CREASY & RESNIK'S MATERNAL-FETAL MEDICINE

Principles and Practice

7th
EDITION

Robert K. Creasy
Robert Resnik
Jay D. Iams
Charles J. Lockwood
Thomas R. Moore
Michael F. Greene

Creasy and Resnik's Maternal-Fetal Medicine

PRINCIPLES AND PRACTICE

Seventh Edition

EDITORS

Robert K. Creasy, MD

Professor Emeritus

Department of Obstetrics, Gynecology, and
Reproductive Sciences
University of Texas Medical School at Houston
Houston, Texas
Corte Madera, California

Robert Resnik, MD

Professor and Chair Emeritus

Department of Reproductive Medicine
University of California, San Diego, School of
Medicine
La Jolla, California

Jay D. Iams, MD

**Frederick P. Zuspan Professor and
Endowed Chair**

Division of Maternal-Fetal Medicine
Vice Chair, Department of Obstetrics
and Gynecology
The Ohio State University College of Medicine
Columbus, Ohio

Charles J. Lockwood, MD, MHCM

Dean, College of Medicine

Professor of Obstetrics and Gynecology
Leslie H. and Abigail S. Wexner Dean's Chair in
Medicine
Vice President for Health Science
The Ohio State University
Columbus, Ohio

Thomas R. Moore, MD

Professor and Chairman

Department of Reproductive Medicine
University of California, San Diego, School of
Medicine
La Jolla, California

Michael F. Greene, MD

Director of Obstetrics

Vincent Department of Obstetrics and Gynecology
Massachusetts General Hospital;
Professor of Obstetrics, Gynecology, and
Reproductive Biology
Harvard Medical School
Boston, Massachusetts

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Judy, Lauren, Pat, Nancy, Peggy, and Laurie
With love and gratitude—for everything*

Sonya S. Abdel-Razeq, MD

Assistant Professor
 Division of Maternal-Fetal Medicine
 Department of Obstetrics, Gynecology, and Reproductive
 Sciences
 Yale University School of Medicine
 New Haven, Connecticut
Imaging of the Face and Neck: Micrognathia; Abnormal Orbits

Vikki M. Abrahams, PhD

Associate Professor
 Research Staff, Reproductive Immunology Unit
 Department of Obstetrics, Gynecology, and Reproductive
 Sciences
 Yale University School of Medicine
 New Haven, Connecticut
Immunology of Pregnancy

Barbara Abrams, DrPH, RD

Professor of Epidemiology, Maternal and Child Health, and
 Public Health Nutrition
 University of California, Berkeley, School of Public Health
 Berkeley, California
Maternal Nutrition

Michael J. Aminoff, MD, DSc

Professor
 Department of Neurology
 University of California, San Francisco, School of Medicine
 San Francisco, California
Neurologic Disorders

Tracy L. Anton, RDMS

Department of Reproductive Medicine
 University of California, San Diego, School of Medicine
 La Jolla, California
*Clinical Applications of Three-Dimensional Sonography in
 Obstetrics*

Seerat Aziz, MD

Assistant Clinical Professor of Radiology
 Department of Radiology and Biomedical Imaging
 University of California, San Francisco, School of Medicine
 San Francisco, California
*Clinical Applications of Three-Dimensional Sonography in
 Obstetrics*

Mert Ozan Bahtiyar, MD

Associate Professor of Obstetrics, Gynecology, and
 Reproductive Sciences
 Director, Fetal Therapy Program
 Fetal Cardiovascular Center
 Fetal Therapy Center
 Yale University School of Medicine
 New Haven, Connecticut
Doppler Ultrasound: Select Fetal and Maternal Applications

Marie H. Beall, MD

Clinical Professor of Obstetrics and Gynecology
 David Geffen School of Medicine at UCLA
 Los Angeles, California
Amniotic Fluid Dynamics

Kurt Benirschke, MD

Professor Emeritus
 Department of Pathology
 University of California, San Diego, School of Medicine
 La Jolla, California
*Normal Early Development
 Multiple Gestation: The Biology of Twinning*

Vincenzo Berghella, MD

Professor of Obstetrics and Gynecology
 Director, Division of Maternal-Fetal Medicine
 Department of Obstetrics and Gynecology
 Jefferson Medical College of Thomas Jefferson University
 Philadelphia, Pennsylvania
*Preterm Labor and Birth
 Cervical Insufficiency*

Daniel G. Blanchard, MD

Professor of Medicine
 Division of Cardiovascular Medicine
 University of California, San Diego, School of Medicine;
 Director, Cardiology Fellowship Program
 UC San Diego Sulpizio Cardiovascular Center
 La Jolla, California
Cardiac Diseases

Kristie Blum, MD

Associate Professor of Medicine
 Director, Hematology/Oncology Fellowship
 Division of Hematology
 Department of Medicine
 The Ohio State University College of Medicine
 Columbus, Ohio
Malignancy and Pregnancy

Lisa M. Bodnar, PhD, MPH, RD

Associate Professor of Epidemiology, Obstetrics and
 Gynecology, and Psychiatry
 Graduate School of Public Health and School of Medicine
 University of Pittsburgh
 Pittsburgh, Pennsylvania
Maternal Nutrition

Bryann Bromley, MD

Associate Clinical Professor of Obstetrics, Gynecology,
and Reproductive Biology
Harvard Medical School;
Department of Obstetrics and Gynecology
Massachusetts General Hospital;
Departments of Obstetrics and Gynecology and Radiology
Brigham and Women's Hospital
Boston, Massachusetts;
Diagnostic Ultrasound Associates
Brookline, Massachusetts
First-Trimester Imaging

Catalin S. Buhimschi, MD

Professor
Departments of Obstetrics and Gynecology and Pediatrics
Director, Division of Maternal-Fetal Medicine
Vice Chair, Department of Obstetrics and Gynecology
The Ohio State University College of Medicine
Columbus, Ohio
Pathogenesis of Spontaneous Preterm Birth

Patrick Catalano, MD

Professor
Department of Reproductive Biology
Case Western Reserve University School of Medicine;
Emeritus Chair, Department of Obstetrics and Gynecology
MetroHealth Medical Center
Cleveland, Ohio
Diabetes in Pregnancy

Christina Chambers, PhD, MPH

Professor of Pediatrics
University of California, San Diego, School of Medicine
La Jolla, California
Teratogenesis and Environmental Exposure

Ronald Clyman, MD

Professor of Pediatrics
Senior Staff, Cardiovascular Research Institute
University of California, San Francisco, School of Medicine
San Francisco, California
Fetal Cardiovascular Physiology

David Cohn, MD

Professor
Department of Obstetrics and Gynecology
Director, Division of Gynecologic Oncology
The Ohio State University College of Medicine
Columbus, Ohio
Malignancy and Pregnancy

Joshua A. Copel, MD

Professor and Vice Chair, Obstetrics
Department of Obstetrics, Gynecology, and Reproductive
Sciences
Professor of Pediatrics
Yale University School of Medicine
New Haven, Connecticut
*Performing and Documenting the Fetal Anatomy Ultrasound
Examination*
Doppler Ultrasound: Select Fetal and Maternal Applications

Robert K. Creasy, MD

Professor Emeritus
Department of Obstetrics, Gynecology, and Reproductive
Sciences
University of Texas Medical School at Houston
Houston, Texas
Corte Madera, California
Intrauterine Growth Restriction

Carlo M. Croce, MD

Professor and Chair
Department of Molecular Virology, Immunology, and Medical
Genetics
The Ohio State University College of Medicine
Columbus, Ohio
Human Basic Genetics and Patterns of Inheritance

Deborah A. D'Agostini, RDMS

Ultrasound Technician, Department of Radiology
UC San Diego Medical Center
San Diego, California
*Clinical Applications of Three-Dimensional Sonography in
Obstetrics*

Mary E. D'Alton, MB, BCh, BAO

Willard C. Rappleye Professor and Chair
Department of Obstetrics and Gynecology
Columbia University College of Physicians and Surgeons;
Director, Obstetrics and Gynecology Services
Columbia University Medical Center
New York, New York
Multiple Gestation: Clinical Characteristics and Management

Lori B. Daniels, MD, MAS

Associate Professor of Medicine
Division of Cardiovascular Medicine
University of California, San Diego, School of Medicine;
Director, Cardiac Care Unit
UC San Diego Sulpizio Cardiovascular Center
La Jolla, California
Cardiac Diseases

Jan Deprest, MD, PhD

Division of Woman and Child
Department of Obstetrics and Gynaecology
University Hospitals Leuven/Katholieke Universiteit Leuven
Leuven, Belgium
Invasive Fetal Therapy

Mitchell P. Dombrowski, MD

Professor
 Department of Obstetrics and Gynecology
 Wayne State University School of Medicine;
 Chairman
 Department of Obstetrics and Gynecology
 St. John Hospital
 Detroit, Michigan
Respiratory Diseases in Pregnancy

Vanja C. Douglas, MD

Assistant Professor
 Department of Neurology
 University of California, San Francisco, School of Medicine
 San Francisco, California
Neurologic Disorders

Patrick Duff, MD

Professor
 Department of Obstetrics and Gynecology
 Associate Dean for Student Affairs
 University of Florida
 Gainesville, Florida
Maternal and Fetal Infections

Antonette T. Dulay, MD

Assistant Professor
 Division of Maternal-Fetal Medicine
 Department of Obstetrics and Gynecology
 The Ohio State University College of Medicine
 Columbus, Ohio
*Imaging of the Face and Neck: Cleft Lip and Palate
 Thoracic Imaging: Pleural Effusion*

Doruk Erkan, MD

Associate Professor of Medicine
 Weill Medical College of Cornell University;
 Associate Physician-Scientist
 Barbara Volcker Center for Women and Rheumatic Diseases
 Associate Attending Rheumatologist and Clinical Researcher
 Hospital for Special Surgery
 New York, New York
Pregnancy and Rheumatic Diseases

Jeffrey R. Fineman, MD

Professor of Pediatrics
 University of California, San Francisco, School of Medicine
 Investigator, Cardiovascular Research Institute
 UCSF Benioff Children's Hospital
 San Francisco, California
Fetal Cardiovascular Physiology

Edmund F. Funai, MD

Professor and Associate Dean
 Department of Obstetrics and Gynecology
 The Ohio State University College of Medicine;
 Chief Operating Officer
 OSU Health System
 Columbus, Ohio
*Pregnancy-Related Hypertension
 Patient Safety in Obstetrics*

Alessandro Ghidini, MD

Professor
 Department of Obstetrics and Gynecology
 Georgetown University School of Medicine
 Washington, DC;
 Director, Perinatal Diagnostic Center
 Inova Alexandria Hospital
 Alexandria, Virginia
Benign Gynecologic Conditions in Pregnancy

April Sandy Gocha, PhD

Biomedical Sciences Graduate Program
 The Ohio State University College of Medicine
 Columbus, Ohio
Human Basic Genetics and Patterns of Inheritance

Eduardo Gratacos, MD, PhD

Head and Professor of Maternal-Fetal Medicine
 Department of Maternal-Fetal Medicine
 Institut Clinic de Ginecologia, Obstetricia i Neonatologia
 (ICGON)
 Hospital Clinic and Institut d'Investigacions Biomèdiques
 August Pi i Sunyer (IDIBAPS)
 University of Barcelona Faculty of Medicine
 Barcelona, Spain
Invasive Fetal Therapy

James M. Greenberg, MD

Professor of Pediatrics
 Department of Pediatrics
 University of Cincinnati College of Medicine;
 Co-Director, Perinatal Institute
 Director, Division of Neonatology
 Cincinnati Children's Hospital Medical Center
 Cincinnati, Ohio
Neonatal Morbidities of Prenatal and Perinatal Origin

Joanna Groden, PhD

Vice Dean for Research
 Professor and Vice Chair
 Department of Molecular Virology, Immunology, and Medical
 Genetics
 The Ohio State University College of Medicine
 Columbus, Ohio
Human Basic Genetics and Patterns of Inheritance

Beth E. Haberman, MD

Associate Professor of Pediatrics
 Department of Pediatrics
 University of Cincinnati College of Medicine;
 Medical Director, Cincinnati Children's NICU
 Division of Neonatology
 Cincinnati Children's Hospital Medical Center
 Cincinnati, Ohio
Neonatal Morbidities of Prenatal and Perinatal Origin

Christina S. Han, MD

Assistant Professor
 Division of Maternal-Fetal Medicine
 Department of Obstetrics, Gynecology, and Reproductive
 Sciences
 Yale University School of Medicine
 New Haven, Connecticut
Imaging of the Face and Neck: Cystic Hygroma; Goiter

Mark A. Hanson, MA, DPhil

Director, Developmental Origins of Health and Disease
 Research Division
 British Heart Foundation Professor of Cardiovascular Science
 University of Southampton Medical School
 Southampton, United Kingdom
Developmental Origins of Health and Disease

Richard Harding, PhD, DSc

Professor
 Department of Anatomy and Developmental Biology
 Monash University
 Melbourne, Victoria, Australia
*Behavioral States in the Fetus: Relationship to Fetal Health
 and Development*

Sylvie Hauguel-de Mouzon, PhD

Director of Research
 Maternal-Fetal Medicine Fellowship
 Department of Obstetrics and Gynecology
 MetroHealth Medical Center
 Cleveland, Ohio
Diabetes in Pregnancy

Joy L. Hawkins, MD

Professor of Anesthesiology
 University of Colorado School of Medicine;
 Director of Obstetric Anesthesia
 University of Colorado Hospital
 Aurora, Colorado
Anesthesia Considerations for Complicated Pregnancies

Michael A. Heneghan, MD, MMedSc

Institute of Liver Studies
 King's College Hospital
 NHS Foundation Trust
 London, United Kingdom
Diseases of the Liver, Biliary System, and Pancreas

Ryan Hodges, PhD, MBBS(Hons)

Hamilton Fairley NHMRC Fellow
 Division of Woman and Child
 Department of Obstetrics and Gynaecology
 University Hospitals Leuven/Katholieke Universiteit Leuven
 Leuven, Belgium
Invasive Fetal Therapy

Andrew D. Hull, BMedSci, BMBS

Professor of Clinical Reproductive Medicine
 Director, Maternal-Fetal Medicine Fellowship
 Department of Reproductive Medicine
 University of California, San Diego, School of Medicine
 La Jolla, California;
 Director, Fetal Care and Genetics Center
 UC San Diego Medical Center
 San Diego, California
*Placenta Previa, Placenta Accreta, Abruptio Placentae, and
 Vasa Previa*

Jay D. Iams, MD

Frederick P. Zuspan Professor and Endowed Chair
 Division of Maternal-Fetal Medicine
 Vice Chair, Department of Obstetrics and Gynecology
 The Ohio State University College of Medicine
 Columbus, Ohio
*Preterm Labor and Birth
 Cervical Insufficiency*

Alan H. Jobe, MD, PhD

Professor of Pediatrics
 Departments of Pulmonary Biology and Neonatology
 University of Cincinnati College of Medicine;
 Director, Division of Perinatal Biology
 Cincinnati Children's Hospital Medical Center
 Cincinnati, Ohio
Fetal Lung Development and Surfactant

Hendrée E. Jones, PhD

Executive Director, UNC Horizons
 Professor, Department of Obstetrics and Gynecology
 University of North Carolina at Chapel Hill School of
 Medicine
 Chapel Hill, North Carolina;
 Adjunct Professor
 Departments of Psychiatry and Behavioral Sciences and
 Obstetrics and Gynecology
 Johns Hopkins University School of Medicine
 Baltimore, Maryland
Substance Abuse in Pregnancy

Anjali J. Kaimal, MD, MAS

Assistant Professor of Obstetrics, Gynecology, and
 Reproductive Biology
 Harvard Medical School
 Massachusetts General Hospital
 Boston, Massachusetts
Assessment of Fetal Health

Beena D. Kamath-Rayne, MD, MPH

Assistant Professor of Pediatrics
 University of Cincinnati College of Medicine;
 Staff, Perinatal Institute and Division of Neonatology
 Cincinnati Children's Hospital Medical Center
 Cincinnati, Ohio
Fetal Lung Development and Surfactant

Thomas F. Kelly, MD

Clinical Professor and Chief, Division of Perinatal Medicine
 Department of Reproductive Medicine
 University of California, San Diego, School of Medicine
 La Jolla, California
Gastrointestinal Disease in Pregnancy

Sarah J. Kilpatrick, MD, PhD

Professor and The Helping Hand of Los Angeles Endowed
 Chair
 Department of Obstetrics and Gynecology
 Associate Dean for Faculty Development
 Cedars-Sinai Medical Center
 Los Angeles, California
Anemia and Pregnancy

S. Katherine Laughon, MD, MS

Vice Chair, Research
 Division of Epidemiology, Statistics and Prevention Research
 Eunice Kennedy Shriver National Institute of Child Health &
 Human Development
 National Institutes of Health
 Bethesda, Maryland
Clinical Aspects of Normal and Abnormal Labor

Robert M. Lawrence, MD

Clinical Professor
 Department of Pediatrics, Division of Immunology and
 Infectious Diseases
 University of Florida College of Medicine
 Gainesville, Florida
The Breast and the Physiology of Lactation

Ruth A. Lawrence, MD

Professor of Pediatrics, Obstetrics, and Gynecology
 University of Rochester School of Medicine and Dentistry;
 Chief, Normal Newborn Services
 Medical Director, Breastfeeding and Human Lactation Study
 Center
 Golisano Children's Hospital at Strong Memorial Hospital
 Rochester, New York
The Breast and the Physiology of Lactation

Ann N. Leung, MD

Professor
 Department of Radiology
 Stanford University School of Medicine
 Stanford, California
Thromboembolic Disease in Pregnancy

Liesbeth Lewi, MD, PhD

Division of Woman and Child
 Department of Obstetrics and Gynaecology
 University Hospitals Leuven/Katholieke Universiteit Leuven
 Leuven, Belgium
Invasive Fetal Therapy

James H. Liu, MD

Arthur H. Bill Professor of Reproductive Biology and Chair
 Department of Reproductive Biology
 Division of Reproductive Endocrinology and Infertility
 Case Western Reserve University School of Medicine
 Cleveland, Ohio
Endocrinology of Pregnancy

Michael D. Lockshin, MD

Professor of Medicine and Obstetrics and Gynecology
 Weill Medical College of Cornell University;
 Director, Barbara Volcker Center
 Hospital for Special Surgery
 New York, New York
Pregnancy and Rheumatic Diseases

Charles J. Lockwood, MD, MHCM

Dean, College of Medicine
 Professor of Obstetrics and Gynecology
 Leslie H. and Abigail S. Wexner Dean's Chair in Medicine
 Vice President for Health Sciences
 The Ohio State University
 Columbus, Ohio
*Recurrent Pregnancy Loss
 Thromboembolic Disease in Pregnancy*

Stephen J. Lye, PhD

Professor and Vice Chair, Research
 Department of Obstetrics and Gynecology
 University of Toronto Faculty of Medicine
 Toronto, Ontario, Canada
Biology of Parturition

Lucy Mackillop, BM, BCh, MA

Attending, Oxford Radcliffe Hospitals NHS Trust
 Women's Centre
 John Radcliffe Hospital
 Oxford, United Kingdom
Diseases of the Liver, Biliary System, and Pancreas

George A. Macones, MD, MSCE

Professor and Chair
 Department of Obstetrics and Gynecology
 Washington University School of Medicine in St. Louis
 St. Louis, Missouri
Evidence-Based Practice in Perinatal Medicine

Mala Mahendroo, PhD

Associate Professor
 Department of Obstetrics and Gynecology
 University of Texas Southwestern Medical School;
 Researcher, Green Center for Reproductive Biological Sciences
 UT Southwestern Medical Center
 Dallas, Texas
Biology of Parturition

Elliott K. Main, MD

Visiting Professor and Medical Director
California Maternal Quality Collaborative;
Department of Obstetrics and Gynecology
Stanford University School of Medicine
Palo Alto, California;
Chair, Department of Obstetrics and Gynecology
California Pacific Medical Center
San Francisco, California
Maternal Mortality

Reena Malhotra, MD

Sonographer, Department of Radiology
North Shore University Hospital/Long Island Medical Center
Manhasset, New York
*Clinical Applications of Three-Dimensional Sonography in
Obstetrics*

Fergal D. Malone, MD

Professor and Chairman
Department of Obstetrics and Gynaecology
Royal College of Surgeons in Ireland;
Consultant Obstetrician and Subspecialist in Maternal-Fetal
Medicine
Rotunda Hospital
Dublin, Ireland
Multiple Gestation: Clinical Characteristics and Management

Kara Beth Markham, MD

Assistant Professor
Division of Maternal-Fetal Medicine
Department of Obstetrics and Gynecology
The Ohio State University College of Medicine
Columbus, Ohio
Pregnancy-Related Hypertension

Stephanie R. Martin, DO

Director of Maternal-Fetal Medicine Services
Southern Colorado Maternal-Fetal Medicine
St. Francis Medical Center/Centura South State
Colorado Springs, Colorado
Intensive Care Considerations for the Critically Ill Parturient

Manish R. Maski, MD

Clinical Instructor in Medicine
Harvard Medical School;
Staff, Department of Nephrology
Beth Israel Deaconess Medical Center
Boston, Massachusetts
Renal Disorders

Joan M. Mastrobattista, MD

Professor
Department of Obstetrics and Gynecology
Baylor College of Medicine;
Ultrasound Clinic Chief
Texas Children's Hospital Pavilion for Women
Houston, Texas
*Maternal Cardiovascular, Respiratory, and Renal Adaptation
to Pregnancy*

Brian M. Mercer, MD

Professor
Department of Reproductive Biology
Case Western Reserve University School of Medicine;
Chairman
Department of Obstetrics and Gynecology
MetroHealth Medical Center
Cleveland, Ohio
*Assessment and Induction of Fetal Pulmonary Maturity
Premature Rupture of the Membranes*

Giacomo Meschia, MD

Professor Emeritus of Physiology
University of Colorado School of Medicine
Aurora, Colorado
Placental Respiratory Gas Exchange and Fetal Oxygenation

Kenneth J. Moise, Jr., MD

Professor
Department of Obstetrics, Gynecology, and Reproductive
Sciences
Department of Pediatric Surgery
University of Texas Medical School at Houston;
Co-Director, Texas Fetal Center
Children's Memorial Hermann Hospital
Houston, Texas
Hemolytic Disease of the Fetus and Newborn

Manju Monga, MD

Professor and Vice Chair of Clinical Affairs
Department of Obstetrics and Gynecology
Baylor College of Medicine
Houston, Texas
*Maternal Cardiovascular, Respiratory, and Renal Adaptation
to Pregnancy*

Ana Monteagudo, MD

Professor
Department of Obstetrics and Gynecology
New York University School of Medicine;
Division of Maternal-Fetal Medicine
NYU Langone Medical Center
New York, New York
Central Nervous System Imaging

Thomas R. Moore, MD

Professor and Chairman
Department of Reproductive Medicine
University of California, San Diego, School of Medicine
La Jolla, California
*Performing and Documenting the Fetal Anatomy Ultrasound
Examination
Placenta and Umbilical Cord Imaging
Uterus and Adnexae Imaging
Diabetes in Pregnancy*

Gil Mor, MD, PhD

Professor
 Research Staff, Reproductive Immunology Unit
 Department of Obstetrics, Gynecology, and Reproductive
 Sciences
 Yale University School of Medicine
 New Haven, Connecticut
Immunology of Pregnancy

Shahla Nader, MD

Professor
 Department of Obstetrics and Gynecology, Division of
 Reproductive Endocrinology
 Department of Internal Medicine, Division of Endocrinology
 University of Texas Medical School at Houston
 Houston, Texas
Thyroid Disease and Pregnancy
Other Endocrine Disorders of Pregnancy

Michael P. Nageotte, MD

Professor
 Department of Obstetrics and Gynecology
 University of California, Irvine, School of Medicine
 Orange, California;
 Associate Chief Medical Officer
 Miller Children's Hospital
 Long Beach, California
Intrapartum Fetal Surveillance

Vivek Narendran, MD

Professor of Pediatrics
 Department of Pediatrics
 University of Cincinnati College of Medicine;
 Medical Director, University Hospital NICU & Newborn
 Nurseries
 Division of Neonatology
 Cincinnati Children's Hospital Medical Center
 Cincinnati, Ohio
Neonatal Morbidities of Prenatal and Perinatal Origin

Jane E. Norman, MD

Professor of Maternal and Fetal Health
 University of Edinburgh/MRC Centre for Reproductive Health
 University of Edinburgh College of Medicine and Veterinary
 Medicine
 Edinburgh, United Kingdom
Pathogenesis of Spontaneous Preterm Birth

Errol R. Norwitz, MD, PhD

Louis E. Phaneuf Professor of Obstetrics and Gynecology and
 Chairman
 Department of Obstetrics and Gynecology
 Tufts University School of Medicine
 Boston, Massachusetts
Biology of Parturition

Christian M. Pettker, MD

Associate Professor
 Department of Obstetrics, Gynecology, and Reproductive
 Sciences
 Yale University School of Medicine
 New Haven, Connecticut
Patient Safety in Obstetrics

Lucilla Poston, PhD

Tommy's Chair and Professor
 Head, Division of Women's Health
 King's College London School of Medicine
 London, United Kingdom
Developmental Origins of Health and Disease

Mona R. Prasad, DO, MPH

Assistant Professor
 Division of Maternal-Fetal Medicine
 Department of Obstetrics and Gynecology
 The Ohio State University College of Medicine
 Columbus, Ohio
Substance Abuse in Pregnancy

Dolores H. Pretorius, MD

Professor of Radiology
 University of California, San Diego, School of Medicine
 Director of Fetal Imaging
 UCSD Center for Fetal Care and Genetics in La Jolla
 La Jolla, California
*Clinical Applications of Three-Dimensional Sonography in
 Obstetrics*

Bhuvanewari Ramaswamy, MD

Assistant Professor
 Department of Medical Oncology
 The Ohio State University College of Medicine
 Columbus, Ohio
Malignancy and Pregnancy

Ronald P. Rapini, MD

Josey Professor and Chair
 Department of Dermatology
 University of Texas Medical School at Houston and MD
 Anderson Cancer Center
 Houston, Texas
The Skin and Pregnancy

Uma M. Reddy, MD, MPH

Medical Officer
 Pregnancy and Perinatology Branch
 Eunice Kennedy Shriver National Institute of Child Health and
 Human Development
 National Institutes of Health
 Bethesda, Maryland
Stillbirth

Robert Resnik, MD

Professor and Chair Emeritus
 Department of Reproductive Medicine
 University of California, San Diego, School of Medicine
 La Jolla, California
*Placenta Previa, Placenta Accreta, Abruptio Placentae, and
 Vasa Previa*
Intrauterine Growth Restriction

Bryan S. Richardson, MD

Professor
 Departments of Obstetrics and Gynecology, Physiology and
 Pharmacology, and Pediatrics
 University of Western Ontario Schulich School of Medicine
 and Dentistry;
 Consultant/Attending, Department of Obstetrics and
 Gynecology
 London Health Science Centre, Victoria Hospital
 London, Ontario, Canada
*Behavioral States in the Fetus: Relationship to Fetal Health
 and Development*

Britton D. Rink, MD, MS

Assistant Professor
 Director of Genetics, Prenatal Diagnosis, and Ultrasound
 Division of Maternal-Fetal Medicine
 Department of Obstetrics and Gynecology
 The Ohio State University College of Medicine
 Columbus, Ohio
Recurrent Pregnancy Loss

Kimberly S. Robbins, MD

Assistant Clinical Professor
 Department of Anesthesiology and Critical Care
 University of California, San Diego, School of Medicine
 La Jolla, California
Intensive Care Considerations for the Critically Ill Parturient

Marc A. Rodger, MD, MSc

Professor
 Departments of Medicine, Epidemiology and Community
 Medicine, and Obstetrics and Gynecology
 University of Ottawa Faculty of Medicine;
 Chief, Division of Hematology
 Head, Thrombosis Program
 Division of Hematology
 Ottawa Hospital;
 Senior Scientist, Clinical Epidemiology Program
 Ottawa Hospital Research Institute
 Ottawa, Ontario, Canada
Coagulation Disorders in Pregnancy

Lorene E. Romine, MD

Assistant Professor of Radiology
 Department of Radiology
 University of California, San Diego, School of Medicine
 La Jolla, California
*Clinical Applications of Three-Dimensional Sonography in
 Obstetrics*

Michael G. Ross, MD, MPH

Professor of Obstetrics and Gynecology
 David Geffen School of Medicine at UCLA
 Fielding School of Public Health at UCLA
 Los Angeles, California;
 Staff Physician, Department of Obstetrics and Gynecology
 Harbor-UCLA Medical Center
 Torrance, California
Amniotic Fluid Dynamics

Jane E. Salmon, MD

Professor of Medicine and Obstetrics and Gynecology
 Weill Medical College of Cornell University;
 Collette Kean Research Chair and Attending Rheumatologist
 Department of Medicine
 Hospital for Special Surgery
 New York, New York
Pregnancy and Rheumatic Diseases

Thomas J. Savides, MD

Professor of Clinical Medicine
 Division of Gastroenterology
 Department of Medicine
 University of California, San Diego, School of Medicine
 La Jolla, California
Gastrointestinal Disease in Pregnancy

Kurt R. Schibler, MD

Professor of Pediatrics
 Department of Pediatrics
 University of Cincinnati College of Medicine;
 Director, Neonatology Clinical Research Core
 Division of Neonatology
 Cincinnati Children's Hospital Medical Center
 Cincinnati, Ohio
Neonatal Morbidities of Prenatal and Perinatal Origin

Anthony R. Scialli, MD

Director, Reproductive Toxicology Center
 Washington, DC
Teratogenesis and Environmental Exposure

Anna Katerina Sfakianaki, MD, MPH

Associate Professor
 Section of Maternal-Fetal Medicine
 Department of Obstetrics, Gynecology, and Reproductive
 Sciences
 Yale University School of Medicine
 New Haven, Connecticut
*Thoracic Imaging: Congenital Diaphragmatic Hernia;
 Cystic Lung Lesions, CCAM, Sequestration; Congenital High
 Airway Obstruction*

Thomas D. Shipp, MD

Associate Professor of Obstetrics, Gynecology, and
 Reproductive Biology
 Harvard Medical School;
 Attending, Department of Obstetrics and Gynecology
 Brigham & Women's Hospital
 Boston, Massachusetts;
 Diagnostic Ultrasound Associates
 Brookline, Massachusetts
First-Trimester Imaging

Robert M. Silver, MD

Professor
 Department of Obstetrics and Gynecology
 Chief, Division of Maternal-Fetal Medicine
 University of Utah School of Medicine
 Salt Lake City, Utah
Coagulation Disorders in Pregnancy

Hyagriv N. Simhan, MD, MS

Associate Professor and Vice Chair, Obstetrical Services
 Department of Obstetrics, Gynecology, and Reproductive
 Sciences
 University of Pittsburgh School of Medicine;
 Division Chief
 Division of Maternal-Fetal Medicine
 Magee-Women's Hospital of the University of Pittsburgh
 Medical Center
 Pittsburgh, Pennsylvania
Preterm Labor and Birth

Mark Sklansky, MD

Professor and Chief
 Division of Pediatric Cardiology
 Department of Medicine
 David Geffen School of Medicine at UCLA
 Los Angeles, California
*Fetal Cardiac Malformations and Arrhythmias: Detection,
 Diagnosis, Management, and Prognosis*

Catherine Y. Spong, MD

Associate Director for Extramural Research
 Eunice Kennedy Shriver National Institute of Child Health and
 Human Development
 National Institutes of Health
 Bethesda, Maryland
Stillbirth

Naomi E. Stotland, MD

Associate Professor
 Department of Obstetrics, Gynecology, and Reproductive
 Sciences
 University of California, San Francisco, School of Medicine;
 Staff Physician, Obstetrics and Gynecology
 San Francisco General Hospital
 San Francisco, California
Maternal Nutrition

Ravi I. Thadhani, MD, MPH

Professor of Medicine
 Harvard Medical School;
 Chief, Division of Nephrology
 Massachusetts General Hospital
 Boston, Massachusetts
Renal Disorders

John M. Thorp, Jr., MD

Hugh McAllister Distinguished Professor of Obstetrics and
 Gynecology
 Department of Obstetrics and Gynecology
 University of North Carolina School of Medicine;
 Division Chief, Women's Primary Healthcare
 Department of Obstetrics and Gynecology
 UNC Hospital
 Chapel Hill, North Carolina
Clinical Aspects of Normal and Abnormal Labor

Ilan E. Timor-Tritsch, MD

Professor
 Department of Obstetrics and Gynecology
 New York University School of Medicine;
 Division of Maternal-Fetal Medicine
 NYU Langone Medical Center
 New York, New York

Management of Depression and Psychoses in Pregnancy and in the Puerperium

As in each edition of this text, the seventh edition continues to reflect, and bear witness to, the ever-expanding knowledge base of maternal and fetal medicine. The past three to four decades have borne the fruit of basic and clinical research in the specialty, the successful endeavors of many.

To assist with the interpretation, collation, and presentation of this information base we welcome the previously established editorial expertise of Dr. Michael F. Greene.

We continue the tradition, established in the first six editions, of attempting to stress the importance of underlying basic science to the clinical issues and the role of proper evaluation of clinical studies. All the continuing chapters have been updated and revised, some extensively, where appropriate. In response to national lay and medical concern, there are completely new chapters on maternal mortality and patient safety. An entirely new and comprehensive section devoted to all aspects of obstetric imaging has been developed (with much appreciation to Dr. Joshua Copel for his input). In addition, the expanded online version reveals a large library of cine loops to complement the various imaging chapters. An e-book version is now available, and updates will be available through Expert Consult.

We desire to express our appreciation and gratitude to all the contributors to past editions and the current edition, thanking those who are returning as well as new authors. We are indebted to Elsevier, and in particular to Maureen Iannuzzi, our content development manager, for her significant management skills, skills laced with patience and pleasantness, and to Stefanie Jewell-Thomas, our senior content strategist.

Finally, we give very special gratitude to our wives, to whom we dedicate this edition, for their continuing support and patience.

Human Basic Genetics and Patterns of Inheritance

JOANNA GRODEN, PhD | APRIL SANDY GOCHA, PhD | CARLO M. CROCE, MD

Impact of Genetics and the Human Genome Project on Medicine in the 21st Century

For most of the 20th century, geneticists were considered as outsiders to the everyday clinical practice of medicine. The exceptions were those medical geneticists who studied rare chromosomal abnormalities, congenital birth defects, and metabolic disorders. Today, however, genetic influences are widely recognized as contributing factors to most human illnesses.¹ The widespread reporting of genetic discoveries in the lay press and the plethora of genetic information available via the Internet have increased the sophistication of patients and their families as medical consumers informed by genetics and genomics.

The importance of genetics in medical practice has grown as a consequence of the immense progress made in genetics and genomics research during the last 50 years. In the first year of the 20th century, Mendel's laws were rediscovered and applied to how we think about many fields, including mechanisms of human disease. Watson and Crick published the structure of DNA in 1953 and ushered in the age of molecular biology. Almost simultaneously, the era of cytogenetics began with the determination of the correct number ($n = 46$) of human chromosomes. Sanger and Gilbert independently published techniques for determining the sequence of DNA in the 1970s; these findings and the automation of the Sanger method in the 1980s led several prominent scientists to propose and initiate the Human Genome Project. Its goal was to obtain a complete DNA sequence of the human genome. In the first year of the 21st century, a draft of the human genome was published simultaneously by the publicly funded Human Genome Project² and a private company, Celera.³ Since then, additional public consortia and private companies have made systematic efforts to catalog DNA sequence variations that may predict or contribute to human disease. These include single nucleotide polymorphisms,⁴ copy number variations of large blocks of sequences,⁵ inversions, deletions, and rare genomic nuances. Most of these data are available in public databases, engendering disease-related discoveries at a rapid pace. The concepts, tools, and techniques of modern genetics and molecular biology have already had a profound impact on biomedical research and will continue to revolutionize our approach to human disease risk management, diagnosis, and treatment over the next decade and beyond.

Genetics plays an important role in the day-to-day practice of obstetrics and gynecology. In obstetric practice, questions about family history and genetic disease often arise in relation

to pregnancy. Amniocentesis, chorionic villus sampling, or other screening methods may detect potential chromosomal defects in the fetus; fetuses examined during pregnancy by ultrasound may have birth defects; specific prenatal diagnostic tests for genetic diseases may be requested by couples who are from at-risk ethnic groups or have a family history of a particular disorder; infertile couples often require evaluation for genetic causes for infertility. In gynecology, genetics is particularly important in disorders of sexual development and gynecologic malignancies, as well as in understanding the important clinical implications of taking a thorough family history.

What Is a Gene?

Genes are the fundamental units of heredity. Concisely, a gene includes all the structural and regulatory information required to express a heritable quality, usually through production of an encoded protein or a ribonucleic acid (RNA) product. The more familiar genes encode proteins (through messenger or mRNA) or RNAs that function in RNA processing (small nuclear or snRNA), ribosome assembly (small nucleolar or snoRNA), or protein translation (transfer or tRNA and ribosomal or rRNA). In addition, there are more recently appreciated classes of regulatory RNAs that function to control gene expression; these include microRNAs (miRNAs), piwi-interacting RNAs (piRNAs), short interfering RNAs (siRNAs), and other noncoding RNAs (ncRNAs). Structural segments of the genome that do not encode RNA or proteins are also considered part of a gene if their mutation produces observable effects. Humans are now thought to have 20,000 to 25,000 distinct protein-coding genes, although this number fluctuates with improved methods for identifying genes and considerations of how DNA sequence variations can be processed to make multiple RNAs and proteins. We shall now outline the chemical nature of genes, the biochemistry of gene function, and the classes and consequences of genetic mutations.

CHEMICAL NATURE OF GENES

Human genes are composed of deoxyribonucleic acid (DNA) (Fig. 1-1). DNA is a negatively charged polymer of nucleotides. Each nucleotide is composed of a "base" attached to a 5-carbon deoxyribose sugar. Four bases are used in cellular DNA, including two purines, adenine (A) and guanine (G), and two pyrimidines, cytosine (C) and thymine (T). The polymer is formed by phosphodiester bonds that connect the 5' carbon atom of one sugar to the 3' carbon of the next; this also imparts directionality to the polymer.

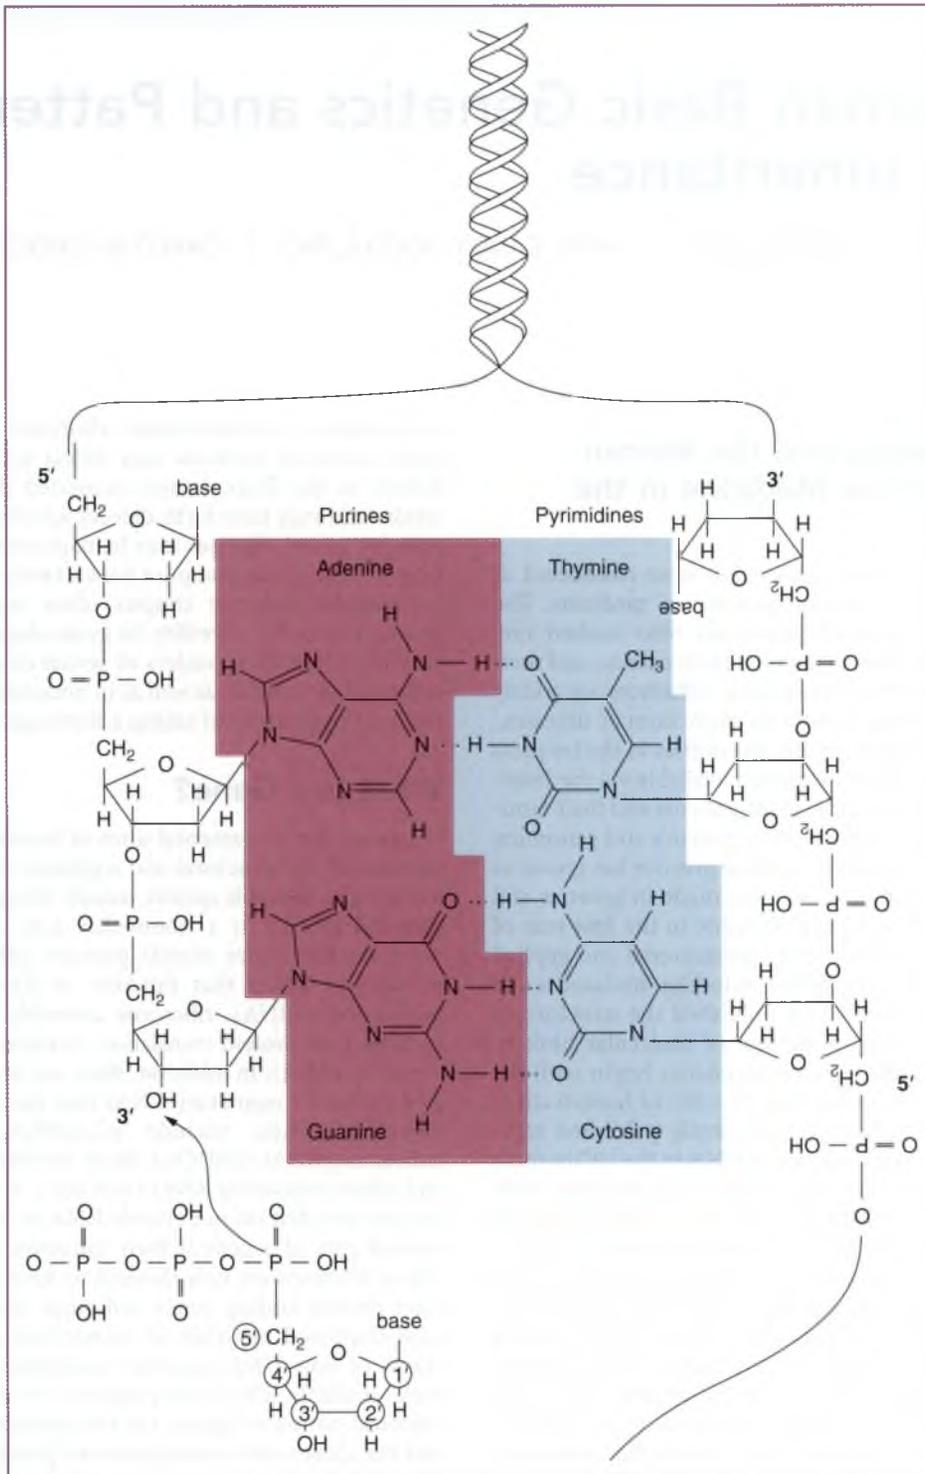

Figure 1-1 Schematic diagram of DNA structure. Each strand of the double helix is a polymer of deoxyribonucleotides. Hydrogen bonds (dotted lines) between base pairs hold the strands together. Each base pair includes one purine base (adenine or guanine) and its complementary pyrimidine base (thymine or cytosine). Two hydrogen bonds form between A:T pairs and three between G:C pairs. The two polymer strands run antiparallel to each other according to the polarity of their sugar backbone. As shown at the bottom of the figure, DNA synthesis proceeds in the 5'-to-3' direction by addition of new nucleoside triphosphates. Energy stored in the triphosphate bond is used for the polymerization reaction. The numbering system for carbon atoms in the deoxyribose sugar is indicated.

Cellular DNA is a double-stranded helix. The two strands run antiparallel; that is, the 5' to 3' orientation of one strand runs in the opposite direction along the helix from that of its complementary strand. The bases in the two strands are paired: A with T, and G with C. Hydrogen bonds between the base pairs—two for each A:T pair and three for each G:C pair—hold the strands together. Each base therefore has a complementary base, and the sequence of bases on one strand implies the complementary sequence on the opposite strand. DNA is replicated in the 5' to 3' direction using the sequence of the complementary strand as a template. Nucleotide precursors used in DNA synthesis have 5' triphosphate groups. Polymerase enzymes use the energy of this triphosphate to catalyze formation of a phosphodiester bond with the hydroxyl group attached to the 3' carbon of the extending strand.

Chemical attributes of DNA are the basis for clinical and forensic molecular diagnostic tests. Because nucleic acids form double-stranded duplexes, synthetic DNA and RNA molecules can be used to probe the integrity and composition of specific genes from patient samples. Noncomplementary base pairs formed by hybridization of DNA from a subject carrying a sequence variant relative to a reference sample are often detected by physicochemical properties such as reduced thermal stability of short (oligonucleotide) hybrids. In vitro DNA synthesis using recombinant polymerase enzymes is the basis for polymerase chain reaction (PCR) amplification of specific gene sequences. DNA sequencing methods are widely used to detect small, nucleotide-level variations, and hybridization-based methods are used to discriminate between some known allelic differences and to assess structural variations such as variations in gene copy number. Whole genome sequencing will become more widely used as its cost and analysis time rapidly decrease.

BIOCHEMISTRY OF GENE FUNCTION

Information Transfer

DNA is an information molecule. The central dogma of molecular biology is that information in DNA is *transcribed* to mRNA, and information in mRNA is then *translated* to protein. DNA is also the template for its own replication. In some instances, such as in retroviruses, RNA is reverse-transcribed into DNA. Although proteins are used to catalyze the synthesis of DNA, RNA, and proteins, proteins do not convey information back to genes. The sequence of RNA nucleotides (A, C, G, and uracil [U] bases coupled to ribose) is the same as in the *coding* or *sense strand* of DNA (except that U replaces T), and the complementary antisense strand of DNA is the template for synthesis. The sequence of amino acids in a protein is determined by a three-letter code of nucleotides in its mRNA (Fig. 1-2). The phase of the reading frame for these three-letter codons is set from the first codon, usually an AUG, which encodes the initial methionine.

Quality Control in Gene Expression

Several mechanisms protect the specificity and fidelity of gene expression in cells. *Promoter* and *enhancer* sequences are binding sites within DNA for proteins that direct transcription of RNA. Promoter sequences are typically adjacent and 5' to the start of mRNA encoding sequences (although some promoter elements are found downstream of the start site, particularly in introns). Enhancers may act at a considerable distance and from either

Figure 1-2 The genetic code. The letters U, C, A, and G correspond to the nucleotide bases. In this diagram, U (uracil) is substituted for T (thymine) to reflect the genetic code as it appears in messenger RNA (mRNA). Three distinct triplets (codons)—UAA, UAG, and UGA—are “nonsense” codons and result in termination of mRNA translation into a polypeptide chain (ter*). All amino acids except methionine and tryptophan have more than one codon; therefore, the genetic code is degenerate. This is the primary reason that many single base-change mutations are “silent.” For example, if the terminal U in a UUU codon is changed to a terminal C (UUC), the codon still codes for phenylalanine. In contrast, changing an A to a T (U) in the β -globin gene (i.e., GAG to GUG) results in substitution of valine for glutamic acid at position 6 in the β -globin amino acid sequence, yielding “sickle cell” globin.

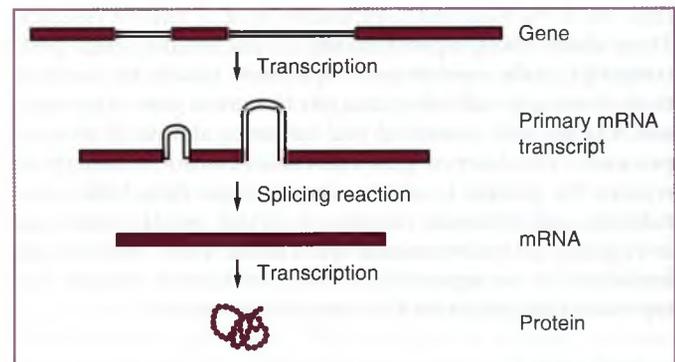

Figure 1-3 Transcription of DNA to RNA and translation of RNA to protein. Introns (light sections) are spliced out of the primary messenger RNA (mRNA) transcript, and exons (dark sections) are joined together to form mature mRNA, which is translated into protein.

the 5' or the 3' direction. The combinations of binding sites present determine the conditions under which the gene is transcribed.

Newly transcribed RNA is generally processed before it is used by a cell. Many processing steps occur cotranscriptionally on the elongated RNA as it is synthesized. Pre-mRNAs typically receive a 5' “cap,” consisting of a methylated guanine molecule, and a poly-adenylated 3' tail. Protein-coding genes typically contain exons that remain in the processed RNA and one or more introns that must be removed by *splicing* (Fig. 1-3). Nucleotide sequences in the RNA recognized by protein and RNA splicing factors determine where splicing occurs. Many RNAs

can be spliced in more than one way to encode a related series of products, greatly increasing the complexity of products that can be encoded by a finite number of genes. For most genes, only spliced RNA is exported from the nucleus. Spliced RNAs that retain premature stop codons are rapidly degraded. Mutations in genes involved in these quality control steps can be identified in the clinic as early and severe genetic disorders, including spinal muscular atrophy (caused by mutations in *SMN1*, which encodes a splicing accessory factor) and fragile X syndrome (caused by mutations in *FMR1*, which encodes an RNA-binding protein). Protein synthesis is also highly regulated. Translation, folding, modification, transport, and sometimes cleavage to create an active form of the protein are all regulated steps in the expression of protein-coding genes.

Epigenetics, another step in the regulation of genes, includes DNA modifications, such as methylation, and modifications of proteins that bind DNA, such as histone methylation, acetylation, ubiquitylation, phosphorylation, and sumoylation, that affect gene expression by regulating DNA access. Although epigenetic changes are heritable, they do not change the inherent DNA sequence but are powerful and reversible modulators of gene expression. Epigenetic changes represent a method by which the environment influences gene expression and are important for a number of cellular processes, including development, differentiation, and genomic stability.⁶ The epigenetic status of the placenta affects fetal development and represents a key link between environmental variables and genetic outcomes.⁷

Other factors that influence gene expression include ncRNAs, specifically miRNAs. Structural predictions suggest that 60% of protein-coding genes are targets of miRNA regulation, and these are at the focus of the expanding field of miRNA research. These short RNAs (approximately 22 nucleotides long) post-transcriptionally regulate gene expression, usually by competitively binding to mRNA transcripts to repress gene expression. miRNAs are well conserved and influence almost all biologic processes. This layer of gene expression control is thought to regulate the genome to silence aberrant transcripts, buffer fluctuations, and otherwise maintain a certain cellular status quo in response to environmental and cellular cues.⁸ miRNAs are implicated in an expanding number of human diseases and represent new targets for therapeutic intervention.

MUTATIONS

Changes in the nucleotide sequence of a gene may occur through environmental damage to DNA, through errors in DNA replication or repair, or through unequal recombination during meiosis. Ultraviolet light, ionizing radiation, and chemicals that intercalate, bind to, or covalently modify DNA are examples of mutation-causing agents. Replication errors often involve changes in the number of a repeated sequence; for example, changes in the number of (CAG)_n repeats encoding polyglutamine in the *huntingtin* gene (*HTT*) can result in alleles associated with Huntington's disease. Replication also plays a crucial role in other mutations. Cells usually respond to high levels of DNA damage by blocking DNA replication and inducing a variety of DNA repair pathways. However, at any one site of DNA damage, replication may occur before repair. A frequent source of human mutation is spontaneous deamination of cytosine (Fig. 1-4). The modified base can be interpreted as a thymine if replication occurs before repair of the G:T

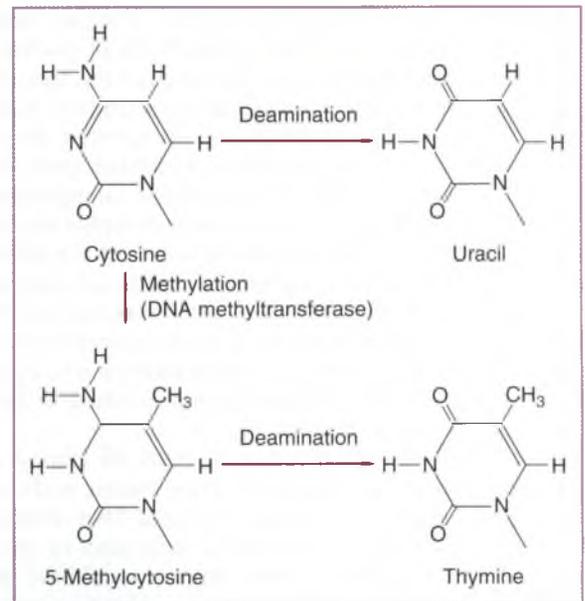

Figure 1-4 Deamination of cytosine. Deamination of cytosine or of its 5-methyl derivative produces a pyrimidine capable of pairing with adenine rather than guanine. Repair enzymes may remove the mismatched base before replication, but replication before repair (or repair of the wrong strand) results in permanent change. Spontaneous deamination of cytosine is a major mechanism of mutation in humans. Deamination of cytosine is also accelerated by some mutagenic chemicals such as hydrazine.

mismatch pair. Ultraviolet light causes photochemical dimerization of adjacent thymine residues that may then be altered during repair or replication; in humans, this is more relevant to somatic mutations in exposed skin cells than to germline mutations. Ionizing radiation, by contrast, penetrates tissues and can cause both base changes and double-strand breaks in DNA. Errors in repair of double-strand breaks result in deletion, inversion, or translocation of large regions of DNA. Many chemicals, including alkylating agents and epoxides, can form chemical adducts with the bases of DNA. If the adduct is not recognized during the next round of DNA replication, the wrong base may be incorporated into the opposite strand. The human genome also includes numerous endogenous retroviruses, retrotransposons, and other potentially mobile DNA elements. Movement of such elements or recombination among them is a source of spontaneous insertions and deletions, respectively.

Changes in the DNA sequence of a gene create distinct alleles of that gene. Alleles can be classified by how they affect the function of the gene. An *amorphic* (or null) allele confers a complete loss of function, a *hypomorphic* allele confers a partial loss of function, a *hypermorphic* allele confers a gain of normal function, a *neomorphic* allele confers a gain of novel function not encoded by the normal gene, and an *antimorphic* or dominant negative allele antagonizes normal function. The practical impact of allele classes is that distinct clinical syndromes may be caused by different alleles of the same gene. For example, different allelic mutations in the androgen receptor gene have been tied to partial or complete androgen insensitivity⁹ (including hypospadias and Reifenstein syndrome), prostate cancer susceptibility, and spinal and bulbar muscular atrophy.¹⁰

Similarly, mutations in the *CFTR* chloride channel cause cystic fibrosis, but some alleles of this gene are associated with pancreatitis or other less severe symptoms. Mutations in the *DTDST* sulfate transporter cause diastrophic dysplasia, atelosteogenesis, or achondrogenesis, depending on the type of mutation present in a disease allele.

A small fraction of changes in genomic DNA affect gene function. Approximately 2% to 5% of the human genome encodes protein or confers regulatory specificity. Even within the protein-coding sequences, many base changes do not alter the encoded amino acid, and these are called *silent substitutions*. Changes in DNA sequence that occurred long ago and do not alter gene function or whose impact is modest or uncertain are often referred to as *polymorphisms*, whereas the term *mutation* is reserved for newly created changes and changes that have significant impacts on gene function, such as disease-causing alleles of disease-associated genes. Mutations that do affect gene function may occur in coding sequences or in sequences required for transcription, processing, or stability of the RNA. The rate of spontaneous mutation in humans can vary widely depending on the size and structural constraints of the gene involved, but estimates range from 10^{-4} mutations per generation for large genes such as *NF1* (mutations cause neurofibromatosis type 1) down to 10^{-6} or 10^{-7} for smaller genes. Given current estimates of roughly 25,000 human genes^{2,3} and given that more than 7 billion humans inhabit the earth, one may expect that each human carries one or more mutations. Several public databases that curate information about human genes and mutations are available online (Table 1-1).

Chromosomes in Humans

Most genes reside in the nucleus and are packaged into discrete units known as *chromosomes*. In the human, there are 46 chromosomes in a normal cell: 22 pairs of autosomes and two sex chromosomes, X and Y (see later discussion). Autosomes are numbered from the largest (1) to the smallest (21 and 22). Each chromosome contains a *centromere*, a constricted region that forms the attachments to the mitotic spindle and governs chromosome movements during mitosis. The *chromosomal arms* radiate on each side of the centromere and terminate in the *telomere* or end of each arm. Each chromosome carries a distinct set of genetic information. Each pair of autosomes is homologous and has an identical set of genes. Normal females have two X chromosomes, whereas normal males have one X

and one Y chromosome. In addition to the nuclear chromosomes, the mitochondrial genome contains approximately 37 genes on a circular unit that resides in this organelle, in anywhere from 100 to 100,000 copies.

