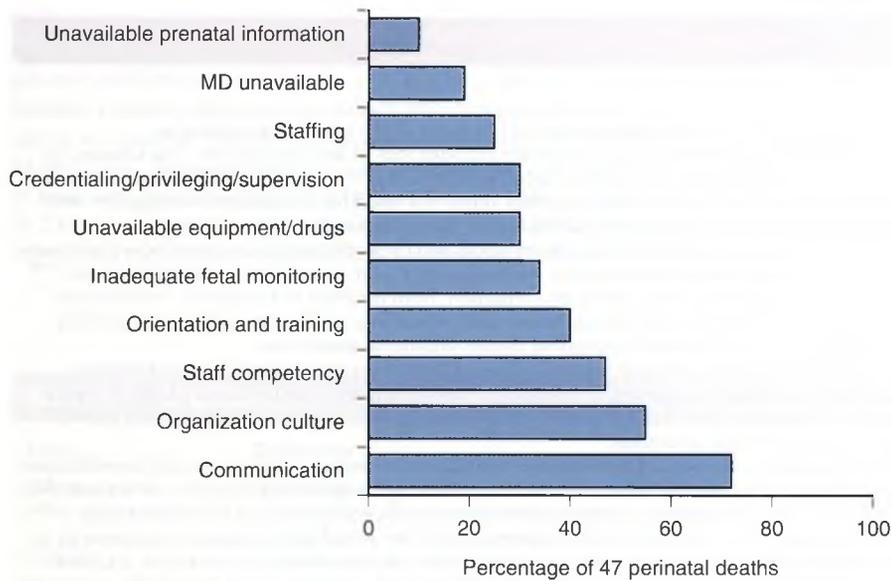

Figure 49-1 Root causes of perinatal sentinel events—The Joint Commission, 1995 to 2004. MD, medical doctor. (Data from Joint Commission on Accreditation of Healthcare Organizations: Sentinel event alert #30: preventing infant death and injury during delivery. www.jointcommission.org/sentinel_event_alert_issue_30_preventing_infant_death_and_injury_during_delivery. Accessed February 1, 2012.)

PROTOCOLS AND GUIDELINES

In response to a review, or in the course of maintaining practice patterns that conform to changing standards, it can be exceptionally useful to develop a series of protocols and guidelines delineating practice. The purpose of such documents is neither to enumerate care in excruciating detail nor to serve as a cookbook, but rather to provide a common foundation for physicians and nurses to use in approaching the patient.²⁶ Initially, such protocols may be directed at the organization of patient care (e.g., admission criteria to different units and appropriate disposition of high-risk cases), as well as practices considered at greatest risk for mismanagement and highest yield for correction (e.g., induction criteria and administration of oxytocin, prostaglandin, and magnesium sulfate).²⁷⁻²⁹

The use of oxytocin is worthy of particular mention because its use can be highly variable and is often subject to the individual preference, and sometimes whim, of the physician.³⁰ The potential harm associated with this drug is often underappreciated,^{30,31} and the implementation of conservative and clearly delineated policies can affect overall communication, medico-legal liability, and patient outcomes.^{27,31,32}

When combined with education and the support of senior physician leadership, protocols and guidelines can have a wide-ranging impact in a relatively short period of time. In an effort to reduce the incidence of scheduled births between 36 0/7 and 38 6/7 weeks that lacked appropriate medical indication, 20 Ohio maternity hospitals collected baseline data for 60 days and then selected locally appropriate IHI Breakthrough Series interventions to reduce the incidence of early-term scheduled births. The rate of scheduled births between 36 0/7 and 38 6/7 weeks without a documented medical indication declined from 25% to less than 5% ($P < .05$) in participating hospitals, and birth certificate data showed inductions without an indication declined from a mean of 13% to 8% ($P < .0027$).³³ It is most remarkable that this work was accomplished largely over a 2-year span.

Guidelines and protocols should be based on evidence whenever possible. However, even if based only on consensus

and expert opinion, guidelines can still provide the level of consistency necessary for smooth workflow and safe practices.²⁶ The Agency for Healthcare Research and Quality (AHRQ) and the U.S. Department of Health and Human Services (DHHS) have developed a National Guideline Clearinghouse (www.guideline.gov) to assist health care teams in implementing and disseminating clinical practice guidelines. These efforts are often initially resisted—particularly by veteran nurses and physicians who are confident in their experience and abilities. However, their acceptance can grow as they build on the culture of safety and teamwork over time.

CHECKLISTS

Checklists in Medicine and Surgery

The use of checklists to improve quality and safety dates back to the 1930s and the first flight tests of the B-17 bomber. Nicknamed the Flying Fortress, this airplane was significantly larger and faster and had a longer range than any prior bomber in the U.S. Army Air Corps. As a result, it required a crew with a much higher skill level, able to cope with the vastly increased complexity of the controls and procedures required to fly safely. One of the first flights ended soon after takeoff in a fiery crash that killed two members of the five-man crew. The crew forgot to release the airplane's gust lock, a device that held the bomber's movable control surfaces in place while the plane was parked on the ground. After takeoff, the plane climbed, stalled, and headed nose first into the ground. Subsequent investigations into the accident showed no mechanical failure but rather pilot error. Experts of the day wondered if it was "too much plane for one man to fly."³⁴ In response, rather than increasing pre-flight training or reducing the complexity of the technology, the test pilots introduced a system of checklists to simplify the processes of takeoff, flight, and landing. From that moment, pilots guided the B-17 bomber through 1.8 million flights without a single accident, and aviation adopted the checklist as a critical tool for all aspects of defense and civil aviation.³⁴

Medicine has adopted the checklist concept to simplify systems that have grown to enormous levels of complexity. Checklists use two strategies to improve care quality and reduce adverse outcomes in medicine. First, they aim to implement evidence-based and best-practice strategies in a systematic fashion, making their use routine and universal. Second, they attempt to improve the function of a team by creating a shared set of standards and goals.

The first application of checklists tested as an intervention to improve outcomes is attributed to work in the intensive care unit (ICU) of Johns Hopkins Hospital. Investigators implemented a checklist for the insertion and care of central line catheters; at the end of the study, the unit that did not use checklists had no change in catheter-related bloodstream infections, whereas the intervention unit showed a decrease from 11 to 0 per 1000 catheter days, with an estimated savings of 43 catheter-related infections, eight lives, and nearly \$2 million over 1 year.³⁵ When expanded to programs in the entire state of Michigan, this same checklist reduced infections by 66%, saving more than 1500 lives and \$175 million over just 18 months.³⁶ What is most remarkable is that the checklist involved only five steps: handwashing, using sterile draping, cleaning the skin with chlorhexidine, avoiding the femoral site, and removing any unnecessary or redundant catheters.

Application of this work to the surgical specialties has shown further remarkable results. A World Health Organization program implemented a 19-item surgical safety checklist in operating room facilities over 1 year in eight hospitals in a diverse range of health care settings.³⁷ Complication rates decreased from 11% to 7% ($P < .001$), and death rates were reduced by nearly 50% (1.5% to 0.8%, $P = .003$). The impact of simple checklists on world health should not be underestimated.

Checklists in Obstetrics

Obstetrics is an excellent field for the development of safety checklists for quality improvement. A large portion of the adverse events in obstetrics are preventable events that occur in previously healthy patients. Labor and delivery units are typically challenged with a highly volatile patient load: It is very common for a unit to go from nearly empty to overfilled in the span of a few hours. The management of labor and delivery is also remarkable for long periods of waiting interrupted by rapid changes and sudden events. Extremes of volume and fluctuations in patient or unit severity status make the management of workloads difficult. Levels of team performance are seen to deteriorate during periods of low and high workload (Fig. 49-2).^{38,39} Checklists are expected to guide an individual or a team through these activities in a stepwise, efficient, and safe manner to avoid omissions and errors. Furthermore, checklists are designed to improve team communication by presenting specific topics for dialogue relating to patient care. The Joint Commission root-cause analyses have demonstrated that communication failures account for approximately 60% of sentinel events, 51% of reportable maternal events, and 68% of reportable perinatal deaths.⁴⁰

Areas in Which Checklists May Have an Impact

Oxytocin Use. Oxytocin is typically administered for induction or augmentation of labor. Patient injury from an adverse drug event is the most common type of inpatient adverse event, and oxytocin, which is used in more than 50% of deliveries in

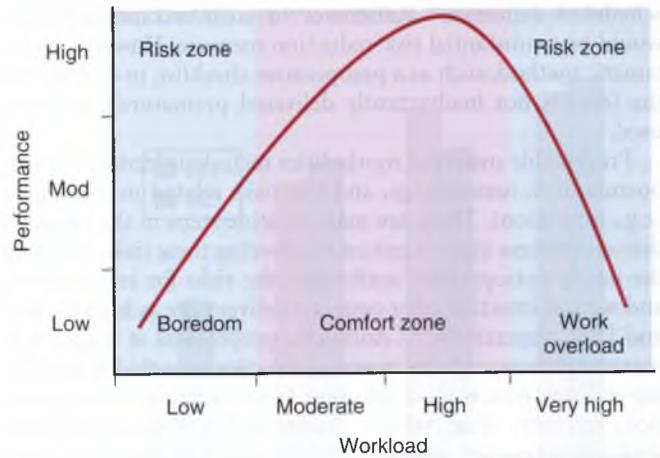

Figure 49-2 Team performance as a function of workload. Low functioning of teams is notable during times of low and high workload. (Data from Emergency Team Coordination Course: Student guide, Andover, MA, 2004, Dynamics Research Corporation; and Huey BM, Wickens CD, National Research Council [U.S.]; Panel on Workload Transition: Workload transition: implications for individual and team performance, Washington, DC, 1993, National Academy Press.)

the United States, is one of the most commonly used medications in obstetrics.³¹ However, there are no universal or evidence-based standards for oxytocin dosages, and patient responses and sensitivities are highly variable.⁴¹ Although considered safe when administered judiciously, the inappropriate use of oxytocin, specifically related to dosage regimens that cause or fail to recognize excess uterine contractions and resultant poor fetal oxygenation, is a common and serious problem. According to a survey of liability cases, approximately 50% of paid liability claims involve alleged misuse of oxytocin.⁴² For these reasons, oxytocin is considered one of the 12 most dangerous medications in a hospital.⁴³ Checklists for oxytocin have been shown to reduce the maximal infusion rate without lengthening labor or increasing operative interventions, and to reduce the rate of adverse outcomes in newborns.³²

“Routine” Cesarean Delivery. In 2007, 31.8% of deliveries in the United States were cesarean, representing a 50% increase over a 10-year span.⁴⁴ In 2005, 1.26 million cesarean deliveries were performed, making it the most common surgical procedure performed in the United States.⁷ Given this prevalence in obstetric care, preventable neonatal and maternal morbidities related to cesarean delivery are an important focus for safety and quality.

When a cesarean delivery is planned, the prevention of neonatal morbidity hinges on the avoidance of iatrogenic prematurity. In a study of more than 13,000 elective cesarean deliveries, risks for neonatal death and other morbidities (respiratory complications, sepsis, ICU admissions) for cesarean delivery at 37 and 38 weeks were increased 110% and 50%, respectively, when compared with cesarean at 39 weeks.⁴⁵ The odds ratios of respiratory morbidity for elective cesarean at 37 and 38 weeks were estimated to be 6.0 and 13.6, respectively, when compared with vaginal delivery at 40 weeks.⁴⁶ Accordingly, ACOG recommends documentation of fetal lung maturity either by historic assessment (i.e., ≥ 39 weeks) or laboratory assessment for all

scheduled deliveries.⁴⁷ Adherence to such recommendations would be a substantial risk-reduction measure. However, a systematic method, such as a preoperative checklist, to ensure that the fetus is not inadvertently delivered prematurely is rarely used.

Preventable maternal morbidities include infection, thromboembolism, hemorrhage, and the risks related to anesthesia (e.g., aspiration). There are many routine steps in the cesarean delivery process that are critical to lowering these risks. Without the use of perioperative antibiotics, the risks for endometritis and wound infection after cesarean delivery are as high as 40% and 15%, respectively.^{48,49} Antibiotic prophylaxis at the time of cesarean delivery reduces maternal infectious morbidity, including endometritis, wound infection, fever, or urinary tract infection, by more than 60%.⁵⁰ Traditionally, to minimize fetal antibiotic exposure, antibiotic prophylaxis has been given after the surgery started and the umbilical cord has been clamped. However, in a recent clinical trial, administration before incision decreased infectious morbidity by a further 60%.⁵¹

Occurring in approximately 1/1000 to 1/2000 pregnancies, venous thromboembolism is a rare complication, making it a leading cause of mortality and serious morbidity in pregnant women.⁵²⁻⁵⁴ This risk represents a nearly tenfold increase compared with non-pregnant women of childbearing age; according to the most recent U.S. vital statistics, pulmonary embolus is the leading cause of maternal mortality, contributing to 19.6% of maternal deaths or 2.3 pregnancy-related deaths per 100,000 live births.⁵⁵ Perioperative pharmacologic thromboprophylaxis is recommended only in high-risk cases, but the use of intermittent pneumatic compression devices for moderate-risk patients should be universal.⁵⁶ Administration of antacids and gastric pro-motility agents before cesarean delivery is considered routine in patients at risk for general anesthesia or aspiration for the prevention of a leading cause of anesthesia-related complications.

Adherence to these simple risk-reduction techniques can be encouraged and improved through the use of checklists. Baseline data from the Johns Hopkins Hospital ICU catheter study demonstrated that physicians complied with all of the evidence-based infection control guidelines only 62% of the time. After implementation of checklists, performance improved and catheter-related infections fell from 11 per 1000 to 0 per 1000.³⁵ In general surgery, checklists have been shown to nearly halve the rate of death and serious complications.³⁷ For these reasons, cesarean delivery is an ideal candidate for checklist development.

Emergent Cesarean Delivery. An emergent cesarean delivery occurs at an exceptionally brisk pace—rarely seen in other medical disciplines—usually in response to an acute hemorrhage, fetal bradycardia, umbilical cord prolapse, or uterine rupture. In most cases, this speed is for the benefit of the fetus or neonate, with a resulting increase in maternal risk for injury. Fetal bradycardia, for example, often requires swift action and depends on a carefully coordinated team. Fetal morbidity and mortality can be greatly affected by a delay of just a few minutes, and animal studies have demonstrated that brain injury can occur as early as 10 minutes into an event of severe asphyxia.^{57,58} Although emergent cesarean deliveries complicate only 0.5% to 1% of all deliveries (and 2.5% of cesareans), they contribute to a significant amount of maternal morbidity.⁵⁹ Major morbidities related to emergent cesarean delivery include increased infectious complications, anesthesia complications (as they more often involve general anesthesia), surgical injury to mother

or neonate, hemorrhage, and inadvertent instrument retention resulting from inadequate counting procedures before the case.

Performance of an emergent cesarean delivery requires the coordination of at least six individuals: surgeon, skilled assistant for the surgery, anesthesiologist, scrub technologist, circulating nurse, and pediatrician or skilled pediatric caregiver. At present, there are no scripted or standardized protocols on how to conduct the emergency cesarean. Although the time from the diagnosis of an emergency to the delivery of the infant may not be appropriate for a checklist, the moment after delivery may provide a time for a team to regroup and reanalyze a situation to ensure all appropriate prophylactic and safety measures have been taken.

PERINATAL PATIENT SAFETY NURSE

To implement many of the strategies described in this chapter, adequate resources must be available to initiate and support new projects. An ideal way to provide such resources is the creation of the perinatal patient safety nurse (PSN) role.⁶⁰ Ideally, the PSN is an advanced-practice perinatal nurse with significant experience in clinical and administrative systems. Knowledge of national standards and guidelines and of the principles and practice of safety science is essential but not required, as these skill sets can be obtained while in the role, as long as the candidate is committed to lifelong learning.

Project management skills are required to formulate and execute patient-centered safety initiatives. Communication skills and the ability to work collaboratively with the leadership team and staff members are desired traits of any leadership position. In addition, the ability to coordinate and provide interdisciplinary educational programs requires an acute understanding of the needs of the provider and the system in the complex setting of an obstetric service. The PSN ensures that patient safety is the first priority—above costs, production, and perceived convenience—in all decisions that affect patients.⁶⁰

One of the PSN's primary responsibilities is to provide a formal method of evaluating clinical care and outcomes for obstetrics services. Occasionally, this involves a root-cause analysis. To identify cases complicated by adverse outcomes and system weaknesses, the nurse may review various sources of information, such as anonymous event reporting systems (see next paragraphs) and labor and neonatal logs, which often contain Apgar scores and comments or concerns. The PSN may also meet with and be available to physicians, resident staff, ancillary caregivers, nurses, and nursing leadership to further be informed of events and to be a sounding board for safety-related concerns. The availability of the PSN, coupled with diverse lines of communication, makes it less likely that a significant adverse event or near miss will not be identified and investigated.¹²

ANONYMOUS EVENT REPORTING

A computerized tool for anonymous event reporting allows any member of the hospital staff to anonymously report medication errors, device-related events, falls, or other events that in the opinion of the staff member may have caused harm to a patient or visitor. There are commercially available products (e.g., from Peminic Corporation, Princeton, NJ), or a customized system could be developed. With the aid of a PSN, who can educate and encourage staff to use the system without fear of reprisal, and who can investigate reports and find trends in the data, it

is possible to discern event patterns and system weaknesses or failures. A user-friendly Web-based system to track complications and identify patterns of adverse events may decrease underreporting.⁶¹

THE OBSTETRIC HOSPITALIST

On some services with residents, uncompensated community physicians provide substantial resident coverage, including supervision of the care of resident clinic patients. However, these supervisory responsibilities are often not clearly delineated and could vary by provider.

In disciplines other than obstetrics, hospitalist systems, which shift care from all primary care providers managing their own hospitalized patients to a system in which patients are transferred to the care of a dedicated in-house physician, are growing rapidly.⁶¹⁻⁶³ In models outside of obstetrics, modest evidence shows that this trend improves quality and safety,^{64,65} and cost savings have been demonstrated.⁶²

Applying this approach to obstetrics has great promise. The term *laborist* has been created to describe the hospitalist in an obstetric setting, and it has been posited that this approach may decrease physician fatigue, burnout, and professional dissatisfaction.⁶⁶ Although this model may somewhat diminish continuity of care, it is attractive from a safety perspective to have a provider immediately available and physically present on the labor floor for emergencies. There may also be benefit from maintaining a cadre of highly skilled obstetricians who become especially accomplished at labor management by limiting their practice to inpatient obstetrics. However, these benefits are speculative, as there is as yet no clear evidence of benefit from this care model.

OBSTETRIC PATIENT SAFETY COMMITTEE

The process of cultural change may be aided by impaneling a multidisciplinary team of obstetricians, anesthesiologists, pediatricians, and nurses to review adverse events and to set priorities for policy development and overall strategic safety planning. Such an approach has been shown to support and foster a change in organizational culture and to address actual and potential errors.^{67,68} At a minimum, with the assistance of the PSN, the committee can review events on a case-by-case basis. Examples of possible interventions, guided by site-specific data, include a shoulder dystocia documentation form, relabeling of magnesium and oxytocin intravenous fluids, and a standardized form for labor progress documentation.¹²

SAFETY ATTITUDES SURVEY OR QUESTIONNAIRE

At the beginning of a comprehensive safety program and at various points along the way, it may be useful to formally assess the overall safety climate by means of a structured and validated survey tool. One such example is the Safety Attitudes Questionnaire (SAQ), a tool adapted from the aviation field and used for the assessment of health care employee perception of teamwork and safety. An SAQ specific to obstetrics has been developed and validated by Sexton and colleagues.^{69,70} This anonymous survey helps detect perceived systemic weaknesses and differences of opinion over time or between employee groups (e.g., staff, nursing, physicians) that result from being trained in contrasting styles or separate silos. The survey consists of a series

Question: Do MDs and RNs work as a well-coordinated team?

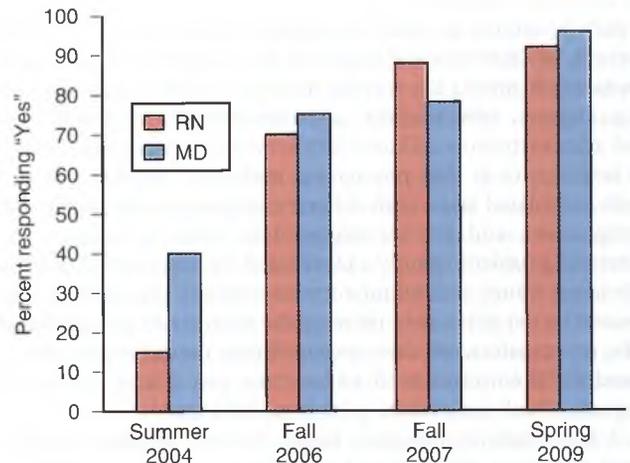

Figure 49-3 Teamwork performance. Serial assessments of physicians' (MD) and nurses' (RN) perceptions of teamwork performance during a comprehensive patient safety initiative.

of statements to which the respondent answers with agreement or disagreement, using a five-point Likert scale. Differences of 10% or more, over time or between groups, are considered clinically significant; overall scores showing 80% agreement that the teamwork climate is favorable are considered the target goal for change.

As an example, we asked our staff, among other questions, about the perception of teamwork at the start of and during our comprehensive safety effort. In response to the question "Do physicians and nurses work as a well-coordinated team?" it was apparent that in the beginning the perception of teamwork as a whole was very low (Fig. 49-3). Also, it was striking that there was a large difference (25 percentage points) *between* physicians and nurses, indicating disagreement about teamwork climate. Over time, the overall perception of teamwork climate improved and the differences between these two domains decreased, indicating an overall favorable teamwork environment. The SAQ has been used to track a perinatal safety program, and improvements in safety climate and culture have been demonstrated with contemporaneous improvements in adverse outcomes.⁷¹ To date, the SAQ is the only safety climate survey that has demonstrated links between safety culture and patient outcomes.⁷²

A more general (not specific to obstetrics) safety culture survey is available at no cost in the public domain. The Hospital Survey on Patient Safety Culture was developed by a private research foundation (Westat, Rockville, Md) under the directive of the Medical Errors Workgroup of the Quality Interagency Coordination Task Force and funded by the AHRQ. The survey's foundations are in studies of accidents, medical error and error reporting, safety climate and culture, and organizational climate and culture. The survey forms and report templates are modifiable as necessary to customize to particular patient unit needs or concerns. The survey places an emphasis on accounting for perceptions of patient safety issues and on error and event reporting. The survey measures seven unit-level aspects of safety culture, three hospital-level aspects of safety culture, and four outcome variables.⁷³⁻⁷⁵ An advantage of this survey is that results can be compared with accumulated national standards reported to AHRQ.

TEAM TRAINING

It may be common, based on outside review or safety culture surveys, to identify weaknesses in the coordination and communication among the various members of the obstetric teams (e.g., nurses, obstetricians, anesthesiologists, neonatologists, and administration and ancillary services). A common finding in health care is that physicians, midwives, nurses, and staff train in isolated silos, with different languages and contrasting perspectives, and yet are expected to work in teams.² This potential problem is only exacerbated by voluntary limits on attending hours and mandatory restrictions on resident duty hours; the net effect is to increase the number of patient hand-offs, or transfers, of care responsibility between providers.⁷⁶ Handoffs themselves tend to be error prone and variable in content, which may create gaps in patient care.⁷⁷

A team training program, based on crew resource management programs initiated and tested by the airline and defense industries, has been shown to enhance communication.⁷⁸ Similar interventions have helped improve teamwork—though not necessarily outcomes—in medicine and obstetrics.⁷⁹⁻⁸² Seminars that are 4 to 8 hours long may include videos, lectures, and role playing and are integrated with a mix of individual attendees (physicians, nurses, ancillary staff) in the obstetric team. Attendees are familiarized with the concept of the “shared mental model” for communication: an organized way for team members to conceptualize how a team works and to predict and to understand how their team members will behave to improve overall team performance.^{83,84} Other specific concepts and techniques that may be included are the situation, background, assessment, recommendation (SBAR)-structured communication and debriefing techniques⁸⁵; concerned, uncomfortable, scared (CUS) communication key words⁸⁶; the two-challenge rule (a quick conflict-resolution technique by which a team member may question an action two times and if a sufficient answer is not provided, may halt that action)⁸⁷; the chain of command; and elements of an effective handoff of care.⁸⁸

ELECTRONIC FETAL MONITORING CERTIFICATION

Fetal heart rate monitoring is subject to significant interobserver variability.^{89,90} Part of the reason for this inconsistency may be the lack of a common language and set of definitions of patterns to describe the fetal heart rate.⁹¹ To standardize the interpretation of electronic fetal monitoring, there may be value in an institutional education program that includes dissemination and review of National Institute of Child Health and Human Development (NICHD) guidelines,^{92,93} review of tracings, allocation of study guides,^{94,95} and voluntary review sessions.¹² This training may culminate in an examination offered by National Certification Corporation (www.nccnet.org), a nonprofit group that offers training and testing of fetal monitoring standards based on the NICHD criteria, or in another objective test of competency.

SIMULATION

A detailed review of medical simulation is beyond the scope of this chapter, but like the other items discussed, it has deep roots in the aviation industry, which commonly simulates known hazards as well as scenarios that have yet to occur.^{96,97} Some have encouraged caution in embracing these techniques,⁹⁸ but others

Figure 49-4 Example of an obstetrics simulation room. This high-fidelity simulation model has one-way (mirrored) glass for observers and facilitators.

point out that few industries have waited for unequivocal proof of benefit when human life was at stake. For example, on January 15, 2009, US Airways flight 1549 struck a flock of geese shortly after takeoff from LaGuardia Airport in New York. Both engines lost power, and the crew quickly decided that the best action was an emergency landing in the Hudson River.⁹⁹ Because this situation is extraordinarily rare, the team’s success depended on the benefits of prior preparation from simulations and on the detailed checklists that existed for the key elements of the procedure.

Simulation has been described in obstetrics and gynecology for approximately the past decade, initially focusing on teaching surgical skills¹⁰⁰ and centered on low-frequency but high-severity events such as shoulder dystocia,¹⁰¹⁻¹⁰³ hemorrhage,¹⁰⁴ and eclampsia.⁸⁰ Simulation may be center based, occurring in a dedicated space that may contain sophisticated mannequins, audiovisual equipment, and other technology that permits a true-to-life (high-fidelity) experience and that facilitates extensive debriefing after the simulation (Fig. 49-4). Alternatively, to cope with the logistic challenges associated with scheduling an obstetric team to be at an offsite center, some services have adopted an in-house approach that makes use of times when the census is low and the staff is more available; in this case, the location is an onsite patient care unit, and the equipment is often more rudimentary.¹⁰⁵ Either approach may allow technical skills to improve to some degree, and both provide the opportunity to improve communication and dynamics between team members, especially those from different disciplines. Units may choose to focus on improving either skills and knowledge or teamwork, although any simulation drill probably enhances both simultaneously. The major professional organizations in obstetrics, ACOG and the Society for Maternal-Fetal Medicine, are devoting considerable resources to simulation development and may be good resources for units just starting out.¹⁰⁶

Simulation training has proved to be an important educational intervention for rare events and emergencies.⁷⁹ The majority of studies have limited their scope to improved performance in subsequent simulations,¹⁰⁷ although some investigators have demonstrated improved clinical results for neonatal

adverse outcomes (e.g., Apgar scores and hypoxic-ischemic encephalopathy)¹⁰⁸ and events such as shoulder dystocia.¹⁰⁹

Evaluation of Progress

The benefits of a comprehensive patient safety program may include increased staff satisfaction and improved safety culture,⁷¹ although arguably the most important variables that should be targeted are actual patient outcomes. To measure the potential impact of improved patient outcomes, an accepted set of quality indicators should be developed or used and scrupulously tracked. One potential set of measures is the obstetric Adverse Outcome Index (AOI) proposed by Mann and colleagues (Box 49-2).¹¹ The AOI, calculated as the percentage of mothers with at least one adverse outcome indicator, can be analyzed for trends on a monthly or quarterly basis. A birth complicated by more than one indicator is counted only once in calculating the AOI. Numerous quality improvement programs have used the obstetric AOI to track progress.^{11,12,82} A modified AOI that does not include perineal lacerations or unplanned newborn admissions more than 24 hours old has also been suggested and used to track quality improvement projects in obstetrics.¹¹⁰ Using administrative and coding data as a source for input into the AOI may not be as reliable as prospective tracking.¹¹¹ It is important to appreciate that each indicator in the AOI is not necessarily preventable—all or even most of the time. However, such events do indeed merit tracking and scrutiny to assess whether improvement in care is warranted.

Fetal traumatic birth injury includes any injury deemed directly related to the obstetric care or birth event (e.g., head trauma, fracture, neurologic injury [e.g., Erb palsy], hemorrhage, or laceration). Unexpected admissions to a neonatal care unit and perinatal deaths include only cases in which a preexisting antepartum maternal complication (e.g., Rh isoimmunization) or fetal complication (e.g., prematurity or anomaly) independent of the delivery was not present.

Beyond the components of the AOI, other process variables or aspects of care related to quality can also be assessed, such as prophylactic antibiotic use with cesarean delivery, use of unapproved abbreviations, episiotomy rates, and the use of thromboprophylaxis where appropriate.

Beyond outcomes measures, process and culture measures are probably worth tracking. Process measures, such as those of the Surgical Care Improvement Project (SCIP), analyze

adherence to recognized, typically evidence-based standards, under the assumption that adherence to these standards will improve quality of care and reduce adverse outcomes. Culture measures, typically using the SAQ or the AHRQ's Hospital Survey on Patient Safety Culture, can track attitudes and perceptions of members of the organization as they change toward safety and quality.

Although it is an active area of research, the optimal set of safety and quality measures has not been, and probably will not be, determined. However, regulatory bodies are increasingly adding their weight to what should and will be required for tracking by hospitals. For The Joint Commission, the Perinatal Care Core Measure Set includes elective deliveries at less than 39 weeks' gestation, primary cesarean rates in low-risk women, appropriate use of antenatal steroids, newborn nosocomial bloodstream infections, and rates of exclusive breastfeeding at discharge.¹¹² The National Quality Forum has endorsed, in addition to those five, additional quality measures for obstetrics, including appropriate use of prophylactic antibiotics before cesarean delivery, appropriate use of thromboprophylaxis at the time of a cesarean, episiotomy rate, birth trauma rate, and birth of infants weighing less than 1500 g at sites with appropriate levels of care.¹¹³

Economics of Patient Safety

The primary impetus driving patient safety efforts is quality care and the elimination of harm, yet economic considerations cannot be ignored in today's health care environment. Few of these efforts can be provided at no cost, although their simplicity and widespread effects create appealing cases for favorable returns on investment. Hospital admissions with associated voluntary event reports are associated with 22% longer stays and 17% higher costs.¹¹⁴ One study reports that the elimination of excess costs related to adverse events could save up to 5.5% of total inpatient costs in the United States,¹¹⁵ and an Australian study estimates that adverse events represent nearly 16% of the total expenditure on direct hospital costs.¹¹⁶ An economic analysis based on the 18 AHRQ patient safety indicators demonstrated that the three obstetrics-specific indicators (obstetric traumas related to cesarean delivery, spontaneous vaginal delivery, and operative vaginal delivery) were not associated with significant additional costs or lengths of stay, although many of the other nonspecific indicators (e.g., pulmonary embolus, postoperative hemorrhage or infection, retained foreign body) that were significant are often seen during obstetric adverse events.¹¹⁷ Unfortunately, however, there is little evidence to guide an economic cost-benefit calculation of patient safety programs.¹¹⁸

A business case can be designed to appeal to a health care organization or liability carrier. As an example, one comprehensive safety effort involved the support of a malpractice liability carrier, which compensated the cost of outside expert review, a PSN, the PSN's initial training in crew resource management training education, the SAQ, and the electronic fetal monitoring examination or certification. Initial costs of this program were estimated at \$210,000, with ongoing yearly costs of \$150,000. This investment is dwarfed by the average payment (\$500,000 to \$1,900,000) for a single obstetric claim; the program effectively pays for itself if it can avert at least one malpractice settlement every 5 years.¹³ Analyses have demonstrated reduced claims and savings in claim payments and reserves, although these studies are hindered by cases that may remain because of long statutes of limitations and open claims.¹¹⁹⁻¹²¹

BOX 49-2 OBSTETRIC ADVERSE OUTCOME INDEX INDICATORS

Apgar, <7 at 5 minutes
 Blood transfusion
 Fetal traumatic birth injury
 Intrapartum or neonatal death >2500 g
 Maternal death
 Maternal admission to intensive care unit (ICU)
 Maternal return to operating room or to labor and delivery department
 Unexpected admission to neonatal ICU, weight >2500 g and for >24 hours
 Uterine rupture

Coping with the Aftermath of Adverse Events

A foundation of the patient safety movement is *nonjudgmental recognition* of the ubiquity of human and system error. This appreciation of human imperfection created a shift from a culture of blame toward a culture of safety. The VA summarizes this philosophy as follows: “We’ll never eliminate all individual errors. The goal is to design systems that are ‘fault tolerant,’ so that when an individual error occurs, it does not result in harm to a patient. That’s why we’ve based VA’s patient safety program ... on prevention, not punishment.”¹²² This paradigm became known as a no-blame patient safety model.

This no-blame culture has been questioned with the introduction of the concept of a just culture.^{123,124} The AHRQ describes a just culture as one that identifies and addresses systems issues that lead individuals to engage in unsafe behaviors while maintaining accountability. Marx¹²³ and the AHRQ are careful to distinguish between human error (e.g., slips), at-risk behavior (e.g., taking shortcuts), and reckless behavior (e.g., ignoring required safety steps), in contrast to an overarching no-blame approach.¹²⁵ For example, an egregious form of recklessness is willful refusal to follow widely accepted and efficacious policies, akin to a pilot refusing to use checklists or a physician consistently refusing to wash his or her hands.

What should form the basis of a just culture in health care? When a preventable error results in an adverse outcome, should the focus be on punishment or on making amends? Should anything at all be done if there is no harm? A similar tension is found in legal theory, which uses principles of retributive and restorative justice.¹²⁶ Retributive justice, based on the principle of *lex talionis* (“an eye for an eye”), describes the “culture of blame,” in which fault is decried and punishment is proportionate to harm. Alternatively, restorative justice encourages responsibility, reparations, and rehabilitation. For example, a physician who ignores time-outs in the operating room would lose operating privileges for 2 weeks in the retributive model; in the restorative model, the physician would receive advanced instruction on checklists and “never events” and be required to co-lead a training module on time-outs for new staff. Loss of privileges would remain a last resort, used only when prior remedies are ignored or ineffective.

Where does the individual physician fit into a just culture that must balance no-blame and accountability? Whereas restorative disciplinary measures are appropriate in cases of misconduct involving willful disregard for safety or standards, as James Reason points out, in the case of a slip, there is little benefit from simply putting “a carcass up on the wall” to show that something has been done.¹²⁷

Without losing sight of the serious consequences to the patient, it is crucial to be cognizant of the fact that adverse outcomes can leave a devastating impact on the caregiver as well, who will often have many years left and thousands of patients to provide care for. Even before an event is reviewed, usually at the first instance of recognition, the emotional and psychological consequences to the caregiver begin. The sickening realization of the mistake turns into dread and agony, then defensiveness and anger. In many ways, the physician becomes a second victim, subject to the phenomenon of secondary trauma, which occurs when one *witnesses* a traumatic event.¹²⁸ Scott and colleagues outlined the trajectory of recovery for the physician after an adverse event, noting six stages: (1) chaos and accident response, (2) intrusive reflections, (3) restoring

personal integrity, (4) enduring the inquisition, (5) obtaining emotional first aid, and (6) moving on.¹²⁹ The last stage encompasses three pathways—dropping out, surviving, or thriving.

In the wake of an error-related adverse event, great care is needed to avoid giving physicians the sense that they are on trial for a crime, because the potential exists for losing good doctors—literally if they drop out, or figuratively if they merely survive—whose only fault is being human. One strategy to consider in evaluating a physician after an error, especially an error that caused harm to a patient, is to focus on the following crucial questions:

1. Was the standard of care met, including adherence to crucial policies and guidelines?
2. Is the physician willing to incorporate lessons learned into future practice?
3. Is the physician committed to maintaining a relationship with the patient and participating in a full disclosure of events?