Each chromosome is a continuous DNA double-helical strand that is packaged into *chromatin*, which consists of protein and DNA. The protein moiety consists of basic *histone* and acidic *nonhistone* proteins. Five major groups of histones are important for proper packing of chromatin, and the heterogeneous nonhistone proteins are required for normal gene expression and higher-order chromosome packaging. Two each of the four core histones (H2A, H2B, H3, and H4) form a histone octamer nucleosome core that binds with DNA in a fashion that permits tight supercoiling and packaging of DNA in the chromosome-like thread on a spool. The fifth histone, H1, binds to DNA at the edge of each nucleosome in the spacer region. A single nucleosome core and spacer consists of about 200 base pairs of DNA. The nucleosome “beads” are further condensed into higher-order structures called *solenoids*, which can be packed into loops of chromatin that are attached to nonhistone matrix proteins. The orderly packaging of DNA into chromatin performs several functions, not the least of which is the packing of an enormous amount of DNA into the small volume of the nucleus. This orderly packing allows each chromosome to be faithfully wound and unwound during replication and cell division. Additionally, chromatin organization plays an important role in the control of gene expression.

CELL CYCLE, MITOSIS, AND MEIOSIS

Cell Cycle

Replicating somatic cells duplicate the complete diploid set of chromosomes before the cell divides into two identical daughter cells, each with chromosomes and genes identical to those of the parent cell. The process of cell division is called *mitosis*, and the period between divisions is called *interphase*. Interphase can be divided into G₁, S, and G₁ phases, a typical cell cycle is depicted in Figure 1-5. During the G₁ phase, synthesis of RNA and proteins occurs as the cell prepares for the DNA replication that will occur in S phase. Not all chromosomes are replicated at the same time, and within each chromosome, the DNA is not synchronously replicated. DNA synthesis is initiated at thousands of origins of replication scattered along each chromosome. During the G₂ phase, between DNA replication and cell division, chromosome regions may be repaired, and the cell is prepared for mitosis. In the G₁ phase, DNA of every chromosome of the diploid set (2n) is present once. Between the S and G₂ phases, every chromosome doubles to become two identical polynucleotides, referred to as *sister chromatids*; at that point, all DNA is present twice ($2 \times 2n = 4n$).

Mitosis

The process of mitosis ensures that each daughter cell contains an identical and complete set of genetic information from the parent cell; Figure 1-6 diagrams this process for 2 of the 46 human chromosomes. Mitosis is a continuous process that can be arbitrarily divided into four stages based on the morphology of the chromosomes and the mitotic apparatus. The beginning of mitosis is characterized by swelling of chromatin, which becomes visible under a light microscope by the end of this *prophase*. In prophase, the two sister chromatids of each

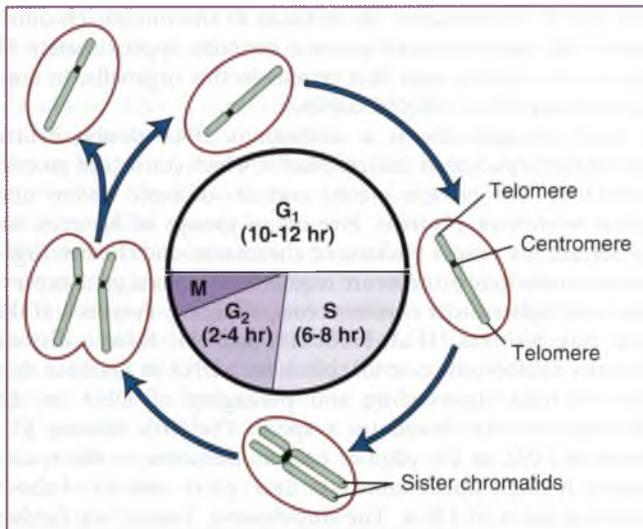

Figure 1-5 Cell cycle of a dividing mammalian cell and approximate duration of each phase of the cycle. In the G_1 phase, the diploid chromosome set ($2n$) is present in one copy. After DNA synthesis (S phase), the diploid chromosome set is present in duplicate ($4n$). After mitosis (M), the DNA content returns to $2n$. The telomeres, centromere, and sister chromatids are indicated. (From Nussbaum RL, McInnes RR, Willard HF: Thompson and Thompson's genetics in medicine, ed 6, Philadelphia, 2001, Saunders.)

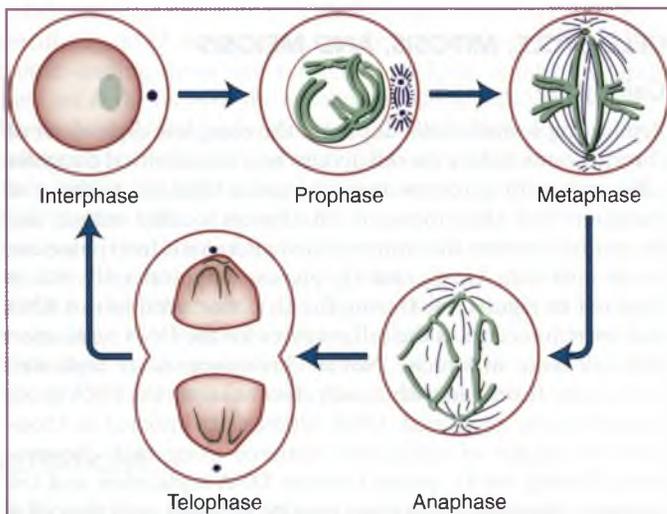

Figure 1-6 Schematic representation of mitosis. Only 2 of the 46 chromosomes are shown. (From Vogel F, Motulsky AG: Human genetics: problems and approaches, New York, 1979, Springer-Verlag.)

chromosome lie closely adjacent. The nuclear membrane disappears, the nucleolus vanishes, and the spindle fibers begin to form from the microtubule-organizing centers, or *centrosomes*, that take positions perpendicular to the eventual cleavage plane of the cell. A protein called *tubulin* forms the microtubules of the spindle and connects with the centromeric region of each chromosome. The chromosomes condense and move to the middle of the spindle at the eventual point of cleavage.

After prophase, the cell enters *metaphase*, when the chromosomes are maximally condensed. The chromosomes line up with the centromeres located on an equatorial plane between

the spindle poles. This is the important phase for cytogenetic technology. When a cell is in metaphase or is entering metaphase from prophase, clinical methods to examine chromosomes cause arrest of further steps in mitosis. Therefore, all sister chromatids ($4n$) are visible in a standard clinical karyotype.

Anaphase begins as the two chromatids of each chromosome separate, connected at first only at the centromere region (*early anaphase*). Once the centromeres separate, the sister chromatids of each chromosome are drawn to opposite poles by the spindle fibers. During telophase, chromosomes lose their visibility under the microscope, spindle fibers are degraded, tubulin is stored away for the next division, and a new nucleolus and nuclear membrane develop. The cytoplasm also divides along the same plane as the equatorial plate in a process called *cytokinesis*. Cytokinesis occurs once the segregating chromosomes approach the spindle poles. Thus, the elaborate process of mitosis and cytokinesis of a single cell results in the segregation of an equal complete set of chromosomes and genetic material in each of the resulting daughter cells.

Meiosis and the Meiotic Cell Cycle

In mitotic cell division, the number of chromosomes remains constant for each daughter cell. In contrast, a property of meiotic cell division is the reduction in the number of chromosomes, from the diploid number in the germline to the haploid number in gametes (i.e., from 46 to 23 in humans). To accomplish this reduction, two successive rounds of meiotic division occur. The first division is a reduction division in which the chromosome number is reduced by one half, and it is accomplished by the pairing of homologous chromosomes. The second meiotic division is similar to most mitotic divisions, except that the total number of chromosomes is haploid rather than diploid. The haploid number is found only in the germline; with fertilization, the diploid chromosome number is restored. The selection of chromosomes from each homologous pair in the haploid cell is completely random, thereby ensuring genetic variability in each germ cell. In addition, recombination occurs during the initial stages of chromosome pairing in the first phase of meiosis, providing an additional layer of genetic diversity in each of the gametes.

Stages of Meiosis. Figure 1-7 depicts the stages of meiosis. DNA synthesis has already occurred before the first meiotic division and does not occur again during the two stages of meiotic division. A major feature of *meiotic division I* is the pairing of homologous chromosomes at homologous regions during prophase I. This complex stage can be subdivided into substages based on the morphology of meiotic chromosomes; these stages are termed *leptonema*, *zygonema*, *pachynema*, *diploonema*, and *diakinesis*. Condensation and pairing occur during leptonema and zygonema (see Fig. 1-7B,C). The paired homologous chromosome regions are connected at a double-structured region, the *synaptonemal complex*, during pachynema. In diploonema, four chromatids of each kind are seen in close approximation side by side (see Fig. 1-7D). Non-sister chromatids become separated, whereas the sister chromatids remain paired. In this stage, the chromatid crossings (*chiasmata* between non-sister chromatids can be seen; they are believed to be sites of recombination. The chromosomes separate at diakinesis (see Fig. 1-7E), then enter meiotic metaphase I and telophase I (see Fig. 1-7F,G).

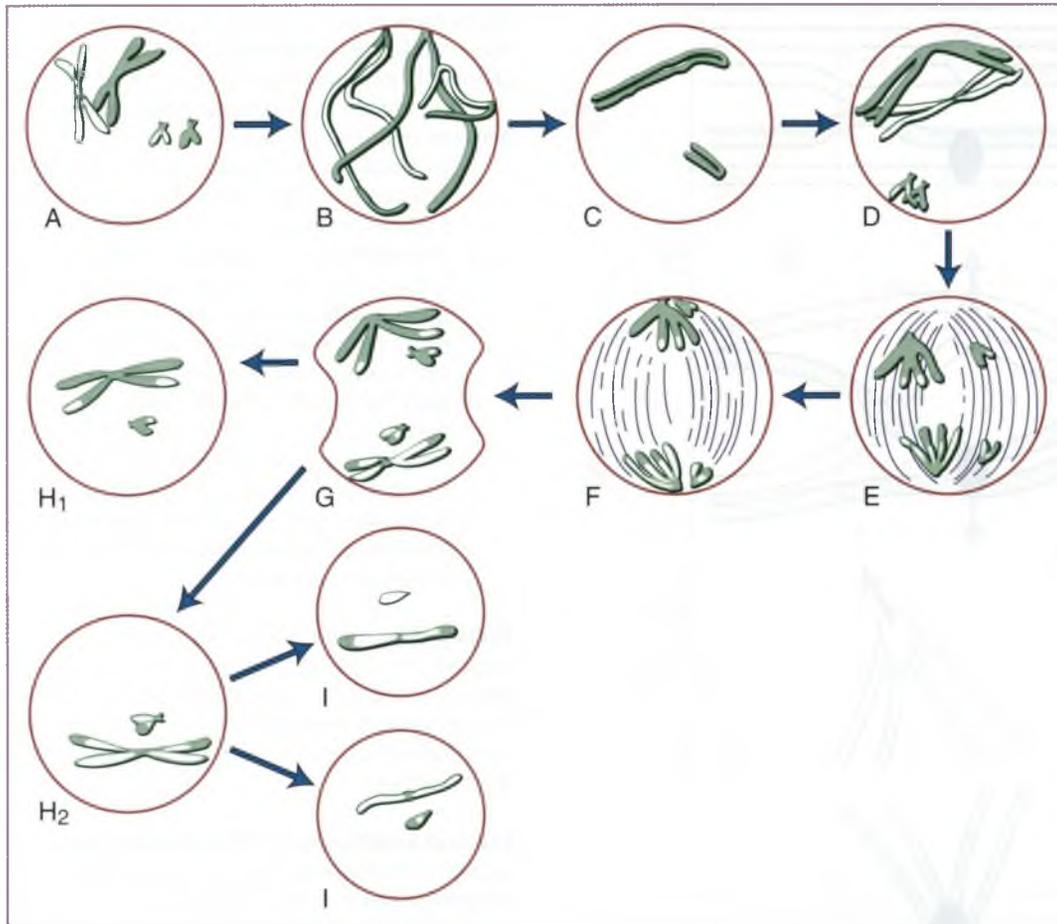

Figure 1-7 The stages of meiosis. Paternal chromosomes are shown in green; maternal chromosomes in white. A, Condensed chromosomes in mitosis. B, Leptotene. C, Zygotene. D, Diplotene with crossing over. E, Diakinesis, anaphase I. F, Anaphase I. G, Telophase I. H₁ and H₂, Metaphase II. I, Resolution of telophase II produces two haploid gametes. (From Vogel F, Motulsky AG: Human genetics: problems and approaches, New York, 1979, Springer-Verlag.)

Meiotic division II is essentially a mitotic division of a fully copied set of haploid chromosomes. From each meiotic metaphase II, two daughter cells are formed (see Fig. 1-7H₁ and H₂), and a random assortment of DNA along the chromosome is accomplished in each at division (see Fig. 1-7I). After meiosis II, the genetic material is distributed to four cells as haploid chromosomes (23 in each cell). There is random distribution of nonhomologous chromosomes to each of the final four haploid daughter cells. For these 23 chromosomes, the number of possible combinations in a single germ cell is 2^{23} , or 8,388,608. Therefore, $2^{23} \times 2^{23}$ equals the number of possible genotypes of the children of any particular combination of parents. This impressive number of variable genotypes is further enhanced by crossover during prophase I of meiosis. Chiasma formation occurs during pairing and may be essential to this process, because there appears to be at least one chiasma per chromosome arm. Chiasmata may facilitate crossover between two non-sister chromatids through breakage and reunion at homologous points (Fig. 1-8).

Sex Differences in Meiosis. There are crucial distinctions between the two sexes in meiosis.

Males. In the male, meiosis is continuous in spermatocytes from puberty through adult life. After meiosis II, sperm cells

acquire the ability to move effectively. The primordial fetal germ cells that produce oogonia in the female give rise at the same time in the male fetus to gonocytes. In these gonocytes, the tubules produce Ad (dark) spermatogonia (Fig. 1-9). During the middle of the second decade of life, spermatogenesis is fully established, and the number of Ad spermatogonia is approximately 4.3 to 6.4×10^8 per testis. Ad spermatogonia undergo continuous divisions. During a given division, one cell may produce two Ad cells, whereas another produces two Ap (pale) cells. These Ap cells develop into B spermatogonia and hence into spermatocytes that undergo meiosis (see Fig. 1-9). Primary spermatocytes are in meiosis I, whereas secondary spermatocytes are in meiosis II. Vogel and Rathenberg¹¹ calculated the approximate number of cell divisions according to age. On this basis, it can be estimated that the total number of cell divisions of human sperm from embryonic age to 28 years is approximately 15 times greater than the number of cell divisions in the life history of an oocyte.

Females. In the primitive gonad destined to become female, the number of ovarian stem cells increases rapidly by mitotic cell division. Between the second and third months of fetal life, oocytes begin to enter meiosis (Fig. 1-10). By the time of birth, mitosis in the female germ cells is finished, and only the two meiotic divisions remain to be fulfilled. After birth, all oogonia

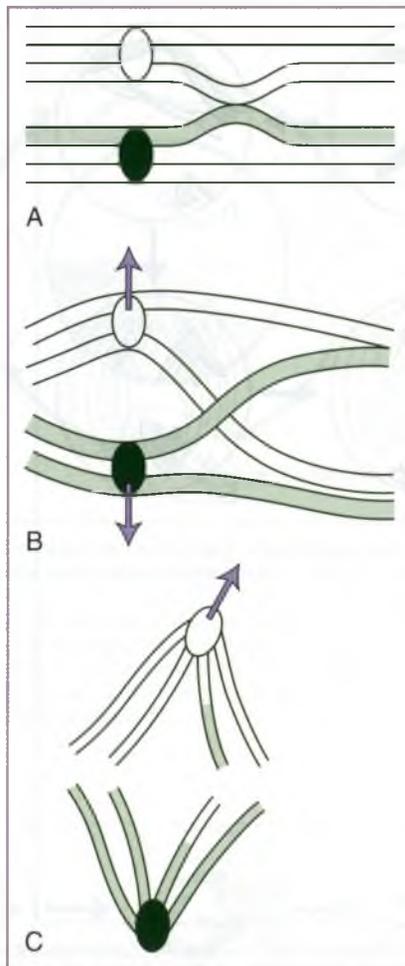

Figure 1-8 Crossing over and chiasma formation. A, Homologous chromatids are attached to each other. B, Crossing over with chiasma occurs. C, Chromatid separation occurs. (From Vogel F, Motulsky AG: Human genetics: problems and approaches, New York, 1979, Springer-Verlag.)

are transformed into oocytes or else degenerate. Fetal germ cells increase from 6×10^5 at 2 months' gestation to 6.8×10^6 during the fifth month. Decline begins at this time and continues to a level of about 2×10^6 at birth. Meiosis remains arrested in the viable oocytes until puberty. At puberty, some oocytes start the division process again. An individual follicle matures at the time of ovulation. At the completion of meiosis I, one of the cells becomes the secondary oocyte, accumulating most of the cytoplasm and organelles, and the other cell becomes the first polar body. The maturing secondary oocyte completes meiotic metaphase II at the time of ovulation. If fertilization occurs, meiosis II in the oocyte is completed, and the second polar body is formed. Only about 400 oocytes eventually mature during the reproductive lifetime of a woman; the rest degenerate. Only one of the four meiotic products develops into a mature oocyte; the other three become polar bodies, which usually are not fertilized.

Recent publications have contested this traditional view of female meiosis, instead controversially proposing that females are not born with a finite number of oocytes. Evidence from mouse models suggests that germline stem cells can replace aged follicles to allow adult oocytogenesis,¹² and that a similar

phenomenon may occur in human ovarian tissue.¹³ Although these results remain debated, they open the possibility for future changes in our understanding of female reproductive biology.

There are, then, three basic differences in traditional meiosis between males and females:

1. In females, one division product becomes a mature germ cell and three become polar bodies. In the male, all four meiotic products become mature germ cells.
2. In females, a low number of embryonic mitotic cell divisions occur very early, followed by early embryonic meiotic cell division that continues to occur until the ninth month of gestation; cell division, arrested for many years, commences again at puberty and is completed only after fertilization. In the male, there is a much longer period of mitotic cell division, followed immediately by meiosis at puberty; meiosis is completed when spermatids develop into mature sperm.
3. In females, very few gametes are produced one at a time, whereas in males, a large number of gametes are produced continuously.

Fertilization. The chromosomes of the egg and sperm are segregated after fertilization into pronuclei, each surrounded by a nuclear membrane, which later fuse. The DNA of the diploid zygote replicates soon after fertilization, and after division, two diploid daughter cells are formed to initiate embryonic development.

Clinical Significance of Mitosis and Meiosis. Proper segregation of chromosomes during meiosis and mitosis ensures that progeny contain appropriate genetic instructions. When errors occur in either process, the individual or cell lineage contains an abnormal number of chromosomes and an unbalanced genetic complement. Meiotic chromosome nondisjunction, which occurs primarily during oogenesis, is responsible for chromosomally abnormal fetuses in a small percentage of recognized pregnancies. Mitotic nondisjunction can also occur during development. Improper segregation occurring early after fertilization may result in a chromosomally unbalanced embryo or mosaicism leading to birth defects and mental retardation.

ANALYSIS OF HUMAN CHROMOSOMES

The era of clinical cytogenetics began with the discovery that human somatic cells contain 46 chromosomes. The use of a simple procedure—hypotonic treatment for spreading the chromosomes of individual cells—enabled medical scientists and physicians to examine chromosomes microscopically in single cells rather than in tissue sections. Between 1956 and 1959, it was recognized that visible changes in the number or structure of chromosomes could result in various birth defects, such as Down syndrome (trisomy 21), Turner syndrome (45,XO) and Klinefelter syndrome (47,XXY). Chromosome disorders are associated with a large incidence of fetal loss, congenital defects, and mental retardation. In the practice of obstetrics and gynecology, clinical indications for chromosome analysis include abnormal phenotype of a newborn infant, unexplained first-trimester spontaneous abortion with no fetal karyotype, pregnancy resulting in stillbirth or neonatal death, fertility problems, and pregnancy in women of advanced age^{14,15} or with a family history of certain chromosomal anomalies.

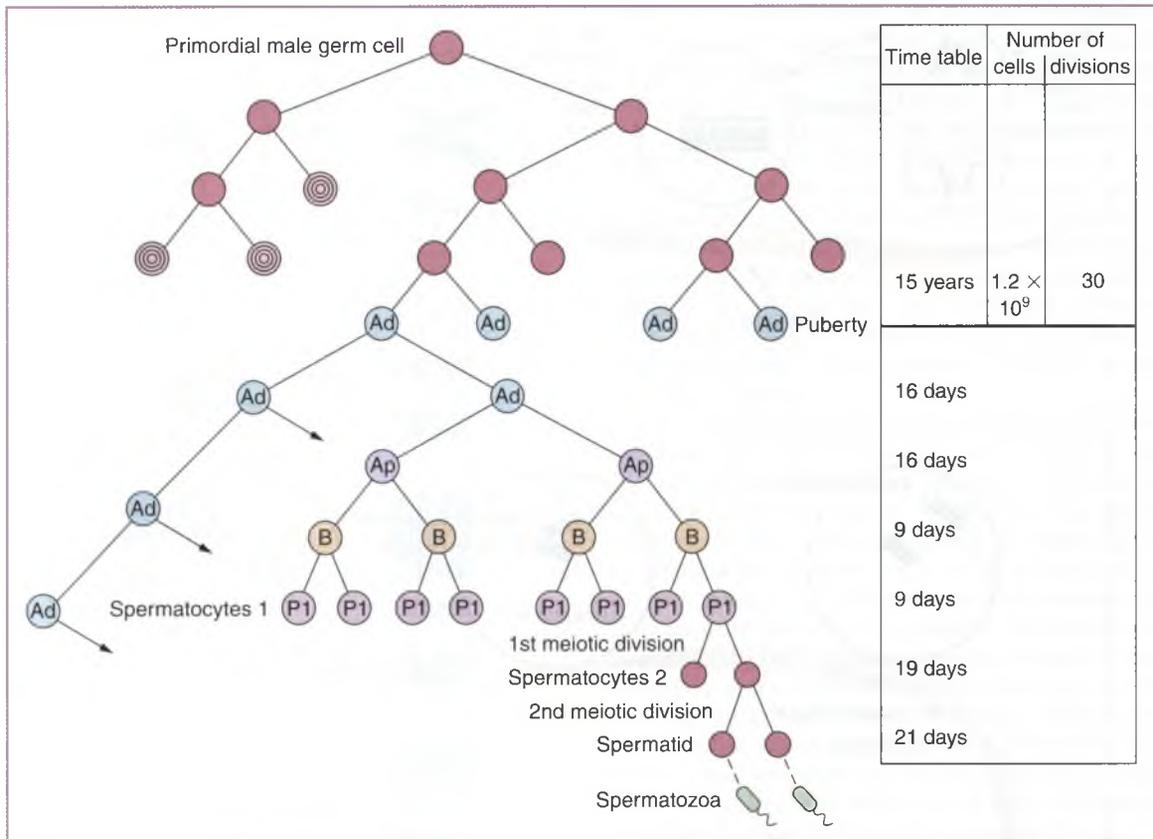

Figure 1-9 Cell divisions during spermatogenesis. The overall number of cell divisions is much higher in spermatogenesis than in oogenesis. This number increases with advancing age. Ad, dark spermatogonia; Ap, pale spermatogonia; B, spermatogonia; P1, spermatocytes. Concentric circles indicate cell atrophy. (From Vogel F, Motulsky AG: Human genetics: problems and approaches, New York, 1979, Springer-Verlag.)

Chromosome Banding

Metaphase chromosomes can be prepared from any cell undergoing mitosis. Before the advent of chromosomal microarrays, clinical and research cytogenetic laboratories routinely performed chromosome analysis on cells derived from peripheral blood, bone marrow, amniotic fluid, skin, or other tissues in situ and in tissue culture. These laboratories used one or more staining procedures that stain each chromosome with variable intensity at specific regions, thereby providing “bands” along the chromosome; the term *banding pattern* is used to identify chromosomes. Each procedure provides different types of morphologic information about an individual chromosome. For convenience, descriptive terminologies for various banding patterns are named for the methods by which they were revealed. Some of the more commonly used methods are the following:

1. *G bands* are revealed by Giemsa staining, which is probably the most widely used banding technique.
2. Quinacrine mustard and similar fluorochromes provide fluorescent staining for *Q bands*. The banding patterns are identical to those in G bands, but a fluorescence microscope is required. Q banding is particularly useful for identifying the Y chromosome in both metaphase and interphase cells.
3. *R bands* are the result of so-called reverse banding. They are produced by controlled denaturation, usually with heat. The pattern in R banding is opposite to that in G

and Q banding: Light bands produced on G and Q banding are dark on R banding, and vice versa.

4. *T bands* are the result of specific staining of the telomeric regions of the chromosome.
5. *C bands* reflect constitutive heterochromatin and are located primarily on the pericentric regions of the chromosome.

Other techniques enhance underlying chromosome instability and are useful in identifying certain aberrations associated with some rare chromosome instability syndromes or specific malignancies.

Figure 1-11 depicts an ideogram of G banding in two normal chromosomes. Starting from the centromeric region, each chromosome is organized into two regions: the p region (*short arm*) and the q region (*long arm*). Each region is further subdivided numerically. These numerical band designations greatly facilitate the descriptive identification of specific chromosomes. A complete male karyotype is depicted in Figure 1-12; a female karyotype would have two X chromosomes instead of one X and one Y chromosome.

Molecular Cytogenetics: Fluorescence in Situ Hybridization and Multicolor Karyotyping

Fluorescent molecular biology techniques have traditionally allowed the evaluation of a chromosomal preparation for gain or loss of specific genes or chromosome regions and for the

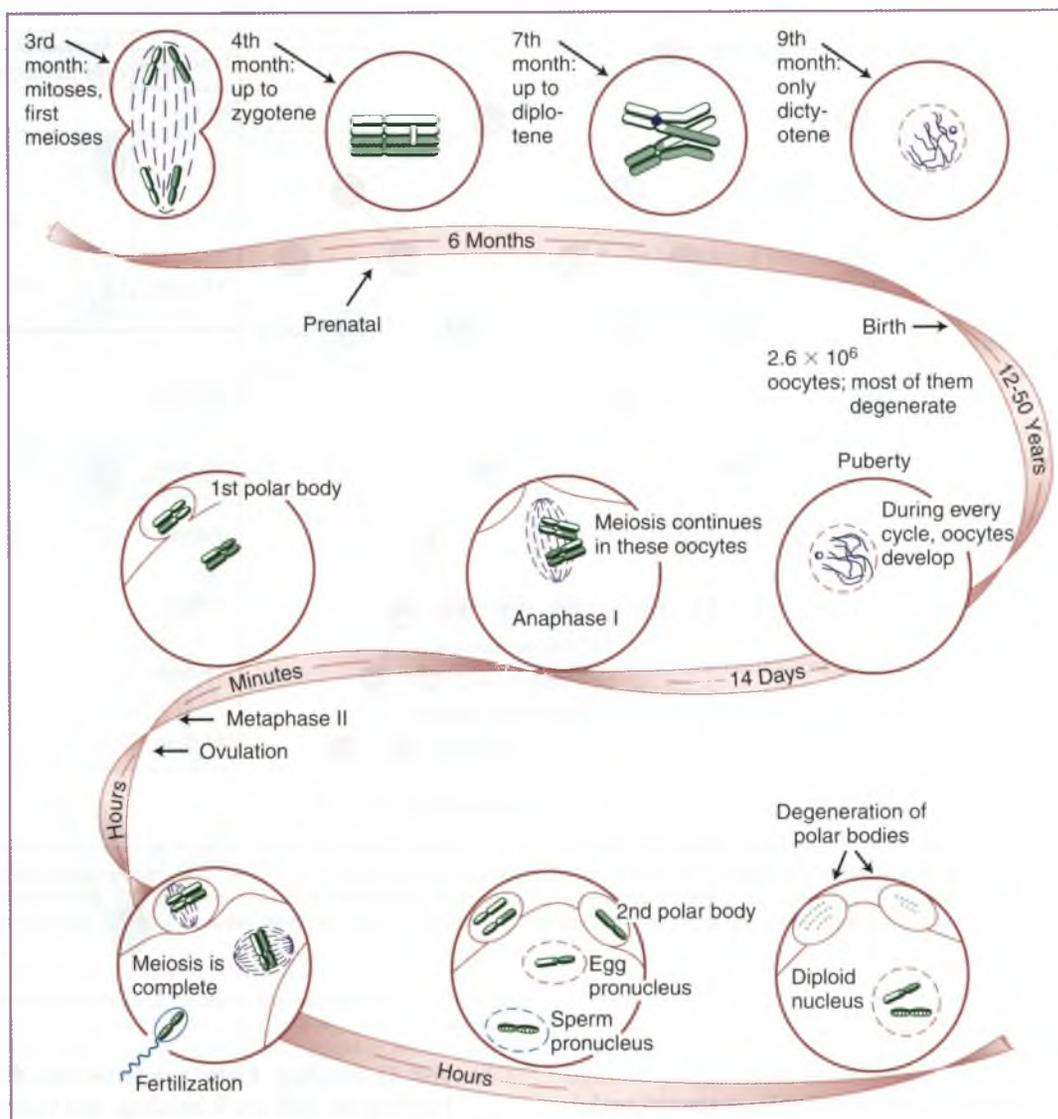

Figure 1-10 Meiosis in the human female. Meiosis begins at about 3 months of fetal development of the female and arrests at about 9 months. During childhood, the cytoplasm of oocytes increases in volume, but the nucleus remains unchanged. About 90% of all oocytes degenerate at the onset of puberty. During the first half of every monthly cycle, the luteinizing hormone of the pituitary stimulates meiosis (end of the prophase that began during embryonic stage; metaphase I, anaphase I, telophase I, and—within a few minutes—prophase II and metaphase II). Then meiosis stops again. A few hours after metaphase I is reached, ovulation is induced by luteinizing hormone. Fertilization occurs in the fallopian tube, and the second meiotic division is completed. Nuclear membranes are formed around the maternal and paternal chromosomes. After some hours, these two pronuclei fuse and the first cleavage division begins. (From Bresch C, Haussmann R: *Klassische und molekulare genetik*, ed 3, Berlin, 1972, Springer-Verlag.)

presence of translocations. Fluorescence in situ hybridization (FISH) uses DNA probes representing specific genes, chromosomal regions, and even whole chromosomes to label DNA molecules with fluorescently tagged nucleotides. After hybridization to metaphase or interphase preparations of chromosomes (or both), these probes specifically bind to the gene, region, or chromosome of interest (Fig. 1-13). This technique facilitates the detection of fine details of chromosome structure, including copy number changes.

Similarly, entire chromosomes can be labeled with *chromosome paint probes*, which specifically detect the chromosome of interest. These probes can be used to detect chromosomal translocations. An extension of this methodology is useful for the fluorescent detection and analysis of all chromosomes

simultaneously, called *spectral karyotyping*, or SKY (Fig. 1-14). SKY individually labels each chromosome with a combination of fluorescent tags so that each one will emit a unique fluorescent signal when hybridized to chromosomal preparations. Sophisticated image analysis programs can then distinguish individual chromosomes, and a metaphase spread will appear as a multicolored array. Signal from each chromosome can be specifically identified, and the entire metaphase spread can be displayed as a karyotype. This method is particularly useful for the identification of translocations between chromosomes.

Copy Number Variation and Array-Based Technologies

Once an “average” human genome was sequenced, the next phase of analysis was to identify genomic variations in

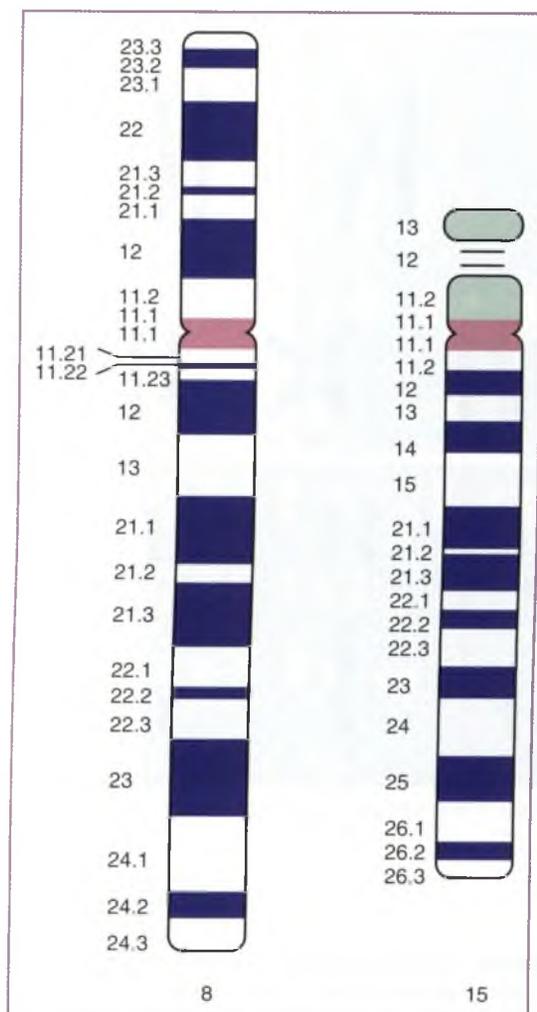

Figure 1-11 An ideogram of two representative chromosomes. Chromosome 8 and chromosome 15 are shown in examples of schematic high-resolution, mid-metaphase Giemsa banding. At the level of resolution demonstrated, a haploid set of 23 chromosomes has a combined total of approximately 550 bands. *Light red* areas represent the centromere, and *blue* and *white* areas represent regions of variable size and staining intensity. The *green* area at the end of chromosome 15 is satellite DNA. A detailed ideogram of the entire human haploid set of chromosomes has been published by the Standing Committee on Human Cytogenetic Nomenclature. (From Mitelman F, editor: ISCN 1995—An international system for human cytogenetic nomenclature: recommendations of the Standing Committee on Human Cytogenetic Nomenclature, Basel, Switzerland, 1995, Karger.)

individuals and in populations. One of the most remarkable findings was the varying number of copies of some segments of DNA scattered throughout the genome.⁵ Copy number variation (CNV) is the most prevalent type of structural variation in the human genome and contributes significantly to genetic heterogeneity. CNVs can be detected by whole-genome-array technologies, often referred to as *array comparative genomic hybridization* (aCGH). This technology allows visualization of CNVs after a normal reference DNA and an experimental DNA sample are fluorescently labeled and hybridized to a whole genomic array (Fig. 1-15). Differences between the reference and experimental samples can be analyzed by careful measurement of intensities of hybridization to these arrays. The results provide a measure of regional duplication and deletion. Some

CNVs are common in populations, but the extent of common CNVs has been difficult to estimate. Development of more population studies and reference databases for control populations and individuals with specific diseases or phenotypes is making it feasible to determine associations between CNV frequency and disease. Some CNVs can contribute to the human phenotype, including rare genomic disorders and mendelian diseases. Other CNVs influence human phenotypic diversity and disease susceptibility. For example, small CNVs, called copy number polymorphisms (CNP), have been associated with susceptibility to psoriasis¹⁶ and with Crohn disease,¹⁷ whereas large CNVs, called microdeletions or microduplications, are over-represented in neurocognitive disorders such as autism¹⁸ and schizophrenia.¹⁹

Array-based technologies can also be used for the detection of single nucleotide polymorphisms (SNPs) for family studies and clinical diagnostics. SNP arrays are replacing many traditional cytogenetic techniques for chromosomal analysis because of their capability for high-throughput analysis. Although chromosomal arrays can provide a wealth of genomic information for each patient, this information also presents challenges for clinicians and laboratories in analysis. SNP databases have been established to help winnow clinical information, including the National Center for Biotechnology Information SNP database and GWAS Central; however, challenges still exist in the application of this vast genomic resource. The significance of many CNVs is still unknown, but increased reporting and collaboration among clinical laboratories will help to identify more relationships between CNVs and human conditions.

CHARACTERISTICS OF THE MORE COMMON CHROMOSOME ABERRATIONS IN HUMANS

Abnormalities in Chromosome Number

Alteration of the number of chromosomes is called *heteroploidy*. A heteroploid individual is *euploid*, if the number of chromosomes is a multiple of the haploid number of 23, or *aneuploid*, if there is any other number of chromosomes. Numeric abnormalities of single chromosomes are usually caused by nondisjunction or anaphase lag, whereas whole-genome abnormalities are referred to as *polyploidization*.

Aneuploidy. Aneuploidy is the most frequently observed chromosome abnormality in clinical cytogenetics, occurring in 3% to 4% of clinically recognized pregnancies. Aneuploidy occurs during both meiosis and mitosis. The most significant cause of aneuploidy is *nondisjunction*, which may occur in mitosis or meiosis but is observed more frequently in meiosis. One pair of chromosomes fails to separate (disjoin) and is transferred in anaphase to one pole. Meiotic nondisjunction can occur in meiosis I or II. The result is that one gamete will have both members of the pair and one will have neither member of that pair (Fig. 1-16). After fertilization, the embryo will either contain an extra third chromosome (trisomy) or have only one of the normal chromosome pair (monosomy).

Anaphase lag is another event that can lead to abnormalities in chromosome number. In this process, one chromosome of a pair does not move as rapidly during the anaphase process as its homologue and is lost. Often this loss leads to a mosaic cell population, one euploid and one monosomic (e.g., 45,XO/46,XX mosaicism).

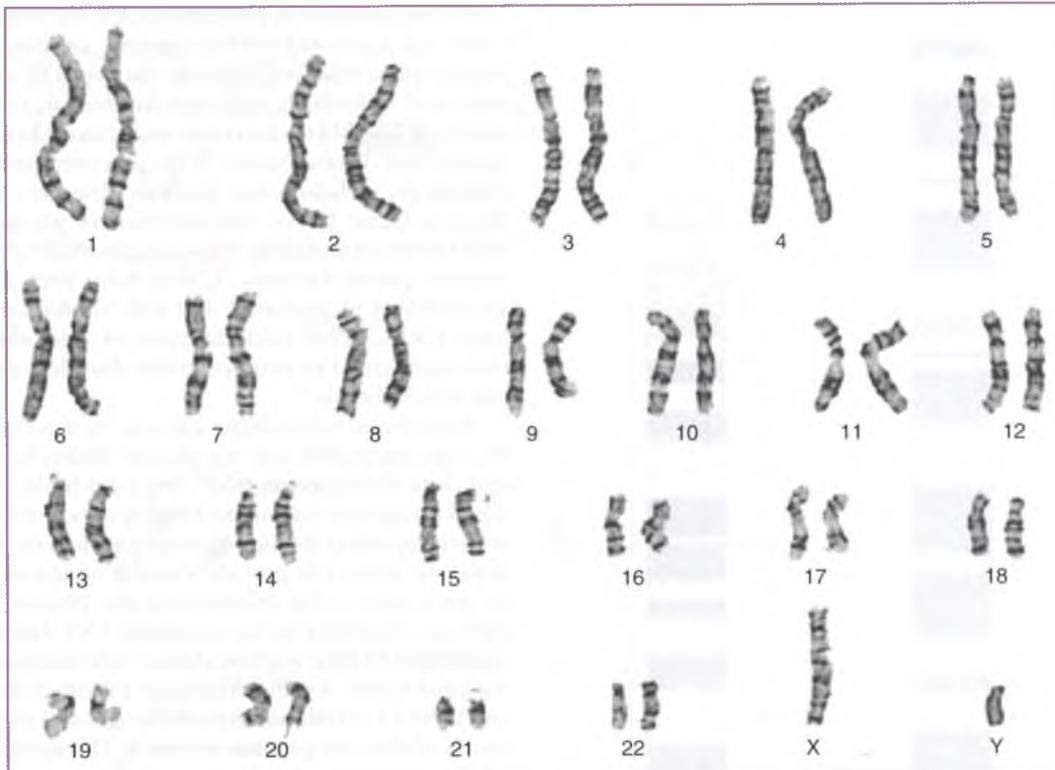

Figure 1-12 A standard G-banded karyogram. There are approximately 550 bands in one haploid set of chromosomes in this karyogram. The sex karyotype is X,Y (male). A female karyogram would show two X chromosomes.

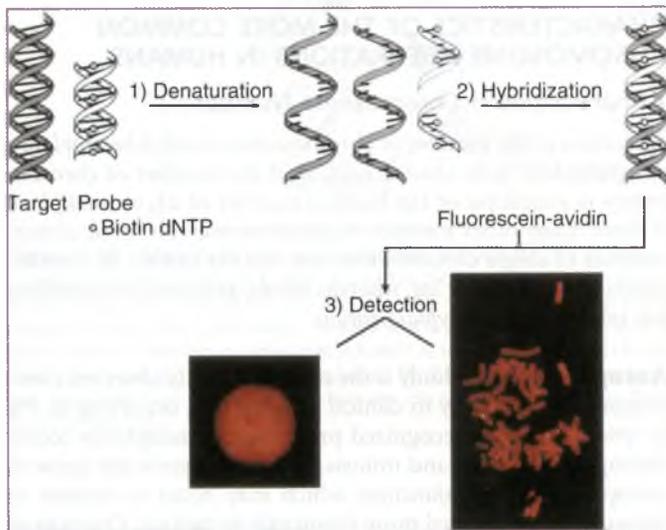

Figure 1-13 A schematic representation of fluorescence in situ hybridization (FISH). The DNA target (chromosome) and a short DNA fragment (probe) containing a nucleotide (e.g., deoxyribonucleotide triphosphate [dNTP]) labeled with biotin are denatured. The probe is specific for a chromosomal region containing the gene or genes of interest. During renaturation, some of the DNA molecules containing the region of interest hybridize with complementary nucleotide sequences in the probe, and with subsequent binding to a fluorochrome marker (fluorescein-avidin) a signal (yellow-green) is produced. The two lower panels demonstrate a metaphase cell and an interphase cell. The probe used is specific for chromosome 7. A control probe for band q36 on the long arm establishes the presence of two number 7 chromosomes. The second probe is specific for the Williams syndrome region at band 7q11.23. This signal is more intense and demonstrates no deletion at region 7q11.23, essentially excluding the diagnosis of Williams syndrome. The signals are easily visible in both metaphase and interphase cells.

Polyplody. Polyploid fetuses are characterized by the presence of the whole genome more than once in every cell. When the increase is by a factor of 1 for each cell, the result is *triploidy*, with 69 chromosomes per cell. Triploidy is most often caused by fertilization of a single egg with two sperm, but it can also result from the duplication of chromosomes during meiosis without division.

Alterations of Chromosome Structure

Structural alterations in chromosomes constitute the other major group of cytogenetic abnormalities. Such defects are seen less frequently than numeric defects and occur in about 0.25% of newborns. However, chromosome rearrangements are a common occurrence in malignancies. Structural rearrangements are balanced if there is no net loss or gain of chromosomal material or unbalanced if there is an abnormal genetic complement.

Deletions and Duplications. The term *deletion* refers to the loss of a chromosome segment. Deletions may occur on the terminal segment of the short or long arm; alternatively, an interstitial deletion may occur anywhere on the chromosome. Deletions can result from chromosomal breakage with loss of the deleted fragment due to its lack of a centromere (Fig. 1-17), or they may result from unequal crossover between homologous chromosomes. When an unequal crossover yields a deletion, the reciprocal event is a duplication in the homologous chromosome. A *ring chromosome* results from terminal deletions of the short and long arms of the same chromosome with joining of the two broken ends (Fig. 1-18).

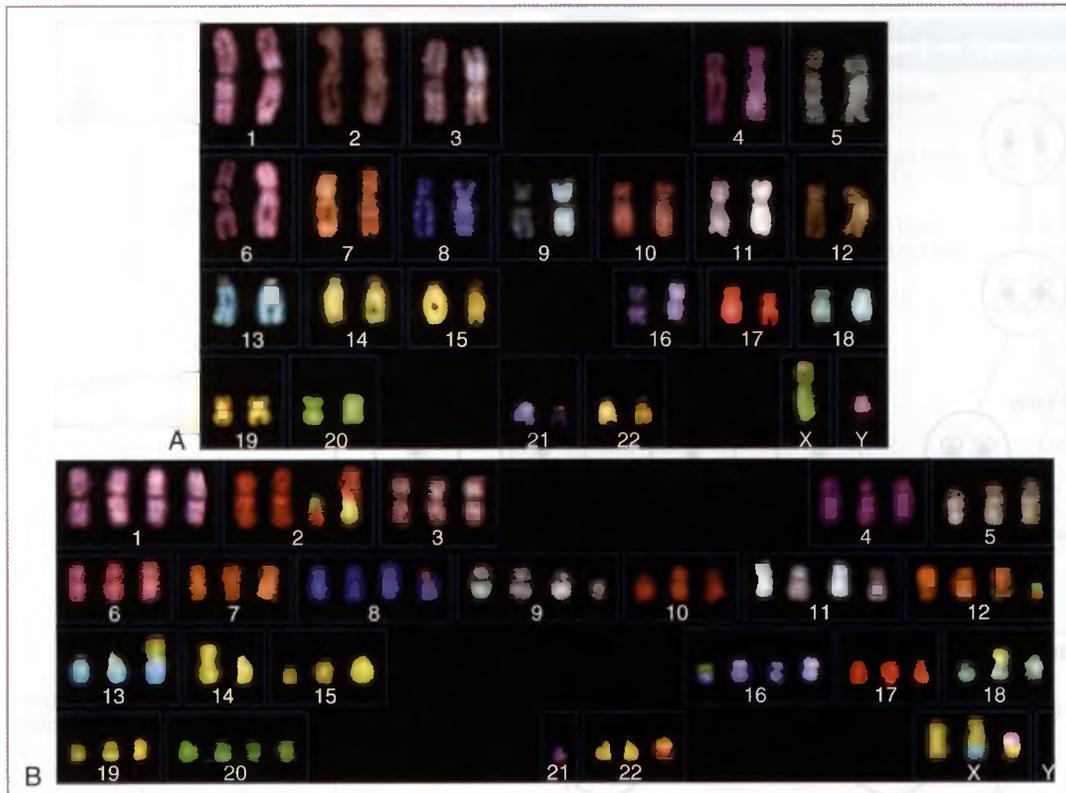

Figure 1-14 Spectral karyotyping (SKY). A, A normal human karyotype after SKY analysis, showing the presence of two copies of each chromosome, each pair with a different color. In addition, the X and Y chromosomes are different colors. B, SKY analysis of a tumor cell line, displaying extra copies of almost all chromosomes. Translocations can be appreciated as chromosomes consisting of two colors. (Courtesy of Dr. Karen Arden, Ludwig Cancer Institute, UCSD School of Medicine, San Diego, CA.)

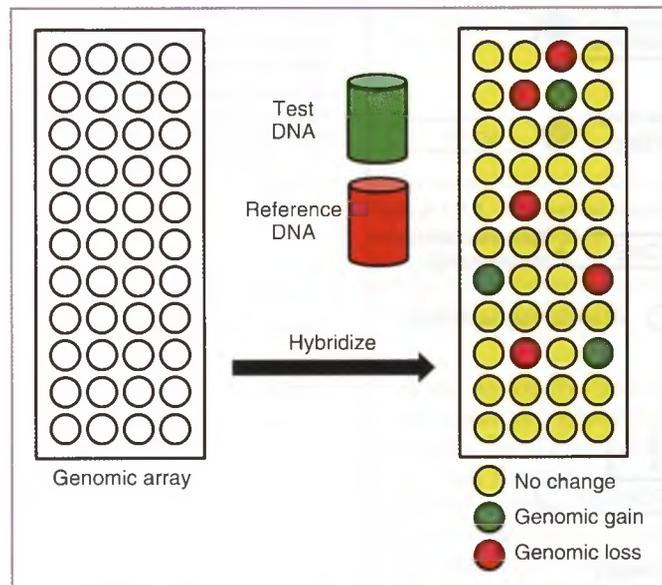

Figure 1-15 Array comparative genomic hybridization. Test DNA (green) and reference DNA (red) are simultaneously hybridized to a complete genome array. Differences in hybridization reflect differences in genomic copy number between the test and reference DNA. In the resulting array, yellow indicates no change in copy number, green indicates test DNA that contains a genomic gain in that area, and red indicates test DNA that contains a genomic loss in that region.

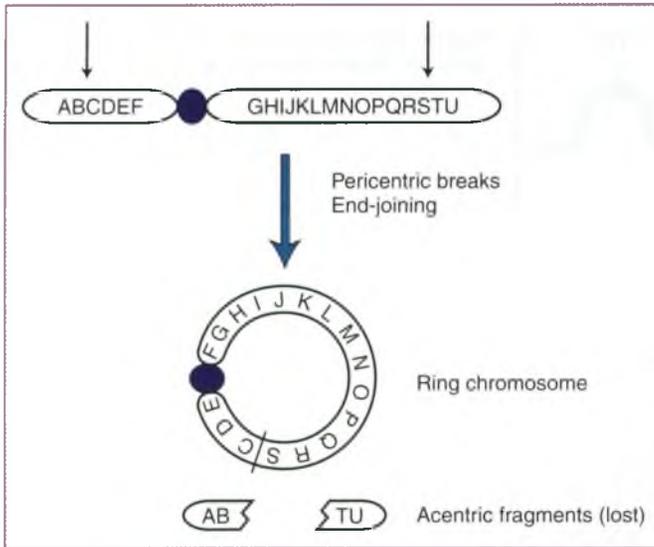

Figure 1-18 Ring chromosome formation. A chromosome with a double-strand break (black arrow) on each side of its centromere (filled oval) can result in terminal deletions (see Fig. 1-17), pericentric inversion, or formation of a ring chromosome through joining of the two centromeric ends from the breaks. In the case of ring chromosome formation, the acentric fragments are lost in the next cell division.

Autosomal Deletion and Duplication Syndromes

Autosomal deletions and duplications can be associated with clinically evident birth defects or milder dysmorphisms. Often the chromosomal defect is unique to the individual, in which case it is difficult to provide prognostic information to the family. In other cases, a number of patients with similar phenotypic abnormalities can be characterized by similar defects. Some of these are cytogenetically detectable, whereas others are smaller and require molecular cytogenetic techniques. These are termed *microdeletion* and *microduplication* syndromes, terms that reflect the size of the deletion or duplication. Array-based genomic technologies have identified an increasing number of diseases caused by microdeletions and microduplications. Some of these are summarized in Table 1-2.

Insertions and Inversions. Interstitially deleted segments can be lost or inserted into sequences on a nonhomologous chromosome (Fig. 1-19). Insertions of deleted segments can also be inverted in orientation.

Inversions often involve the centromere (*pericentric*) rather than noncentromeric areas (*paracentric*). Figure 1-20 is a diagrammatic representation of a pericentric inversion. Inversions reduce pairing between homologous chromosomes; crossing over may be suppressed within inverted heterozygote chromosomes. For homologous chromosomes to pair, one must form a loop in the region of the inversion (Fig. 1-21). If the inversion is pericentric, the centromere lies within the loop. When crossing over occurs, each of the two chromatids within the crossover has both a duplication and a deletion. If gametes are formed with the abnormal chromosomes, the fetus will be monosomic for one portion of the chromosome and trisomic for another portion. One result of abnormal chromosome recombination is increased spontaneous abortion due to duplication or deficiency of a chromosomal region.

TABLE 1-2 Diagnosis of Microdeletion Syndromes

Syndrome	Chromosome Band	Chromosome Defect
Alagille	20p12.1-p11.23	Deletion
Angelman	15q11-q13	Deletion (maternal genes)
Cri du chat	5p15.2-p15.3	Deletion
DiGeorge*	22q11.21-q11.23	Deletion
Miller-Dieker	17p13.3	Deletion
Prader-Willi	15q11-q13	Deletion (paternal genes)
Rubenstein-Taybi	16p13.3	Deletion
Smith-Magenis	17p11.2	Deletion
WAGR	11p13	Deletion
Williams	7q11.23	Deletion
Wolf-Hirschhorn	4p16.3	Deletion

*Patients with velocardiofacial (Shprintzen) syndrome and others of the CATCH 22 group also have deletions at 22q11.21-q11.23. WAGR, Wilms tumor, aniridia, genital anomalies, growth retardation.

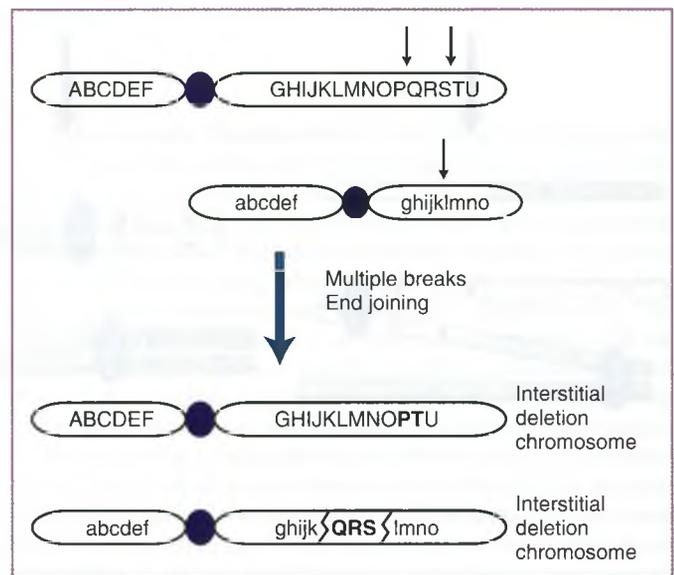

Figure 1-19 Interstitial translocations. Interstitial translocations can result from repair through end joining of fragments from nonhomologous chromosomes. In the example illustrated, a fragment QRS is liberated from one chromosome and inserted at a break between k and l in the recipient chromosome.

When pericentric inversions occur as a new mutation, the result is usually a phenotypically normal individual. However, when a carrier of a pericentric inversion reproduces, the pairing events just described may occur. If fertilization involves the abnormal gametes, there is a risk for abnormal progeny. If a pericentric inversion is observed in a phenotypically abnormal child, parental karyotyping is indicated.

An exception to this rule involves a pericentric inversion affecting chromosome 9, the most common inversion observed in humans. The frequency of this inversion was found to be approximately 5% in 14,000 amniotic fluid cultures. In the 30 or so instances in which parental karyotyping was performed, invariably one or the other parent carried a pericentric inversion affecting one copy of chromosome 9. One explanation for the apparently benign status of pericentric inversion in this

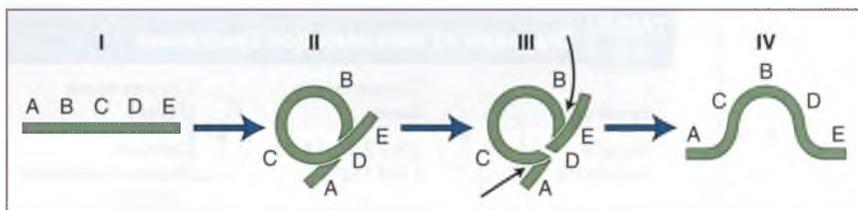

Figure 1-20 An example of a possible mechanism for development of a pericentric inversion. I, Normal sequence of coded information on the chromosome. II, Formation of a loop involving a chromosome region. III, Breakage and reunion at the arrows, where the chromosome loop intersects itself. IV, Formation of the inverted information sequence after reunion.

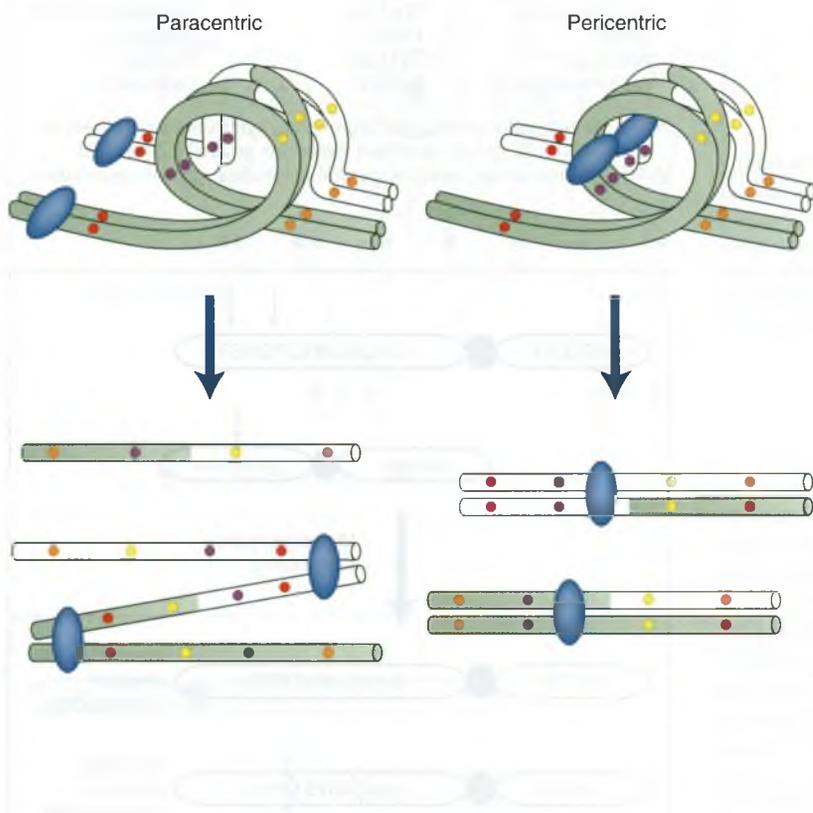

Figure 1-21 Inversions. Crossing over within the inversion loop of an inversion heterozygote results in aberrant chromatids with duplications or deficiencies. Results are shown when the centromere is outside (left) or within (right) the inversion loop.

chromosome is that the region contains highly repetitive or genetically silent regions in the genome. Another explanation could be that inversions involving relatively short DNA sequences may not be involved in crossover.

Translocations. A translocation is the most common form of chromosome structural rearrangement in humans. There are two types: *reciprocal* (Fig. 1-22) and *robertsonian* (Fig. 1-23).

Reciprocal Translocation. If a reciprocal translocation is balanced, phenotypic abnormalities are uncommon. Unbalanced translocations result in miscarriage, stillbirth, or the live birth of an infant with multiple malformations, developmental delay, and mental retardation. Reciprocal translocations almost always involve nonhomologous chromosomes affecting any of the 23 chromosome pairs, including the X and Y.

Gametogenesis in heterozygous carriers of translocations is especially significant because of the increased risk for chromosome segregation that produces gametes with unbalanced chromosomes in the diploid set (see Fig. 1-22). In a reciprocal translocation, there will be four chromosomes with segments in common (see Fig. 1-22). During meiosis, homologous segments must align for crossing over to occur, so that in a

translocation set of four, a *quadrivalent* is formed. During meiosis I, the four chromosomes may segregate randomly in two daughter cells with several results.

In 2:2 alternate segregation (see Fig. 1-22), one centromere segregates to one daughter cell, and the next centromere segregates to the other daughter cell. This is the only mode that leads to a normal or balanced normal karyotype. Adjacent segregation and 3:1 nondisjunction segregation produce unbalanced gametes.

If a gamete is chromosomally unbalanced, the odds are increased for spontaneous abortion. In familial translocations, the risk of unbalanced progeny seems to depend on the method of ascertainment. For example, if a familial reciprocal translocation is ascertained by a chromosomally unbalanced live birth or stillbirth, the risk for subsequent chromosomally unbalanced children is approximately 15%, and the risk for spontaneous abortion or stillbirth is approximately 25%. In contrast, if the ascertainment is unbiased, the risk for chromosomally unbalanced live birth is 1% to 2%, but the risk for miscarriage or stillbirth remains at 25%.

There is also a parental sex influence on the risk for chromosomally unbalanced progeny associated with certain types

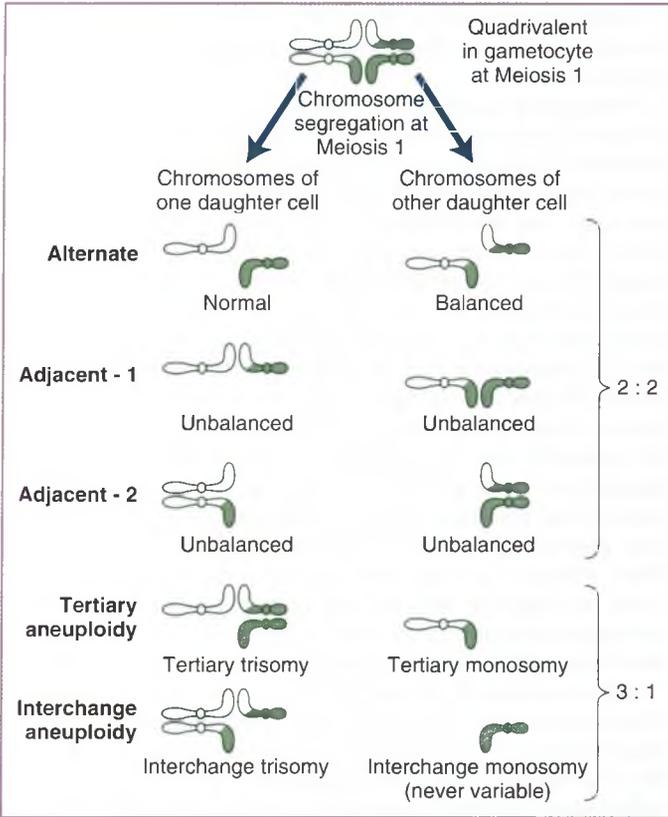

Figure 1-22 Chromosome segregation during meiosis in a reciprocal translocation heterozygote. (Modified from Gardner RJM, Sutherland GR: Chromosome abnormalities and genetic counseling, New York, 1989, Oxford University Press.)

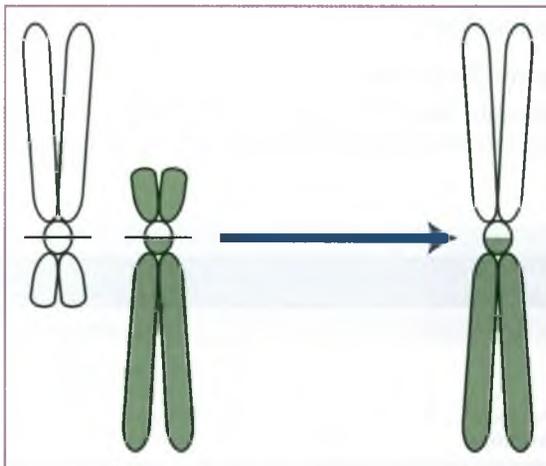

Figure 1-23 Formation of a centric fusion (monocentric) robertsonian translocation. Robertsonian translocations involve only the acrocentric chromosomes.

of segregants. In general, the risk for unbalanced progeny is higher if the female parent carries the translocation than it is with a paternal carrier. In addition, a viable conceptus is influenced by the type of configuration produced during meiosis by the translocated chromosomes. In general, larger translocated fragments and more asymmetric pairing are associated with a greater likelihood for abnormal outcome of pregnancy.

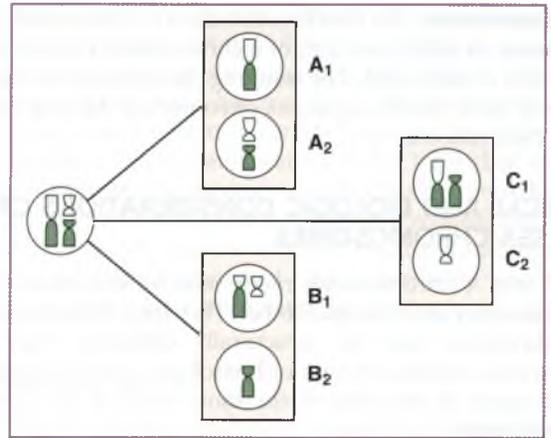

Figure 1-24 Gametogenesis for robertsonian translocation. A₁ is balanced with 22 chromosomes, including t(14q21q). A₂ is normal with 22 chromosomes. B₁ is abnormal with 23 chromosomes, including t(14q21q) and 21; this gamete would produce an infant with Down syndrome for chromosome 21. B₂ is abnormal with 22 chromosomes and monosomy for chromosome 21. C₁ is abnormal with 23 chromosomes, including t(14q21q) and 14. C₂ is abnormal with 22 chromosomes and no chromosome 14.

Robertsonian Translocation. Robertsonian translocations involve only the acrocentric chromosome pairs 13, 14, 15, 21, and 22. They are joined end to end at the centromere and may be homologous (e.g., t21;21) or nonhomologous (e.g., t13;14). Robertsonian translocation is named for an insect cytogeneticist, W. R. B. Robertson, who in 1916 was the first to describe a translocation involving two acrocentric chromosomes. The robertsonian translocation is unique because the fusion of two acrocentric chromosomes usually involves the centromere (see Fig. 1-23) or regions close to the centromere. However, reciprocal translocations may also include acrocentric chromosomes.

Robertsonian translocations are almost always nonhomologous. Most homologous robertsonian translocations produce nonviable conceptuses. For example, translocation 14;14 would result in either trisomy 14 or monosomy 14, both of which are nonviable.

The most common nonhomologous robertsonian translocation in humans is 13;14. Approximately 80% of all nonhomologous robertsonian translocations involve chromosomes 13, 14, and 15. The next most common translocations involve one chromosome from pairs 13, 14, and 15 and one chromosome from pairs 21 and 22.

Figure 1-24 illustrates gametogenesis in a nonhomologous 14;21 robertsonian translocation carrier and also represents the model for segregation during gametogenesis with any robertsonian translocation. Translocation carriers theoretically produce six types of gametes in equal proportions. Monosomic gametes are typically nonviable, as are many trisomies (e.g., trisomy 14 or 15). As illustrated, three gametes may result in viable conceptuses and one (B₁) may produce a liveborn abnormal infant.

Robertsonian translocation 14;21 is the most medically significant type in terms of incidence and genetic risk. In contrast, the most frequent robertsonian translocation, 13;14, rarely produces chromosomally unbalanced progeny. Nonetheless, genetic counseling and consideration of prenatal diagnosis are recommended for all families with a robertsonian or reciprocal chromosome translocation.

Isochromosomes. An isochromosome is a structural rearrangement in which one arm of a chromosome is lost and the other arm is duplicated. The resulting chromosome is a mirror image of itself. Isochromosomes often involve the long arm of the X chromosome.

CLINICAL AND BIOLOGIC CONSIDERATIONS OF THE SEX CHROMOSOMES

The X and Y chromosomes merit separate discussions from the autosomes and from each other. They have distinct patterns of inheritance and are structurally different. They pair during male meiosis because of homology in the pseudoautosomal region at the ends of the short arms of the X and Y chromosomes.

Embryonically, the primitive gonad is undifferentiated. Phenotypic sex in humans is determined by the presence or absence of the Y chromosome. This is the case for two reasons. First, in the absence of the Y chromosome, the primitive gonad will differentiate into an ovary and female genitalia will form; therefore, the female sex is the default sex. Second, the *SRY* gene, present on the Y chromosome, is necessary and sufficient for testis formation and the differentiation of male external genitalia.

The X chromosome is present in two copies in females but in only one copy in males. To equalize dosage (copy number) differences in critical X-chromosome genes between the two sexes, one of the X chromosomes is randomly inactivated in somatic cells of the female during *X inactivation*²⁰; in cells with more than two X chromosomes, all but one are inactivated. This ensures that in any diploid cell, regardless of sex, only a single active X chromosome is present. X inactivation results in complete inactivation of about 90% of the genes on the X chromosome, leaving the remaining 10% of genes active. Many of these are clustered on the short arm of X, so aneuploidies involving this region may have greater clinical significance than those on the long arm. X chromosome inactivation occurs through the X inactivation center on Xq13, which contains a noncoding RNA, called *XIST*, that is first expressed on the allele of the inactive X chromosome. Expression of *XIST* is antagonized by

a complementary noncoding RNA, *TSIX*, which controls X inactivation by recruiting silencing protein complexes to the inactive X.

Although X inactivation is random in normal somatic cells, structural abnormalities of the X chromosome often result in nonrandom X inactivation. In general, when a structural abnormality involves only one X chromosome (i.e., deletion, isochromosome, ring chromosome), the abnormal X chromosome almost always is the one inactivated.¹³ If the structural abnormality is a translocation between part of one X chromosome and an autosome, the "normal" X is the one genetically inactivated. Although this pattern is not proven, it is assumed that if the X chromosome translocated to an autosome were to be genetically inactivated, part or all of that autosome might also become inactive, rendering the cell functionally monosomic for the autosome and thus nonviable. This phenomenon helps to explain why some females heterozygous for X-linked recessive biochemical disorders, such as Duchenne muscular dystrophy, have phenotypic expression of that disorder. In such instances, if the mutant X chromosome is the one involved in the X autosome translocation and the normal allele is inactive by virtue of being on the normal inactive X chromosome, it is likely that the female will express the disease.

Abnormalities of the sex chromosomes or genes on the sex chromosomes may affect any of the stages of sexual and reproductive development. Although an increased number of either the X or the Y chromosome enhances the likelihood of mental retardation and other anatomic anomalies, aneuploidy of the sex chromosome does not alter prenatal fetal development nearly as much as aneuploidy of an autosome. Many mutations or deletions in the X chromosome do result in X-linked mental retardation. Numeric and structural sex chromosome aneuploidies are summarized in Table 1-3, and in the following paragraphs a few of the more common sex chromosome aberrations are described.

Turner Syndrome

Although Turner syndrome occurs in approximately 1 of every 10,000 liveborn females, it is one of the chromosomal

TABLE 1-3 Numeric and Structural X-Chromosomal Aneuploidies in Humans

Karyotype	Phenotype	Approximate Frequency
XXY	Klinefelter syndrome	1 per 700 males
XXXY	Klinefelter variant	1 per 2500 males
XXXXY	Low-grade mental deficiency; severe sexual underdevelopment; radioulnar synostosis	Rare
XXX	Sometimes mild oligophrenia; occasionally disturbances of gonadal function	1 per 1000 females
XXXX	Growth retardation; severe mental retardation	Rare
XXXXX	Multiple physical defects; severe mental retardation	Rare
XXY/XY and XXY/XX mosaics	Klinefelter-like, sometimes milder in symptomatology	5%-25% of all Klinefelter-like patients
XXX/XX mosaics	Like XXX	Rare
XO	Turner syndrome	1 per 2500 females at birth
XO/XX and XO/XXX mosaics	Like Turner syndrome, but very different degrees of manifestation	Not uncommon
Various structural anomalies of X chromosomes	—	Not uncommon
XYY	Increased stature; occasionally behavioral abnormalities	1 per 800 males
XXYY	Increased stature; otherwise resembling Klinefelter syndrome	Rare

From Vogel F, Motulsky AG: Human genetics: problems and approaches, New York, 1979, Springer-Verlag.

abnormalities most commonly observed in studies of spontaneous abortuses. It is unknown why this chromosomal defect that usually results in spontaneous fetal loss is also compatible with survival. It is often detected prenatally through ascertainment of a cystic hygroma by fetal ultrasound examination during the first or second trimester. Although there is wide variability in the phenotypic expression of Turner syndrome, it is one sex chromosome abnormality that should be identifiable by physical examination of the newborn.

Turner syndrome is associated with a 45,XO karyotype. Sex chromosome mosaics (e.g., 46,XX/45,XO) and individuals with structurally abnormal karyotypes (e.g., 46,X/delX and 46,X/isoX) are all phenotypic females, like those with 45,XO Turner syndrome, but they have fewer of the typical manifestations associated with the 45,XO phenotype. The paternally derived X chromosome is more often missing in the 45,XO karyotype.

Some of the common features of the 45,XO phenotype and the frequencies with which they are seen are listed in Table 1-4. Mental retardation is not normally seen in this syndrome unless a small ring X chromosome is present. Although there is inadequate information at present to permit assessment of longevity and cause of death in adult life, the general health prognosis is good for childhood and young adult life in those with this phenotype. Renal anomalies, when present, rarely cause significant health problems; if congenital heart disease is part of the phenotype, surgery is usually effective. The congenital lymphedema usually disappears during infancy. If webbing of the neck poses a cosmetic problem, it can be corrected by plastic surgery. Short stature, however, is a persistent problem. If a diagnosis is made early, height increase and external sexual development may be managed with the collaboration of a knowledgeable endocrinologist. In particular, growth hormone therapy is standard and results in a significant increase in adult height. Affected patients are almost always sterile. The emotional adjustment to this issue should be part of any medical management of gonadal dysgenesis.

If the diagnosis of 45,XO karyotype or a variant is missed during infancy or childhood, complaints of persisting short stature or amenorrhea may finally bring the patient to the

physician. Often this delay precludes any specific therapy for the short stature. In rare variants of Turner syndrome, some cells may carry a Y chromosome, suggesting that such an individual was initially an XY male but that the Y chromosome was lost. Occasionally, the Y chromosome line is found only in the germ cells, and the clinical manifestation in the individual may be virilization during adolescence or an unexplained growth spurt. In such cases, it is imperative to perform a gonadal biopsy for histologic and chromosome analysis. If a Y chromosome cell line is demonstrated in gonadal tissue, extirpation is indicated to prevent subsequent malignant transformation in gonadal cells.

Klinefelter Syndrome

Klinefelter syndrome, which occurs in approximately 1 of every 700 to 1000 liveborn males, is associated with a 47,XXY karyotype. Major physical features of Klinefelter syndrome are as follows:

1. Relatively tall and slim body type, with relatively long limbs (especially the legs) is seen beginning in childhood.
2. Hypogonadism is seen at puberty, with small, soft testes and usually a small penis. Infertility is the rule. Gynecomastia is frequent, and cryptorchidism or hypospadias may be seen. Lack of virilization at puberty is common; indeed, it is often the reason for the patient to seek medical attention.
3. There is a tendency toward lower verbal comprehension and poorer performance on intelligence quotient tests, with learning disabilities a common feature. There is a higher incidence of behavioral and social problems, often requiring professional help.

There are several karyotypic variants of Klinefelter syndrome with more than two X chromosomes (e.g., the karyotype 48,XXXYY). As the number of X chromosomes increases, there is a corresponding increase in the severity of the phenotype, with a greater incidence of mental retardation and with more physical abnormalities than in the typical syndrome. Approximately 15% of individuals with some of the Klinefelter phenotype have 47,XXY/46,XY mosaicism. Such mosaic individuals have more variable phenotypes and have a somewhat better prognosis for testicular function. In general, chromosome aneuploidies that include the Y chromosome are less likely to be diagnosed clinically during infancy or childhood. In fact, individuals are often first diagnosed during evaluation for infertility.

PREVALENCE OF CHROMOSOME DISORDERS IN HUMANS

Table 1-5 summarizes studies on the incidence of sex chromosome and autosomal chromosome abnormalities in humans.¹⁴

The most common autosomal numeric disorders in liveborn humans are trisomy 21, trisomy 18, and trisomy 13. Trisomy 21 is the most common aneuploidy among liveborn humans, and balanced reciprocal translocations occur almost as frequently. Trisomy 13 occurs at a much lower frequency than trisomy 18 or trisomy 21, possibly because of increased fetal demise with this mutation.¹⁴ Among sex chromosomes, aneuploidies 45,X, 47,YYY, and 47,XXY are seen in liveborn infants.

It is noteworthy that the incidence of common chromosome abnormalities such as trisomy 21 is almost 10 times greater than

TABLE 1-4 45,XO Phenotype: Major Features and Their Incidence

Feature	Incidence (%)
Small stature, often noted at birth	100
Ovarian dysgenesis with variable degree of hypoplasia of germinal elements	90+
Transient congenital lymphedema, especially notable over the dorsum of the hands and feet	80+
Shieldlike, broad chest with widely spaced, inverted, and/or hypoplastic nipples	80+
Prominent auricles	80+
Low posterior hairline, giving the appearance of a short neck	80+
Webbing of posterior neck	50
Anomalies of elbow, including cubitus valgus	70
Short metacarpal and/or metatarsal	50
Narrow, hyperconvex, and/or deep-set nails	70
Renal anomalies	60+
Cardiac anomalies (coarctation of the aorta in 70% of cases)	20+
Hearing loss	50

TABLE 1-5 Incidence of Chromosomal Abnormalities in Surveys of Newborns

Type of Abnormality	Number	Approximate Incidence
Sex chromosome aneuploidy		
Males (43,612 newborns)		
47,XXY	45	1/1000
47,XYY	45	1/1000
Other X or Y aneuploidy	32	1/1350
Total	122	1/360 male births
Females (24,547 newborns)		
45,X	6	1/4000
47,XXX	27	1/900
Other X aneuploidy	9	1/2700
Total	42	1/580 female births
Autosomal aneuploidy (68,159 newborns)		
Trisomy 21	82	1/830
Trisomy 18	9	1/7500
Trisomy 13	3	1/22,700
Other aneuploidy	2	1/34,000
Total	96	1/700 live births
Structural abnormalities (68,159 newborns) (sex chromosomes and autosomes)		
Balanced rearrangements		
Robertsonian	62	1/1100
Other	77	1/885
Unbalanced rearrangements		
Robertsonian	5	1/13,600
Other	38	1/1800
Total	182	1/375 live births
All chromosome abnormalities	442	1/154 live births

From Hsu LYF: Prenatal diagnosis of chromosomal abnormalities through amniocentesis. In Milunsky A, editor: Genetic disorders and the fetus, ed 4, Baltimore, 1998, Johns Hopkins University Press, p 179.

the incidence of genetic diseases such as achondroplasia, hemophilia A, and Duchenne muscular dystrophy. The cumulative data on chromosome abnormalities reveal an unanticipated finding: Chromosome analysis in newborns from several worldwide population samples showed the overall incidence of chromosome abnormalities to be 0.5% to 0.6%. In a large series of almost 55,000 infants, more than two thirds had no significant physical abnormality in association with these chromosomal defects, and among the one third with significant phenotype abnormalities, almost 66% had trisomy 21.¹⁴

CHROMOSOME ABNORMALITIES IN ABORTUSES AND STILLBIRTHS

About 15% of pregnancies terminate in spontaneous abortions, and at least 80% of those do so in the first trimester. The incidence of chromosome abnormalities in spontaneous abortuses during the first trimester has been reported to be as high as 61.5%.²¹ Table 1-6 summarizes the karyotype incidence in chromosomally abnormal abortuses.¹⁴ For comparison, note the incidence of chromosome abnormalities in liveborn infants (see Table 1-5). At an incidence of 19%, 45,XO is the most common chromosome abnormality found in first-trimester spontaneous abortions. Comparison with the relatively low incidence of 45,XO in liveborn infants suggests that most conceptuses with

this karyotype are aborted spontaneously. Trisomic embryos are seen for all autosomes except chromosomes 1, 5, 11, 12, 17, and 19.

The studies of Creasy and colleagues²² and Hassold²³ offer a comparison between karyotypic abnormalities in live births and in spontaneous abortions (Table 1-7). Triploidy or tetraploidy and trisomy 16 are the most common autosomal abnormalities in spontaneous abortuses but are never seen in live births. Comparison of the overall incidence of about 1 per 830 live births for trisomy 21 with the incidence in abortuses suggests that approximately 78% of trisomy 21 conceptuses are aborted spontaneously.

SUMMARY OF MATERNAL-FETAL INDICATIONS FOR CHROMOSOME ANALYSIS

Among all genetic aspects of maternal-fetal medicine, chromosome mutations and clinical syndromes associated with a

dysmorphic phenotype constitute the category that most often requires the physician's attention. It is worthwhile, therefore, to review indications for the consideration, at least, of chromosome analysis as part of the evaluation of fetus, infant, or parents. The following situations would justify chromosome analysis.

Abnormal Phenotype in a Newborn Infant

Most abnormal phenotypes in the newborn resulting from chromosome abnormalities reflect abnormal autosomes. The important findings that should prompt karyotyping include (1) low birth weight or early evidence of failure to thrive; (2) any indication of developmental delay, in particular mental retardation; (3) abnormal (dysmorphic) features of the head and face, such as microcephaly, micrognathia, and abnormalities of eyes, ears, and mouth; (4) abnormalities of the hands and feet; and (5) congenital defects of various internal organs.

A single isolated malformation or mental retardation without an associated physical malformation significantly reduces the likelihood of a chromosome abnormality. Disorders of the sex chromosomes are more likely to be associated with phenotypic ambiguity of the external genitalia and perhaps slight abnormality in growth pattern. Certainly, any newborn manifesting sexual ambiguity should undergo a chromosome analysis. In addition to helping to exclude the possibility of a life-threatening genetic disorder (e.g., adrenogenital syndrome), the identification of sex genotype by chromosome analysis will assist attending physicians in their decisions about therapy and counseling for the parents. For the infant with suspected autosomal abnormalities, in whom chromosomal genotype is urgently needed to inform decisions about the infant's care, rapid chromosome analysis can be obtained by culture of bone marrow aspirate. If a familial chromosome mutation, such as unbalanced translocation, is detected in the infant, karyotyping of other kindred is indicated.

Unexplained First-Trimester Spontaneous Abortion with No Fetal Karyotype

Couples often seek medical help because of recurrent first-trimester abortions when there is no previous karyotype for aborted tissue. Many genetic centers now recommend parental karyotyping after several (usually two or three) spontaneous abortions have occurred. The likelihood of a parental genome mutation is probably greatest if the couple has already produced a child with birth defects. When a parental chromosome structural abnormality is identified, genetic counseling and prenatal fetal monitoring in all subsequent pregnancies are advised.

Stillbirth or Neonatal Death

Unless an explanation is obvious, any evaluation of a stillborn infant or a child dying in the neonatal period should include chromosome analysis. There is an approximately 10% incidence of chromosomal abnormalities in such infants identified by traditional karyotyping, compared with less than 1% for liveborn infants surviving the neonatal period. The likelihood of finding a chromosome mutation is increased significantly if intrauterine growth retardation or phenotypic birth defects are present. The National Institute of Child Health and Human Development (NICHD) Stillbirth Collaborative Research Network conducted a population-based study of stillbirth, complementing standard postmortem examinations and karyotype analyses with SNP arrays to detect CNVs of at least 500 kilobases in

placental or fetal tissue.²⁴ The findings in 532 stillbirths demonstrated that microarray analysis was more often informative and provided better detection of genetic abnormalities than standard analysis (aneuploidy or pathogenic CNVs, 8.3% versus 5.8%, respectively; $P = .007$). In addition, microarray analysis identified more genetic abnormalities among antepartum stillbirths ($n = 443$; 8.8% versus 6.5%; $P = .02$) and stillbirths with congenital anomalies ($n = 67$; 29.9% versus 19.4%; $P = .008$). Microarray analysis increased the diagnosis of genetic abnormalities by 41.9% in all stillbirths, 34.5% in antepartum stillbirths, and 53.8% in stillbirths with anomalies.

Fertility Problems

Among women presenting with amenorrhea and couples presenting with a history of infertility or spontaneous abortion, the incidence of chromosomal defects is between 3% and 6%. In some men presenting with infertility, deletions in the Y chromosome have been found.²⁵ Others have spermatogenic failure or absence of sufficient sperm production. The Y chromosome expresses more than 100 testis-specific transcripts. Several deletions that extinguish expression of some of these transcripts have been found in association with spermatogenic failure. Screening for such deletions in infertile men is now a standard part of clinical evaluation. In addition, other Y-chromosome structural variants have been described with the use of techniques such as high-resolution aCGH (described earlier). Some of these structural variants affect gene copy number, although additional research is necessary to address the phenotypic effects of such structural variants.

Neoplasia

All patients with cancer present with some element of genomic instability or specific chromosomal defects that are pathognomonic for specific cancers, especially hematologic malignancies.

Detection of Fetal Aneuploidy

There is an increased risk of chromosomal abnormalities among fetuses conceived in women older than 30 to 35 years.²⁶ In contemporary practice, aneuploidy screening is offered to all pregnant women, including the option of first-trimester nuchal fold measurement combined with serum biomarker screening or second-trimester serum screening, or both. In addition, increased paternal age after 30 years old also increases the rate of de novo fetal chromosomal abnormalities at an approximate rate of two additional mutations per year.²⁷ Screen-positive patients are traditionally offered chorionic villus sampling (CVS) or amniocentesis, with karyotype assessment of the chorionic fibroblasts or amniocytes, respectively. However, chromosomal microarray analysis appears to offer both advantages and disadvantages over traditional karyotype analysis in this setting.²⁸ In one study of samples obtained from women undergoing prenatal diagnosis at multiple centers, both standard karyotyping and chromosomal microarray analysis were performed on each sample. A total of 4406 women underwent prenatal diagnosis because of advanced maternal age (46.6%), abnormal result on Down syndrome screening (18.8%), structural anomalies on ultrasonography (25.2%), or other indications (9.4%). Microarray analysis was successfully performed on 4340 (98.8%) of these fetal samples, and 87.9% of samples could be used without tissue culture. Of note, microarray analysis of the 4282 non-mosaic samples identified all the aneuploidies and unbalanced

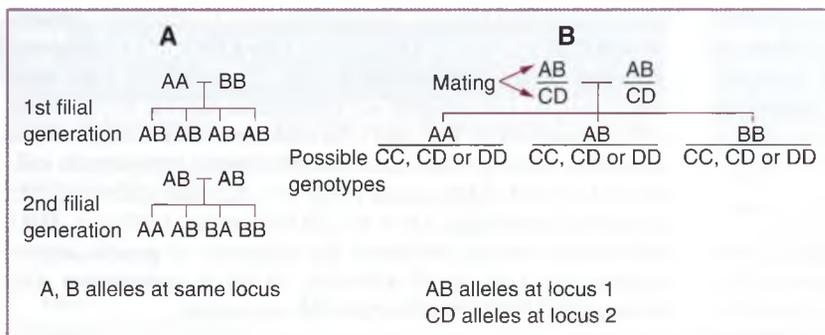

Figure 1-25 Mendel's first and second laws. **A**, Segregation: With A and B representing alleles at the same locus, a mating of homozygous A and homozygous B individuals results in heterozygotes for A and B in each offspring. Mating of AB heterozygotes results in a 1-2-1 segregation ratio in offspring. **B**, Independent assortment: The segregation of genotypes for A and B at locus 1 is independent of the segregation of alleles C and D at locus 2. (From Kelly TE: Clinical genetics and genetic counseling, Chicago, 1980, Year Book Medical.)

rearrangements that were also identified on karyotyping but did not identify balanced translocations and fetal triploidy. However, in samples with a putatively normal karyotype, microarray analysis revealed clinically relevant deletions or duplications in 6.0% of those with a structural anomaly and in 1.7% of those whose indications were advanced maternal age or a positive screening result. Therefore, chromosomal microarray analysis can identify additional, clinically significant cytogenetic information compared with karyotyping but does not identify balanced translocations and triploidies.

The fetus and placenta are the source of about 5% of the cell-free DNA in maternal plasma. In mothers whose fetus has trisomy 21, there are 2.5% more chromosome 21 transcripts present in her blood than if her fetus is unaffected. This difference has been exploited to detect fetal trisomy by analysis of cell-free DNA in maternal blood. Studies to evaluate the reliability of cell-free DNA analysis reported that, although a small percentage of cases were noninformative, trisomy 21 was detected in plasma samples with almost 100% accuracy.²⁹⁻³¹

The American College of Obstetricians and Gynecologists (ACOG) has opined that cell-free DNA appears to be the most effective screening test (98% detection rate with a 0.5% false-positive rate) for aneuploidy in high-risk women. This group recommends the use of cell-free DNA as a primary, not definitive, screening test for women at increased risk of aneuploidy or as a follow-up test for women with a positive first-trimester or second-trimester screening test result.³² Because of the possibility of false-positive and false-negative results, the ACOG suggests that the finding of a fetal structural anomaly should prompt more conventional invasive prenatal tests.

Whereas the detection of many fetal structural anomalies has traditionally prompted karyotype analysis or, more recently, chromosomal microarray analysis, there are reports of whole genomic sequencing (WGS) on amniotic fluid specimens. This technique has the potential to revolutionize prenatal testing by allowing precise diagnosis of the causes of structural abnormalities. In one report, the presence of anomalies and polyhydramnios in a fetus with a balanced de novo translocation prompted WGS, which detected a disrupted CHD7 gene—a causal locus in CHARGE syndrome (coloboma, heart defect, atresia of the choanae, retardation, and genital and ear anomalies).³³

Patterns of Inheritance

Single-gene traits are those determined by a single locus. They segregate on the basis of two fundamental laws of genetics in diploid organisms that were established by Gregor Mendel

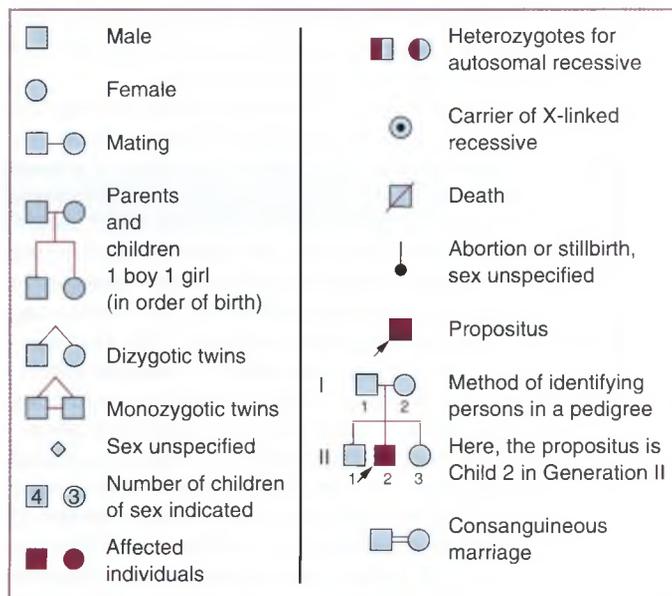

Figure 1-26 Symbols commonly used in pedigree charts. (From Nussbaum RL, McInnes RR, Willard HF: Thompson and Thompson's genetics in medicine, ed 6, Philadelphia, 2001, Saunders.)

using garden peas in 1857. These two laws are *segregation* (Fig. 1-25A) and *independent assortment* (see Fig. 1-25B). In medical genetics, the term *mendelian disorders* refers to single-gene phenotypes that segregate distinctly within families and generally occur in the proportions noted by Mendel in his experiments. Specific phenotypic or genotypic traits are inherited in distinct fashions, depending on whether the responsible gene is on the X chromosome or an autosome and whether one or two mutant alleles of that gene are necessary for a phenotype. A phenotype is *dominant* if it is expressed when present on only one chromosome of a pair; *recessive* traits are expressed only when present on both chromosomes. A dominant trait has the same phenotype when present on either one or two chromosome pairs. If a phenotype is expressed when present as a single copy but is expressed more strongly when present on two chromosomes, the trait is said to be *codominant*. The late Victor McKusick's catalog of single-gene phenotypes and mendelian disorders³⁴ is available online³⁵ (see Table 1-1) and is an indispensable reference for human genetic traits and disorders.

Familial studies for genetic evaluation require the development of a pedigree or a graphic representation of family history data. Figure 1-26 illustrates symbols that are useful

in this process. This aspect of data gathering serves several functions:

1. It assists in the determination of transmission for the gene expression in question (i.e., recessive, dominant, sex-linked, or autosomal).
2. There is a greater likelihood that all possible genetic issues will be included in the data gathering when a formal pedigree is assembled.
3. If consanguinity is present, the pedigree helps to associate consanguinity with individuals in subsequent generations who are expressing the phenotype of a particular heritable disorder.

AUTOSOMAL DOMINANT MODE OF INHERITANCE

In autosomal dominant inheritance, the disease is expressed in the heterozygote. The probability of transmitting the gene to progeny is 50% with each pregnancy. The pedigree in Figure 1-27 demonstrates the features of inheritance of an autosomal dominant disease: gene expression in each generation, approximately half of the offspring affected (both males and females), and father-to-son transmission.

Criteria for Autosomal Dominant Inheritance

The criteria for autosomal dominant inheritance may be summarized as follows:

1. Expression of the gene rarely skips a generation.
2. Affected individuals, if reproductively fit, transmit the gene to progeny with a probability of 50%.
3. The sexes are affected equally, and there is father-to-son transmission.
4. A person in the kindred who is not affected will not transmit the gene to progeny.

Other Characteristics

Other characteristics, although not exclusive properties of autosomal dominant disease, seem to associate with this group of diseases more frequently.

Variable Expressivity. Variable expressivity refers to the degree of severity of expression of a trait and is commonly seen in those in kindreds with autosomal dominant traits. In neurofibromatosis, for example, affected kindred may exhibit a range of phenotypic expression, from some café-au-lait spots with a few tumors to extensive café-au-lait spots with massive neurofibromata.

Penetrance. Penetrance refers to whether there is any recognition of phenotypic expression of a particular mutant allele. If an allele is fully penetrant, the trait is always expressed in individuals in whom it is present. On the other hand, if an allele

displays incomplete penetrance, not all individuals with that gene will display a recognizable phenotype. For example, in the autosomal dominant form of retinoblastoma, the mutant gene is only 80% penetrant. This means that in 20% of individuals who inherit the gene for retinoblastoma, the disease phenotype will not be expressed.

Penetrance may also be influenced by the means available to detect expression of the gene. For example, in autosomal dominant hypercholesterolemia, a myocardial infarction (a manifestation of gene expression and penetrance) may not appear until well into adult life. However, in this disorder, there is a laboratory test for expression—the serum cholesterol level, which becomes elevated early in life, before angina pectoris is diagnosed.

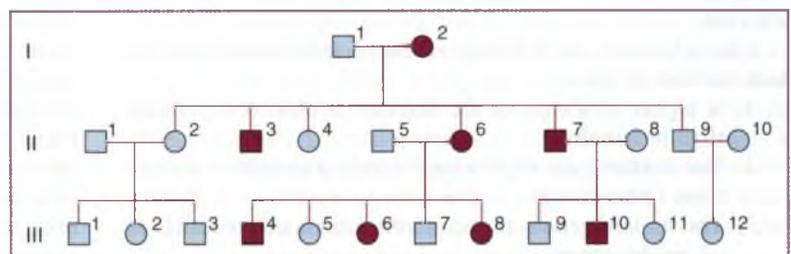

New Mutations. It is not uncommon for an autosomal dominant disorder to appear in kindred for the first time as a new mutation. New mutations are also seen with sex-linked recessive disorders. For example, in a form of autosomal dominant dwarfism called achondroplasia, almost 80% of individual cases represent new mutations. When this phenomenon can be identified with certainty, parents may be reassured that the recurrence risk is probably no greater than that for the general population; that is, the recurrence risk for offspring of the affected individual is 50%. New mutations for some autosomal dominant diseases appear to be related to paternal age.²⁷

AUTOSOMAL RECESSIVE MODE OF INHERITANCE

For autosomal recessive diseases, mutant genes are expressed only in homozygous individuals. Consanguinity and common ethnic background are often clues to autosomal recessive inheritance when the specific gene mutation has not been identified. A pedigree consistent with autosomal recessive inheritance is shown in Figure 1-28. Primary features consistent with autosomal recessive inheritance may be summarized as follows:

1. Both males and females are affected.
2. Unless consanguinity or random selection of heterozygous matings in each generation occurs, mutant gene expression may appear to skip generations (in contrast to autosomal dominant inheritance, which rarely skips generations).
3. Parents are usually unaffected, but unaffected siblings of affected homozygotes may be heterozygous carriers. Affected individuals rarely have affected children.
4. After identification of a propositus, the recurrence risk for homozygous affected progeny in each subsequent pregnancy is one chance in four.
5. If the incidence of the disorder is rare, consanguineous parentage or a common ethnic background is often present.

Figure 1-27 Stereotypical pedigree of autosomal dominant inheritance. Half the offspring of affected persons (7 of 14) are affected. The condition is transmitted only by affected family members, never by unaffected ones. Equal numbers of males and females are affected. Male-to-male transmission is seen. (From Nussbaum RL, McInnes RR, Willard HF: Thompson and Thompson's genetics in medicine, ed 6, Philadelphia, 2001, Saunders.)

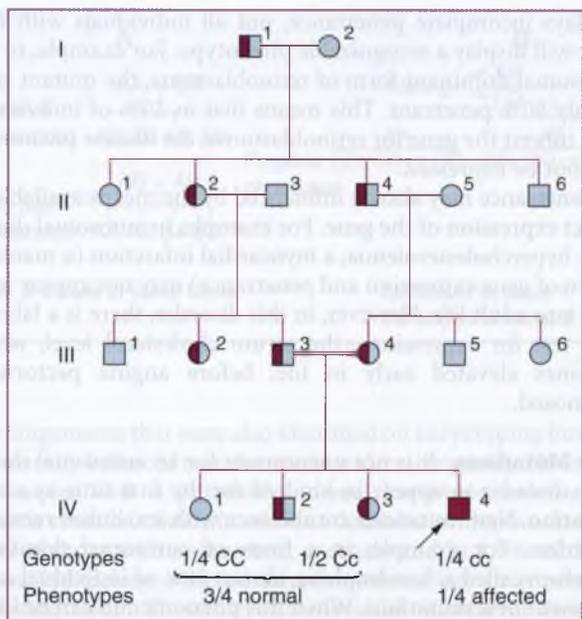

Figure 1-28 Stereotypical pedigree of autosomal recessive inheritance, including a cousin marriage. A mutant allele from a common ancestor (I-1) has been transmitted down two lines of descent to "meet itself" in IV-4 (arrow). (From Nussbaum RL, McInnes RR, Willard HF: Thompson and Thompson's genetics in medicine, ed 6, Philadelphia, 2001, Saunders.)

SEX-LINKED MODE OF INHERITANCE

In this discussion, the term *sex-linked* refers to inheritance from the X chromosome. For this group of genetic diseases, the male is considered to be hemizygous in relation to X-linked genes, whereas females are almost always heterozygous. However, because of patterns of X inactivation, females of some X-linked disorders may be more mildly affected than males with the same disorder.

Hemophilia A is among the best-known X-linked recessive diseases. For illustrative purposes, we shall use the symbol X_h to represent the recessive allele for hemophilia A on the X chromosome and X_H to represent the normal or dominant allele. The diagrams in Figure 1-29 demonstrate progeny genotypes in matings between an affected male and a normal female (see Fig. 1-29A) and matings between a normal male and a heterozygous, phenotypically normal female (see Fig. 1-29B). If the father is affected, all sons will be normal and all daughters will be phenotypically normal, heterozygous carriers. In the other mating cross, each daughter will have a 50% chance of being a normal homozygote and a 50% chance of being a heterozygous carrier who is phenotypically normal, whereas each son will have a 50% chance of being normal and a 50% chance of being affected.

Characteristics of X-linked recessive inheritance may be summarized as follows:

1. A higher incidence of the disorder is observed in males than in females.
2. The mutant gene expression is never transmitted directly from father to son.
3. The mutant gene is transmitted from an affected male to all his daughters.

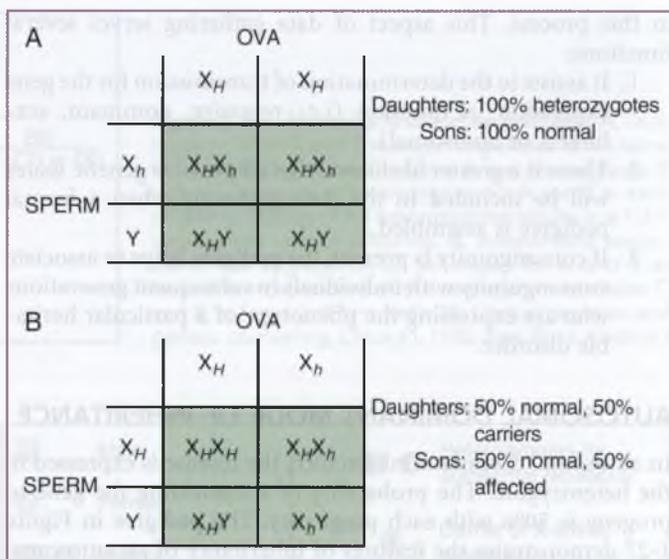

Figure 1-29 Sex-linked recessive inheritance patterns. A, Cross between a male with the gene for hemophilia A (X_h) and a female homozygous for the normal allele (X_H). B, Cross between a normal male and a female carrier of the recessive gene. (From Nussbaum RL, McInnes RR, Willard HF: Thompson and Thompson's genetics in medicine, ed 6, Philadelphia, 2001, Saunders.)

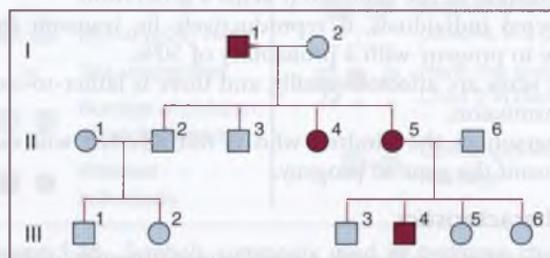

Figure 1-30 Stereotypical pedigree of X-linked dominant inheritance. Affected males have no affected sons and no normal daughters. (From Nussbaum RL, McInnes RR, Willard HF: Thompson and Thompson's genetics in medicine, ed 6, Philadelphia, 2001, Saunders, 2001.)

4. The trait is transmitted through a series of carrier females, and affected males in a kindred are related to one another through the females.
5. For sporadic cases, there may be an increase in the age at which the maternal grandfather fathered the mother of an affected child (similar to the increase in paternal age for certain new dominant mutations).

In contrast to X-linked recessive inheritance, X-linked dominant disorders are almost twice as common in females as in males (Fig. 1-30). For example, none of the sons of a male affected with vitamin D-resistant rickets will be affected, but all of his daughters will inherit the mutant gene, and because the mutant is dominant, they will all have the disease. A female with one X-linked mutant dominant allele will have the disease, and the transmission to her progeny, assuming a hemizygous normal mate, will be indistinguishable from that observed in autosomal dominant inheritance. As a group, the X-linked dominant disorders are relatively uncommon; examples include vitamin D-resistant rickets (hypophosphatemia) and the X-linked blood group X.

The distinguishing features of X-linked dominant inheritance are summarized as follows:

1. All daughters of affected males have the disorder, but no sons are affected.
2. Heterozygous affected females transmit the mutant allele at a rate of 50% to progeny of both sexes. If the affected female is homozygous, all her children will be affected.
3. The incidence of X-linked dominant disease may be twice as common in females as in males.

Some rare disorders are exclusively or almost exclusively seen in females. Examples are Rett syndrome and incontinentia pigmenti type 2, which appear to be X-linked dominant conditions in which affected males die before birth.

MULTIFACTORIAL INHERITANCE

Not everything that runs in families is genetic and not everything that is genetic runs in families. The phenotype we observe in any one person is produced by the interaction of a particular genotype with the environment. Environmental and sociologic factors such as diet, age at first pregnancy, socioeconomic level, access to health care, and environmental conditions often segregate in families along with genes. An excellent example is the occurrence in families of cholera or tuberculosis. Although susceptibility to infectious diseases can be modulated by genetic inheritance, the susceptibility of a family to these diseases is most likely the result of unsanitary conditions (cholera) or chronic exposure (tuberculosis). Another example is susceptibility to type II diabetes, wherein carriers may express this trait only when overweight. Some genetic disorders are sufficiently devastating that they are rarely, if ever, transmitted between generations, and most cases occur as *de novo* mutations. Examples of genetic disorders for which many patients have no family history include chromosomal abnormalities (e.g., Down syndrome), contiguous gene syndromes (e.g., Prader-Willi syndrome, Angelman syndrome, Smith-Magenis syndrome), and single-gene disorders for which one copy of the gene is not enough (called *haploinsufficiency*) (e.g., neurofibromatosis type I). Clinicians should be aware that common disorders often have both genetic and nongenetic components to their etiology. A clinician who might encounter either familial clusters or rare genetic disorders should be familiar with the concepts used to distinguish genetic from nongenetic transmission.

Heritability

A measure of the genetic contribution to disease is *heritability*, which is defined as the amount of phenotypic variation explained by genes relative to the total amount of variation. A more detailed treatment of statistical estimates of heritability can be found in texts devoted to genetic analysis.^{36,37} High heritability does not imply the action of a single gene but rather a greater contribution of genes compared with environmental or stochastic factors for the characteristic being studied. Disorders (or susceptibility to them) may be inherited as monogenic, oligogenic, or polygenic in a given family. A disease with high heritability may also be inherited in different families through mutations of different genes. A disease that is caused by any of several mutations in the same gene shows *allelic heterogeneity*. A disease that can be caused by changes in any of several different genes shows *locus heterogeneity*. A disease caused by environmental factors that mimics a genetic disorder is said to *phenocopy* that disorder.

Recurrence Risk

One common statistical measure that estimates heritability is the recurrence risk to family members of an index case or proband. This is often expressed as the ratio of risk in a first-degree relative divided by the risk in the general population. Recurrence risk to full siblings is a common measure, but depending on the structure of available patient populations, first cousin, grandparent/grandchild, and other comparisons have been used.

Twin Studies

Twin studies are extremely valuable in distinguishing effects of shared genes from effects of shared environment, particularly for diseases with complex etiologies. A genetic contribution to a trait or disease can be seen as a difference in recurrence risk or concordance rate between monozygotic twins (who are derived from a single fertilization event and therefore are genetically identical) and dizygotic twins (who are derived by independent fertilization of two eggs released in the same cycle and therefore share half of their genes). All twins generally share both prenatal and postnatal environments. Monozygotic twins also share all of their genetic complement, but dizygotic twins share only half of theirs. Therefore, any substantial difference in concordance rate (or recurrence risk) between monozygotic and dizygotic twins as a group is taken as evidence of a genetic component.

Complex Inheritance

Many common disorders show complex inheritance. Allergy, asthma, autism, cancer, cleft lip and palate, diabetes, dizygotic twinning, handedness, hypertension, multiple sclerosis, neural tube defects, obesity, and schizophrenia are all examples of such complex traits with population frequencies greater than 1%. Such disorders may have rare single-gene (monogenic) forms, but most cases have more complex etiologies. Complex disorders include examples of polygenic inheritance, in which several genes contribute to the disease in the absence of environmental effects, and multifactorial inheritance, in which genes and environment interact to produce disease. In practice, a complex trait may have monogenic, polygenic, and multifactorial forms—and possibly more than one of each. Although such etiologic heterogeneity makes identification of the underlying genes (and environmental risk factors) more difficult, several characteristic features help to identify disorders with complex inheritance.

Complex inheritance may involve either *quantitative traits* or *qualitative traits*. In a quantitative trait, each causal gene or nongenetic factor contributes incrementally to a measurable outcome, such as height, body mass index, or age at onset of disease. A qualitative trait has alternative outcomes that either are nonquantitative or are very imprecisely quantified in practice; each causal gene contributes to meeting a threshold for expression of the trait or to the probability of expressing the trait, such as susceptibility to disease. Note that these modes are not completely distinct: susceptibility genes may act quantitatively on the probability of disease for each individual, but clinical outcome may be qualitative (e.g., presence or absence of the disease). Disease genes may act additively to reach a qualitative threshold for disease and also, beyond the threshold, contribute to disease severity. Stratifying patients by intermediate phenotypes, disease severity, or known risk factors may simplify the inheritance patterns of some complex traits.

Recent technical advances have greatly increased our ability to identify individual genes in complex disorders. The public availability of the consensus human genome sequence, along with deep databases of SNPs, CNVs, and high-throughput genotyping platforms allows investigators to interrogate the entire genomes of clinical subjects for genetic linkage or statistical associations to clinical phenotypes. Maps defining common human haplotypes (arrangements of alleles at successive loci along an individual chromosome) have added further power to study designs for detecting disease genes in genome-wide association studies (GWAS—also called whole-genome association studies, or WGAS). Expanded repositories (and consortia of smaller repositories) for both clinical data and physical samples have begun to allow statistically highly significant genetic findings for disorders that previously had resisted less powerful analyses; an example is the Wellcome Trust Case Control Consortium.³⁸ Continued progress in identifying genes contributing to complex traits is expected over the next several years. This places additional importance on the ability of practicing physicians to identify clinical presentations and families that fit particular inheritance patterns. For the most up-to-date information on specific genes, loci, and disorders, the reader is encouraged to consult online sources, particularly the OMIM³⁵ and PubMed databases maintained by the National Center for Biotechnology Information in the National Library of Medicine (www.ncbi.nlm.nih.gov).

Characteristic Features of Complex Traits

Regression to the Mean. Complex traits involve the inheritance of many alleles at multiple loci that determine the phenotype of an individual in a particular environment. Offspring of severely affected individuals tend to be less extreme in phenotype than the parents; that is, they regress to the mean of the population. Independent assortment in meiosis results in different combinations of genes being passed to offspring, and changes of environment result in varying traits expressed by the offspring. Using a familiar example of a nondisease trait, very tall parents will have taller than average children, but in general children of the tallest parents will not inherit all of the “tall factors” that the parents have.

Heritability. Complex traits have heritability estimates that span a wide range. They are, by definition, less heritable than fully penetrant monogenic traits but more heritable than would be expected by chance alone. The range of heritability reflects the varying degree to which genes determine the outcome of each trait. The higher the ratio of recurrence risk in a family member to risk in the general population (or the higher the ratio of monozygotic twin concordance to dizygotic twin concordance), the more genetically tractable the disease is likely to be.

Threshold Traits. The rate of development can determine outcome in a threshold trait. The idea of a threshold trait is that if an event does not happen by a specified time in development (a developmental threshold), then a consequent phenotype, such as a physical malformation or cognitive deficit, will ensue. Developmental rates are generally determined by a combination of genetic and environmental factors.

Penetrance, Probability, and Severity. The likelihood of having a disorder or trait, given the right genotype, is called

penetrance. For simple mendelian disorders, penetrance may be at or near 100%. For traits with environmental cofactors or developmental threshold effects, the penetrance can be much lower. For some disorders, the penetrance (in terms of either likelihood or severity of the disorder) is part of the pattern of inheritance within a family. Affected relatives of a severely affected proband are likely to be more severely affected than the average case. This is the other side of regression to the mean: returning to our nondisease example, the children of very tall parents may not be as tall as their parents, but they will probably be taller than average. Taking a disease example, for a liveborn infant with unilateral cleft lip, the recurrence risk to future siblings is 2.5%, but for a liveborn infant with bilateral cleft lip and palate, the recurrence risk is 6% (see later discussion).

Increased Risk across Diagnostic Categories. Another frequent feature of complex inheritance is that relatives of the proband may be at increased risk for related diagnostic categories. This has been suggested for categories of psychiatric illness, for some autoimmune disorders, and for some malformation syndromes. The implication of this is that overlapping sets of genes and environmental factors can lead to dysfunction that manifests as related clinical entities.

Rarer Forms Show Increased Relative Risk. Forms of multifactorial disease that are less frequent in the general population tend to have higher recurrence risk ratios for families of an affected proband. For example, pyloric stenosis is five times more common in males than in females in the general population. As Table 1-8 shows, male relatives of any proband face a higher risk than their sisters, but relatives of female probands face much higher risk than relatives of male probands.

Common Disorders with Multifactorial Inheritance

Cleft Lip and Cleft Palate. Cleft lip malformation may occur with or without cleft palate (orofacial cleft) but is etiologically distinct from cleft palate alone.³⁹ These common malformations occur as a component of more than 200 described human syndromes, including several single-gene disorders, chromosomal abnormalities, and syndromes of exposure to teratogens (e.g., thalidomide). Developmentally, cleft lip with or without cleft palate results from a failure in the fusion of the frontal prominence with the maxillary process at about 7 weeks of fetal development. The incidence is twofold to fourfold higher in males than in females and varies among ethnogeographic

TABLE 1-8 Recurrence Risk of Pyloric Stenosis for First-Degree Relatives

	Risk (%)	Relative to General Population Risk
Male relatives of male patients	4.6	×10
Female relatives of male patients	2.6	×25
Male relatives of female patients	18.2	×35
Female relatives of female patients	8.1	×80

Adapted from Thompson MW: Thompson and Thompson's genetics in medicine, ed 4, Philadelphia, 1986, Saunders. Based on data from Bonaïti-Pellié C: Risk tables for genetic counselling in some common congenital malformations, J Med Genet 11:374, 1974.

groups: 0.4 per 1000 births in African Americans, 1 per 1000 births in Caucasians, and 1.7 per 1000 births in Japanese. However, the recurrence risk to first-degree relatives is lower in Japan than in Europe, suggesting a greater environmental influence in Japan.⁴⁰ Within a population, the recurrence risk varies with the severity of the defect in the proband, as described previously. Examples are shown in Table 1-9.