At all times, but particularly when these answers are clearly yes, physicians deserve maximal support.¹³⁰ It may be especially powerful if the physician can maintain a role as an advocate for the patient’s best interests throughout the process, including deliberations regarding potential compensation. Ultimately, in the wake of an adverse event, the patient and the entire team of caregivers will need additional support and monitoring.

Conclusions

The patient safety movement is now in full swing, and regulatory agencies are paying increasing attention to obstetric care.¹⁹ Of the many potential tools and strategies available to enhance safety, the integral components are evidence-based standardization, enhancements in communication, and, if financial constraints allow, a dedicated PSN. The application of principles of patient safety to outpatient settings is just beginning.¹³¹

Unfortunately, evidence of benefit of these approaches is only slowly emerging. Few randomized clinical trials exist, because these types of interventions tend to focus not on building a corpus of evidence but rather on timely quality improvement. In fact, as recently suggested by Berwick, the type of study design most commonly found in the literature may arguably be the most feasible, if not the most appropriate, for studying the “complex, unstable, [and] nonlinear social change” characterized by quality improvement initiatives.¹³² A clinical trial would require suspending all other quality improvement activities for a service over a substantial period of time; this would not be practical in today’s setting of stringent government oversight and high patient expectations.

Nevertheless, the application of the techniques described in this chapter is beginning to show improved obstetric care in a variety of areas,^{12,109,133} and some of these results have occurred with more impact, less effort, less expense, and certainly less time than traditional basic science and translational approaches to advancing care. Engaging in these processes can evolve a unit into a high-reliability organization, where safety is a paramount end, teams are valued over the individual, effective and transparent communication is constantly reinforced, and the unexpected becomes expected.¹³⁴ Patient safety science is an emerging discipline, and maternal-fetal medicine specialists, many with leadership responsibilities, should be familiar with its essential principles.

Maternal Mortality

ELLIOTT K. MAIN, MD

Maternal mortality is a tragedy for families, for providers, and for society. Deaths during childbirth have affected the course of kingdoms and been a recurring theme in literature. Historic cemeteries document the large numbers of young mothers buried with their newborns, and maternal death still strikes a nerve today. Reports of trends or causes of maternal mortality invariably receive much attention in the media and on the Internet. Although the maternal mortality rate is now low in resource-rich countries, these deaths reflect much larger numbers of mothers with near misses or severe morbidity. Maternal mortality is a summary indicator of maternity care, and combined with infant mortality it is a measure of the quality of a country's maternal-child health care system.¹ In addition to being a significant public health statistic, maternal mortality has also become a driver for improving the safety and quality of maternity services at the state and national levels.

In this chapter, maternal mortality is examined through multiple lenses—public health, medical, and quality improvement—but it can also be examined through political, personal, and medicolegal lenses. There are various definitions of maternal mortality, each with advantages and limitations. There have been significant changes in how the data are collected and analyzed, with corresponding changes in the rates reported. The leading causes of pregnancy-associated deaths in resource-rich countries such as the United States will be reviewed here, including a profile of women at greatest risk for maternal death. The concept of preventability has been variously defined and differs by cause. Opportunities to reduce maternal mortality will be reviewed, with a special focus on anticipation, prevention, and rapid response to obstetric emergencies. The role of maternal-fetal medicine specialists and other obstetric leaders in promotion of quality and safety will be described.

MEASUREMENT

Although maternal mortality is reported per 100,000 live births, this should not be considered a *rate*, because some of the deaths occur in women with nonviable pregnancies (e.g., ectopic pregnancies, miscarriages, terminations, stillbirths), which are not in the denominator of live births. Because the proper denominator, the total number of pregnant women, is unknowable (there is no system for collecting early pregnancy losses), the countable number, live births, is used as an approximation, which leads to the correct term, a *maternal mortality ratio*. However, as *maternal mortality rate* (MMR) is far more commonly used, it is the term used in this chapter.

The popular definition involving a mother who dies during pregnancy or childbirth has given way to classifications based on both temporal and clinical characteristics. Issues include the

following: How long after delivery should cases be included (e.g., up to 42 days, or 365 days)? Does the cause of death need to be directly related to an obstetric condition, or should cases be included where the death was related to an underlying medical condition that was aggravated or affected by the pregnancy? Should any death that occurred during or after a pregnancy from any and every cause be included, knowing the uncertainty of relating the death to the pregnancy? There are public health and clinical reasons to use any of these approaches.

The World Health Organization (WHO) defines a maternal mortality as “the death of a woman while pregnant or within 42 days of termination of pregnancy, irrespective of the duration or the site of the pregnancy from any cause related to or aggravated by the pregnancy or its management but not from incidental or accidental causes.”² The data source is solely the death certificate, which in turn has been reclassified using the disease codes from the 10th revision of the International Statistical Classification of Diseases and Related Health Problems (ICD-10). Cases with obstetric (or “O”) codes are classified as a maternal death (excepting O96, late obstetric death). This standard approach is performed annually by the U.S. National Center for Health Statistics and produces the official maternal death statistics for states and for the nation. This definition is also used for time trends and for international comparisons.

In recognition of the limitations of ICD-10 coding, the United States has a complementary system for evaluating maternal deaths, which is based in the Division of Reproductive Health at the Centers for Disease Control and Prevention (CDC). The Pregnancy Mortality Surveillance System was started in 1985 in consultation with the American College of Obstetricians and Gynecologists (ACOG) and state health departments.³ By linking birth and death certificates, they can identify considerably more deaths than those reported on death certificates alone. Furthermore, acknowledging that pregnancy can cause mortality beyond the 42 days after delivery, the CDC extended their definition to 365 days after delivery. The new terms in the United States are *pregnancy-associated mortality* for any death occurring within a year after the termination of the pregnancy, and *pregnancy-related mortality* for those deaths within the year, regardless of the duration or the site of the pregnancy, from any cause related to or aggravated by the pregnancy or its management, but not from incidental or accidental causes.⁴ This extended limit to 1 year is then referred to as the *pregnancy-related maternal mortality rate*. These definitions are recommended by the CDC and ACOG for state maternal mortality review committees to better understand the true scope and range of maternal deaths in their communities. Some states also examine all pregnancy-associated deaths, including non-pregnancy-related deaths such as motor vehicle accidents (the most common cause) for evidence of seat belt use, or homicides

for evidence of domestic violence, as well as other deaths from medical causes not related to pregnancy. Other states have used pregnancy-related deaths to identify and focus on obstetric quality-improvement opportunities.

The terms *direct* and *indirect maternal deaths* are no longer commonly used in U.S. public health documents, but they are widely used in other countries and do have clinical recognition. A direct maternal mortality is defined as “deaths resulting from obstetric complications of the pregnant state (pregnancy, labor and puerperium) from interventions, omissions, incorrect treatment or from a chain of events resulting from any of the above.”⁵ In contrast, indirect maternal mortality is defined as “deaths resulting from previous existing disease, or disease that developed during the pregnancy and which was not of direct obstetric cause, but was aggravated by the physiological effects of pregnancy.”⁵ The CDC expanded this concept to include cases where diagnosis or treatment was delayed by the pregnancy. As the U.S. maternal population has aged and developed more underlying conditions (e.g., morbid obesity), the number of indirect deaths has increased. In practice, the distinction between direct and indirect is more useful for understanding causes than for clinical care. Another important term is *late maternal death*—those deaths occurring between 42 and 365 days after the delivery and otherwise categorized as pregnancy-related deaths. This population is important because it includes many cardiovascular causes of maternal mortality.

TRENDS IN RATE AND DATA COLLECTION ISSUES

The dramatic fall in U.S. MMR during the 20th century has been heralded as a success for both public health programs and obstetric providers (Fig. 50-1).⁶ The decline, from rates approximating 900/100,000 births in 1901 to 9/100,000 in 1991, occurred in other resource-rich countries also. This success has been attributed to many factors: the movement of most births to hospitals, improved hygiene and aseptic technique, common use of prenatal care including screening for preeclampsia, the introduction of blood transfusions and antibiotics, widespread availability of obstetric anesthesia, an increase in training and expertise of obstetric providers, and an improvement in the overall health of the population. Although all of these may be

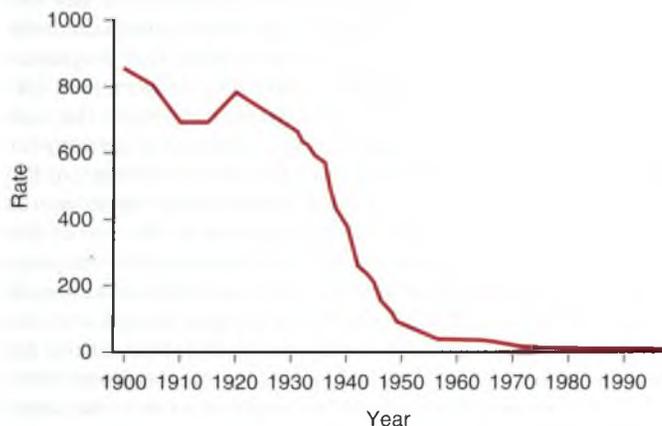

Figure 50-1 U.S. maternal mortality rate, 1900 to 1997. Rate is the number of deaths per 100,000 live births. (From Centers for Disease Control and Prevention: *Healthier mothers and babies*, MMWR Morb Mortal Wkly Rep 48:849–857, 1999.)

important, the period of greatest decline was in the 1930s and 1940s, when many hospital-based advances were being introduced. Although the United States in the 1930s was not resource-rich, the advent of state and city maternal mortality review committees focused attention on causes of and solutions for maternal mortality. Developing community consensus that involves collaboration between the public health system and hospitals and providers, together with forming a local maternal-mortality review committee, should be considered the model when maternal mortality and morbidity are addressed.

More recently, however, the national U.S. metrics have been rising: the latest (2007) MMR reported was 12.7 (Fig. 50-2).⁷ Reasons for the rise include improved ascertainment and higher rates of clinical and population risk factors. Notably, African-American MMRs (Fig. 50-3)⁸ are nearly four times higher than white, Hispanic, or Asian rates, and they have increased as overall rates have risen. The magnitude of disparity between African Americans and other ethnic groups is higher in the MMR than in any other health indicator. Although the high African-American MMR is clearly multifactorial, no effective reduction strategies have been introduced (more on this later). This rise in overall MMR, and in the African-American MMR in particular, has sparked national debate, with attention

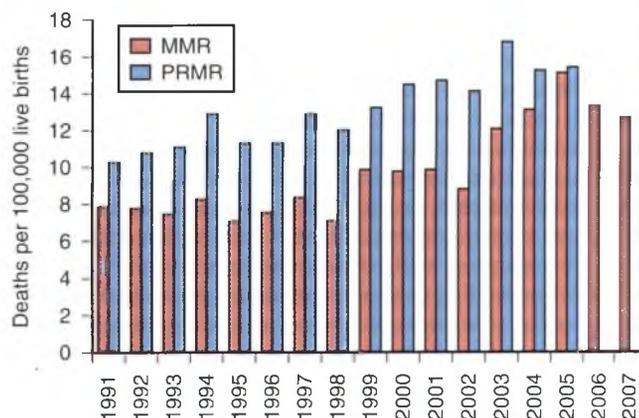

Figure 50-2 U.S. maternal mortality rate (MMR) from 1991 to 2007 and pregnancy-related mortality rate (PRMR) from 1991 to 2005. (From Callaghan WM: *Overview of maternal mortality in the United States*, Semin Perinatol 36:2–6, 2012.)

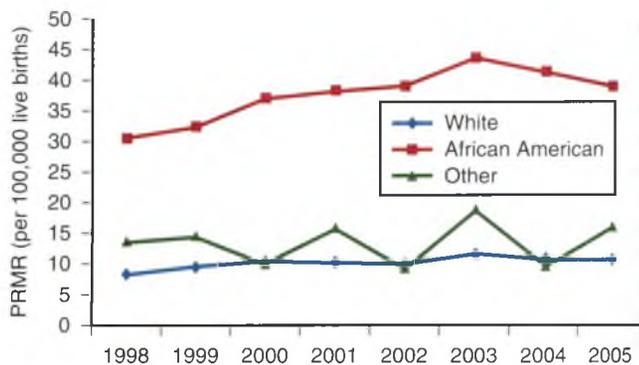

Figure 50-3 U.S. pregnancy-related mortality ratios (PRMR) by race from 1998 to 2005. (From Berg CJ, Callaghan WM, Syverson C, et al: *Pregnancy-related mortality in the United States, 1998 to 2005*, Obstet Gynecol 116:1302–1309, 2010.)

focused on the quality of maternity care, changes in risk factors among pregnant women, and the improved ability to collect accurate maternal mortality data in recent years.

State and national MMRs are underestimated when compared with analyses using enhanced surveillance techniques, such as linked birth and death certificates. In the United States between 1999 and 2007, a series of changes were made to improve the accuracy of maternal mortality data. ICD-10-coded death certificates had more categories for maternal death than ICD-9 had. A new standard death certificate was introduced in 2003 that offered a “pregnancy checkbox” to identify women who were pregnant at the time of death or had delivered within the prior 42 days (or, in some states, 365 days). Given the small numbers of maternal deaths, modest improvements in case ascertainment would be expected to lead to increased rates. Clinical factors that contributed to the higher risk for maternal mortality in this time interval included increases in maternal age and obesity, a 50% rise in cesarean rate, a 40% rise in occurrence of obstetric hemorrhage, and a 100% rise in obstetric interventions such as inductions. Thus, it is difficult to determine the relative contributions of improved data collection and of clinical and patient factors to the increased MMR.

In 2012, because of uncertainties about data collection (e.g., different states have different rules), the National Center for Health Statistics suspended national reporting of MMR for several years in the hope that these issues can be clarified. Recently, a pan-European surveillance program for maternal mortality and severe maternal morbidity also concluded that current population-based data reports were beset by problems, with under-ascertainment of mortalities, poor data-collection systems, and lack of acceptance of the uniform definitions of severe maternal morbidity.⁹ The Euro-Peristat Scientific Committee strongly recommended a return to confidential maternal mortality review committees.⁹

Regardless of the causes, the U.S. MMR rate is higher than it should be. In the United Kingdom, an excellent system for confidential maternal mortality reviews (U.K. Confidential Enquiries into Maternal Deaths⁵) results in nearly 100% ascertainment and has produced triennial reports since 1952. The latest reported MMR in the United Kingdom (covering the period 2006 to 2008) is 6.8 per 100,000, approximately half that seen in the United States for the same time period (and the United States does not have complete ascertainment!), despite the fact that both countries have large numbers of disadvantaged minorities from Africa and South Asia who have much higher MMRs than other racial or ethnic groups.

DEMOGRAPHICS

Most U.S. reviews of maternal mortality note that women who die in childbirth share several key demographic features. On average, they are more disadvantaged, older, and heavier, they have no prenatal care, and they are much more often African American than those who do not die in childbirth. Although these statistics serve to identify the highest-risk populations, they should not divert attention from the occurrence of maternal deaths in all social strata, among women in their teens, women who are slender, women who have complete prenatal care, and women of any race. For example, the MMR for women in their twenties was 12.4/100,000 live births, but for women between 35 and 39 years old it was doubled (24.1), and for women 40 years old or more, it was 54.9. In the U.K.

Confidential Enquiry,⁵ similar trends (but lower overall rates) were seen: MMRs of 9.0, 18.8, and 29.2, respectively. In a recent review of all maternal deaths in California using a linked data set and chart reviews, women older than 35 accounted for 17% of the births but fully 37% of the pregnancy-related mortalities.¹⁰ The story for obesity is similar. In the United Kingdom, 27% of the maternal deaths were in women with a body mass index (BMI) of greater than 30 (i.e., obese), and in California, 22.9% of the pregnancy-related deaths were in women with a BMI of greater than 30 (as compared with the general obstetric population, with a rate of 15.7%). Advancing maternal age and obesity are associated with increased rates of underlying medical problems, especially hypertension, diabetes, and cardiac disease. Formal studies of the increased risk for death with advancing maternal age are lacking, but preexisting disease is likely to be the main driver.

Causes and Preventability of Maternal Mortality

It is understood that obstetric hemorrhage, preeclampsia, and sepsis drive the low MMRs in resource-poor countries, but these are also among the leading causes of maternal mortality in resource-rich societies. A rising and under-recognized cause of death in resource-rich countries is maternal cardiovascular disease. Most studies of maternal mortality categorize maternal deaths by the causal pathway, regardless of the final event that led to cessation of heart and lung function, so the latter may not appear on the death certificate. For example, a mother's death from intracranial bleeding related to severe preeclampsia with untreated hypertension would typically be categorized as a death related to preeclampsia rather than to intracranial hemorrhage. Today, women who suffer a maternal mortality have often had complex courses in the intensive care unit (ICU). Instead of the death being categorized by the final ICU diagnosis (often multiorgan failure), it is generally the process that led to admission to the ICU that is reported.

Figure 50-4 shows the cause-specific, pregnancy-related mortality rates reported by the CDC for three recent time

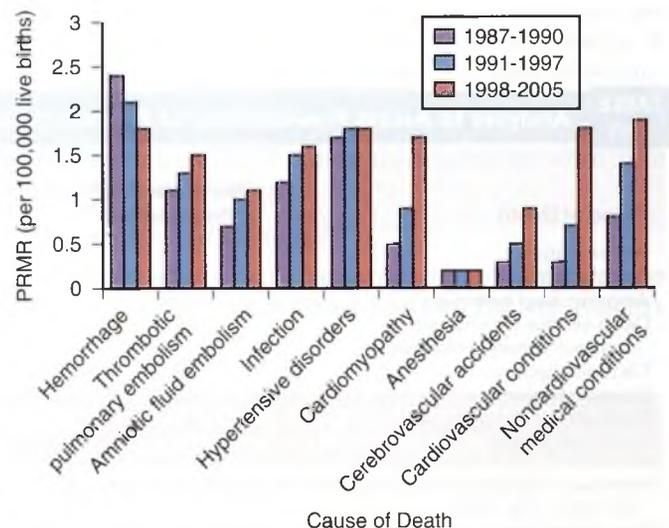

Figure 50-4 Cause-specific, pregnancy-related mortality rates (PRMR) for 1987 to 1990, 1991 to 1997, and 1998 to 2005, in the United States. (From Callaghan WM: Overview of maternal mortality in the United States, *Semin Perinatol* 36:2-6, 2012.)

periods. Cardiomyopathy and other cardiovascular conditions combined are now the leading cause of maternal mortality. Cardiomyopathy alone (peripartum and postpartum) accounts for two thirds of these deaths, an observation consistent with recent maternal mortality case-review analyses in California, New York, and the U.K. Confidential Enquiry.

To determine how many maternal mortalities might have been prevented, preventability analyses are performed, but they are done retrospectively and typically without interviewing staff and family to gather complete details. The number of preventable maternal deaths is therefore probably underestimated. A hospital-based study found that a low percentage (28%) of deaths were potentially preventable.¹¹ Population-based studies have found higher numbers. A statewide review in North Carolina found large variations in preventability depending on the specific cause.¹² In this analysis, 93% of hemorrhage-related deaths and 60% of preeclampsia-related deaths were preventable. In the California Pregnancy-Associated Mortality Review, reviewers were uncomfortable with categorical decisions about preventability, preferring a graded list of evidence (strong, good, some, none) about whether the outcome might have been altered.¹⁰ The U.K. Confidential Enquiry asks directly whether there was substandard care, and whether it had a major or minor effect on outcomes.⁵ Comparative results are shown in Table 50-1. Despite the variable approaches, the results are similar: preventability varies with the cause. Hemorrhage and preeclampsia present high opportunities for preventability; pulmonary embolism, sepsis, and cardiomyopathy are intermediate; and, in these analyses, deaths from amniotic fluid embolism were deemed unpreventable.

IMPROVEMENT OPPORTUNITIES

The pathophysiology, diagnostic criteria, and treatment approaches for potentially lethal maternal conditions are discussed in other chapters. Here, we focus on the differences between women who died and women who survived with the same diagnosis, and on lessons gleaned from maternal mortality reviews. Opportunities for improvement may be found for the health system, the hospital, the providers, and the patient

and her family. Detailed case analyses of maternal mortality can drive advancement in obstetric care and improvements in maternity outcomes. The U.K. Confidential Enquiry series,⁵ the California¹⁰ and New York¹³ pregnancy-related mortality reports, and The Joint Commission Sentinel Event Report on Maternal Mortality^{13a} all used the WHO maternal mortality surveillance and response cycle, which involves turning case reviews into practice recommendations (Fig. 50-5).¹⁴ The following paragraphs focus on selected causes of maternal mortality and suggest improvements that should be considered by all providers and hospitals. These are drawn from multiple sources, but the reader is especially referred to the U.K. review⁵ and to Clark and Hankins.¹⁵

Obstetric Hemorrhage

Worldwide, excessive blood loss at birth is the most common cause of maternal death, and it is the leading cause of severe

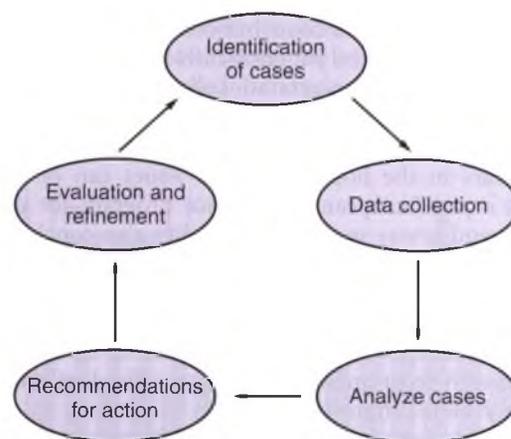

Figure 50-5 The World Health Organization's maternal mortality surveillance and response cycle. Case reviews are turned into recommendations for practice change, and the changes are evaluated during the next cycle. (From World Health Organization: *Beyond the numbers: reviewing maternal deaths and complications to make pregnancy safer*, Geneva, 2004, World Health Organization.)

TABLE 50-1 Analyses to Assess Preventability of Pregnancy-Related Mortality

Cause of Death	North Carolina*: "Preventable"	California†: "Good or strong chance to alter the outcome"	United Kingdom‡: "Substandard care that had a major contribution"
Hemorrhage	93%	69%	44%
Preeclampsia	60%	50%	64%
Amniotic fluid embolism	0%	0%	15%
Deep venous thrombosis and pulmonary embolism	17%	53%	33%
Cardiomyopathy	22%	25%	25%
Sepsis/infection	43%	50%	46%
Total number of pregnancy- related deaths	40	40	44

maternal morbidity in resource-rich countries. With the advent of modern bloodbanking, intensive care, and interventions (e.g., prostaglandins, intrauterine balloons) for control of uterine atony, mortality has fallen. However, hemorrhage still accounts for more than 10% of maternal deaths in the United States, with a cause-specific MMR of 1.6 per 100,000. In the United Kingdom, the rate of loss from hemorrhage is only 0.4 per 100,000. Why are women still dying from hemorrhage in resource-rich countries? Case reviews have identified institutional issues, such as the failure to have a response team with a plan, delay and denial (i.e., assuming the bleeding will improve), and the lack of availability of and familiarity with blood component therapy. Rates of hemorrhage and subsequent use of blood transfusions have risen in all resource-rich countries studied.¹⁶

The increasing frequency of multiple prior cesarean births has led to an epidemic of placental implantation issues, from placenta previa to accreta to percreta. Women who refuse blood products (e.g., for religious reasons) need special planning. Long inductions followed by cesarean birth appear to be a special risk.

However, obstetric hemorrhage has the lowest case-fatality rate of all the causes of maternal mortality, so despite its being common, most patients survive it. The most dangerous clinical settings are hemorrhage occurring in women who have disseminated intravascular coagulation, placental implantation abnormalities, and broad ligament or posterior uterine tears that result in internal bleeding only. Maternal mortality committees in New York, California, and the United Kingdom have reviewed obstetric hemorrhage and have identified several key improvement opportunities for reducing mortalities (Box 50-1).¹⁷

Amniotic Fluid Embolism

Amniotic fluid embolism (AFE) is one of the most feared complications of delivery, but it no longer results in near-universal maternal mortality.^{18,19} Most patients with AFE present with sudden cardiovascular collapse during labor or delivery, followed by profuse bleeding and disseminated intravascular coagulation. The cardiovascular event may be milder (e.g., oxygen desaturation), but the cases that result in a maternal death are usually dramatic. Population-based series have identified an AFE frequency of 2 to 6 per 100,000 live births, with a mortality rate of 25% to 40%. Recently reported AFE-specific mortality rates are 0.57 per 100,000 for the United Kingdom and 1.1 for the United States.^{5,7} In case reviews, some deaths occurred after very slow responses and undertreatment of coagulopathy, but

others occurred despite intensive support after catastrophic cardiovascular collapse. For severe cases, there may be little chance, but early and very aggressive treatment is warranted (Box 50-2).

Venous Thromboembolic Events

Venous thromboembolism (VTE) causes approximately 10% of maternal deaths, most of which occur after pulmonary emboli. The two strategies followed to reduce maternal mortality from VTE are primary prevention and early recognition. In the United States over the past decade, there has been much debate about the need for VTE prophylaxis at the time of delivery, particularly after cesarean birth. The incidence of deep venous thrombosis is so low that it has been difficult to stage a trial robust enough to show statistical benefit from interventions. The United Kingdom made a national push to lower the rate of deaths from VTE, and in the most recent triennium they achieved an impressive 50% reduction from a baseline of the two prior 3-year periods. The U.K. Confidential Enquiry⁵ identifies better risk assessment and wider use of prophylaxis as being important to their success. The current U.K. rate is 0.79 per 100,000, and in the United States it is nearly twice that (1.5). Because maternal deaths in the United Kingdom were reduced after national prevention protocols were adopted, most U.S. hospitals now follow recommendations for prophylaxis released by The Joint Commission and ACOG, which advocate sequential compression devices after all cesarean births and for women at prolonged bed rest. For women who have risk factors for VTE, the most common of which is obesity, optimal management is uncertain.²⁰ The dosage of low-molecular-weight heparin and the length of postpartum thromboprophylaxis are unresolved for women who are obese or morbidly obese (BMI > 40), and for those who have other risk factors such as a history of VTE, thrombophilias, nephrotic proteinuria (including severe preeclampsia), and multiple-unit transfusions.

Case reviews have documented the difficulty in recognizing the signs and symptoms of pulmonary embolism in pregnant and postpartum women because of the overlap with normal pregnancy symptoms.¹⁰ Any episode of sudden onset of shortness of breath with tachypnea and tachycardia in a pregnant or postpartum woman deserves full evaluation. Imaging studies, in particular computed tomography (CT) examinations, are controversial because of concerns about excessive radiation. A recently published algorithm for imaging of suspected pulmonary embolism in pregnancy calls for serial use of Doppler ultrasonography of the leg, chest radiography, and ventilation-perfusion studies, with CT angiograms reserved for when these results are inconclusive²¹ (Box 50-3).

Preeclampsia and Eclampsia

Preeclampsia and obstetric hemorrhage provide the greatest opportunities to prevent maternal mortality. The large majority

BOX 50-1 REDUCING MATERNAL MORTALITY: OBSTETRIC HEMORRHAGE

Every obstetric unit needs a hemorrhage-response protocol, and members should train as a team.

Every obstetric unit needs a protocol for massive transfusions. Nursing and medical staff must be able to identify and respond to clinical triggers.

Intrauterine balloons and uterine compression sutures should be available, and all maternity providers should be familiar with them.

Women with a placenta previa and more than one prior cesarean should deliver in a center with a large blood bank and surgical support for a rapid cesarean hysterectomy.

BOX 50-2 REDUCING MATERNAL MORTALITY: AMNIOTIC FLUID EMBOLISM

Aggressive and immediate cardiopulmonary support (intubation and pressors)

Immediate initiation of the massive-hemorrhage protocol, with an emphasis on large quantities of coagulation factors

Immediate involvement of senior staff from anesthesia, obstetric, and critical care departments

**BOX 50-3 REDUCING MATERNAL MORTALITY:
VENOUS THROMBOEMBOLISM**

Use sequential compression devices during and after all cesarean deliveries.

Use anticoagulant thromboprophylaxis for patients with high-risk conditions (e.g., obesity, thrombophilias, history of venous thromboembolism, nephrotic levels of proteinuria) and for those who received multiple-unit transfusions and are no longer bleeding.

Start anticoagulant thromboprophylaxis 12 hours after delivery, duration of treatment will depend on the high-risk condition.

New, sudden-onset shortness of breath, tachypnea, and tachycardia should be evaluated promptly.

of women who die from preeclampsia die from intracranial hemorrhage, a substantial number from liver failure, and a few from lung complications. Undertreated hypertension, particularly in patients with low or borderline platelets, has emerged as the greatest risk factor for intracranial hemorrhage and the greatest opportunity to improve care. National guidelines in the United Kingdom and the United States now recommend aggressive treatment of systolic hypertension at 150 mm Hg, if confirmed as lasting for 5 to 10 minutes.²² Protocols for progressive intravenous labetalol or hydralazine are described in Chapter 48. Not all intracranial hemorrhages can be prevented with hypertensive therapy, but it is anticipated that a substantial portion might be.

Prevention of maternal deaths from HELLP syndrome (*hemolysis, elevated liver enzymes, and low platelets*) depends on early recognition and prompt delivery. In addition to labor and delivery personnel, emergency department staff and primary care providers must also recognize that women who present in the third trimester with nausea, vomiting, or malaise should have a complete blood count including platelets, and liver function tests should be completed before discharge home. Severe preeclampsia and HELLP syndrome are medical emergencies that call for physician attendance until stabilized. If local facilities are not sufficient for full support, coordination with and possible transfer to a tertiary center should be considered.

Mothers with superimposed preeclampsia and older multiparas with HELLP syndrome have the highest risk for severe complications.²³ Consultations with a maternal-fetal medicine specialist and a team approach can be critical for these patients, who often have multisystem dysfunction. The blood bank should also be consulted early.

Mothers with severe preeclampsia, particularly postpartum mothers, may go to the emergency department. The staff there must be aware that a systolic pressure of 150 mm Hg is a severe emergency and requires prompt care (Box 50-4).

Cardiovascular Disease

Cardiovascular disease is the leading cause of pregnancy-related mortality in the United States and the United Kingdom. Cardiovascular-related deaths often occur more than 42 days after the birth, obscuring their importance as a cause of maternal mortality. Two thirds of deaths from cardiovascular disease are from cardiomyopathies. Obesity, African-American race, advancing maternal age, multiple gestations, and hypertension (both chronic and preeclamptic) are additive risk factors.²⁴ Higher-risk women with symptoms should be fully evaluated.

**BOX 50-4 REDUCING MATERNAL MORTALITY:
PREECLAMPSIA**

Aggressively treat both systolic and diastolic hypertension. Protocols for the use of intravenous labetalol and hydralazine should be introduced and widely used in the labor and delivery and the emergency departments.

Laboratory evaluations should be mandatory for all patients who present in the third trimester with nausea, vomiting, or malaise.

The emergency department should have repeated education sessions covering recognition and treatment of severe preeclampsia.

**BOX 50-5 REDUCING MATERNAL MORTALITY:
CARDIOVASCULAR DISEASE**

New-onset wheezing during pregnancy and the requirement for more than one pillow when prone deserve further evaluation for cardiac dysfunction.

All pregnant women with known underlying cardiac disease should have a consultation with and be co-managed by a maternal-fetal medicine specialist and a cardiologist.

Cardiomyopathies should be recognized and diagnosed, but if this fails, they should be properly evaluated at the time of autopsy.²⁵ Diagnostic pearls include the following:

- 1) Pregnancy is rarely a time for new-onset asthma, so new wheezes are more likely to be cardiac in origin.
- 2) Although shortness of breath is common in the third trimester, pregnant women should be able to lie nearly flat without a worsening of symptoms.

Underlying structural heart disease is responsible for the majority of the remaining cases of maternal mortality from cardiac disease. This diverse group of diagnoses requires co-management and consultation between maternal-fetal medicine specialists and a cardiologist before and during a pregnancy (Box 50-5).

Suicides and Homicides

Suicide and homicide account for more pregnancy-associated deaths than any other cause of maternal mortality including hemorrhage, preeclampsia, or AFE. In a recent study examining a multistate sample from the National Violent Death Reporting System, the rate of pregnancy-associated death (during pregnancy or up to 365 days after delivery) caused by suicide was 2.0, and caused by homicide was 2.9 per 100,000.²⁶ In this careful study, intimate-partner violence was a major contributor to both homicide (45%) and suicide (54%), a finding confirmed by other studies. The demographic risk factors otherwise differ between these two causes of death. Victims of pregnancy-associated suicide were more likely to be older, and white or Native American. In the United Kingdom, the Confidential Enquiry also found that more than half of the mothers who committed suicide were white, married, employed, living in comfortable circumstances, and older than 30 years.⁵ In contrast, suicide victims associated with substance use were more likely to be younger, single, and unemployed. In all studies, the

large majority of suicides occurred in the postpartum period, half up to 42 days and half between 42 and 365 days after the delivery. The suicide method was decidedly more violent in pregnancy-associated suicides than is generally seen among nonpregnant and non-postpartum women, with hanging and jumping from a height being most common, and with relatively few drug overdoses. In the U.K. series, serious mental illness, mainly psychosis and severe depressive illness, was present in 57%.

In cases of pregnancy-associated homicides, 42% of suspects were current or former intimate partners. In the United States, pregnancy-associated deaths occur disproportionately in African-American, younger (<25 years), and unmarried women. In contrast to suicides, 77% of the pregnancy-associated homicides occurred during pregnancy as opposed to the first postpartum year.

The question of whether suicides and homicides occur in greater frequency during pregnancy and in the year after the birth than in similar nonpregnant populations is controversial, and different assessment techniques have led to different results.²⁷ Most studies find that the proportion of deaths caused by violent means is higher in the pregnant and postpartum population, but more carefully done studies suggest that the absolute rates of suicide and homicide are not statistically higher. This may in part be attributed to the generally better health of women who become pregnant than women of the same age who are not pregnant. Regardless of the absolute overall risk, suicide and homicide are among the highest causes of pregnancy-associated mortality. Women at highest risk for suicide are those with underlying psychiatric disease or involved with intimate-partner violence, and women at highest risk for homicide are young unmarried women involved with intimate-partner violence (Box 50-6).

African-American Maternal Mortality Rates

The reasons that MMRs for African-American women are threefold to fourfold higher than for other racial and ethnic groups are complex. Women with similar levels of poverty and reduced access to care who are not African Americans do not have these high MMRs. One hypothesis is that lifelong exposure to an environment of disrespect, called status syndrome,²⁸ in this case induced by skin color, manifests as adverse health outcomes. Other proposed contributors to the high MMRs include higher rates of morbid obesity, lifestyle issues, substandard care at resource-poor facilities, poor relationships with and miscommunications with health care providers, and a higher prevalence of underlying medical conditions such as hypertension. Still other studies have identified not higher frequencies of pregnancy complications but increased severity of comorbidities,²⁹ or higher case-fatality rates for each

BOX 50-6 REDUCING MATERNAL MORTALITY: SUICIDE AND HOMICIDE

- Women with underlying major psychiatric disease (psychosis or severe depression) or involved in intimate-partner violence are at higher risk for suicide.
- Women who are younger, unmarried, and involved in intimate-partner violence are at higher risk of being victims of homicide.

complication.³⁰ Regardless of the cause, health providers in all disciplines should be aware that African-American women have higher risk and merit thorough evaluation of any symptoms in pregnancy and the postpartum period.

Although most causes of maternal mortality are increased in African-American women, cardiomyopathy, VTE, and preeclampsia appear to be at particularly high rates. This is probably related to underlying risk factors such as obesity and hypertension, but it should heighten vigilance during their pregnancies. Further research is critical.

Role of Obstetric Leaders in Reducing Maternal Mortality

Senior obstetricians and maternal-fetal medicine specialists are the natural leaders for local and state initiatives to reduce maternal mortality. Every hospital should have an ongoing safety and quality improvement program that is distinct from the usual peer review process. This change in hospital organization requires regional leadership at tertiary facilities. The first step is to address the topics presented here (e.g., obstetric hemorrhage, AFE, preeclampsia, VTE, cardiac disease, suicide prevention, and the care of African-American women) and determine how to implement improvements in care. The programs should also cover more general quality-improvement issues, such as the need for triggers that demand physician evaluation and the increased use of protocols for the care of complicated patients.