Cleft Palate. In cleft palate without cleft lip, the secondary palate fails to fuse. The general incidence is approximately 1 in 2500 births, and it is more common in females than males. Little ethnic variation is noted, and the recurrence risk is approximately 2%. Isolated cleft palate appears genetically distinct from cleft lip with or without cleft palate. At least one gene for isolated cleft palate, *SATB2*, has been identified.^{41,42}

Neural Tube Defects. The group of neural tube malformations is of special importance because they are prevalent and their risk can be significantly altered by diet. Mid-trimester prenatal diagnosis relies on prenatal screening for these disorders in all pregnancies. Expression of neural tube defects can be highly variable among individuals, ranging from anencephaly at one extreme to lumbar meningocele with little or no neurologic impairment at the other. The spectrum includes encephalocele, iniencephaly, meningomyelocele (usually involving the lower thoracic and lumbar spine and often called spina bifida cystica), and spina bifida. Defects arise through failure of the embryonic neural tube to close within 28 days after conception. The incidence in European-derived populations can vary substantially, from less than 1 per 1000 to almost 1 per 100 births. One study of medical records showed an approximately 10-fold decrease

in neural tube defects in England and Wales between 1964 and 2004, attributable both to a reduction in the occurrence of neural tube defects and to termination after early diagnosis.⁴³ The overall U.S. incidence is approximately 1 per 1000, but it is lower for individuals of African or Asian ancestry. Recurrence risks for anencephaly and spina bifida probands are shown in Table 1-9.

Epidemiologic and experimental animal studies have suggested that neural tube defects have characteristics indicating threshold traits as well as substantial environmental factors. For example, the importance of dietary folate in preventing neural tube defects is well documented. The incidence of this defect in Canada decreased by 50% after folate supplementation of cereals was implemented in the United States and Canada in 1998.⁴⁴ Known genetic risk factors include genes for folate and homocysteine metabolism as well as loci thought to present folate-independent risk. Work in animal models has suggested inositol as another potential metabolic factor.⁴⁵⁻⁴⁷

Pyloric Stenosis. Pyloric stenosis is the most common disorder requiring corrective surgery in infants, with an incidence of 1 to 5 of every 1000 live births. Heritability is inferred from the high recurrence risk in relatives. Carter and Evans first proposed sex-modified multifactorial inheritance in 1969.⁴⁸ Males are at higher risk than females, irrespective of family history, but the ratio of recurrence risk to general risk is higher in affected females (see Table 1-8). Mitchell and Risch⁴⁹ concluded that family studies were inconsistent with a single major locus causing pyloric stenosis, and they set model-based limits for the effect of any single locus at no greater than a fivefold increase in recurrence risk across the general population. However, single-gene effects can be seen in some extended families. Evidence from patient material⁵⁰ and the study of targeted mutations in mice^{51,52} indicate that the neuronal nitric oxide synthase gene, *NOS1*, is one locus that is associated with pyloric stenosis. An additional locus and further evidence for genetic heterogeneity were suggested by linkage analysis in a multigenerational family with 10 affected members.⁵³

Celiac Disease. Autoimmune reaction in celiac disease causes inflammatory injury to the mucosa of the small intestine, resulting in malabsorption. Once thought to be uncommon, celiac disease (or gluten-sensitive enteropathy) is now thought to affect as many as 1 of every 120 to 300 people in Europe and North America. Several factors point to multifactorial inheritance, and the recurrence risk in siblings is 10% or higher. Concordance rates for monozygotic twins are more than fourfold higher than for dizygotic twins.⁵⁴ Exposure to gluten in wheat (or other grains, such as rye or barley) is an environmental factor for genetically susceptible individuals. Genetic linkage to human leukocyte antigen has been reported, as well as linkage to several additional genetic loci.⁵⁵⁻⁵⁷ Among regions showing significant linkage, variations in *CTLA4* and *MYO9B* genes show strong association with disease.

Inflammatory Bowel Disease (Crohn Disease). Genetic components of autoimmune disease directed against the gastrointestinal tract have also been mapped in studies of Crohn disease and ulcerative colitis. Together, these somewhat overlapping diagnoses occur in 2 to 3 of every 1000 people in the United States. Genetic effects of at least 11 distinct loci for inflammatory bowel disease have been identified in this complex trait,

including linkage to the human leukocyte antigen region of chromosome 6p. As an interesting example of molecular analysis in a complex trait, Rioux and coworkers⁵⁸ mapped one locus on chromosome 5q, *IBD5*, to a cluster of inflammatory cytokine genes; several of the genes in this interval were polymorphic between patients and population control subjects, but causality for any one gene could not be determined because of strong linkage disequilibrium across the implicated region. An uncommon allele at the locus encoding the interleukin-23R cytokine receptor was identified as providing a protective effect in a GWAS.⁵⁹

Hirschsprung Disease. Congenital megacolon caused by lack of enteric ganglia along the intestine is a relatively well-studied complex genetic trait. Incidence is about 1 in 5000 births, including both short-segment and long-segment forms. Both dominant inheritance and recessive inheritance have been observed; penetrance is variable. Single-gene mutations associated with varying penetrance for Hirschsprung disease have been identified that illuminate biochemical pathways with unique importance for the establishment of enteric ganglia. Aganglionic megacolon also occurs in more complicated disorders, including cartilage-hair hypoplasia, Smith-Lemli-Opitz syndrome type II, and primary central hypoventilation syndrome. Variations in the *RET* oncogene appear to be the major risk factor in patients with Hirschsprung disease. Mutations in genes encoding endothelin 3, endothelin receptor B, and endothelin-converting enzyme, as well as neurturin, glial-derived neurotrophic factor, and the transcriptional regulator *SOX10* have been identified as risk-conferring in both human and animal studies. An exhaustive search for genetic linkage implicated two additional loci that act as oligogenic determinants of the expression of some *RET* alleles.⁶⁰ Mutation of a transcriptional enhancer of the autosomal *RET* gene confers sex-dependent risk for Hirschsprung disease.⁶¹

Congenital Heart Defects. The overall incidence of congenital heart disease is 5 to 7 per 1000 live births, and this is the leading cause of death from birth defects.⁶² This heterogeneous group of defects can be caused by single-gene mutations, chromosomal abnormalities (trisomy 21), and teratogens such as rubella and maternal diabetes. Table 1-10, abstracted from the

classic study of Nora,⁶³ summarizes the empiric recurrence risk for six common congenital heart defects. More recent familial recurrence data support the heritability of additional congenital heart defects, including transposition of the great arteries and congenitally corrected transposition of the great arteries (reviewed by Calcagni and coworkers⁶⁴). Patients with heart malformations associated with chromosomal abnormalities often present differently despite having the same cytologic findings. Allelic heterogeneity at some single-gene loci or modifying effects of either environmental factors or other genes may account for some diversity in clinical findings. For example, rare alleles of *NK2 homeobox 5*, which encodes the transcription factor *NKX2.5* have been separately implicated in atrial septal defects, hypoplastic left heart syndrome, and tetralogy of Fallot. Similarly, mutations in the *GATA4* transcription factor are reported for both atrioventricular canal defects and atrial septal defects. Mutations in the *Notch* signaling pathway are also seen in different forms of congenital heart defects.

MITOCHONDRIAL INHERITANCE

Mutations in mitochondria produce unique patterns of inheritance. Normally, all mitochondria in the fertilized oocyte come from the mother; this is termed *matrilineal* inheritance. Mitochondria are the only organelles in animal cells that carry their own DNA (i.e., mitochondrial DNA, or mtDNA). Human mitochondria contain a circular genome of 16,571 base pairs that includes 13 protein-coding regions and 22 tRNA-encoding genes (GenBank reference sequence NC_001807). In contrast to nuclear genes, which are present in two copies per diploid cell, the mitochondrial genome is present once per mitochondrion and therefore in a variable, yet high, number of copies per cell (100 to 100,000). Perhaps because of the generation of free radicals during energy production, mtDNA is subject to a relatively high rate of mutation. Mutations in mtDNA create a mixture of normal and mutant mitochondria, called *heteroplasmy*. At cell division, mitochondria segregate randomly to the two daughter cells. Because of this *replicative segregation*, a cell lineage may ultimately inherit only mutant mtDNA (*homoplasmy*). Segregation of either inherited or de novo mtDNA mutations among cell lineages can also result in a mosaic pattern across tissues of a single individual.

Modern reproductive approaches have allowed a closer examination of mtDNA transfer and inheritance as in vitro manipulation of oocytes to increase fertilization potential has become more technically feasible. Cytoplasmic and nuclear transfer from donor oocytes is used to assist reproduction and results in possible heteroplasmy of offspring. The possible effects of this generated heteroplasmy are currently being investigated; mitochondrial dysfunction is possible and may depend on the genetic likeness between donor and host.⁶⁵

Phenotypic expression of mitochondrial mutations depends on the extent of heteroplasmy, the cell type involved, and the fraction of the cell type affected. Organ systems most frequently affected by mitochondrial mutations are those with high energy requirements, particularly muscle and brain. Mutations that reduce energy production by mitochondria may produce disease whenever energy production capacity falls below a threshold level. This may be episodic if the energy threshold is crossed only during exertion or other stressors. Leber optic atrophy is perhaps the best-known example of inherited disease caused by mutations in mtDNA. Mitochondrial myopathy (a

TABLE 1-10 Frequency of Six Common Congenital Heart Defects in Sibs of Probands

Anomaly	Frequency in Sibs* (%)	Expected Frequency [†] (%)
Ventricular septal defect	4.3	4.2
Patent ductus arteriosus	3.2	2.9
Tetralogy of Fallot	2.2	2.6
Atrial septal defect	3.2	2.6
Pulmonary stenosis	2.9	2.6
Aortic stenosis	2.6	2.1

[†] \sqrt{p} , where p is the population frequency of the specific defect. From Nussbaum RL, McInnes RR, Willard HF: Thompson and Thompson's genetics in medicine, ed 6, Philadelphia, 2001, Saunders.

complex including neurodegeneration, pigmentary retinopathy, and Leigh syndrome), MERRF disease (myoclonic epilepsy with ragged red fibers), MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes), and hypertrophic cardiomyopathy are also attributable to mutations in mtDNA. Most of these are not identifiable at birth but become evident with age as later-onset, maternally inherited disorders.

Dynamic Mutations and Trinucleotide Repeats

Repetitive DNA sequences can give rise to mutations through a variety of mechanisms. Repeats of two, three, or four nucleotides are especially prone to changes in repeat length. The mutation rate depends on the repeat length of the starting allele, the genomic context, and other factors. Small changes in allele repeat length have been attributed to “slippage” of the DNA polymerase (or, more probably, the newly synthesized DNA fragment) during replication. Much larger changes in repeat length are more likely to be caused by unequal crossing over during meiosis.⁶⁶ Alleles that change within a pedigree are said to be *dynamic*. Dynamic mutations can show other unusual features of inheritance. *Premutation alleles* are those that are expanded sufficiently to be highly dynamic but are not yet disease-causing. Further expansion of the repeat results in transmission of disease alleles to offspring at a high frequency. Disease alleles are themselves dynamic and, if transmitted, may give rise to alleles with more severe phenotypes and earlier onset; this is called *anticipation*. Most dynamic mutations seen in humans thus far are caused by instability of *trinucleotide repeats*—specifically, CAG repeats encoding polyglutamine in the protein and other trinucleotides in noncoding sequences that alter expression of the encoded products.

Expanded polyglutamine repeats cause neurodegenerative disorders that have several features in common. These disorders show dominant inheritance, late onset, and neurologic symptoms that include motor signs. Examples include Huntington disease, several forms of spinocerebellar ataxia, dentatorubropallidolusian atrophy, and spinobulbar muscular atrophy. Although these disorders typically have late onset, age at onset varies inversely with the length of repeat and parental origins of the expanded allele. Extremely rarely patients have been reported to have Huntington disease as young as 2 years of age with paternal origin. Expanded polyglutamine-containing proteins are cytotoxic in several experimental contexts. The interpretation of these disorders is that expanded polyglutamine destabilizes protein structure, and the misfolded protein, often found in insoluble aggregates, impairs cellular function and ultimately leads to cell death. For a given repeat length, toxicity increases with solubility,⁶⁷ which favors a surface area model for toxicity.⁶⁸

Amplification of polyalanine homopolymers can also be associated with disease, including some evident at birth. An amplified GCG repeat encoding polyalanine in the poly(A)-binding protein gene (*PABPN1*) is associated with autosomal dominant oculopharyngeal muscular dystrophy, apparently through a toxic gain-of-function mechanism.⁶⁹ Nondynamic amplification of polyalanine (including each of the alanine codons) in the homeobox gene *HOXD13* causes synpolydactyly, and the severity of phenotypes correlates with the extent of amplification.^{70,71} Expanded polyalanine in another homeobox gene, *ARX*, results in an X-linked infantile spasm syndrome

equivalent to that seen by inactivating mutations of the same gene; it is recessive in female carriers, suggesting that, in at least one example, polyalanine expansions may act by inactivating the protein rather than through gain of toxicity. All 10 polyalanine expansions associated with human disease to date have been nucleic acid-binding proteins. In-frame loss of polyalanine repeats in at least some of these sites is also mutagenic, leading to premature ovarian failure for *FOXL2* polyalanine reductions and congenital central hypoventilation syndrome for *PHOX2B* and *ASCL1*.

Trinucleotide repeat expansions in noncoding sequences can also cause disease by altering gene expression. One example is Friedreich ataxia, an autosomal recessive neurologic disorder with juvenile onset. The most common form is caused by loss-of-function alleles of the *FRDA* (*frataxin*) gene. The most frequent class of *FRDA* allele in patients is expansion of a GAA repeat in an intron of the gene, which accounts for 98% of mutant alleles.⁷² Extremely long repeats induce an epigenetic modification that silences expression of that copy of the gene. GAA expansion alleles and rare protein-inactivating alleles have roughly the same effect on gene function.

Another example of a mutation caused by a noncoding repeat expansion is fragile X syndrome (which includes mental retardation, macro-orchidism, and facial dysmorphism). The most frequent cause of fragile X syndrome is expansion of a CGG repeat in the 5' untranslated region of the *FMR1* gene. CpG dinucleotides are targets of methylation,⁷³ and DNA of the expanded allele is hypermethylated compared with both normal and premutation (stable intermediate-length repeat) alleles. Hypermethylation in or near transcriptional control elements results in loss of *FMR1* expression of the expanded allele in affected males. Expanded CGG alleles are equivalent to isolated cases hemizygous for missense and splice-site mutations, confirming that this repeat expansion acts as a loss-of-function allele.

Autosomal dominant myotonic dystrophy (MD1) is a third example. Expansion of a CTG trinucleotide repeat in the 3' untranslated region of the *DMPK* protein kinase gene is strongly correlated with the disease and shows anticipation in families; however, the pathogenic mechanism remains unclear.

IMPRINTING

Genomic imprinting is another mode of inheritance with an atypical pattern. Although most genes seem to have equivalent expression from alleles inherited from the father and the mother, it is now known that the expression of several genes differs between the parental alleles. This phenomenon has been termed genomic imprinting, because the two parental alleles are distinguished by some sort of mark. This mark is a reversible form of chromatin modification, perhaps methylation of one of the parental alleles, that occurs during gametogenesis and before fertilization. The mark then suppresses expression of this allele after conception. This mark is reversible in the germline, so that the parent-of-origin mark can be placed anew during gametogenesis.⁷⁴

Imprinting is known to be important for normal fetal and placental development, because knockout of imprinted genes adversely affects developmental growth. However, imprinting is also implicated in disease. Prader-Willi syndrome and Angelman syndrome are examples of the phenotypic effects of imprinting. Prader-Willi syndrome is characterized by neonatal

hypotonia, childhood obesity with excessive eating, small hands and feet, hypogonadism, and mild mental retardation. Angelman syndrome is characterized by severe mental retardation, seizures, a characteristic spastic movement disorder, and an abnormal facial appearance. Although it is now known that these syndromes are caused by the loss of different genes, both syndromes can result from deletions of the same region on chromosome 15, 15q11-q13. In about 70% of cases, Prader-Willi syndrome results from the deletion of this region on the copy of chromosome 15 inherited from the father (i.e., the affected individual has only the maternal copy of this region). In about 70% of cases of Angelman syndrome, the same region is deleted and inherited from the mother, so these patients have only the paternal copy of this region. Uniparental disomy (two copies of the paternal or the maternal gene) also leads to Angelman syndrome or Prader-Willi syndrome, respectively.

Several rare disorders have now been attributed to imprinting effects. At this point, it is unclear whether imprinting is an important factor in more common disorders, but it is likely that it is involved in several human genetic disorders.

Genetic Testing and DNA Diagnostics

The realization in the 1980s that DNA variations, or polymorphisms, occur fairly frequently among individuals led to the development of both DNA forensics and molecular diagnostics for genetic disorders and risk factors.⁷⁵ DNA diagnostics in medicine can use either direct assays for a specific mutation or linkage analysis with polymorphisms linked to a disease locus. Direct assays for specific mutations are most useful when relatively few distinct mutations account for most patients with a particular form of disease. As analysis methods have become faster, cheaper, and more highly automated, performing direct sequencing of a disease gene without knowing the precise mutation has become increasingly practical, particularly for genes in which a high proportion of patients may have *de novo* mutations.

Indirect assays such as linkage analysis (Fig. 1-31) were traditionally useful for risk assessment when a disease gene had been mapped in pedigrees but was not yet identified at the molecular level. Linkage analysis requires cooperation of other family members, including usually at least one affected member, to identify marker alleles on the disease-associated chromosome in that particular pedigree. Recombination between the marker and the disease gene is a potential caveat if a single marker is used; use of markers on each side of the disease gene at least makes this evident, and the likelihood of recombination can be built into the risk assessment. In practice, linkage assays for identified diseases have become much less necessary because a high proportion of significant disease genes can be assayed directly. However, linkage analysis and family studies remain crucial to the successful identification of disease and disease susceptibility genes.

The initial molecular diagnostic techniques to make use of the recombinant DNA revolution were based on restriction fragment length polymorphisms (RFLPs) (see Fig. 1-31). RFLPs are typically assayed by Southern blotting,⁷⁶ which requires substantial amounts of DNA and is relatively labor intensive and difficult to automate, making it expensive (Fig 1-32). This approach is still used to identify large repeat expansions for genes subject to dynamic mutations.

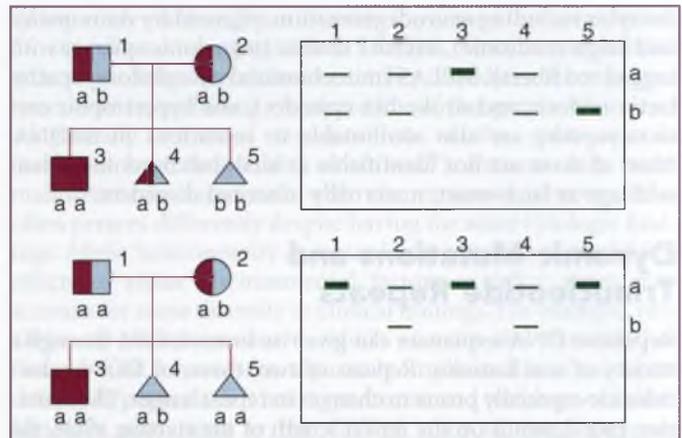

Figure 1-31 Schematic illustration of linkage by DNA probe analysis of restriction fragment length polymorphisms (RFLPs). Left, Pedigrees for two families. The darker symbols represent heterozygosity or homozygosity for the disease gene. Members tested are listed numerically. Lighter triangles represent fetuses in putative pregnancies. Letters *a* and *b* represent DNA restriction fragment lengths. Right, Gel electrophoresis patterns for the RFLPs. (Modified from Emery AEH: An introduction to recombinant DNA, New York, 1980, John Wiley & Sons.)

The development of PCR by Mullis and coworkers in the mid-1980s allowed selective amplification of any desired sequence of DNA and radically changed the power of DNA diagnostics in terms of sample requirements and the types of assays one could perform.^{77,78} Linkage markers in current use include simple sequence repeat length polymorphisms (SSLPs) and, increasingly, biallelic SNPs. SNPs in particular have the advantage of being assayable in multiplex formats, so that many distinct polymorphic sites may be interrogated in a single biochemical reaction. Several different technologies for SNP detection have been and continue to be developed to allow simultaneous detection of larger numbers of loci at smaller marginal cost. Finally, as more is known about normal CNVs and those associated with specific diseases, the detection of CNVs will become increasingly used in diagnostics.

METHODS USED IN GENETIC TESTING

The recent decline in automated sequencing costs and the development of multiple technologic options to carry out automated sequencing have resulted in its common use in genetic testing. This section provides an overview of many methods to evaluate genetic sequence variation and disease-gene characterization; however, it is most likely that during the next decade, automated genome sequencing will become the method of choice for most applications.

Hybridization-Based Methods

Nucleic acid hybridization is a simple, physical-chemical process with well-described parameters^{79,80} that forms the basis for a wide variety of molecular genetic tests. The rate and stability of nucleic acid duplexes depend on the concentration of each strand, the temperature, the ionic strength of the solution, and the presence of hydrogen bond competitors such as urea and formamide. Tests based on whole-genome Southern blots were among the first available for identification of mutations with no cytologic correlate. As discussed earlier, hybridization of

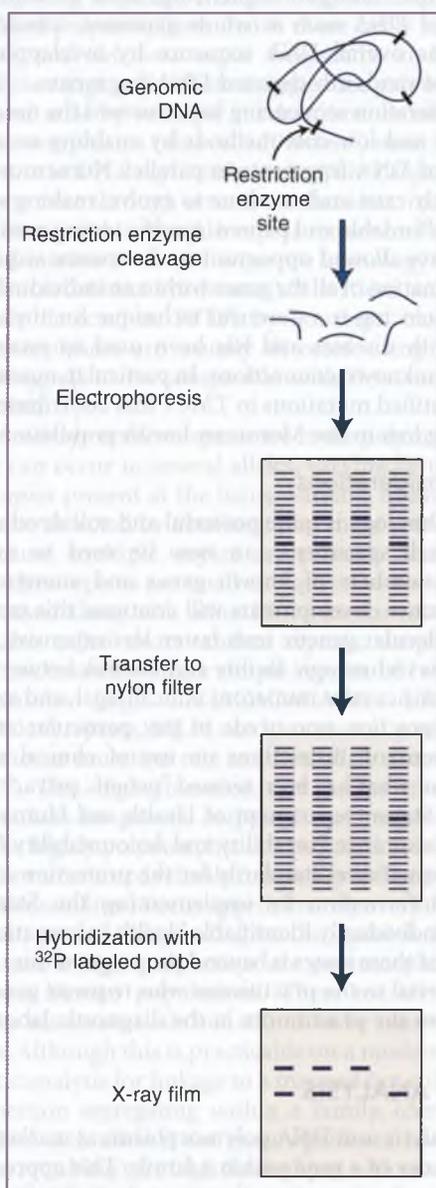

Figure 1-32 Southern blotting. DNA is cleaved by a restriction enzyme, separated according to size by agarose gel electrophoresis, and transferred to a filter. After hybridization of the DNA to a labeled probe and exposure of the filter to x-ray film, complementary sequences can be identified.

fluorescently labeled probes to fixed chromosomal spreads (FISH, SKY) allows the identification of microdeletions, microduplications, translocations, and other cytologic abnormalities that would be difficult to detect without molecular probes. Other methods include hybridization of patient DNA to allele-specific oligonucleotides to discriminate single base changes. An example of detection by allele-specific oligonucleotides is given in the reverse dot-blot analysis shown in Figure 1-33. In a reverse dot-blot analysis, the probe sequence is bound to the support matrix while the amplified patient sample is labeled and hybridized to the oligonucleotides; using this approach, a patient sample can be tested for several mutations in a single assay.

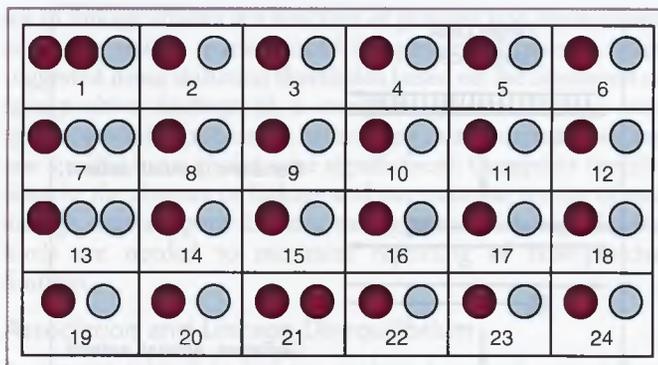

Figure 1-33 Reverse dot-blot analysis for cystic fibrosis (CF) mutations. Twenty-seven CF mutations were analyzed in this study. The complete panel represents a single filter subdivided into 24 sections. Each section is numbered for specific mutation analysis. Sections 1, 7, and 13 analyze two separate mutations. Circles on the left in each numbered section contain normal oligonucleotide sequences from the CF gene region on chromosome 7. The sequences in each section represent different regions on the gene where a mutation has been identified. Complementary normal sequences, after amplification by polymerase chain reaction (PCR), hybridize as indicated by the red circles. The blue circles represent effort at hybridization between mutant sequences fixed to the filter and DNA sequences obtained from the patient and amplified by PCR. If the patient does not have a CF mutation among the group of 27 in this analysis, there is no hybridization and the circle remains open. In this analysis, sections 1 and 21 demonstrate that this patient has two CF mutations and would be designated a compound heterozygote. This individual would most likely have clinical manifestations of CF.

Polymerase Chain Reaction

The ability to amplify DNA segments through PCR revolutionized DNA diagnostics for both medicine and forensics beginning in the mid-1980s.^{77,81,82} Synthetic oligonucleotides are used to prime DNA synthesis so that synthesis directed from each primer includes the sequence complementary to the other primer (Fig. 1-34). Multiple temperature-dependent cycles of DNA denaturation, primer annealing, and elongation of DNA synthesis create an exponential increase in copy number or amplification of the DNA sequence between the two primers. When PCR is used to amplify specific DNA fragments, multiple diagnostic tests can be performed on minimal amounts of starting material.

Variations in length, such as in dynamic mutations, can be assayed directly by PCR amplification followed by gel electrophoresis to determine the size of the PCR product. Anonymous marker loci (e.g., SNPs, SSLPs) can be assayed in the same way for gene mapping and forensic studies. SNPs are amplified singly or in a multiplex combination of loci and detected by electrophoretic, hybridization, or spectroscopic methods. SNP-based assays are expected to have increasing clinical impact in coming years because they allow highly parallel analysis. Multiplex PCR amplifications can allow parallel analysis of many genetic loci simultaneously. SNP microarray chips allow simultaneous analysis of hundreds of thousands of SNPs from a single sample, helping elucidate the contributions of single nucleotide variations in a variety of diseases and conditions. Software modification can allow SNP-based assays to detect CNVs. SNP data collections, amassed through large-scale projects such as the International Haplotype Map (HapMap) Project and the Encyclopedia of DNA Elements (ENCODE), are

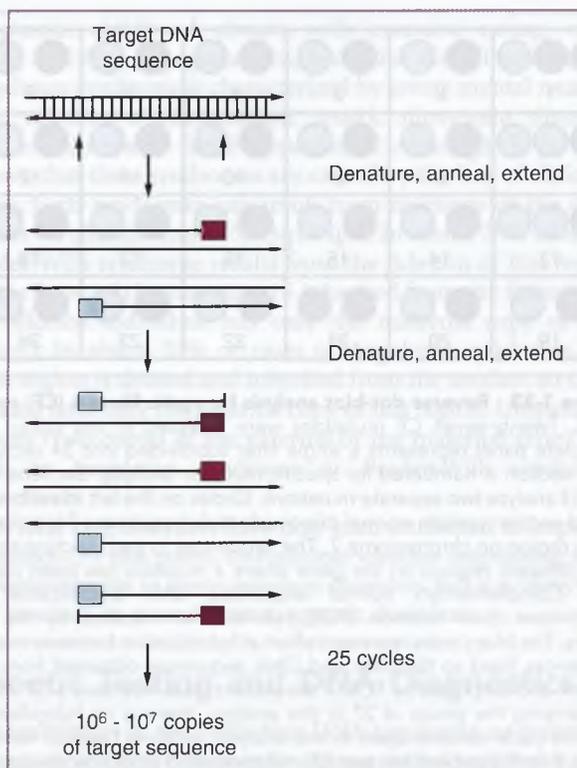

Figure 1-34 Polymerase chain reaction (PCR). Repeated synthesis of a specific target DNA sequence (upward arrows) results in exponential amplification. The reaction proceeds from the primers (blue squares, red squares) in the 3' direction on each strand. The first two cycles of the PCR are shown.

building variant databases that can be used to correlate unknown genetic variants with specific phenotypes.

Common mutations can also be assayed by PCR with the use of primers specific for each allele or by allele-specific oligonucleotide hybridization. For genes in which no single mutation is common among patients, such as the hereditary hearing loss gene *GJB2* novel sequence variations can be identified by direct DNA sequencing of PCR products from that gene.

DNA Sequencing

Modern genetics, and clinical diagnostics in particular, relies heavily on knowing the exact sequence of nucleotides in genes. Methods to identify sequences of small RNA molecules first began to appear in the late 1960s. However, the appearance in 1977 of two methods for DNA sequencing of longer fragments was a major breakthrough. The *chemical cleavage method*⁸³ uses base-specific chemistries to cleave a specified base from its sugar, followed by a second reaction to cleave the phosphodiester bond adjacent to the resulting abasic site. The *chain termination method*⁸⁴ uses enzymatic synthesis of DNA in the presence of dideoxynucleotides; dideoxynucleotides prevent further synthesis beyond their site of incorporation because they lack the 3' hydroxyl group (see Fig. 1-1). The chain termination method is widely used today and has been developed to include fluorescent labels for detection of individual nucleotides. Automated DNA sequencers have increased throughput and reduced time for sequencing reactions by using capillary electrophoresis and computer-based laser detection systems to read each nucleotide

from a sample. Shotgun sequencing, used to sequence large fragments of DNA such as whole genomes, consists of reassembling the overall DNA sequence by overlapping smaller sequences of randomly digested DNA fragments.

Next-generation sequencing has answered the need for high-throughput and low-cost methods by enabling sequencing of thousands of DNA fragments in parallel. Numerous technologies currently exist and continue to evolve, making sequencing ever more affordable and patient-specific testing possible. These advances have allowed opportunities for exome sequencing, or the determination of all the genes within an individual's genome. Exome sequencing is a powerful technique for the association of genes with diseases and has been used to establish many previously unknown connections. In particular, exome sequencing has identified mutations in *TMC1* that contribute to hereditary hearing loss in the Moroccan Jewish population.⁸⁵

Other Considerations

Current technology is quite powerful and still developing. Vanishingly small specimens can now be used to query ever-expanding numbers of known genes and anonymous DNA markers. Future developments will continue this trend toward making molecular genetic tests faster, less expensive, and more reliable. This technologic facility and the link between diagnostics and forensics raise numerous ethical, legal, and social issues. In current practice, one needs to pay particular attention to informed consent, restrictions on use of clinical material in research, and what has been termed "genetic privacy." Through the United States Department of Health and Human Services, the Health Insurance Portability and Accountability Act of 1996 (HIPAA) set national standards for the protection and privacy of health information by implementing the Standards for Privacy of Individually Identifiable Health Information. Further discussion of these issues is beyond the scope of this chapter but they are as vital to the practitioner who requests genetic testing as they are to the practitioner in the diagnostic laboratory.

LINKAGE ANALYSIS

Linkage analysis uses DNA polymorphisms as markers to follow the inheritance of a gene within a family. This approach is used to identify unknown genes that contribute to disease and to follow disease-associated chromosomal segments in affected families before the causal mutation is pinpointed. Linkage analysis takes advantage of meiotic recombination by counting how frequently two loci are inherited together. By comparing the inheritance of a disease with inheritance of alleles at several known DNA polymorphisms (marker loci), it is possible to map the positions of disease genes. Theoretically, any single-gene disorder should be amenable to carrier identification and prenatal diagnosis by linkage analysis once the gene is mapped.

DNA polymorphisms are codominantly inherited, meaning that each allele carried by an individual should be detected in a well-designed assay. Several kinds of DNA polymorphisms are frequent in the human genome and have been used in linkage studies, historically and currently.

RFLPs arise through insertions (often of mobile repetitive elements, such as Alu), deletions, and base changes at restriction sites (particularly through deamination of C residues in CG dinucleotides). Assays for RFLP markers by Southern blotting were described previously. RFLPs that have diagnostic importance are usually either converted to a PCR-based assay focused

on the underlying sequence change or replaced for diagnostic use by a linked polymorphism that is more easily assayed.

Insertions and deletions occur frequently in the human genome. These range in size from a single base pair to multigene segments and arise by multiple mechanisms. Small insertion-deletion polymorphisms (also called “indels”) most likely occur through errors in DNA replication and repair. Larger insertions and deletions arise through several mechanisms, including retrotransposition (such as for Alu repeat sequences) and illegitimate recombination at sites of sequence homology (a frequent finding in microdeletion syndromes). Insertions and deletions were initially detected as RFLPs by Southern blotting. Now indel polymorphisms are usually detected using PCR-based methods designed to be compatible with detection of SNPs, CNVs, or both.

Variable number tandem repeats are more polymorphic than RFLPs and can occur in several alleles, varying by the number of repeat copies present at the locus. Variable number tandem repeats can be detected by Southern blot more sensitively than RFLPs, because multiple copies are present. Some variable number tandem repeats are small enough to be assayed by PCR and can be used along with other PCR-based markers.

SSLPs (also called short tandem repeats, simple sequence repeats, or microsatellites) are simple repeats of two, three, or four nucleotides (e.g., CACACACACACA). Like variable number tandem repeats, SSLPs can have several possible alleles. The spontaneous mutation rate to a new allele size ranges from 10^{-3} to 10^{-6} . This high mutation rate makes microsatellites useful as markers for genetic mapping: they mutate frequently enough to be highly polymorphic in a population but are stable enough to be transmitted reliably in a pedigree. Simple sequence repeats (microsatellites) occur approximately every 30 kilobases in the human genome (depending on the repeat-length threshold used), and a high proportion are polymorphic, to some extent, across human populations. These markers are easily assayed on a moderate scale but still must be resolved by electrophoresis. Although this is practicable on a modest scale, such as diagnostic analysis for linkage to a mapped but still unknown disease mutation segregating within a family, identifying the correct size of each allele is the most significant bottleneck for applications requiring very high throughput with many markers.

SNPs are by far the most frequent class of polymorphism in the human genome. On average, any two copies of the human genome have 1 polymorphism in approximately every 1000 base pairs. Millions of SNPs have been cataloged across the human genome.⁸⁶ On a small scale, these polymorphisms can be detected using the direct analysis methods described for detection of specific mutations. However, for large linkage studies, the number of single genotypes that must be generated is quite large, and higher throughput methods, such as SNP microarray chips, are being developed.

Identifying New Disease Genes

Linkage data to identify new disease genes are analyzed by computer algorithms that assess their statistical significance. Although many linkage analysis packages are available, a recurrent question arises with respect to the statistical threshold for declaring linkage. As pointed out by Lander and Kruglyak,⁸⁷ each genome scan is really a series of discrete hypotheses. Statistical thresholds must be set to account for the number of hypotheses tested. Lander and Kruglyak argued that in the current era, the number of hypotheses that must be accounted

for in linkage studies is a function of genome size, because one continues testing markers until the genome is covered. They suggested using statistical thresholds based on the likelihood of false-positive findings in a complete genome linkage scan (genome-wide significance) rather than in a discrete test of any one specific locus (point-wise significance). Computer simulations in the absence of linkage and permutation testing of real linkage data support the idea that genome-wide significance levels are needed to minimize reporting of false-positive findings.

Association and Linkage Disequilibrium

A concept related to linkage analysis is genetic association. Rather than explicitly following coinheritance of traits and markers through a family pedigree, association studies follow covariation of traits and markers in a population. Case and control samples are compared for alleles at each locus to determine whether one or more alleles are significantly overrepresented (disease-associated alleles) or underrepresented (protective alleles) in disease cases. One of the best-studied examples of genetic association is the increased risk of late-onset Alzheimer disease for individuals with certain alleles of the apolipoprotein E gene (*APOE*).^{88,89} The amino acid variants encoded by the E4 allele of *APOE* are thought to be directly responsible for the increased risk. However, a strong association of a polymorphism with a disease does not necessarily mean that the polymorphism causes the disease, although it does provide immediate diagnostic value. Associations that are not causal occur by *linkage disequilibrium*. Linkage disequilibrium essentially means that specific alleles at two loci are inherited together throughout a population. This occurs when the genetic distance between the loci is small compared with the number of generations in which the two alleles could have separated by recombination in that population. Association studies that take best advantage of population-based linkage disequilibrium may provide the next opportunity to discover genes that act in multifactorial and genetically heterogeneous diseases. Current efforts in this area include both maps of human DNA polymorphisms⁸⁶ and maps of regions coinheritance by linkage disequilibrium in the general population.⁹⁰ Contributing to linkage disequilibrium, separate genetic loci can affect one another's expression; these “interacting loci” may be important considerations for studies of phenotypic variations and disease states.

The technical feasibility of simultaneously following very large numbers of DNA variations in large numbers of clinical subjects has allowed the development of very powerful GWAS designs. A substantial number of these studies first appeared in 2007, including a large study that combined analysis of several unrelated diseases and traits simultaneously.³⁸ By examining variations chosen to represent most, if not all, common variations (either directly or through linkage disequilibrium with the tested variations) and combining subjects ascertained by collaborating clinical groups, such studies have enormous statistical power for detecting previously unsuspected genetic susceptibilities for disease and will play a large role in the development of personalized medicine.

Conclusion

Genetics plays an important role in the day-to-day practice of obstetrics. We have summarized the basic concepts of genetics as they apply to the understanding and treatment of human

Normal Early Development

KURT BENIRSCHKE, MD

The developing fertilized ovum enters the uterine cavity on about the 4th day after fertilization. During its journey through the fallopian tube, its cells proliferate in the zona pellucida (Fig. 2-1), and shortly before entering the uterus, a blastocyst cavity is formed. Differentiation of a human ovum into embryonic and future placental cells first occurs in a 58-cell morula, as described by Hertig.¹ His specimen was 6 days old and had five embryonic cells (also called the inner cell mass, or stem cells), and 53 trophoblastic cells constituted the wall of this uterine blastocyst. The polar bodies and an apparently degenerating zona pellucida were still present in the specimen, features that would be lost shortly before implantation. These landmarks are of importance now when embryonic stem cells are being harvested and when prenatal diagnosis, intracytoplasmic sperm injection, and other aspects of assisted reproductive technology (ART) are actively being pursued. ART was first thought of as remediation for patients with obstructed fallopian tubes, as was the case for the mother of Louise Brown.² For this accomplishment, Robert Edwards received the Nobel Prize. The process of ART has now become a specialty effort of many reproductive biologists, and in most cases now it is used to aid reproduction in elderly women.

There are many ways by which ART is accomplished. The simplest and most often employed method is to use hormones to produce superovulation in the patient, so long as there is anticipation that fertilizable eggs are still present. Another method, perhaps now more commonly applied, is to harvest eggs from a willing donor (after superovulation) and do in vitro fertilization (IVF). Furthermore, intracytoplasmic sperm injection may be employed, as mentioned earlier, and is used primarily for “male factors.” Most of these methods have in common that the developing embryo is placed into a culture medium (usually for up to 5 days; often the culture dish contains more than one embryo, and the culture media are usually proprietary). The best-looking embryo or two are selected for transfer to the woman. In addition, prenatal genetic diagnosis, which involves removing one of the cultured embryonic cells to examine its genetic content, even its DNA, is now possible. This allows the avoidance of trisomies and other heritable genetic diseases. It also has become a controversial practice, as many of the stored embryos are being frozen in liquid nitrogen and many have been the source of embryonic stem cells. One remarkable aspect of ART is that, for as yet unknown reasons, blastocysts/embryos often duplicate to form monozygotic twins, even if only one embryo has been transferred. Thus, the famous “octomom” had six embryos transferred but ended up with two sets of “identical” twins plus four additional infants. The many problems that are associated with ART were well considered in the presidential address given by Nunley,³ which

dealt with the “slippery slopes of advanced reproductive technologies.”

Proliferation of the trophoblastic shell after this stage of development is rapid, and a segmentation cavity develops, with the more slowly reproducing embryonic cells assuming a marginal, polar position. The adjacent trophoblastic cells enlarge and secure implantation, which is assumed to take place on about the 6th or 7th day after fertilization (Fig. 2-2). Attraction to certain regions of the endometrium is presumed to take place in response to molecular signals expressed on the respective surfaces,^{4,5} and it occurs only during a window of receptivity that is regulated by hormonal action on the endometrium.⁶ With the very rapid enlargement occurring in the anchoring trophoblast cells, the endometrial cells are dissociated by mechanisms to be discussed later (see *Microscopic Development*, later). The entire blastocyst thus comes to assume an interstitial position (i.e., it sinks entirely into the endometrium at the site of attachment). The process may well be aided by the collapse of the blastocyst cavity that occurs at this time (see Fig. 2-2). A deposition of fibrin or occasionally a coagulum at the site of penetration is a common event thereafter, and then the implanted trophoblastic shell comes to be surrounded by endometrium (decidua) on all sides (Fig. 2-3). Presumably, some endometrial proliferation at the edge seals the defect.

The portion of decidua lying between blastocyst and myometrium is the decidua basalis; the portion covering the decidua capsularis becomes part of the chorion laeve. Eventually, the latter comes to lie on the outside of the placental membranes. The decidua on the opposite side of the uterus is the decidua vera. At the time of implantation, the 0.1-mm blastocyst can be detected only by a dissecting microscope. Within a few days, however, it will constitute a polypoid protrusion that can be readily seen by careful inspection of the endometrium. Thus, the approximately 14-day-old ovum (Fig. 2-4) looks like a polyp and already has a differentiated, elongated embryo with amnion and yolk sac cavities.

Occasionally, a small clot, the *Schlusskoagulum*, is attached to the implantation site. Its presence, which may be clinically detected by spotting (Hartman sign), may lead to misinterpretation of the length of gestation. Decidual hemorrhages and small areas of necrosis at the site of trophoblastic penetration are common at this time and later.

Macroscopic Development

In most reports of early implantation, the ovum was found in the upper portion of the fundus, and the development of the placenta was followed by ultrasonography. For example, Rizos and colleagues⁷ found the 16-week placenta to be attached

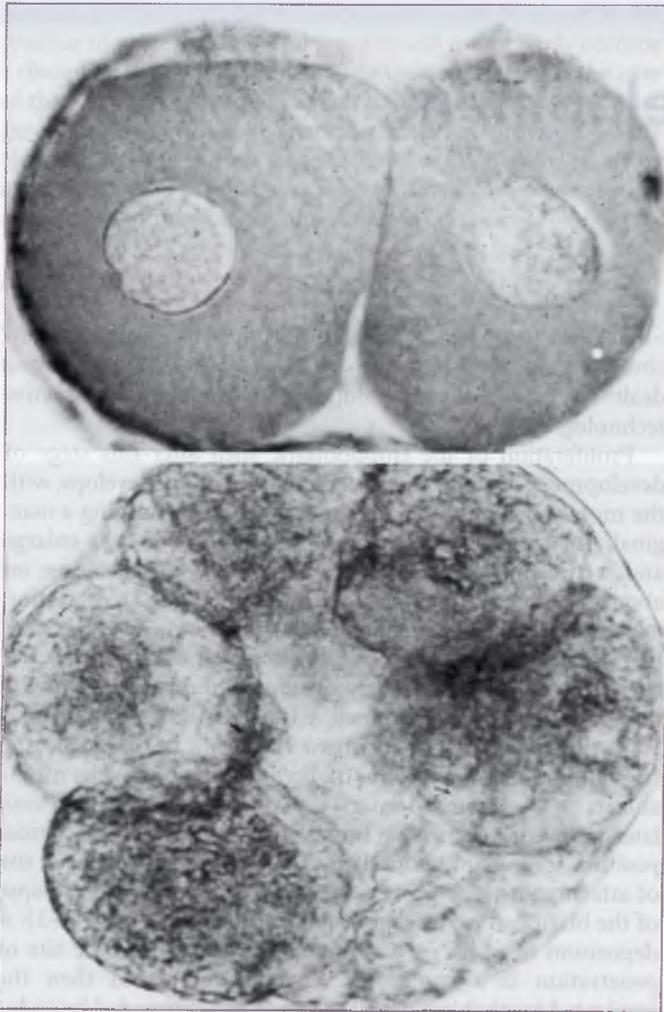

Figure 2-1 Two-cell stage (30 hours) and eight-cell morula. (Courtesy of A. T. Hertig.)

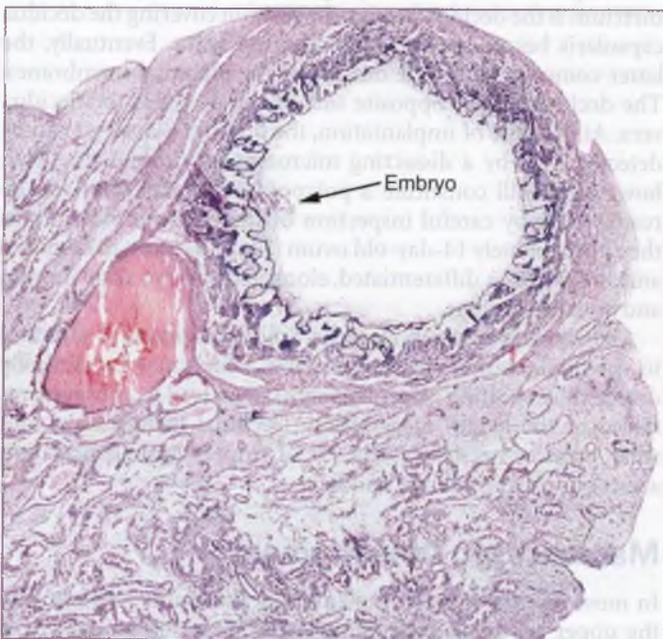

Figure 2-3 An embryo sectioned longitudinally at approximately 14½ days of gestation.

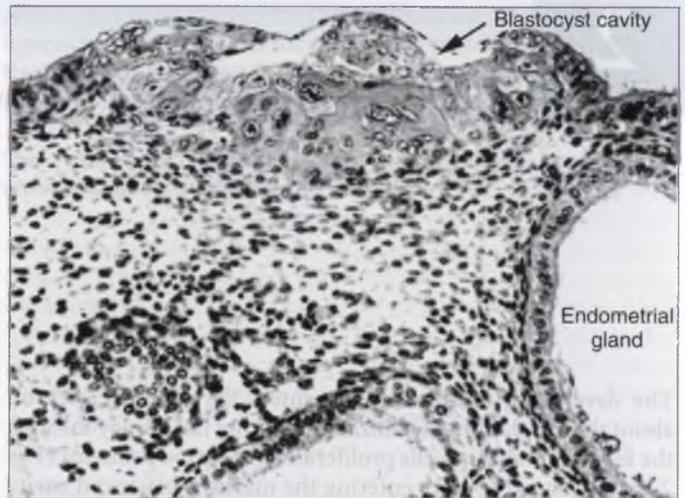

Figure 2-2 Implanted human embryo at a gestational age of approximately 7½ days. The blastocyst cavity has collapsed, and early invasion into the endometrial cavity has occurred with giant cells. The embryo is a small ball in the blastocyst cavity. (Courtesy of A. T. Hertig.)

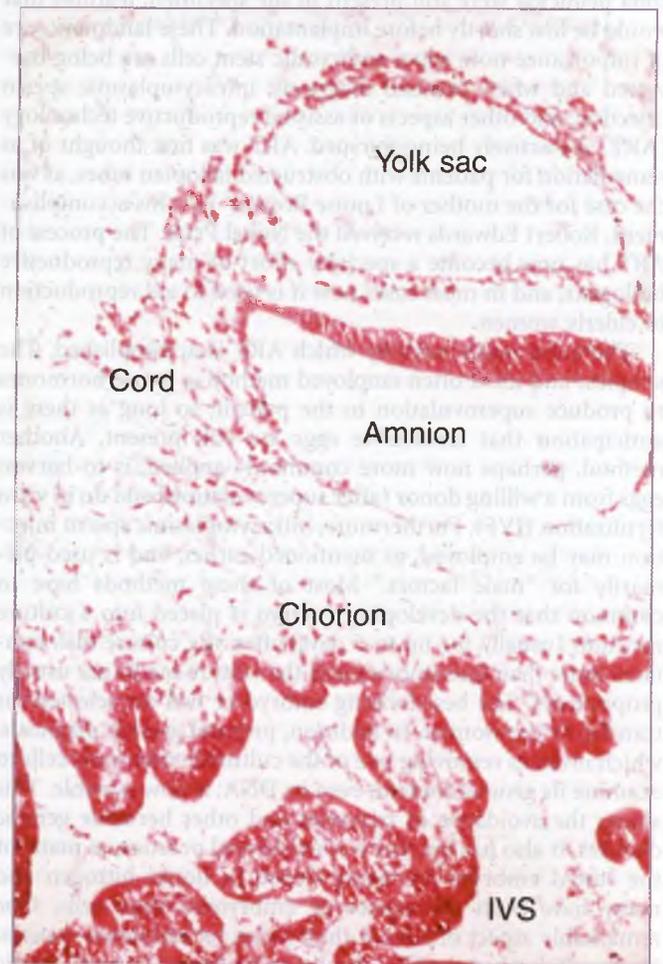

Figure 2-4 Human embryo at approximately 14 days' development. The chorion extends its connective tissue into the developing villi. The umbilical cord develops from the embryonic mesoderm. The amnion is contiguous with the embryonic ectoderm and will fill with fluid, and then the embryo will "herniate" into the amniotic cavity. IVS, intervillous space.

anteriorly in 37% of patients, posteriorly in 24%, in a fundal position in 34%, and both anteriorly and posteriorly in 4%. Others have used sonography to measure placental size and volume prenatally and have correlated their findings with fetal outcome.⁸ Of interest is the finding from sonographic study that low implantation of the placenta in the uterus occurs frequently, with the formation of an apparent placenta previa. Moreover, a low implantation may change through differential growth of the placenta and uterus and apparent marginal placental atrophy. Thus, even though low implantation is observed in early gestation, at term the situation often does not clinically resemble placenta previa.⁹ In the report by Rizos and colleagues,⁷ only 5 of 47 patients in whom placenta previa was diagnosed with ultrasound between 16 and 18 weeks actually had this condition when delivery occurred at term. These findings are important in the interpretation of the shape of the placenta at term and necessitate revision of former impressions.

Most commonly, the placenta develops in the uterine fundus. Through rapid expansion of the extraembryonic cavity (the exocoelom) and proliferation of the trophoblastic shell, the ovum bulges into the endometrial cavity at the time of the first missed menstrual period. The surface is flecked by tiny hemorrhages and necrotic decidua. With continued expansion of the embryonic cavity, the surface becomes attenuated, the peripheral villi atrophy, and the future placental “membranes” form. They consist of decidua capsularis on the outside, hyalinized villi and trophoblast in the middle, and the membranous chorion laeve (and amnion) on the inside.

The relationship of these membranes to the remainder of the uterus was subsequently traced in numerous pregnant uteri in a series collected by Boyd and Hamilton.¹⁰ Their observations suggested that the membranes truly fuse with the decidua vera of the side opposite to implantation in the 4th month of pregnancy, thereby obliterating the endometrial cavity. The decidua capsularis appeared to degenerate in their specimens before this time, and what is present on the outside of the term-delivered placenta was construed to be decidua vera attached to chorion. With the atrophy of peripheral villi and attachment of the membranes to the opposite side of the uterus, the macroscopic delineation of the placenta is essentially completed. Next, the formation of amnion, yolk sac, and body stalk is described.

Figures 2-3 through 2-9 demonstrate the developing placenta and finally an embryo at 7 weeks with an embryonic crown-rump length of 15 mm; the width of the entire specimen is approximately 25 mm. With the “herniation” of the chorion laeve into the endometrial cavity, its surface has been smoothed and stretched. At the edge, the decidua is thrown into a fold, and minute coagula are present. When a tangential section is removed, the extension of the villous tissue for some distance onto the abembryonic pole of the cavity can be seen. The villi have already completely atrophied at the apex. The embryo is contained in the amniotic sac, which does not completely fill the chorionic cavity (Fig. 2-10). It is suspended in the cavity by a gel (magma reticulare) that liquefies on touching. When the sac is opened, the embryo and umbilical cord emerge (see Fig. 2-9).

An understanding of the morphogenesis of these structures is essential and can be gained from a study of Figure 2-4. In this histologic section, the embryo is sectioned longitudinally. The ectoderm appears as a dark streak and is continuous with the amniotic sac epithelium that lies below. On the other side of

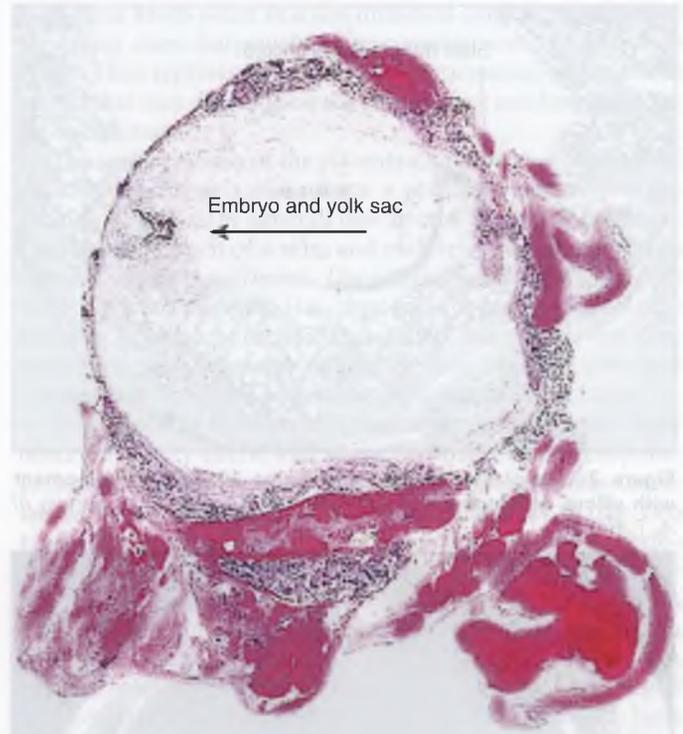

Figure 2-5 Spontaneous abortion at about 20 days of development. The embryonic disk can be seen at the upper left pole, accompanied by the primitive yolk sac and the future stalk (umbilical cord) at the lower left of the embryo. Arrow shows the embryo with yolk sac and amniotic cavity. Note the large quantity of extraembryonic mesenchyme (the exocoelom). (Courtesy of Kaiser Hospital, San Diego.)