In addition, obstetric and maternal-fetal medicine specialists should take the lead in state or regional maternal-mortality reviews. These can effect local quality improvements, but also, more importantly, as happened in the 1930s, they can help create a public agenda for improving the care of women and infants.

Maternal and Fetal Infections

PATRICK DUFF, MD

Infectious disease is the single most common problem encountered by the obstetrician. Some conditions, such as urinary tract infections, endometritis, and mastitis, pose a risk primarily to the mother. Other disorders, such as group B streptococcal (GBS) infection, herpes simplex virus (HSV) infection, rubella, cytomegalovirus (CMV) infection, and toxoplasmosis are of principal concern because of the risk of fetal or neonatal complications. Still others, such as human immunodeficiency virus (HIV) infection and syphilis, can cause serious morbidity for both mother and baby.

This chapter reviews the 29 most common infections that occur during pregnancy. Each section considers the epidemiology, pathogenesis, diagnosis, and treatment of an individual infectious disease with which the obstetrician should be familiar.

Candidiasis (Monilial Vaginitis)

Vulvovaginal candidiasis (VVC) is primarily caused by *Candida albicans*. Other species are responsible for fewer than 10% of cases. *C. albicans* is a saprophytic yeast that exists as part of the endogenous flora of the vagina. The organism is present in the vagina of approximately 25% to 30% of sexually active women.¹ It may become an opportunistic pathogen, especially if host defense mechanisms are compromised. However, the biologic mechanisms that allow this commensal microorganism to become a pathogen are not completely understood.² Systemic candidiasis is a rare event in gravid patients, occurring only in the presence of disease entities causing significant debilitation (e.g., sepsis, malignancy). VVC is a much more common infection and is the second most common cause of vaginitis after bacterial vaginosis (BV).

EPIDEMIOLOGY

Seventy-five percent of women will have at least one episode of VVC during their lifetime, and 40% to 45% will have two or more episodes.¹ *C. albicans* is the predominant yeast isolated (>90% of cases) from patients with VVC, with other species (i.e., *Candida glabrata*, *Candida parapsilosis*, and *Candida tropicalis*) recovered less commonly. In the past, it was believed that non-*albicans* species were becoming increasingly common, especially in cases of recurrent VVC. However, Sobel and colleagues³ reported that *C. albicans* was recovered from 401 (94%) of 425 women with recurrent VVC.

Predisposing factors associated with vaginal colonization with *C. albicans* include diabetes mellitus, pregnancy, obesity, recent use of antibiotics or steroids, and immunosuppression. Pregnancy is associated with not only increased colonization but also increased susceptibility to infection and lower cure rates. Previously, oral contraceptives were thought to increase

colonization of yeast in the vagina. However, since the advent of low-dose oral contraceptives, no increase in *Candida* isolation among oral contraceptive users has been observed.⁴

Other risk factors for *C. albicans* have been described. Among a population of women attending a sexually transmitted disease (STD) clinic, Eckert and associates⁵ reported that the principal risk factors were condom use, luteal phase of the menstrual cycle, sexual frequency greater than four times per month, recent antibiotic use, young age, past gonococcal infection, and absence of current BV. Beigi and coworkers⁶ noted additional risk factors, including use of marijuana, use of depo-medroxyprogesterone acetate, sexual activity within the past 5 days, concurrent *Lactobacillus* colonization, and concurrent GBS colonization.

Symptomatic VVC affects 15% of pregnant women. The hormonal environment of pregnancy, in which high levels of estrogen produce an increased concentration of vaginal glycogen, accounts for the increased frequency of symptomatic infection in gravid patients. In addition, suppression of cell-mediated immunity in pregnancy may decrease the ability to limit fungal proliferation.

PATHOGENESIS

As mentioned previously, the pathogenesis by which *C. albicans* evolves from a commensal microorganism colonizing the vagina to the pathogenic microbe involved in vulvovaginal vaginitis, invasive *Candida* infections, and disseminated *Candida* sepsis is poorly understood. Kalo-Klein and Witkin⁷ suggested that hormonal status may modulate the immune system and, as a result, influence the pathogenicity of *Candida* species. They observed that host responses to *C. albicans* were decreased in the luteal phase. Giraldo and colleagues⁸ reported that a polymorphism in the gene coding for mannose-binding lectin (MBL), a critical component of the mucosal innate immune system, was more frequently found in women with recurrent VVC than in those with acute VVC or controls.

The pathogenesis of invasive candidiasis is similar to that associated with bacterial microorganisms. Initially, there must be colonization resulting from adhesion of *C. albicans* to the skin or vaginal mucosa. This is followed by penetration of epithelial barriers, resulting in locally invasive or widely disseminated disease.⁹

Congenital candidiasis characteristically manifests at birth or within the first 24 hours after birth. It usually results from an intrauterine infection or heavy maternal vaginal colonization at the time of labor and delivery. The potential mechanisms for intrauterine *Candida* infection are similar to those of bacterial intra-amniotic infection, including hematogenous spread from mother to fetus, invasion of intact membranes, and ascending infection after rupture of the membranes.^{9,10} The

presence of an intrauterine foreign body, most commonly a cerclage suture, is also a recognized risk factor for congenital candidiasis. VVC has not been associated with preterm birth, preterm labor, low birth weight, or premature rupture of the membranes (PROM).^{10,11}

Recurrent VVC is defined as four or more episodes of symptomatic VVC within 1 year. Recurrent VVC occurs in a small percentage of women (<5%). The pathogenesis of recurrent VVC is poorly understood, and the majority of those affected do not have any apparent predisposing or underlying conditions. *C. glabrata* and other non-*albicans* *Candida* species are recovered from 10% to 20% of women with recurrent VVC.^{12,13}

DIAGNOSIS

The clinical manifestations of VVC in pregnancy are similar to those in the nonpregnant state; they include pruritus and burning, dysuria, dyspareunia, fissures, excoriations with secondary infection, and pruritus ani. The vaginal discharge is usually thick, white, and curdlike.

The diagnosis of VVC can be made when either (1) a 10% potassium hydroxide (KOH) wet preparation or Gram stain of a vaginal discharge sample reveals yeasts or pseudohyphae or (2) a culture discloses yeast.¹² The vaginal pH in women with VVC is normal (<4.5). Women with a positive KOH wet mount should be treated for VVC. Women who have a negative KOH smear despite clinical signs and symptoms suggestive of VVC should have vaginal cultures for yeast. For patients with recurrent VVC, the laboratory should be requested to identify the species of *Candida* recovered.

The clinical manifestations of congenital candidiasis range from superficial skin infection and oral infection to severe systemic disease with hemorrhage and necrosis of the heart, lungs, kidneys, and other organs. The most common route of infection is by direct contact during delivery through an infected vagina. Oropharyngeal candidiasis of the neonate (thrush) is the most frequent manifestation of congenital infection.

TREATMENT

The regimens recommended by the Centers for Disease Control and Prevention (CDC) for the treatment of VVC are listed in Table 51-1.¹² Short-course topical formulations (i.e., single-dose and 1- to 3-day regimens) effectively treat uncomplicated VVC, resulting in relief of symptoms and negative cultures in 80% to 90% of patients who complete therapy. Intravaginal preparations of butoconazole, clotrimazole, miconazole, and tioconazole are available over the counter (OTC). According to the CDC, women who previously were diagnosed with VVC are not necessarily more likely to accurately diagnose themselves. Therefore, women whose symptoms persist after use of an OTC preparation or who have a recurrence of symptoms within 2 months should be assessed with office-based testing.¹²

VVC is not usually acquired through sexual intercourse, so treatment of sex partners is not recommended. Treatment of partners should be considered for women who have recurrent VVC and for male sex partners with balanitis.¹²

The CDC recommends topical azole therapies as the first line of treatment for VVC during pregnancy. These topical medications should be applied for 7 days. For complicated cases of VVC, a longer duration of initial therapy (e.g., 7 to 14 days of topical therapy or a 150-mg oral dose of fluconazole every third day for a total of three doses) should be considered.¹²

Trichomoniasis

CLINICAL PRESENTATION

Trichomonas vaginalis is a common cause of vaginitis, with infection often characterized by intense pruritus, strong odor, and dysuria. Physical examination typically reveals a malodorous, yellow-green, frothy discharge. However, variations of the gross appearance occur in approximately 50% of cases, and many women show minimal or no symptoms. The diagnosis may be confirmed by saline microscopy, which reveals many

TABLE 51-1 Recommended Regimens for Treatment of Vulvovaginal Candidiasis in Pregnant and Nonpregnant Women

Antifungal Agent	Formulation	Regimen
INTRAVAGINAL AGENTS		
Butoconazole	2% cream*	5 g intravaginally for 3 days
	2% cream (Butoconazole 1—sustained release)	5 g single intravaginal application
Clotrimazole	1% cream*	5 g intravaginally for 7-14 days
	100-mg vaginal tablet	One tablet daily for 7 days
	100-mg vaginal tablet	Two tablets at one time daily for 3 days
Miconazole	2% cream*	5 g intravaginally for 7 days
	100-mg vaginal suppository*	One suppository daily for 7 days
	200-mg vaginal suppository*	One suppository daily for 3 days
	1200-mg vaginal suppository*	One suppository daily for 1 day
Nystatin	100,000-unit vaginal tablet	One tablet daily for 14 days
Tioconazole	6.5% ointment*	5 g intravaginally in a single application
Terconazole	0.4% cream	5 g intravaginally for 7 days
	0.8% cream	5 g intravaginally for 3 days
	80-mg vaginal suppository	One suppository daily for 3 days
ORAL AGENT		
Fluconazole	150-mg oral tablet	One tablet in single dose. Repeat in 3 days if indicated.

*Over-the-counter preparation.

From Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines, 2006, MMWR Recomm Rep 55(RR-11):1-94, 2006.

leukocytes and bacteria; trichomonads are recognized by their size (slightly larger than leukocytes) and active flagellae. The sensitivity of wet mount is only 60% to 70%.¹⁴ Cultures for *Trichomonas* are more sensitive than wet mount, and commercial systems are available to facilitate culture of this parasite. Currently two point-of-care diagnostic tests are available—the OSOM Trichomonas Rapid Test (Genzyme Diagnostics, Cambridge, MA) and the Affirm VP III (Becton Dickinson, San Jose, CA). These tests have better sensitivity than wet mount, but false-positive results may be a problem, especially in low-prevalence populations.

The prevalence of *T. vaginalis* vaginitis in pregnancy ranges from less than 10% to 50%, depending on the patient population. Consequently, it has been difficult to establish whether the incidence of this vaginal infection truly is increased in pregnant women.

ADVERSE EFFECTS IN PREGNANCY

An increased rate of PROM at term has been linked to positive genital tract cultures for *T. vaginalis* (27.5% incidence with infection versus 12.8% without; $P < .03$).¹⁵ In the large National Institutes of Health infection and prematurity study, *T. vaginalis* infection at midpregnancy was associated significantly with low birth weight (odds ratio [OR] = 1.3; 95% confidence interval [CI], 1.1 to 1.5), preterm delivery (OR = 1.3; CI, 1.1 to 1.4), and PROM (OR = 1.4, CI, 1.1 to 1.6), even after adjustment for confounding factors and colonization with other microbes.¹⁶ In addition, trichomoniasis has been associated with increased rates of HIV transmission.^{17,18}

TREATMENT

The recommended treatment for trichomoniasis is oral metronidazole, 2 g in a single dose. An alternative regimen is metronidazole, 500 mg orally twice a day for 7 days.¹² No consistent association has been demonstrated between use of metronidazole in pregnancy and teratogenesis or mutagenesis in infants.¹⁹ Tinidazole, another nitroimidazole drug, has been approved by the U.S. Food and Drug Administration (FDA) for treatment of trichomoniasis (2 g orally in a single dose). However, metronidazole should be favored in pregnant women because of its superior safety profile and decreased cost. Topical agents often are unsuccessful in relieving symptoms or in eradicating this protozoan.

Among women with asymptomatic trichomoniasis in pregnancy, treatment during the second trimester (two 2.0-g doses 48 hours apart at 16 to 23 weeks, repeated at 24 to 29 weeks) did not result in better pregnancy outcomes than did placebo. Indeed, those given metronidazole had a significantly higher frequency of preterm delivery.²⁰ Accordingly, although symptomatic pregnant women with trichomoniasis should be treated to relieve symptoms, routine screening and treatment are not recommended.

Bacterial Vaginosis

EPIDEMIOLOGY AND PATHOGENESIS

This infection was formerly called nonspecific vaginitis, *Gardnerella vaginalis* vaginitis, or *Haemophilus vaginalis* vaginitis; bacterial vaginosis (BV) is now the preferred term. The

condition is marked by a major shift in vaginal flora from the normal predominance of lactobacilli to a predominance of anaerobes, which are increased 100-fold compared with normal secretions. *G. vaginalis* is present in 95% of cases but also is present in 30% to 40% of normal women. *Mycoplasma hominis* in vaginal secretions is increased significantly in cases of BV.

BV is the most common type of infectious vaginitis. Between 10% and 30% of pregnant women fulfill the criteria for BV, but half of them are asymptomatic.

DIAGNOSIS

Clinically, the principal manifestation of BV is a malodorous, thin, gray discharge. Itching is usually not prominent. Diagnosis of BV is based on the presence of three of the following four clinical features: (1) an amine-like or fishy odor that may be accentuated after addition of KOH or after coitus (owing to the alkaline pH of semen); (2) a thin, homogeneous, gray or white discharge; (3) an elevated pH (>4.5); and (4) on wet mount, “clue” cells (squamous epithelial cells so heavily stippled with bacteria that their borders are obscured). Typically in cases of BV, clue cells account for more than 20% of epithelial cells, and there are few leukocytes. An experienced observer will notice an increase in the numbers and kinds of bacteria and a reduction in numbers of lactobacilli. A Gram stain of vaginal secretions also demonstrates the shift in bacteria and clue cells.

ADVERSE EFFECTS IN PREGNANCY

Evidence consistently has associated BV with an increased likelihood of preterm delivery,²¹⁻²⁴ clinical chorioamnionitis,²³ histologic chorioamnionitis,²⁶ and endometritis.²⁷ The OR for preterm labor in patients with BV has varied from 1.4 to 8.0.

TREATMENT

Among nonpregnant women, the most consistent cure rates (90%) have been achieved with metronidazole, 500 mg twice a day for 7 days. Lower cure rates (60% to 80%) are observed with a single 2.0-g dose of metronidazole. Oral clindamycin (300 mg twice a day for 7 days) is effective in treating nonpregnant patients and appears to be safe in pregnancy. Vaginal clindamycin cream (2%) and metronidazole gel (0.75%) also are effective in nonpregnant women. The preferred regimens in pregnancy are shown in Box 51-1.^{12,28-30}

In view of the consistent association of BV with adverse pregnancy outcomes, clinical treatment trials have been undertaken. Three trials, all conducted in patients who were considered to be at high risk (i.e., a previous preterm birth or other high-risk demographic features), demonstrated improvement in outcome with prenatal treatment of BV (Table 51-2). In a group of women who experienced a spontaneous preterm birth due to preterm labor or PROM during a previous pregnancy,

Metronidazole 500 mg PO bid for 7 days
or
Clindamycin 300 mg PO bid for 7 days

TABLE 51-2 Studies of Bacterial Vaginosis in Pregnancy in Patients at High Risk for Preterm Delivery

Study	Design	Study Population	Incidence of Preterm Birth		
			Antibiotic Treatment (%)	No Treatment or Placebo (%)	Significance (P)
Morales et al, 1994	Randomized, placebo-controlled	80 women with previous spontaneous preterm birth in Florida	18	39	<.05
Hauth et al, 1995	Randomized, placebo-controlled	258 women with previous preterm birth or low maternal weight in Alabama	31	49	.006
McGregor et al, 1995	Nonrandomized, two-phase trial	1260 women in Colorado with a 15% preterm birth rate	9.8	18.8	.02

Modified from Gibbs RS, Eschenbach DA: Use of antibiotics to prevent preterm birth, *Am J Obstet Gynecol* 177:375, 1997.

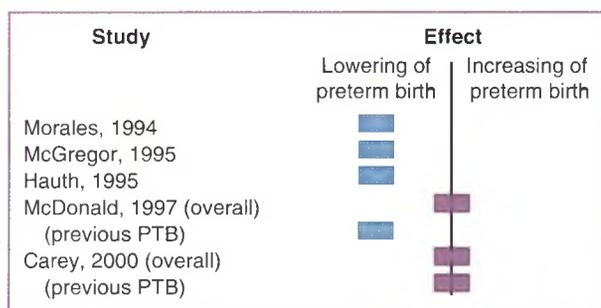

Figure 51-1 Bacterial vaginosis treatment trials. Summary of treatment trials of bacterial vaginosis in pregnancy to prevent preterm birth (PTB).

treatment of BV with oral metronidazole led to a significant reduction in preterm births, low birth weight, and PROM ($P < .05$ for each).³¹ In a prospective, two-phase trial involving 1260 women, treatment of BV significantly decreased the rate of preterm births ($P < .05$).³² Finally, among women at risk because of a previous preterm birth or low maternal weight, treatment with a combination of metronidazole and erythromycin significantly improved pregnancy outcome compared with placebo in those patients who had BV ($P < .006$); in patients without BV, pregnancy outcome was not improved.³³

In a treatment trial of women at low risk for preterm delivery, oral metronidazole (twice daily for 2 days at 24 weeks, with repeat treatment, if needed, at 29 weeks) led to no reduction in the rate of preterm birth overall but produced a significant reduction in the subgroup of women with a previous preterm birth.³⁴ In the Maternal-Fetal Medicine Units Network treatment trial of women with asymptomatic BV, the treatment regimen also was short (two 2.0-g doses at 16 to 24 weeks and again at 24 to 30 weeks, with the repeat treatment given at least 14 days after the initial doses). Use of metronidazole in this regimen led to no significant improvement overall or in any subgroup (e.g., women with a previous preterm birth).³⁵ These studies are summarized in Figure 51-1. In view of these disparate results, the American College of Obstetricians and Gynecologists (ACOG) concluded in 2001, "Currently, there are insufficient data to suggest [that] screening and treating women at either low or high risk will reduce the overall rate of preterm birth."³⁶

However, Goldenberg and colleagues³⁷ reached a different conclusion, taking into consideration the metronidazole

BOX 51-2 RECOMMENDATIONS FOR MANAGEMENT OF BACTERIAL VAGINOSIS (BV) IN PREGNANCY

Symptomatic pregnant women with BV can be treated safely in any trimester with oral metronidazole or clindamycin. Routine screening and treatment of BV in asymptomatic women at low risk for preterm birth *cannot* be endorsed (U.S. Preventive Services Task Force: D recommendation). Screening for BV may be considered in asymptomatic women at high risk for preterm birth, such as those with a previous preterm birth. Women who test positive should be treated. The value of rescreening and retreatment is unclear.

regimen used. We agree with their recommendation for treatment with oral metronidazole for at least 7 days in women at high risk (i.e., those with a previous preterm birth). Screening and treatment of these high-risk women should occur at the first prenatal visit. Recommendations for management of BV in pregnancy are presented in Box 51-2.

Gonorrhea

Gonorrhea, which is caused by the gram-negative diplococcus, *Neisseria gonorrhoeae*, is probably the oldest known STD. Almost 340,000 new infections with *N. gonorrhoeae* were reported in the United States in 2004,³⁸ making gonorrhea the second most commonly reported communicable disease in the nation.

EPIDEMIOLOGY

The CDC received 339,593 reports of gonorrhea in 2005. However, even this volume of reports underestimates the incidence, and public health experts estimate that 600,000 new cases of *N. gonorrhoeae* infection occur each year in the United States. From 1975 through 1997, there was a dramatic decrease of 74% in reported cases of gonorrhea. In 1998, an 8.9% increase occurred, followed by plateauing of the number of reported cases.^{38,39} In 2003, for the first time, the reported gonorrhea rate was higher among women (118.8 per 100,000 population) than among men (113 per 100,000).⁴⁰ In 2005, both the number of reported cases and the prevalence rate of gonorrhea increased for the first time in almost a decade.

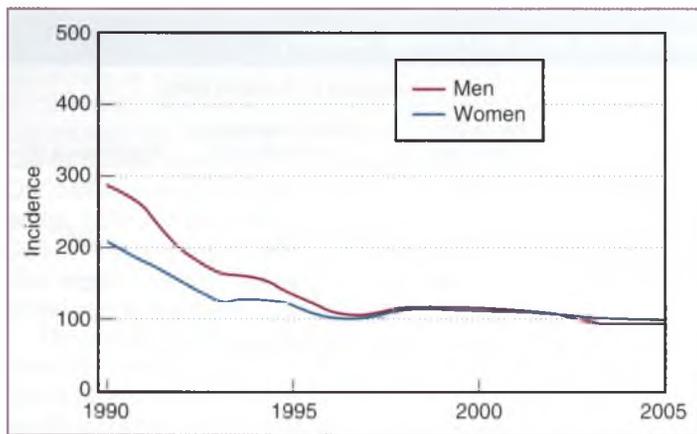

Figure 51-2 Incidence of gonorrhea per 100,000 population, by sex—United States, 1990-2005. The gonorrhea incidence in the United States has declined overall since 1975, but it increased in 2005 for the first time since 1999. In 2005, the incidence was slightly higher among women than among men.

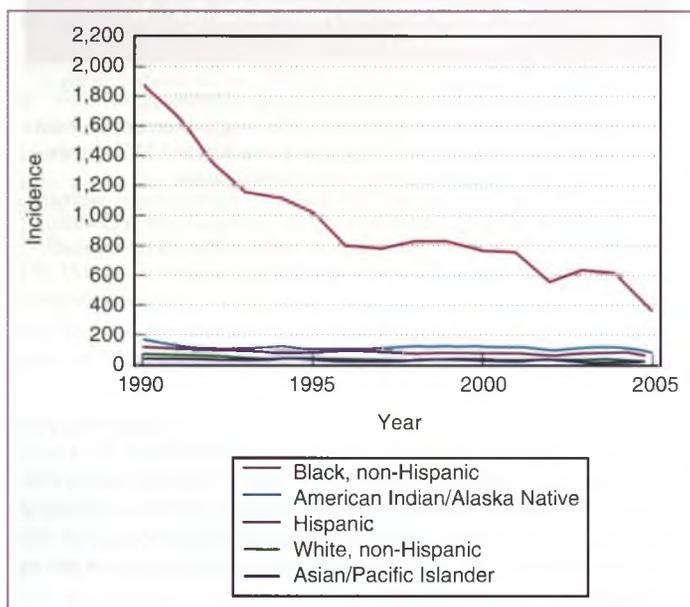

Figure 51-3 Incidence of gonorrhea per 100,000 population, by race/ethnicity—United States, 1990-2005. Gonorrhea incidence among blacks decreased considerably during the 1990s, but blacks continue to have the highest rate among all races/ethnicities. In 2005, the incidence of gonorrhea among non-Hispanic blacks was approximately 18 times greater than among non-Hispanic whites.

In a cross-sectional cohort study, The National Longitudinal Study of Adolescent Health reported that the overall prevalence of gonorrhea in the United States was 0.43% (CI, 0.29% to 0.63%).⁴¹ The prevalence of gonorrhea in pregnancy ranges from 0% to 10%, with marked variations according to risk status and geographic locale.⁴²

A number of risk factors for gonorrhea among sexually active women have been identified. Young age is the greatest risk factor, with sexually active women younger than 25 years of age being at highest risk for gonorrhea infection. Other risk factors include previous gonococcal infection, presence of other STDs, multiple sex partners, new sex partners, inconsistent condom use, drug use, and commercial sex work. Nonwhite race, low socioeconomic status, inner-city dwelling, and unmarried status are additional risk factors for infection (Figs. 51-2 and 51-3).¹²

PATHOGENESIS

Transmission of *N. gonorrhoeae* occurs almost solely by sexual contact, and the risk of transmission from an infected male to a female partner is 50% to 90% with a single exposure.⁴³ The incubation period is 3 to 5 days.

Infection with *N. gonorrhoeae* in pregnancy is a major concern. Although gonococcal ophthalmia neonatorum has been recognized since the late 19th century as a significant consequence of maternal infection with *N. gonorrhoeae*, it is only in the last 50 years that an association has been recognized between maternal infection with *N. gonorrhoeae* and disseminated gonococcal infection (DGI), amniotic infection syndrome, and perinatal complications including preterm PROM (pPROM), chorioamnionitis, preterm delivery, intrauterine growth restriction, neonatal sepsis, and postpartum endometritis.⁴

Adherence of *N. gonorrhoeae* to the mucosal epithelium of the genital tract is the initial step in the pathogenesis of gonococcal infection. Attachment of *N. gonorrhoeae* is mediated by pili and other surface proteins (e.g., porin protein, opacity-associated proteins, reduction-modifiable protein). Lipopolysaccharides, immunoglobulin A, and iron-repressible proteins are additional gonococcal virulence factors. Once *N. gonorrhoeae* attaches to mucosal cells, it enters the cell via endocytosis. Subsequently, the organism releases endotoxin, resulting in widespread cell damage.⁴⁴

CLINICAL MANIFESTATIONS

Anogenital Gonorrhea

The clinical manifestations of gonococcal infection are dependent on the site of inoculation and whether the infection remains localized or spreads systematically. The overwhelming majority of women with *N. gonorrhoeae* infection are asymptomatic, and this observation is particularly true in pregnancy. The endocervix is the primary site of infection. When symptoms develop, they usually include vaginal discharge and dysuria. On examination, a mucopurulent discharge is usually apparent in the endocervical canal. Inflammation of the Skene or Bartholin glands may occur. In patients who engage in rectal intercourse, a mucopurulent proctitis may also be apparent.

Disseminated Gonococcal Infection

DGI is an important presentation of gonorrhea in pregnancy. Pregnant women, especially during the second and third

trimesters, appear to be at increased risk for disseminated infection, which has two stages. The early, bacteremic stage is characterized by chills, fever, and typical skin lesions. The lesions appear initially as small vesicles, which become pustules and develop a hemorrhagic base. The center becomes necrotic. Such lesions can occur anywhere on the body but are most frequently present on the volar aspects of the arms, hands, and fingers. They fade without residual scarring. Blood cultures are positive for *N. gonorrhoeae* in 50% of patients for whom culture is done during the bacteremic stage. DGI is occasionally complicated by perihepatitis (Fitz-Hugh–Curtis syndrome) and rarely by endocarditis or meningitis. Joint symptoms are frequently present during this stage, as well as in the second, septic arthritis phase. This stage is characterized by a purulent synovial effusion. The knees, ankles, and wrists are most commonly affected. Blood cultures during this stage are usually sterile. Gonococci may be isolated from the septic joints during the second stage. The infection may become chronic or progress to septic arthritis and joint destruction.¹²

Pharyngeal Gonorrhea

Most patients with pharyngeal *N. gonorrhoeae* infection are asymptomatic. If they are symptomatic, the most common finding is a mild sore throat and erythema; lesions and exudates may also be present. Pharyngeal gonorrhea is more common during pregnancy than in nonpregnant women.⁴⁵

Neonatal Gonococcal Ophthalmia

Gonococcal ophthalmia neonatorum has been recognized since 1881. Introduction of routine prophylaxis with silver nitrate resulted in a rapid reduction in this complication. Most newborns who have gonorrhea acquire it during passage through an infected cervical canal. Gonococcal ophthalmia is usually observed within 4 days after birth, but incubation periods of up to 21 days have been reported. A frank purulent conjunctivitis occurs and usually affects both eyes. If left untreated, gonococcal ophthalmia can rapidly progress to corneal ulceration, resulting in corneal scarring and blindness.

Gonococcal Infection in Pregnancy and in the Neonate

The effects of gonorrheal infection on both mother and fetus were not fully appreciated until the 1970s.^{4,46,47} Studies at that time identified an association between untreated maternal endocervical gonorrhea and perinatal complications, including PROM, preterm delivery, chorioamnionitis, neonatal sepsis, and maternal postpartum sepsis.

The amniotic infection syndrome is an additional manifestation of gonococcal infection in pregnancy. This condition is characterized by placental, fetal membrane, and umbilical cord inflammation that occurs after pPROM and is associated with infected oral and gastric aspirate, leukocytosis, neonatal infection, and maternal fever. Preterm delivery is common, and perinatal morbidity may be significant.⁴⁶

DIAGNOSIS

The diagnosis of infection with *N. gonorrhoeae* requires sampling of potentially infected sites. Available methods include culture, nucleic acid hybridization tests, and nucleic acid amplification tests (NAATs).⁴⁸ The CDC has not provided guidance with respect to general or targeted screening for gonorrhea infection⁴⁹ as it has for *Chlamydia trachomatis* infection. Even

in the absence of formal guidelines, however, gonorrhea screening has been implemented in conjunction with routine chlamydial screening. Implementation of these joint screening protocols has been shown to be cost-effective.

Screening for gonorrhea during pregnancy is clearly cost-effective if the prevalence exceeds 1%. Therefore, the CDC recommends that all pregnant women at risk for gonorrhea, as well as those living in an area where the prevalence of *N. gonorrhoeae* is high, be tested for *N. gonorrhoeae* at their first prenatal visit.¹² Targeted patients include the following:

1. Partners of men with gonorrhea or urethritis
2. Patients known to have other STDs, including HIV infection
3. Patients with multiple sex partners
4. Young, unmarried inner-city women
5. Intravenous drug users
6. Women with symptoms or signs of lower genital tract infection

The CDC and the ACOG recommend that at-risk women be rescreened for *N. gonorrhoeae* during the third trimester.^{12,50} A study published in 2003 demonstrated the value of repeat screening in the third trimester for at-risk women who had an initial negative test early in pregnancy.⁴² In this study, 38 (5.1%) of 751 at-risk women had gonorrhea (based on a positive DNA direct assay) at their first prenatal visit, and an additional 19 women (2.5%) were newly positive at their third-trimester screen. In other words, approximately one third of at-risk women testing positive for *N. gonorrhoeae* were identified only on the repeat third-trimester screen.

Several reliable nonculture assays for detection of *N. gonorrhoeae* have become available and are increasingly being used.⁴⁸ They include nonamplified DNA probe tests (discussed later) and NAATs such as polymerase chain reaction (PCR), ligase chain reaction (LCR), transcription-mediated amplification (TMA), and strand displacement assay (SDA). These newer technologies compare favorably to culture with selective media. For nonamplified DNA probes, the sensitivity ranges from 89% to 97%, and the specificity is 99%. For NAATs, the sensitivity and specificity are both excellent (>99%).

Although the introduction of dual, single-swab NAATs for detection of *C. trachomatis* and *N. gonorrhoeae* has simplified testing and facilitated expansion of STD screening to nontraditional settings, there is a downside to this technique.⁵¹ First, the prevalence of *N. gonorrhoeae* is substantially lower than that of *C. trachomatis*, especially in most community-based settings.⁵² As a result, when providers intend to screen primarily for *C. trachomatis*, they are also screening for *N. gonorrhoeae*. The potential for false-positive *N. gonorrhoeae* test results increases because the positive predictive value of a test decreases as the prevalence of the disease decreases. Second, as NAATs replace culture assays, fewer isolates are available for antibiotic susceptibility testing. As a result, monitoring of trends in antimicrobial susceptibility of *N. gonorrhoeae*, a major public health issue, may be compromised.

TREATMENT

The treatment of gonococcal infection in pregnant women is similar to that in nonpregnant women, with the exception that tetracycline should not be used to treat concomitant chlamydial infection. Both asymptomatic and symptomatic infections should be treated.

The treatment of gonococcal infection in the United States has been influenced by two factors. First, there has been increasing prevalence and spread of infections caused by antibiotic-resistant *N. gonorrhoeae*, such as penicillinase-producing *N. gonorrhoeae*, tetracycline-resistant *N. gonorrhoeae*, and strains of the organism that have chromosomally-mediated resistance. Moreover, quinolone-resistant *N. gonorrhoeae* (QRNG) has now emerged as a major public health problem.^{12,53} QRNG continues to increase in prevalence, making treatment of gonorrhea with quinolones such as ciprofloxacin inadvisable in many geographic areas and populations. According to the CDC,¹² resistance to ciprofloxacin usually indicates resistance to other quinolones as well. QRNG is common in parts of Europe, the Middle East, Asia, and the Pacific and is becoming increasingly common in the United States. For example, in California the rate of QRNG increased from less than 1% in 1999 to more than 20% in the second half of 2003.⁵⁴ Similarly high rates of QRNG have been reported in Hawaii.⁵⁵ As a result, in 2005, the CDC advised that quinolones should not be used in California or Hawaii.⁵⁶ In 2004, 6.8% of isolates collected by the CDC's Gonococcal Isolate Surveillance Project (GISP) were resistant to ciprofloxacin.⁵⁷ QRNG was more common among men who have sex with men (MSM) than among heterosexual men (23.9% versus 2.9%).^{39,58} Subsequently, the prevalence of QRNG increased in other areas of the United States, leading to changes in recommended treatment regimens by other states and local areas. In a 2007 update to its Sexually Transmitted Diseases Treatment Guidelines, the CDC announced that quinolones are no longer recommended for the treatment of gonorrheal infections.⁵⁹

The second factor that influences treatment recommendations is the high frequency (20% to 50%) of coexisting chlamydial infection in women infected with *N. gonorrhoeae*. This finding has led to the recommendation that women treated for gonococcal infection should also be treated simultaneously for chlamydia.¹² Current CDC recommendations for the treatment of *N. gonorrhoeae* during pregnancy are listed in Boxes 51-3 and 51-4.

Ceftriaxone in a single intramuscular injection of 250 mg provides sustained, high bactericidal levels in blood and is safe and

effective for treatment of uncomplicated gonorrhea, curing 98.9% of urethral, cervical, and anorectal infections.^{12,60} The antimicrobial spectrum of cefixime is similar to that of ceftriaxone. Cefixime in a 400-mg oral dose, cures 97.4% of uncomplicated cases of urethral, cervical, and anogenital gonorrhea.⁶⁰ Ciprofloxacin is safe, is inexpensive, and can be administered orally, but it is no longer universally effective against *N. gonorrhoeae* in the United States. The same holds true for ofloxacin and levofloxacin. In addition, quinolones should not be used during pregnancy because they can injure cartilage in the developing fetus.

Several alternative antimicrobial agents are suggested by the CDC for treatment of uncomplicated gonococcal infections of the cervix, urethra, and anorectum. Spectinomycin is effective (cure rate >98%), but it is expensive and is available only as an injection. In addition, it is not readily available any longer. During pregnancy, it is useful for patients who are allergic to cephalosporins. Alternative single-dose cephalosporins include ceftizoxime 500 mg IM, cefoxitin 2 g IM with probenecid 1 g orally, and cefotaxime 500 mg IM. Alternative single-dose oral quinolones (not recommended for pregnancy) include gatifloxacin 400 mg, norfloxacin 800 mg, and lomefloxacin 400 mg. The CDC suggests cefpodoxime and cefuroxime axetil as additional oral alternatives for treatment of uncomplicated urogenital gonorrhea.¹²

As noted by the CDC, effective management of STDs such as gonorrhea requires treatment of the woman's current sex partner or partners to prevent reinfection. Patients should be instructed to refer their sex partners for evaluation and treatment. Alternatively, patient-delivered treatment for sex partners is also effective.^{12,61}

Pregnant women should not be given quinolones or tetracyclines. In pregnant women, *N. gonorrhoeae* infection should be treated with one of the recommended or alternative cephalosporins. Those who cannot tolerate cephalosporins should be given spectinomycin 2 g IM as a single dose, if it is available. Either amoxicillin or azithromycin is recommended as treatment for presumed concomitant chlamydial infection during pregnancy.¹²

Patients with DGI should be hospitalized for initial therapy (see Box 51-4). In addition, they should be evaluated clinically

BOX 51-3 RECOMMENDATIONS FOR THE TREATMENT OF UNCOMPLICATED GONORRHEA OF THE CERVIX, URETHRA, AND RECTUM

RECOMMENDED REGIMENS (IN ADDITION TO TREATMENT FOR CHLAMYDIAL INFECTION IF NOT RULED OUT)

- Ceftriaxone*
250 mg IM in a single dose
- Cefixime* 400 mg PO in a single dose

ALTERNATIVE REGIMENS

- Spectinomycin* 2 g IM in a single dose
- Single-dose cephalosporin* regimens

*Recommended for use in pregnancy.