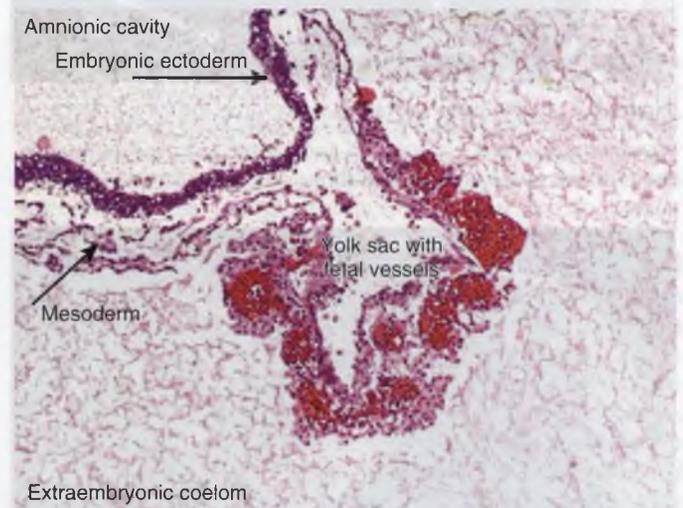

Figure 2-6 Spontaneous abortion at about 20 days of development. The primitive yolk sac contains vessels filled with embryonic blood and its cavity is lined by future intestinal cells—the endoderm. (Courtesy of Kaiser Hospital, San Diego.)

the embryo lie the endoderm and yolk sac. The mesoderm is seen to “flow” from the left caudal pole of the embryo onto the inner surface of the trophoblastic shell. This streak of mesoderm ultimately becomes the substance of the umbilical cord. As the embryo grows and folds so as to enclose the endoderm,

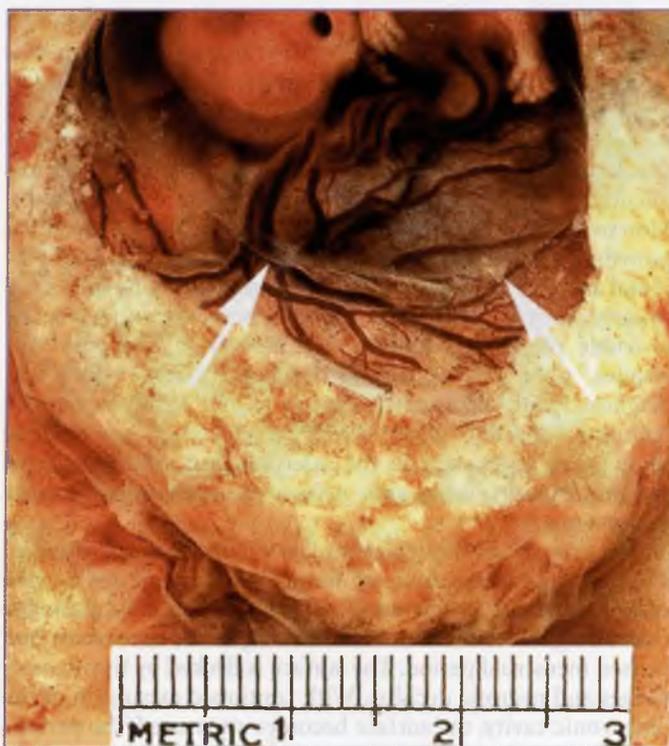

Figure 2-10 Pregnancy at 8 weeks with 20-mm embryo. The top portion of the chorion laeve has been removed, thus disclosing amnion at arrows.

the amnion enlarges and the embryo may be thought of as herniating into this amniotic sac. A portion of the primitive yolk sac will be enclosed by the embryo to become its gut; another portion will be exteriorized (i.e., will lie outside the amniotic sac) and will be connected by the omphalomesenteric (vitelline) vessels and duct. Most often, these yolk structures disappear completely in later development; only in occasional term placentas can the calcified atrophic remnant of yolk sac be found at the periphery as a tiny (3-mm), yellow, extra-amniotic disk.

Once the amniotic sac has enclosed the entire embryo, it reflects on the umbilical cord, whose entire length it will eventually cover and to which it will be strongly adherent. At 8 weeks, the amnion is a thin translucent membrane (see Fig. 2-10). It does not fully expand to cover the inside of the entire chorionic sac until about 12 weeks. It never completely grows together with the chorion, however, so that in most term placentas the amnion may be dislodged from the chorion and the placental surface. This becomes particularly obvious in meconium discharge. The amnion does not have any blood vessels but is composed of a single layer of ectodermal epithelium, peripheral to which is a layer of delicate connective tissue with some macrophages.¹¹ Sophisticated studies have now shown that amnion and chorion also possess sheets of delicate elastic membranes.¹² It is presumed that these aid in the elasticity of the membranes and help prevent accidental premature rupture. Betraying the ectodermal origin of the amnion are small plaques of squamous metaplasia near the insertion of the term placenta's umbilical cord that must not be mistaken for amnion nodosum.

When the embryonic cells differentiate into mesoderm, endoderm, and ectoderm, the mesoderm is first clearly seen at

the caudal pole of the embryonic disk (see Fig. 2-4). The mesodermal cells rapidly proliferate and send a column of cells streaming toward the inner surface of the trophoblastic cavity, which they then come to line. This column is ultimately destined to become the umbilical cord, and blood vessels and a rudimentary allantoic sac grow into this body stalk from the primitive yolk sac—hence the term *chorioallantoic vessels*. It is commonly thought that the inner cell mass, the future embryo, lies centrally in the early stages of implantation, and that for this reason the umbilical cord comes to be attached to the center of the placenta.

Aberrant attachment, such as at the margin or to the membranes (velamentous insertion), may be explained by one of two contradictory hypotheses. According to one hypothesis, the embryo had a less than perfect central position at the time of implantation and was perhaps even on the opposite side; thus, when the mesoderm proliferated, the location of the cord was established on the surface of the endometrium, the area destined to become membranes. This possible arrangement is well shown in Figures 2-5 and 2-6. The second hypothesis suggests that abnormal central implantation occurred but that the area of implantation was less than optimal for placental development. Subsequently, the expansion of the placenta occurred to one side rather than in a uniform centrifugal manner. The already established location of the cord therefore changed from a central to a lateral position, a process called trophotropism that is also witnessed in the migration of the placenta that was earlier thought to be a placenta previa.

This second hypothesis is supported by the much more common marginal or velamentous portion of the cords in multiple pregnancy, where one can imagine competition for space by and collision of expanding placentas. In term placentas, moreover, marginal placenta atrophy is often found, and the finding of succenturiate (accessory) lobes can best be explained by this mechanism. Also, the ultrasonographic finding of a “wandering” placenta favors this assumption, as does the fact that most of the few early embryos studied had a relatively central implantation. The first hypothesis is supported by the finding of a much higher frequency of velamentous insertion of the cord in aborted specimens than in term placentas.¹³

The umbilical cord measures approximately 55 cm in length at term, but extreme variations occur for largely unknown reasons. Because a normal cord weighs as much as 100 g and the segments of cord supplied with the placenta vary so much, the cord and membranes should be removed before the placental weight is ascertained. More often than not, the cord is spiraled, most commonly in a sinistral manner. Numerous theories have been presented to explain this helical arrangement, but the cause remains largely unknown. Because such twists do not exist with longitudinal orientation in bicornuate uteri, and because of the mobility of the primate fetus in its uterus simplex, it is most likely that fetal movements are the cause of the cord twisting.^{14,15} Further support for this explanation comes from the entwinement of cords in monoamniotic twins.

The cord contains two umbilical arteries and one vein. A second rudimentary vein, the omphalomesenteric (vitelline) vessels, and the allantoic duct of early embryonic stages atrophy, and on rare occasions discontinuous remnants of these structures are found in the term cord. The two umbilical arteries anastomose through a variably constructed vessel within 2 cm of the insertion of the cord in almost all normal placentas; this is the so-called Hyrtl anastomosis. There are no nerves in the

cord. True knots occur in a few umbilical cords, particularly in very long ones, but much more common are so-called false knots. They represent redundancies (varicosities) of umbilical vessels that may protrude on the cord surface and have no clinical significance.

The surface vessels of the placenta represent ramifications of the umbilical vessels and pursue a predictable course on the chorionic surface. In general, one arterial branch is accompanied by one branch of a vein, and each terminal pair of vessels supplies one fetal cotyledon. The arteries may be recognized by their superficial location (i.e., they cross over the veins). Anastomoses between superficial vessels do not occur—for that matter, no such connections ever develop between umbilical vessels. Each district is isolated and distinct from the other.

Two types of surface vascular arrangements have been observed: a very coarse and sparse vasculature and finely dispersed vessels. No significantly different fetal outcomes correlate with these features, however, and mixtures of the two types exist in single placentas. The number of terminal perforating vessels determines the number of fetal-placental cotyledons or districts. In most placentas, the number is about 20, somewhat greater than the number of lobules that can be seen from the maternal side of the mature placenta. In general, there is correspondence of fetal lobules with maternal septal subdivisions when injection studies are performed of both circulations.¹⁶

Authors who have performed such dual injections suggest that the intervillous circulation is achieved by the injection of blood from a decidual artery into the center of a fetal cotyledon, which there disperses from a central cavity in the villous tissue to the periphery of the cotyledon and to the undersurface of the chorion, from where it is drained by veins in the septa and decidual base.¹⁷ The loose central structure of cotyledons can easily be demonstrated when a placenta is horizontally sectioned. This more conventional model of cotyledonary arrangement of villous structure and intervillous circulation has been challenged by Gruenwald,¹⁸ who envisioned a different lobular architecture, with arterial openings occurring at the periphery of cotyledons, a concept that has not yet been unequivocally refuted. The former notion that all intervillous blood flows laterally to the marginal sinus, however, is no longer acceptable.

The normal term placenta from which membranes and cord have been trimmed weighs between 400 and 600 g. There is enormous variability in placental size and shape, as there is in fetal weight. Some variations can be explained by racial differences, altitude, pathologic circumstances of implantation, diseases, or maternal habits such as smoking. In many cases, however, the deviations from “normal” are as difficult to explain as the factors that ultimately determine fetal and placental growth in general. Systematic studies of placental structure have given insight into the complexities; they have been summarized in the careful analysis by Teasdale.¹⁹ Absolute growth, as determined by DNA, RNA, and protein content, occurs in the placenta to the 36th week of gestation. Thereafter, proliferation of cells does not normally occur, and the placenta undergoes only further maturational changes. Previous studies have suggested an expansion of the villous surface to between 11 and 13 m² at term, whereas Teasdale’s careful measurements suggest that the maximum is reached with 10.6 m² at 36 weeks, decreasing to 9.4 m² at term. The fetal-to-placental ratio is estimated to change from 5:1 in the third trimester to 7:1 at term, most

rapidly increasing during the last month of gestation. Reasons for discrepancies of these measurements reported in the literature are partly explained by inconsistent handling of the organ at delivery. Thus, a variable amount of blood may be trapped, depending on the time of cord clamping. It is widely accepted now that the delivered placenta has a smaller volume—in particular it is less thick—than before delivery, as ascertained by sonography.²⁰ Therefore, for quantitative assessment, a histometric analysis must accompany such correlative study. Apparently, the slight increase in placental volume occurring in the last month of pregnancy results from an expansion of the non-parenchymal space (i.e., villous capillary size, decidua, septa, and fibrin). Thus, during the last month of gestation, fetal growth occurs without commensurate increase in placental volume, indicating that changes must occur in perfusion or transport function of the placenta to ensure enhanced delivery of metabolic substrates to the fetus. Significant advances in technology are likely to reveal new factors that regulate fetal and placental growth. The evolution of microarrays for the ascertainment of gene activity promises to become of major importance.²¹

Macroscopically, a delivered normal term placenta can be described as a disk-shaped, round or ovoid structure measuring 18 × 20 cm in diameter and approximately 2 cm thick. The cord is normally inserted near the center of the disk (marginal in 7% and on the membranes in 1%); it measures 40 to 60 cm in length and 1.5 cm in thickness. Its two arteries spiral around its one vein. The membranes are attached at the periphery of the placental disk and have some degenerated yellow decidua on their outer surface and a smooth glistening inner amniotic surface. The amnion is only slightly adherent to the chorionic face of the placenta, from which it can be stripped by forceps, but it is firmly attached to the cord, upon which it reflects.

The fetal surface of the placenta is blue because of the fetal villous blood content seen through the membranes; most maternal blood has been expelled by the uterine contractions that expelled the placenta. Irregular whitish plaques of subchorionic fibrin project slightly between fetal vessels and produce what has been referred to as a bosselated surface; the plaques are indicative of a mature organ and result from eddying of the maternal blood in the intervillous space as it turns direction.

The maternal surface usually has a film of loosely attached blood clot, which when removed discloses the thin, grayish layer of decidua basalis and fibrin that comes away with delivery. In the fibrin, yellow granules and streaks of calcification characterize maturity. They are extremely variable in amount and have no clinical significance. The maternal surface is usually broken up into irregular lobules (cotyledons) by crevices that continue into partial or complete septa between fetal cotyledons. These septa are constructed of decidual cells and cellular trophoblast. On sectioning, the dark red villous tissue reflects the content of fetal blood. Loosely structured areas represent intervillous lakes, the presumed sites of first blood injections (“spurts”) from decidual arteries.

Microscopic Development

It is likely that some adhesion molecules are essential for blastocyst attachment to the endometrium.^{4,22} Once the trophoblastic shell has attached, marked changes occur on its surface and invasion is accomplished by dissociation and ingestion of endometrial cells. A completely interstitial implantation of the

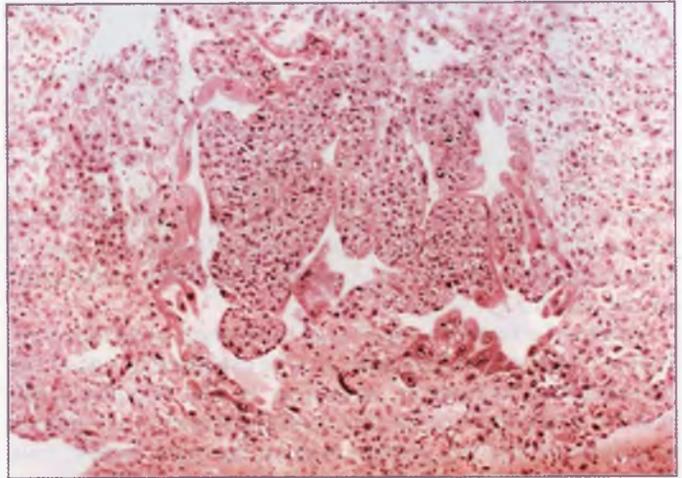

Figure 2-11 Trophoblastic shell of a 13-day-old ovum. Cell columns composed of solid cytotrophoblast are covered by syncytiotrophoblast lining the entire intervillous space, which is still devoid of maternal blood. H&E, ×300.

blastocyst is accomplished on the 9th day of gestation. The trophoblastic shell has proliferated appreciably, particularly at its basal portions, and most trophoblastic cells possess disproportionately large nuclei and may form a syncytium. In the mass of trophoblastic cells develop clefts (lacunae) that coalesce to form the most primitive type of the future intervillous space.

At about this time or on the next day, the somewhat congested decidual vessels are tapped into by the trophoblast, as the cytokine transforming growth factor (TGF)- β is abundantly present in the decidua and is assumed to be immunosuppressive. It thus may also be important in the degradation of decidual cells. TGF- α , in contrast, stimulates the growth of extravillous trophoblast. The first maternal leukocytes have been observed on day 11 in this primitive intervillous space, later to be followed by blood, thus establishing the primitive intervillous circulation.¹ At the same time, the trophoblastic cells can be seen to differentiate into a central cellular type (cytotrophoblast and extravillous trophoblast, and into the future Langhans layer) and peripheral syncytiotrophoblast (Fig. 2-11). The syncytial nuclei never undergo mitosis and grow only by the incorporation of cytotrophoblastic nuclei and cytoplasm; only the latter cells are capable of mitosis.^{23,24} Recent studies indicate that the formation of the syncytium from cytotrophoblast is very complex. Debieve and Thomas²⁵ provided evidence that inhibin is involved; others have identified that it requires a protein (“syncytin”) derived in primates from a genetic contribution of a retroviral envelope gene.²⁶⁻²⁸

On day 13, the first connective tissue may be observed in the central portion of the future villi. It will rapidly expand peripherally into the cell columns of trophoblast. Evidence suggests that this connective tissue core derives from the mesoderm of the extraembryonic space and perhaps the body stalk (see Fig. 2-4) and not by central “delamination” from trophoblast. By the 30th day, a truly villous ovum is formed, and the basic future development of the villous structure is delineated.

Nevertheless, the basic question of the interaction of the trophoblast with its immediate environment is crucial for our understanding of the invasive nature of extravillous trophoblast. Here, the availability of vascular endothelial growth factor (VEGF) may be of great importance. This protein is not only

secreted by trophoblast but also by decidual cells and by the decidual macrophages as well. Moreover, the extravillous trophoblastic cells that are embedded in the self-secreted extracellular matrix (the fibrinoid) additionally express the respective extracellular matrix (ECM) receptors, the integrins. These are the heterodimeric integral membrane proteins that may be switched on or off, and the switching can also take place during the invasion process. For example, the integrins interact with the vascular wall matrices, the decidual/uterine natural killer (NK) cells, decidual macrophages, and other cell types in accomplishing the task of trophoblast invasion. They are similarly essential for the remodeling of the decidual floor. In addition, matrix metalloproteinases (MMPs) of several types help in the destruction of decidua, invasion of maternal spiral arterioles, destruction of collagen, and so on. Much of this process has been described in great detail (see Chapter 9 of Benirschke and colleagues²⁹).

Villi are found around the entire circumference at first, only to atrophy over the pole later. Commencing almost simultaneously, on the 14th day and subsequently, is the development of villous capillaries. Moreover, fetal macrophages (the Hofbauer cells) infiltrate the villi. Although in 1968 Hertig¹ discussed in great detail how villous capillaries also derive from delaminated trophoblastic cells by the internal detachment of angioblastic cells, more likely their origin is from fetal mesoderm or endoderm. These are not the idle problems of an embryologist but pertain directly to an understanding of the genesis of hydatidiform moles. If villous connective tissue and vessels are definitely derived from the embryo (rather than from the trophoblast), hydatidiform moles must at one time have had an embryo. Occasionally, complete hydatidiform moles have been shown to contain degenerated embryos, but in most cases the embryo

and its vessels have disappeared.^{30,31} Villous vessels coalesce and connect to the omphalomesenteric and later allantoic vessels of the embryonic body stalk, and a true fetal circulation is active by 21 days.³² The initial fetal blood cells come from yolk sac (see Fig. 2-5), and only after the 2nd month do they issue from fetal hematopoietic islands. With an established circulation, the villi are now called tertiary villi.²²

The villous structure changes appreciably during further development, and the gestational age can be crudely estimated from the histologic appearance of the villi. In young placentas, the mesenchymal core of the villus is extremely loosely structured, appearing almost edematous (Fig. 2-12). Capillaries are filled with nucleated cells and lie very close to the villous surface. The surface is uniformly covered by an inner layer of cellular cytotrophoblast, which contains numerous mitoses and in turn is covered by a thick layer of syncytium that contains abundant organelles in its metabolically active cytoplasm. The syncytium is functionally the most important part of the placenta. With advancing age, the villi elongate, lose their central edema, branch successively, and decrease in diameter. At term they contain little mesenchyme and are filled with distended capillaries. Cytotrophoblastic mitoses are rare after 36 weeks in normal placentas. The syncytium tends to form buds and “knots,” many of which break loose and are swept into the intervillous circulation, which takes them to the maternal lung, where they are destroyed by apoptosis. They have no mitotic capability, and they are presumably the source of the large quantities of “cell-free DNA” in the maternal circulation that is now used for genotyping.³³ Fibrin and fibrinoid, also eosinophilic but composed of a variety of novel protein compounds, are normally accumulated in ever-increasing quantities on the surface of the villi, in the subchorionic area, and along the floor

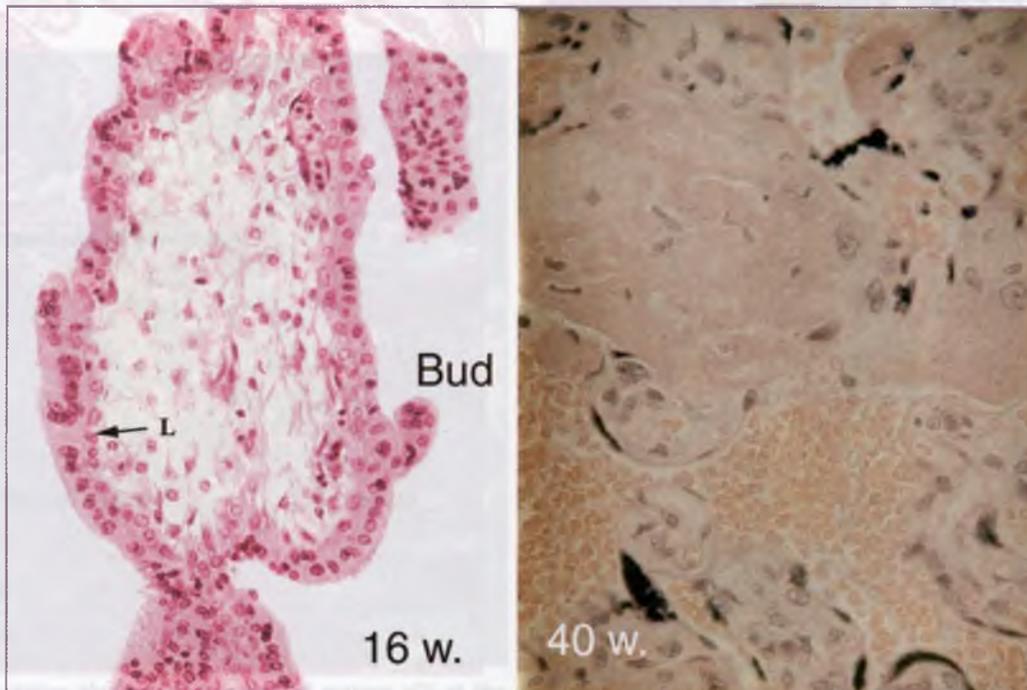

Figure 2-12 Placental villi. *Left:* Villus of 16-week-old placenta. Note the very loosely structured mesenchymal core containing isolated macrophages, the thin-walled fetal capillaries filled with nucleated red blood cells, and the double-layered trophoblastic surface. Langhans cells (L) at arrow (cytotrophoblast). Syncytial “buds” begin to form. *Right:* A section of a villus of a term placenta reveals dark syncytial buds and fibrinoid deposits. H&E, $\times 160$.

of the placenta, where Rohr and Nitabuch fibrin layers mingle within the decidua basalis. Fibrinoid of the placenta is a complex admixture of true fibrin and a variety of proteins such as laminins and collagens.³⁴ Near term, some of these fibrin deposits become calcified in a normal process that may become excessive in the postmature placenta. The amount of calcium varies greatly but has no deleterious influence on placental function. The placental septa, composed of cellular extravillous trophoblast ("X cells" or intermediate trophoblast) and decidua, often undergo cystic change as a sign of maturity.

The X cell, now more commonly called the extravillous trophoblast, has recently been the focus of attention. It is a separate lineage of trophoblast that is set aside very early in embryonic development and is intimately related to fibrinoid deposition and to the production of the major basic protein and placental lactogen. Most so-called placental-site giant cells are X cells and are often confused with decidual stromal elements.^{30,35} From these basal trophoblastic elements come a variety of enzymes, especially stromelysin-3, to prepare for the invasion of the decidual floor and blood vessels.³⁶ These cells also infiltrate into the orifices of basal decidual spiral arterioles (Fig. 2-13). Hustin and colleagues^{37,38} offered evidence that these extravillous trophoblastic cells completely occlude these vessels in early pregnancy, thus allowing only a filtrate of maternal blood to enter the intervillous space. This hypothesis was challenged with studies using Doppler flow in rhesus monkeys.³⁹ These investigations showed an early vascular connection of the maternal arterial circulation with the intervillous space, although flow was of low resistance and pulsatility from day 20 on. The population of Hofbauer cells derives from circulating fetal blood, and

immunohistochemical studies show that this large population of cells represents fully differentiated phagocytes.⁴⁰ After hemolysis, they are seen to produce hemosiderin; in the chorionic surface, they actively transport meconium after its discharge, and it is speculated that they remove antifetal antibodies.

At the site of implantation, trophoblastic cells intermingle extensively with decidua basalis; indeed, they penetrate into the superficial portions of myometrium. These areas are often characterized by scattered lymphocyte infiltration and decidual necrosis.⁴¹ Cytotrophoblastic cells enter the opened mouths of maternal arterioles and penetrate deeply along their endothelial linings; indeed, packets of villi "herniate" into open maternal vessels.⁴² Some trophoblastic cells infiltrate the decidua and myometrium, often fusing to form placental giant cells (Fig. 2-14); others invade the spiral arterioles from the outside. They cause considerable local change, including fibrin deposition, and they alter the normally contractile vessels to presumably rigid uteroplacental arteries. Thrombosis is not found normally but is a common finding when hypertensive changes are superimposed. It is the presence of the decidua basalis that prevents the development of placenta accreta. If prior curettage has removed the endometrium focally, or if in the long distant past

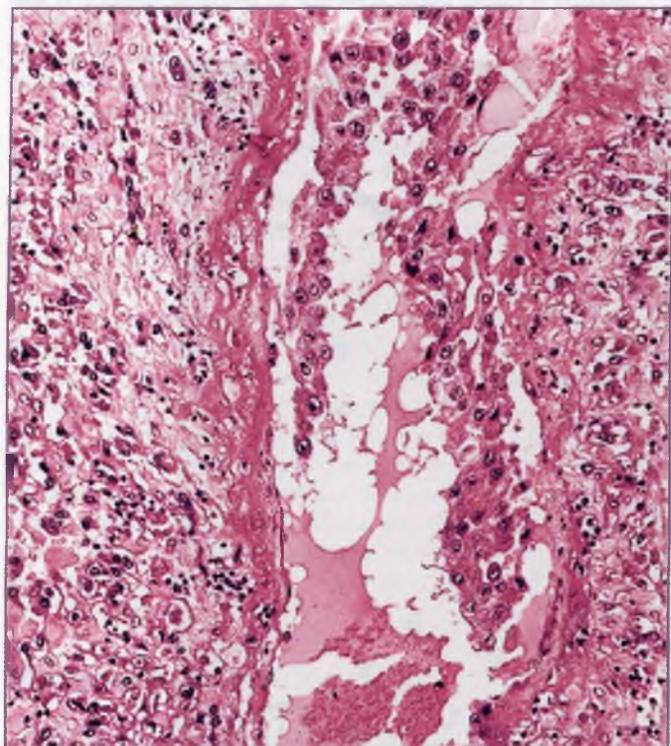

Figure 2-13 Term placental floor with infiltration of extravillous cytotrophoblast into a spiral arteriole. The walls of the arteriole have been transformed with fibrin deposits. The dark cells in the endometrial stroma are also extravillous trophoblast. H&E, x128.

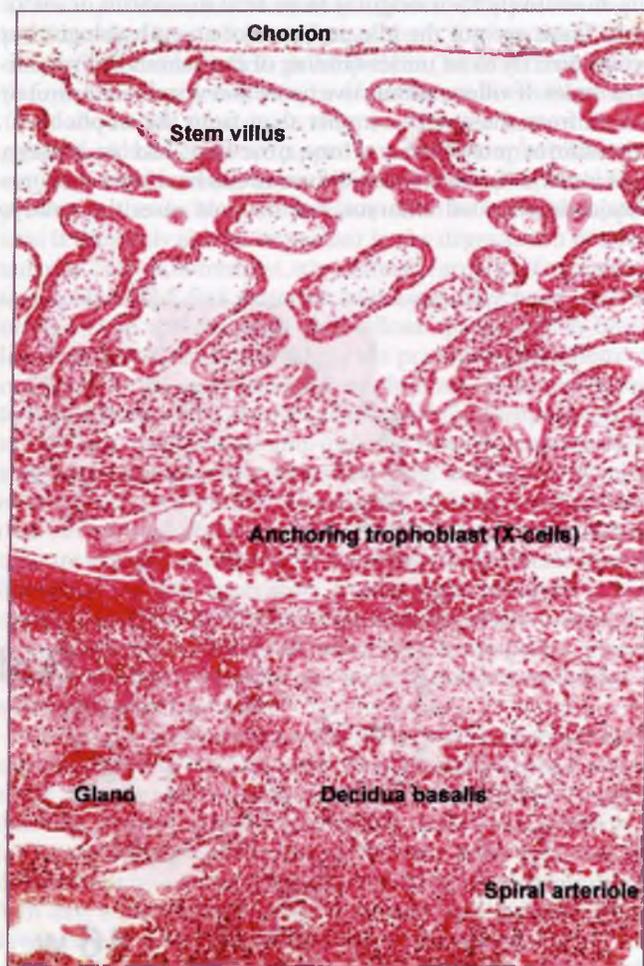

Figure 2-14 Implantation site of first-trimester placenta. The anchoring villi are composed of cytotrophoblast, and diffusely infiltrated placental giant cells can be seen. H&E, x40. (From Benirschke K, Kaufmann P, Baergen RN: *The pathology of the human placenta*, ed 5, New York, 2006, Springer-Verlag.)

steam cauterly was used to destroy the endometrium of hemorrhaging patients, placenta accreta may occur. Currently, the most common antecedent is prior cesarean section; in such cases, placenta increta or percreta may develop, depending on the manner by which the earlier cesarean sections were repaired. What remains somewhat mysterious is how the “invading” trophoblast “knows” when to stop invading so as to leave a layer of decidua basalis in place. It may relate to the decidual presence of NK cells and immunologic interactions, but this remains a topic for further research.

Electron microscopic study of placental villi in general supports the findings made by light microscopy, but it adds significant new details. The arborization of villi and their complexity are best appreciated in scanning electron micrographs (Fig. 2-15). In the more peripheral areas of cotyledons, the villi appear histologically more mature (i.e., they are smaller and have more branches and less stroma). The syncytial surface is covered by numerous minute microvilli, and syncytial bridges are occasionally seen. In the central portion of the cotyledon, the villi are plump and less branched. Freeze-fracture scanning electron microscopy discloses the proximity of fetal vessels to the basement membrane and the profusely microvillous surface of the syncytium (Fig. 2-16). With advancing maturity, the Langhans cytotrophoblastic layer not only becomes less prominent but also is interrupted in many more places. Here, then, the fetal capillaries abut a thin layer of syncytium, presumably the most efficient site of transfer.

These electron micrographic features of maturity are also found more frequently in the periphery of cotyledons than in their more immature-appearing centers, but qualitative differences do not exist.⁴³ The slightly different electron micrographic features of villi relate in part to the state of contraction of fetal capillaries (Fig. 2-17), and they may in part be the result of

Volume of Amniotic Fluid

Wynn, Department of Obstetrics, Gynecology and Pathology, SUNY Health Sciences Center, Brooklyn, NY.)

oxygen supply. Desmosomes have been identified by scanning and transmission electron microscopy in the trophoblast.⁴⁴ They interlock syncytium with cytotrophoblast, and when found with free membranes in cytoplasm of the syncytium, they presumably represent the remnants of the fusion-incorporation process of cytotrophoblast into syncytium. The structure of the syncytiotrophoblastic cytoplasm is extremely complex. It is filled with minute vacuoles, ribosomes, mitochondria, and other usual cytoplasmic components. On the other hand, the cytotrophoblastic cytoplasm is relatively simple, reflecting its presumed primary function as precursor cells for syncytium.

It has also been shown that oxygen affects the trophoblastic infiltration into the decidua, in part through hypoxia-inducible factor 1 (HIF-1) and HIF-2 α . Numerous genes are turned on by the level of oxygen in the intervillous blood, especially after the 12th week of gestation, when the oxygen pressure rises to around 18 mm Hg.⁴⁵

Genetic Aspects

A large variety of genes control the implantation and the development of the placenta.⁴⁶ Most recently, the “imprinting” of DNA (methylation) has become a major new direction of research, as it has become evident that *paternal* genes are largely responsible for the placental development, whereas *maternal* genes control that of the embryo.⁴⁷ Thus, for example, the complete hydatidiform mole with its androgenetic origin confers excessive development of the placenta. Cytosine methylation is also critical for normal angiogenesis,⁴⁸ whereas the egg genome is strikingly undermethylated. The paternal genome, in con-

trast, has considerably more methylation.⁴⁹ In fact, this methylation is accomplished by yet another gene—*TET1*.⁵⁰

INDIVIDUAL GENES OF EMBRYONIC DEVELOPMENT

As research expands our knowledge of genetic control, it becomes apparent that numerous genes direct embryonic and placental development. The following is a brief list of some of the principal players now recognized.

HOX: The HOX gene complex provides specific regional differences of the anterior-posterior axis of vertebrate embryos.⁵¹

SOX: The large number of proteins encoded in the SOX family of genes are especially important for various aspects of embryonic development.⁵² Thus, SOX9 proteins specify collagen type II and the anti-Müllerian hormone, whereas SOX2 targets lens structure, embryonic stem cells, inner cell mass, and so on. Indeed, the SOX gene complex provides a complex array of factors.

TBX: The genes (about 17) in the TBX family produce proteins that are essential for the embryonic development of extremities and the fetal heart.

SHH: This family of sonic hedgehog genes also regulates extremity development.⁵³ An abnormal sonic hedgehog gene expression is presumably also the cause of holoprosencephaly.⁵⁴

Amniotic Fluid Dynamics

MICHAEL G. ROSS, MD, MPH | MARIE H. BEALL, MD

Amniotic fluid (AF) is necessary for normal human fetal growth and development. It protects the fetus from mechanical trauma, and its bacteriostatic properties may help to maintain a sterile intrauterine environment. The space created by the AF allows fetal movement and aids in the normal development of both the lungs and the limbs. Finally, AF offers convenient access to fetal cells and metabolic byproducts, and it has been used for fetal diagnosis more often than any other gestational tissue.

The existence of AF has been appreciated since ancient times. Leonardo da Vinci drew the fetus floating in the fluid, and William Harvey hypothesized that the fetus was nourished by it. However, it was only in the late 19th century that AF became available for study other than at delivery, and fluid sampling by amniocentesis was rarely performed until the second half of the 20th century. Genetic amniocentesis for fetal diagnosis (i.e., for sex determination) was first performed in 1956.¹ Research on the characteristics of AF is, therefore, a relatively recent phenomenon. This chapter reviews the current state of knowledge regarding the volume, composition, production, resorption, and volume regulation of AF.

Volume of Amniotic Fluid

In the first trimester of pregnancy, the amnion does not contact the placenta or decidua, and the amniotic cavity is surrounded by the fluid-filled exocoelomic cavity.² The exocoelomic fluid participates in the exchange of molecules between mother and fetus; the function of the AF at this early gestational period is uncertain.

By the end of the first trimester of human gestation, the exocoelomic cavity progressively obliterated, and the amniotic cavity is the only significant deposit of extrafetal fluid. AF volumes have been directly measured in the first half of pregnancy, and during this period volume increases logarithmically.³ AF volumes were first estimated in the latter two thirds of human pregnancies through the use of dye dilution techniques.⁴ These original quantitative findings have been supported by semiquantitative measurements of AF volume performed with ultrasound (Fig. 3-1).⁴⁻⁶

All of these methods also demonstrate that AF volume increases progressively between 10 and 30 weeks of gestation. Typically, volume increases from less than 10 mL at 8 weeks³ to 630 mL at 22 weeks and 770 mL at 28 weeks' gestation.⁶ After 30 weeks, the increase slows, and AF volume may remain unchanged until 36 to 38 weeks, when it tends to decrease. As a pregnancy proceeds past the due date, AF volume decreases sharply, averaging 515 mL at 41 weeks. Subsequently, there is a 33% decline in AF volume per week,⁷⁻⁹ consistent with the increased incidence of oligohydramnios in post-term gestations.

The rate of change of AF volume depends on the gestational age. Total AF volume increases at a rate of 10 mL/wk at the beginning of the fetal period, increasing to 50 to 60 mL/wk at 19 to 25 weeks' gestation, then decreasing until the rate of change equals zero (i.e., volume is at maximum) at 34 weeks. Thereafter, total AF volume falls, with the decrease averaging 60 to 70 mL/wk at 40 weeks. Although the basic mechanisms that produce these alterations in AF volume throughout gestation are unclear, it is important to note that, when expressed as a percentage, the rate of change decreases consistently throughout the fetal period. Therefore, the decrease in AF volume near term represents a natural progression rather than an aberration.

The volume of AF may be dramatically altered in pathologic states. Excessive AF volume (polyhydramnios) may total many liters, and the volume of AF in conditions of reduced fluid (oligohydramnios) may be zero. Fetal anatomic abnormalities such as renal agenesis or esophageal atresia may affect the normal processes for production and resorption of AF, respectively, leading to abnormal AF volumes. In addition, transient changes such as maternal dehydration or fetal anemia may alter AF flow and therefore AF volume. AF volume abnormalities may also occur without apparent cause. Abnormalities of AF volume in general have been associated with poorer perinatal outcomes.¹⁰⁻¹³ Specific issues are discussed elsewhere in the text.

Production and Composition of Amniotic Fluid

The AF in the first trimester of pregnancy has rarely been the subject of study. It appears that human AF in the first trimester is isotonic with maternal or fetal plasma¹⁴ but contains minimal protein components. First-trimester AF also demonstrates an extremely low oxygen tension and an increased concentration of sugar alcohols, the product of anaerobic metabolism.¹⁵ In the second half of pregnancy, the human fetus produces dilute urine, which is a major component of AF, causing the AF composition to diverge from that of serum. In particular, human AF osmolality decreases by 20 to 30 mOsm/kg with advancing gestation to levels approximately 85% to 90% of maternal serum osmolality.¹⁶ In the same period, AF urea, creatinine, and uric acid increase, resulting in AF concentrations of urinary byproducts two to three times higher than in fetal plasma.¹⁶

It is thought that early AF arises as a transudate of plasma, either from the fetus through nonkeratinized fetal skin or from the mother across the uterine decidua or the placenta surface or both; however, the actual mechanism is unknown.¹⁷ Production and resorption of AF have been extensively studied in the

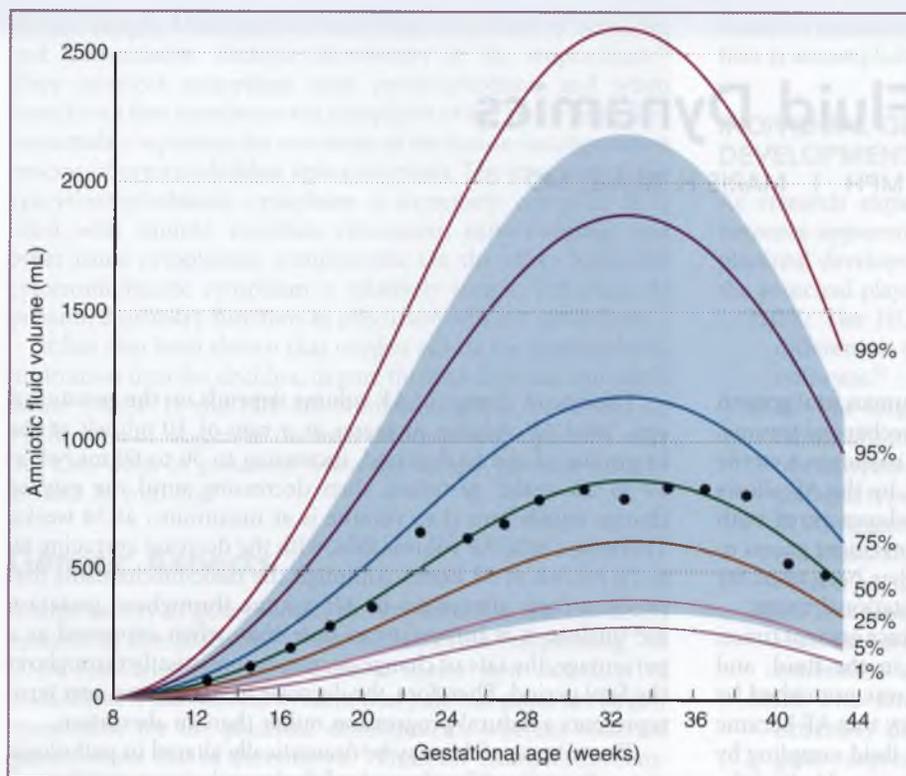

Figure 3-1 Amniotic fluid volumes from 8 to 44 weeks of human gestation. Dots represent mean measurements for each 2-week interval. Shaded area indicates the 95% confidence interval (2.5 to 97.5 percentiles). (From Brace RA, Wolf EJ: *Normal amniotic fluid volume changes throughout pregnancy*, *Am J Obstet Gynecol* 161:382–388, 1989.)

latter half of pregnancy, most commonly in the sheep model. Evidence suggests that the entire volume of AF turns over on a daily basis,¹⁸ making this a highly dynamic system. The volume of AF is influenced by a complex interplay of productive and absorptive mechanisms (Fig. 3-2).¹⁹ These

mechanisms act to maintain AF volume, and there is some evidence that they may be regulated to normalize AF volume in pathologic conditions.

The major contributors to AF volume in the latter portion of pregnancy are fetal urine and fluid produced by the fetal lung. Minor contributors are transudation across the umbilical cord and skin and water produced as a result of fetal metabolism. Although some data on these processes in the human fetus are available, the bulk of the information about fetal AF circulation derives from animal models, primarily the sheep.

URINE PRODUCTION

Although the mesonephros can produce urine by 5 weeks of gestation, the metanephros (the adult kidney) develops later, with nephrons formed at 9 to 11 weeks,²⁰ at which time fetal urine is excreted into the AF. The amount of urine produced increases progressively with advancing gestation, and it constitutes a significant proportion of the AF in the second half of pregnancy.²¹ The amount of urine produced by the human fetus has been estimated by the use of ultrasound assessment of fetal bladder volume.²² Although there continues to be uncertainty regarding the accuracy of noninvasive measurements, human fetal urine output appears to increase from 110 mL/kg/24 hr at 25 weeks to almost 200 mL/kg/24 hr at term,^{22,23} in the range of 25% of body weight per day or almost 1000 mL/day near term.^{22,24–26} In near-term fetal sheep, with direct methods used for measuring urine production rates, similar high values have been found.^{27–29} There may be a tendency for the urine flow rate to decrease after 40 weeks' gestation, particularly if oligohydramnios is present.³⁰

Reduction or absence of fetal urine flow is commonly associated with oligohydramnios, indicating that urine flow is

probably necessary to maintain normal AF volume. The mature fetus can also respond to changes in internal fluid status by modulating urine flow. In sheep, increased fetal blood pressure stimulates fetal secretion of atrial natriuretic factor³¹ and an accompanying diuresis,³² whereas increased plasma osmolality stimulates fetal vasopressin secretion and an antidiuretic response.^{33,34} These findings indicate that AF volume could be regulated through the mechanism of altered fetal urine flow. However, in the sheep, fetal hypoxia increases urine flow³⁵ but AF volume is maintained. These data suggest that regulation of AF volume is mediated by other mechanisms in addition to changes in urine production.

LUNG FLUID PRODUCTION

It appears that all mammalian fetuses secrete fluid from their lungs. The AF phospholipids (lecithin, sphingomyelin, and phosphatidylglycerol) used to predict human fetal lung maturity are evidence that human fetuses are not exceptions to this statement. The rate of fluid production by the human fetal lungs has not been measured, and available data are derived from the ovine fetus. During the last third of gestation, the fetal lamb secretes an average of 100 mL/day per kilogram of fetal weight from the lungs. Under physiologic conditions, half of the fluid exiting the lungs enters the AF and half is swallowed³⁶; therefore, although total lung fluid production approximates one-third that of urine production, the net AF contribution made by lung fluid is only one-sixth that of urine. Fetal lung fluid flow is mediated by active transport of chloride ions across the lung epithelium³⁷ and is isotonic to plasma, unlike the increasingly hypotonic urine. Lung fluid production is affected by diverse fetal endocrine factors. Increased arginine vasopressin (AVP),³⁸ catecholamines,³⁹ and cortisol⁴⁰ decrease lung fluid production, effects that may help to explain the enhanced clearance of lung fluid in fetuses delivered after labor, compared with elective cesarean delivery.^{41,42} However, almost all active stimuli have been demonstrated to reduce production of fetal lung liquid, indicating that lung liquid production functions at maximal capacity. Ovine fetuses with tracheal occlusion (used as a treatment for severe diaphragmatic hernia) demonstrate only a minor reduction in AF volume.⁴³ Modulation of lung fluid production is therefore unlikely to be a significant regulator of AF volume. In addition, experiments in instrumented ovine fetuses failed to demonstrate any effect of lung liquid on the regulation of AF volume.^{44,45} Current opinion is that fetal lung fluid secretion is likely most important in providing for pulmonary expansion, which promotes airway and alveolar development.

MINOR SOURCES OF AMNIOTIC FLUID

There are a number of other proposed sources for AF water; these include transudation across fetal skin before keratinization, transudation across the umbilical cord, saliva, and water produced as a byproduct of fetal metabolism. Fetal skin keratinizes at the beginning of the third trimester, making it an unlikely source for AF in the latter part of pregnancy.^{46,47} Fetal oral and nasal secretions do not appear to be a significant source of AF water.⁴⁸ Little is known regarding the actual value of other alternative sources of AF water, but at this time they are not thought to be important contributors to AF volume.

Resorption of Amniotic Fluid

FETAL SWALLOWING

One major route of resorption of AF is fetal swallowing. Studies of near-term pregnancies suggest that the human fetus swallows up to 760 mL/day,^{49,50} which is considerably less than the volume of urine produced each day. However, these estimates may be unreliable because fetal swallowing may be reduced beginning a few days before delivery.⁵¹ In fetal sheep, the daily volume swallowed increases from approximately 130 mL/kg/day at 0.75 term to more than 400 mL/kg/day near term,⁵² in contrast to a relatively constant urine production of 300 to 600 mL/kg/day,⁵³ again suggesting that the fluid produced exceeds the swallowed volume.

A series of studies measured ovine fetal swallowing activity by esophageal electromyography and swallowed volume with the use of a flow probe placed around the fetal esophagus.⁵⁴ These studies demonstrated that near-term fetal swallowing increases in response to dipsogenic (e.g., central or systemic hypertonicity,⁵⁵ central angiotensin II⁵⁶) or orexigenic (central neuropeptide Y⁵⁷) stimulation and decreases with acute arterial hypotension⁵⁸ or hypoxia.^{36,59} Therefore, near-term fetal swallowed volume is subject to periodic increases as mechanisms for "thirst" and "appetite" develop functionality. However, despite the fetal ability to modulate swallowing, this modulation is unlikely to be responsible for AF volume regulation. Fetal sheep subject to hypoxia maintained normal AF volume⁶⁰ despite decreased swallowing and increased urine flow, suggesting that another mechanism is responsible for AF volume regulation.

INTRAMEMBRANOUS FLOW

The amount of fluid swallowed by the fetus does not equal the amount of fluid produced by the kidneys and lungs in either human or ovine gestation. Because the volume of AF does not greatly increase during the last half of pregnancy, another route of fluid absorption is implied. The most likely route is the intramembranous (IM) pathway; the route of absorption from the amniotic cavity directly across the amnion into the fetal vessels.

Injection of distilled water into the AF is followed by a lowering of fetal serum osmolality,⁶¹ indicating absorption of free water. This occurs before any change in maternal osmolality. In sheep, the permeability of the amnion to inert solutes such as technetium (Tc) and inulin is greater from the AF toward the fetal circulation than in the other direction. This asymmetry of membrane permeability is not seen in vitro. These findings suggest that a continuous flow of water and solutes from AF to the fetal circulation (IM flow) occurs in vivo⁶² in addition to the bidirectional (diffusional) flow of water and solutes seen both in vivo and in vitro. Other studies have supported the thesis that compounds can cross directly from the AF to the fetal circulation: Both AVP⁶³ and furosemide⁶⁴ are taken up into the fetal circulation and are biologically active when injected into the AF after fetal esophageal ligation. Experimental estimates of the net IM flow have ranged from 200 to 400 mL/day in fetal sheep.^{61,65,66} This, combined with fetal swallowing, approximately equals the flow of urine and lung liquid under homeostatic conditions.

Although IM flow has never been directly detected in humans, indirect evidence supports its presence. For example,

studies using intra-amniotic chromium 51 (^{51}Cr) injection demonstrated appearance of the tracer in the circulation of fetuses with impaired swallowing.⁶⁷ In nonhuman primates, IM flow would explain the absorption of AF Tc⁶¹ and AVP⁶³ in fetuses after esophageal ligation. Mathematical models of human AF dynamics also suggest significant IM flows of water and electrolytes.^{68,69}

Other routes for absorption of AF have been investigated but have not been found to be important in the movement of water out of the AF. In particular, *transmembranous* water flow (from AF to maternal blood) is far less than IM flow.^{70,71} In the following discussion, IM flow is assumed to be the mechanism for fluid resorption from the AF other than by swallowing, with the understanding that other pathways may yet be discovered.

Possible Mechanisms to Regulate Amniotic Fluid Volume via Intramembranous Flow

As described earlier, fetal urine and lung output and fetal swallowing can all be modulated, but there is little evidence that this modulation serves as a mechanism for the maintenance of normal AF volume. By contrast, some experimental observations suggest that IM flow rates may be regulated to normalize AF volume. A description of membrane water flow and fetal membrane anatomy follows, together with some proposals for the mechanisms and regulation of IM flow.

MEMBRANE WATER FLOW

The AF serves as a fetal water compartment. Fetal water ultimately derives from the mother via the placenta, making membrane water permeability of interest in the accumulation as well as the circulation of AF. The water permeability of biologic membranes can be described mathematically, and values of membrane permeability thus defined can be used to compare one membrane with another. As a background for discussion of the possible mechanisms of water flux in pregnancy, a review of the basic concepts of membrane water permeability is provided.

There are five major routes for membrane transfer (of any moiety): (1) simple diffusion of lipophilic substances (e.g., oxygen), (2) diffusion of hydrophilic substances through transmembrane channels (the common mechanism for membrane water flow), (3) facilitated diffusion (such as occurs with D-glucose), (4) active transport (such as for certain electrolytes), and (5) receptor-mediated endocytosis (a mechanism of transfer of large molecules, such as immunoglobulin G).⁷² In addition to transcellular flow across the cell membrane, water and solutes may cross biologic membranes between cells (paracellular flow).

Except for the specific active transport systems, simple diffusion of any compound (in moles per second [mol/sec]) across the membrane along physical gradients can be described as follows:

$$J_s = PS(c_1 - c_2) + \frac{(c_1 - c_2) \cdot (1 - \sigma)}{\ln\left(\frac{c_1}{c_2}\right)} \cdot J_v + \frac{t^+ \cdot I}{F} \quad [1]$$

where c_1 and c_2 (in mol/m³) represent the unbound solute concentrations on opposite sides of the membrane, with $c_1 > c_2$. P represents the solute permeability of the membrane (in m/sec), S stands for the surface area for diffusion (in m²), and σ is the reflection coefficient (dimensionless), which is a measure of the exclusion of the solute by the membrane. J_s is the solute flux (in mol/sec), t^+ is the cationic transfer number (dimensionless), I is the electrical current (in coulombs per second [C/sec]), and F is the Faraday constant (in coulombs per mole).⁷³ J_s is influenced by the solubility of the compound under investigation: Lipid-insoluble compounds have low flow and, in turn, low permeability in the absence of membrane channels. However, the mathematical description presented here makes no assumption about the route of passive membrane flow. The volume (water) flow (J_v) can be simplified to become the well-known Starling equation:

$$J_v = LpS[\Delta P - \sigma RT(c_1 - c_2)] \quad [2]$$

where Lp is the hydraulic conductance (in m³/N·s), S is the surface area (in m²), ΔP is the hydrostatic pressure difference (in N/m²), σ is the reflection coefficient, R is the gas constant (in N·m/kmol in degrees Kelvin), T is temperature (in degrees Kelvin), and c_1 and c_2 represent the osmotic pressure on opposite sides of the membrane (in mol/m³). Flow of water depends on the magnitude of the hydrostatic and osmotic pressure difference.⁷³⁻⁷⁵

Experimental studies on biologic membranes often report the membrane permeability, P (usually in cm/sec) or the flux, J (in mL/sec/cm²). At times, the filtration coefficient, LpS , is also reported (in mL/min per unit of force [mm Hg or mOsm/L] per kilogram). Flux is used when the reflection coefficient of the solute responsible for the osmotic force is unknown. The filtration coefficient is used when the surface area of the membrane being tested is unknown; this is often the case, for example, in whole-placenta preparations.⁷⁶ Membrane water permeabilities are reported as the permeability associated with flow of water in a given direction and under a given type of force or as the diffusional permeability (bidirectional). Because one membrane may have different osmotic, hydrostatic, and diffusional permeabilities,⁷⁷ an understanding of the forces driving membrane water flow is critical in understanding flow regulatory mechanisms (see later discussion).

Understanding the forces driving membrane water flow can have clinical relevance. For example, there is evidence that maternal dehydration is associated with oligohydramnios, presumably on an osmotic basis,^{78,79} and that rehydration can increase fetal urine flow and AF volume.^{80,81} Hypoproteinemia with decreased maternal plasma oncotic pressure may be associated with an increase in AF.⁸² Finally, water flow considerations have been used to describe the physiology of twin-twin transfusion syndrome, leading to accurate prediction of the success of various treatment modalities.^{83,84}

MEMBRANE ANATOMY

In sheep, an extensive network of microscopic blood vessels is located between the outer surface of the amnion and the chorion,⁸⁵ presumably providing the surface area for IM flow. In primates, including humans, IM flow likely occurs across the fetal surface of the placenta, where fetal vessels course under the amnion. In vivo studies of ovine IM flow suggest that

membrane water flow is proportionate to the AF volume and that water flow can be independent of the clearance of other molecules.⁸⁶⁻⁸⁸ In the sheep, the filtration coefficient of the amnion has been estimated to be 0.00137 mL/min/mm Hg per kilogram of fetal weight,⁷⁶ although IM flow rates under control conditions *in vivo* have not been directly measured. In the human, membrane ultrastructure changes are observed with polyhydramnios or oligohydramnios,⁸⁹ suggesting that alterations in IM flow may contribute to idiopathic AF abnormalities.

Presumably, IM flow is dependent on the water permeability of the fetal membranes and blood vessels. Despite the relative ease of measurement, chorioamnion permeability to water *in vitro* has rarely been assessed. In one experiment, human amnion overlying the chorionic plate was studied in an Ussing chamber at 38° C. The membrane diffusional permeability to water was measured at 2.2×10^{-4} cm/sec.⁹⁰ Another experiment found an osmotic permeability of 1.5×10^{-2} cm/sec in human amnion.⁷⁷ These values are similar to values obtained in renal tubular epithelium,⁹¹⁻⁹³ and indicate that the amnion is a “leaky” epithelium with the potential for significant water flux. When human amnion and chorion were both tested, the amnion appeared to be a more effective barrier to the diffusion of water.⁹⁴ Similarly, in the sheep, the permeability of amniochorion was $2.0 \pm 0.3 \times 10^{-4}$ cm/sec and the permeability of amnion alone was $2.5 \pm 0.7 \times 10^{-4}$ cm/sec.⁸⁶ This, coupled with the fact that the fetal vessels occur between the amnion and the chorion, suggests that the amnion is the membrane more likely to be involved in regulation of IM water flow.

Possible Regulation of Intramembranous Flow

Studies in the ovine model suggest that flow through the IM pathway can be modulated to achieve AF volume homeostasis. Because fetal swallowing is a major route of AF fluid resorption, esophageal ligation may be expected to increase AF volume significantly. Although AF volume did increase significantly 3 days after ovine fetal esophageal occlusion,⁹⁵ longer periods (i.e., 9 days) of esophageal ligation reduced AF volume in preterm sheep despite continued production of urine.⁶⁰ Similarly, esophageal ligation of fetal sheep over a period of 1 month did not increase AF volume.⁹⁶ In the absence of swallowing but with continued fetal urine production, normalized AF volume suggests an increase in IM flow. In addition, AF resorption was found to increase markedly after infusion of exogenous fluid to the AF cavity⁹⁷ and after increased fetal urine output stimulated by a fetal intravenous volume infusion.⁸⁸

Collectively, these studies suggest that IM flow may be under feedback regulation. That is, in the sheep, AF volume expansion increases IM resorption, ultimately resulting in normalization of the AF volume. In contrast, human fetuses with esophageal obstruction demonstrate dramatic polyhydramnios. The reason for this difference between the two species is unknown, but despite the failure of putative regulatory mechanisms to normalize AF volume in the human, there is evidence of membrane changes with human polyhydramnios (see later discussion) that suggests a partial compensatory response.