From Centers for Disease Control and Prevention: Update to CDC's sexually transmitted diseases treatment guidelines, 2006: fluoroquinolones no longer recommended for treatment of gonococcal infections, MMWR Morb Mortal Wkly Rep 56(14):332-336, 2007.

BOX 51-4 RECOMMENDATIONS FOR THE TREATMENT OF COMPLICATED GONORRHEA (DISSEMINATED GONOCOCCAL INFECTION, MENINGITIS, ENDOCARDITIS)

RECOMMENDED REGIMEN

- Ceftriaxone*
1 g IM or IV q24h

ALTERNATIVE REGIMENS

- Cefotaxime* 1 g IV q8h
- Ceftizoxime* 1 g IV q8h
- Spectinomycin* 2 g IM q12h

*Recommended for use in pregnancy.

From Centers for Disease Control and Prevention: Update to CDC's sexually transmitted diseases treatment guidelines, 2006: fluoroquinolones no longer recommended for treatment of gonococcal infections, MMWR Morb Mortal Wkly Rep 56(14):332-336, 2007.

for evidence of endocarditis or meningitis. All of the recommended and alternative regimens for DGI should be continued for 24 to 48 hours after improvement begins. At that time, therapy may be switched to cefixime, 400 mg orally twice daily. With gonococcal meningitis and endocarditis, the recommended regimen is ceftriaxone 1 to 2 g IV every 12 hours. Meningitis requires 10 to 14 days of therapy, and treatment for endocarditis should be continued for a minimum of 4 weeks.¹²

With use of the recommended treatment, follow-up testing to document eradication of gonorrhea is no longer recommended. Instead, rescreening in 2 to 3 months to identify reinfection is suggested. If other antimicrobial agents are used for the treatment of *N. gonorrhoeae*, follow-up assessment is suggested. Follow-up cultures should be obtained from the infected site 3 to 7 days after completion of treatment. Specimens should be obtained from the anal canal as well as the endocervix; failure to obtain a specimen from the anal canal results in missing 50% of resistant *N. gonorrhoeae* strains. With NAATs, repeat testing should be performed 3 weeks after treatment. Patients who have symptoms that persist after treatment should be evaluated by culture, and isolated organisms should be tested for antimicrobial susceptibility.¹²

PREVENTION

Primary prevention of gonorrhea requires adopting safe sex practices, including condom use; limiting the number of sex partners; and ensuring that sex partners are evaluated and treated. The increasing frequency of asymptomatic gonorrhea infection in women makes screening for *N. gonorrhoeae* during the antepartum period an important aspect of preventing the perinatal morbidity associated with this organism. At-risk patients should be rescreened in the third trimester. Instillation of a prophylactic agent into the eyes of all newborn infants is recommended to prevent gonococcal ophthalmia neonatorum. The recommended agents are erythromycin (0.5%) ophthalmic ointment, tetracycline (1%) ophthalmic ointment, and silver nitrate (1%) aqueous solution.

Chlamydial Infection

C. trachomatis infection is the most common bacterial STD in the United States, with an estimated 3 million new infections annually. The estimated cost of untreated chlamydial infections and their sequelae is more than \$2 billion annually.^{12,62}

In women, untreated chlamydial infection results in substantial adverse reproductive effects, including pelvic inflammatory disease and its sequelae of tubal factor infertility, ectopic pregnancy, and chronic pelvic pain. Chlamydial infection during pregnancy is associated with several adverse maternal outcomes, including preterm delivery, pPROM, low birth weight, and neonatal death.^{4,63} Untreated *C. trachomatis* infection also may result in neonatal conjunctivitis or pneumonia or both.^{4,64}

C. trachomatis may be differentiated on a serologic basis into 15 recognized serotypes. Three of these serotypes (L1, L2, L3) cause lymphogranuloma venereum. The other serotypes cause endemic blinding trachoma (types A, B, Ba, and C) or inclusion conjunctivitis, newborn pneumonia, urethritis, cervicitis, endometritis, pelvic inflammatory disease, and the acute urethral syndrome (strains D through K).⁴

EPIDEMIOLOGY

As noted by Peipert,⁶⁵ the prevalence of *C. trachomatis* infection depends on the characteristics of the population studied. Prevalence rates in the United States vary significantly, ranging from 4% to 12% among family planning clinic attendees, from 2% to 7% among college students, and from 6% to 20% among STD clinic attendees.⁴ In the National Longitudinal Study of Adolescent Health,⁶⁶ the overall prevalence of chlamydial infection was found to be 4.19%, with women (4.74%; CI, 3.93% to 5.71%) more likely to be infected than men (3.67%; CI, 2.93% to 4.58%). In 2005, more than 975,000 cases of chlamydial genital infection were reported to the CDC, almost 50,000 more than in 2004. The CDC estimates that the true frequency of chlamydial infection each year is 3 million cases, most of which are not reported to public health officials.⁶²

The prevalence of *C. trachomatis* infection among pregnant women is about 2% to 3% but may be higher in certain high-risk populations.⁴ Among pregnant women, risk factors for chlamydial infection include the following:

1. Unmarried status
2. Age younger than 25 years
3. Multiple sex partners
4. New sex partner in past 3 months
5. Black race
6. Presence of another STD
7. Partners with nongonococcal urethritis
8. Presence of mucopurulent endocervicitis
9. Sterile pyuria (acute urethral syndrome)
10. Resident of socially disadvantaged community
11. Late or no prenatal care

Detection rates as high as 25% to 30% have been reported in screening and prospective studies of such populations. In the Preterm Prediction Study of the National Institute of Child Health and Human Development Maternal-Fetal Medicine Units Network, the overall prevalence of *C. trachomatis* among pregnant women was 11%.⁶ In a follow-up study, Sheffield and colleagues⁶⁷ demonstrated that chlamydial infection resolved spontaneously in almost half of infected pregnant women, especially in older women and with increasing time since diagnosis.

Infants born to women with an untreated chlamydial infection of the cervix have a 60% to 70% risk of acquiring the infection during passage through the birth canal. Approximately 25% to 50% of exposed infants acquire conjunctivitis in the first 2 weeks of life, and 10% to 20% develop pneumonia within 3 or 4 months.⁴

PATHOGENESIS

Chlamydiae are obligate intracellular bacteria separated into their own order, Chlamydiales, on the basis of a unique growth cycle that distinguishes them from all other microorganisms. This cycle involves infection of the susceptible host cell by a chlamydia-specific phagocytic process, so that these organisms are preferentially ingested. After attachment and ingestion, the chlamydiae remain in a phagosome throughout the growth cycle, but surface antigens of chlamydiae appear to inhibit phagolysosomal fusion. These two virulence factors (i.e., enhanced ingestion and inhibition of phagolysosomal fusion) attest to an exquisitely adapted parasitism.

Once in the cell, the chlamydial *elementary body*, which is the infectious particle, changes to a metabolically active replicating

form called the *reticulate body*, which synthesizes its own macromolecules and divides by binary fission. Chlamydiae are energy parasites; because they do not synthesize their own adenosine triphosphate, energy-rich compounds must be supplied to them by the host cell. By the end of the growth cycle (approximately 48 hours), most reticulate bodies have reorganized into elementary bodies, which are released through mechanical disruption of the host cell to initiate a new infection cycle.

Chlamydia are unique bacteria in that they do not stain with Gram stain and they are obligate intracellular parasites. However, they contain DNA and RNA, are susceptible to certain antibiotics, have a rigid cell wall similar in structure and content to those of gram-negative bacteria, and multiply by binary fission. They may be regarded as bacteria that have adapted to an intracellular environment. They need viable cells for multiplication and survival.⁴

ADVERSE PREGNANCY OUTCOME

Controversy exists as to whether maternal cervical *C. trachomatis* infection is associated with adverse pregnancy outcome. Although some studies have demonstrated an association of maternal chlamydial infection with preterm birth, low birth weight, pPROM, and perinatal death,⁶⁸⁻⁷⁰ others have failed to confirm such an association.^{4,71} Harrison⁷² and Sweet⁷³ and their colleagues demonstrated that a subgroup of infected women in whom immunoglobulin M (IgM) antibody was present were at significantly increased risk for pPROM, preterm birth, and delivery of a low-birth-weight infant. These authors postulated that IgM seropositivity reflects recent acquisition and acute chlamydial infection, which may play a more important role than chronic infection.⁶³

In an historical control study, Ryan and colleagues⁷⁴ reported that untreated chlamydia-infected pregnant women in a high-prevalence population (21% positive) had a significantly increased incidence of pPROM and of low-birth-weight infants and decreased perinatal survival compared with treated women or women not infected with *Chlamydia*. Similarly, Cohen and coworkers⁷⁵ reported that treatment of chlamydial infection resulted in decreased rates of preterm delivery, pPROM, preterm labor, and fetal growth restriction. There were experimental design flaws or limitations in both studies. However, because it is unethical to conduct a prospective, randomized, placebo-controlled trial in which some patients are not treated, these studies provide the best available evidence of the adverse perinatal effects of untreated chlamydial infection.

The role of cervical chlamydial infection in producing postpartum endometritis is also controversial. Early studies in the ophthalmology literature demonstrated an association between inclusion conjunctivitis in newborns and an increased risk for postpartum infection in their mothers. In a prospective study, Wager and associates⁷⁶ demonstrated that pregnant women with chlamydial cervical infection at their initial prenatal visit were at increased risk for endometritis after vaginal delivery. However, multiple other studies have failed to confirm such an association.^{72,73,77-79}

DIAGNOSIS

Until recently, the optimum diagnostic test for chlamydial infection was tissue culture. However, culture requires cold storage, a susceptible tissue culture cell line, a 1-week waiting

time for results, and substantial technical expertise. In addition, culture is expensive and, with the advent of NAATs, has been shown to be relatively insensitive (65% to 85%).

Before the introduction of NAATs, antigen-detection methods were widely used. To a large extent, these tests have now been replaced by DNA/RNA-based methods, both nonamplified and amplified types. Nonamplified tests such as the Gen-Probe PACE-2 assay (Gen-Probe, San Diego, CA) use DNA/RNA hybridization technology. In a large multicenter study, Black and coauthors⁸⁰ reported that the sensitivity of PACE-2 ranged from 60.8% to 71.6%, and the specificity ranged from 99.5% to 99.6%. An important advantage of DNA probe-based testing is that it can be used in conjunction with a probe for the detection of *N. gonorrhoeae* in a single swab. Additional advantages include ease of transport, ability to batch specimens, and decreased cost. As a result, by the late 1990s, the DNA probe had become the most widely used diagnostic test for *C. trachomatis* infection in the United States.

More recently, DNA/RNA amplification technology has been introduced into clinical practice. NAATs have excellent sensitivity and specificity for chlamydial testing. Clinically available NAATs include tests based on PCR (Roche Molecular Systems, Branchburg, NJ), TMA (AMP.CT, Gen-Probe), and SDA (Bectun Dickinson, Sparks, MD). LCR-based tests (Abbott Laboratories, Chicago) are no longer available. NAATs have performed better than culture, antigen detection, or DNA probe techniques for detection of *C. trachomatis*.^{12,81,82} A major advantage of NAATs is their ability to identify patients with a low inoculum of *C. trachomatis*. Moreover, their excellent sensitivity and specificity for detecting *Chlamydia* in urine specimens allows noninvasive screening for *C. trachomatis*. However, use of a vaginal swab has been shown to have equivalent or better sensitivity and specificity and is better accepted by patients, especially when patient-obtained specimens are used.⁸³⁻⁸⁵

The CDC recommends that all pregnant women be routinely tested for *C. trachomatis* at their first prenatal visit.¹² Women younger than 25 years of age and those at increased risk for chlamydial infection should be retested during the third trimester to prevent maternal postnatal complications and chlamydial infection in the infant. In addition, the CDC suggests that first-trimester screening might prevent the adverse effects of chlamydial infection during pregnancy (e.g., preterm birth, pPROM, low birth weight).

TREATMENT

Screening of sexually active women for chlamydial infection is a national priority in the United States.^{86,87} Identification and treatment of women infected with *C. trachomatis* prevents horizontal transmission to sex partners and vertical transmission of *C. trachomatis* to infants during birth.¹² In addition, treatment of chlamydial infection early in pregnancy seems to reduce the rate of adverse pregnancy outcomes (e.g., preterm birth, intrauterine growth restriction, low birth weight, pPROM).^{4,65}

The CDC recommendations for treatment of chlamydial infection in pregnant women are listed in Box 51-5. Doxycycline, ofloxacin, and levofloxacin are recommended for non-pregnant women but are contraindicated in pregnancy. In 2006, azithromycin, as a single 1-g dose, was added to the list of recommended regimens for treatment of chlamydial infection during pregnancy. Single-dose therapy with azithromycin definitely improves patient compliance.¹²

BOX 51-5 TREATMENT RECOMMENDATIONS FOR CHLAMYDIAL INFECTION IN PREGNANT WOMEN

RECOMMENDED REGIMENS

Azithromycin 1 g PO in a single dose
Amoxicillin 500 mg PO tid for 7 days

ALTERNATIVE REGIMENS

Erythromycin base 500 mg PO qid for 7 days
Erythromycin base 250 mg PO qid for 14 days
Erythromycin ethylsuccinate 800 mg PO qid for 7 days
Erythromycin ethylsuccinate 400 mg PO qid for 14 days

From Centers for Disease Control and Prevention: *Sexually transmitted diseases treatment guidelines, 2010*, MMWR Morb Mortal Wkly Rep 59(RR-12):1–111, 2010.

Amoxicillin, 500 mg orally three times daily for 7 days, was initially demonstrated to be effective for treatment of chlamydial infection during pregnancy by Crombleholme and colleagues.⁸⁸ Multiple studies have since confirmed the efficacy and safety of amoxicillin, including a Cochrane Collaboration review of 11 randomized trials for the treatment of chlamydia during pregnancy.⁸⁹

Although erythromycin regimens were once the mainstay for treatment of chlamydial infection during pregnancy, the frequent gastrointestinal side effects associated with erythromycin, which lead to noncompliance, have reduced its value in this context.¹² In an observational cohort, Rahangdale and coworkers⁹⁰ reported that the treatment efficacy for erythromycin was 64%, compared with 97% for azithromycin and 95% for amoxicillin. Erythromycin estolate is contraindicated in pregnancy due to drug-related hepatotoxicity. The lower-dose, 14-day regimens for erythromycin can be used for women who are allergic to amoxicillin and azithromycin.

In light of the sequelae that can occur in the mother and newborn infant if chlamydial infection persists, repeat testing, preferably by NAATS, is recommended for all pregnant women 3 weeks after completion of therapy to ensure cure. Sex partners should be referred for evaluation, testing, and treatment. The CDC suggests that, if concerns exist that sex partners will not seek evaluation and treatment, consideration should be given for delivery of antibiotic therapy (either a prescription or medication) by female patients to their sex partners. This approach decreases the rate of persistent or recurrent *Chlamydia* compared with standard partner referral.^{12,61,91}

PREVENTION

Primary prevention of chlamydial infection requires decreasing the risk of exposure to men infected with *C. trachomatis*. Although abstinence would accomplish this objective, it is often not a practical approach. Mutual monogamous relationships and safe sexual behaviors, particularly the consistent use of condoms, are effective preventive measures. No vaccine for *Chlamydia* is available at this time.

Secondary prevention requires population-based screening for chlamydia and treatment of infected women and their sex partners. As discussed previously, routine screening of all

pregnant women at the first prenatal visit and screening of all nonpregnant women 25 years of age and younger is recommended. In addition, women older than 25 years of age who are at increased risk for chlamydial infection (e.g., multiple sex partners, recent new sex partner, previous chlamydial infection, other STDs) should be screened. This approach has been shown to both reduce the prevalence of chlamydial infection and decrease the risk of complications such as pelvic inflammatory disease and perinatal transmission.⁸⁷

Human Papillomavirus Infection

Human papillomavirus (HPV) is a double-stranded DNA virus that is a member of the papovavirus family. More than 100 HPV types have been identified; of these, 35 primarily infect the genital tract. HPV is the most common sexually transmitted infection in the United States, with approximately 6.2 million new HPV infections occurring each year.⁹²

HPV infection may result in either clinically apparent, grossly visible disease (e.g., genital warts) or subclinical disease. The majority of HPV infections are asymptomatic, unrecognized, or subclinical. The common genital HPV types can be divided into two major categories based on their oncogenic potential. HPV types in the low oncogenic risk group include types 6, 11, 42, 43, and 44. These types are associated primarily with genital warts. The high oncogenic risk group includes types 16, 18, 20, 31, 45, 54, 55, 56, 64, and 68. These high-risk types are frequently detected in women with high-grade squamous intraepithelial neoplasia and invasive cancers. Most of the clinically apparent lesions are the classic genital warts (condyloma acuminatum). An estimated 1% of sexually active adults are diagnosed annually with genital warts.

EPIDEMIOLOGY

Sexual transmission is the primary route for transmission of HPV, and both urogenital and anorectal infections are seen.⁴ The highest-risk groups for HPV infection are sexually active adolescents and young adults, with 75% of new HPV infections occurring among those 15 to 24 years old. HPV is highly contagious, and transmission rates are high, with approximately 65% of sex partners becoming infected. Although it is rare, perinatal transmission, especially of HPV types 6 and 11, can occur.⁴

Risk factors for HPV infection include early onset of sexual activity, multiple sexual partners, increased frequency of intercourse, exposure to a sex partner with genital warts, failure to use condoms, and cigarette smoking.⁴ In addition, Winer and colleagues⁹³ observed that smoking, oral contraceptive use, and report of a new male partner were predictive of new HPV infection. Furthermore, pregnancy is associated with an increased prevalence of HPV infection and genital warts, and immunosuppressive states result in increased viral titers of HPV and more rapid progression of HPV disease-associated cervical intraepithelial neoplasia (CIN).⁴

Respiratory papillomatosis (laryngeal papilloma) is a rare disease in the neonate that is caused by HPV-6 and HPV-11. Laryngeal papillomas can be particularly troublesome, because they may produce respiratory distress secondary to obstruction and because recurrence after treatment is common. Transplacental and intrapartum transmission of HPV can occur, as well as infection via contact during the neonatal period.⁴

The fact that genital papillomavirus infection is so common and respiratory papillomatosis is rare means that the risk of intrapartum transmission is low, perhaps on the order of 1 case of juvenile respiratory papillomatosis per 1000 children born to infected mothers. Watts and associates⁹⁴ reported that, among 151 pregnant women evaluated for HPV by clinical, colposcopic, and PCR tests at less than 20, 34, and 36 weeks of gestation, 112 (74%) had evidence of HPV. HPV was identified in only 3 (4%) of 80 infants born to women with HPV detected at 34 to 36 weeks' gestation, but it also was found in 5 (8%) of 63 infants born to women in whom HPV DNA was not detected. Tenti and coworkers⁹⁵ also confirmed that pregnant women with latent HPV infection have a low potential for transmitting the virus to the oropharyngeal mucosa of their newborns. Although these authors reported that HPV DNA was detected in 11 neonates born vaginally to HPV-positive women (vertical transmission rate, 30%; CI, 15.9% to 47%), all infants tested negative by 5 weeks after birth and remained so throughout the 18-month follow-up period. These findings suggest that the infants who were HPV-positive at birth were contaminated but not infected.

Other studies have supported the finding that the risk of perinatal transmission of HPV is low.^{96,97} Of these, the most informative was the study by Smith and colleagues.⁹⁶ They detected HPV type-specific concordance in only 1 mother/infant pair among the 6 (3.7%) infants born to 164 mothers with cervical HPV infection. In addition, one third of the HPV-positive newborns were born to mothers who tested negative for HPV DNA during pregnancy.

PATHOGENESIS

Genital HPV infections are transmitted primarily by sexual activity. Clinical lesions and subclinical infections occur in the urogenital and anorectal areas. As noted previously, the infectivity rate is high. The average incubation period is 2 to 3 months.

The HPV viral genome consists of three major regions; two protein-encoding regions (the early and late gene regions) and a noncoding upstream regulatory region (URR). The URR controls transcription of both the early and the late region, resulting in regulation of viral proteins and production of infectious particles. The early region contains open reading frames (ORFs), which are transcriptional units that encode for a series of proteins designated E₁, E₂, E₄, E₅, E₆, and E₇. Early region gene expression controls replication, transcription, and cellular transformation of viral DNA. Most importantly, it also plays a role in unregulated cellular proliferation. E₆ and E₇ are the oncogenic genes, and they code proteins critical for host cell immortalization and transformation. The late gene region contains two ORFs (L₁ and L₂), which encode structural proteins responsible for production of the viral capsid. The L₁ protein is the key component of the recently introduced HPV vaccine and is highly immunogenic.⁹⁸

Acute HPV infection occurs when microtrauma secondary to sexual intercourse allows virus to enter the skin or mucosa of the genital tract. The postpubertal adolescent cervix is characterized by a large transformation zone which is more susceptible to minor trauma during sexual intercourse. The immature columnar epithelial cells in the broad transformation zone are particularly susceptible to HPV. This observation may explain why young, sexually active adolescents are at the greatest risk for acquiring HPV infection. The virus enters cells in the basal

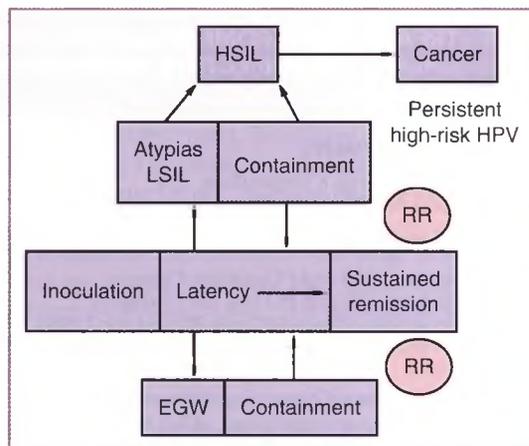

Figure 51-4 Natural history of human papillomavirus (HPV) infection. EGW, external genital warts; HSIL, high-grade squamous intraepithelial lesion; LSIL, low-grade intraepithelial lesion; RR, recurrences.

layer of the epithelium and matures as it passes through the parabasal, spinous, and granular layers of the epithelium.^{93,99}

After acute HPV infection, several clinical scenarios can occur (Fig. 51-4). Latent viral infection occurs when the HPV genome is stabilized as a nonintegrated episome and remains in host cells without causing clinical or morphologic changes in the squamous epithelium of the genital tract. Latency can lead to sustained remission, which is the case in most HPV infections. Alternatively, active infection may occur, depending on the type of HPV present. Low-risk HPV types, especially 6 and 11, cause proliferation of squamous epithelial cells with resultant formation of genital warts. High-risk oncogenic HPV types may become integrated into the host genome, resulting in CIN. CIN may progress to precancerous lesions (CIN 2 and 3) and, ultimately, to invasive cervical cancer. Alternatively, CIN may resolve spontaneously, especially CIN 1 and, to a lesser extent, CIN 2.

DIAGNOSIS

Genital Warts

The diagnosis of genital warts is usually made by visual inspection. Biopsy is required only in certain circumstances: (1) the diagnosis is uncertain; (2) the lesions do not respond to standard therapy; (3) the disease worsens during therapy; (4) the patient is immunocompromised; or (5) the warts are pigmented, indurated, fixed, bleeding, or ulcerated. Use of HPV nucleic acid tests is not recommended in the routine diagnosis and management of visible genital warts.¹²

Asymptomatic Human Papillomavirus Infection

Because HPV cannot be cultured, detection of asymptomatic infection requires identification of viral nucleic acid (DNA or RNA) or capsid protein.^{12,100} Only the Digene Hybrid Capture 2 (HC 2) High-Risk HPV DNA Test (Qiagen Digene, Gaithersburg, MD) is approved by the FDA for clinical use. This test uses liquid nucleic acid hybridization to detect 13 high-risk HPV types (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68). Type-specific results are not reported; rather, the specimen is

identified as positive or negative for high-risk HPV. In particular, the HC 2 High-Risk HPV test is approved for triage of women who have Papanicolaou (Pap) test results showing atypical squamous cells of undetermined significance (ASC-US) and, in combination with the Pap test, for cervical cancer screening in women older than 30 years of age.

Less sensitive methods for detection of suspected HPV infection include cytologic evidence of HPV (koilocytosis), colposcopy, biopsy, and acetic acid application. Although they are not available for clinical use, PCR assays targeting genetically conserved regions of the L₁ gene and HPV serologic assays to detect antibodies to the L₁ viral protein have been used in research and epidemiologic studies.

TREATMENT

Options for treatment of genital warts during pregnancy are limited. The safety of podophyllin resin, podofilox, or imiquimod in pregnancy has not been established. Trichloroacetic acid (TCA) or bichloroacetic acid (BCA), 80% to 90% solution, may be used on a weekly basis. Alternatively, the lesions may be excised by scissors, scalpel, curettage, electrosurgery, or laser. Cryosurgery can be used to treat vaginal lesions.¹² Treatment should be limited to patients who have multiple, confluent lesions.

As noted by the CDC, it is unclear whether cesarean delivery prevents juvenile-onset recurrent respiratory papillomatosis.^{12,101} Therefore, cesarean delivery should not be performed solely to prevent transmission of HPV infection to the newborn. Cesarean delivery should be considered if obstruction of the pelvic outlet is likely or if vaginal delivery would result in excessive bleeding because of multiple confluent lesions.

PREVENTION

Transmission of HPV occurs through contact with infected genital skin, mucous membranes, or body fluids from a sex partner with clinical or subclinical HPV infection. As with other STDs, preventing the spread of HPV to a susceptible population is more cost-effective than secondary prevention. Prevention of HPV transmission incorporates the following approaches: (1) abstinence; (2) long-term mutual monogamy with a single partner; (3) limiting the number of sexual partners; (4) limiting sexual contacts to men who have been abstinent for a longer period of time; (5) having a circumcised partner; (6) using latex condoms; and (7) receiving the HPV vaccine.

The most exciting new development for prevention of HPV infection is the introduction into clinical practice of HPV vaccines. The first such vaccine to become available was the quadrivalent HPV vaccine, Gardasil (Merck & Co.), which protects against HPV types 6, 11, 16, and 18.¹⁰⁰ The second vaccine was a bivalent preparation (Cervarix, Glaxo Smith Kline). It contains viruslike-particle antigens for HPV-16 and HPV-18.¹⁰²

Neither routine surveillance for HPV infection nor partner notification is deemed useful for HPV prevention. The rationale for this conclusion is that HPV is so prevalent that most partners are already infected. In addition, no prevention or treatment strategies are recommended for partners. Similarly, no specific treatment or prevention strategies are recommended for prevention of perinatal transmission of HPV. Therefore, as discussed earlier, cesarean delivery for prevention of HPV infection in newborns is not indicated.

BOX 51-6 CLASSIFICATION OF URINARY TRACT INFECTIONS

- Asymptomatic bacteriuria (ASB)
- Acute uncomplicated cystitis
- Recurrent cystitis
- Acute uncomplicated pyelonephritis
- Complicated urinary tract infection
 - Multiple frequent recurrences
 - High probability of drug-resistant uropathogen
 - Increased risk for sepsis syndrome

Urinary Tract Infection

Urinary tract infections (UTIs) are a major public health problem in the United States, affecting approximately 11 million women annually, with an associated direct cost of \$1.6 billion.¹⁰³ In women, UTIs are divided into five major categories (Box 51-6).^{104,105}

Women are 14 times more likely to develop UTIs than men. Presumably, this female predominance is the result of several factors, including (1) a shorter urethra; (2) continuous contamination of the external one third of the urethra by pathogenic bacteria from the vagina and rectum; (3) failure of females to empty their bladders as completely as males; and (4) movement of bacteria into the female bladder during sexual intercourse.⁴

UTI is the most common medical complication of pregnancy. UTIs occur in up to 20% of pregnancies and account for 10% of antepartum hospitalizations.^{4,106} Among pregnant women, almost all UTIs fall into three categories: (1) asymptomatic bacteriuria (ASB); (2) acute cystitis; and (3) acute pyelonephritis. Of critical importance is the recognition that the normal physiologic changes associated with pregnancy (e.g., progesterone effect on ureteral smooth muscle peristalsis, obstruction of the ureters by the enlarging uterus) predispose pregnant women with ASB to the development of acute pyelonephritis. Moreover, UTIs in pregnancy place the fetus and mother at risk for substantial morbidity and even mortality.^{4,104}

ASYMPTOMATIC BACTERIURIA

Epidemiology

Obstetricians have long recognized the serious nature of symptomatic UTIs in pregnancy. However, it was not until the early 1960s that Kass demonstrated that significant bacteriuria can occur in the absence of symptoms or signs of UTI.¹⁰⁷ He established quantitative bacteriology as the indispensable laboratory aid for diagnosis, follow-up, and confirmation of cure of UTI. From these studies evolved the commonly accepted definition of ASB: the presence of 10⁵ or more colonies of a bacterial organism per milliliter of urine on two consecutive clean-catch, midstream-voided specimens in the absence of signs or symptoms of UTI. Persistent ASB was identified in 6% of pregnant patients. Acute pyelonephritis developed in 40% of the patients with ASB who received placebo, but pyelonephritis rarely occurred when bacteriuria was eliminated. Kass also reported that rates of neonatal death and prematurity were two to three

times greater in bacteriuric women receiving placebo than in nonbacteriuric women or bacteriuric women whose infection was eliminated by antibiotics. He concluded that detection of maternal bacteriuria would identify patients at risk for pyelonephritis and premature delivery and maintained that pyelonephritis in pregnancy could be prevented by detection and treatment of bacteriuria in early pregnancy. Moreover, Kass estimated that 10% of premature births could be prevented by such a program.¹⁰⁷

Most cases of ASB in pregnancy are detected at the initial prenatal visit, and relatively few pregnant women acquire bacteriuria after the initial visit. Therefore, the bacteriuria antedates the pregnancy. The prevalence of ASB in pregnant women ranges from 2% to 11%. An increased prevalence of bacteriuria in females has been associated with lower socioeconomic status, diminished availability of medical care, and increased parity. Thurman and coworkers determined that women with sickle cell trait are not more susceptible than other pregnant women to ASB.¹⁰⁸

Untreated ASB during pregnancy often leads to acute pyelonephritis. Women with ASB in early pregnancy are at a 20- to 30-fold increased risk of developing acute pyelonephritis during the pregnancy, compared to pregnant women without bacteriuria.¹⁰⁹ Studies performed in the 1960s, using sulfonamides or nitrofurantoin, demonstrated that antimicrobial treatment of ASB during pregnancy significantly reduced the risk of developing pyelonephritis, from about 20% to 35% to between 1% and 4%. Before the advent of universal screening for ASB in early pregnancy, the reported rate of acute pyelonephritis in pregnancy was 3% to 4%; afterward, it was 1% to 2%.^{110,111} Similarly, studies in Europe assessing the implementation of screening and treatment programs for ASB in pregnant women demonstrated a significant reduction in the rate of acute pyelonephritis in pregnancy.^{112,113} For this reason, it is important that the presence of bacteriuria be identified. Other claims, such as that ASB predisposes the patient to anemia, preeclampsia, and chronic renal disease, are controversial and unproven.

Kass¹⁰⁷ initially reported an association between ASB and prematurity and observed that eradication of bacteriuria with antimicrobial therapy significantly reduced the rate of preterm delivery. He proposed that early detection and treatment of bacteriuria would prevent 10% to 20% of preterm births. Subsequently, numerous studies demonstrated conflicting results regarding bacteriuria and prematurity. Kincaid-Smith and Bullen¹¹⁴ suggested the hypothesis that underlying renal disease is the major cause of the excessive risk of prematurity or low birth weight among bacteriuric pregnant women.

More recent studies, including meta-analyses, demonstrated an association between ASB and low birth weight and preterm delivery.¹¹⁵⁻¹¹⁸ Bacteriuria is only one of many factors that may influence the onset of premature labor. Because both the incidence of bacteriuria in pregnancy and the incidence of prematurity vary inversely with socioeconomic status, any relationship between bacteriuria and gestational length and birth weight may be complex and difficult to establish. In an attempt to resolve this controversy, Romero and colleagues¹¹⁵ used the technique of meta-analysis to assess the relationship between ASB and preterm delivery or low birth weight. Meta-analysis confirmed a statistically significant increased risk for low-birth-weight infants among bacteriuric women. Their study also demonstrated a significant association between bacteriuria and preterm delivery and showed a statistically significant reduction

in the incidence of low-birth-weight infants among bacteriuric women treated in eight placebo-controlled treatment trials.

Meis and colleagues¹¹⁷ demonstrated in a multivariate analysis that bacteriuria significantly increased the occurrence of preterm birth (relative risk, 2.03; CI, 1.50 to 2.75). Schieve and colleagues,¹¹⁶ in an analysis of 150,000 births in the University of Illinois Perinatal Network database, reported that women with antepartum UTI were at increased risk for delivering preterm and low-birth-weight infants. With multivariate analysis, the ORs were 1.4 (CI, 1.2 to 1.6) and 1.3 (CI, 1.1 to 1.4) for low-birth-weight infants and preterm birth, respectively. Moreover, Smaill¹¹⁸ reported a meta-analysis of treatment versus placebo trials for ASB in pregnancy that demonstrated a one-third reduction in the rate of low-birth-weight infants (from 15% to 10%) in women whose bacteriuria was treated. Therefore, it appears that maternal ASB is a risk factor for preterm delivery and low birth weight and that this risk can be reduced by screening and treatment of ASB in pregnant women.¹¹⁹ With recognition that ASB increases the risk for development of acute pyelonephritis as well as preterm delivery and low birth weight, the ACOG and the U.S. Preventive Services Task Force recommend screening to detect ASB in pregnancy.^{120,121}

Symptomatic UTI is more often found in pregnant women than in nonpregnant women. This observation suggests that some factors present during gestation allow bacteria to replicate in the urine and ascend to the upper urinary tract. Several findings support this view.⁴ The normal female urinary tract undergoes dramatic physiologic and anatomic changes during pregnancy. Briefly, a decrease in ureteral muscle tone and activity results in a lower rate of passage of urine throughout the urinary collecting system. The upper ureters and renal pelves become dilated, resulting in a physiologic hydronephrosis of pregnancy. These changes are caused by the effects of progesterone on muscle tone and peristalsis and, more importantly, by mechanical obstruction of the enlarging uterus. Changes in the bladder also occur during pregnancy, including decreased tone, increased capacity, and incomplete emptying, all of which predispose to vesicoureteric reflux. Hypotonia of the bladder musculature, vesicoureteric reflux, and dilation of the ureters and renal pelves result in static columns of urine in the ureters, facilitating the ascending migration of bacteria to the upper urinary tract after bladder infection is established. The hypokinetic collecting system reduces urine flow, and urinary stasis occurs, predisposing to infection.

Alterations in the physical and chemical properties of urine during pregnancy exacerbate bacteriuria, further predisposing to ascending infection. Because of the increased excretion of bicarbonate, urinary pH rises, encouraging bacterial growth. Glycosuria, which is common in pregnancy, favors an increase in the rate of bacterial multiplication. The increased urinary excretion of estrogens may also be a factor in the pathogenesis of symptomatic UTI during pregnancy. In animal experiments, estrogen enhances the growth of strains of *Escherichia coli* that cause pyelonephritis and predispose to renal leukocyte migration, phagocytosis, and complement activity. The cumulative effect of these physiologic factors is an increased risk that infection in the bladder may ascend to the kidneys.

Pathogenic characteristics of microorganisms such as *E. coli* are major determinants of UTI. These include pili (adherence), K antigen (antiphagocytic activity), hemolysin (cytotoxicity), and antimicrobial resistance. Host susceptibility factors include anatomic or functional abnormalities of the urinary tract and

uroepithelial and vaginal epithelial cells with increased attachment of uropathogenic *E. coli*. Women who do not secrete the ABO blood group antigens are particularly likely to harbor pathogenic *E. coli* in the urogenital epithelium.

Pathogenesis

In general, the urinary tract is sterile, with the exception of the distal urethra, which is often colonized with bacteria from the skin and vaginal and anal flora. Ascension of bacteria from the urethra into the bladder results in ASB. Bacteria associated with ASB derive from the normal flora of the gastrointestinal tract, vagina, and periurethral area. In addition, instrumentation of the urinary tract (e.g., bladder catheterization) may introduce bacteria into the bladder of patients without prior colonization. In women with ASB, bacteria persist in the urinary tract but do not elicit sufficient host response to result in either symptoms or eradication of the bacteria from the urinary tract. Factors such as host susceptibility, bacterial virulence, incomplete bladder emptying, obstruction, or presence of a foreign body such as a catheter predispose to persistence of bacteria.¹⁰⁹

As noted in many studies, *E. coli* is overwhelmingly the most frequently recovered microorganism in patients with ASB, including pregnant women.⁴ Other gram-negative enterobacteria such as *Klebsiella* and *Proteus* and gram-positive bacteria such as *Staphylococcus saprophyticus*, GBS, and the enterococcus cause the remaining cases of ASB in young, sexually active women.

A series of studies compared genetic markers or phenotypic expression of potential bacterial virulence factors among *E. coli* strains isolated from various types of UTIs.^{109,122,123} One of those publications¹²³ focused on *E. coli* isolates from pregnant women. *E. coli* strains recovered from patients with ASB demonstrated a lower frequency of genetic markers or phenotypic expression of virulence factors than did those from patients with acute cystitis or acute pyelonephritis.

Several studies have shown that the incidence of ASB in nonpregnant women is comparable to the incidence in pregnant women in the same locale.¹⁰⁷⁻¹⁰⁹ It appears that most women in whom bacteriuria is first discovered during pregnancy actually acquired ASB earlier in life. Although pregnancy per se does not cause any major increase in incidence of bacteriuria, it does predispose to the development of acute pyelonephritis in bacteriuric patients.

Diagnosis

Although the diagnosis of ASB was originally based on obtaining two consecutive midstream urine cultures containing at least 100,000 colony-forming units per milliliter (CFU/mL) of a uropathogen, a single positive urine specimen is used for clinical diagnosis.^{4,124} Urine cultures are relatively expensive and require 24 to 48 hours for results. Therefore, inexpensive, rapid, office-based screening tests have undergone clinical testing. These include microscopic urinalysis, nitrite and leukocyte esterase dipstick, Gram stain, Uricult dip slide, Cult-Dip Plus, and the Uristat test. However, although it is more costly than rapid tests, urine culture remains the screening test of choice for detecting ASB in pregnancy.^{4,124-126}

Investigations have confirmed the lack of sensitivity and specificity of alternative methodologies for the diagnosis of ASB, particularly in pregnant women.^{127,128} As noted by McNair and colleagues,¹²⁷ the potential serious sequelae of undiagnosed

and untreated ASB mandate that urine culture be used to detect ASB in pregnant women. Both the U.S. Preventive Services Task Force and the Infectious Disease Society of America (IDSA) concur with this recommendation.^{109,121} The rapid diagnostic tests are of primary value for follow-up surveillance in patients who initially have a negative urine culture.

Treatment

Clinical trials demonstrate that treatment of ASB reduces the risk of acute pyelonephritis in pregnancy by 80% to 90%, to about 1% to 4%.¹²⁹⁻¹³¹ In addition, screening and treatment of ASB significantly reduces the risks for preterm delivery and delivery of a low-birth-weight infant.¹¹⁵⁻¹¹⁸

Treatment should be designed to maintain sterile urine throughout pregnancy, using the shortest possible course of antimicrobial agents in order to minimize the cost and the toxic effects of these drugs in mother and fetus. Because most antibacterial agents are excreted by glomerular filtration, therapeutic concentrations are readily achieved in the urine. In fact, the concentration of these drugs in urine greatly exceeds that required for the treatment of most UTIs. Even drugs that do not reach therapeutic concentrations in serum, such as nitrofurantoin, reach significant concentrations in urine.¹³²

No single agent is clearly better than another. At present, it is generally accepted that short courses of treatment are preferable, because (1) the duration of initial therapy does not affect the recurrence rate; (2) a short course minimizes the adverse drug effects in mother and fetus; (3) emergence of resistant bacteria is discouraged; (4) patient compliance is enhanced; and (5) costs are kept to a minimum.

Although a 3-day course of antibiotic therapy is recommended for the treatment of uncomplicated UTI in nonpregnant women, until recently a 7-day course was preferred for pregnant women.¹⁰⁵ However, a Cochrane Collaboration systematic review concluded that there was insufficient evidence to recommend a duration of antimicrobial therapy for pregnant women among the single-dose, 3-day, 4-day, and 7-day treatment regimens.¹³³ Most experts prefer the 7-day approach. Treatment of ASB is empiric, and in vitro susceptibility testing is not recommended for the initial positive culture.^{126,128}

A wide variety of antimicrobial agents have been used successfully for management of ASB in pregnancy (Table 51-3).

TABLE 51-3 Antimicrobial Treatment of Asymptomatic Bacteriuria and Acute Cystitis during Pregnancy

Antimicrobial Agent	Regimen
3-DAY OR 7-DAY TREATMENTS	
Ampicillin*	250 mg four times daily
Amoxicillin*	500 mg tid or 875 mg bid
Cephalexin*	250-500 mg four times daily
Nitrofurantoin monohydrate macrocrystals	100 mg bid
Sulfisoxazole	Initial 2-g dose, then 1 g four times daily
TMP-SMX DS	160/800 mg bid
SUPPRESSIVE THERAPY	
Nitrofurantoin monohydrate macrocrystals	100 mg qhs (duration of pregnancy)
TMP-SMX DS	160/800 mg qhs (duration of pregnancy)

*Only in geographic areas with low levels of resistant *Escherichia coli*. DS, double strength; TMP-SMX, trimethoprim-sulfamethoxazole.

These include β -lactam antibiotics such as ampicillin and cephalosporins which do not pose any significant risk to the fetus. Other commonly used antibiotics include short-acting sulfonamides, nitrofurantoin, and trimethoprim-sulfamethoxazole (TMP-SMX).

The quinolones are not approved for use during pregnancy because of concerns regarding their teratogenic effect on fetal cartilage. However, use of fluoroquinolones for resistant microorganisms is appropriate. In such instances, ciprofloxacin 250 mg twice daily or levofloxacin 250 mg daily may be used. Use of ampicillin or amoxicillin has been questioned for treatment of UTIs because the predominant etiologic organism is *E. coli*, and resistance rates of *E. coli* to ampicillin in the United States are 30% or greater.¹⁰⁵ Of additional concern is the decreased susceptibility of *E. coli* to TMP-SMX, which ranges from 5% to 15% depending on the geographic area.^{105,134-136}

When short courses of therapy are prescribed for ASB during pregnancy, continuous surveillance for recurrent bacteriuria by repeat urine cultures is essential. Persistent ASB should necessitate continuous antimicrobial therapy for the duration of pregnancy. A single daily dose of nitrofurantoin, 100 mg, preferably after the evening meal, is recommended. Alternatively, a sulfonamide preparation such as TMP-SMX may be prescribed (one double-strength [DS] tablet daily).

Prevention

Because ASB antedates pregnancy and typically is not acquired during pregnancy, there is no effective prevention strategy. Recurrent ASB has been noted in up to 30% of pregnant women.¹³⁷ Close monitoring with frequent urine cultures after diagnosis and treatment of ASB in early pregnancy can prevent recurrent or persistent ASB. Most importantly, diagnosis, treatment, and eradication of ASB in pregnant women substantially reduce the occurrence of acute pyelonephritis and preterm delivery.

CYSTITIS IN PREGNANCY

Acute cystitis is a distinct syndrome characterized by urinary urgency, frequency, dysuria, and suprapubic discomfort in the absence of systemic symptoms such as high fever and costovertebral angle tenderness. Gross hematuria may be present; the urine culture is invariably positive for bacterial growth. The gold standard for diagnosing acute cystitis, in the past, was a quantitative culture containing at least 100,000 CFU/mL. Stamm and coworkers¹³⁸ demonstrated that a urine culture positive for bacterial growth with more than 100 CFU/mL, in combination with symptoms of dysuria and frequency, is sufficient to confirm the diagnosis of cystitis, particularly if the urine sample was obtained by catheterization.

Epidemiology

The incidence of acute cystitis among pregnant women ranges from 0.3% to 1.3%.¹²³ Harris and Gilstrap¹³⁹ reported a recurrence rate of 1.3% for cystitis during pregnancy. Although increased diagnosis and treatment of ASB reduced the incidence of pyelonephritis at their institution, the incidence of acute cystitis remained constant. On initial screening, 64% of the patients who ultimately developed cystitis had negative urine cultures; in contrast, only a minority of those patients with ASB or acute pyelonephritis had negative cultures. The authors noted that the recurrence pattern in patients with acute

cystitis was also different from that in patients with either bacteriuria or acute pyelonephritis. Disease recurred in 75% of patients with acute pyelonephritis who were not given suppressive antimicrobial therapy, compared with only 17% of patients with acute cystitis.

Acute cystitis tends to occur during the second trimester.¹³⁹ This timing also differs from the pattern seen with ASB (in which almost all cases are diagnosed in the first trimester) or with acute pyelonephritis (diagnosed in the first and third trimesters). In addition, acute cystitis does not increase the risk for preterm birth, low birth weight, or acute pyelonephritis.^{4,104,124} In fact, the only morbidity associated with acute cystitis in pregnancy is maternal discomfort.

Pathogenesis

As reported by Scholes and associates,¹⁴⁰ the major risk factors for acute cystitis in young women are a history of prior acute cystitis and frequent or recent sexual activity. By 24 years of age, approximately 1 in 3 women have experienced at least one episode of acute cystitis, and 30% to 40% have one or more recurrences.¹⁴¹ Nonsecretors of ABO blood group antigens are at increased risk for recurrent cystitis.¹⁴²

As in ASB, the microorganisms associated with acute cystitis originate from the flora of the gastrointestinal tract, vagina, and periurethral area and ascend via the urethra to colonize and infect the bladder. The bacteria most commonly isolated from the urine of women with acute cystitis are *E. coli* (80% to 85%), *S. saprophyticus*, *Klebsiella pneumoniae*, *Proteus mirabilis*, GBS, and the enterococcus.⁴

Diagnosis

In nonpregnant women, the diagnosis of acute uncomplicated cystitis relies on symptoms of dysuria, urgency, and frequency plus evidence of pyuria by microscopy or dipstick. In pregnant patients, culture confirmation is recommended.⁴ Once cystitis is suspected, either a catheterized specimen or a clean-catch midstream specimen for urinalysis and culture should be obtained before treatment with antibiotics. However, because of the symptomatology of acute cystitis and the danger of upward extension of the infection to the kidney, it is not advisable to await the results of culture. The constellation of symptoms and demonstration of white blood cells and bacteria on urinalysis should be sufficient grounds for beginning therapy.

Urine dipstick testing has replaced microscopy because it is cheaper, faster, and more convenient. The presence of either nitrite or leukocyte esterase is considered a positive result, with a sensitivity of 75% and a specificity of 82%.¹⁴³ Whereas a positive result is highly predictive of UTI, a negative dipstick test does not rule out an infection in acutely symptomatic women.¹⁴⁴ A clean-catch midstream urine or catheter specimen with greater than 10² bacteria per milliliter obtained from an acutely dysuric woman is diagnostic of acute cystitis.¹³⁸

Treatment

Pregnant women with acute cystitis should receive immediate therapy with an antibiotic agent. The duration of therapy should be 3 days for the initial infection and 7 to 10 days for a recurrent infection. Single-dose therapy is not recommended in pregnancy. The antimicrobial agents used to treat cystitis in pregnancy are similar to those for ASB and are summarized in Table 51-3. Relief of symptoms occurs in more than 90% of women within 72 hours after treatment initiation.¹⁴³

In pregnant women with acute cystitis, a “test of cure” urine culture should be performed 1 to 2 weeks after completion of therapy. If it is positive, a different regimen than that used initially should be started. Continuous prophylaxis is recommended for women who have three or more symptomatic UTIs in a 12-month period. Either nitrofurantoin or TMP-SMX double strength (DS), one tablet of either drug daily, is recommended. Postcoital prophylaxis is an alternative option.⁴

Prevention

Because the risk for acute cystitis is not associated with the presence of ASB, screening for and treatment of ASB early in pregnancy does not reduce the incidence of acute cystitis in pregnancy. Moreover, one of the major risk factors for acute cystitis—use of a diaphragm and spermicide for contraception—is not an issue during pregnancy. However, recurrent acute cystitis can be prevented with daily antibiotic prophylaxis. Nitrofurantoin and TMP-SMX are acceptable alternatives.

ACUTE PYELONEPHRITIS

Acute pyelonephritis is one of the most common medical complications of pregnancy.^{4,143} Despite recommendations for routine screening of pregnant women and treatment of ASB, the incidence of acute pyelonephritis in pregnancy ranges from 1% to 2.5%. In a recent large, prospective cohort at Parkland Hospital, the incidence of antepartum acute pyelonephritis was 14 per 1000 deliveries.¹⁴³ Recurrence during the same pregnancy is common, occurring in 10% to 18% of cases. In addition, acute pyelonephritis in pregnancy can cause significant maternal morbidity and, in rare instances, maternal and fetal mortality.^{4,106,143}

Epidemiology

The major risk factors for acute pyelonephritis are previous episodes of acute pyelonephritis and the presence of ASB.⁴ In the absence of routine screening and treatment of ASB, up to 40% of pregnant women with ASB will develop acute pyelonephritis. Therefore, screening and treatment of ASB dramatically reduces the incidence of pyelonephritis as well. With universal screening, the reported incidence is 1% to 2%.^{110,111,145} Among pregnant women not receiving suppressive antimicrobial therapy to prevent acute pyelonephritis for the duration of pregnancy, recurrence has been observed in up to 60%; with suppressive therapy, the recurrence rate is less than 10%.^{4,145} Other predisposing factors for acute pyelonephritis during pregnancy include obstructive and neurologic diseases affecting the urinary tract and the presence of ureteral or renal calculi.

Hill and coworkers¹⁴³ examined the incidence of risk factors among women with acute antepartum pyelonephritis. Overall, 13% had at least one maternal risk factor for antepartum pyelonephritis. As demonstrated in the older literature, the most common risk factor was a previous history of pyelonephritis and ASB. Other factors include young maternal age and nulliparity.

Pathogenesis

Although ASB is no more frequent in pregnant than in nonpregnant women, acute pyelonephritis is a much more frequent sequela during pregnancy. Several factors during pregnancy facilitate bacterial replication in urine and ascent to the upper

urinary tract. Decreased bladder tone with increased capacity and incomplete emptying create a predisposition for vesicoureteric reflux to occur. Moreover, the physiologic hydronephrosis of pregnancy, caused by the effects of progesterone on muscle tone and peristalsis in the ureters and the mechanical obstruction of the enlarging uterus, facilitates ascent of bacteria into the upper urinary tract.⁴

Alterations in the physical and chemical properties of urine during pregnancy also facilitate ascending infection. Bacterial growth is enhanced by the elevated urinary pH during pregnancy. Glycosuria is more frequent and also enhances bacterial growth. The increased urinary excretion of estrogen also may play a role in the pathogenesis of acute antepartum pyelonephritis. Estrogen has been shown to accelerate the growth of strains of *E. coli* that cause pyelonephritis.^{4,146,147}

Pathogenic mechanisms also exist in the microorganisms associated with acute pyelonephritis. The requisite first step for establishing colonization or infection in the urinary tract is bacterial adherence to urogenital epithelium. *E. coli* attaches to uroepithelium via two adhesions: P fimbriae (pap encoded adhesions) and type 1 pili. The prevalence of *E. coli* strains expressing P fimbriae from patients with acute pyelonephritis (75% to 100%) is significantly greater than among fecal strains from persons without UTI. On the other hand, type 1 pili are almost universally expressed among uropathogenic and fecal commensal *E. coli* strains.¹⁴⁸

The most common bacteria associated with acute pyelonephritis are *E. coli*, *Klebsiella* species, *Proteus* species, and other *Enterobacter* species. Dunlow and Duff¹⁴⁹ reported that, in a group of women with antepartum pyelonephritis, *E. coli* (80%) was the dominant pathogen, with *K. pneumoniae* (7.4%), *Staphylococcus aureus* (6.7%), and *P. mirabilis* (2%) isolated much less frequently. More recently, Hill and colleagues¹⁴³ observed that the predominant microorganisms recovered from patients with acute antepartum pyelonephritis were *E. coli* (70%), *Klebsiella-Enterobacter* (3%), *Proteus* (2%), and gram-positive bacteria, including GBS (10%).

Diagnosis

Acute pyelonephritis is characterized by fever, chills, flank pain, dysuria, urgency, and frequency. Nausea and vomiting may also be present. On physical examination, fever and costovertebral angle tenderness are often present. Laboratory abnormalities include pyuria and bacteriuria. White blood cell casts are highly predictive of acute pyelonephritis. The diagnosis is ultimately confirmed by a positive urine culture.⁴

As noted by Sheffield and Cunningham,¹⁰⁴ the clinical findings of acute pyelonephritis in pregnancy are similar to those described in nonpregnant women. Onset of symptoms is usually abrupt. Fever is universal, and the diagnosis is suspect if it is absent. In at least 50% of cases occurring during pregnancy, pyelonephritis is unilateral and on the right side. Unilateral left side and bilateral infections are each present in 25% of cases. Most likely, right ureteral obstruction secondary to uterine dextrorotation explains the right-sided predominance seen in pregnancy.

Although 10% to 20% of pregnant women with acute pyelonephritis are bacteremic, the usefulness of obtaining routine blood cultures in cases of suspected acute uncomplicated pyelonephritis has been questioned.^{150,151} The rationale for this new approach includes the facts that blood cultures are expensive, the bacterium isolated is invariably the organism recovered

from the urine culture, and change of antibiotics usually is based on lack of clinical response rather than culture results.

Pyelonephritis is not only a serious risk for preterm labor and delivery but also a serious threat to maternal well-being. Up to 20% of pregnant women with acute pyelonephritis develop evidence of multiorgan system involvement secondary to endotoxemia and the sepsis syndrome.^{4,152,153} The primary pathogenic mechanism results from endothelial activation followed by capillary fluid leakage and extravasation, with resultant decreased perfusion of vital organs. This vascular derangement worsens the hypovolemia that is often present as a result of fever and vomiting, leading to hypotension.

Multiple sepsis-related complications have been reported in pregnant women with acute pyelonephritis. Anemia, caused by hemolysis initiated by endotoxemia, occurs in 23% to 66% of these patients. Rarely, evidence of disseminated intravascular coagulation (DIC) may be present. With severe sepsis, DIC is common and is associated with potentially serious complications (e.g., purpura fulminans).^{4,152,153}

Before the recognition that aggressive fluid resuscitation is a critical component of the management of acute pyelonephritis in pregnancy, approximately 20% of pregnant women with acute pyelonephritis had transient renal dysfunction, as documented by decreased creatinine clearance.¹⁵⁴ With aggressive fluid resuscitation, the rate of renal dysfunction is 7%.¹⁴³ Although renal dysfunction may be transient, it is important to recognize its presence so that nephrotoxic antimicrobial agents (e.g., aminoglycosides) can be withheld or used with caution. In addition, antibiotics that are excreted by the kidney should be administered in reduced dosages.

Cunningham and coworkers¹⁵³ initially reported that acute pyelonephritis of pregnancy may be complicated by adult respiratory distress syndrome (ARDS). Acute respiratory insufficiency, the most common serious complication of severe sepsis, develops in 2% to 8% of pregnant women with acute pyelonephritis.^{4,143,155} The pathophysiology is related to cytokine inflammatory injury to vascular endothelium, which leads to increased alveolar membrane permeability. ARDS should be suspected in patients who present with dyspnea, tachypnea, hypoxemia, or a chest radiograph suggestive of pulmonary edema or ARDS.

Towers and colleagues¹⁵⁵ identified several risk factors for ARDS in patients with antepartum pyelonephritis: elevated maternal heart rate (>110 beats/min), use of a tocolytic agent, use of ampicillin as the sole antibiotic, temperature 103°F or higher within the first 24 hours, and fluid overload. More recently, in a study of 440 cases of acute antepartum pyelonephritis, Hill and coworkers¹⁴³ reported that women with respiratory insufficiency received more intravenous fluids during the first 48 hours and had higher maximum temperatures, higher heart rates, lower hematocrits, and higher rates of septicemia. Moreover, tachypnea was present only in patients with respiratory insufficiency. Although most cases with pulmonary capillary injury respond to oxygen supplementation and diuresis, intubation and mechanical ventilation are required in severe cases. The cytokine inflammatory response may also lead to uterine contractions.¹²⁴

Treatment

The management of acute pyelonephritis in pregnant women has changed dramatically since the 1990s. Traditionally, patients with acute pyelonephritis were hospitalized and treated with parenteral antimicrobial therapy, but more recent studies have

demonstrated that, for women with mild to moderate disease, oral therapy on an outpatient basis is appropriate. In addition, the duration of therapy has been reduced from 6 weeks to 2 weeks.¹⁵⁶⁻¹⁵⁸

Hooton¹⁵⁶ outlined factors that should be considered when selecting agents for empiric treatment of uncomplicated acute pyelonephritis:

1. Antimicrobial spectrum of the agent
2. Pharmacokinetics allowing for infrequent dosing intervals
3. Prevalence of resistance among uropathogens in the geographic area
4. Duration of adequate urinary and renal tissue levels
5. Effect of antimicrobial agent on the fecal and vaginal flora
6. Adverse side effects
7. Cost
8. Public health concerns regarding development of resistance

Limited information has been published to assist in determining optimal antimicrobial regimens and duration of therapy for treatment of acute uncomplicated pyelonephritis in pregnant women. Moreover, the management of acute pyelonephritis has become more complex with the trend for increasing resistance of uropathogens, especially resistance to ampicillin and TMP-SMX.^{136,156}

For purposes of treatment, patients with acute uncomplicated pyelonephritis may be stratified into two groups: those with severe disease, who require hospitalization and parenteral antibiotics, and those with mild to moderate disease, who can be treated on an outpatient basis with oral agents. As described in the IDSA guidelines, mild disease is characterized by low-grade fever, normal or slightly elevated white blood cell count, and absence of nausea and vomiting.¹³⁶ Patients requiring hospitalization are those with high fever, high white blood cell count, vomiting, dehydration, evidence of sepsis, or no response during an initial period of observation.

The management of acute pyelonephritis in pregnant women follows many of the same principles used for nonpregnant women, with several important differences. In general, fluoroquinolones should be avoided in pregnancy, unless no alternative antimicrobial agent is available. Second, although earlier studies suggested that outpatient oral therapy is an acceptable alternative for mild to moderate pyelonephritis,^{151,159,160} most experts currently recommend that pregnant women with acute pyelonephritis be initially assessed during a 12- to 24-hour hospital stay before a decision is made about outpatient management. Finally, because of the potential for renal dysfunction and respiratory insufficiency in pregnant women with acute pyelonephritis, careful monitoring of renal function, urinary output, and respiratory status, including pulse oximetry, is necessary.

Management of acute pyelonephritis in pregnancy is outlined in Box 51-7. Because of the frequency of dehydration, respiratory insufficiency, and renal dysfunction associated with acute pyelonephritis in pregnancy, aggressive fluid resuscitation with crystalloid solutions such as lactated Ringer solution or normal saline is critical. Fluid resuscitation must be balanced with the risk of pulmonary edema, so close monitoring of respiratory status with pulse oximetry is imperative. Blood cultures should be obtained from patients who have evidence of severe sepsis, from those who fail to respond to initial therapy, and from those who are immunosuppressed.

BOX 51-7 MANAGEMENT OF ACUTE PYELONEPHRITIS IN PREGNANT WOMEN

In-hospital observation with assessment for 12-24 hr
 Urinalysis and urine culture
 Complete blood count, serum creatinine, electrolytes
 Frequent monitoring of vital signs (especially for onset of tachypnea)
 Monitoring of urine output (consider Foley catheter)
 Intravenous crystalloid fluid resuscitation to maintain urine output at ≥ 30 -50 mL/hr
 Chest radiograph and arterial blood gas analysis in patients with dyspnea or tachypnea suggestive of adult respiratory distress syndrome
 Intravenous antimicrobial therapy
 Patients who respond to initial parenteral antimicrobial and fluid resuscitation may be discharged after 12-24 hr of observation with oral antimicrobial agent to complete 14 days of therapy
 Patients with high fever, signs of respiratory insufficiency, poor urine output, evidence of sepsis, or inability to tolerate oral medication require hospitalization

TABLE 51-4 Antimicrobial Treatment of Acute Pyelonephritis in Pregnant Women

Agent	Dosage
OUTPATIENT REGIMENS (14 DAYS)	
Amoxicillin	500 mg tid
Amoxicillin-clavulanate	875/125 mg bid
TMP-SMX DS	160/800 mg bid
PARENTERAL REGIMENS	
Ceftriaxone	1-2 g q24h
Cefepime	2 g q8h
Cefotetan	2 g q12h
Cefotaxime	1-2 g q8h
TMP-SMX	2 mg/kg q6h
Ampicillin	2 g q6h
PLUS Gentamicin	7 mg/kg/ideal body weight q24h
Cefazolin	1-2 g q8h
PLUS Gentamicin	7 mg/kg/ideal body weight q24h
OR Aztreonam	1-2 g q8 to 12h (in lieu of gentamicin)
Ampicillin-sulbactam	1.5 g q6h
Piperacillin-tazobactam	3.75 g q6-8h

DS, double strength; TMP-SMX, trimethoprim-sulfamethoxazole.

Vital signs, including respiratory rate, and urine output should be closely monitored. Tachypnea, hypotension, and oliguria are signs of impending sepsis or septic shock. In gestations beyond 24 weeks, uterine activity and fetal heart rate should be monitored closely. If uterine contractions persist despite rehydration, tocolytic therapy should be considered, with due consideration to the synergistic cardiovascular effects of tocolytics and sepsis. Use of a cooling blanket or acetaminophen or both reduces cardiovascular stress. This intervention is important in early pregnancy because of the possible teratogenic effects of hyperthermia.¹⁰⁴ Similarly, if preterm labor is a concern, untreated hyperthermia increases the metabolic needs of the fetus.

A number of antimicrobial regimens may be used to treat acute pyelonephritis in pregnancy (Table 51-4). Given the high incidence of resistance by *E. coli* to ampicillin and

first-generation cephalosporins (cephalexin, cefazolin), these agents are not recommended.⁴ Ceftriaxone, 1 to 2 g IV as a single daily dose, is effective and, given its extended spectrum, provides excellent coverage against the major uropathogens (except *Enterococcus*). After discharge, ceftriaxone can be continued as a single daily dose of 1 to 2 g for home parenteral therapy. Alternatively, an oral cephalosporin or TMP-SMX can be given, depending on the results of susceptibility studies. Some authors favor an initial combination of ampicillin plus gentamicin.¹⁰⁴ Patients should respond within 48 hours. For patients who do not respond, investigation for urinary obstruction or complications of renal infection (e.g., perinephric abscess) should be undertaken. Once hospitalized patients have been afebrile and asymptomatic for 24 to 48 hours, they may be discharged to complete a 14-day course of therapy.

Administration of aminoglycosides requires particular caution. Although rare with the dosage and duration of aminoglycosides used in the treatment of acute uncomplicated pyelonephritis, both maternal and fetal nephrotoxicity and ototoxicity have been reported, especially with prolonged use. The more frequent occurrence of renal dysfunction in pregnant women with acute pyelonephritis should raise additional concerns regarding the use of aminoglycosides.⁴ Therefore, unless the causative microorganism is resistant to other antimicrobials or the patient is allergic to other agents, aminoglycoside use is best avoided. A possible exception is the pregnant woman with severe septic shock, for whom an aminoglycoside should be used to provide coverage against highly resistant gram-negative enterobacteria such as *Pseudomonas aeruginosa*, *Enterobacter* species, or *Citrobacter* species. In pregnant women receiving an aminoglycoside, serum levels should be monitored to ensure adequate serum concentrations and prevent toxicity. Either multidose gentamicin (3-5 mg/kg/24 hours in 3 divided doses) or single-dose gentamicin (7 mg/kg of ideal body weight every 24 hours) is appropriate.

Prevention

Both secondary and tertiary prevention strategies are critical to prevent acute pyelonephritis during pregnancy. As previously noted, the major factors associated with development of acute pyelonephritis in pregnancy are the presence of ASB which antedates the pregnancy and the physiologic changes of pregnancy that predispose to ascent of bacteria to the upper urinary tract.

There are no known methods of primary prevention for acute pyelonephritis. However, screening for, and eradication of, bacteriuria early in pregnancy substantially reduces the incidence of acute pyelonephritis. Daily nighttime suppressive therapy after treatment of acute pyelonephritis significantly reduces the risk for recurrent acute pyelonephritis during pregnancy or immediately after delivery.

After completion of therapy for acute pyelonephritis during pregnancy, 30% to 40% of women have recurrent bacteriuria. If this infection is left untreated, approximately 25% develop recurrent pyelonephritis. Harris and Gilstrap¹³⁹ reported that, among patients not receiving suppressive antimicrobial regimens for the duration of pregnancy, 60% had a recurrent episode of acute pyelonephritis, whereas in the group maintained on suppressive therapy, the recurrence rate was only 2.7%. Other studies have reported a similar high rate of recurrence in pregnant women after an episode of acute pyelonephritis if they did not receive suppressive therapy.¹⁶¹

The recommended drug for suppression after treatment of acute pyelonephritis in pregnancy is nitrofurantoin, 100 mg at bedtime for the duration of the pregnancy. Alternatively, TMP-SMX DS 160/800 mg daily at bedtime may be given, recognizing that the sulfa moiety in the sulfamethoxazole confers a small risk of kernicterus in the newborn if given in the third trimester. An acceptable alternative to daily suppressive therapy is to obtain urine cultures every 2 weeks for the duration of pregnancy in order to detect and promptly treat recurrent bacteriuria.¹⁶² Although recurrent or persistent bacteriuria was found to be more common with this latter approach, the rates of acute pyelonephritis were similar in the urine culture group and the suppressive therapy group. Daily suppressive therapy is more cost-effective than frequent reculturing.

Chorioamnionitis

Bacterial infection of the amniotic cavity is a major cause of perinatal mortality and maternal morbidity. Significant associations between clinical intra-amniotic infection and long-term neurologic development in the newborn, including cerebral palsy, have been reported (see Chapter 58).

A number of terms for this infection have been used, including “clinical chorioamnionitis,” “amnionitis,” “intrapartum infection,” “amniotic fluid infection,” and “intra-amniotic infection.” The term *clinical chorioamnionitis* distinguishes the clinical syndrome of fever and uterine tenderness from asymptomatic colonization, subclinical infection of the amniotic cavity, or histologic inflammation of the placenta and fetal membranes in the absence of maternal symptoms.

Clinical chorioamnionitis occurs in 0.5% to 10% of pregnancies.¹⁶³ Histologic chorioamnionitis occurs more frequently than does clinically evident infection, being present in up to 20% of term deliveries and more than half of preterm deliveries.

PATHOGENESIS

With the onset of labor or with rupture of the membranes, bacteria from the lower genital tract are able to ascend into the amniotic cavity. This is the most common pathway for development of clinical chorioamnionitis. Occasional cases occurring in the absence of membrane rupture or labor support a less frequent hematogenous or transplacental route of infection. For example, fulminating clinical chorioamnionitis with intact membranes may be caused by *Listeria monocytogenes*. Less commonly, the infection may develop as a consequence of obstetric procedures such as cervical cerclage, amniocentesis, or percutaneous umbilical blood sampling. The absolute risk of chorioamnionitis is low with all of these procedures; it occurs in 2% to 8% of patients after cerclage, in fewer than 1% after amniocentesis, and in up to 5% after intrauterine transfusion. Bacteria also may reach the amniotic cavity from extragenital sources such as the urinary tract or periodontal tissue.

EPIDEMIOLOGY

Clinical chorioamnionitis is a leading risk factor for neonatal sepsis. Yancey and coworkers¹⁶⁴ found this infection to have an OR of 25 for suspected or proven neonatal sepsis, by far the highest ratio compared with other obstetric risk factors such as preterm delivery, ruptured membranes lasting longer than 12 hours, postpartum endometritis, or maternal carriage of GBS.

Risk factors for clinical chorioamnionitis are largely obstetric conditions in patients experiencing protracted labor. They include the following:

- Low parity
- Prolonged labor
- Prolonged rupture of membranes
- Multiple vaginal examinations in labor
- Internal fetal monitoring
- Maternal BV¹⁶⁵⁻¹⁶⁹
- Microbiology

As with other pelvic infections, clinical chorioamnionitis is usually polymicrobial in origin. The most common organisms found in the amniotic fluid of women with chorioamnionitis are *Bacteroides* species (25%), *G. vaginalis* (24%), GBS (12%), other aerobic streptococci (13%), *E. coli* (10%), and other aerobic gram-negative rods (10%).¹⁷⁰

A role for genital mycoplasmas has been suggested by case reports of their isolation from amniotic fluid of clinically infected patients and by a controlled study reporting that 35% of fluid specimens from patients with chorioamnionitis yielded *M. hominis*, whereas only 8% of matched control fluids had this organism ($P < .001$).¹⁷¹

Present evidence suggests a small role, if any, for *C. trachomatis* in amniotic fluid infections. This organism rarely is isolated in cases of clinical chorioamnionitis, and no significant antibody changes to *C. trachomatis* have been noted in sera of women with this infection. Pregnant women with cervical *C. trachomatis* infections do not have higher rates of intrapartum fever.^{73,172}

DIAGNOSIS

The clinical diagnosis of chorioamnionitis requires a high index of suspicion. Usual laboratory indicators of infection, such as positive stains for organisms or leukocytes and positive cultures, are found much more frequently than is clinically evident infection. Diagnosis typically is based on the signs of maternal fever, maternal or fetal tachycardia, uterine tenderness, foul odor of the amniotic fluid, and peripheral blood leukocytosis. Bacteremia occurs in approximately 10% of women with chorioamnionitis. Because peripheral blood leukocytosis occurs commonly in normal labor, a high white blood cell count ($>15,000/\text{mL}$) supports, but is not diagnostic of, infection.

Direct examination of the amniotic fluid, via amniocentesis or aspiration through an intrauterine pressure catheter, may provide important diagnostic information. Positive Gram staining of amniotic fluid for bacteria or leukocytes occurs significantly more often in women with clinical chorioamnionitis than in matched controls.¹⁷⁰ In patients with suspected amnionitis, low amniotic fluid glucose levels are a good predictor of a positive amniotic fluid culture but a poorer predictor of clinical chorioamnionitis. If the amniotic fluid glucose concentration is greater than 20 mg/dL, the likelihood of a positive culture is less than 2%. If the glucose level is less than 5 mg/dL, the likelihood of a positive culture rises to approximately 90%.^{173,174} Although the test is not readily available to the clinician, an elevated concentration of interleukin 6 (IL-6) in the amniotic fluid is the most sensitive and specific marker for predicting a positive amniotic fluid culture.¹⁷⁴

MANAGEMENT

If acute chorioamnionitis is suspected, prompt institution of intravenous antibiotics and delivery of the fetus are required.

TABLE 51-5 Rates of Neonatal Sepsis after Intrapartum versus Immediate Postpartum Antibiotic Treatment in Cases of Intra-Amniotic Infection

Study	N	Rate of Neonatal Sepsis (%)		
		Intrapartum Treatment	Neonatal Treatment	P
Sperling et al, 1987 ¹⁷⁵	257	2.8	19.6	.001
Gibbs et al, 1988 ¹⁷⁷	45	0	21	.03
Gilstrap et al, 1988 ¹⁷⁶	273	1.5	5.7	.06

Regarding the timing of delivery, excellent maternal-neonatal outcome has been reported without the use of arbitrary time limits. Gibbs and colleagues¹⁷⁰ reported on a policy in which cesarean delivery was performed only for standard obstetric indications and not for the presence of clinical chorioamnionitis alone. The mean time from diagnosis to delivery was between 3 and 5 hours, and more than 90% of patients were delivered within 12 hours after diagnosis. Those who were delivered vaginally had lower rates of morbidity. No critical interval from diagnosis of chorioamnionitis to delivery could be identified.