Factors that downregulate IM flow are less well characterized, and there is no evidence of reduced IM resorption as an adaptive response to oligohydramnios. Downregulation of IM flow is possible because prolactin reduces the upregulation of

IM flow resulting from osmotic challenge in the sheep model⁹⁸ and may reduce diffusional permeability to water in human⁹⁹ and guinea pig¹⁰⁰ amnion. Feedback regulation also requires an AF volume “sensor.” Intrauterine volume changes do not appear to trigger alterations in IM flow because the expansion of intra-amniotic volume by injection of fluid into an intra-amniotic balloon did not cause a compensatory change in AF volume in a sheep model.¹⁰¹

Understanding of the specific mechanisms and regulation of IM flow is crucial to the understanding of AF homeostasis. Bulk water flow across an epithelial membrane requires a motive force. IM flow may be driven by the significant osmotic gradient between the hypotonic AF and isotonic fetal plasma⁶¹ in humans and sheep, although in rats and mice the osmotic gradient does not favor AF-to-plasma flow.^{102,104} One explanation may be that solute concentration at the membrane surface differs significantly from that in the plasma or in the AF as a whole, a phenomenon known as the unstirred layer effect.¹⁰⁵ Gross hydrostatic forces are unlikely to drive AF to fetal flow because the pressure in the fetal vessels exceeds that in the amniotic cavity. Hydrostatic forces could be developed between the AF and interstitial space, with another force (e.g., a local osmotic force) promoting water flow into the bloodstream. Local changes in hydrostatic or osmotic pressure have been proposed to drive IM flow, but none of these has been demonstrated *in vivo*.

A variety of molecules have been proposed to regulate IM flow. Because esophageal ligation of fetal sheep resulted in upregulation of fetal chorioamnion vascular endothelial growth factor (VEGF) gene expression,¹⁰⁶ it was proposed that VEGF-induced neovascularization potentiates AF water resorption. The investigators further speculated that fetal urine or lung fluid, or both, may contain factors that upregulate VEGF, although more recent work by the same group demonstrated no effect of lung liquid on the rate of IM flow.^{44,45} The association of increased VEGF (and presumably vessel growth and permeability¹⁰⁷) with increased IM flow, coupled with the difference observed between the asymmetrical flow *in vivo* and the symmetrical permeability of amnion *in vitro*, has also led to the suggestion that the rate of IM flow is regulated by the fetal vessel endothelium rather than the amnion.⁶²

In animal studies, when fetal urine output was increased by an intravenous volume load, there was an increase in AF resorption despite a constant membrane diffusional permeability to technetium.⁸⁸ In addition, artificial alteration of the osmolality and oncotic pressure of the AF revealed that IM flow was highly correlated with osmotic differences, although there was a component of IM flow that was not osmotic dependent. Because this flow pathway was also permeable to protein, with a reflection coefficient near zero, this residual flow was believed to be similar to fluid flow in the lymph system.¹⁰⁸ These findings, in aggregate, have been interpreted to indicate active transport of bulk fluid (i.e., water and solutes) from the AF to the fetal circulation, either in the amnion or in the fetal vessel wall. This theory has not been widely accepted because active transport of fluid has not been demonstrated in any other tissue and would be highly energy dependent.

Most authors believe that IM flow occurs through conventional paracellular and transcellular channels, driven by osmotic and hydrostatic forces, perhaps through an unstirred layer effect. Mathematical modeling indicates that relatively small IM sodium fluxes can be associated with significant changes in AF volume, suggesting that active transport of sodium may be a

regulator of IM flow.⁶⁹ However, the observation that a portion of IM flow is independent of osmotic differences suggests that other forces may also be significant.¹⁰⁸

Upregulation of VEGF expression or sodium transfer alone cannot explain AF composition changes after fetal esophageal ligation because AF electrolyte composition indicates that water flow increases disproportionately to that of solute (i.e., electrolyte).⁶⁵ The passage of free water across a biologic membrane is a characteristic of transcellular flow, a process mediated by cell membrane water channels (aquaporins). Although water flow through these channels is passive, the expression and location of the channels are modulated in other tissues (e.g., kidney) to regulate water flux. Therefore, aquaporin gene expression may be modulated to affect IM flow. Studies have demonstrated expression of the genes *AQP1* through *AQP9* in fetal membrane and placenta in a variety of species,¹⁰⁹ suggesting that these aquaporins could participate in the regulation of gestational water flow.

In the human, expression of *AQP1*, *AQP3*, *AQP8*, and *AQP9* was increased in the amnion in idiopathic polyhydramnios.¹¹⁰⁻¹¹² These increases in local aquaporin expression may be directly related to the AF volume disturbance because hypotonic culture medium increased the gene expression of *AQP8* in amnion cells in culture,¹¹³ and forskolin, an adenylate cyclase activator, increased the expression of *AQP1*, *AQP8*, and *AQP9* in cultured amniocytes.¹¹⁴ Oligohydramnios has been associated with a decrease in *AQP1* and *AQP3* expression in human amnion.^{115,116} Changes seen in both polyhydramnios and oligohydramnios are consistent with compensatory changes tending to correct the AF volume abnormality. In the sheep, *AQP1* protein increased in chorioallantoic membranes when the fetus was made hypoxic, suggesting a mechanism for the increased IM flow associated with ovine fetal hypoxia.¹¹⁷ In the mouse model, mice lacking

the gene for *AQP1*¹¹⁸ or *AQP8*¹¹⁹ had significantly increased AF volumes, along with other significant differences.

Although most of the major sources of AF inflow and outflow can be modulated, only IM flow can be shown to undergo modulation in response to primary changes in AF volume, suggesting IM flow as the candidate mechanism for AF volume homeostasis. Expression of various aquaporins also demonstrates an association with existing AF volume and the potential for modulation with changes in AF, suggesting the mechanism by which IM flow is modulated. This remains an area of active investigation.

Conclusion

AF is an important component of successful gestation. It provides an environment for normal development and serves as a convenient source of diagnostic material. Normal AF volumes can vary widely among individuals. In addition, a variety of pathologic conditions may be associated with frankly abnormal AF volume. Early in gestation, AF appears to be a transudate of fetal serum, although the specifics of early AF production and resorption are little studied. In the second half of pregnancy, human AF is hypo-osmolar to serum and contains increased concentrations of urea and creatinine. AF is produced largely by fetal urine and lung flow and is resorbed via fetal swallowing and IM flow. All of these flows can be modulated, but modulation of IM flow is the most likely mechanism for maintaining AF volume. The ability to therapeutically alter the production or resorption of AF would represent an important option in the treatment of pathologic alterations in AF volume.

Multiple Gestation: The Biology of Twinning

KURT BENIRSCHKE, MD

Incidence of Twinning

The incidence of twinning is increasing as the population ages and as the new modalities of assisted reproductive technology (ART) become widely used. Not only have artificial reproductive techniques led to a marked increase in higher-order multiple births (triplets, quadruplets, even octuplets) but also they are followed by an increase in prematurity rates and congenital anomalies.¹⁻³ The statistics, which are usually derived from national or regional birth records and rely on reporting by physicians or other personnel attending births, do not accurately reflect the occurrence of twins at conception, because the much higher prenatal mortality of twins (as abortion or fetus papyraceus) is not taken into account. Thoughtful reviews of the multiple gestation “epidemic” are available.⁴⁻⁶ Some countries have chosen to deny transfer of more than one blastocyst.⁷ There has been a documented increase of monozygotic twinning (i.e., identified as monochorionic) when various ART procedures are used, and placental abnormalities are also more frequent.⁸ A good example is provided by the so-called Octomom, a woman who had six embryos transferred but delivered eight babies. Two of the transferred embryos had split. A detailed discussion of ART methodology and its outcome may be found in the recent work of Benirschke and colleagues.⁹

In 1953, Guttmacher¹⁰ suggested that 1.05% to 1.35% of pregnancies were twins, the reason for the wide variation being large differences in the frequency of the twinning process among different populations. Data collated from various countries reveal that the variability relates largely to the ethnic stock of the population under consideration. Moreover, although the dizygotic (DZ) twinning rate varies widely under different circumstances, the monozygotic (MZ) twinning rate is considered to be remarkably constant, usually between 3.5 and 4 per 1000 pregnancies,¹¹ although Murphy and Hey¹² found the rate to have slightly increased in the 1990s. In recent national statistics, 3.3% of 4 million births in the United States were multiples, or 1 in 30 gestations.^{12a}

When the twinning rate of a population is known, the frequencies of higher-order births can be roughly calculated by Hellin’s hypothesis, which states that, when the frequency of twinning is n , that of triplets is n^2 , that of quadruplets is n^3 , and so on. The highest number recorded so far is nine offspring.¹³ Since 1973, there has been a steady rise in the incidence of twins and triplets, so that currently at least 1 in 43 births is a twin and 1 in 1341 pregnancies results in triplets.^{2,14} In part, this increase has been attributed to delayed childbearing, but the use of ovulation-enhancing drugs has also been implicated. While

acknowledging the increased DZ twinning frequency attributed to clomiphene, Tong and coworkers¹⁵ found that the DZ-to-MZ ratio had significantly declined, from 1.12 in 1960 to 0.05 in 1978, and suggested adverse environmental factors as a possible cause.

Types of Twins

Twins who possess characteristics that make them virtually indistinguishable are referred to as “identical,” whereas twins who are unlike are considered “fraternal.” Identical twins always have the same sex, but fraternal twins may be of different sexes. However, these terms, although popular, are scientifically less useful and are best replaced by the terms *monozygotic* (MZ) and *dizygotic* (DZ), respectively, to indicate the mechanism of origin of the two types of twins. An important reason for this preference is that MZ twins with discordant phenotypes (e.g., cleft lip) would be misclassified in the former system as fraternal.

To assess the frequency of MZ and DZ twins, investigators have commonly used the Weinberg differential method. This method suggests that the frequency of MZ twins can be deduced from a twin sample when the sex of the twin pairs is known. For example, if the numbers of male and female conceptuses were approximately equal and all twins were fraternal (DZ), there would be 50 male-female pairs, 25 male-male pairs, and 25 female-female pairs among every 100 pairs of twins. Any excess of like-sex twins may therefore be assumed to be the population of MZ twins. This number can be calculated by the following formula:

$$\text{MZ twins} = (\text{like-sex pairs} - \text{unlike-sex pairs}) \\ + \text{number of pregnancies}$$

When this formula is applied to national birth statistics, approximately one third of twins in the United States are found to be MZ, although it must be said that the tautology of Weinberg, as Boklage¹⁶ called it, has often been criticized. Moreover, there is a very high twinning rate among the Yoruba tribe in Nigeria, resulting from a higher frequency of double ovulation, and a low twinning rate in Japan due to a lower frequency of double ovulation.

This formula also supports the notion that MZ twinning occurs with a relatively uniform incidence in different populations and rises only slightly with advancing maternal age.¹¹ In contrast, the rate of DZ twinning increases with maternal age to about 35 years and then falls abruptly. The rate also increases with parity, is higher in conceptions that occur in the first 3 months of marriage, and decreases during periods of

malnutrition, as was demonstrated during World War II. James¹⁷ deduced that DZ twinning also increases with coital frequency, and numerous studies indicate that DZ twins occur in certain families, presumably because of the presence of genetic factors leading to double ovulation. These factors are expressed in the mother but may be transmitted through males. Only a few pedigrees suggest that MZ twinning is inherited, and most authorities have concluded that it is a random event. There is also some, occasionally disputed, evidence that ART has increased the frequency of MZ twin births as well, perhaps because of some type of damage to the blastocyst.¹⁸⁻²²

Much has been written about the possible occurrence of "third twins," or the uncommon twins that may arise from possibly irregular ovulation events, such as polar body fertilization. Bulmer¹¹ concluded that such an event is unlikely to have been described. Bieber and colleagues,²³ however, suggested that the development of an acardiac triploid twin (a malformed MZ twin without a heart) represents such an example. As explained later, the topic is important only because the evidence that DZ twins come from two ovulations does not rest on very firm knowledge; there is currently no proof that two corpora lutea are present in DZ twin births. Goldgar and Kimberling²⁴ developed a genetic model to discriminate between DZ and polar body twins. They found that only near-centromeric genetic loci can be confidently used to make such a crucial distinction.

Twins may also originate from fertilization by sperm of two fathers, and the suggestion by James¹⁷ that DZ twinning is influenced by coital rates relates to this phenomenon of superfecundation. Few cases have been verified. In the ninth reported case, one white male twin and one African-American male twin were presumably conceived by two documented coital events that occurred 1 week apart.²⁵

Causes of Twinning

The causes of MZ and DZ twinning are incompletely understood. It is commonly assumed that DZ twinning occurs because of double ovulation, and occasional case descriptions support this assumption. Meyer and Meyer²⁶ described two 14-day implantation sites with two corpora lutea of similar age in contralateral ovaries. Moreover, multiple pregnancy can be induced by hormonal induction of ovulation, and the polyovulation can be followed via ultrasonography.^{27,28} Serum gonadotropin levels in twin-prone Nigerian women are higher than in control subjects,²⁹ and lower levels are found in Japanese women, who are less likely to produce fraternal twins.³⁰ For these and other reasons, it is reasonable to assume that DZ twinning is the result of somewhat elevated serum gonadotropin levels, leading to double ovulation. Moreover, it is assumed that gonadotropin levels are influenced by maternal age, nutrition, parity, and maternal genotype, among other factors. It has also been found that DZ twinning correlates with a mutation on chromosome 3 that codes for a receptor gene,³¹ whereas Healey and colleagues³² questioned a relationship to the fragile X syndrome. More recently, a number of additional factors have been found to affect the ovulation rate. In sheep and cattle, specific mutations have been correlated with multiple ovulation,³³ and insulin-like growth factor-1 has been found to interact with ovulation and folliculogenesis.³⁴

Although these assumptions may be correct, they are not proven, and the existence of two corpora lutea is rarely

ascertained when twins are born. The use of ovulation-enhancing agents has led to an increase in MZ twins, but this is most easily identified in triplets.³⁵ We observed the same phenomenon in placental examinations of triplets and quadruplets. This finding seems at first contradictory, but accidents in preservation of the zona pellucida have been witnessed in assisted reproduction of domestic animals, and such accidents are possibly also the basis for these unexpected events. In addition, the occurrence of two ova in one follicle is well documented, as are many abnormal fertilization events.

More important questions about the validity of this concept of DZ twinning are statistical and remain unanswered. Non-right handedness is found not only in MZ and DZ twins but also in their close relatives at a higher rate than would be expected in the general population.³⁶ The same observations have been made with respect to certain forms of schizophrenia, suggesting that the traditional MZ and DZ divisions may be incorrect. A full spectrum may exist between the two classes, and the MZ twinning process may relate to a factor interfering with the development of brain symmetry in the embryo. It has been suggested that there is a continuum between MZ and DZ twinning propensity.

The mechanisms leading to MZ twinning are even more obscure. That such twins exist can be verified not only by their physical similarity but also by their identity in genetic characters. Exhaustive blood group analysis, finding no differences in the face of different parental markers, was formerly used to verify identity. Chromosomal markers have been used for the diagnosis of MZ twins with apparently greater assurance,^{37,38} but most recently the direct comparison of DNA variations is being used for zygosity diagnosis. The determination of restriction fragment length polymorphism (RFLP) compares fragments of DNA and is decisive. This technique can use a variety of tissues, including blood and placenta.^{39,40} The methodology has now been greatly simplified and automated so that zygosity diagnosis can be achieved quickly, reliably, and inexpensively.⁴¹

The facts that MZ twins occur slightly more frequently with advancing maternal age,¹¹ that discordant malformations often occur, that conjoined twins develop, and that MZ twinning can be induced by teratogens⁴² have led to the hypothesis that MZ twins result from a teratologic event. Boklage³⁶ suggested a disturbance in the process of symmetry development in the embryo. It has been possible to produce MZ twins by separation of early blastomeres in a few animal genera (e.g., *Triturus*, *Ovis*, *Bos*, *Mus*), but such physical events do not occur in early human embryonic stages. On the other hand, there is some evidence that MZ twinning may be more frequent after ART procedures, although some have disputed this conclusion. Steinman and Valderrama,^{43,44} who have had an interest in the mechanism, suggested that the possible reduction of calcium ions (needed for cell adhesion) may be causative because of the composition of the culture fluids and length of exposure in *in vitro* fertilization.

Because of these uncertainties, it has been convenient to speak of the "twinning impetus," an external and perhaps teratogenic agency that is randomly distributed and that may lead to twins only up to a certain stage before the embryonic axis is established. Experiments in mice with vincristine have supported this hypothesis.⁴² If teratogens had their effect later, twins would not result; rather, anomalies in the singleton might develop. Further, it is assumed that this twinning impetus may

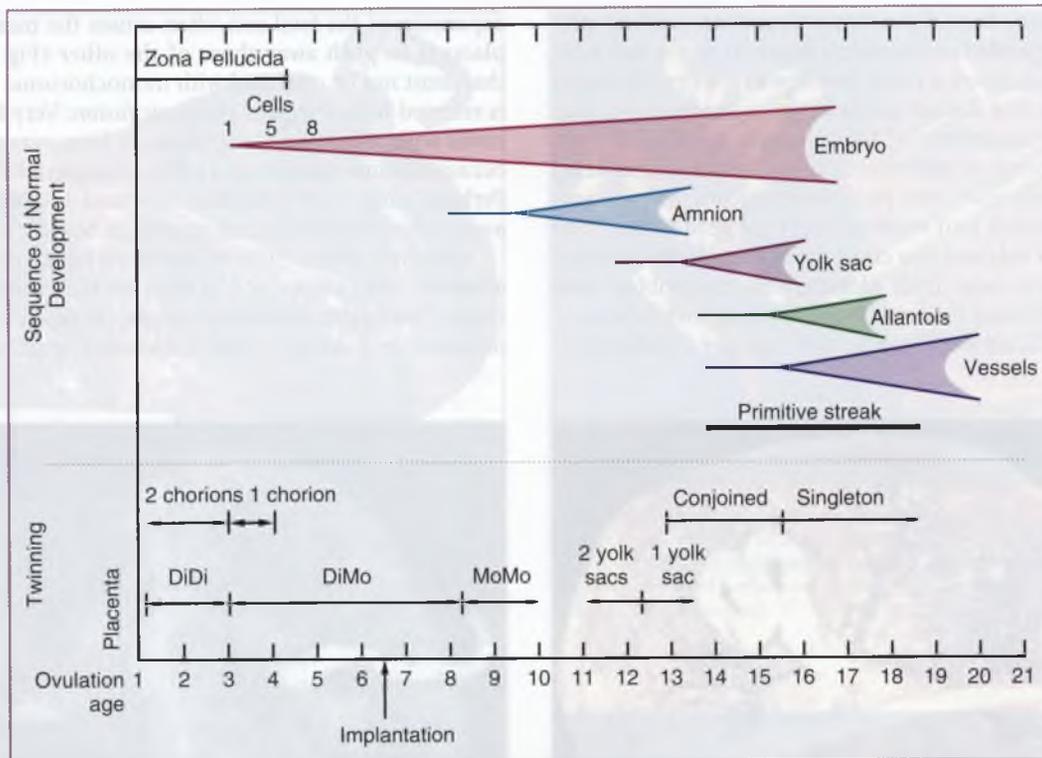

Figure 4-1 Schematic representation of monozygotic twinning event superimposed on temporal events of embryogenesis. The embryonic events in the upper portion are sketched according to the publications of early human embryos by Hertig (1968). The twinning event is depicted in the lower portion, with resulting placental types indicated. DiDi, diamniotic dichorionic; DiMo, diamniotic monochorionic; MoMo, monoamniotic monochorionic. (From Benirschke K, Kim CK: *Multiple pregnancy*, N Engl J Med 288:1276, 1973. Reprinted by permission from *The New England Journal of Medicine*.)

lead to separation of only the embryonic cells but will not lead to the splitting of already formed cavities. Therefore, when the embryonic events are plotted against embryonic age, one may deduce from the placental configuration the approximate timing of the twinning process (Fig. 4-1).

Placentation in Twinning

There are two principally different placental types, monochorionic and dichorionic placentas (Fig. 4-2), and it is essential that they be so identified at birth. Indeed, it is also desirable to differentiate these placentas prenatally by ascertaining the thickness of the “dividing membranes” sonographically. Winn and associates⁴⁵ established criteria for this measurement and suggested that a maximal thickness of 2 mm is diagnostic of monochorionicity with an 82% accuracy. Subsequent studies showed the reliability of this methodology, especially in the mid-trimester. Oligohydramnios is its most serious limitation.^{46,47} Numerous surveys of placental types of twins have shown that heterosexual (assuredly DZ) twins almost always have a dichorionic placenta, and monochorionic twins are always of the same sex. These basic facts lead to the assumption that all monochorionic twins are MZ; however, exceptions have also been reported on very rare occasions.^{48,49} Moreover, a few cases of mixed type (dichorionic and monochorionic) have been described, especially in association with the twin-to-twin transfusion syndrome (TTTS).⁵⁰ Most likely, such twins arise at the interface between dichorionic and monochorionic twinning

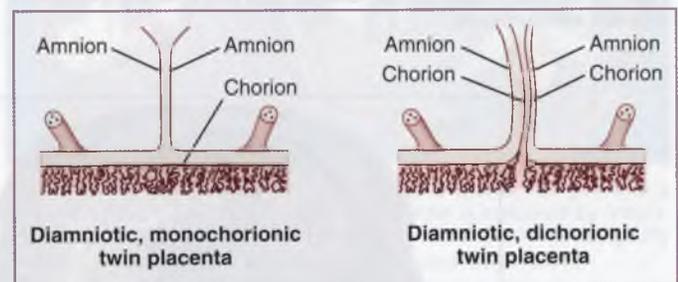

Figure 4-2 The two principal types of twin placentation. Left, Diamniotic monochorionic placenta, always monozygotic. Right, Diamniotic dichorionic placenta, which may or may not be fused.

events (at approximately day 3) (see Fig. 4-1). Blood chimerism in DZ twins most likely occurs similarly from fusion of the chorions (see later discussion).

Some MZ twins may be endowed with dichorionic placentas (i.e., twins that separated during the first 2 days after fertilization) (see Fig. 4-1). However, most MZ twins have a placenta with diamniotic and monochorionic membranes (Fig. 4-3). Monoamniotic twins, which are by necessity also monochorionic, occur least commonly (approximate incidence, 1%). Conjoined twins are monoamniotic and are less common still, because it probably becomes increasingly difficult for a rapidly growing embryo to submit to the twinning impetus.

DZ twins always have dichorionic placentation. Their placentas may be separated or intimately fused (Figs. 4-4 and 4-5). If the placentas are fused, a ridge develops in the central fusion plane that allows easy distinction from the monochorionic placenta. With rare exceptions,^{51,52} blood vessels never cross from one side to the other in dichorionic twin placentas, and when the dividing membranes (that portion separating the two sacs) are carefully dissected, four separate layers can be identified: one amnion on either side and two chorions in the middle. Between the two chorions, one finds degenerated trophoblast and atrophied villi, features that render the dividing membranes of a diamniotic dichorionic twin pair opaque. Differential

expansion of the fetal sacs often causes the membranes of one placenta to push away those of the other (Fig. 4-6), a feature that must not be confused with monochorionic placentation. It is referred to as *irregular chorionic fusion*. Very few verified DZ twins with monochorionic placenta have occurred, even with occasional anastomoses and with consequent blood chimerism. Perhaps most have not been reported because they are not ascertained, which requires genetic or blood group studies.

Although 20% to 30% of MZ twins have a dichorionic placentation, most often the placentas of MZ twins are monochorionic. The latter type is most commonly fused, and the dividing membranes consist of two translucent amnions only. When

Figure 4-3 Diamniotic monochorionic twin placenta with numerous vascular anastomoses.

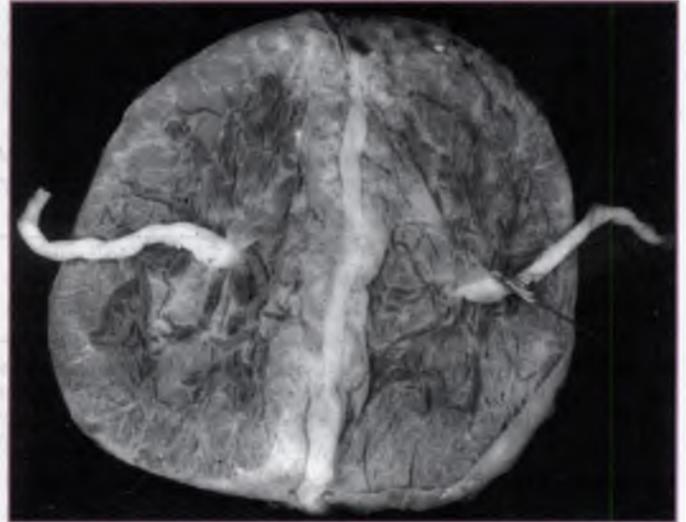

Figure 4-5 Diamniotic dichorionic twin placenta, fused. The umbilical cord on the left had a single umbilical artery. Note the close approximation of two placental disks with ridge formed by membranes in center.

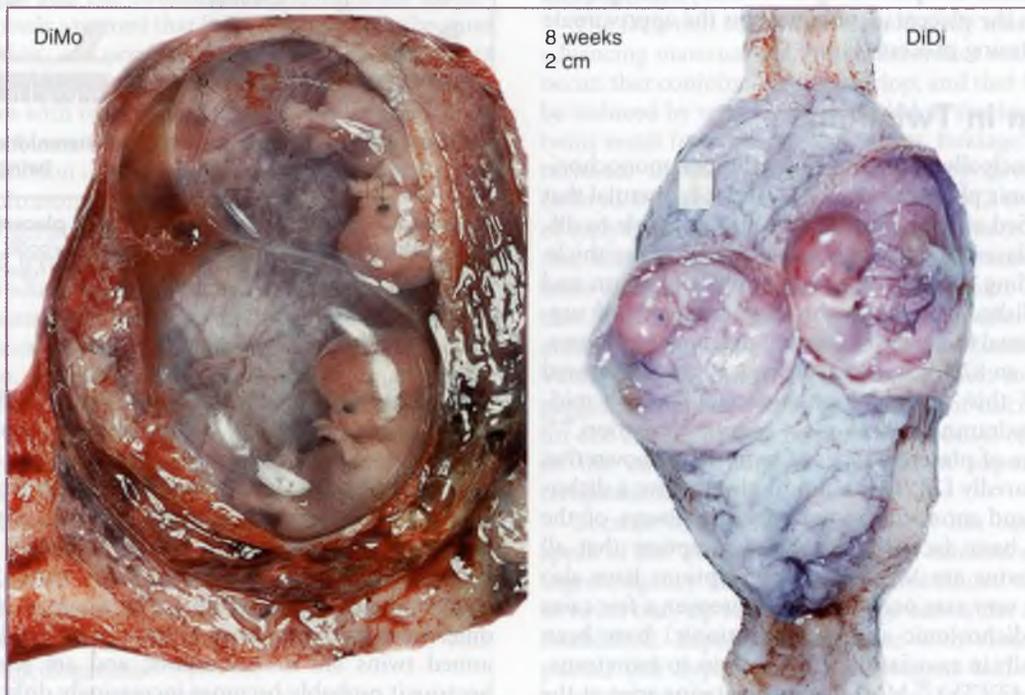

Figure 4-4 Twin gestations in utero, both at 8 weeks. Left, Monochorionic diamniotic twins. Right, Dichorionic diamniotic twins.

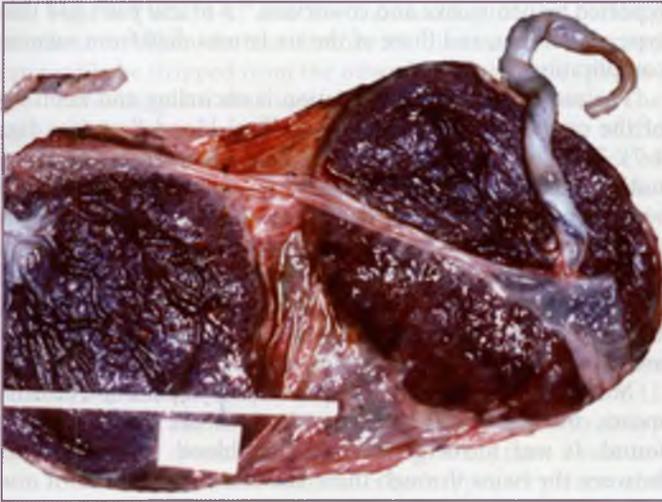

Figure 4-6 Diamniotic dichorionic (separate) twin placenta. The membranous sac of the left twin has pushed away the right membranes so that fusion of dividing membranes occurs over the right placenta (irregular chorionic fusion).

these amnions are separated from each other, the single chorion that remains on the placental surface is evident. The chorion carries the fetal blood vessels, and various types of interfetal vascular communications that occur regularly in monochorionic twins may be evident.

The two principal types of membrane relationships are shown in Figure 4-2. Monoamniotic twins are less common and carry a mortality rate of approximately 50% to 60% because the cords are frequently encircled and knotting may lead to cessation of umbilical blood flow. Fetal demise usually occurs during the first part of pregnancy; after 32 weeks' gestation, no further mortality can be expected from entangling,^{53,54} which by then can be identified sonographically.⁵⁵ The chronic stasis induced by cord entanglement can lead to stillbirth and also to thrombosis with calcification of fetal vessels (Fig. 4-7). The possibility also exists that formerly diamniotic membranes may become disrupted during gestation, with increased fetal mortality ensuing.⁵⁶ The perinatal mortality rate of diamniotic monochorionic twins is next highest (approximately 25%) because of the high frequency of the interfetal TTTS. The mortality rate is lowest for dichorionic twins (approximately 8.9%). These estimates were verified by a large study of twins in Belgium.⁵⁷

The relationship of placentas among triplets, quadruplets, and higher-order multiple births generally follows the same principles, except that monochorionic and dichorionic placentations may coexist (Fig. 4-8). With these higher numbers, there is more frequent association of placental anomalies, particularly marginal and velamentous insertions of the umbilical cord (see Figs. 4-8 and 4-9) and single umbilical artery (see Fig. 4-9). The cause of these anomalies may be related to the crowding of placentas and competition for space or to primary disturbances of blastocyst nidation.

VELAMENTOUS INSERTION OF UMBILICAL CORD AND VASA PREVIA

With the six to nine times higher incidence of velamentous umbilical cord insertion in twin placentas and an even higher

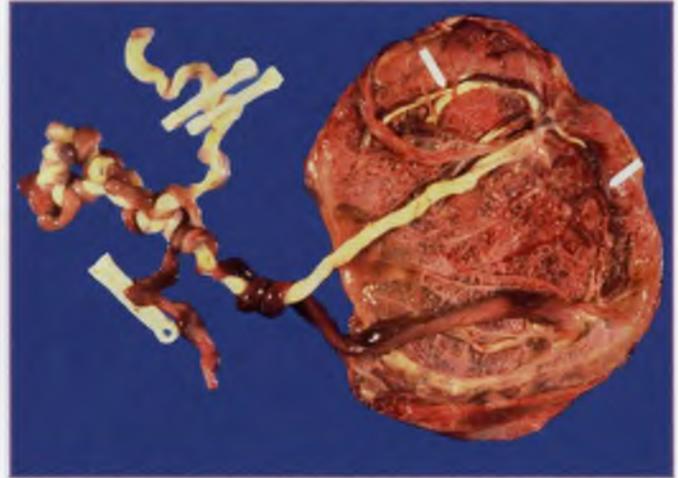

Figure 4-7 Monoamniotic twin placenta. There is marked encircling of the umbilical cords and fetal demise of the dark cord's twin. The other twin died also and had massive central nervous system damage. Notice the thrombosis of surface vessels and calcifications (yellow) of organized thrombi (white arrows).

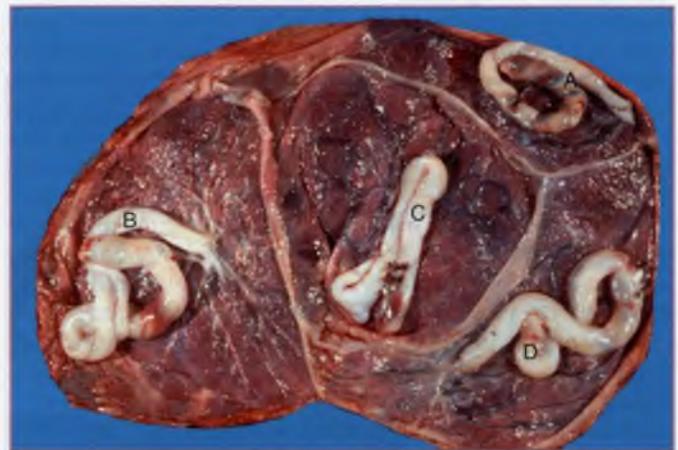

Figure 4-8 Placenta of quadruplets at 28.5 weeks. The placenta is tetrachorionic and intimately fused. Birth order is indicated by letters; infants A, C, and D were female, and B was male. Cord A is marginally inserted. Despite intimate fusion, there are no anastomoses.

incidence in higher-order multiple births, the presence of vasa previa in multiple pregnancy must be anticipated. It is a serious complication and is often lethal because of exsanguination during delivery (Fig. 4-10). Membranous vessels originating from a cord with velamentous insertion radiate toward the placental surface and are not protected by Wharton jelly. Therefore, they may thrombose or may be compressed during labor. When the membranes are ruptured during delivery and these vessels have a transcervical position (vasa previa), the rupture may lead to exsanguinating hemorrhage. Not only may the first twin exsanguinate but the second twin may exsanguinate through interfetal placental anastomoses if the placentation is monochorionic. Vasa previa may exist not only over the cervical os but also over the dividing membrane when the second twin's cord has a velamentous insertion on the dividing membranes. Fetal hemorrhage leading to death within 3 minutes has been

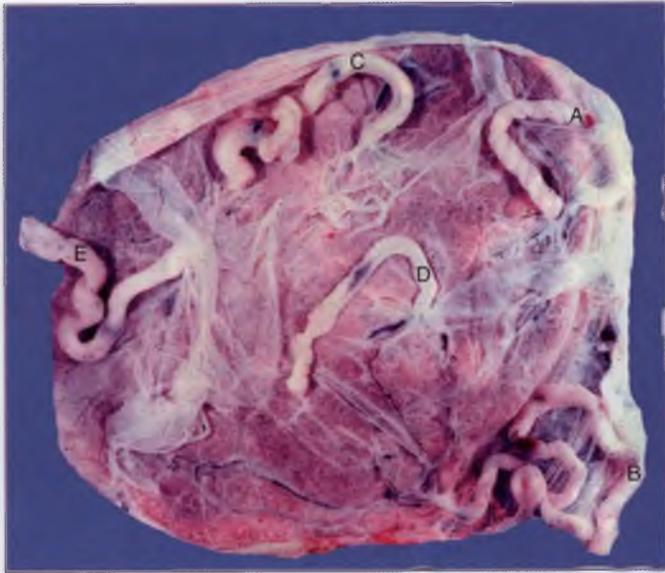

Figure 4-9 Immature monochorionic quintuplet placenta. All five infants died from hyaline membrane disease, and one had a single umbilical artery. There are numerous anastomoses. (From Benirschke K, Kaufmann P, Baergen RN: *The pathology of the human placenta*, New York, Springer-Verlag, 2006.)

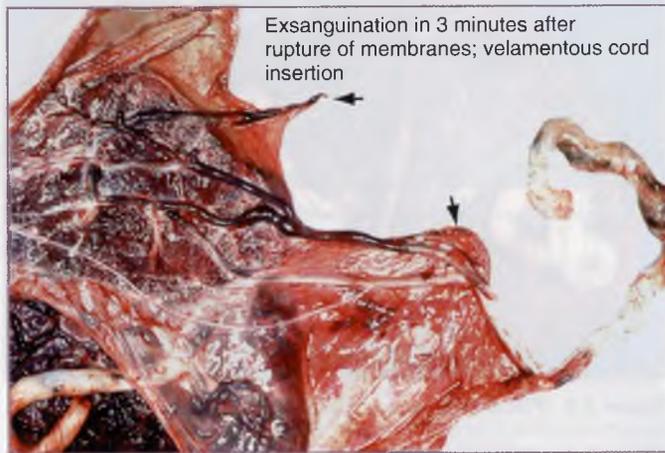

Figure 4-10 Fatal vasa previa in twin A of an intimately fused diamniotic dichorionic twin placenta. The disrupted vessel is indicated by arrows. The mother was admitted 4 hours after rupture of membranes with no history of significant bleeding. Twin A had an Apgar score of 1 and could not be resuscitated. Twin B lived. The left half of the placenta had marked pallor (on the maternal surface) because of fetal hemorrhage.

observed when the diamniotic dichorionic membranes of the second twin were ruptured.⁵⁸ In nine cases collected by Antoine and colleagues,⁵⁹ no first twin survived, and 62.5% of the second twins eventually succumbed as the result of this hemorrhage. The clinical management of vasa previa is discussed in detail in Chapter 46.

MONOAMNIOTIC TWINS

Monoamniotic twins are all MZ, and all must also have a single chorion. Monoamniotic twins are the least common type, occurring from 1 in 33 to 1 in 661 twin births. In the series

reported by Benirschke and coworkers,⁵⁸ 3 of 250 pairs had this type of placenta, and three of the six fetuses died from various complications.

The most common complication is encircling and knotting of the cords with cessation of umbilical blood flow (see Fig. 4-7). The degree of cord knotting is at times astonishing and testifies to the extent of fetal movements. In the past, double survival of monoamniotic twins was so uncommon that such cases were deemed worthy of case reports.⁶⁰ Preterm delivery, at 32 to 34 weeks' gestation, has led to increased survival of monoamniotic twins. Locking of the twins during delivery is rarely observed with monoamniotic twins, because almost all are delivered by cesarean section.

Most monochorionic twins have interfetal placental anastomoses, but such vessel communications are not invariably found. It was formerly believed that blood was exchanged between the twins through these anastomoses, and that if one twin succumbed before birth, thromboplastin, possibly originating in the macerating fetus, might lead to disseminated intravascular coagulation in the surviving twin. This phenomenon would be restricted to monochorionic placentation and was thought to occur in triplets as well. An alternative view for the demise of the second twin, and one that now has assumed greater likelihood, is that severe and acute hypotension develops because of exsanguination into an already dead twin via large anastomoses,⁶⁰⁻⁶² very much like the mechanism that led to the demise of the famous conjoined twin Eng after his brother, Chang, died.

Because of the high mortality rate, it is imperative to make an antepartum diagnosis. However, determination of a clear course of action has awaited accumulation of adequate statistics to delineate exactly when in the course of pregnancy one or both twins is likely to succumb from cord encircling. Rodis and colleagues⁶³ provided some of these data; they showed a 90% survival rate when adequate antenatal care was provided.

The umbilical cords of monoamniotic twins usually arise near each other on the placenta, and in rare circumstances they are partially fused. Less often, they are velamentous. The fusion of cords represents a gradual transition to the invariably monoamniotic conjoined twins that are thought to form only slightly later, at the end of the twinning spectrum shown in Figure 4-1. Conjoined twins may have two cords with three vessels each, forked cords, anomalous vessels, or, at the other end of the spectrum, one cord with only one artery and one vein. Congenital anomalies, more common among twins in general, are particularly common in monoamniotic and conjoined twins. The more frequent occurrence of sirenomelia—100 to 150 times more often in twins than in singletons—has led to insights into the relationship of this anomaly with pulmonary hypoplasia, a regular finding in sirens because of a deficient urinary tract. When one monoamniotic twin is a siren and the other is normal, the amniotic fluid produced by the second twin apparently protects the siren from experiencing pulmonary hypoplasia. When the placenta is diamniotic, this protection does not occur.⁶⁴

DIAMNIOTIC MONOCHORIONIC TWINS

Diamniotic monochorionic twins are MZ; the placenta is usually fused, and the umbilical cords often have a marginal or velamentous insertion. The diagnosis is readily apparent from the absence of a ridge at the base of the dividing membranes

(see Figs. 4-3 and 4-4) and the translucency of the dividing membranes. When the membranes are dissected, one amnion can readily be stripped from the other, leaving a single (placental) chorionic plate that carries the fetal blood vessels. The amnions do not necessarily meet at the vascular equator of the two placental beds but may shift irregularly from one side to the other, presumably because of fetal movements and the relative fluid contents of the two sacs. The diamniotic monochorionic placenta is the most common type observed in MZ twins (approximately 70%) (see Fig. 4-1). A review by Trevett and Johnson detailed all its major complications.⁶⁵

The diamniotic monochorionic twin placenta (and, less commonly, the monoamniotic twin placenta) almost always possesses interfetal blood vessel communications (Figs. 4-11 and 4-12). The anastomosis is more often an artery-to-artery (arterioarterial) communication (see Fig. 4-11) than a vein-to-vein communication, and sometimes both types are present and multiple. These vessels allow blood to shift readily from one side

to the other, equalizing blood volumes and pressures. They are most readily demonstrated, after the amnion has been removed, by careful inspection, by stroking of blood from one side to the other, or by injection. It is generally impractical to inject the entire placenta from the cord vessels, because rather large volumes are needed and the placental blood must not have been clotted. One can verify the existence of anastomoses more readily by first cutting off the cords and then injecting water or milk into those vessels that are thought to be anastomotic (see Fig. 4-12).

The large anastomoses have important practical clinical implications. Through these communications, the second twin may exsanguinate if vasa previa of the first twin are ruptured or, of course, if the cord of the first twin is not clamped. In the rare event that the diagnosis of a twin gestation is not made until the time of delivery, the practice of permitting placental transfusion to occur or of removing umbilical cord blood should be done only after it is confirmed that twins do not exist. Otherwise, the second twin may rapidly exsanguinate through these commonly large-caliber vessels (Fig. 4-13).

It must also be realized that interfetal anastomoses of larger caliber may lead to significant shifts of blood between fetuses. This is particularly important when one fetus dies. The vascular bed of the dead twin relaxes, and a substantial amount of blood from the survivor may enter the dead twin, causing anemia in the survivor, possibly with destructive consequences. It now appears likely that the appreciable frequency of cerebral palsy in a surviving monochorionic twin is caused by acute hypotension after one twin dies, which results from major blood shifts between the twins through placental anastomoses.^{60,66} This feature is grossly similar in appearance to that of the twins shown in Figure 4-14, who died from TTTS due to an arteriovenous anastomosis. One twin has much more blood than the other. When this condition is the result of large-vessel anastomoses rather than an arteriovenous shunt (described later),

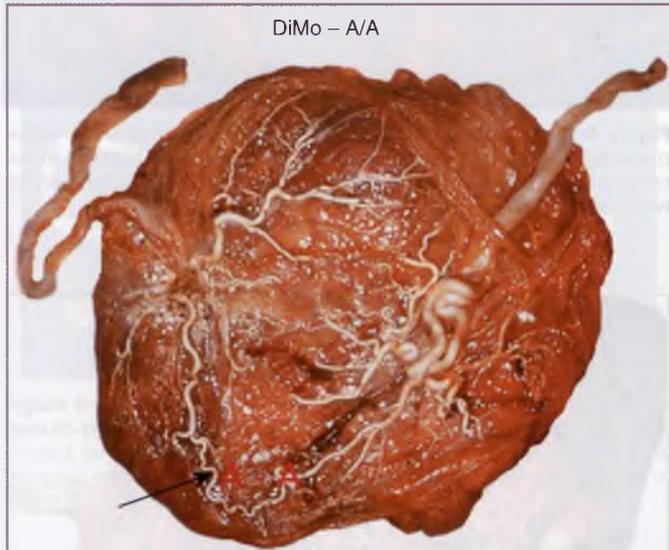

Figure 4-11 Diamniotic monochorionic (DiMo) twin placenta. One large direct artery-to-artery (A/A) anastomosis after injection with milk is shown.

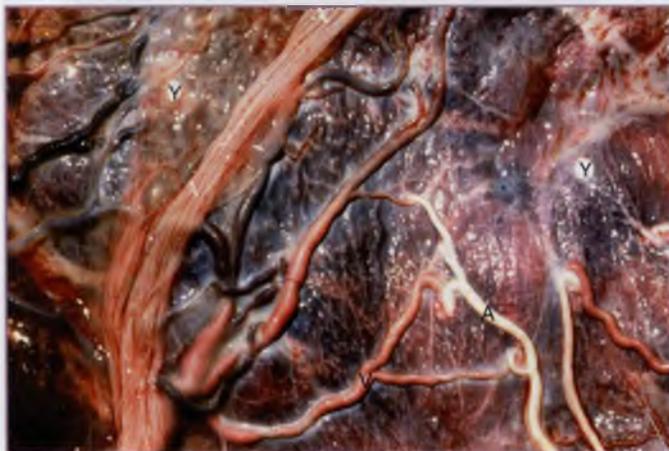

Figure 4-12 Placenta of twin-to-twin transfusion syndrome. Milk is being injected into the arteries of the donor twin. Several arteriovenous shared cotyledons can be seen. A, artery; V, vein; Y, remains of yolk sac.

Figure 4-13 Diamniotic monochorionic twin placenta showing a portion of the vascular equator. The amnions have been stripped off; only the chorionic surface is seen. Arteries lie on top of veins. Twin A, at the top, displays a normal cotyledonary supply at left, with an artery feeding the cotyledon and a vein returning it to the same fetus. To the right of the yellow patch of subchorionic fibrin is an artery-to-artery anastomosis. An arteriovenous shunt is demonstrated at the far right. These twins came to term because the artery-to-artery anastomosis immediately compensated for any irregularity of blood volume arising from the shunt.

Figure 4-14 Diamniotic monochorionic twins. The plethoric twin (*right*) died first, and as a consequence, the larger fetus (*left*) bled back, through the shared vessels, into the plethoric fetus. The smaller fetus had a velamentous cord insertion.

such twins have been erroneously said to have the classic transfusion syndrome. Twins with such marked differences in blood content near term are never the result of TTTS.

Twin-to-Twin Transfusion Syndrome

The most important anastomosis, the arteriovenous shunt, is also the most difficult to diagnose by inspection of the placenta after delivery. It is not a direct communication; instead, it occurs when one cotyledon is fed by an artery from one twin and the blood is then drained by a vein into the other twin. The arteriovenous shunt is diagrammatically shown in Figure 4-15, and the common vascular relationships at a twin vascular equator are seen in Figure 4-13. To recognize such a shared cotyledon, one must follow all terminal arterial branches (arteries cross over veins) and ascertain whether a vein is returning to the same twin, as is normally the case (see Fig. 4-13, *left*) or whether the cotyledon is drained to the other twin (see Fig. 4-13, *right*). To verify the existence of a common or shared cotyledon, one may inject the artery with water; the shared cotyledon rises and blanches, and the water then drains through the vein of the other twin, blanching the common or shared cotyledon (Fig. 4-16). This arrangement has been referred to as the *third circulation*. It is incorrect, however, to assume that there are other,

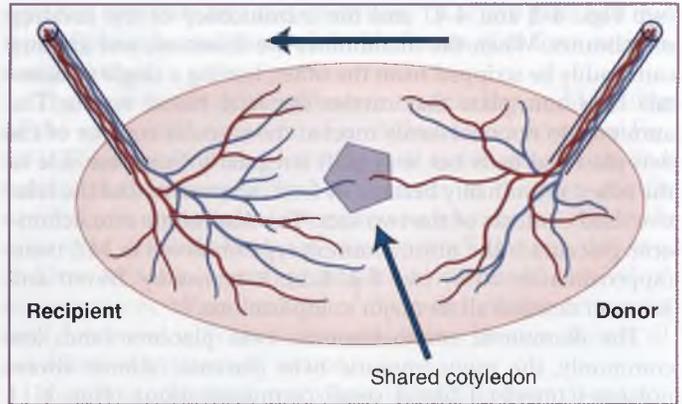

Figure 4-15 Diagram of the basis for the twin-to-twin transfusion syndrome.

Figure 4-16 Immature placenta. In this cross section of an immature placenta, one cotyledon was injected with water, after which the villous tissue blanched. This "shared cotyledon" is the basis for the twin-to-twin transfusion syndrome.

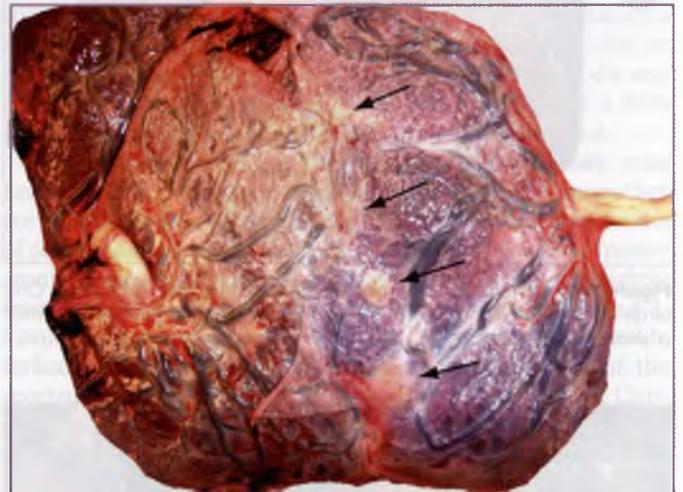

Figure 4-17 Monochorionic twin placenta of a laser-treated, twin-to-twin transfusion syndrome pregnancy. The laser-occluded districts are indicated by arrows. After laser therapy, the pregnancy lasted another 2 months and the twins did well.

deep anastomoses, as often discussed. Villi are never connected only deep in the placenta, and they can exchange blood only through common shared cotyledons. The situation is different after laser surgery⁶⁷ (Fig. 4-17).

Arteriovenous shunts may exist singly or may be multiple, and they may shunt blood in opposing directions. If they are not accompanied by artery-to-artery or vein-to-vein anastomoses, one fetus will continuously donate blood into the recipient (Figs. 4-18 through 4-20). This is the basis of the TTTS, which

Figure 4-18 Diamniotic monochorionic twin abortus resulting from twin-to-twin transfusion syndrome. The recipient (top right) is plethoric and larger, and the donor (top left) is anemic and smaller. The maternal side of the monochorionic twin placenta (bottom) is shown in Figure 4-19.

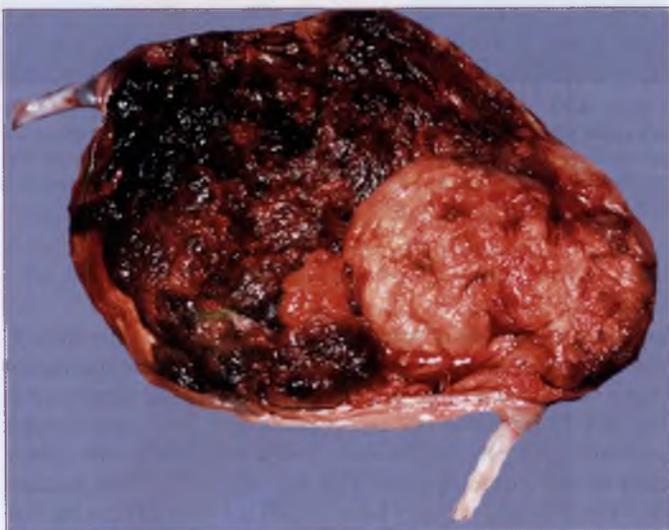

Figure 4-19 Twin placenta of twins with twin-to-twin transfusion syndrome, maternal side. This is the placenta of the set of twins shown in Figure 4-18. Notice the smaller quantity and anemia of the donor villous tissue.

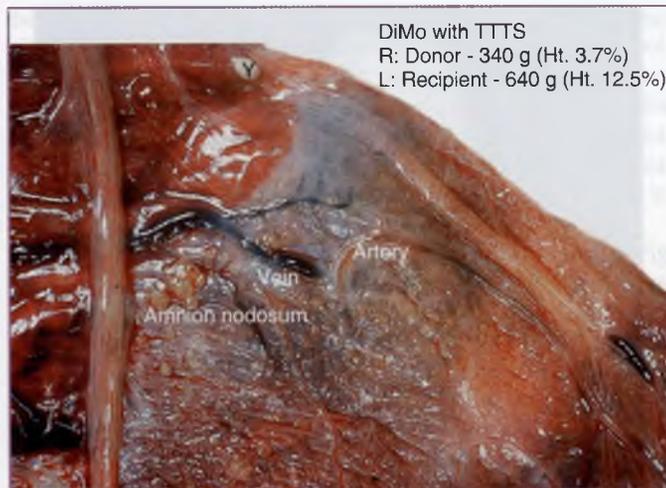

Figure 4-20 Placenta of diamniotic monochorionic (DiMo) twins with twin-to-twin transfusion syndrome (TTTS). A single arteriovenous anastomosis with common duct is present. leads to plethora and hypervolemia (hypertension) of the recipient and anemia (hypotension) of the donor. Cardiac compensation (hypertrophy in the recipient) ensues first and can be seen in abortuses afflicted by the TTTS; this is followed by a wide spectrum of bodily growth differences (Fig. 4-21; see Fig. 4-18). A common symptom is rapid uterine expansion resulting from hydramnios of the recipient, presumed to be secondary to excessive fetal urination. The hydramnios usually manifests between 20 and 30 weeks of pregnancy, may reach enormous proportions, and is frequently the cause of preterm labor. The amniotic sac of the donor may be dry, and amnion nodosum may develop. The donor fetus is referred to as being “stuck.” The severity and time of noted growth discrepancy probably depends on the size and number of arteriovenous shunts as well as their directions. On occasion, the syndrome first becomes symptomatic when a formerly balanced blood exchange becomes unstable because of spontaneous thrombosis of a placental vein.⁶⁸

At times, one twin dies in utero, the hydramnios disappears, and the pregnancy goes to term with one twin normal and the other a fetus papyraceus.⁵⁸ When the twins are born, usually prematurely, they may differ remarkably in size; indeed, they may be so discordant that they seem to be DZ twins. Catch-up growth occurs postnatally but often it is incomplete, and the twins remain discordant even though they are MZ. Moreover, evidence exists that the donor twin suffers more anomalies.

Clinical management of the various complications of twin gestation, especially treatment of arteriovenous anastomoses with laser ablation, is described in greater detail in Chapter 38.

Abnormalities of Twin Gestation

FETUS PAPYRACEUS

When one or more of the fetuses in a multiple gestation dies before birth and the pregnancy continues, the fluid of the dead twin's tissues is gradually absorbed, the amniotic fluid disappears, and the fetus is compressed and becomes incorporated

Figure 4-21 Aborted monozygotic twins with twin-to-twin transfusion syndrome at 11 weeks' gestation. The recipient (*left*) had a heart size of 440 mg; the donor's heart was 193 mg. Otherwise, the growth differential at this young gestational age was less significant (31 versus 20 g).

into the membranes (Fig. 4-22). It is then called a fetus compressus, fetus papyraceus, or membranous twin. The condition occurs in both DZ and MZ twins and is a regular finding when multiple gestations are surgically reduced. This has become much more common in recent years as many fetuses are conceived with ART.^{69,70}

The existence of the fetus papyraceus has important practical and theoretical implications. First, a birth with such an association is not usually entered into statistics as a twin gestation; as a result, the frequency of twinning is underestimated. Furthermore, the presence of a fetus papyraceus is often not recognized at birth. Figure 4-23 shows a twin placenta from what was thought to be an abruptio placentae of a singleton birth. One placenta was normal, and the other was a shriveled, diminutive, and separate organ of a DZ fetus papyraceus. The small embryo presumably died early, but the preservation of the cord is remarkable. It is possible that this fetus papyraceus was a chromosomally abnormal conceptus that would ordinarily have been aborted had it not been for the normal twin. This would support one hypothesis that has been proposed for the

Figure 4-22 Diamniotic dichorionic twin pregnancy with one fetus papyraceus. This fetus died because of cord entanglement around the leg.