Three studies demonstrated a significant advantage for intrapartum rather than immediate postpartum antibiotic treatment (Table 51-5). In a nonrandomized trial, Sperling and coworkers¹⁷⁵ reported a lower incidence of neonatal sepsis when antibiotic treatment was begun at the time of diagnosis, compared with treatment begun immediately after delivery. Gilstrap and colleagues¹⁷⁶ found an almost fourfold reduction in neonatal sepsis with use of intrapartum treatment (5.7% versus 1.5%, $P = .06$). In a randomized trial, Gibbs and colleagues¹⁷⁷ used ampicillin (2 g intravenously every 6 hours) plus gentamicin (1.5 mg/kg every 8 hours), initiating treatment either intrapartum or immediately postpartum. In addition, clindamycin was used after umbilical cord clamping if cesarean delivery was performed, because of the high failure rate of ampicillin and gentamicin alone in women delivered abdominally. Maternal outcome was improved, and confirmed neonatal sepsis was decreased by intrapartum treatment. Other regimens employing an extended-spectrum penicillin (e.g., ampicillin plus a β -lactamase inhibitor) or other agents with similar activity may be equally effective, but no comparative trials have been performed.

The duration of postpartum antibiotic therapy needed for patients with clinical chorioamnionitis was addressed in a randomized clinical trial by Edwards and Duff.¹⁷⁸ They showed that one additional intravenous dose of a broad-spectrum combination of antibiotics (ampicillin, 2 g, plus gentamicin, 1.5 mg/kg) was sufficient postpartum therapy for women with clinical chorioamnionitis. As mentioned previously, it is imperative that a drug with excellent anaerobic coverage—such as clindamycin, 900 mg IV, or metronidazole, 500 mg IV—be given intraoperatively to women undergoing cesarean delivery. Failure to add a drug with specific anaerobic coverage will result in an unacceptably high rate of treatment failure, exceeding 20%.

Short-Term Outcome

Since 1979, reports from systematically collected data on the outcome of mothers and neonates in pregnancies complicated

by intra-amniotic infection have shown a vastly improved perinatal outcome compared with older studies. Maternal outcome has been excellent, with no deaths, few cases of septic shock, and rare pelvic abscesses. The cesarean delivery rate has been increased twofold to threefold in all studies, usually because of dystocia. Perinatal mortality has been increased in cases of clinical chorioamnionitis, but little of the excess mortality can be attributed to infection per se. Among term infants born after clinical chorioamnionitis, perinatal mortality has been less than 1%.^{175-177,179}

Yoder and colleagues¹⁷⁹ published a case-control study of 67 patients with microbiologically confirmed clinical chorioamnionitis at term. There was only one perinatal death, which was unrelated to infection. Cerebrospinal fluid cultures were negative in all 49 infants sampled, and there was no clinical evidence of meningitis. Chest radiographs were interpreted as “possible” pneumonia in 20% and as “unequivocal” pneumonia in only 4%. Neonatal bacteremia was documented in 8%. There was no significant difference in the frequency of low Apgar scores between the chorioamnionitis group and the control group.

Preterm neonates born to mothers with clinical chorioamnionitis experience a higher frequency of complications than do those born to mothers without this disorder. Garite and Freeman¹⁸⁰ observed that the perinatal death rate was significantly higher in 47 preterm neonates with chorioamnionitis than in 204 uninfected neonates with similar birth weights (13% versus 3%, $P < .05$). The group with chorioamnionitis also included a significantly higher number with respiratory distress syndrome (34% versus 16%, $P < .01$) and infection (17% versus 7%, $P < .05$).

Patients with clinical chorioamnionitis are more likely to require cesarean delivery, often for uterine dysfunction, inadequate uterine response to oxytocin, or abnormal labor progress even when uterine activity is adequate. The combination of prematurity and chorioamnionitis increases the risk of serious sequelae in the neonate.

Long-Term Outcome

There is increasing evidence that intrauterine infection is associated with increased risks of respiratory distress syndrome, periventricular leukomalacia, and cerebral palsy. The unifying hypothesis for these varying morbidities is that intra-amniotic infection leads to fetal infection and to an overexuberant fetal production of cytokines, which leads, in turn, to pulmonary and central nervous system (CNS) damage. This “fetal inflammatory response syndrome” has been likened to the systemic inflammatory response syndrome in adults. Several studies have linked maternal infection with cerebral palsy and with cystic necrosis of the white matter in preterm and term infants. Intrauterine exposure to maternal infection is associated with an increased risk of cerebral palsy (OR, 9.3) in infants of normal birth weight.¹⁸¹ The results of a 2000 meta-analysis are summarized in Table 51-6.

Amniotic fluid concentrations of the inflammatory cytokines (IL-1 β , IL-6, and tumor necrosis factor [TNF]) are higher in preterm infants with periventricular leukomalacia than in those without such lesions.¹⁸² In addition, the presence of cerebral palsy at 3 years of age is more common in infants who were delivered preterm with funisitis or elevated amniotic fluid concentrations of IL-6 or IL-8.¹⁸³ Among preterm infants, respiratory distress syndrome has been significantly associated with

high levels of TNF in amniotic fluid, with positive cultures of amniotic fluid, and with severe histologic chorioamnionitis, even after adjustment for birth weight, infant gender, race, and mode of delivery. Collectively, these observations have aroused renewed interest in the importance of the long-term effects of intrauterine infection, as well as strategies to avoid

their serious complications.¹⁸⁴ These issues also are addressed in Chapter 72.

PREVENTION

Numerous approaches have been tested as preventive techniques. Chlorhexidine vaginal washes during labor^{185,186} and selected infection-control measures¹⁶⁸ have been ineffective. Antepartum treatment of BV has not been shown to decrease the rate of chorioamnionitis.¹⁸⁷ Use of broad-spectrum antibiotics in patients with preterm labor but intact membranes appears to be ineffective overall in decreasing the frequency of chorioamnionitis.¹⁸⁸

Intrapartum prophylaxis to prevent neonatal GBS sepsis decreases the frequency of chorioamnionitis. Use of a screening-based strategy (which results in more women receiving antibiotics) compared with a risk-based strategy produces lower rates of chorioamnionitis.¹⁸⁹ In addition, active management of labor,¹⁹⁰ induction of labor (compared with expectant management) after PROM at term,¹⁹¹ and use of prophylactic antibiotics in selected patients with pPROM¹⁹²⁻¹⁹⁵ have each been shown to decrease the rate of chorioamnionitis.

Episiotomy Infection

Although episiotomy and vaginal laceration repair are commonly performed after a vaginal delivery, infection is an infrequent complication. Shy and Eschenbach¹⁹⁶ classified episiotomy infections according to the extent of the structures involved (Fig. 51-5). The same classification may be used for infections of perineal lacerations.

TABLE 51-6 Meta-Analysis of Chorioamnionitis as a Risk Factor for Cerebral Palsy and Cystic Periventricular Leukomalacia

Diagnosis	N	RR (95% CI)
PRETERM INFANTS		
Cerebral Palsy		
Clinical chorioamnionitis	11	1.9 (1.4-2.5)
Histologic chorioamnionitis	5	1.6 (0.9-2.7)
Cystic Periventricular Leukomalacia		
Clinical chorioamnionitis	6	3.0 (2.2-4.0)
Histologic chorioamnionitis	7	2.1 (1.5-2.9)
TERM INFANTS		
Cerebral Palsy		
Clinical chorioamnionitis	2	4.7 (1.3-16.2)
Histologic chorioamnionitis	1	8.9 (1.9-40)

CI, confidence interval; RR, relative risk.

Data from Grether JK, Nelson KB: Maternal infection and cerebral palsy in infants of normal birth weight, *JAMA* 278:207, 1997; Wu YW, Colford JM Jr: Chorioamnionitis as a risk factor for cerebral palsy: a meta-analysis, *JAMA* 284:1417, 2000.

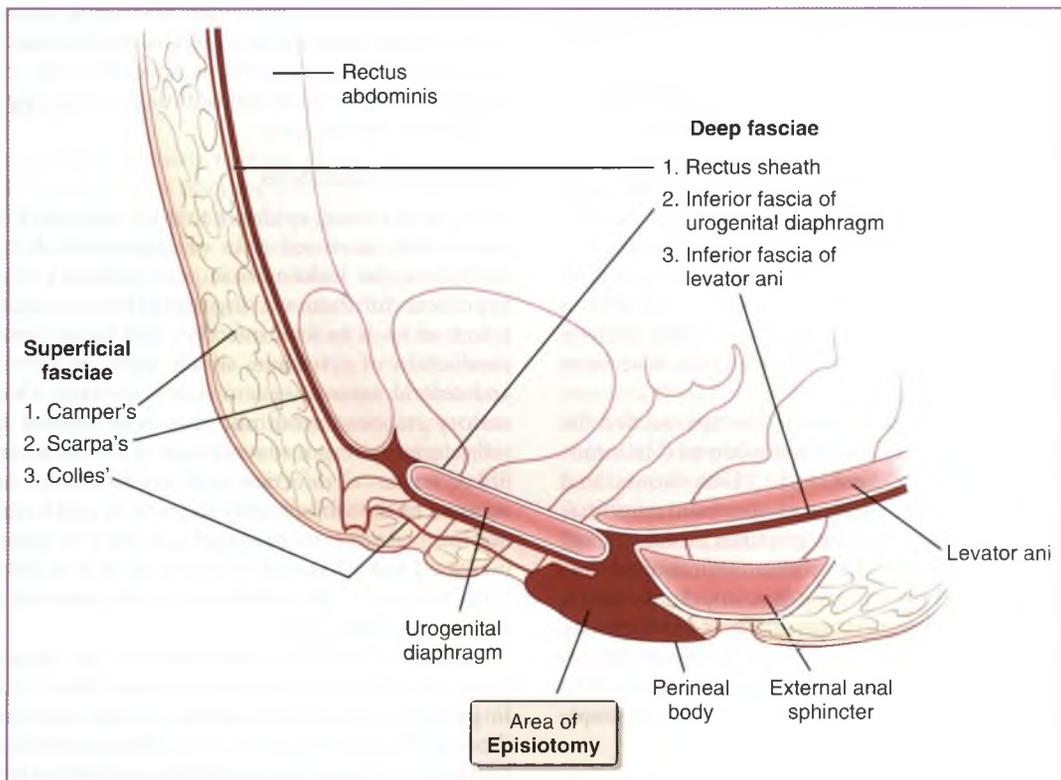

Figure 51-5 Structures potentially involved in episiotomy infection. Paramedian sagittal section of the fascial layers of the perineum. (From Shy KK, Eschenbach DA: Fatal perineal cellulitis from an episiotomy site, *Obstet Gynecol* 54:292, 1979. Reprinted with permission of the American College of Obstetricians and Gynecologists.)

SIMPLE EPISIOTOMY INFECTION

A localized infection may involve only the skin and subcutaneous tissue (including the Camper fascia of the perineum) adjacent to the episiotomy. Signs are local edema and erythema with exudate; more extensive findings should raise the suspicion of a deeper infection. Treatment consists of opening, exploring, and debriding the perineal wound. Drainage alone usually is adequate, but appropriate antibiotics should be given if there is marked superficial cellulitis or isolation of group A streptococci. The episiotomy incision should not be immediately resutured. Most episiotomy wounds will heal well by secondary intention. Wounds involving the external anal sphincter or rectal mucosa may be repaired after the field is free of infection.

There has been considerable interest in early repair of episiotomy dehiscence. Such dehiscence usually is associated with infection. Early repair requires prompt and meticulous débridement at the time of diagnosis, followed by antibiotics and frequent cleansing. When the tissue appears healthy (usually after about 1 week or longer), a definitive repair can be undertaken. For fourth-degree lacerations, a bowel preparation should be given before the repair. Such repair is an attractive option compared with the delay of 2 to 3 months recommended in older literature.¹⁹⁷⁻²⁰⁰

NECROTIZING FASCIITIS

With necrotizing fasciitis, both layers of the superficial perineal fascia (i.e., the Camper and Colles fascias) become necrotic, and infection spreads along the fascial planes to the abdominal wall, thigh, and/or buttock. Typically, the deep perineal fascia (i.e., inferior fascia of the urogenital diaphragm) is not involved. Skin findings are variable but initially include edema and erythema without clear borders. Later, there is progressive, brawny edema of the skin. The skin becomes blue or brown, and bullae or frank gangrene may occur. As the infection progresses, either loss of sensation or hyperesthesia may develop.

Associated findings include marked hemoconcentration, although often after fluid replacement the patient is anemic. Hypocalcemia also may develop because of the saponification of fatty acids. Traditionally, this infection has been associated with group A streptococci, but anaerobic bacteria also play an important role.

For therapy to be effective, appropriate antibiotics must be combined with adequate débridement. Indications for surgical exploration include extension beyond the labia, unilateral or markedly asymmetric edema, signs of systemic toxicity or deterioration, and failure of the infection to resolve within 24 to 48 hours. At surgery, necrotizing fasciitis may be recognized by separation of the skin from the deep fascia, absence of bleeding along incision lines, and a serosanguineous discharge. Dissection must be wide enough to remove all necrotic tissue.

MYONECROSIS

Myonecrosis is an infection that involves the muscle beneath the deep fascia. It often is the result of a myotoxin elaborated by *Clostridium perfringens*, but it occasionally can result from an extension of necrotizing fasciitis. Onset may be early and typically is accompanied by severe pain. Treatment of this condition also consists of extensive débridement and high-dose

antibiotics, including penicillin, if clostridia infection is suspected.

Clinicians should recognize that not all vulvar edema in the puerperum signifies serious perineal infection. In fact, most cases of vulvar edema result from less serious causes, such as hematoma, prolonged bearing-down in labor, generalized edema from preeclampsia, allergic reactions, or trauma. In these instances, however, the edema usually is bilateral, does not extend to the buttock or abdominal wall, and is not accompanied by signs of systemic toxicity.

Puerperal Endometritis

EPIDEMIOLOGY

The frequency of endometritis in women after planned cesarean delivery ranges from 5% to 15%, depending on maternal socioeconomic status. If cesarean delivery is performed after an extended period of labor and ruptured membranes, the incidence of endometritis is approximately 30% to 35% without antibiotic prophylaxis and approximately 10% or even less with prophylaxis. In highly indigent patient populations, the frequency of postcesarean endometritis may be higher.²⁰¹

PATHOGENESIS

Endometritis is a polymicrobial infection caused by microorganisms that are part of the normal vaginal flora. These aerobic and anaerobic bacteria gain access to the upper genital tract, peritoneal cavity, and bloodstream as a result of vaginal examinations during labor and manipulations during surgery. The most common pathogens are GBS, anaerobic gram-positive cocci (streptococci and peptostreptococci species), anaerobic gram-negative bacilli (predominantly *E. coli*, *K. pneumoniae*, and *Proteus* species), and anaerobic gram-negative bacilli (principally *Bacteroides* and *Prevotella* species). *C. trachomatis* is not a common cause of early-onset puerperal endometritis but has been implicated in late-onset infection. The genital mycoplasmas, *M. hominis* and *Ureaplasma urealyticum*, may be pathogenic in some patients, but they usually are present in association with other, more highly virulent bacteria.^{201,202}

The principal risk factors for endometritis are cesarean delivery, young age, low socioeconomic status, extended duration of labor, extended duration of ruptured membranes, and multiple vaginal examinations. Preexisting infection of the lower genital tract due to gonorrhea, GBS, or BV also predisposes to ascending infection after delivery.²⁰³

DIAGNOSIS

Patients with endometritis typically have a fever of 38°C or higher within 36 hours after delivery. Associated findings include malaise, tachycardia, lower abdominal pain and tenderness, uterine tenderness, and malodorous lochia. A small number of patients have a tender, indurated, inflammatory mass in the broad ligament, posterior cul-de-sac, or retrovesical space.

The initial differential diagnosis of puerperal fever should include endometritis, atelectasis, pneumonia, viral syndrome, pyelonephritis, and appendicitis. Distinction among these disorders usually can be made on the basis of physical examination and selected laboratory tests such as a peripheral white blood cell count, urinalysis and culture, and, in some patients, chest

radiography. Blood cultures are indicated for patients who have a poor initial response to therapy or for those who are immunocompromised or who are at increased risk for bacterial endocarditis. Cultures of the lower genital tract and endometrium are rarely indicated. Such cultures are difficult to obtain without contamination from lower genital tract flora. In addition, by the time the culture results are available, most patients already have responded to treatment and have been discharged from the hospital.

TREATMENT

The most commonly used regimen for treatment of puerperal endometritis is the combination of clindamycin (900 mg IV every 8 hours) plus gentamicin (7 mg/kg of ideal body weight every 24 hours). An alternative regimen is metronidazole (500 mg IV every 12 hours) plus penicillin (5 million units IV every 6 hours) or ampicillin (2 g IV every 6 hours) plus gentamicin (7 mg/kg of ideal body weight every 24 hours). Both of these combination regimens provide excellent coverage against most of the potential pelvic pathogens. Broad-spectrum single agents such as cefotetan (2 g IV every 12 hours), ticarcillin plus clavulanic acid (3.1 g IV every 6 hours), ampicillin plus sulbactam (3 g IV every 6 hours), piperacillin plus tazobactam (3.375 g IV every 6 hours), imipenem-cilastatin (500 mg IV every 6 hours), or ertapenem (1 g IV every 24 hours) may be used for treatment of endometritis. However, in most hospital formularies, these broad-spectrum single agents are more expensive than the generic combination regimens listed earlier.²⁰⁴

Once intravenous antibiotics are begun, approximately 90% to 95% of patients experience defervescence within 48 to 72 hours. Once the patient has been afebrile and asymptomatic for approximately 24 hours, parenteral antibiotics should be discontinued and the patient discharged. As a general rule, an extended course of oral antibiotics is not necessary after discharge.²⁰⁵ There are at least two exceptions to this general rule. First, patients who have had a vaginal delivery and who defervescence within 24 hours are candidates for early discharge. In these individuals, a short course of an oral antibiotic such as amoxicillin-clavulanate (875 mg orally every 12 hours) may be substituted for continued parenteral therapy. Second, patients who have had a staphylococcal bacteremia may require a more extended period of administration of parenteral and oral antibiotics.²⁰⁴

Patients who fail to respond to the antibiotic therapy outlined here usually have one of two problems. The first is a resistant organism. In patients who are treated with clindamycin plus gentamicin, the principal resistant organism is enterococcus. This organism can be adequately covered by adding ampicillin (2 g IV every 6 hours) or penicillin (5 million units IV every 6 hours) to the treatment regimen. For those who are taking a broad-spectrum single agent, potential weaknesses in coverage include some aerobic and some anaerobic gram-negative bacilli. These patients should be changed to the triple-drug regimen (clindamycin or metronidazole, plus penicillin or ampicillin, plus gentamicin).

The second major cause of treatment failure is an abdominal wound infection. Some patients have an actual incisional abscess. In these cases, the wound should be opened to provide drainage. An antibiotic that has excellent antistaphylococcal coverage, including coverage of methicillin-resistant *S. aureus* (MRSA) should be added to the treatment regimen; an example is vancomycin, 1 g IV every 12 hours. Some women do not have

frank pus in the incision but rather an extensive cellulitis in the soft tissue around the incision. In these patients, the wound does not have to be opened. However, an antistaphylococcal antibiotic should be added to the treatment regimen.²⁰⁴

Other possible causes of a poor response to treatment include pelvic abscess, septic pelvic vein thrombophlebitis, and drug reaction. The management of pelvic abscess and septic pelvic vein thrombophlebitis is discussed in the following sections. Drug reaction should be suspected if the patient has a peripheral blood eosinophilia and if the temperature elevation corresponds with the time of drug administration. In these individuals, discontinuation of the antibiotic usually results in prompt resolution of fever.

PREVENTION

Ideally, the best approach to endometritis is prevention of infection. In this regard, prophylactic antibiotics clearly are of proven value in reducing the frequency of postcesarean endometritis, particularly in women having surgery after an extended period of labor and ruptured membranes. I recommend cefazolin (1 g IV for patients with a BMI <30 and 2 g for patients with a BMI >30) plus azithromycin (500 mg IV), administered 30 to 60 minutes before the start of surgery. Patients who have an immediate hypersensitivity reaction to β -lactam antibiotics should receive a single dose of clindamycin (900 mg IV) plus gentamicin (1.5 mg/kg IV) 30 to 60 minutes before surgery.²⁰⁵

Another important method for preventing endometritis is to remove the placenta by gentle traction on the umbilical cord rather than manually. Several investigators^{206,207} have confirmed that, when other factors are controlled, manual removal of the placenta significantly increases the frequency of postcesarean endometritis.

Wound Infection

EPIDEMIOLOGY AND PATHOGENESIS

Approximately 3% to 5% of women who have a cesarean delivery develop a wound infection. The principal risk factors for this complication are low socioeconomic status, extended duration of labor, extended duration of ruptured membranes, preexisting infection such as chorioamnionitis, obesity, insulin-dependent diabetes, an immunodeficiency disorder, corticosteroid or immunosuppressive therapy, and poor surgical technique. The major organisms that cause postcesarean wound infection are *S. aureus*, aerobic streptococci, and aerobic and anaerobic gram-negative bacilli.²⁰⁸

DIAGNOSIS

The diagnosis of wound infection should be a paramount consideration in a woman who has had a poor initial clinical response to antibiotic therapy for endometritis. Clinical examination usually shows erythema, induration, and tenderness at the margins of the abdominal incision, and pus exudes from within the incision. Some patients have an extensive cellulitis without actual purulent drainage.

Clinical examination usually is sufficient to establish the correct diagnosis. Culture of the wound exudate should be performed routinely because of the possibility of a MRSA infection.²⁰⁹

TREATMENT

If frank pus or significant serosanguineous effusion is present in the incision, the wound must be opened and drained completely. Antibiotic therapy should be modified to provide coverage against staphylococci, particularly MRSA. Vancomycin, 1 g IV every 12 hours, is an excellent choice in this clinical situation.²⁰⁴

Once the wound has been opened, it should be repacked two to three times daily with gauze dampened with saline. A clean dressing should be applied, and the wound should initially be allowed to heal by secondary intention. After all signs of infection have resolved and healthy granulation tissue is apparent, a secondary closure may be considered. Antibiotics should be continued until the base of the wound is clean and all signs of cellulitis have resolved. Patients usually can be treated on an outpatient basis once the acute signs of infection have subsided.

Necrotizing fasciitis is an uncommon but extremely serious complication of abdominal wound infection. It has also been reported in association with infection of the episiotomy site (see earlier discussion). This condition is particularly likely to occur in patients who have insulin-dependent diabetes, cancer, or an immunodeficiency disorder. Multiple bacterial pathogens, particularly anaerobes, have been isolated from patients with necrotizing fasciitis.

This condition should be suspected if the margins of the wound become discolored, cyanotic, and devoid of sensation. When the wound is opened, the subcutaneous tissue is easily dissected free of the underlying fascia, but muscle tissue is not affected. If the diagnosis is uncertain, a biopsy of the margin of the wound should be obtained and examined immediately by frozen section.

Necrotizing fasciitis is a life-threatening condition that requires aggressive medical and surgical management. Broad-spectrum antibiotics with activity against all potential pathogens should be administered. The patient's intravascular volume should be maintained with infusions of crystalloid, and electrolyte abnormalities should be promptly corrected. Of greatest importance, the wound must be completely débrided and all necrotic tissue removed. In many instances, the required dissection is extensive and is best managed in consultation with an experienced general or plastic surgeon.

Pelvic Abscess

EPIDEMIOLOGY AND PATHOGENESIS

Since the advent of modern antibiotics, pelvic abscesses after cesarean or vaginal delivery have become extremely rare. When they do occur, they usually develop in women who initially had postcesarean endometritis. The frequency of pelvic abscess as a complication of endometritis is less than 1%.²⁰¹

Pelvic abscesses typically are located in the anterior or posterior cul-de-sac or within the leaves of the broad ligament. The bacteria usually isolated from abscess cavities are anaerobic gram-positive organisms such as *Peptococci* and *Peptostreptococci* species, anaerobic gram-negative bacilli (particularly *Bacteroides* and *Prevotella* species), and aerobic gram-negative bacilli such as *E. coli*, *Klebsiella*, and *Proteus* species.^{202,203}

DIAGNOSIS

Patients who have a pelvic abscess typically experience persistent fever despite appropriate antibiotic therapy for

endometritis. In addition, they usually have malaise, tachycardia, tachypnea, lower abdominal pain and tenderness, and a palpable pelvic mass. The peripheral white blood cell count is elevated ($>20,000/\text{mm}^3$), and there is a shift toward immature cell forms. The diagnosis of pelvic abscess may be confirmed by ultrasound studies, computed tomographic (CT) scanning, or magnetic resonance imaging (MRI).²¹⁰ The latter two tests are slightly more sensitive, but more expensive, than ultrasonography.

TREATMENT

Patients who develop an abscess require surgical drainage in addition to broad-spectrum antibiotic therapy. If the abscess is located in the posterior cul-de-sac, colpotomy drainage may be feasible. For abscesses located anterior or lateral to the uterus, drainage may be accomplished by CT- or ultrasound-guided placement of a catheter drain. If access to the abscess cavity is limited by the interposition of bowel, or if the abscess is extensive, open laparotomy is indicated.²⁰⁷

Patients also must receive antibiotics that have excellent activity against multiple aerobic and anaerobic pathogens. One regimen that has been tested extensively in obstetric patients with serious infections is the combination of penicillin (5 million units IV every 6 hours) or ampicillin (2 g IV every 6 hours), plus gentamicin (7 mg/kg of ideal body weight every 24 hours), plus clindamycin (900 mg IV every 8 hours) or metronidazole (500 mg IV every 12 hours). If the patient is allergic to β -lactam antibiotics, vancomycin (1 g IV every 12 hours) can be substituted for penicillin or ampicillin. Aztreonam (1 g IV every 8 hours) can be used in lieu of gentamicin if the patient is at risk for nephrotoxicity. Alternatively, broad-spectrum agents, such as one of the carbapenems—imipenem-cilastatin (500 mg IV every 6 hours), meropenem (1 g IV every 8 hours), or ertapenem (1 g IV every 24 hours)—provide excellent coverage against the usual pathogens responsible for an abscess. Intravenous antibiotics should be continued until the patient has been afebrile and asymptomatic for a minimum of 24 to 48 hours. Thereafter, the patient should be treated with a combination of oral antibiotics that cover the major pathogens.²⁰⁴ One appropriate regimen is ofloxacin (400 mg every 24 hours) or levofloxacin (750 mg every 24 hours) plus metronidazole (500 mg twice daily) to complete a total treatment course of 10 to 14 days.¹²

Sepsis Syndrome (Septic Shock)

EPIDEMIOLOGY AND PATHOGENESIS

The term "severe sepsis" refers to infection-induced organ dysfunction or hypoperfusion abnormalities. *Septic shock* implies hypotension that is not reversed with fluid resuscitation and which is associated with multiorgan dysfunction.²⁰⁸ In obstetric patients, the most common predisposing conditions for septic shock are septic abortion, acute pyelonephritis, chorioamnionitis, and puerperal endometritis. Fewer than 2% of patients with any of these conditions develop septic shock. The most common pathogenic organisms are *E. coli*, *K. pneumoniae*, and *Proteus* species. Highly virulent, drug-resistant organisms such as *Pseudomonas*, *Enterobacter*, and *Serratia* species are uncommon except in immunosuppressed patients.²⁰⁹

Aerobic gram-negative bacilli such as *E. coli* have a complex lipopolysaccharide in their cell wall, termed *endotoxin*. When

released into the systemic circulation, endotoxin causes a variety of immunologic, hematologic, neurohormonal, and hemodynamic derangements that ultimately result in multiple-organ dysfunction.^{211,213}

In the early stages of septic shock, patients usually are restless, disoriented, tachycardic, and hypotensive. Although hypothermia may be present initially, most patients subsequently have a high fever. The skin may be warm and flushed owing to a preliminary phase of vasodilation. Later, extensive vasoconstriction occurs, and the skin becomes cool and clammy. Cardiac arrhythmias may develop, and signs of myocardial ischemia may occur. Jaundice, typically due to hemolysis, may be evident. Urinary output decreases, and spontaneous bleeding from the genitourinary tract or venipuncture sites may occur as a result of a coagulopathy. ARDS is a common complication of sepsis and is usually manifested by dyspnea, stridor, cough, tachypnea, bilateral rales, and wheezing. In addition to these systemic signs and symptoms, affected patients also may have specific findings related to their primary site of infection, such as uterine tenderness in women with endometritis or chorioamnionitis or flank tenderness in patients with pyelonephritis.^{212,213}

DIAGNOSIS

The differential diagnosis of septic shock in obstetric patients includes hypovolemic and cardiogenic shock, diabetic ketoacidosis, anaphylactic reaction, anesthetic reaction, pulmonary embolism, or amniotic fluid embolism. Distinction among these disorders usually can be made on the basis of a detailed history and physical examination and selected laboratory studies. The white blood cell count initially may be decreased in septic shock but subsequently becomes elevated. The hematocrit may be decreased if blood loss has occurred. The platelet count and serum fibrinogen concentration are typically decreased. The serum concentration of fibrin degradation products, such as the D-dimer, is usually elevated. The prothrombin time and activated partial thromboplastin time (aPTT) are frequently prolonged. Serum concentrations of transaminase enzymes and bilirubin often are increased. The blood urea nitrogen and serum creatinine concentrations are also increased.

Septic patients should have a chest radiograph to determine whether pneumonia or ARDS is present. In addition, a CT scan, MRI, or ultrasound study may be of value in localizing an abscess. Patients also require continuous electrocardiographic monitoring to detect arrhythmias or signs of myocardial ischemia. Blood samples for culture should be obtained, one drawn percutaneously and one drawn through each vascular device that has been in place longer than 48 hours.²¹¹

TREATMENT

The first priority in treatment is fluid resuscitation with isotonic crystalloids such as lactated Ringer solution or normal saline or colloids. There is no firm evidence that one type of solution is better than another, although crystalloids are used more commonly. Intravenous fluid administration should be titrated in accordance with the patient's pulse, blood pressure, and urine output. If the initial fluid infusion is not successful in restoring hemodynamic stability, a right-sided heart catheter should be inserted to monitor pulmonary artery wedge pressure. Treatment goals of fluid resuscitation include a central venous pressure of 8 to 12 mm Hg, a mean arterial pressure of

65 mm Hg or higher, urine output of 0.5 mL/kg or greater, and a mixed venous oxygen saturation of 70% or greater.²¹¹

The "7-3 rule" is helpful in guiding fluid resuscitation. Ringer lactate or normal saline should be infused at a rate of 10 mL/min for 15 minutes. If the pulmonary capillary wedge pressure (PCWP) does not increase by more than 3 mm Hg, the bolus should be repeated. If the PCWP increases by 7 mm Hg or more, the fluid bolus should be withheld. The optimal PCWP in septic patients is 12 to 16 mm Hg. Transfusion of red blood cells is indicated to maintain a hemoglobin concentration of 7.0 to 9.0 g/L.²¹¹

If fluid resuscitation alone does not restore adequate tissue perfusion, vasopressors should be administered. Possible choices include norepinephrine (5 to 15 µg/min), dopamine (starting dose, 1 to 3 µg/kg/min), and vasopressin (0.01 to 0.03 U/min). There is no difference in mortality among patients treated with one of these agents versus the others. However, dopamine is associated with more arrhythmic events than norepinephrine and is more likely to require discontinuation because of adverse effects. In patients with persistent low cardiac output and low blood pressure in the face of adequate fluid resuscitation, dobutamine is the preferred vasopressor. In addition, patients should be treated with intravenous corticosteroids (hydrocortisone, 200 to 300 mg/day for 7 days in three or four divided doses or by continuous infusion).^{211,214}

Patients in septic shock also must receive broad-spectrum antibiotics. The triple combination of penicillin or ampicillin, plus clindamycin or metronidazole, plus gentamicin (in the doses specified earlier for treatment of pelvic abscess) is an excellent initial regimen. Alternatively, a broad-spectrum antibiotic such as imipenem-cilastatin (500 mg IV every 6 hours), meropenem (1 g IV every 8 hours), ertapenem (1 g IV every 24 hours), piperacillin-tazobactam (3.375 g IV every 6 hours), ampicillin-sulbactam (3 g IV every 6 hours), or ticarcillin-clavulanic acid (3.1 g IV every 6 hours) can be administered. The duration of antibiotic therapy should be 5 to 10 days, depending on the rapidity of the patient's response.²⁰⁴

Patients also may require surgery to evacuate retained products of conception, to drain a pelvic abscess, or to remove an infected intravascular catheter. Indicated surgery should never be delayed because the patient is unstable, since operative intervention may be precisely the step necessary to reverse septic shock.

The patient's core temperature should be maintained as close to normal as possible by use of antipyretics and a cooling blanket. Coagulation abnormalities should be corrected. Insulin should be administered as needed to maintain euglycemia. Granulocyte colony-stimulating factor (G-CSF) may be indicated for severely neutropenic patients. Patients also should receive prophylaxis for deep venous thrombosis with low-molecular-weight heparin and stress ulcer prophylaxis with histamine₂ (H₂) receptor blockers.^{211,214}

Patients should receive oxygen supplementation and be observed closely for evidence of ARDS, which is one of the major causes of mortality in patients with severe sepsis.²¹⁵ Oxygenation should be monitored by means of a pulse oximeter or radial artery catheter. If evidence of respiratory failure develops, the patient should be intubated promptly and supported with mechanical ventilation and positive end-expiratory pressure.^{211,215}

The prognosis in patients with septic shock clearly depends on the severity of the underlying illness. In otherwise healthy

patients, mortality should not exceed 15%. The prognosis for complete recovery is excellent, provided that the patient receives timely therapy.^{215,216}

Septic Pelvic Vein Thrombophlebitis

EPIDEMIOLOGY AND PATHOGENESIS

Like pelvic abscess, septic pelvic vein thrombophlebitis is extremely rare in modern obstetrics, occurring in approximately 1 of every 2000 pregnancies overall and in fewer than 1% of patients who have puerperal endometritis.²¹⁷ Septic pelvic vein thrombophlebitis occurs in two distinct forms. The most commonly described disorder is acute thrombosis of one (usually the right) or both ovarian veins (ovarian vein syndrome).²¹⁸ Affected patients typically develop a moderate temperature elevation in association with lower abdominal pain during the first 48 to 96 hours after delivery. The pain usually localizes to the side of the affected vein but may radiate into the groin, upper abdomen, or flank. In addition, nausea, vomiting, and abdominal bloating may be present.

On physical examination, the patient is usually tachycardic; tachypnea, dyspnea, and even stridor may be evident if septic pulmonary embolization has occurred. The abdomen is tender, and bowel sounds often are decreased or absent. Most patients have voluntary and involuntary guarding, and 50% to 70% have a tender, rope-like mass that originates near one cornua and extends laterally and cephalad toward the upper abdomen. The principal conditions that should be considered in the differential diagnosis of ovarian vein syndrome are acute pyelonephritis, nephrolithiasis, appendicitis, broad-ligament hematoma, adnexal torsion, and pelvic abscess.

The second presentation of septic pelvic vein thrombophlebitis has been termed "enigmatic fever."²¹⁹ These patients usually have been treated initially for presumed puerperal endometritis. Subsequently, they experience some subjective improvement, with the exception of persistent fever. They do not appear to be seriously ill, and positive findings are limited to persistent fever and tachycardia. Disorders that must be considered in the differential diagnosis of enigmatic fever are drug reaction, viral syndrome, recrudescence of connective tissue disease, and pelvic abscess.

DIAGNOSIS

CT and MRI are the diagnostic tests of greatest value in confirming the diagnosis of pelvic vein thrombophlebitis.²²⁰ These tests are most sensitive in detecting large thrombi in the major pelvic vessels. They are not as useful in identifying thrombi in smaller vessels. In some cases, the diagnosis is one of exclusion and is confirmed by observing the patient's response to an empiric trial of heparin.²¹⁷

TREATMENT

The traditional treatment for presumed septic pelvic vein thrombophlebitis is therapeutic anticoagulation with intravenous heparin. The dose of heparin should be adjusted to maintain the aPTT at approximately 2 times normal. Alternatively, medication may be adjusted to achieve a serum heparin concentration of 0.2 to 0.7 IU/mL. Intravenous heparin should be continued for 7 to 10 days, depending on the response to

treatment. Long-term anticoagulation with oral agents probably is unnecessary unless the patient has massive clotting throughout the pelvic venous plexus or has sustained a pulmonary embolism. Patients should be given broad-spectrum antibiotics, such as those used for treating pelvic abscess, throughout the period of heparin administration.^{217,221}

Once medical therapy has been initiated, there is usually objective evidence of a response within 48 to 72 hours. If no improvement is observed, surgical intervention may be considered. The surgical approach should be tailored to the specific intraoperative findings. In most instances, treatment requires only ligation of the affected vessels. Extension of the thrombosis along the vena cava to the point of origin of the renal veins may require embolectomy. Excision of the infected vessel and removal of the ipsilateral adnexa and uterus are indicated only in the presence of a well-defined abscess. Consultation should be obtained from an experienced vascular surgeon if surgical intervention becomes necessary.²²¹

Mastitis

EPIDEMIOLOGY AND PATHOGENESIS

Mastitis occurs in 5% to 10% of lactating women.²²² The principal causative organisms are *S. aureus* and viridans streptococci. These organisms are part of the mother's skin flora and are introduced into the milk ducts when the infant suckles.^{222,223}

DIAGNOSIS

Affected women initially experience malaise, followed by a relatively high fever (39°C or higher) and chills. Thereafter, an erythematous, tender area appears in the affected breast. In addition, patients also may experience pain and tenderness in the ipsilateral axilla, and the milk from the infected breast may be discolored. In a small percentage of patients, an actual abscess forms within the affected breast.²²³

The diagnosis of mastitis is usually established on the basis of the patient's symptoms and clinical examination findings. Culture of milk from the infected breast is of value in confirming an infection caused by MRSA, particularly when an actual breast abscess is present.

TREATMENT

Mastitis usually can be treated successfully with oral antibiotics that have excellent coverage against staphylococci and streptococci. Initially, sodium dicloxacillin, 500 mg orally four times daily, is preferable. In a woman with a history of a mild allergic reaction to penicillin, cephalexin (500 mg orally four times daily) may be substituted for sodium dicloxacillin. With a history of a serious immediate hypersensitivity reaction to penicillin, clindamycin (300 mg orally every 8 hours) or TMP-SMX DS twice daily, is an appropriate alternative. Both drugs are highly active against MRSA; the latter is less expensive and less likely to cause diarrhea. The duration of antibiotic therapy depends on the patient's response to treatment but usually should extend for 7 to 10 days.²⁰⁴

There are no reports to suggest that nursing from the infected breast is contraindicated. Therefore, the patient should be encouraged to continue nursing once the tenderness in the affected breast has decreased.

Hospitalization and treatment with intravenous antibiotics should be considered for immunosuppressed patients and for those who are at particular risk for complications should staphylococcal bacteremia develop (e.g., patients with prosthetic heart valves). In addition, women with a breast abscess should be hospitalized for intravenous antibiotic therapy and surgical drainage. The most appropriate intravenous drug is vancomycin (1 g every 12 hours). Other agents with excellent antistaphylococcal coverage include linezolid (600 mg every 12 hours) and quinupristin/dalfopristin (7.5 mg/kg every 8 hours). These latter two drugs are extremely expensive and should not routinely be used as first-line agents.²⁰⁴

PREVENTION

In an effort to prevent mastitis, lactating women should be advised to take measures to prevent drying and cracking of the nipples. Specifically, they should avoid the use of alcohol-based products for cleaning the nipples and should apply a moisturizing agent such as lanolin to the nipple and areola after nursing.

Cytomegalovirus Infection

EPIDEMIOLOGY AND PATHOGENESIS OF MATERNAL AND FETAL INFECTION

CMV is a DNA virus that is a member of the herpesvirus family. Like other members of this family, CMV may remain latent in host cells after the initial infection. Recurrent infection is usually caused by reactivation of an endogenous latent virus rather than reinfection with a new viral strain.^{225,226}

CMV is not highly contagious; close personal contact is required for infection to occur. Horizontal transmission may result from transplantation of an infected organ or transfusion of infected blood, sexual contact, or contact with contaminated saliva or urine. Vertical transmission may occur as a result of transplacental infection, exposure to contaminated genital tract secretions during delivery, or breastfeeding. The incubation period of CMV ranges from 28 to 60 days.²²⁷

Among young children, the most important risk factor for infection is close contact with playmates (e.g., handling toys that are contaminated by infected saliva).^{228,229} Most children who acquire CMV infection are asymptomatic. When clinical manifestations are present, they include malaise, low-grade fever, lymphadenopathy, and hepatosplenomegaly. Most immunocompetent adults with CMV also are asymptomatic or have only mild symptoms suggestive of a flulike illness. However, in an immunosuppressed patient, CMV infection can be quite serious, causing chorioretinitis and severe pneumonia.

The diagnosis of CMV infection is confirmed by viral culture or PCR. The highest concentrations of virus are in plasma, urine, seminal fluid, saliva, and breast milk, with most cultures becoming positive within 72 to 96 hours. PCR methodology permits identification of viral antigen within 24 hours.^{225,227}

Serologic methods also are of value in establishing the diagnosis of CMV infection. Positive IgM titers usually decline rapidly over a period of 30 to 60 days, but they can remain elevated for as long as 12 months. There is no single IgG titer that clearly differentiates acute from recurrent infection. However, a fourfold or greater change in the IgG titer over 2 weeks usually is consistent with recent acute infection. Another useful test for differentiating acute from recurrent infection is

assessment of the avidity of IgG antibody. Low- to moderate-avidity IgG antibody, combined with the presence of IgM antibody, is consistent with acute infection. If high-avidity IgG antibody is present, the patient typically has recurrent infection. The presence of CMV in the serum, detected by PCR, also is most consistent with acute infection, although viremia can occur with recurrent infection.^{230,231}

Approximately 50% to 80% of adult women in the United States have serologic evidence of past CMV infection. However, the presence of antibodies is not perfectly protective against either reinfection or vertical transmission of infection from mother to fetus. Therefore, either recurrent or primary infection in a pregnant woman poses a risk to the fetus.^{229,232}

Antepartum (congenital) infection results from hematogenous dissemination of virus across the placenta and poses the greatest risk to the fetus. Dissemination is much more likely in the presence of a primary maternal infection. Among women who acquire primary CMV infection during pregnancy, approximately half will infect their fetus. The overall risk of congenital infection is greatest when maternal infection occurs during the third trimester, but the probability of severe fetal injury is highest when it occurs in the first trimester.

Approximately 5% to 15% of infants who develop congenital CMV infection as a result of primary maternal infection are symptomatic at birth. The most common clinical manifestations of severe neonatal infection are hepatosplenomegaly, intracranial calcifications, jaundice, growth restriction, microcephaly, chorioretinitis, hearing loss, thrombocytopenia, hyperbilirubinemia, and hepatitis. Approximately 30% of severely infected infants die, and 80% of survivors have major morbidity, despite antiviral therapy. Among the 85% to 90% of infants with congenital CMV infection who are asymptomatic at birth, 10% to 15% subsequently develop hearing loss, chorioretinitis, or dental defects within the first 2 years of life.^{229,232}

Pregnant women who experience recurrent or reactivated CMV infection are much less likely to transmit infection to their fetus. If recurrent infection develops during pregnancy, approximately 5% to 10% of infants become infected; however, none of these neonates will be symptomatic at birth. The most common sequelae are hearing loss, visual deficits, and mild developmental delays.²³²⁻²³⁵

Perinatal infection can occur during delivery as a result of exposure to infected genital tract secretions. Infection also can occur as a result of breastfeeding. However, when the virus is acquired in one of these ways, infants rarely have major abnormalities.

DIAGNOSIS OF CONGENITAL INFECTION

The most sensitive and specific test for diagnosing congenital CMV infection is the identification of CMV in amniotic fluid by either culture or PCR.^{234,235} This test is of greater accuracy than cordocentesis for two major reasons. First, it can be performed at gestational ages when sampling of cord blood is technically not possible (<20 weeks). Second, fetal anti-CMV-specific IgM antibody is usually not apparent until 23 weeks' gestation or later, which may be many weeks after infection has occurred.

Identification of the virus in amniotic fluid by culture or PCR does not necessarily delineate the severity of fetal injury. In this context, ultrasonography is invaluable in providing information about the condition of the fetus. The principal

sonographic findings suggestive of serious fetal injury are placentomegaly, microcephaly, ventriculomegaly, periventricular calcification, fetal hydrops, growth restriction, and oligohydramnios. Less common findings include fetal heart block, echogenic bowel, meconium peritonitis, renal dysplasia, ascites, and pleural effusions.

TREATMENT

Until recently, no consistently effective therapy for congenital CMV infection was available. However, in 2005, Nigro and colleagues²³⁶ published a prospective cohort study from eight medical centers in Italy describing the use of hyperimmune globulin (Cytogam, CSL Behring) as treatment and prophylaxis for congenital CMV infection. Of 157 women with confirmed primary CMV infection, 148 were asymptomatic and were identified by routine serologic screening; 8 women had symptomatic viral infection, and 1 was identified because her fetus had abnormal ultrasound findings. Forty-five women had had a primary infection longer than 6 weeks before enrollment, underwent amniocentesis, and had CMV detected in amniotic fluid by PCR or culture. Thirty-one of these women received intravenous treatment with CMV-specific hyperimmune globulin, 200 units (mg)/kg of maternal body weight. Nine of the 31 received one or two additional infusions into either the amniotic fluid or the umbilical cord because their fetuses had persistent abnormalities on ultrasound. Fourteen women declined treatment; 7 of these women had infants who were acutely symptomatic at the time of delivery. In contrast, only 1 of the 31 treated women had an infant with clinical disease at birth (adjusted OR, 0.02, $P < .001$).

In this same investigation,²³⁶ 84 additional women did not have an amniocentesis because their infection occurred within 6 weeks before enrollment, their gestational age was less than 20 weeks, or they declined amniocentesis. Thirty-seven of these women received hyperimmune globulin, 100 units (mg)/kg every month until delivery, and 47 declined treatment. Six of the treated women delivered infected infants, as did 19 of the untreated women (adjusted OR, 0.32, $P < .04$). No adverse effects of hyperimmune globulin were observed in either group receiving immunotherapy.

This report by Nigro and colleagues had several shortcomings.²³⁷ The design of the study was neither randomized nor controlled. There are at least some biologic reasons to question whether the remarkable success reported by the authors will be maintained in larger, randomized studies. The authors also did not address the financial and logistic issues associated with screening large obstetric populations for CMV infection, triaging the inevitable patients with false-positive results, offering amniocentesis and targeted sonography to women who seroconvert, and then treating at-risk patients with hyperimmune globulin. Nevertheless, the authors' observations are extremely interesting and offer the best available therapy for this dangerous perinatal infection.

More recently, Jaquemard and coworkers²³⁷ described the use of high doses of valacyclovir for treatment of congenital CMV infection. They treated 20 women with oral valacyclovir, 2 g four times daily, and noted therapeutic concentrations of the drug in fetal blood and a corresponding decrease in the viral load in fetal serum after treatment.

Figure 51-6 presents a management algorithm for obstetric patients with suspected CMV infection.

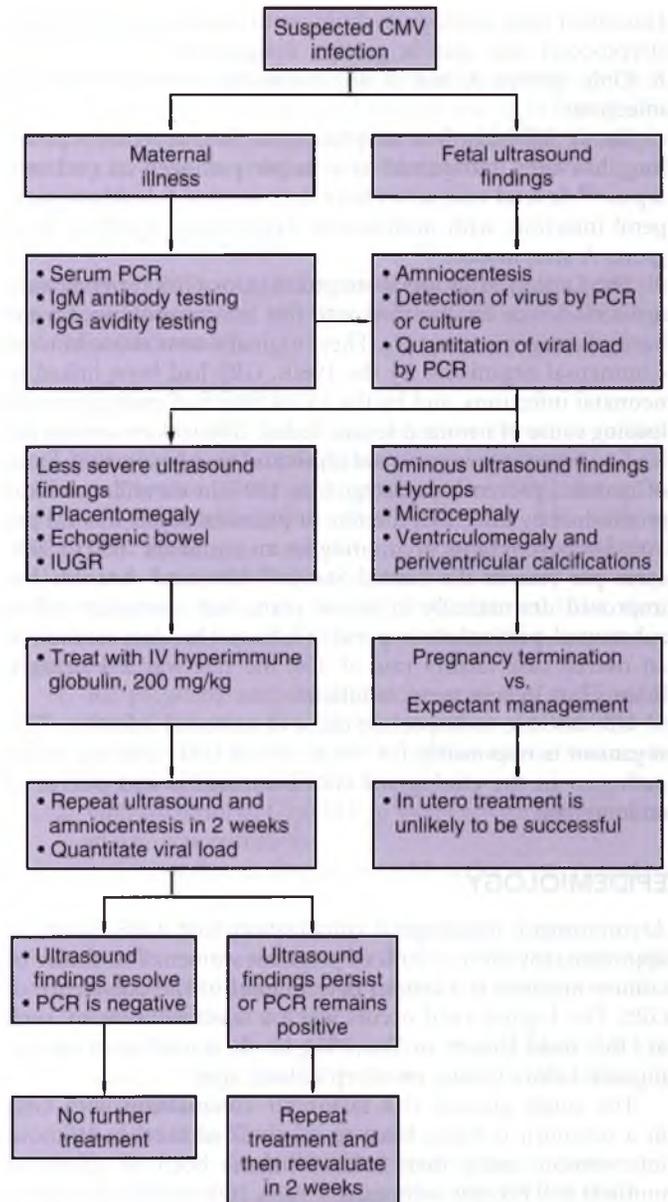

Figure 51-6 Management algorithm for suspected cytomegalovirus infection in pregnancy. CMV, cytomegalovirus; Ig, immunoglobulin; IUGR, intrauterine growth restriction; PCR, polymerase chain reaction.

PREVENTION

Ideally, preventive measures should be employed to ensure that women do not contract CMV infection during pregnancy. One simple measure is using CMV-negative blood products when transfusing pregnant women or fetuses. In addition, women should be encouraged to use careful hand washing techniques after handling infant diapers and children's toys. They also should adopt safe sexual practices if they are not already engaged in a mutually faithful, monogamous sexual relationship.^{225,228}

Group B Streptococcal Infection

The hemolytic streptococci cause a variety of infections and are significant causes of perinatal morbidity and mortality. In 1933,

Lancefield used serologic techniques to subdivide β -hemolytic streptococci into specific groups, designated A, B, C, D, and E. Only groups A and B are commonly involved obstetric infections.

Group A β -hemolytic streptococcus (*Streptococcus pyogenes*) long has been recognized as a major pathogen in perinatal sepsis.²³⁸ Several case series have documented fulminant puerperal infection, with multisystem dysfunction, resulting from group A streptococci.²³⁹

The Lancefield group B streptococci, or GBS (*Streptococcus agalactiae*), can be classified into five major serotypes on the basis of antigenic structure. They originally were thought to be commensal organisms. By the 1960s, GBS had been linked to neonatal infections, and by the 1970s they had emerged as the leading cause of neonatal sepsis. Today, GBS still are among the leading organisms in perinatal sepsis and have become the focus of national prevention strategies. In 1995, in surveillance areas established by the CDC, the rate of perinatal sepsis was 1.3 per 1000 liveborn infants, accounting for an estimated 7000 to 8000 cases per year in the United States.²⁴⁰ Neonatal outcome has improved dramatically in recent years, but morbidity still is substantial, particularly in preterm infants. One data set showed an overall case fatality rate of 4%; the rate was 2% in term infants but 16% in preterm infants.

GBS also are an important cause of maternal infection. This organism is responsible for 1% to 5% of UTIs and is a major pathogen in the etiology of chorioamnionitis and puerperal endometritis.

EPIDEMIOLOGY

Asymptomatic rectovaginal colonization with GBS occurs in approximately 20% to 30% of pregnant women. The choice of culture medium is a crucial determinant of the prevalence of GBS. The highest yield occurs when a selective medium, such as LIM, Todd-Hewitt, or Trans-Vag broth, is used as an enriching step before plating on sheep's blood agar.

The single greatest risk factor for colonization with GBS in a newborn is being born to a colonized mother. Without intervention, more than half of infants born to colonized mothers will become colonized.²⁴¹ Also, 16% to 45% of nursery personnel are carriers of GBS infection, and nosocomial acquisition in newborns is common. Nosocomial transmission is one of the key mechanisms in cases of late-onset GBS infection. There clearly is an association between heavy growth of GBS in the maternal genital tract and the development of GBS sepsis in neonates. However, a surprisingly high percentage of neonates with GBS sepsis (perhaps 25%) are born to women with light colonization. Therefore, focusing solely on heavily colonized women in preventive approaches is inadequate.

The documented colonization rate for GBS has been far higher than the attack rate in terms of neonatal infection. Overall, sepsis develops in only 1% of infants of colonized mothers. The following are well-established risk factors for GBS neonatal sepsis²⁴²:

- Prematurity (or low birth weight as its surrogate)
- Maternal intrapartum fever (presumably as a result of chorioamnionitis)
- Ruptured membranes for longer than 18 hours
- A previous infant infected with GBS disease
- GBS bacteriuria in the present pregnancy

Because of the preponderance of term infants overall, 70% to 80% of cases of neonatal GBS infection in the United States occur in infants born after 36 weeks' gestation.^{243,244} Today, approximately half of cases are early in onset (first week of life). Previously, before implementation of intrapartum antibiotic prophylaxis (IAP), at least three quarters of cases were of the early-onset variety.²⁴² The most common diagnosis with early-onset disease is bacteremia (89%); meningitis but not bacteremia is diagnosed in 10%, and both bacteremia and meningitis in 1%. Pneumonia often is present in association with bacteremia.²⁴²

CLINICAL MANIFESTATIONS IN THE NEONATE

Two clinically distinct neonatal GBS infections have been identified: early- and late-onset disease.²⁴⁵

Early-Onset Infection

Early-onset infection appears within the first week of life, usually within 48 hours. It is characterized by rapid clinical deterioration and a high mortality rate. The association between gestational age and early-onset GBS infection is shown in Table 51-7. In its most fulminant form, early-onset GBS infection manifests as septic shock accompanied by respiratory distress and leads to death within several hours despite appropriate antibiotic therapy. In less severe disease, pneumonia may be the dominant clinical finding. Although pulmonary disease predominates in early-onset disease, meningitis may also be present. The case fatality rate for early-onset disease is now approximately 4.5%.²⁴³ Current nationwide prevention strategies have decreased the number of cases of early-onset GBS sepsis by an estimated 3900 per year and the number of deaths by 200 per year.²⁴²

Late-Onset Infection

Late-onset infection with GBS occurs more insidiously, usually after the first week of life. In most cases, meningitis is the predominant clinical manifestation. Although the mortality rate in late-onset GBS infection is lower (2%) than with early-onset disease, up to 50% of babies with meningitis subsequently develop neurologic sequelae. Late-onset disease may result in localized infections involving the middle ear, sinuses, conjunctiva, breasts, lungs, bones, joints, or skin. Meningitis appears to be related to the serotype of GBS. More than 80% of early-onset GBS infections in which meningitis is present are caused by Lancefield type III organisms; in late-onset disease, 95% of meningitis is attributable to this subtype.

Although early-onset disease is acquired mainly via transmission from the mother's genital tract either before or during

TABLE 51-7 Early-Onset Group B Streptococcal Disease, by Gestational Age, 1993-1998

Gestational Age (wk)	% of Cases	Case Fatality Rate (%)
≤33	9	30

≥37	83	2

Data from Schrag SJ, Zywicki S, Farley MM, et al: Group B streptococcal disease: the era of intrapartum antibiotic prophylaxis, *N Engl J Med* 342:15, 2000.

parturition, such a route is not implicated in late-onset disease. Nosocomial transmission of GBS can occur in the nursery from colonized nursing staff or from other infants. Current prevention strategies have not decreased the number of cases of late-onset GBS disease in newborns.²⁴²

CLINICAL MANIFESTATIONS IN THE MOTHER

GBS is a major cause of puerperal infection. Features of GBS puerperal infection include the development of a high fever within 12 hours after delivery, tachycardia, abdominal distention, and endometritis. Some patients have no localizing signs early in the course of the infection.

DIAGNOSIS

The gold standard for the identification of GBS is culture. According to the CDC guidelines, the culture swab should be placed first in the lower half of the vagina, then along the perineum, and then in the outer portion of the anus. The swab should initially be incubated in a nutrient broth and then subcultured on selective blood agar.²⁴² Failure to use selective media or to obtain a combined vaginal-rectal specimen reduces the yield of positive cultures by approximately 50%.

Nucleic acid amplification tests have been used to detect GBS colonization. The specimen is first incubated in selective broth (enriched sample), and then the nucleic acid amplification test is applied. The sensitivity of the test is excellent, ranging from 93% to 100%, with specificity in the range of 93% to 99%. The enrichment process may require up to 24 hours, negating the time-saving advantage of the rapid test. However, when the nucleic acid amplification test is performed on a nonenriched specimen, the sensitivity drops to 63% to 94% and the specificity to 65% to 97%. Moreover, this testing methodology is somewhat complex and is not yet available in all hospitals 24 hours a day, 7 days a week.²⁴²⁻²⁴⁴

Most colonized neonates are asymptomatic, and the clinical manifestations of neonatal infection are not sufficient for diagnosis in the absence of a positive culture. The diagnosis should be suspected if the clinical manifestations occur in the setting of a risk factor for infection.

TREATMENT

Penicillin G remains the drug of choice for symptomatic GBS infection in both mother and neonate if the infecting organism has been identified. In most instances, however, treatment must be initiated before the availability of culture results. In these cases, a broad-spectrum approach for empirically treating the mother with chorioamnionitis or puerperal sepsis and the neonate with sepsis is required. Ampicillin frequently is used in such situations and provides adequate treatment for GBS infection. Alternative drugs for patients with a contraindication to penicillin are a cephalosporin in those not at risk for immediate penicillin hypersensitivity or vancomycin in patients who are at risk (e.g., those with immediate urticaria or bronchospasm as manifestations of penicillin allergy). Because of rising resistance, clindamycin no longer can be relied upon to treat GBS infection unless susceptibility to this antibiotic has been demonstrated for a given isolate. The frequency of resistance to erythromycin is now so high (25% to 30%) that it should not be used under any circumstances for prophylaxis.²⁴²

PREVENTION

Because of the severity of early-onset GBS neonatal infection, major efforts have been directed toward use of IAP in gravid women whose genital tracts are colonized with GBS. Strategies can be classified as antepartum, intrapartum, neonatal, and immunologic.

Antepartum Strategies

Antepartum strategies to reduce maternal carrier rates generally have been unsuccessful owing to recolonization and therefore are not recommended.

Intrapartum Strategies

Intrapartum strategies have been the most attractive to date from both clinical and cost-effectiveness perspectives.

To standardize a national approach, in 1996, the CDC published recommendations that were also endorsed by the ACOG. These recommendations have been disseminated widely and have resulted in dramatic decreases in early-onset neonatal GBS sepsis. In 2002 and again in 2010, these guidelines were revised.^{242,245} They are summarized here and in Figure 51-7:

1. All pregnant women should be screened at 35 to 37 weeks' gestation for GBS colonization. IAP should be given at the time of labor or rupture of membranes to those identified as GBS carriers.
2. GBS bacteriuria: Give IAP to women with GBS in urine in any concentration.
 - a. Prenatal screening at 35 to 37 weeks is not necessary in these patients.
 - b. Treat bacteriuria by usual standards of care.
3. Women with previous birth of an infant with GBS disease should receive IAP; prenatal screening is not necessary for these women.
4. If the result of the GBS culture is not known at the time of labor, give IAP under any of the following circumstances:
 - a. Less than 37 weeks' gestation
 - b. Rupture of membranes at least 18 hours earlier
 - c. Temperature at or greater than 100.4°F (38.0°C)
5. In cases of onset of labor or rupture of membranes earlier than 37 weeks with "significant risk for imminent preterm delivery," treat as follows:
 - a. If the patient had a negative screening culture for GBS within the past 4 weeks, IAP is not indicated.
 - b. If colonization status is unknown at admission, perform screening culture and initiate IAP; if the culture is negative, stop IAP.
6. For cesarean delivery before rupture of membranes and before labor, IAP is not indicated.
7. Penicillin G is the drug of choice.
 - a. The recommended dose for penicillin G is 5 million units initially, then 2.5 to 3.0 million units every 4 hours intravenously until delivery.
 - b. Ampicillin remains an alternative. The dose is 2 g intravenously initially, followed by 1 g every 4 hours until delivery.
8. For patients with penicillin allergy, treat as follows:
 - a. If not at high risk for anaphylaxis: The drug of choice is cefazolin, 2 g intravenously, then 1 g every 8 hours until delivery.

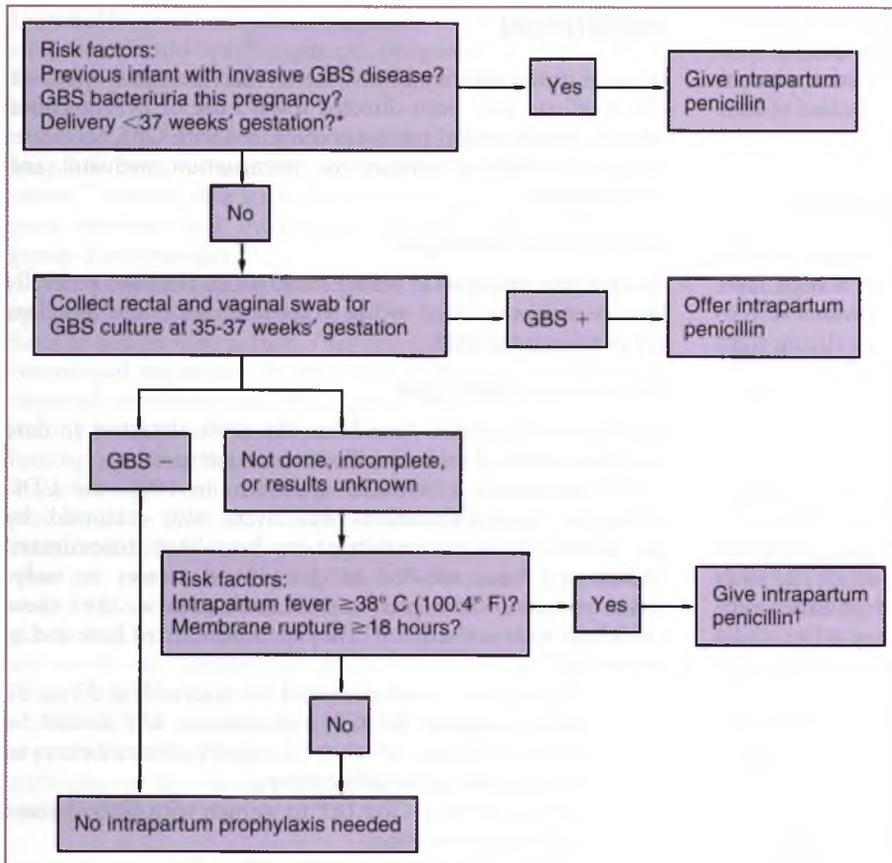

Figure 51-7 Algorithm for prevention of early-onset group B streptococcal (GBS) disease in neonates with prenatal screening at 35 to 37 weeks.

*If membranes rupture before 37 weeks' gestation and the mother has not begun labor, collect GBS culture and administer antibiotics until cultures are completed and the results are negative.

†Broader-spectrum antibiotics may be considered at the physician's discretion, based on clinical indications (e.g., ampicillin plus gentamicin to treat clinical chorioamnionitis).

(Adapted from Centers for Disease Control and Prevention: Prevention of perinatal group B streptococcal disease: a public health perspective, *MMWR Morb Mortal Wkly Rep* 45[RR-7]:1, 1996.)

- b. If at high risk for anaphylaxis and GBS is susceptible: The drug of choice is clindamycin, 900 mg intravenously every 8 hours.
 - c. If at high risk for anaphylaxis and GBS is resistant to clindamycin or of unknown susceptibility: The drug of choice is vancomycin, 1 g every 12 hours.
9. From a clinical perspective, IAP has its greatest protective effect when it is administered at least 4 hours before delivery. De Cueto and coworkers showed that the rate of neonatal GBS transmission was 56% when antibiotics were administered less than 1 hour before delivery, 29% when antibiotics were administered 2 to 4 hours before delivery, and 1% to 2% when antibiotics were administered more than 4 hours before delivery.²⁴⁶

This observation is not surprising given the findings reported by McNanley and associates, who conducted a prospective cohort study in which penicillin was used for prophylaxis.²⁴⁷ Mean colony counts of GBS in vaginal cultures decreased 5-fold within 2 hours after antibiotic administration, 50-fold within 4 hours, and almost 1000-fold within 6 hours. However, even administration less than 4 hours before delivery may still achieve therapeutic concentrations of antibiotics in fetal serum. Notably, Barber and coworkers²⁴⁸ treated 98 colonized women with penicillin, 5 million units IV initially, followed by 2.5 million units every 4 hours. Fetuses exposed to antibiotics for less than 4 hours actually had higher serum concentrations than those exposed for longer than 4 hours.

10. Routine use of prophylaxis for newborns whose mothers received IAP is not recommended. Antibiotics should be given to infants only if sepsis is suspected clinically.

The guidelines suggest penicillin G as the drug of choice for IAP and list ampicillin as an "acceptable alternative." Concern about ampicillin's broader spectrum of activity is the reason for this recommendation. However, when evaluated in a randomized clinical trial, IAP with either ampicillin or penicillin significantly increased the likelihood of recovery of ampicillin-resistant gram-negative organisms from the lower genital tract, and there was no difference between the two drugs for this effect.²⁴⁹ In light of these reassuring data, the choice of whether to use penicillin or ampicillin for IAP should be based on cost and availability.

Another caveat involves the technique used for collection of the screening culture. The guidelines call for sampling the vagina and rectum. However, two thirds of women report at least mild pain associated with collection of the rectal sample.²⁵⁰ Furthermore, Jamie and colleagues²⁵¹ evaluated whether there was any advantage to sampling the vagina and rectum, compared with sampling the vagina and perianal skin. They found no difference in culture positivity in a cohort of 200 women. Therefore, it seems reasonable to obtain samples for screening cultures for GBS colonization from the distal vagina and perianal skin.

Neonatal Strategies

Measures to prevent GBS infection in the newborn have focused on reports of decreases in neonatal early-onset disease when

penicillin was given at birth. Although initial reports were encouraging, most trials in low-birth-weight infants have not found this approach to be effective. These results are not surprising in view of Boyer and Gotoff's observation²⁵² that up to 40% of neonates in whom GBS sepsis develops are already bacteremic at birth, suggesting that a single dose of penicillin after delivery may be "too little and too late."

Immunologic Strategies

The immunologic approach is appealing, but a vaccine has not yet been developed. Such a vaccine would need to be polyvalent to cover all serotypes involved in early-onset sepsis. One limitation of this approach is that it would not be optimally protective for infants born before 32 weeks' gestation because of modest placental transfer of maternal antibody before that time. Thus, the most vulnerable infants would be left with minimal protection. Nevertheless, it is estimated that a vaccine approach would prevent up to 90% of cases of neonatal GBS infection.²⁵³

Summary

No current approach is foolproof. However, the application of IAP has resulted in a significant reduction in the rate of early-onset neonatal GBS infection. In 2004, the rate was 0.34 per 1000 live births, less than one third of the rate only 10 years before. In addition, IAP also reduces the risk of maternal infection, both chorioamnionitis and endometritis.

Herpes Simplex Infection

HSV may infect the mother, the newborn, or, on rare occasions, the fetus. In the adult, typical lesions are vesicular or ulcerative, involving only the skin and mucous membranes. More widespread infection involving the CNS is an extremely unusual complication in adults and most often develops in people with underlying debilitating disease. On the other hand, because of an incompletely developed immune system, the newborn is subject to systemic, and frequently lethal, disease.

EPIDEMIOLOGY

In adults, the virus commonly causes infection of the oral cavity, skin, and lower genital tract. In the past, HSV type 1 (HSV-1) was thought to be responsible for infection of the mouth and of the skin above the waist, whereas HSV-2 was implicated in infection of the genitalia and of the skin below the waist. However, both viruses can cause either genital or oropharyngeal lesions, which are indistinguishable clinically. Furthermore, in some populations, HSV-1 has been reported to account for 30% to 40% of new cases of genital herpes,²⁵⁴ but genital HSV-1 recurs much less commonly than genital HSV-2.^{254,255}

Genital herpes is spread by sexual contact. The prevalence of serum antibodies to HSV-2 is increasing in the United States. In the years 1988-1994, 21.9% of the population age 12 years or older was found to be seropositive, representing a 30% increase since the period 1976-1980 and corresponding to 45 million cases of infection.²⁵⁶ The disease is not more severe or more protracted in pregnancy.

Clinically, there are three syndromes of genital herpes:

1. *First-episode primary genital herpes* is the clinical presentation in a patient without antibodies to either HSV-1 or HSV-2. Its clinical manifestations include severe local symptoms, with lesions lasting 3 to 6 weeks, regional

adenopathy, constitutional symptoms, and, in a small percentage of cases, viral meningitis. However, as many as two thirds of women with HSV-2 antibodies have acquired the infection asymptotically.²⁵⁷ This observation represents a major change from previous concepts.

2. *First-episode nonprimary genital herpes* is the initial clinical episode with either HSV-1 or HSV-2 in a patient who has antibodies to the other viral serotype. Because the antibody response is directed against epitopes within areas of homology in the glycoprotein G expressed by each viral type, there is some cross-reactivity. Therefore, the presentation is more similar to recurrent episodes than to first-episode primary genital herpes.
3. *Recurrent genital herpes infections* are much milder and shorter, with lesions lasting 3 to 10 days. The shortened course of infection reflects the preexisting presence of antibody to the viral serotype causing the recurrent infection.

Transplacental infection of the fetus resulting in congenital infection is a rare complication of maternal infection. Only a few such documented cases have been reported.²⁵⁸⁻²⁶⁰ Brown and coworkers showed that, overall, maternal seroconversion to HSV-2 during pregnancy does not result in greater risks of low birth weight, preterm delivery, fetal growth restriction, stillbirth, or neonatal death.²⁵⁹ When recurrent episodes occur during pregnancy, there appears to be no increase in the incidence of abortion or low-birth-weight infants.

A major perinatal problem is neonatal herpes infection. Exact estimates of its frequency are subject to error, because up to 50% of infants with culture-proven fatal disease do not show typical lesions on the skin or mucous membranes. In addition, application of treatment recommendations probably has decreased the incidence of neonatal disease. The disease manifests at the end of the first week of life. The presentation may include skin lesions, cough, cyanosis, tachypnea, dyspnea, jaundice, seizures, and DIC.

Neonatal herpes is acquired perinatally from an infected lower maternal genital tract, most commonly during a vaginal delivery. In a study by Brown and colleagues,²⁵⁹ only those women with very recent infection (i.e., presence of virus in the genital tract but without development of type-specific antibody) had infected infants. In that situation, the risk was high (four of nine cases). The risk is considerably lower (1% to 2%) among women with recurrent, clinically evident infection. In one study, the incidence of infection in infants born vaginally to women with asymptomatic recurrent infection was 0 in 34 cases.²⁶¹ However, asymptotically colonized patients can give birth to seriously infected neonates. In a referral nursery, 70% of mothers of infected infants had asymptomatic infections. Among infants with disseminated herpes, the risk of death or serious sequelae exceeds 40%, even with antiviral therapy.²⁶²

DIAGNOSIS

The clinical diagnosis of genital herpes is based on the typical painful crops of vesicles and ulcers in various stages of progression. With primary infection, tender inguinal adenopathy, fever, and other constitutional symptoms may occur. Primary genital herpes lesions resolve without scarring after 3 to 6 weeks. The frequency of clinically detectable recurrences varies widely among individuals, but about 50% of patients have recurrent disease within 6 months. Recurrences are milder, with fewer lesions, fewer constitutional symptoms, and a shorter course (usually 3 to 10 days).

Because many patients present with genital herpes infection after the vesicles have evolved into ulcers, clinical diagnosis based on the classic presentation of grouped, painful vesicles has a low sensitivity and specificity. Furthermore, making the diagnosis of genital herpes has social and future implications. Therefore, first-episode infections should be confirmed by laboratory tests.