Figure 4-23 Placenta of a 35-year-old woman thought to have abruptio placentae. Diamniotic dichorionic separate twin placentas are present. The fetus papyraceus is attached to cord. The embryo was golden-yellow and about 1 cm long. The surviving twin associated with this pregnancy had aplasia cutis.

rapid fall in the rate of twin gestations in women older than 35 years of age. Such a fetus papyraceus in diamniotic monozygotic twins is also often overlooked. The example illustrated in Figure 4-23 was small and compressed. This fetus papyraceus is particularly interesting because it was associated with aplasia cutis of the surviving twin. The diffuse form of this unusual skin condition has always been associated with MZ twins, one a fetus papyraceus, in cases in which the placenta has been examined.⁷¹ The inference is that diffuse patchy aplasia cutis (in contrast to that in the scalp midline) is the result of a prenatal insult associated with the death of one MZ twin.

Another insight into prenatal life afforded by the fetus papyraceus relates to the mechanism that leads to amnion nodosum. When one twin dies, so does the amnion of its sac. This occurs earliest on the diamniotic dividing membranes (Fig. 4-24). Because the amnion does not possess blood vessels, its growth and maintenance must be supported by nutrients and oxygen from adjacent tissues. The large area of dividing membranes, which are in contact only with amniotic fluid, must be maintained by this fluid. The amnion dies because of the disappearance of fluid or deficiency of its oxygen content. Amnion nodosum, or impaction of vernix, occurs secondarily after epithelial death.

ACARDIAC TWIN

The most bizarre malformation recorded, acardiac twin, occurs only in one twin of a pair of MZ twins. The normal twin maintains the acardiac twin by perfusion through two anastomoses, one artery to artery and one vein to vein. The circulation of the acardiac twin is therefore reversed, and most authors have assumed that this reversal of circulation may also be the cause of the malformation.⁷² This concept is challenged by the occasional observation of an acardiac twin with different chromosomal constitution from that of the always diploid normal twin. Two trisomic acardiac fetuses and one triploid acardiac have

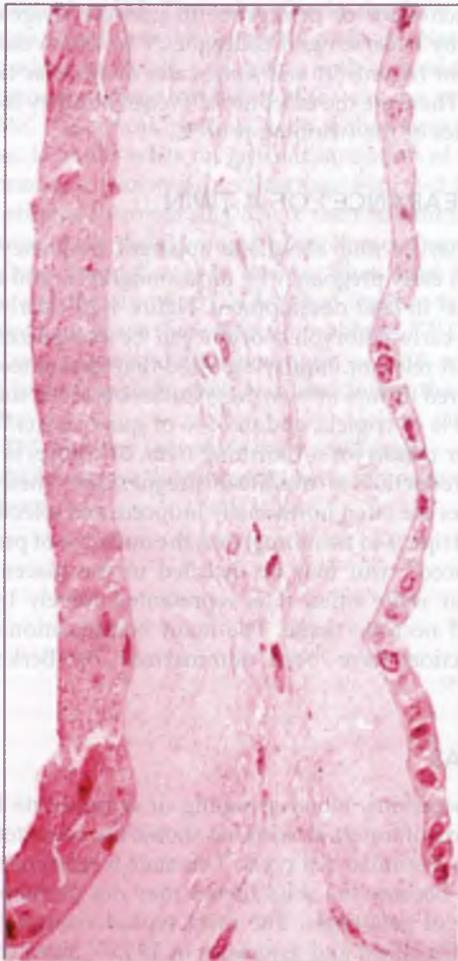

Figure 4-24 Cross section of diamniotic dividing membranes. The left twin had died, and with it the entire amniotic epithelium.

been described, findings that suggest major errors in fertilization.^{23,73} Genetic study in the case studied by Bieber and colleagues²³ indicated the likelihood of origin by fertilization of a polar body for the triploid embryo. It is then remarkable that for every acardiac twin for which adequate placental examination has been made, a monochorionic (usually monoamniotic) placenta has been found, thought to be diagnostic of monozygosity.

Occasionally, an acardiac fetus is also a fetus papyraceus (Fig. 4-25), and only radiographs disclose its identity. Acardiac fetuses usually have no heart, as the name implies. Occasionally, however, a misshapen heart, commonly two chambered, is found. The wide range of sizes and shapes among acardiac twins has led to a complex taxonomy. Most often, acardiac twins possess legs but lack arms; they often have no head or a head that is markedly abnormal. An acardiac fetus may look like an inside-out teratomatous mass (Fig. 4-26), although the fetus can be distinguished from a teratoma by the presence of an

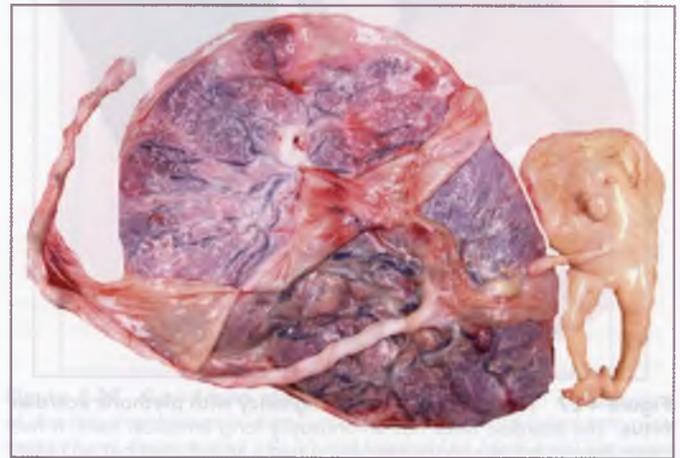

Figure 4-25 Triplet pregnancy with two survivors and one macerated acardiac fetus. This is a triamniotic dichorionic placenta. The umbilical cord of the acardiac fetus had been interrupted by laser ablation 3 months earlier.

Figure 4-26 Diamniotic monochorionic term twin placenta. The (amorphous) acardiac twin is at right. It was a skin-covered ball of fat with few bones. The umbilical cord was very short. (Courtesy of the late N. Eastman, Johns Hopkins School of Medicine, Baltimore.)

Figure 4-27 Monoamniotic twin pregnancy with plethoric acardiac fetus. The acardiac fetus has an unusually long umbilical cord. It had been seen to move sonographically; it had a spinal cord but no brain.

umbilical cord. The cord is almost invariably short, betraying the immobility of the acardiac fetus, and it usually possesses only one artery. Occasionally, however, acardiac fetuses have been witnessed to move, and in such cases the cord may be quite long (Fig. 4-27).

Acardiac fetuses are often referred to as representing the twin reversed arterial perfusion sequence (TRAP). They can now be detected prenatally by the absence of cardiac activity and reversal of flow on Doppler sonography.⁷⁴ Because the normal twin perfuses this acardiac fetus in a reversed fashion, cardiac hypertrophy and failure may develop in the donor. Healey⁷⁵ identified a 35% mortality rate for the so-called pump twin. Prenatal removal, cord ligation, and other therapies have been advocated.

Finally, the possibility of “irregular splitting” exists in the formation of MZ twins. During the early event of producing identical twins, one embryo may receive more embryoblasts than the other. This concept and its relevance to acardiatics have been described in some detail by Benirschke.⁷⁶

OTHER ANOMALIES

It has long been known that malformations occur more commonly in twins than in singletons; this increase results from the

higher incidence of structural defects in MZ twins.⁷⁷ These anomalies may be concordant, but more frequently they are discordant, even in MZ twins. The causes of some anomalies are more readily comprehended than those of others; examples are the discordant development of conjoined twins and perhaps the acardiac anomaly and aplasia cutis that may be associated with sudden drops in blood pressure before birth. It is plausible that some other disruptions, such as porencephaly, occur as a result of interfetal vascular embolization or coagulation, and that other deformations are caused by crowding. In a large number of structural defects, however, the pathogenesis appears to be linked in some way to the twinning process itself. For example, anencephaly and sirenomelia occur inexplicably commonly as discordant anomalies in MZ twins. These data suggest that further studies may provide significant insight into not only the poorly understood twinning process itself but also the pathogenesis of many congenital anomalies.⁷⁸

Perhaps the most perplexing discordance occurs in the so-called heterokaryotic MZ twins (i.e., MZ twins with different karyotypes and phenotypes). On first impression, the idea of MZ twins with different karyotypes appears to be contradictory. However, if chromosomal nondisjunction of cells occurs just before or at the time of twinning, the process that causes mosaicism in a singleton may lead to MZ twins with different chromosome sets. Most often this has been described for the sex chromosomes, and XO/XXX, XO/XX, and even XO/XY twins have been reported with appropriate divergence of phenotypes. Sixteen such cases of divergence in gonadal dysgenesis were described by Pedersen and colleagues,⁷⁹ to which cases of discordance for trisomy 21 and some cases of acardiac twins must be added. These are the exceptional events, but they indicate the complexities of the twinning process.

“DISAPPEARANCE” OF A TWIN

A word may be said about the apparent frequency of twins detected in early pregnancy by ultrasonography and their “disappearance” in later development. Figure 4-23 clearly indicates that even early embryonic death can be recognized in term placentas. A relevant inquiry reported that spontaneous reduction occurred in 36% of twin pregnancies observed sonographically, in 53% of triplets, and in 65% of quadruplets.⁸⁰

Another reason for a vanishing twin, of course, is the selective fetal reduction of multifetal pregnancies. These multiple pregnancies are often hormonally induced, and selective reduction from triplets to twins improves the outcome of pregnancy.⁸¹ The “reduced” twin may be detected in the placental membranes, but more often it is represented merely by a small amount of necrotic tissue. The many complications of selective reduction have been summarized by Berkovitz and associates.⁸²

CHIMERAS

On rare occasions, blood grouping or lymphocyte karyotype examination of fraternal twins has shown the coexistence of two genetically dissimilar cell types. This state is referred to as *blood chimerism* because the solid tissues may not participate in the admixture of genotypes. The most typical example was published by Dunsford and associates in 1953.⁸³ Since then, many more such chimeras have been described. Blood chimerism is best explained by the existence of transplacental anastomoses

in fraternal twins that allow bone marrow-like blood cell precursors, circulating in one embryo, to migrate and settle in the other twin. Because blood chimerism happens so early in embryonic life, this graft is tolerated as “self” and survives permanently without any ill effect. Although blood chimerism occurs with regularity in marmosets and frequently in twin cattle, where it may cause freemartinism, it is very uncommon in humans, in whom such anastomoses between presumably dichorionic twins have been identified only rarely.

Identification of Twin Zygosity

The zygosity of twins is of interest to the twins and their parents, to physicians who may treat the children in the future, and to scientists. An attempt should be made to establish the zygosity at birth and to register the objective findings in the chart. Performing this task at the birth is particularly appropriate because of the availability of the placenta, examination of which can aid materially in the process. A good example for this need was provided by St. Clair and colleagues,⁸⁴ who treated presumed DZ twins for renal transplantation. DNA tests established “identity” only 15 years later, after successful transplantation; immunosuppressive therapy was discontinued only then.

The most efficient way to identify zygosity is as follows: Gender examination allows the classification of male-female pairs as fraternal or DZ. The twins should also have a dichorionic placenta, which may be separated or fused. Next, the placenta is studied in detail, and twins with a monochorionic placenta (monoamniotic or diamniotic) can be set aside as being of MZ (“identical”) origin, even if they have dissimilar phenotypes. If doubt exists on gross examination of the dividing membranes, a transverse section (see Figs. 4-2 and 4-28) should be studied histologically. There then remain the case of like-sex twins with dichorionic placental membranes whose zygosity cannot immediately be known. They must be studied genetically, and the study of DNA polymorphism is currently the best way to approach these difficult problems.³⁹⁻⁴¹ Cameron⁸⁵ examined sex, placentas, and genotypes of 668 consecutive twin pairs in Birmingham, England, and found the following distribution:

- 35% DZ, because they were male and female
- 20% MZ, because they were monochorionic (and had the same sex)

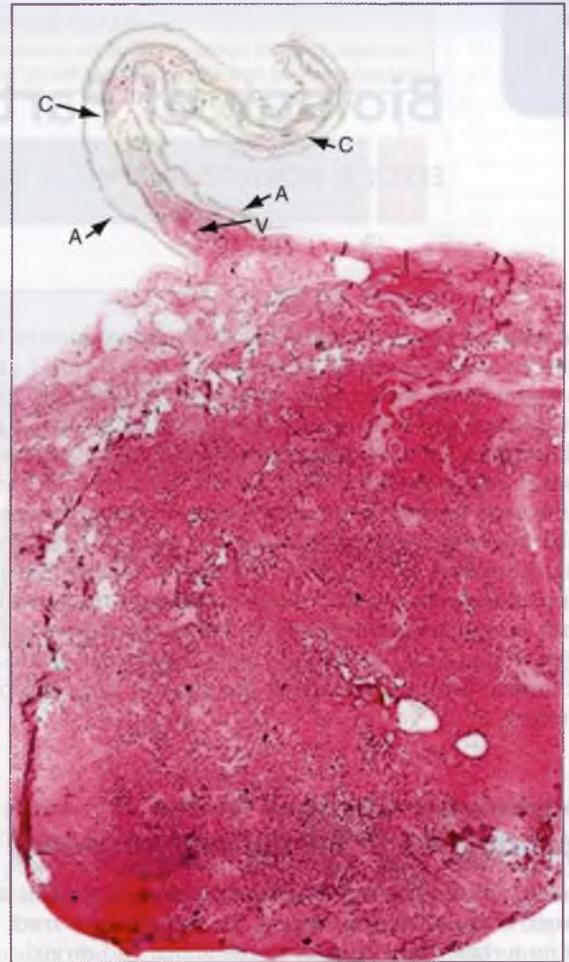

Figure 4-28 Fused twin placenta. A transverse section at the point of dividing membranes in diamniotic (A) dichorionic (C) fused twin placenta shows degenerated villi (V) and trophoblast (dark area) between the membranes. Inflammation of the chorial vessel is present at left.

- 45% of the same sex but with dichorionic membranes; when these last were genotyped, 36% were DZ because of genetic differences
- 8% MZ, because of genetic identity

Biology of Parturition

ERROL R. NORWITZ, MD, PhD | MALA MAHENDROO, PhD | STEPHEN J. LYE, PhD

Labor is the physiologic process by which the products of conception are passed from the uterus to the outside world, and it is common to all mammalian viviparous species. The timely onset of labor and birth is an important determinant of perinatal outcome. Considerable evidence suggests that the fetus is in control of the timing of labor, although maternal factors are also involved. Progress in understanding of the molecular and cellular mechanisms responsible for the onset of labor is slow primarily because of the lack of an adequate animal model and because of the autocrine and paracrine nature of the parturition cascade in humans, which precludes direct investigation. This chapter summarizes the current state of knowledge on the biologic mechanisms responsible for the onset of labor at term in the human.

Morphologic Changes in the Reproductive Tract during Pregnancy

Pregnancy is associated with gestational age-dependent morphologic changes in all tissues of the reproductive tract. The most important changes occur in the uterus and cervix.

THE UTERUS

The uterus undergoes a dramatic increase in weight (from 4 to 70 g in the nonpregnant state to 1100 to 1200 g at term) and in volume (from 10 mL to 5 L) during pregnancy. The number of myometrial cells increases in early pregnancy (myometrial hyperplasia) but thereafter remains stable. Myometrial growth in the latter half of pregnancy results primarily from the increase in cell size (hypertrophy) that occurs under the influence of the sex steroids, especially estrogen.¹ This is accompanied by an increase in fibrous and connective tissue as well as blood vessels and lymphatics. In the latter half of pregnancy, distention leads to gradual thinning of the uterine wall. However, this thinning is not uniform throughout the uterus. For example, the lower portion of the uterus (the isthmus) does not undergo hypertrophy and becomes increasingly thin and distensible as pregnancy progresses, thereby forming the lower uterine segment.²

The increase in size of the uterus is accompanied by a 10-fold increase in uterine blood flow—from 2% of cardiac output in the nonpregnant state to 17% at term.^{3,4} Moreover, pregnancy is associated with a redistribution of blood flow within the uterus. In the nonpregnant state, uterine blood flow is equally divided between myometrium and endometrium. As pregnancy progresses, 80% to 90% of uterine blood flow goes to the placenta, with the remainder distributed equally between the endometrium and myometrium.⁵ Although the cellular mechanisms responsible for the increase in uteroplacental blood flow in pregnancy are not fully understood, the increase in flow

parallels the increase in placental size and decrease in placental vascular resistance, most likely related to the sensitivity of the uterine vasculature to circulating levels of estrogen.⁶ However, a number of other biologically active hormones may be involved at the level of the uterine arteries, including vascular endothelial growth factor (VEGF),⁷ angiotensin II,^{8,9} nitric oxide,⁹⁻¹¹ and prostacyclin (also known as prostaglandin I₂ [PGI₂]).^{11,12}

THE CERVIX

The cervix (“neck” of the uterus) is made up of a number of different cell types, including epithelial cells, fibroblasts, and smooth muscle cells, which make up approximately 10% of the stroma. In addition, the cervix contains blood vessels and a fibrous connective tissue composed of fibrillar collagen I and, to a lesser extent, collagen III, elastin, matricellular proteins, glycosaminoglycans, and proteoglycans.¹³ Magnetic resonance imaging and radiographic data reveal that the collagen fibers in the cervical stroma are aligned in three preferential directions. The mechanical response of the tissue is dependent on both collagen directionality and structure.¹⁴

As early as the first trimester of pregnancy, the cervix begins a progressive remodeling that continues for the remainder of pregnancy. Cervical remodeling can be loosely divided into four overlapping phases: (1) *softening* during most of pregnancy, (2) *ripening* during the last 1 to 2 weeks of gestation, (3) *dilation* during active labor, and (4) *postpartum repair* after delivery (Fig. 5-1).^{15,16} Cervical softening begins early in pregnancy and is the longest of all the phases. It is characterized by a discernible increase in tissue compliance with maintenance of its tensile strength. During the softening phase, there is marked proliferation of epithelial and fibroblast cells. In addition, there are dynamic changes in the extracellular matrix, including changes in the processing and assembly of collagen fibrils that result in collagen fibers with reduced mechanical strength. When cervical ripening occurs at the end of pregnancy, there is increased tissue vascularization. The connective tissues of the cervix undergo further biochemical modifications that result in a maximal increase in tissue viscoelasticity. These modifications include alterations in water content, collagen, and proteoglycan composition.¹⁷ Advancing gestational age is associated also with an increase in hyaluronan content within the cervix, which leads to increased water content and dispersion of collagen fibers.^{18,19} When these biochemical changes occur early in pregnancy, it can lead to cervical dilation in the absence of significant uterine contractions. This has traditionally been referred to as cervical insufficiency (or cervical incompetence), although in its true form it is probably extremely rare.

Cervical changes throughout gestation are mediated through the coordinated efforts of mechanical factors, endocrine factors, and local hormones (primarily prostaglandins). Mechanical

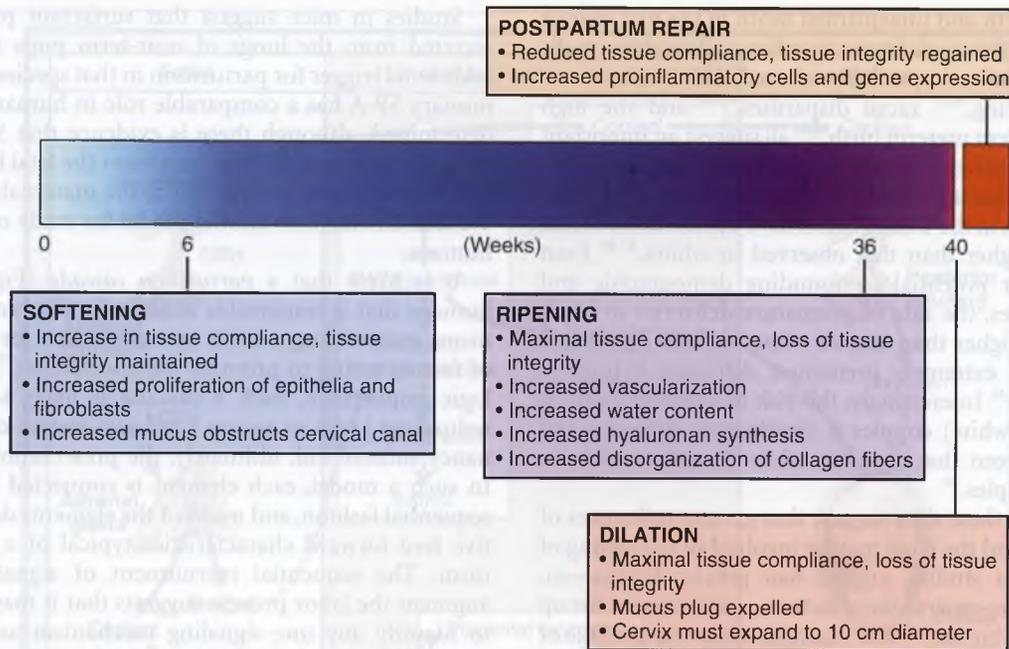

Figure 5-1 Proposed model of cervical remodeling in human pregnancy. Cervical remodeling is a progressive process that begins early in pregnancy. The four phases of cervical remodeling are shown: softening, ripening, dilation, and postpartum repair.

factors include cervical stretch and pressure exerted by the fetal presenting part, whereas endocrine factors include such hormones as progesterone, estrogen, oxytocin, and relaxin.²⁰ With the onset of labor, the factors responsible for the rapid progression of cervical effacement and dilation most likely include a combination of biochemical changes, the mechanical forces of traction caused by myometrial contractions, and pressure resulting from descent of the fetal head.²⁰ After birth, the cervix undergoes a repair phase of remodeling to ensure protection of the reproductive tract from environmental insults and to prepare for subsequent pregnancies.^{16,21}

Diagnosis of Labor

Labor is a clinical diagnosis. It is characterized clinically by regular, painful uterine contractions that increase in frequency and intensity with progressive cervical effacement and dilation leading, ultimately, to expulsion of the products of conception. In normal labor, there appears to be a time-dependent relationship between these factors. Biochemical connective tissue changes in the cervix usually precede uterine contractions and cervical dilation, which, in turn, occur before spontaneous rupture of the fetal membranes. Similarly, pro-contractile biochemical changes in the uterus precede active and effective uterine contractions. The presence of uterine contractions in the absence of cervical change does not meet criteria for the diagnosis of labor and should be referred to as *preterm contractions*.

Timing of Labor

The timely onset of labor and birth is an important determinant of perinatal outcome. The mean duration of a human singleton pregnancy is 280 days (40 weeks) from the first day of the last normal menstrual period. *Term* is defined as

the period from 37 weeks to 42 weeks of gestation. Both *preterm* births (defined as delivery before 37 weeks' gestation²²) and *post-term* births (delivery after 42 weeks' gestation²³) are associated with increased neonatal morbidity and mortality. The lower limit by which preterm birth rates are currently defined in the United States is 20 weeks, although a growing body of literature suggests that all births at or after 16 weeks' gestation should be included, whether the fetus is born alive or not.²⁴⁻²⁸

Considerable evidence suggests that, in most mammalian viviparous animals, the fetus is in control of the timing of labor.²⁹⁻³⁶ During the time of Hippocrates, it was believed that the fetus presented head first so that it could kick its legs up against the fundus of the uterus and propel itself through the birth canal. We have moved away from this simple and mechanical view of labor, but the factors responsible for the initiation and maintenance of labor at term are still not well understood. The past few decades have seen a marked change in the nature of the hypotheses to explain the onset of labor. Initial investigations centered on changes in the profile of circulating hormone levels in the maternal and fetal circulations (endocrine events). More recent studies have focused on the biochemical dialog that occurs at the fetal-maternal interface (paracrine and autocrine events) in an attempt to understand in detail the molecular mechanisms that regulate parturition.

GENETIC INFLUENCES ON THE TIMING OF LABOR

Horse-donkey crossbreeding experiments performed in the 1950s resulted in a gestational length intermediate between that of horses (340 days) and that of donkeys (365 days), suggesting an important role for the *fetal* genotype in the initiation of labor.^{31,32} Moreover, human fetuses who fail to trigger labor at the appropriate gestational age, thereby allowing the pregnancy to continue after term, have an increased risk of both

antepartum stillbirth and unexplained death in the first year of life,³⁷⁻³⁹ suggesting that such fetuses may have subtle abnormalities in their hypothalamic-pituitary-adrenal (HPA) axis.

Familial clustering,^{40,41} racial disparities,⁴²⁻⁴⁶ and the high incidence of recurrent preterm birth^{47,48} all suggest an important role for *maternal* genetic factors in the timing of labor. For example, black (including African-American, African, and Afro-Caribbean) women in the United States have a preterm birth rate that is twofold higher than that observed in whites.⁴²⁻⁴⁶ Even after adjusting for potential confounding demographic and behavioral variables, the rate of premature deliveries in black women remains higher than that in white women, and this is especially true of extremely premature deliveries before 28 weeks' gestation.^{44,45} Interestingly, the risk of preterm birth in interracial (black-white) couples is significantly different and intermediate between that of white-white (8.6%) and black-black (14.8%) couples.⁴⁹

Taken together, these data suggest that genetic influences of both the mother and the fetus may be involved in the timing of labor. More recent studies suggest that genetic factors—or, more correctly, gene-environment factors—may account for up to 20% of preterm births.⁵⁰⁻⁵⁴ For example, maternal carriage of the 308(G>A) polymorphism in the promoter region of the gene encoding tumor necrosis factor- α (TNF- α) is associated with an increased risk of spontaneous preterm birth (odds ratio [OR] = 2.7; 95% confidence interval [CI], 1.7 to 4.5),^{55,56} which is further increased in the presence of bacterial vaginosis (OR = 6.1; 95% CI, 1.9 to 21.0).⁵⁵⁻⁵⁷ The risk of spontaneous preterm birth is increased even further if the woman with the TNF- α gene promoter polymorphism and bacterial vaginosis also happens to be black (OR = 17).⁵⁷

Hormonal Control of Labor

The hypothesis that the fetus is in control of the timing of labor has been elegantly demonstrated in domestic ruminants, such as sheep and cows, and involves activation at term of the fetal HPA axis.⁵⁸ In such animals, a sharp rise in the concentration of adrenocorticotrophic hormone (ACTH) and cortisol in the fetal circulation 15 to 20 days before delivery⁵⁹ results in increased expression in the ruminant placenta of the trophoblast cytochrome P450 (CYP) enzyme 17 α -hydroxylase/C_{17,20}-lyase (CYP17), which catalyzes the conversion of pregnenolone to 17 α -hydroxypregnenolone and dehydroepiandrosterone. The resultant fall in progesterone and rise in estrone and 17 β -estradiol levels in the maternal circulation stimulate the uterus to produce PGF_{2 α} , which provides the impetus for labor in such animals.^{34,59-61} However, because human placentas lack the glucocorticoid-inducible CYP17 enzyme,³² this mechanism does not apply. Despite these observations, recent data suggest that there may be more similarities than differences between species. In both ruminants and humans, fetal adrenal C19 precursors are used to form estrogens. Androstenedione and dehydroepiandrosterone sulfate (DHEAS) are secreted by the fetal adrenal gland, and their secretion is stimulated by ACTH and hypoxia; DHEAS and androstenedione infused into the fetus can be metabolized into estrone and estradiol, respectively. The result is a progressive increase in conjugated estrogens in maternal plasma during the latter part of gestation, which precedes the sharp rise in estrogen that occurs just before delivery in response to cortisol-mediated induction of the CYP enzyme in ruminants and other nonprimate species.

Studies in mice suggest that surfactant protein-A (SP-A) secreted from the lungs of near-term pups may provide an additional trigger for parturition in that species.⁶² Whether pulmonary SP-A has a comparable role in humans remains to be determined, although there is evidence that SP-A originating from the maternal decidua (not from the fetal lungs) may regulate prostaglandin production at the maternal-fetal interface.⁶³ We lack an adequate animal model for study of these events in humans.

It is likely that a *parturition cascade* (Fig. 5-2) exists in humans that is responsible at term for the removal of mechanisms maintaining uterine quiescence and for the recruitment of factors acting to promote uterine activity.³⁵ Given its teleologic importance, such a cascade is likely to have multiple redundant loops to ensure a fail-safe system of securing pregnancy success and, ultimately, the preservation of the species. In such a model, each element is connected to the next in a sequential fashion, and many of the elements demonstrate positive feed-forward characteristics typical of a cascade mechanism. The sequential recruitment of signals that serve to augment the labor process suggests that it may not be possible to identify any one signaling mechanism as being uniquely responsible for the initiation of labor. It may therefore be prudent to describe such mechanisms as being responsible for promoting, rather than initiating, the process of labor.⁶⁴

In brief, human labor is a multifactorial physiologic event involving an integrated set of changes within the maternal tissues of the uterus (myometrium, decidua, and uterine cervix) and fetal membranes that occur gradually over a period of days to weeks. Such changes include, but are not limited to, an increase in prostaglandin synthesis and release within the uterus, an increase in myometrial gap junction formation, and upregulation of myometrial oxytocin receptors (i.e., uterine activation). Once the myometrium and cervix are prepared, endocrine and paracrine/autocrine factors from the fetal membranes and placenta bring about a switch in the pattern of myometrial activity from irregular contractures to regular contractions (i.e., uterine stimulation).⁶⁵ The fetus may coordinate this switch in myometrial activity through its influence on placental steroid hormone production, through mechanical distention of the uterus, and through secretion of neurohypophyseal hormones and other stimulators of prostaglandin synthesis. The roles of several specific hormones and pathways involved in the timing of labor are discussed in the following sections.

FETAL HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

In every animal species studied, there is an increase in the concentration of the major adrenal glucocorticoid product in the fetal circulation during late gestation (cortisol in the sheep and human; corticosterone in the rat and mouse). As in other mammalian viviparous species, the final common pathway toward parturition in the human appears to be maturation and activation of the fetal HPA axis. The result is a dramatic increase in production of the C19 steroid DHEAS from the intermediate (fetal) zone of the fetal adrenal. As noted, DHEAS is directly aromatized in the placenta to estrone, and it can also be 16-hydroxylated in the fetal liver and converted in the placenta to estriol (16-hydroxy-17 β -estradiol) (see Fig. 5-2). This occurs because the human placenta is an incomplete steroidogenic organ, and estrogen synthesis by the placenta requires C19 as a steroid precursor.^{34,66,67}

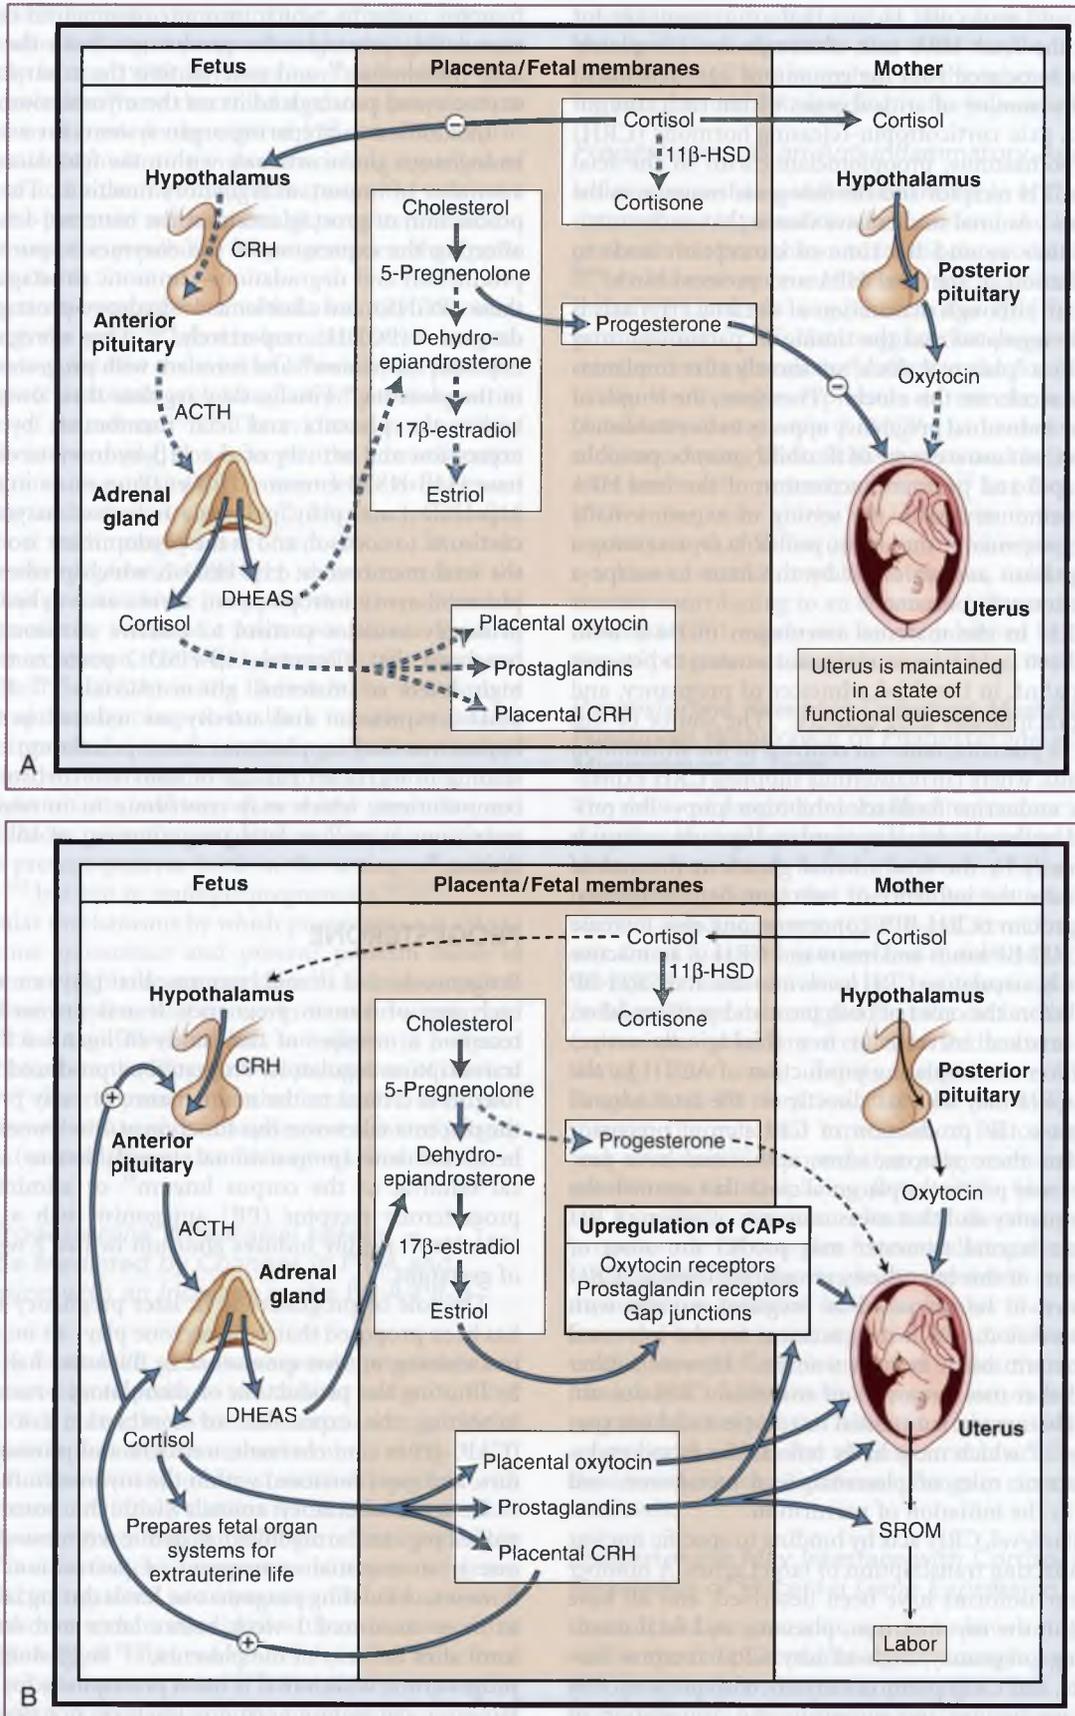

Figure 5-2 Proposed parturition cascade for labor induction at term. The spontaneous induction of labor at term in the human is regulated by a series of paracrine and autocrine hormones acting in an integrated parturition cascade. **A**, The factors responsible for maintaining uterine quiescence throughout gestation are shown. **B**, The factors responsible for the onset of labor are shown. They include the withdrawal of the inhibitory effects of progesterone on uterine contractility and the recruitment of cascades that promote estrogen (estriol) production and lead to upregulation of the contraction-associated proteins (CAPs) in the uterus. ACTH, adrenocorticotropic hormone (corticotropin); CRH, corticotropin-releasing hormone; DHEAS, dehydroepiandrosterone sulfate; 11 β -HSD, 11 β -hydroxysteroid dehydrogenase; SROM, spontaneous rupture of membranes.

The cellular and molecular factors that are responsible for maturation of the fetal HPA axis, although not completely understood, are associated with the gestational age-dependent upregulation of a number of critical genes within each component of the HPA axis: corticotropin-releasing hormone (CRH) in the fetal hypothalamus, proopiomelanocortin in the fetal pituitary, and ACTH receptor and steroidogenic enzymes in the fetal adrenal gland. Animal studies have shown that undernutrition of the mother around the time of conception leads to precocious activation of the fetal HPA and preterm birth.^{68,69} This suggests that, although maturation of the fetal HPA axis is developmentally regulated and the timing of parturition may be determined by a “placental clock” set shortly after implantation, stress may accelerate this clock.⁷⁰ Therefore, the length of gestation for any individual pregnancy appears to be established early in gestation, but some degree of flexibility may be possible. For example, rapid and profound activation of the fetal HPA axis has been demonstrated in the setting of experimentally induced fetal hypoxemia in the sheep, probably representing a functional adaptation and an effort by the fetus to escape a hostile intrauterine environment.⁵⁹

Levels of CRH in the maternal circulation increase from between 10 and 100 pg/mL in nonpregnant women to between 500 and 3000 pg/mL in the third trimester of pregnancy, and then decrease precipitously after delivery.⁷¹ The source of this excess CRH is the placenta, and—in contrast to the situation in the hypothalamus, where corticosteroids suppress CRH expression in a classic endocrine feedback inhibition loop—the production of CRH by the placenta is upregulated by corticosteroids produced primarily by the fetal adrenal glands at the end of pregnancy.⁷² Under the influence of estrogen, hepatic-derived CRH-binding protein (CRH-BP) concentrations also increase in pregnancy. CRH-BP binds and maintains CRH in an inactive form. Importantly, circulating CRH levels increase and CRH-BP levels decrease before the onset of both term and preterm labor, resulting in a marked increase in free (biologically active) CRH.⁷³ In addition to stimulating production of ACTH by the fetal pituitary, CRH may also act directly on the fetal adrenal glands to promote the production of C19 steroid precursor (DHEAS).^{74,75} For these reasons, some authorities have proposed that CRH may prime the placental clock that controls the duration of pregnancy and that measurements of plasma CRH levels in the late second trimester may predict the onset of labor.⁷⁰ In support of this hypothesis, circulating levels of CRH have been shown to be increased in pregnant women with anxiety and depression, which may account for the increased incidence of preterm birth in such women.⁷⁶ However, other studies showed that measurements of maternal CRH are not clinically useful because of substantial inpatient and outpatient variability,⁷⁷⁻⁷⁹ which most likely reflects the mixed endocrine and paracrine roles of placental, fetal membrane, and decidual CRH in the initiation of parturition.

At a molecular level, CRH acts by binding to specific nuclear receptors and affecting transcription of target genes. A number of CRH receptor isoforms have been described, and all have been identified in the myometrium, placenta, and fetal membranes.⁸⁰ During pregnancy, high-affinity CRH receptor isoforms dominate, and CRH promotes myometrial quiescence by inhibiting the production and increasing the degradation of prostaglandins, increasing intracellular cyclic adenosine monophosphate (cAMP), and stimulating nitric oxide synthase activity.^{80,81} At term, CRH acts primarily through its low-affinity

receptor isoforms, which promote myometrial contractility by stimulating prostaglandin production from the decidua and fetal membranes⁸² and potentiating the contractile effects of oxytocin and prostaglandins on the myometrium.⁸³

In addition to preparing organ systems for extrauterine life, endogenous glucocorticoids within the fetoplacental unit have a number of important regulatory functions. They regulate the production of prostaglandins at the maternal-fetal interface by affecting the expression of the enzymes responsible for their production and degradation—amniotic prostaglandin H synthase (PGHS) and chorionic 15-hydroxy-prostaglandin dehydrogenase (PGDH), respectively.^{84,85} They upregulate placental oxytocin expression⁸⁶ and interfere with progesterone signaling in the placenta.³⁶ Finally, they regulate their own levels locally within the placenta and fetal membranes by affecting the expression and activity of the 11 β -hydroxysteroid dehydrogenase (11 β -HSD) enzyme. This enzyme exists in two isoforms: 11 β -HSD-1 acts principally as a reductase enzyme, converting cortisone to cortisol, and is the predominant isoform found in the fetal membranes; 11 β -HSD-2, which predominates in the placental syncytiotrophoblast, serves as a dehydrogenase that primarily oxidizes cortisol to inactive cortisone. It has been proposed that placental 11 β -HSD-2 protects the fetus from high levels of maternal glucocorticoids.^{87,89} Placental 11 β -HSD-2 expression and activity are reduced in the setting of hypoxemia and in placentas from preeclamptic pregnancies, leading to increased passage of maternal cortisol into the fetal compartment, which may contribute to intrauterine growth restriction as well as fetal programming of subsequent adult disease.⁹⁰

PROGESTERONE

Progesterone is a steroid hormone that plays an integral role in each step of human pregnancy. It acts primarily through its receptor, a member of the family of ligand-activated nuclear transcription regulators. Progesterone produced by the corpus luteum is critical to the maintenance of early pregnancy until the placenta takes over this function at 7 to 9 weeks' gestation—hence its name, (*progestational steroidal ketone*). Indeed, surgical removal of the corpus luteum⁹¹ or administration of a progesterone receptor (PR) antagonist such as mifepristone (RU-486)⁹² readily induces abortion before 7 weeks (49 days) of gestation.

The role of progesterone in later pregnancy is less clear. It has been proposed that progesterone plays an important role in maintaining uterine quiescence in the latter half of pregnancy by limiting the production of stimulatory prostaglandins and inhibiting the expression of contraction-associated protein (CAP) genes (ion channels, oxytocin and prostaglandin receptors, and gap junctions) within the myometrium.^{35,36}

In most laboratory animals (with the noted exception of guinea pigs and armadillos), systemic withdrawal of progesterone is an essential component of parturition.³⁶ In humans, however, circulating progesterone levels during labor are similar to those measured 1 week before labor and remain elevated until after delivery of the placenta,^{32,93} suggesting that systemic progesterone withdrawal is not a prerequisite for labor at term. However, circulating hormone levels do not necessarily reflect tissue levels. In the 1960s, Csapo and Pinto-Dantas put forth the idea of a “progesterone blockage,” suggesting that the myometrial quiescence of human pregnancy is maintained by steady

levels of progesterone, just as in pregnancies of other species.⁹⁴ The earliest studies looking at progesterone levels in labor were done separately in the 1970s by Csapo and colleagues⁹⁵ and Cousins and coworkers⁹⁶ and described a relative progesterone deficiency and an increase in the ratio of 17 β -estradiol to progesterone in patients presenting in preterm labor, regardless of etiology. These and other findings have prompted extensive research into the potential mechanisms of progesterone action on the uterus and the possibility of progesterone therapy to prevent preterm birth.

Although systemic progesterone withdrawal may not correlate directly with the onset of labor in humans, there is increasing evidence to suggest that the onset of labor may be preceded by a physiologic (functional) withdrawal of progesterone activity at the level of the uterus.^{35,36,97} The evidence in support of this hypothesis is mounting. For example, the administration of a PR antagonist (e.g., RU-486) at term leads to increased uterine activity and cervical ripening.⁹⁸ Moreover, antenatal supplementation with progesterone from 16 to 20 weeks through 36 weeks of gestation has been shown to reduce the rate of recurrent preterm birth in approximately one third of women at high risk by virtue of a prior spontaneous preterm birth,^{99,100} an intervention that was approved by the Food and Drug Administration (FDA) in the United States in February 2011.¹⁰¹ This improvement in preterm birth rate also translated into improved perinatal outcome, including significant reductions in the incidence of respiratory distress syndrome, very-low-birth-weight infants, and overall neonatal morbidity and mortality.^{99,100} More recently, progesterone supplementation was shown to prevent preterm birth in the setting of cervical shortening,¹⁰²⁻¹⁰⁵ but not in multiple pregnancies.¹⁰⁶⁻¹¹⁰

The molecular mechanisms by which progesterone is able to maintain uterine quiescence and prevent preterm birth in selected women at high risk are not clear.¹¹¹ It is also unclear why progesterone supplementation works in some women and not others,^{99,100} but the difference does not appear to be based on genetic variations in the PR gene¹¹² or prevention of cervical shortening.^{113,114} Several putative mechanisms have been proposed in the literature to explain the quiescent effect of progesterone on the uterus. These can be summarized briefly as follows.

Functional Progesterone Withdrawal before Labor May Be Mediated by Changes in PR-A and PR-B Expression with an Increase in the PR-A/PR-B Ratio

The single-copy human PR gene uses separate promoters and translational start sites to produce two distinct isoforms, PR-A (94 kDa) and PR-B (116 kDa), which are identical except for an additional 165 amino acids in the amino terminus of PR-B.^{115,116} Although PR-B shares many of its structural domains with PR-A, they are two functionally distinct transcripts that mediate their own response genes and physiologic effects with little overlap. PR-B is an activator of progesterone-responsive genes, whereas PR-A acts, in general, as a repressor of PR-B function.¹¹⁷ The onset of labor at term is associated with an increase in the myometrial PR-A/PR-B ratio, which results in a functional withdrawal of progesterone action.¹¹⁸⁻¹²³ The factors responsible for this differential expression with the onset of labor are not known, but they may include prostaglandins (both PGE₂ and PGF_{2 α}), inflammatory cytokines (e.g., TNF- α), and estrogen activation. The changes seen in the PR-A/PR-B ratio in the

myometrium are also seen in the cervix¹²⁴ and fetal membranes.¹²⁵ Studies indicate that there may be an additional PR isoform (PR-C) that contributes to the onset of labor by inhibiting progesterone-PR signaling in the myometrium.¹²⁶

Progesterone as an Anti-inflammatory Agent

Inflammation has a well-established role in the initiation and maintenance of parturition, both at term and before term. Progesterone has been shown to inhibit the production and activity of key inflammatory mediators at the maternal-fetal interface, including cytokines (e.g., interleukin-1 β [IL-1 β], IL-8) and prostaglandins.¹²⁷⁻¹²⁹ Data suggest that progesterone may also exert an anti-inflammatory effect at the level of the myometrium. For example, expression of the chemokine, monocyte chemoattractant protein 1 (MCP-1), increases in human myometrium during labor, both at term and before term, and in association with myometrial stretch.¹³⁰ In other model systems, MCP-1 has been shown to induce an influx of peripheral monocytes that differentiate into macrophages and secrete cytokines, matrix metalloproteinases, and prostaglandins, thereby contributing to an enhanced inflammatory state. Myometrial MCP-1 expression can be inhibited by the administration of progesterone, both in vivo and in vitro.¹³⁰

Progesterone Receptor Cofactors Mediate a Functional Withdrawal of Progesterone in the Myometrium at Term

The ability of progesterone to bind its receptor and affect transcription of target genes is reduced in uterine tissues obtained after, compared with before, the onset of labor.¹³¹ Condon and colleagues¹³² showed that the PR coactivators cAMP response element-binding protein (CREB) and steroid receptor coactivators 2 and 3, as well as acetylated histone H3, are decreased in the myometrium of women in labor compared with women not in labor. These data suggest that the decline in PR coactivator expression and histone acetylation in the uterus near term and during labor may impair progesterone-PR functioning. Progesterone-PR function may also be antagonized directly through the increased expression of PR co-repressors. Dong and coworkers¹³³ reported that polypyrimidine tract binding protein-associated splicing factor (PSF) blocked PR binding to its DNA response element, thereby preventing the progesterone-PR complex from regulating the transcription of target genes. PSF appears to be expressed at higher levels in myometrium collected from the fundus than in myometrium from the lower uterine segment,¹³⁴ and, at least in the rodent model, its expression is increased before the onset of labor.¹³³ Modulation of PR function by coactivators and co-repressors may therefore explain, at least in part, how it is possible to have a functional withdrawal of progesterone action at the level of the uterus without a significant change in circulating progesterone levels.

Progesterone May Interfere with Cortisol-Mediated Regulation of Placental Gene Expression

Cortisol and progesterone appear to have antagonistic actions within the fetoplacental unit. For example, cortisol increases, and progesterone decreases, prostaglandin⁹⁰ and CRH gene expression.¹³⁵ These data suggest that the cortisol-dominant environment of the fetoplacental unit just before the onset of labor may act locally through a series of autocrine and paracrine pathways to overcome the efforts of progesterone

to maintain uterine quiescence and prevent myometrial contractions.

Progesterone May Act Also through Nongenomic Pathways

In addition to its well-described genomic effects, progesterone may act through nongenomic (DNA-independent) pathways. For example, several investigators have shown that selected progesterone metabolites (e.g., 5 β -dihydroprogesterone)—but not progesterone itself—are capable of intercalating themselves into the lipid bilayer of the cell membrane, binding directly to and distorting the heptahelical oxytocin receptor and thereby inhibiting oxytocin binding and downstream signaling.¹³⁶⁻¹³⁸ A functional withdrawal of this progesterone metabolite-mediated inhibition of oxytocin action on the myometrium at term would promote myometrial contractility and labor.

Possible Role for a Cell Membrane-Bound Progesterone Receptor in Myometrium

Recent studies have identified a specific membrane-bound progesterone receptor in a number of human tissues, including uterine tissues, but the function of this receptor in pregnancy and labor has yet to be fully elucidated.¹²³

Effect of Progesterone on Fetal Membranes

Using an in vitro explant model, investigators have shown that progesterone inhibits TNF- α -induced apoptosis (programmed cell death) in human fetal membranes.^{139,140} Given that one third of preterm deliveries occur in the setting of preterm premature rupture of the membranes, the observation that exogenous progesterone may prevent or minimize injury to the fetal membranes in the setting of intrauterine infection or inflammation is compelling. In this same model, progesterone was also seen to inhibit basal apoptosis in the fetal membranes, suggesting that this mechanism may also be important for normal labor at term.¹³⁹

ESTROGENS

In the rhesus monkey, infusion of a C19 steroid precursor (androstenedione) leads to preterm delivery.¹⁴¹ This effect is blocked by concurrent infusion of the aromatase inhibitor Δ^4 -hydroxyandrostenedione,¹⁴² demonstrating that conversion of C19 steroid precursors to estrogen at the level of the fetoplacental unit is important. However, systemic infusion of estrogen failed to induce delivery,^{141,143} suggesting that the action of estrogen is most likely paracrine or autocrine, or both. Levels of estrogen in the maternal circulation are significantly elevated throughout gestation and are derived primarily from the placenta. In contrast to the situation in many animal species (e.g., sheep), the high circulating levels of estrogens in the human are already at the dissociation constant (K_d) for the estrogen receptor (ER), which explains why there is no need for an additional increase in estrogen production at term.

At the cellular level, estrogens exert their effect by binding to specific nuclear receptors and effecting the transcription of target genes. Two distinct estrogen receptors are described: ER α and ER β . Each is coded by its own gene (*ESR1* and *ESR2*, respectively), and requires dimerization before binding to its ligand. At the level of the uterus, ER α appears to be dominant. Expression of ER α increases in concert with an increase in the PR-A/PR-B ratio with increasing gestational age in nonlaboring

myometrium.^{144,145} These findings suggest that functional estrogen activation and functional progesterone withdrawal are linked. For most of pregnancy, progesterone decreases myometrial estrogen responsiveness by inhibiting ER α expression. Such an interaction would explain why the human myometrium is refractory to the high levels of circulating estrogens for most of pregnancy. At term, functional progesterone withdrawal removes the suppression of myometrial ER α expression, leading to an increase in myometrial estrogen responsiveness. Estrogen can then act to transform the myometrium into a contractile phenotype. This model may explain why disruption of progesterone action alone can trigger the parturition cascade. The link between functional progesterone withdrawal and functional estrogen activation may be a critical mechanism for the endocrine and paracrine control of human labor at term.

PROSTAGLANDINS

Endogenous levels of prostaglandins in the decidua are lower in pregnancy than in the endometrium at any stage of the menstrual cycle,^{128,146} primarily because of a decrease in prostaglandin synthesis.¹²⁸ This is true also of prostaglandin production in other uterine tissues. Together with the observation that the administration of exogenous prostaglandins (intravenously, intra-amniotically, or vaginally) has the ability to induce abortion in all species examined and at any stage of gestation,¹⁴⁷⁻¹⁴⁹ these findings support the hypothesis that pregnancy is maintained by a mechanism that tonically suppresses prostaglandin synthesis, release, and activity throughout gestation.