The “gold standard” diagnostic test to detect the presence of herpesvirus infection has been the viral culture. The virus grows rapidly, and most positive cultures are identifiable at 48 to 72 hours. Culture of vesicular fluid has the highest yield, and the sensitivity of culture decreases with increasing duration of active lesions. The diagnosis of herpes infection can be made using the Tzanck smear or the Pap smear. However, neither of these tests can differentiate among HSV-1, HSV-2, and varicella-zoster virus infection, and neither of them has a high sensitivity or specificity.

PCR to detect HSV DNA probably is the most useful diagnostic test. Results are available in a matter of hours, and PCR exceeds culture in identifying positive cases. With the use of PCR, the frequency of asymptomatic viral shedding of HSV particles has been shown to be eight times higher than previously reported based on culture.²⁶³⁻²⁶⁵

Previously, HSV antibody tests could not discriminate infection with HSV-1 from that with HSV-2. Newer IgG assays that are specific to the respective glycoprotein G of each type now allow clinicians to distinguish between these infections.²⁶⁶ However, the role of serologic testing in making the diagnosis of genital herpes is controversial. Furthermore, cost-effectiveness analyses regarding whether pregnant women should be screened for serologic evidence of prior HSV-2 infection have had mixed results.^{267,268}

TREATMENT

During clinically evident episodes, treatment consists of supportive measures such as oral analgesics, strict attention to hygiene, and topical anesthetics. Secondary infections such as candidiasis also should be treated. Many women find that frequent bathing, followed by thorough drying of the affected area with a hair dryer, provides temporary relief.

Acyclovir, 400 mg orally three times daily, is highly effective for treatment of primary or recurrent infection. The usual course of treatment is 5 to 10 days. When used twice daily, acyclovir also is highly effective in reducing the frequency of recurrent infection. Suppressing therapy with acyclovir has been demonstrated to be safe and effective for 6 years or longer.²⁶⁹ Valacyclovir is better absorbed and has a longer half-life than acyclovir; however, it is significantly more expensive. The appropriate dose of valacyclovir for treatment of infection is 1000 mg twice daily. For suppression of recurrence, the dose is 1000 mg daily.

MANAGEMENT OF HERPES INFECTION IN PREGNANCY

Because of the severity of neonatal herpes infection and the lack of satisfactory therapy, the only way of preventing neonatal infection is to avoid contact between the fetus and the infected maternal lower genital tract by means of cesarean delivery. Accordingly, cesarean delivery is recommended when typical herpes lesions are present at labor, regardless of the time since membrane rupture.^{12,270,271}

In 1986, Arvin and colleagues²⁷² reported the findings of HSV cultures in a series of 515 pregnant women with recurrent herpes infection. Seventeen women had positive antepartum cultures, but none was positive at delivery. Of 354 asymptomatic mothers, 5 (1.4%) had positive results at delivery, but none had positive antepartum cultures. The likelihood of asymptomatic shedding at delivery was 1.3%. Brown and colleagues²⁵⁹ published a cohort study that included more than 40,000 women. Testing for HSV included both culture and PCR. Among the 202 women from whom HSV was isolated at the time of labor, 10 infants developed HSV infection. Those born by cesarean delivery were less likely to develop HSV infection than those born vaginally (1.2% versus 7.7%; $P < .047$).

For gravidas with recurrent genital herpes, treatment with acyclovir (400 mg three times daily) starting at 36 weeks' gestation decreases the proportion of patients with clinical lesions at the time of labor and lessens the need for cesarean delivery.²⁷³ Such an approach has been shown to be cost-effective.²⁷⁴

There are no data supporting a risk to the fetus from maternal administration of acyclovir or valacyclovir. However, we believe that acyclovir should be the drug of choice for suppression of recurrent genital herpes during the third trimester, because this drug has been the most extensively studied.

Current recommendations for prenatal and intrapartum care include the following:

1. Obstetricians should ask all pregnant women about a history of genital herpes.
2. If the diagnosis of genital herpes has not been previously confirmed by culture or PCR, specimens should be obtained during an active episode of apparent HSV infection.
3. Serial cultures beginning at 34 to 36 weeks are *not* recommended for *asymptomatic* women with a history of herpes infection.
4. The patient with a history of genital herpes should be instructed to come to the hospital early in labor or immediately if PROM has occurred. The patient also should be informed of the low risk of asymptomatic infection at delivery (1%) and the low risk of neonatal infection after delivery through an asymptotically infected genital tract.
5. When the patient arrives in labor or with membrane rupture, a careful pelvic examination should be performed. If no lesions are present, vaginal delivery is acceptable. If lesions are observed, cesarean should be performed.

Women with nongenital herpes do not require any special precautions during labor and delivery, apart from barrier isolation of the infected skin, gown and glove precautions, and proper disposal of linen and dressings. Precautions should be taken to avoid contact of the newborn with the infected maternal skin. After the lesions have become encrusted, the mother may handle and feed her infant.

Human Immunodeficiency Virus Infection

EPIDEMIOLOGY

HIV infection is caused by a single-stranded, enveloped RNA retrovirus. Two major strains of the virus have been identified, HIV-1 and HIV-2, each with several substrains. HIV-1 infection is more widely prevalent throughout the world. HIV-2 infection

is uncommon in the United States except among patients who have traveled to areas of the world where this infection is endemic (e.g., sub-Saharan Africa) or who have shared needles with, or had sex with, someone from that area of the world.²⁷⁵

In the United States, HIV infection is more common in African-American and Hispanic women than in Caucasian women. The most common mechanism of transmission of infection is heterosexual contact. Intravenous drug use also is an extremely important mechanism of transmission. Transmission through organ donation, artificial insemination, or blood transfusion is exceedingly rare. Important risk factors for sexual transmission of HIV infection include multiple sex partners; receptive anal intercourse; unprotected intercourse; concurrent STDs, especially those that cause genital ulcers; sexual contact with an uncircumcised male; severe illness in the infected partner; sex during menstruation; and bleeding during intercourse (e.g., from sexual assault).²⁷⁶

PATHOGENESIS

HIV infection evolves through four major stages. The first stage of infection is the *acute retroviral illness*.²⁷⁷ Within several weeks after exposure, the patient typically develops a severe flulike illness characterized by malaise, poor appetite, weight loss, low-grade fever, and generalized lymphadenopathy. Over a period of several weeks, this phase of the illness gradually resolves, and the patient enters the *latent phase of infection*. In this phase, the viral load in the plasma tends to be relatively low, and the virus is primarily concentrated in lymphatic tissue, where it replicates at a slow rate despite antiretroviral therapy. With appropriate antiretroviral therapy and supportive care, the latent phase of illness may extend beyond 10 years in many patients. Over time, however, the viral load progressively increases, and patients enter a *symptomatic phase* of the infection. Eventually, all infected patients develop *acquired immunodeficiency syndrome (AIDS)*, albeit at a much slower rate than in the early years of the HIV epidemic.

DIAGNOSIS

Opportunistic diseases are the hallmark of HIV infection. The most common serious opportunistic disease in women is *Pneumocystis jiroveci* pneumonia; second most common is *Mycobacterium avium-intracellulare* infection. Other important opportunistic diseases include tuberculosis, toxoplasmosis, CMV infection, candidiasis, and non-Hodgkin lymphoma.²⁷⁸

The initial screening test for HIV infection should be the enzyme immunoassay (EIA) for HIV-1 and HIV-2. If this test is positive, a confirmatory test such as the Western blot or immunofluorescent assay (IFA) should be performed. If both tests are positive, the probability of a false-positive sequence is extremely low. A new test that detects antibody to the virus and identifies the p-24 antigen has been introduced and may detect patients earlier in the course of their disease when they are antigenemic but have not yet developed antibody to the virus.²⁷⁷ PCR methodology, which usually is used to quantitate the viral load, can also be used to confirm infection in patients who have problematic antibody screens.²⁷⁷

The CDC now recommends universal screening for HIV infection in pregnant women. The "opt out" strategy is the one most likely to ensure compliance with screening. With this strategy, HIV testing is considered part of the routine prenatal

laboratory panel. Patients must specifically decline the screening test; otherwise, it is routinely performed.

TREATMENT

In the absence of any intervention, the risk of perinatal transmission of HIV infection is approximately 25%.²⁷⁹ With the interventions outlined in this section, perinatal transmission should be reduced to less than 2%.²⁸⁰ Most cases of transmission occur at the time of delivery. Antenatal transmission is possible, typically as a result of invasive antepartum procedures such as amniocentesis or chorionic villus sampling. Postnatal transmission also can occur from breastfeeding. The principal risk factors for perinatal transmission of HIV infection are as follows:

- History of a previous affected infant
- Severe maternal disease
- Preterm delivery
- Intrapartum blood exposure as a result of events such as vaginal lacerations, episiotomy, or instrumental delivery
- Time since rupture of membranes greater than 4 hours
- Invasive antepartum procedures
- Chorioamnionitis
- Concurrent STDs
- Vaginal delivery in the presence of an elevated viral load

At the time of her first prenatal appointment, the HIV-infected patient should have a CD4⁺ T-cell count and viral load measurement to assess her degree of immunosuppression. She should be screened for all other STDs, such as gonorrhea, chlamydia, syphilis, hepatitis B, and hepatitis C. She also should be tested for tuberculosis. If her CD4⁺ count is greater than 200 cells/mm³, the purified protein derivative (PPD) should be a reliable screening test for tuberculosis. If the CD4⁺ count is less than 200/mm³, a negative test may be the result of anergy, and such patients should have a chest radiograph to exclude tuberculosis. Patients should be tested for toxoplasmosis and CMV infection as well, because both may cause serious perinatal infection, which can be successfully treated with either antibiotics or immunotherapy.

In an effort to prevent opportunistic infections, the HIV-positive pregnant woman should be vaccinated for pneumococcal infection, influenza, hepatitis A and B, meningococcal infection, tetanus, diphtheria, and pertussis. She also should receive prophylactic antibiotics to protect against other pathogens.²⁷⁸ If her CD4⁺ count is less than 200/mm³ and she previously has had an infection with *P. jiroveci*, she should receive TMP-SMX DS, 1 tablet daily. This medication also provides protection against toxoplasmosis infection. If her tuberculin skin test is positive and her chest radiograph shows no evidence of active disease, she should receive prophylaxis with isoniazid (INH), 300 mg orally each day, plus pyridoxine, 50 mg daily. The latter drug is administered to prevent peripheral neurotoxicity from isoniazid. If the patient's CD4⁺ count falls to a range of 50 to 75 cells/mm³, she should receive prophylaxis against *M. avium-intracellulare* with azithromycin, 1200 mg orally each week. If a patient has recurrent candidiasis, she can be treated with fluconazole, 150 mg orally, each day. If her CD4⁺ count falls to less than 50/mm³, she also should receive prophylaxis with fluconazole to prevent cryptococcal infection. A patient with recurrent herpes simplex infection should receive prophylaxis with acyclovir, 400 mg PO twice daily.

The single most important intervention is treatment with highly active antiretroviral therapy (HAART).^{281,282} The ACTG-076 trial²⁷⁹ was the first to demonstrate that treatment of pregnant women with prophylactic zidovudine is highly effective in reducing the rate of perinatal transmission of HIV infection. In that trial, the observed frequency of transmission was reduced from 26% in the placebo group to 8% in those patients who received zidovudine. Subsequent uncontrolled studies showed that treatment of the mother with combination chemotherapy reduces the rate of perinatal transmission to less than 2%.²⁸⁰

The antiretroviral agents currently available are summarized in Table 51-8. The combination of zidovudine (300 mg) and lamivudine (150 mg) (Combivir, twice daily) plus ritonavir (400 mg) and lopinavir (100 mg) (Kaletra, twice daily) is a regimen that is safe in pregnancy, well tolerated, and highly effective. The patient's response to treatment should be evaluated by obtaining serial measurements of viral load. If a clear response to treatment has not occurred within 12 to 16 weeks, the patient should have viral genotyping to determine whether she has a resistant organism. If resistance is identified, the entire

TABLE 51-8 Drugs for Treatment of Human Immunodeficiency Virus Infection

Agent	Usual Adult Dose	Major Adverse Effects
NUCLEOTIDE ANALOGUE		
Tenofovir (Viread)	300 mg daily	GI irritation, elevation in transaminase concentrations, decrease in serum carnitine, nephrotoxicity
NUCLEOSIDE ANALOGUES		
Abacavir (Ziagen)	300 mg bid	Hypersensitivity reaction
Didanosine (DDI, Videx) or Videx EC	200 mg bid 400 mg daily	Pancreatitis, peripheral neuropathy, increased risk of MI
Emtricitabine (Emtriva)	200 mg daily	Headache, diarrhea, nausea, rash, hyperpigmentation, hepatitis
Lamivudine (3TC, Epivir)	150 mg bid or 300 mg daily	Marrow suppression
Stavudine (d4T, Zerit)	40 mg bid	Peripheral sensory neuropathy
Zalcitabine (ddC, Hivid)	0.75 mg q8h	Peripheral neuropathy, pancreatitis
Zidovudine (AZT, Retrovir)	300 mg bid	Marrow suppression
COMBINATION NUCLEOSIDE ANALOGUES		
Combivir (zidovudine + lamivudine)	1 tablet bid	Marrow suppression
Trizivir (zidovudine + lamivudine + abacavir)	1 tablet bid	Marrow suppression
NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS		
Delavirdine (Rescriptor)	400 mg tid	Rash, hepatitis
Efavirenz (Sustiva)	600 mg daily	Rash, CNS changes. Drug is teratogenic and should not be used in pregnancy.
Etravirine (Intelence)	200 mg bid	Rash, nausea, peripheral neuropathy, hepatitis
Nevirapine (Viramune)	200 mg bid	Rash, hepatitis
UNIQUE TRIPLE COMBINATION		
Atripla (efavirenz + emtricitabine + tenofovir)	Single daily dose: 600/200/300 mg	Lactic acidosis, severe hepatomegaly, steatosis
PROTEASE INHIBITORS		
Amprenavir (Agenerase)	1200 mg bid	Rash and GI irritation
Atazanavir (Reyataz)	400 mg daily	Hyperbilirubinemia, prolonged Q-T interval, hyperlipidemia
Darunavir (Prezista)—must be given with ritonavir	600/100 mg bid	Diarrhea, nausea, headache, increased transaminase activity, increased serum lipids
Indinavir (Crixivan)	800 mg tid	Nephrolithiasis, GI upset
Lopinavir/ritonavir (Kaletra)	2 gelatin capsules (200/50 mg) bid	Diarrhea, nausea, fatigue, headache, asthenia
Nelfinavir (Viracept)	1250 mg bid	Diarrhea, fatigue, poor concentration
Ritonavir (Norvir)	100-400 mg bid	GI irritation, seizures, hepatitis, diabetes, marrow suppression
Tipranavir (Aptivus)—must be given with ritonavir	500/200 mg bid	Hepatitis, diarrhea, nausea, vomiting, abdominal pain
Saquinavir:		GI irritation, peripheral neuropathy, headache, rash
Hard gel cap (Invirase)	400 or 1000 mg bid	
Soft gel cap (Fortovase)	1200 mg tid	
FUSION INHIBITOR		
Enfuvirtide (Fuzeon)	90 mg bid	GI irritation, rash, hypotension, injection site reaction
INTEGRASE INHIBITOR		
Raltegravir (Isentress)	400 mg bid	Diarrhea, nausea, headache
VIRAL ENTRY INHIBITOR		
Maraviroc (Selzentry)	150-600 mg bid	Cough, fever, rash, abdominal pain, postural hypotension, MI, hepatotoxicity

CNS, central nervous system; GI, gastrointestinal tract; MI, myocardial infarction.

antiviral regimen should be changed in accordance with the susceptibility pattern identified. Although all of these agents have potentially serious side effects in the mother, only efavirenz is clearly teratogenic in the fetus.

If the therapy reduces the patient's viral load to less than 1000 copies/mL, vaginal delivery is acceptable, provided that there are no other indications for cesarean delivery. During labor, every precaution should be taken to minimize contact of the infant's skin and mucous membranes with contaminated maternal blood and genital tract secretions. Specifically, amniotomy, scalp monitoring, scalp pH assessment, episiotomy, and instrumental delivery should be avoided if at all possible.

If the patient does not have an optimal response to therapy and her viral load remains greater than 1000 copies/mL, she should be delivered by cesarean at approximately 38 weeks' gestation, before the onset of labor and rupture of membranes. Amniocentesis should not be routinely performed before this procedure, because it poses a small risk of transmitting HIV infection to the infant.

Regardless of the method of delivery, the patient should receive intravenous zidovudine during delivery (2 mg/kg for 1 hour, then 1 mg/kg/hr until delivery). For those patients scheduled for cesarean delivery, the infusion should begin approximately 3 hours before surgery. Infants delivered to infected mothers typically are treated with antiretroviral agents for at least 6 weeks after delivery.²⁸³⁻²⁸⁷ The mother should be counseled to avoid breastfeeding.

If the HIV status of the patient is unknown and she is admitted in labor, a rapid serologic screening test should be performed. Current assays should yield reliable results within 1 hour. Management of seropositive patients and their infants should proceed as outlined earlier until definitive testing is completed.^{288,289}

Listeriosis

EPIDEMIOLOGY AND PATHOGENESIS

Listeriosis is an infection caused by *L. monocytogenes*, a motile, non-spore-forming, gram-positive bacillus. Although seven species of *Listeria* are recognized, *L. monocytogenes* is the principal human pathogen. Patients who are immunocompromised and pregnant women and their newborns are particularly susceptible to infection with *L. monocytogenes*. Of concern to the obstetrician is the association between maternal listerial infection and stillbirth, preterm labor, and fetal infection. High perinatal morbidity and mortality rates have been reported for listerial infection in pregnancy.²⁹⁰⁻²⁹⁴

As with GBS infection, neonatal listeriosis has been divided into two serologically and clinically distinct types. *Early-onset* disease, associated with serotypes Ia and IVb, takes the form of a diffuse sepsis with involvement of multiple organs, including the lungs, liver, and CNS. Early-onset listeriosis is associated with a high rate of stillbirth and a high neonatal mortality rate. It appears to occur more frequently in low-birth-weight infants. *Late-onset* listeriosis manifests as meningitis, usually in term infants born to mothers with uneventful perinatal courses. Neurologic sequelae, such as hydrocephalus and mental retardation, are common with late-onset disease. In addition, a mortality rate approaching 40% has been reported.²⁹⁰⁻²⁹⁴

It is possible that an ascending route of infection from cervical colonization with *L. monocytogenes* plays a role in the pathogenesis of neonatal infection. However, the more

important and more common route of infection is hematogenous dissemination of the organism through the placenta, which leads to placental abscesses and ultimately to fetal septicemia.

Human listeriosis manifests in both epidemic and sporadic forms. The *epidemic* form is associated with contamination of food and food products. Foods that particularly pose a risk include fresh, unpasteurized cheeses (e.g., Mexican "queso fresco") and processed meats such as hot dogs.²⁹⁵ Cherubin and colleagues²⁹³ reviewed more than 120 cases of listeriosis. They identified pregnancy and neonatal status as two of the major risk factors for this disease. Indeed, the deaths associated with listeriosis occurred predominantly among premature and still-born infants delivered to infected pregnant women. Moreover, the earlier the stage of gestation when infection manifested, the higher the risk of fetal death.

The *sporadic* form of listeriosis occurs more commonly than the epidemic form. The incidence of listeriosis appears to be decreasing. The crude incidence in 2003 was 3.1 cases per 1 million population. The decrease in the last decade is thought to be the result of a lower prevalence of *L. monocytogenes* contamination of ready-to-eat foods.²⁹⁶

DIAGNOSIS

Approximately one third of pregnant women with listeriosis are asymptomatic. When symptomatic, affected patients present with a flulike syndrome characterized by fever, chills, malaise, myalgias, back pain, and upper respiratory symptoms.²⁹⁷ The viral-like prodrome characterizes the bacteremic stage of listeriosis. Gellin and Broome²⁹¹ suggested that this is probably the time when the placenta and fetus are seeded with *L. monocytogenes*. Maternal infection tends to be mild and is not associated with significant morbidity. However, diffuse sepsis may occur on occasion, particularly in an immunosuppressed patient. No specific clinical manifestations help to distinguish listeriosis from other infections that may occur during pregnancy. Therefore, pregnant women presenting with these symptoms in the late second or early third trimester should be evaluated for possible listeriosis.

Early-onset neonatal listeriosis occurs in infants who are infected in utero, often before the start of labor, and manifests during the first few hours to days of life. Late-onset neonatal listeriosis occurs in term infants who appear healthy at birth and manifest infection several days to weeks after delivery.²⁹¹ Meningitis is more common than sepsis with late-onset disease. Either intrapartum transmission or nosocomial transmission after delivery can result in late-onset infection.²⁹¹

Because of the high mortality rate associated with both early- and late-onset neonatal listerial infection, it is crucial that the obstetrician maintain a high index of suspicion that any febrile illness in pregnancy may be due to *L. monocytogenes*. In patients with these symptoms, blood cultures should be obtained for *L. monocytogenes* as soon as possible. Because colonies of *L. monocytogenes* may be mistaken on Gram staining for diphtheroids and therefore ignored, it is important to inform the microbiologist that listeria infection is a concern. In febrile pregnant women, a Gram stain revealing gram-positive pleomorphic rods with rounded ends is highly suggestive of *L. monocytogenes*.

TREATMENT

Penicillin G and ampicillin are effective in vivo against *L. monocytogenes*. Optimal therapy includes a combination of

ampicillin (1 to 2 g intravenously every 4 to 6 hours) plus gentamicin (1.5 mg intravenously every 8 hours or 7 mg/kg ideal body weight every 24 hours intravenously). For the newborn, the ampicillin dosage is 200 mg/kg/day in four to six divided doses. The duration of treatment is usually 1 week. A single case report has suggested that, after documentation by amniocentesis of intrauterine listerial infection, antibiotic treatment without immediate delivery may be successful and may result in a normal healthy fetus.^{298,299} An earlier study³⁰⁰ also suggested that rapid diagnosis and aggressive antibiotic management in the antenatal patient with listeriosis may reduce the complications of this illness. The same authors reviewed reported cases of listerial septicemia and antepartum antibiotic use and noted that there was one maternal death and that 16 of 20 infants survived. These data compared favorably to the perinatal mortality rate of 33% to 73% observed in cases of untreated maternal disease.

Mumps

EPIDEMIOLOGY AND PATHOGENESIS

Mumps is an acute, generalized nonexanthematous infection with a predilection for the parotid and salivary glands. The infection also can affect the brain, pancreas, and gonads. Mumps is caused by an RNA virus that is a member of the paramyxovirus family. It is transmitted by saliva and respiratory droplet contamination and has been recovered from salivary and respiratory secretions from 7 days before the onset of parotitis until 9 days afterward. The usual incubation period is 14 to 18 days.

DIAGNOSIS

The prodrome of mumps consists of fever, malaise, myalgias, and anorexia. Parotitis follows within 24 hours and is characterized by swollen and tender parotid glands. In most cases, parotitis is bilateral. The submaxillary glands are involved less often and almost never without parotid gland involvement. The sublingual glands rarely are affected. Although mumps usually is a self-limited disease, it can cause aseptic meningitis, pancreatitis, mastitis, thyroiditis, myocarditis, nephritis, and arthritis.

ADVERSE EFFECTS IN PREGNANCY

Mumps in pregnant women is generally benign and no more severe than in nonpregnant patients. Aseptic meningitis in pregnant patients is neither more common nor more severe. Mortality in association with mumps is extremely rare in both pregnant and nonpregnant patients.

Mumps during the first trimester is associated with a twofold increase in the incidence of spontaneous abortion. There is no association between maternal mumps infection and preterm delivery, fetal growth restriction, or perinatal mortality.³⁰¹

Whether mumps infection may result in congenital disease remains controversial.³⁰² Despite animal studies in which mumps virus induced congenital malformations, definitive evidence of a teratogenic potential for mumps virus in humans has not been reported. Siegal³⁰³ observed that the rate of congenital malformations in infants born to women who had mumps during pregnancy (2 of 117) was no different than the rate in infants born to uninfected mothers (2 of 123). The predominant concern has been the postulated association between

maternal mumps infection and the development of congenital cardiac abnormalities, specifically endocardial fibroelastosis, in the infant.³⁰⁴ The issue remains unresolved.

TREATMENT

The treatment of mumps, in both pregnant and nonpregnant patients, is supportive therapy. Analgesics, bed rest, and application of cold or heat to the parotid glands are useful. Maternal mumps is not an indication for termination of pregnancy. The live-attenuated mumps vaccine is effective in preventing primary mumps. Ninety-five percent of vaccinated susceptible subjects develop antibodies without clinically adverse reactions. The duration of protection afforded by immunization is usually lifelong.

Although mumps vaccine virus has been recovered from fetal and placental tissue when vaccination occurred during pregnancy, there is no evidence that the vaccine virus is teratogenic in humans. Nevertheless, given the innocuous nature of mumps in pregnancy, immunization with the mumps live-virus vaccine in pregnancy is contraindicated on the theoretical grounds that the developing fetus might be harmed. Women vaccinated with mumps vaccine should not become pregnant for at least 1 month.

Parvovirus Infection

EPIDEMIOLOGY AND PATHOGENESIS

Parvovirus infection is a rare, but potentially extremely serious, perinatal complication. The infection is caused by a DNA organism, the B19 parvovirus. The virus is transmitted primarily by respiratory droplets and infected blood products. Immunity to parvovirus increases progressively throughout childhood and young adult life. Approximately 50% to 60% of women of reproductive age have evidence of prior infection, and immunity is long-lasting.^{305,306}

The incubation period for parvovirus is 10 to 20 days. The most common clinical manifestation of infection is erythema infectiosum (fifth disease), which usually includes a low-grade fever, malaise, myalgias, arthralgias, and a "slapped cheek" facial rash. An erythematous, lace-like rash also may extend onto the torso and upper extremities. In children, parvovirus infection also can cause transient aplastic crisis. This same disorder may occur in adults who have an underlying hemoglobinopathy.³⁰⁶

When maternal parvovirus infection occurs during pregnancy, the virus can cross the placenta and infect red cell progenitors in the fetal bone marrow. The virus attaches to the i antigen on red cell stem cells and suppresses erythropoiesis, thereby resulting in severe anemia and high-output congestive heart failure. This same antigen also is present on fetal myocardial cells, and in some fetuses, the viral infection causes a cardiomyopathy that further contributes to heart failure.³⁰⁶

The most obvious manifestation of congenital infection is hydrops fetalis. The risk of hydrops is directly related to the gestational age at which maternal infection occurs. If infection develops during the first 12 weeks of gestation, the risk of hydrops varies from less than 5% to approximately 10%. If infection occurs during weeks 13 through 20, the risk of infection decreases to 5% or less. If infection occurs beyond the 20th week of gestation, the risk of fetal hydrops is 1% or less.³⁰⁷⁻³⁰⁹

TABLE 51-9 Possible Results of Serologic Tests for Parvovirus after Documented Exposure

IgM	IgG	Interpretation
Negative	Negative	Susceptible
Negative	Positive	Prior immunity—protected against second infections
Positive	Negative	Acute infection—within previous 7 days
Positive	Positive	Subacute infection >7 days and <120 days

DIAGNOSIS

The best way to confirm the diagnosis of maternal parvovirus infection is through serologic testing. Table 51-9 illustrates the possible combinations of serologic test results that may occur in women who are being evaluated for parvovirus infection. In addition, the detection of parvovirus in maternal serum by PCR is also convincing evidence of primary infection.

Once maternal infection is confirmed, the fetus should be evaluated for evidence of anemia. The best test for this is ultrasound assessment of the middle cerebral artery (MCA) via Doppler velocimetry. Serial examinations should be performed for at least 8 weeks after documentation of maternal seroconversion, because the incubation period for fetal infection may be longer than that observed in children and adults.

The most obvious ultrasound manifestation of fetal anemia is hydrops. However, by the time sonographic evidence of hydrops is present, the fetal hematocrit is likely to be less than 20%. Therefore, a more precise way to detect evolving fetal anemia is to measure peak systolic blood flow (cm/sec) in the fetal MCA.³¹⁰ Increases in peak systolic velocity in this vessel correlate well with fetal hematocrit. If velocimetry indicates fetal anemia, a cordocentesis should be performed to determine the fetal hematocrit. If anemia is confirmed, an intrauterine blood transfusion should be performed.

TREATMENT

Two retrospective studies have demonstrated that intrauterine transfusion is lifesaving in the setting of congenital parvovirus infection. The first investigation was published by Fairley and colleagues.³¹¹ They reviewed 66 cases of fetal hydrops caused by parvovirus infection. Twenty-six fetuses were dead at the time of diagnosis, and two were electively aborted. Twelve of the 38 live fetuses had an intrauterine transfusion, three of whom died. Among the 26 fetuses who did not receive an intrauterine transfusion, 13 died. The OR for fetal death in infants who received a transfusion was 0.14 (CI, 0.02 to 0.96). A second important study was published by Rodis and associates.³¹² They surveyed specialists in maternal-fetal medicine and reported the outcomes of 460 cases of parvovirus infection. Twenty-seven of 164 fetuses who received an intrauterine transfusion died. Of the 296 fetuses who did not receive an intrauterine transfusion, 138 died. The observed difference in outcome was highly significant ($P < .001$). Although cases of spontaneous resolution of fetal hydrops have been reported, the studies presented here clearly support a firm recommendation for intrauterine transfusion (Level II evidence, level “A” recommendation).

Infants who survive intrauterine infection with parvovirus usually have an excellent long-term prognosis.³¹³ However, isolated case reports have been published documenting neurologic morbidity and prolonged, transfusion-dependent anemia.^{314,315} More recently, Nagel and colleagues³¹⁶ reported an 8-year follow-up of 16 hydropic fetuses who received intrauterine transfusions for congenital parvovirus infection and survived. Eleven (68%) of the children were normal, and 5 (32%) had delayed psychomotor development. In light of these reports, a third-trimester ultrasound study to reassess fetal growth and evaluate the anatomy of the CNS, together with long-term surveillance for neurologic problems after the infant's birth, seems to be a prudent course of management.

Rubella

EPIDEMIOLOGY

Rubella (also called “German measles” or “3-day measles”) is caused by an RNA virus. Rubella infection develops primarily in young children and adolescents and is most common in the springtime. Major epidemics of rubella occurred in the United States in 1935 and 1964; minor sporadic epidemics occurred approximately every 7 years until the late 1960s. With licensure of an effective vaccine in 1969, the frequency of rubella declined markedly. In 1999, the incidence of rubella was 0.1 per 100,000.³¹⁷ Persistence of this infection appears to be caused by failure to vaccinate susceptible individuals rather than by a lack of immunogenicity of the vaccine.³¹⁸

The rubella virus is spread by respiratory droplets. From the upper respiratory tract, the virus travels quickly to the cervical lymph nodes and then is disseminated hematogenously throughout the body. The incubation period is approximately 2 to 3 weeks. The virus is present in blood and nasopharyngeal secretions for several days before appearance of the characteristic rash and continues to be shed from the nasopharynx for several days after appearance of the rash. Therefore, the patient may be contagious for a period of 7 to 10 days.³¹⁸

Antibody against rubella does not normally appear in the serum until after the rash has developed. Acquired immunity to rubella usually lasts for life. Second infections have occurred after both natural infections and vaccination, but recurrent infections usually are not associated with serious illness, viremia, or congenital infection.

CLINICAL PRESENTATION

Most infections with rubella in both children and adults are subclinical. Of those individuals who do show symptoms, most have mild constitutional symptoms such as malaise, headache, myalgias, and arthralgias. The principal clinical manifestation of rubella is a widely disseminated, nonpruritic, erythematous, maculopapular rash. Postauricular adenopathy and mild conjunctivitis also are common. These clinical manifestations usually are short-lived and typically resolve within 3 to 5 days.

DIAGNOSIS

The differential diagnosis of rubella includes rubeola, roseola, other viral exanthems, and drug reaction. Rubella usually can be distinguished from these other conditions on the basis of the characteristic rash and serologic testing. Serum IgM antibody

concentration reaches a peak 7 to 10 days after the onset of illness and then declines over a period of 4 weeks. The serum concentration of IgG rises more slowly, but antibody levels persist throughout the lifetime of the individual.³¹⁸

CONGENITAL RUBELLA INFECTION

Because of the success of rubella vaccination campaigns, the incidence of congenital rubella syndrome (CRS) in the United States has declined dramatically. Fewer than 50 cases of congenital rubella occur each year. However, approximately 10% to 20% of women in the United States remain susceptible to rubella, and their fetuses are at risk for serious injury should infection occur during pregnancy.³¹⁹

Rubella virus crosses the placenta by hematogenous dissemination, and the frequency of congenital infection is critically dependent on the time of exposure to the virus. The fetus is not at risk from infection acquired before the time of conception. However, at least 50% of infants exposed to the virus within 12 weeks after conception will manifest signs of congenital infection. The rate of congenital infection declines sharply with advancing gestational age, so that very few fetuses are affected if infection occurs beyond 18 weeks' gestation.^{320,321}

The four most common anomalies associated with CRS are deafness (affecting 60% to 75% of fetuses), eye defects such as cataracts or retinopathy (10% to 30%), CNS defects (10% to 25%), and cardiac malformations (10% to 20%). The most common cardiac abnormality is patent ductus arteriosus, although supravulvar pulmonary stenosis is perhaps the most pathognomonic. Other possible abnormalities include microcephaly, mental retardation, pneumonia, fetal growth restriction, hepatosplenomegaly, hemolytic anemia, and thrombocytopenia.³²⁰⁻³²³

A variety of tests have been proposed for the diagnosis of CRS. Fetal blood, obtained by cordocentesis, can be used to determine the total and viral-specific IgM concentrations. However, cordocentesis technically is difficult before 20 weeks' gestation, and fetal immunoglobulins usually cannot be detected before 22 to 24 weeks. Chorionic villi, fetal blood, and amniotic fluid samples all can be tested via PCR for rubella antigen. Because of its lower complication rate, amniocentesis is the procedure of choice. Although these tests can demonstrate that rubella virus is present in the fetal compartment, they do not indicate the degree of fetal injury. Furthermore, the possibility of false-positive test results cannot be excluded. Accordingly, detailed ultrasound examination is the best test to determine whether serious fetal injury has occurred as a result of maternal rubella infection. Possible anomalies detected by ultrasound include growth restriction, microcephaly, CNS abnormalities, and cardiac malformations.

The prognosis for infants with CRS is guarded. Approximately 50% of affected individuals have to attend schools for the hearing impaired. An additional 25% require at least some special schooling because of hearing impairment, and only 25% are able to attend mainstream schools.³²²

PREVENTION OF RUBELLA INFECTION

Ideally, women of reproductive age should have a preconception appointment when they are contemplating pregnancy. At that time, they should be evaluated for immunity to rubella. If serologic testing demonstrates that they are susceptible, they

should be vaccinated with rubella vaccine before conception occurs. If preconception counseling is not possible, patients should have a test for rubella at the time of their first prenatal appointment. Women who are susceptible to rubella should be counseled to avoid exposure to other individuals who may have viral exanthems.

If a susceptible woman subsequently is exposed to rubella, serologic tests should be obtained to determine whether acute infection has occurred. If acute infection is documented by identification of IgM antibody, the patient should be counseled about the risk of CRS. The diagnostic tests for detection of congenital infection should be reviewed, and the patient should be offered the option of pregnancy termination, depending on the assessed risk of serious fetal injury.

Pregnant women who are susceptible to rubella should be vaccinated immediately after delivery. The rubella vaccine is available in monovalent, bivalent (measles-rubella), and trivalent (measles-mumps-rubella) forms. Approximately 95% of patients who receive rubella vaccine seroconvert, and antibody levels persist for at least 18 years in more than 90% of vaccinees.

Adverse effects of vaccination are minimal, even in adults. Fewer than 25% of patients experience mild constitutional symptoms such as low-grade fever and malaise. Fewer than 10% of vaccinees have arthralgias, and fewer than 1% develop frank arthritis. Other complaints, such as pain and paresthesias, have been rare. Women who have received the vaccine cannot transmit infection to susceptible contacts, such as young children in the home, and vaccinated women may breastfeed their infants. In addition, the vaccine can be administered in conjunction with immunoglobulin preparations such as Rh immune globulin.^{319,323} Women who receive rubella vaccine should practice secure contraception for at least 1 month after vaccination.³²⁴