Overwhelming evidence suggests a role for prostaglandins in the process of labor, both at term and before term,^{35,36} which is probably common to all mammalian viviparous species. For example, mice lacking a functional PGF_{2 α} receptor, cytosolic phospholipase A₂ (PLA₂), or prostaglandin H₂ synthase type 1 (PGHS-1) protein demonstrate a delay in the onset of labor.¹⁵⁰ In the human, exogenous prostaglandins stimulate uterine contractility both in vitro and in vivo,¹⁵¹ and drugs that block prostaglandin synthesis can inhibit uterine contractility and prolong gestation.¹⁵² All human uterine tissues contain receptors for the naturally occurring prostanoids and are capable of producing prostaglandins,¹⁵³ although their production is carefully regulated and compartmentalized within the uterus: the fetal membranes produce almost exclusively PGE₂, the decidua synthesizes mainly PGF_{2 α} but also small amounts of PGE₂ and PGD₂, and the myometrium mainly produces prostacyclin. These compounds are structurally similar but can have different and often antagonistic actions. For example, PGF_{2 α} , thromboxane, PGE₁, and PGE₃ promote myometrial contractility by increasing calcium influx into myometrial cells and enhancing gap junction formation,¹⁵³⁻¹⁵⁵ whereas PGE₂, PGD₂, and prostacyclin have the opposite effect and inhibit contractions.¹⁵³

Prostaglandin levels increase in maternal plasma, urine, and amniotic fluid before the onset of uterine contractions,^{153,156,157} suggesting that it is a cause and not a consequence of labor. Regulation of prostaglandin synthesis occurs at several different levels of the arachidonic acid cascade (Fig. 5-3). Prostaglandins are synthesized from unesterified (free) arachidonic acid that is released from membrane phospholipids through the actions of a series of phospholipase enzymes, the most important of which appears to be PLA₂. Expression of PLA₂ increases gradually in the fetal membranes throughout gestation, but it does not

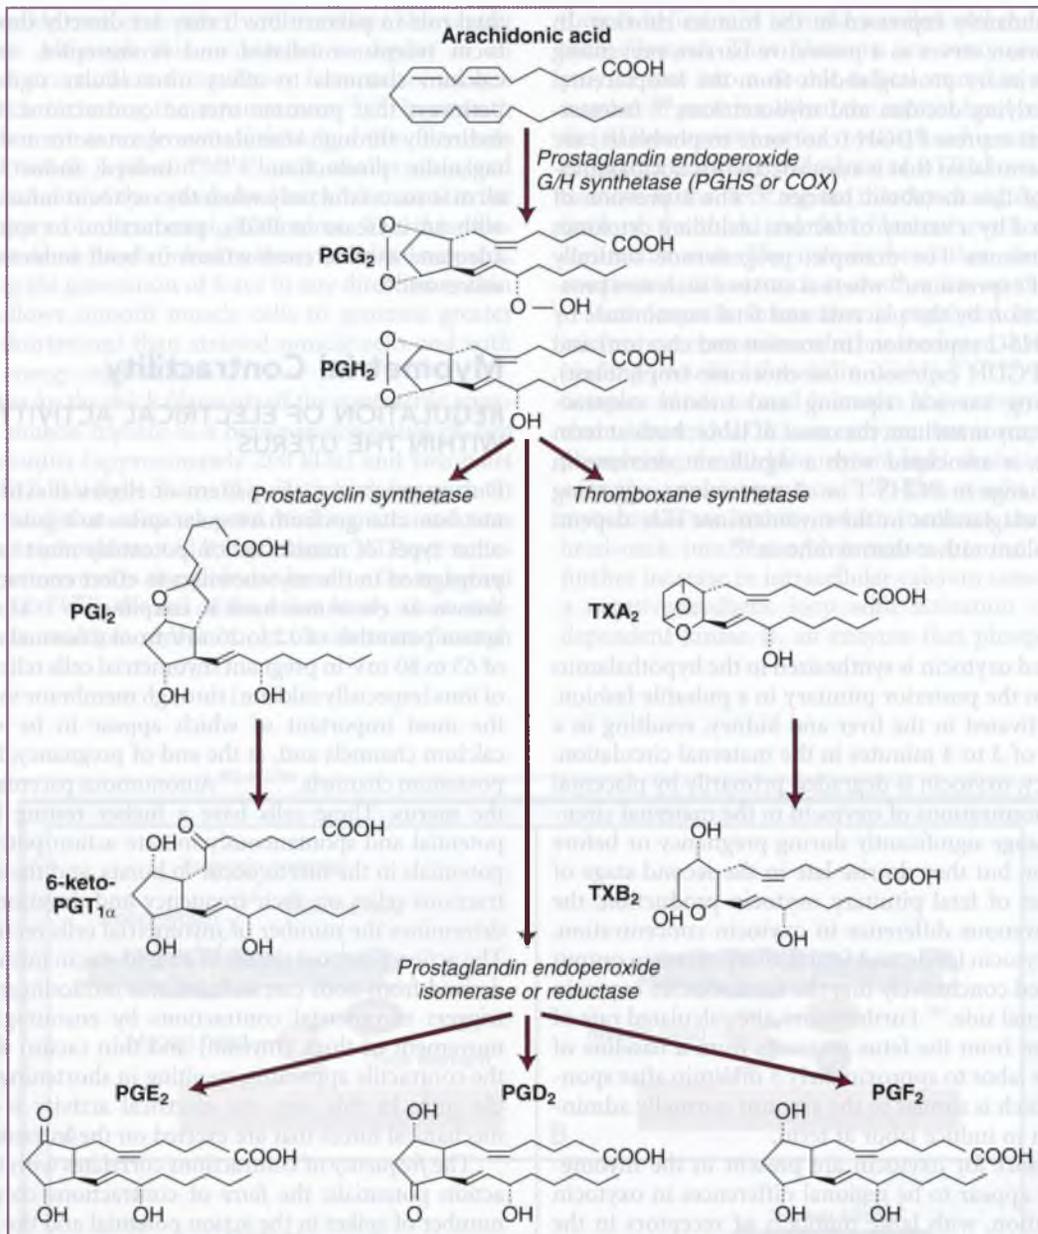

Figure 5-3 Schematic representation of the eicosanoid cascade. Dietary linoleic acid (18:3 ω -6) is lengthened and desaturated to form arachidonic acid, which is then esterified and incorporated into phospholipid within cell membranes. In response to a number of hormonal and inflammatory stimuli, phospholipase (PL) enzymes (primarily PLA₂) release free (unesterified) arachidonic acid from membrane phospholipid, which can then be enzymically converted to one of the eicosanoid metabolites. COX, cyclooxygenase; PG, prostaglandin; PGHS, prostaglandin H synthase; TX, thromboxane.

appear to show further increase at the time of labor. Thereafter, arachidonic acid is metabolized to the intermediate metabolite (PGH₂) by PGHS enzymes, which have both cyclooxygenase and peroxidase activities. PGHS exists in two forms, each a product of a distinct gene: PGHS-1 (which is constitutively expressed) and PGHS-2 (also known as cyclooxygenase-2 [COX-2]), the inducible form that can be upregulated by growth factors and cytokines. Several studies have suggested that the transcription factor, nuclear factor κ B (NF- κ B), is an important regulator of PGHS-2 expression.³⁶

PGH₂ is rapidly converted to one of the primary (biologically active) prostaglandins through various prostaglandin synthase

enzymes (see Fig. 5-3). These hormones act locally in a paracrine or autocrine fashion (or both) by binding to specific prostaglandin receptors on adjacent cells. In addition, unesterified arachidonic acid can diffuse into the cell and interact directly with nuclear transcription factors to regulate the transcription of target genes, including cytokines and other hormones. The primary prostaglandins are then metabolized and excreted. The major pathway in the degradation of PGE₂ and PGF_{2 α} involves the action of a nicotinamide adenine dinucleotide (NAD⁺)-dependent PGDH that oxidizes 15-hydroxy groups, resulting in the formation of 15-keto and 13,14-dihydro-15-keto compounds with markedly reduced biologic activity.

PGDH is abundantly expressed in the human chorion. In this way, the chorion serves as a protective barrier, preventing transfer of the primary prostaglandins from the fetoplacental unit to the underlying decidua and myometrium.¹⁵⁸ Interestingly, the cells that express PGDH (chorionic trophoblasts) are decreased in preterm labor that is associated with chorioamnionitis and a loss of this metabolic barrier.¹⁵⁹ The expression of PGDH is regulated by a variety of factors, including cytokines and steroid hormones. For example, progesterone tonically stimulates PGDH expression,⁸⁴ whereas cortisol increases prostaglandin production by the placenta and fetal membranes by upregulating PGHS-2 expression (in amnion and chorion) and downregulating PGDH expression (in chorionic trophoblast), thereby promoting cervical ripening and uterine contractions.^{79,81,82} In the myometrium, the onset of labor, both at term and before term, is associated with a significant decrease in PGDH but no change in PGHS-1 or -2 expression, suggesting that levels of prostaglandins in the myometrium may depend largely on catabolism rather than synthesis.¹⁶⁰

OXYTOCIN

Maternally derived oxytocin is synthesized in the hypothalamus and released from the posterior pituitary in a pulsatile fashion. It is rapidly inactivated in the liver and kidney, resulting in a biologic half-life of 3 to 4 minutes in the maternal circulation. During pregnancy, oxytocin is degraded primarily by placental oxytocinase. Concentrations of oxytocin in the maternal circulation do not change significantly during pregnancy or before the onset of labor, but they do rise late in the second stage of labor.^{161,162} Studies of fetal pituitary oxytocin production, the umbilical arteriovenous difference in oxytocin concentration, amniotic fluid oxytocin levels, and fetal urinary oxytocin output have demonstrated conclusively that the fetus secretes oxytocin toward the maternal side.¹⁶³ Furthermore, the calculated rate of oxytocin secretion from the fetus increases from a baseline of 1 mU/min before labor to approximately 3 mU/min after spontaneous labor, which is similar to the amount normally administered to women to induce labor at term.

Specific receptors for oxytocin are present in the myometrium, and there appear to be regional differences in oxytocin receptor distribution, with large numbers of receptors in the fundal area and few receptors in the lower uterine segment and cervix.^{164,165} Myometrial oxytocin receptor concentrations increase 50- to 100-fold in the first trimester of pregnancy compared with the nonpregnant state, and they increase an additional 200- to 300-fold during pregnancy, reaching a maximum during early labor.^{153,159,160,164-166} This is mediated primarily by the sex steroid hormones, with estrogen promoting and progesterone inhibiting myometrial oxytocin receptor gene expression.¹⁵⁹ This rise in receptor concentration is paralleled by an increase in myometrial sensitivity to circulating levels of oxytocin.^{153,159} Activation of myometrial oxytocin receptors results in interaction with the guanosine triphosphate binding proteins of the $G\alpha_{q/11}$ subfamily of G proteins that stimulate phospholipase C activity, resulting in increased production of inositol triphosphate¹⁶⁷ and influx of calcium.¹⁶⁸

Specific high-affinity oxytocin binding sites have also been isolated from amnion and decidua parietalis, but not from decidua vera.^{162,169} However, neither amnion nor decidual cells are contractile, and the action of oxytocin on these tissues remains uncertain. It has been suggested that oxytocin plays a

dual role in parturition. It may act directly through both oxytocin receptor-mediated and nonreceptor, voltage-mediated calcium channels to affect intracellular signal transduction pathways that promote uterine contractions. It may also act indirectly through stimulation of amniotic and decidual prostaglandin production.^{162,166,169} Indeed, induction of labor at term is successful only when the oxytocin infusion is associated with an increase in $PGF_{2\alpha}$ production, in spite of seemingly adequate uterine contractions in both induction failures and successes.¹⁶²

Myometrial Contractility

REGULATION OF ELECTRICAL ACTIVITY WITHIN THE UTERUS

During pregnancy, the pattern of electrical activity in the myometrium changes from irregular spikes to regular activity. As with other types of muscle, action potentials must be generated and propagated in the myometrium to effect contractions, a process known as electromechanical coupling.^{170,171} The generation of action potentials of 12 to 25 mV from a normal resting potential of 65 to 80 mV in pregnant myometrial cells relies on rapid shifts of ions (especially calcium) through membrane ion channels,^{172,173} the most important of which appear to be voltage-sensitive calcium channels and, at the end of pregnancy, fast sodium and potassium channels.^{167,174-178} Autonomous pacemaker cells exist in the uterus. These cells have a higher resting transmembrane potential and spontaneously initiate action potentials.¹⁷⁹ Action potentials in the uterus occur in bursts, and the strength of contractions relies on their frequency and duration. This, in turn, determines the number of myometrial cells recruited for action. The action potential results in a rapid rise in intracellular calcium derived from both extracellular and intracellular sources, which triggers myometrial contractions by encouraging the relative movement of thick (myosin) and thin (actin) filaments within the contractile apparatus, resulting in shortening of the contractile unit. In this way, the electrical activity is translated into mechanical forces that are exerted on the intrauterine contents.

The *frequency* of contractions correlates with the frequency of action potentials; the *force* of contractions correlates with the number of spikes in the action potential and the number of cells activated together; and the *duration* of contractions correlates with the duration of the action potentials. As labor progresses, electrical activity becomes more organized and increases in amplitude and duration. The strength of contractions, which is best measured as intrauterine pressure in millimeters of mercury (mm Hg), varies with the stage of labor. Early labor contractions have a peak intensity of 25 to 30 mm Hg, and this increases to 60 to 65 mm Hg during active labor.¹⁸⁰ A number of factors influence the strength of the uterine contractions, including parity, cervical status, exogenous oxytocin, and labor analgesia (especially epidural analgesia). For example, the more rapid labor observed in multiparous compared with nulliparous women is caused not by increased intrauterine pressures during labor (indeed, multiparous women have lower intrauterine pressures than nulliparas)¹⁸¹ but by a reduction in the resistance of the pelvic floor.

MECHANICS OF MYOMETRIAL CONTRACTIONS

The structural basis for contractions is the relative movement of thick and thin filaments in the contractile apparatus, which

allows them to slide over each other with resultant shortening of the myocyte. Although this movement is similar in all muscles, several structural and regulatory features are unique to smooth muscle including the myometrium.^{182,183} In smooth muscle, the sarcomere arrangement of thick and thin filaments seen in striated muscle is present on a much smaller scale, and intermediate filaments of the cytoskeletal network maintain the structural integrity of these mini-sarcomeres. The thin filaments insert into dense bands linked by the cytoskeletal network, thereby allowing the generation of force in any direction within the cell. This allows smooth muscle cells to generate greater force (greater shortening) than striated muscle cells and with relatively little energy expenditure.

Myosin makes up the thick filaments of the contractile apparatus. Smooth muscle myosin is a hexamer consisting of two heavy-chain subunits (approximately 200 kDa) and two pairs each of 20- and 17-kDa light chains (Fig. 5-4). Each heavy chain has a globular head that contains actin binding sites and sites with adenosine triphosphate (ATP) hydrolysis (ATPase) activity. A neck region connects the globular head to the α -helical tail, which interacts with the tail of the other heavy-chain subunits. In this way, multiple myosin molecules interact through

their α -helical tails to make a coiled-coil rod, which forms the thick filament. Thin filaments are composed of actin, which polymerizes into a double-helical strand in association with a number of proteins. When the myosin head interacts with actin, the ATPase activity in the myosin head is activated. The energy generated from the hydrolysis of ATP allows the myosin head to move in the neck region, thereby changing the relative positions of the thick and thin filaments with shortening of the contractile unit. The myosin head then detaches and, when reactivated, can reattach at another site on the actin filament.

Actin-myosin interaction is regulated by the intracellular calcium concentration, which is mediated through the calcium-binding protein, calmodulin (CaM).^{167,184,185} The calcium-CaM complex binds to and increases the activity of myosin light-chain kinase (MLCK), an enzyme that is responsible for phosphorylating the 20-kDa myosin light chain on a serine residue near the amino terminus.^{185,186} This results in an increase in myosin ATPase activity, which increases the flexibility of the head-neck junction and increases uterine contractility.¹⁸² A further increase in intracellular calcium concentration triggers a negative-feedback loop with activation of calcium-CaM-dependent kinase II, an enzyme that phosphorylates MLCK,

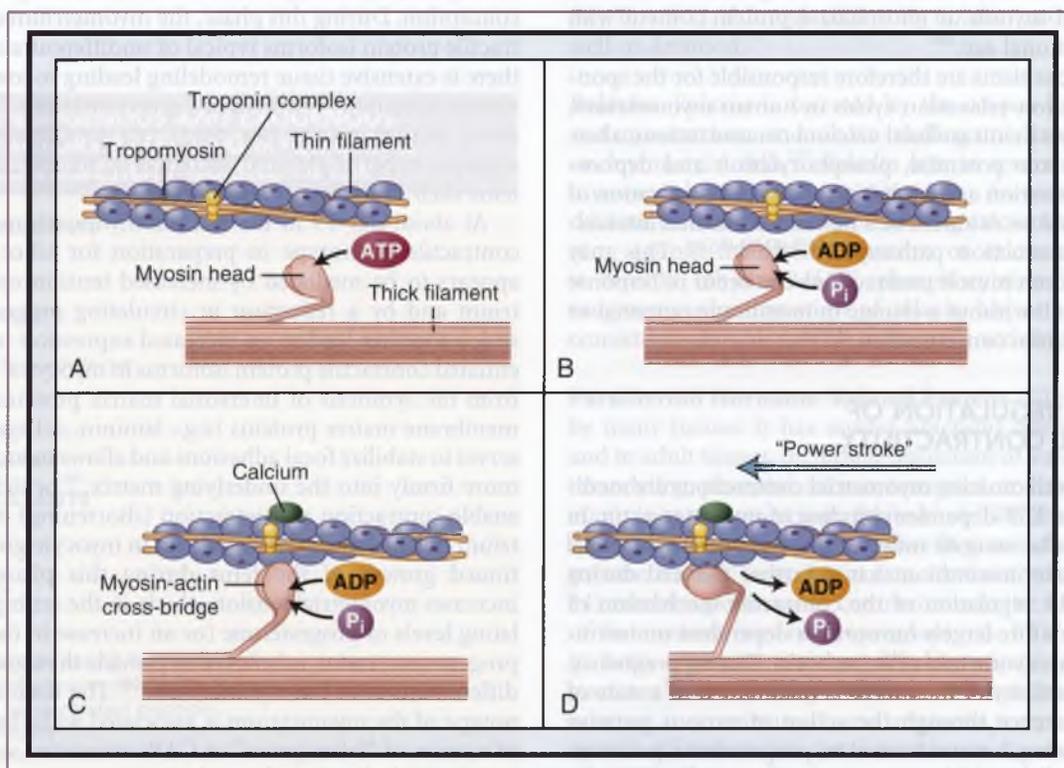

Figure 5-4 Mechanics of muscle contraction. A, The appearance of the contractile unit is illustrated. The thick filament refers to myosin; the thin filament is actin. Myosin-binding sites on the actin filaments are covered by a thin filament known as tropomyosin that obscures the myosin-binding sites, preventing the myosin heads from attaching to actin and forming cross-bridges. Adenosine triphosphate (ATP) binds to the myosin head. The troponin complex is attached to the tropomyosin filament. B, The hydrolysis of ATP into adenosine diphosphate (ADP) and inorganic phosphate (Pi) allows the myosin head to assume its resting position. C, The binding of calcium to the troponin complex results in a conformational change that allows binding sites between actin and myosin to be exposed and actin-myosin cross-bridges to be formed. D, The formation of actin-myosin cross-bridges results in release of Pi and ADP, causing the myosin heads to bend and slide past the myosin fibers. This "power stroke" results in a shortening of the contractile unit and generation of force within the muscle. At the end of the power stroke, the myosin head releases the actin-binding site, is cocked back to its farthest position, and binds to a new molecule of ATP in preparation for another contraction. The binding of myosin heads occurs asynchronously (i.e., some myosin heads are binding actin filaments while other heads are releasing them), which allows the muscle to generate a continuous smooth force. Cross-bridges must therefore form repeatedly during a single muscle contraction.

leading to a decrease in affinity of MLCK for calcium-CaM, a decrease in MLCK activity, and a subsequent decrease in myometrial contractility.^{185,187}

Many intracellular proteins interact with actin and further regulate actin-myosin interactions. Tropomyosin does so by binding to calcium-CaM, making it less available for binding to MLCK; calponin directly inhibits myosin ATPase activity; and caldesmon acts through both of these mechanisms. The phosphatase group of enzymes also plays an important role in determining the sensitivity of the contractile apparatus to electrical stimuli and changes in intracellular calcium concentrations.¹⁸⁸⁻¹⁹¹

Phosphatases can be regulated by direct effects on catalytic subunits or by targeting of regulatory proteins.^{189,190,192} For example, MLCK phosphatase is responsible for dephosphorylating and thus inactivating MLCK; phosphatases also remove phosphate groups from and relieve the inhibitory actions of the actin-associated regulatory proteins, calponin and caldesmon.^{188,192}

A number of external stimuli also affect myometrial contractility. For example, myometrial stretch (tension) leads to an increase in intracellular calcium concentration and MLCK phosphorylation.^{184,188} The increase in intracellular calcium concentration typically precedes MLCK phosphorylation, and maximal phosphorylation is evident before maximal force is achieved. For the same amount of tension, less phosphorylation occurs in myometrium from late pregnancy than from non-pregnant myometrium,¹⁹³ and this effect is seen without an increase in actin-myosin or phosphatase protein content with increasing gestational age.¹⁸⁴

Multiple mechanisms are therefore responsible for the spontaneous contraction-relaxation cycles in human myometrium, including changes in intracellular calcium concentrations, alteration in membrane potential, phosphorylation and dephosphorylation (activation and inhibition) of MLCK, activation of phosphatases, and recruitment of a number of distinct intracellular signal transduction pathways.^{167,178,183,184,187,191} This may explain why smooth muscle contractions can occur in response to external stimuli without a change in membrane potential or intracellular calcium concentration.^{182,183}

HORMONAL REGULATION OF MYOMETRIAL CONTRACTILITY

As in other smooth muscles, myometrial contractions are mediated through the ATP-dependent binding of myosin to actin. In contrast to vascular smooth muscle cells, however, myometrial cells have a sparse innervation that is further reduced during pregnancy.¹⁹⁴ The regulation of the contractile mechanism of the uterus is therefore largely humoral or dependent on intrinsic factors within myometrial cells (or both). During pregnancy, the contractile activity of the uterus is maintained in a state of functional quiescence through the action of various putative inhibitors including, but not limited to, progesterone, prostacyclin, relaxin, parathyroid hormone-related peptide (PTHrP), nitric oxide, calcitonin gene-related peptide, adrenomedullin, and vasoactive intestinal peptide. The onset of uterine contractions at term is a consequence of release from the inhibitory effects of pregnancy on the myometrium as well as recruitment of uterine stimulants such as oxytocin and stimulatory prostaglandins (e.g., PGF_{2α}, PGE₂).¹⁹⁵

Not surprisingly, investigation of the control of myometrial contractility during pregnancy has focused on the physiologic, endocrine, and molecular events that occur a few days before

the onset of labor, both at term and before term. Traditionally it was thought that, during most of pregnancy, the myometrium was a relatively inert organ whose role was limited to growing and protecting the products of conception. However, studies primarily on rats have challenged this notion and suggested that the myometrium undergoes a tightly regulated program of differentiation throughout pregnancy. In this model, labor can be viewed as the terminal differentiation state of the myometrium, with downregulation of inhibitory pathways and activation of contractile processes. This model explains why tocolysis in the setting of active preterm labor is largely ineffective.³⁵

The program of myometrial differentiation includes four distinct states or phenotypes: proliferative, synthetic, contractile, and labor. In early pregnancy, uterine myocytes exhibit a high level of proliferation, as evidenced by increased expression of cell cycle markers and antiapoptotic factors such as BCL2.¹⁹⁶ Myocyte proliferation during this phase is mediated in large part by estrogen-induced expression of insulin-like growth factor-1 (IGF-1).¹⁹⁷ In the rat, the proliferative phenotype ends abruptly on day 14 (of 23) of gestation, and the myocytes differentiate to a synthetic phenotype. The switch from a proliferative to a synthetic phenotype most likely results from stretch-induced hypoxic injury to the myometrium that induces expression of stress-activated caspases.¹⁹⁶ The synthetic phase of myometrial differentiation is maintained by progesterone and by tension on the uterine wall exerted by the expanding conception. During this phase, the myometrium expresses contractile protein isoforms typical of undifferentiated cells,¹⁹⁸ and there is extensive tissue remodeling leading to loss of focal cell-matrix adhesion.¹⁹⁹ Growth of the myometrium during the synthetic period results not from cell proliferation but from myocyte hypertrophy and secretion of interstitial matrix proteins such as collagen I and fibronectin.²⁰⁰

At about day 19 in the rat, the myometrium switches to a contractile phenotype in preparation for labor. This change appears to be mediated by increased tension on the myometrium and by a reduction in circulating progesterone levels, which together lead to an increased expression of more differentiated contractile protein isoforms in myocytes¹⁹⁸ and a switch from the synthesis of interstitial matrix proteins to basement membrane matrix proteins (e.g., laminin, collagen IV).²⁰⁰ This serves to stabilize focal adhesions and allows myocytes to anchor more firmly into the underlying matrix,¹⁹⁹ which is critical to enable contraction and retraction (shortening) of the myometrium during labor. The slowdown in myocyte growth and continued growth of the fetus during this phase significantly increases myometrial tension which, in the setting of low circulating levels of progesterone (or an increase in the estrogen-to-progesterone ratio), is believed to provide the signal for terminal differentiation of the myometrium.¹⁹⁷ The resultant labor phenotype of the myometrium is associated with the upregulation of a series of "labor genes" or CAPs associated with contractile activity, including ion channels that increase myocyte excitability, gap junctions (connexin-43) that increase the synchronization of contractions, and receptors for uterotonic agonists such as oxytocin and the stimulatory prostaglandins.

At a cellular and molecular level, the upregulation of the CAPs appears to be mediated at the level of gene transcription. It results from increased expression of FOS (c-fos) and other members of the activating protein AP-1 family of transcription factors (e.g., FRA1, FRA2) within myometrial cells caused by uterine stretch and hormonal factors, primarily estrogen.¹⁹⁶

There also appear to be regional differences in gene expression within the myometrium. For example, genes that promote contractile activity (e.g., connexin-43, oxytocin receptors, prostaglandin receptors EP1/4 and FP) are more highly expressed in the uterine fundus, whereas genes associated with contractile inhibition (e.g., EP2/4, CRH receptor subtype 1) are expressed more highly in the lower uterine segment.^{201,202} The molecular mechanisms responsible for the regionalization of gene expression within the uterus have yet to be determined, although recent reports of higher levels of the PR co-repressor, PSE, in the uterine fundus suggests the possibility of regionalized differences in functional withdrawal of progesterone.¹³⁴

The roles of a number of specific stimulants and relaxants involved in myometrial contractility during labor are discussed in the following sections.

Uterine Stimulants

Box 5-1 summarizes uterine stimulants implicated in uterine contractions during labor. *Oxytocin* is a potent endogenous uterotonic agent (discussed earlier) that is capable of stimulating uterine contractions if given exogenously at intravenous infusion rates of 1 to 2 mU/min at term. *Prostaglandins* (discussed earlier) cause uterine contractions and cervical effacement and dilation and can be used clinically for induction of labor. A number of other, less well recognized uterine factors

BOX 5-1 ENDOGENOUS AND EXOGENOUS FACTORS AFFECTING MYOMETRIAL CONTRACTILITY DURING LABOR

UTERINE STIMULANTS

Endogenous

- Oxytocin
- Prostaglandins
- Endothelin
- Epidermal growth factor

Exogenous

- Oxytocin
- Prostaglandins

UTERINE RELAXANTS

Endogenous

- Relaxin
- Nitric oxide
- L-Arginine
- Magnesium
- Corticotropin-releasing hormone
- Parathyroid hormone-related protein
- Calcitonin gene-related peptide
- Adrenomedullin
- Progesterone

Exogenous

- β -Adrenergic agonists (ritodrine hydrochloride, terbutaline sulfate, salbutamol, fenoterol)
- Oxytocin receptor antagonist (atosiban)
- Magnesium sulfate
- Calcium channel blockers (nifedipine, nitrendipine, diltiazem, verapamil)
- Prostaglandin inhibitors (indomethacin)
- Phosphodiesterase inhibitor (aminophylline)
- Nitric oxide donor (nitroglycerin, sodium nitroprusside)

have also been implicated in the generation of uterine contractions.

Endothelin. Endothelin is a 21-amino acid peptide with potent vasoconstrictor properties that binds to specific receptors on vascular endothelial cells to regulate vascular hemostasis. Endothelin receptors have been isolated in amnion, chorion, endometrium, and myometrium,^{153,203} and they increase in the myometrium during labor.^{203,204} Endothelin promotes uterine contractility directly by increasing intracellular calcium concentrations^{153,205} and indirectly by stimulating prostaglandin production by the decidua and fetal membranes.²⁰³

Epidermal Growth Factor. Epidermal growth factor (EGF) is a ubiquitous growth factor that plays an important role in the regulation of cell growth, proliferation, and differentiation. It acts by binding to specific cell-surface tyrosine-kinase receptors that have been identified also in decidua and myometrium, and it appears to be upregulated by estrogen.¹⁵³ EGF appears to promote uterine contractility directly by increasing intracellular calcium concentrations²⁰⁶ and indirectly by mobilizing arachidonic acid and increasing the synthesis and release of prostaglandins by the decidua and fetal membranes.²⁰³

Uterine Relaxants

A number of endogenous uterine relaxants have been described (see Box 5-1), although their roles in labor and delivery are not well understood.

Relaxin. Relaxin is secreted by the corpus luteum, placenta, and myometrium, and relaxin binding sites have been identified on myometrial cells.²⁰⁷ Relaxin acts in several ways to inhibit myometrial contractile activity: it decreases intracellular calcium concentrations by promoting calcium efflux and inhibiting agonist-mediated activation of calcium channels, and it directly inhibits MLCK phosphorylation.^{167,178,207} However, exogenous administration of relaxin has not been shown to consistently inhibit uterine contractile activity.²⁰⁸

Parathyroid Hormone-Related Protein. PTHrP is produced by many tissues. It has several functions during development and in adult tissues, including regulation of vascular tone, bone remodeling, placental calcium transport, and myometrial relaxation. In rat myometrium, the level of PTHrP mRNA increases during late gestation and is higher in gravid than in nonpregnant myometrium.²⁰⁹ In pregnant rats, administration of PTHrP-(1-34) inhibits spontaneous contractions in the longitudinal layer of the myometrium; in nonpregnant rats, PTHrP-(1-34) inhibits both oxytocin- and acetylcholine-stimulated uterine contractions^{210,211} and delays but does not completely abrogate the increase in connexin-43 and oxytocin receptor gene expression.²¹² PTHrP-(1-34) has been shown to exert a significant relaxant effect on human myometrium collected from late-gestation tissues obtained before, but not after, the onset of labor.²¹³ Taken together, these data suggest that the onset of labor is associated with a removal of the ability of PTHrP to exert its myometrial relaxant effect.

Calcitonin Gene-Related Peptide and Adrenomedullin. Circulating levels of calcitonin gene-related peptide (CGRP) and adrenomedullin are increased during pregnancy, and both have been implicated in the maintenance of myometrial quiescence

throughout gestation.²¹⁴⁻²¹⁶ CGRP has been shown to inhibit myometrial contractility in rats,²¹⁴ humans,²¹⁷ and mice²¹⁸ during pregnancy. However, this effect disappears after the onset of labor, suggesting that progesterone may be required to mediate CGRP activity.²¹⁴ Adrenomedullin has been shown to inhibit spontaneous as well as bradykinin- and galanin-induced uterine contractions in rats,^{215,219} but its role in human pregnancy is not well established.

Nitric Oxide. Nitric oxide and its substrate, L-arginine, as well as nitric oxide donors (e.g., sodium nitroprusside), have been shown to cause relaxation of myometrial contractile activity both in vitro and in vivo, and this effect is reversed by the nitric oxide synthase inhibitor, L-nitro-arginine methyl ester (L-NAME).²²⁰ Nitric oxide activates the guanylate cyclase pathway, leading to the production of cyclic guanosine monophosphate (cGMP), which decreases intracellular calcium concentrations and interferes with myosin light chain phosphorylation.^{221,222}

Magnesium. Magnesium is present in the extracellular fluid of the myometrium in very high concentrations (10 nM), which results in increased intracellular magnesium levels, inhibition of calcium entry into myometrial cells via L- and T-type voltage-operated calcium channels, and enhanced sensitivity of potassium channels,^{167,178} all of which lead to hyperpolarization and myometrial cell relaxation. Moreover, because they are both cations, magnesium competes with calcium within the cell for calmodulin binding, resulting in decreased affinity of calmodulin complexes for MLCK, which further favors myometrial relaxation.²²³

Non-naturally Occurring Uterine Relaxants. In addition to naturally occurring uterine relaxants, a number of agents have been developed to stop preterm labor (see Box 5-1). Unfortunately, the ability of these tocolytic agents to prevent preterm birth has been largely disappointing.³⁵

β-Adrenergic receptor agonists act through specific receptors on myometrial cells to activate cAMP-dependent protein kinase A, which inhibits myosin light chain phosphorylation²²⁴ and decreases intracellular calcium concentrations,^{167,178} thereby leading to myometrial relaxation.

Synthetic competitive oxytocin receptor antagonists such as atosiban (which has mixed vasopressin and oxytocin receptor specificity) inhibit uterine contractility both in vitro and in vivo.²²⁵⁻²²⁷ The relative absence of oxytocin receptors in other organ systems suggests that such agents should have few side effects, and this has been borne out by a number of clinical trials.²²⁸⁻²³⁰

Calcium channel blockers function primarily by inhibiting the entry of calcium ions via voltage-dependent L-type calcium channels, which causes uterine relaxation but can also have adverse effects on the atrioventricular conduction pathway in the heart.

Prostaglandin synthesis inhibitors inactivate the cyclooxygenase enzyme responsible for the conversion of arachidonic acid to the intermediate metabolite (PGH₂), which is subsequently converted to PGE₂ and PGF_{2α}. Aspirin causes irreversible acetylation of the cyclooxygenase enzyme, whereas indomethacin is a competitive (reversible) inhibitor. Although these agents are relatively effective, their adverse effects on the developing fetus (including premature closure of the ductus arteriosus and persistent pulmonary hypertension) have significantly limited their

use. Moreover, these adverse effects can be seen with both non-selective cyclooxygenase inhibitors (e.g., indomethacin) and those that are selective for the inducible isoform, COX-2 (e.g., meloxicam, celecoxib).

Role of the Cervix in Labor

The onset of forceful, coordinated uterine contractions was once considered the key initiator of cervical change to facilitate birth. However, studies in humans and animals have confirmed that cervical remodeling begins long before the onset of uterine contractions. Both processes, while independent, must be coordinately regulated for successful parturition.^{13,15,21,231,232} The concept that cervical remodeling occurs weeks and months before delivery is supported by studies demonstrating that a shortened cervical length (defined variably as <1.5 cm or <2.0 cm), measured by transvaginal ultrasound at 16 to 24 weeks' gestation, is a significant risk factor for preterm birth in both high- and low-risk populations.^{102-105,233,234} Each phase of cervical remodeling (see Fig. 5-1) is accompanied by specific molecular changes under the control of a distinct hormonal milieu. Although understanding of the molecular mechanisms that regulate cervical remodeling remains incomplete, recent advances suggest that remodeling begins early in pregnancy and that a progressive and incremental transformation from a rigid to a compliant cervix occurs over the course of gestation.^{232,235}

CERVICAL SOFTENING

In 1895, the physician Ernst Ludwig Hegar reported that compared to the nonpregnant state, the pregnant cervix was softer and more easily palpable in the first trimester. This change served as a reliable indicator of pregnancy.²³⁶ This observation was prime evidence that cervical softening begins in early pregnancy. More recently, the decline in cervical length from early to late pregnancy as measured by transvaginal ultrasound has provided evidence that modifications to cervical structure begin relatively early in pregnancy.²³⁷ Fibrillar collagens are the main structural protein in the cervix. Regulated alterations in processing and assembly of collagen fibers, as well as a reduction in the matricellular proteins thrombospondin 2 and tenascin C, lead to modifications of cervical collagen architecture and reduced mechanical strength.^{231,238,239} The importance of extracellular matrix structure to cervical function is further highlighted by the fact that women with genetic defects in collagen processing or assembly have an increased incidence of preterm birth due to cervical insufficiency.²⁴⁰

Changes in the mechanical properties of the cervix are accompanied by an increase in cellular proliferation of both stromal and epithelial cells. In particular, the columnar glandular epithelia undergo a marked proliferation, and these cells secrete mucus that serves as a physical barrier and contains immunoglobulins in addition to other factors that provide immunologic protection against ascending infection. This thick mucus obstructs the cervical canal and is commonly referred to as the *mucus plug*. Throughout the softening phase of cervical remodeling, the ratio of progesterone to estrogen is high and likely regulates early modifications in cervical structure. Relaxin is a peptide hormone made by the corpus luteum that has been implicated in cervical epithelial and stromal cell proliferation and in connective tissue remodeling.²⁴¹

CERVICAL RIPENING

Cervical ripening is a more accelerated phase of remodeling that begins in the 1 to 2 weeks preceding onset of labor. This phase is characterized by increased synthesis of the hydrophilic glycosaminoglycan, hyaluronan, and expression of genes encoding hyaluronan synthase.²⁴² Hyaluronan's functions are dependent on its size and on cell-specific expression of hyaluronan-binding molecules. Hyaluronan is reported to interact with receptors expressed by cervical epithelia, such as CD44 and Toll-like receptor 4 (TLR-4), and with proteoglycans expressed in the cervical stroma, such as versican.^{18,243,244} Hyaluronan is predominantly found in a large-molecular-weight isoform during ripening. This isoform is likely to contribute to the increased tissue hydration of the cervix at term, further disorganizing the collagen architecture and resulting in a maximal decline in cervical tensile strength.^{18,245,246} During ripening, the cervical epithelium continues to provide a protective barrier against invading organisms and modulates steroid hormone metabolism to establish a local environment that is rich in estrogen and low in progesterone.

Although circulating progesterone levels do not decline until after birth, reduced endocervical expression of the enzyme 17 β -HSD-2 and changes in expression of PR isoforms contribute to loss of progesterone functional activity and increased estrogen action.^{247,248} The fact that administration of mifepristone, a PR antagonist, induces cervical ripening and preterm labor highlights the importance of progesterone in the maintenance of pregnancy. It also demonstrates that loss of progesterone functional activity leads to cervical ripening and labor.²⁴⁹ The functional loss of progesterone action results in enhanced sensitivity of ERs which, along with an increase in local estrogen concentration, causes activation of processes that facilitate cervical ripening. Observations that transvaginal progesterone supplementation from 16 to 20 weeks through 36 weeks of gestation is able to prevent preterm birth in some women who are at high risk due to cervical shortening support the notion that the local steroid hormone milieu is important for cervical ripening.^{102-105,250}

CERVICAL DILATION

Cervical dilation and effacement begins with the onset of uterine contractions and continues throughout labor. The mucus plug that obstructs the cervical canal is expelled at this time, and the cervix must open to a diameter of 10 cm to allow passage of a term fetus. *Cervical effacement* describes the process by which the cervix shortens until it becomes a thin, circular opening. Although it is difficult to discern processes that are distinct to this phase of cervical remodeling, compared with ripening or postpartum repair, it is likely that the biochemical changes activated during this phase are regulated by both hormonal factors, mechanical forces induced by myometrial contraction, and descent of the fetus. Hyaluronidase is an enzyme that breaks down large-molecular-weight hyaluronan, and its activity increases during this phase, which may contribute to complete loss of tissue competence.^{245,246,251} Indeed, cervical application of hyaluronidase at term has been reported to reduce the duration of labor and increase the rate of vaginal delivery.^{252,253}

Prostaglandins are proposed to have important functions in cervical ripening and dilation. Exogenous administration of prostaglandins promotes cervical changes that mimic ripening

and dilation, including increased solubility of collagen and alteration in extracellular matrix composition. The rate-limiting enzyme in prostaglandin synthesis is PGHS. As discussed earlier, two isoforms of PGHS exist, PGHS-1 and PGHS-2. Expression of the PGHS-2 isoform is upregulated in the endocervical epithelium with labor.²⁵⁴ The critical role of prostaglandins in physiologic ripening and dilation remains to be established, given that the prostaglandins PGE₂ and PGF_{2 α} are not increased in the cervical mucosa at term. In addition, administration of the PR antagonist mifepristone induces cervical ripening and dilation without an increase in prostaglandin production.^{255,256}

POSTPARTUM REPAIR

After delivery, the cervix undergoes an extensive repair process to remove extracellular matrix components that promote matrix disorganization and to upregulate the synthesis of new matrix molecules leading to an organized matrix with increased tensile strength. Numerous immunohistochemical studies have shown an increase in leukocyte cell infiltration in this phase of cervical remodeling; the leukocytes likely secrete proteases to break down poorly assembled extracellular matrix components.^{257,258} Although proinflammatory genes are not activated during cervical ripening, gene expression microarrays confirm their activation during the postpartum repair process.^{259,260} In addition to the inflammatory response, there is also activation of anti-inflammatory mediators, increased synthesis of extracellular matrix molecules, and increased expression of antimicrobials and defense molecules in the cervical epithelium.

Achieving a Successful Delivery

Labor is not a passive process in which uterine contractions push a rigid object through a fixed aperture. The ability of the fetus to successfully negotiate the pelvis during delivery depends on the complex interaction of three critical variables: the forces generated by the uterine musculature (the powers); the size and orientation of the fetus (the passenger); and the size, shape, and resistance of the bony pelvis and soft tissues of the pelvic floor (the passage). Because of the asymmetry in the shape of both the fetal head and the maternal pelvis, the fetus needs to undergo a series of orchestrated rotations (referred to as the cardinal movements) to allow it to negotiate the birth canal successfully. Further discussion of the mechanics of labor and delivery are beyond the scope of this chapter, but they have been reviewed in detail elsewhere.¹⁹⁵ Suffice it to say that timely onset of labor does not guarantee an uneventful delivery and a healthy, undamaged child.

Conclusions

Labor is a physiologic and continuous process. The factors responsible for the onset and maintenance of normal labor at term are not completely understood and continue to be actively investigated. A better understanding of the mechanisms responsible for the onset of labor at term will further knowledge about disorders of parturition, such as preterm and prolonged (post-term) labor, and improve our ability to secure a successful pregnancy outcome.

Immunology of Pregnancy

GIL MOR, MD, PhD | VIKKI M. ABRAHAMS, PhD

Pregnancy as an Allograft

Occurrences of recurrent abortion, preeclampsia, or hemolytic diseases of the newborn raise the rhetorical question, “Why did your mother reject you?” However, when considering the complexity of maternal-fetal immune interactions and the vast number of successful pregnancies, perhaps the more appropriate question is, “Why *didn't* your mother reject you?” More than 60 years ago, the renowned transplant immunologist, Sir Peter Medawar, proposed a theory as to why the fetus, a semi-allograft, is not rejected by the maternal immune system.¹ He recognized for the first time the unique immunology of the maternal-fetal interface and its potential relevance for transplantation. In his original work, he described the “fetal allograft analogy,” wherein the fetus is viewed as semi-allogeneic because it is made up, in part, of paternal antigens and therefore foreign to the maternal immune system and yet, through unknown mechanisms, evades rejection by the maternal immune system. Subsequent studies demonstrated the presence of an active maternal immune system at the implantation site, and this provided evidence to support Medawar’s thesis. As a result, investigators began to pursue the mechanisms by which the fetus might escape such maternal immune surveillance. Alterations in these pathways in pregnancy complications (e.g., recurrent abortion, preeclampsia) in which the immune system is thought to play a central role have been proffered as further evidence for the Medawar hypothesis of the semi-allogeneic fetus.

Since Medawar’s original observation, numerous studies have been performed to explain this paradigm, many of which have centered on how the fetus and placenta evade or restrain an active and aggressive maternal immune system. The objective of this chapter is to review some of the significant events involved in human implantation related to the interaction between the maternal immune system and the fetus, to challenge some traditional concepts, and to propose a new perspective for the role of the immune system in pregnancy.

DEFINING THE IMMUNOLOGY OF PREGNANCY

In 1991, Colbern and Main redefined the conceptual framework of reproductive immunology as maternal-placental tolerance rather than maternal-fetal tolerance, focusing on the interaction of the maternal immune system with the placenta rather than the fetus.² The embryo in early development divides into two groups of cells: the internal inner cell mass, which gives rise to the embryo, and the external embryonic trophoectoderm, which becomes the trophoblast cells and, later, the placenta. Cells from the placenta directly interact with the mother’s uterine cells, which include abundant leukocytes, and therefore with the maternal immune system, and these placental cells are able to avoid immune rejection. In contrast, the fetus itself has no direct

contact with maternal cells. Moreover, the fetus is known to express paternal major histocompatibility complex (MHC)* antigens. Therefore, as postulated by Medawar, the fetus would be rejected as a true allograft if it were removed from its cocoon provided by the placenta and fetal membranes and transplanted into the thigh muscle or kidney capsule of the mother.

General Concepts of Immunology

TYPES OF IMMUNE RESPONSE

The immune system eliminates foreign material in two ways: through natural or innate immunity and through adaptive immunity. *Innate immunity* produces a relatively unsophisticated response that prevents the access of pathogens to the body. This is a primitive evolutionary system that occurs without need for prior exposure to similar pathogens. The primary cell types involved in these responses are phagocytic cells such as macrophages and granulocytes. These cells express pattern recognition receptors (PRRs) that sense conserved pathogen-derived or related sequences on the surface of microbes and trigger an immune response. As a result, the phagocytic cells produce proinflammatory cytokines, release degradative enzymes, generate intense respiratory bursts of free radicals, and, ultimately, engulf and destroy the invading microorganism. Thus, the innate immune system provides the first line of defense against invading microbes. Furthermore, the innate immune system is critical for priming the adaptive immune response.

Adaptive immunity is an additional, more sophisticated response found in higher species, including humans. Cells of the innate immune system process phagocytosed foreign material and present its antigens to cells of the adaptive immune system for possible reactions. This immune response is highly specific and normally is potentiated by repeated antigenic encounters. Adaptive immunity consists of two types of immune responses: *humoral immunity*, in which antibodies are produced, and *cellular immunity*, which involves cell lysis by specialized lymphocytes (cytolytic T cells). Adaptive immunity is characterized by an anamnestic response that enables the immune cells to “remember” the foreign antigenic encounter and react to further exposures to the same antigen faster and more vigorously.

CYTOKINES AND THE IMMUNE RESPONSE

Immune cells mediate their effects by releasing cytokines; through these secreted factors, they can establish particular

*See Table 6-1 for definitions for abbreviations used throughout this chapter.

TABLE 6-1
Definitions for Abbreviations

Abbreviation	Definition
ACA	Acute chorioamnionitis
APC	Antigen-presenting cells
ASC	Apoptosis-associated speck-like protein containing a CARD
BBB	Blood-brain barrier
CCA	Chronic chorioamnionitis
DAMP	Damage-associated molecular pattern
DC	Dendritic cell
uDC	Uterine dendritic cell
FasL	Fas ligand
FIRS	Fetal inflammatory response syndrome
HLA	Human leukocyte antigen
IDO	Indoleamine 2,3-dioxygenase
iE-DAP	γ -D-glutamyl-meso-diaminopimelic acid
IFN	Interferon
IL	Interleukin
IP-10	Interferon-inducible protein 10
LPS	Lipopolysaccharide
LRR	Leucine-rich repeat
MDP	Muramyl dipeptide
MHC	Major histocompatibility complex
MyD88	Myeloid differentiation factor 88
NK	Natural killer (cell)
dNK	Decidual natural killer (cell)
eNK	Endometrial natural killer (cell)
uNK	Uterine natural killer (cell)
NLR	NOD-like receptor
PAMP	Pathogen-associated molecular pattern
PDG	Peptidoglycan
PLGF	Placental growth factor
PRR	Pattern recognition receptor
RIP2	RICK
T _H	T helper lymphocyte
TLR	Toll-like receptor
TNF	Tumor necrosis factor
Treg	T regulatory cell
VEGF	Vascular endothelial growth factor

microenvironments. In other words, immune cells, through their production of cytokines, can create either a proinflammatory or an anti-inflammatory environment. Moreover, the cytokine profile created by immune cells can shape the characteristics of subsequent immune responses. For example, naive T helper lymphocytes (T_H0 cells) originate in the thymus and play a major role in creating specific microenvironments within the periphery, depending on their differentiation status. If a T_H0 cell differentiates into a T_H1 cell, it secretes interleukin-2 (IL-2) and interferon- γ (IFN- γ), setting the stage for a cellular, cytotoxic immune response. Conversely, T_H2 lymphocytes secrete cytokines, such as IL-4, IL-6, and IL-10, that are predominately involved in antibody production. Furthermore, the actions of T_H1 and T_H2 cells are closely intertwined, both acting in concert and responding to counter-regulatory effects of their cytokines. T_H1 cytokines produce proinflammatory cytokines that, while acting to reinforce the cytolytic immune response, also down-regulate the production of T_H2-type cytokines.

As discussed later, the pregnant endometrium or decidua is populated by abundant numbers of maternal immune cells, both during implantation and throughout gestation. Therefore, it is clear that the maternal immune system interacts, at different stages and under various circumstances, with the invading trophoblast. Our objective is to understand the types of interactions that occur and their roles in the support of a normal

pregnancy. The following sections summarize some of the main hypotheses proposed to explain the trophoblast-maternal immune interaction.

Maternal Immune Response to the Trophoblast: The Pregnant Uterus as an Immune Privileged Site

Implantation is the process by which the blastocyst becomes intimately connected with the maternal endometrium (decidua). During this period, the semi-allogeneic trophoblast comes in direct contact with resident uterine and blood-borne maternal immune cells. However, as mentioned earlier, fetal rejection by the maternal immune system is prevented in most cases, by mechanisms yet to be defined. Over the years, several mechanisms have been proposed to explain the immune privileged state of the maternal decidua. Because of space limitations, only five of the main proposed mechanisms are discussed here: (1) a mechanical barrier effect of the placenta; (2) systemic suppression of the maternal immune system during pregnancy; (3) the absence of MHC class I molecules on the trophoblast; (4) a local and systemic cytokine shift from a T_H1 to a T_H2 cytokine profile; and (5) local immune suppression mediated by the Fas/Fas ligand (FasL) system.

THE PLACENTA AS A MECHANICAL BARRIER

Until the late 1980s, the most popular of the five theories was the belief that a mechanical barrier formed by the placenta prevented the movement of immune cells in both directions across the maternal-fetal interface. The barrier thus created a state of immunologic ignorance in which fetal antigens were never presented to, and therefore never detected by, the maternal immune system. Scientists believed that the barrier, which is formed in the pregnant uterus by the trophoblast and the decidua, prevented movement of activated, alloreactive immune cells from the maternal circulation to the fetal side. Similarly, this barrier isolated the fetus and prevented the escape of fetal cells into the maternal circulation.³

Challenging the mechanical barrier theory were studies showing that the trophoblast-decidua interface is less inert or impermeable than was first envisioned. Evidence for bidirectional cellular trafficking across the maternal-fetal interface includes the migration of maternal cells into the fetus³ and the presence of fetal cells in the maternal circulation.⁴ Such bidirectionality is now known to be the case in most of the immune privileged tissues, including the brain's blood-brain barrier.⁴

Fetal cells may be observed in the mother decades after the pregnancy.⁵ These cells, like stem cells, have the potential to infiltrate maternal tissues and differentiate into liver, muscle, and skin cells, transforming the mother into a chimera. Originally it was thought that these fetal cells were responsible for triggering autoimmune diseases, which afflict women more often than men.⁶ However, more recent studies have demonstrated that they may play a critical role in repairing the mother's tissues after damage by a pathologic process. In one case study, a woman suffering from hepatitis stopped treatment against medical advice, yet she did well clinically and her disease abated. Moreover, her liver specimen was found to contain male cells that had originated from her previous pregnancies, suggesting that these "leftover" fetal cells in the mother's circulation

produced new liver cells and were, at least in part, responsible for her recovery."^{5,7,8}

SYSTEMIC IMMUNE SUPPRESSION

The second theory postulates that pregnancy is a state of systemic immune suppression, and, therefore, maternal immune cells are unable to reject the fetus. This concept was studied by numerous investigators and eventually became conventional wisdom. Indeed, a wide array of factors in human serum have been found to have profound *in vitro* immunosuppressive activities.⁹ However, if this hypothesis is carefully analyzed, it is difficult to imagine how, from an evolutionary point of view, pregnancy would involve a stage of profound immune suppression. Early humans were not able to wash their hands or clean their food, and with the absence of antiseptics, they were continually exposed to bacteria, parasites, and other microorganisms. If pregnant women had been systemically immunologically suppressed, they would not have survived, and the human species would have become extinct. Even today in many parts of the world, pregnant women are continually exposed to harsh, unsanitary conditions, and a suppressed immune system would make it impossible for the mother and fetus to survive. Furthermore, in regions where human immunodeficiency virus (HIV) infection is pandemic, such as Africa, HIV-positive women do not rapidly develop the acquired immunodeficiency syndrome (AIDS) during pregnancy. In fact, studies clearly demonstrate that maternal antiviral immunity is not affected by pregnancy.¹⁰ Together, these observations argue against the existence of such nonspecific immune suppression.

CYTOKINE SHIFT

As the definition of pregnancy as a T_H2 or anti-inflammatory state was enthusiastically embraced, numerous studies attempted to prove the hypothesis¹¹ and to demonstrate that a shift in the type of cytokines produced would lead to abortion or pregnancy complications. Although many studies provided support for this notion, a similar number argued against it.^{12,13} The reason for these contradictory results may be oversimplification

of disparate observations made during pregnancy. In these studies, pregnancy was evaluated as a single event, whereas in reality it has three distinct immunologic phases that are characterized by different biologic processes and can be symbolized by how the pregnant woman feels.

Immunologically, implantation, placentation, and the first and early second trimesters of pregnancy resemble an open wound that requires a strong inflammatory response. During this first phase, the embryo has to break through the epithelial lining of the uterus to implant, damage endometrial tissues to invade, and replace the endothelium and vascular smooth muscle of the maternal blood vessels to secure an adequate blood supply. All of these activities create a veritable battleground of invading cells, dying cells, and repairing cells. An inflammatory environment is required for repair of the uterine epithelium and removal of cellular debris. During this period, the mother's well-being is affected: She feels ill because, in addition to hormone changes and other factors, there is an active immune response. Therefore, the first trimester of pregnancy is a proinflammatory phase (Fig. 6-1).

The second immunologic phase of pregnancy is, in many ways, the optimal time for the mother. This is a period of rapid fetal growth and development. The mother, placenta, and fetus are symbiotic, and the predominant immunologic feature is induction of an anti-inflammatory state. The woman no longer suffers from nausea as she did in the first stage, in part because the immune response is no longer the predominant endocrine feature.

During the last immunologic phase of pregnancy, the fetus has completed its development, and all of its organs are functional and ready to deal with the external world. Now the mother needs to deliver the baby, and this can be achieved only through renewed inflammation. Parturition is characterized by an influx into the myometrium of immune cells that promote recrudescence of an inflammatory process. This proinflammatory environment promotes contraction of the uterus, expulsion of the baby, and rejection of the placenta.

To summarize, pregnancy is both a proinflammatory and an anti-inflammatory condition, depending on the stage of gestation (see Fig. 6-1).¹⁴

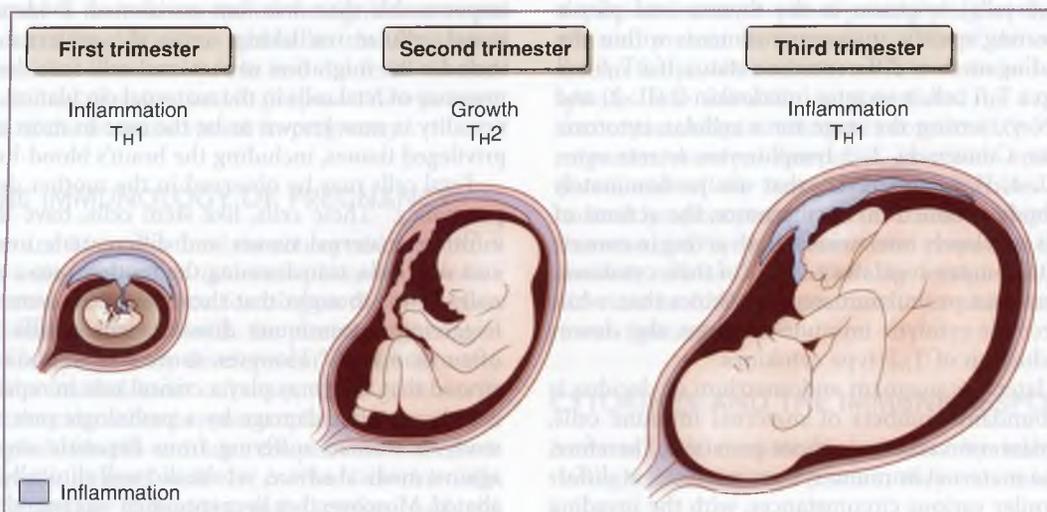

Figure 6-1 Inflammation and pregnancy. Each stage of pregnancy is characterized by a unique inflammatory environment. The first and third trimesters are proinflammatory (T_H1 environment), whereas the second trimester represents an anti-inflammatory stage (T_H2).

LACK OF EXPRESSION OF HUMAN LEUKOCYTE ANTIGENS

A more recently postulated theory is based on the fact that polymorphic MHC class I and II molecules have not been detected on the trophoblast.¹⁵ Class I antigens are expressed on the surface of most nucleated cells and serve as important recognition molecules. In humans, these antigens are also known as human leukocyte antigens (HLA). HLA class I genes are located on a single chromosomal region (6p.21.3). They are subdivided into two groups, HLA class Ia and class Ib genes, according to their polymorphism, tissue distribution, and functions. HLA-A, -B and -C class Ia genes exhibit a very high level of polymorphism and are almost ubiquitously expressed in somatic tissues; their immunologic functions are well established. They modulate antiviral and antitumoral immune responses through interactions with T cell and natural killer (NK) cell receptors. In contrast, HLA-E, -F, and -G class Ib genes are characterized by limited polymorphism and restricted tissue distribution, and their roles are poorly understood. The statement that the human placenta does not express polymorphic MHC class I molecules is not entirely accurate. The human placenta does not express the polymorphic HLA-A and HLA-B class I antigens, but it does express HLA-C molecules. In addition, HLA-G and HLA-E molecules are also expressed by the human placenta.^{16,17}

Using immunostaining with antibodies against class I molecules, Loke and King and their colleagues divided the human trophoblast into two distinct populations: the villous trophoblast in contact with maternal blood at the intervillous interface, which is class I negative, and the extravillous trophoblast invading the uterine decidua, which is class I positive.^{18,19} Based on these findings, it was suggested that there are two fetal-maternal interfaces in human reproduction and that they differ immunologically. A trophoblast population that is immunologically neutral is in contact with the systemic maternal immune system, and a local, immunologically active population of trophoblast cells migrating into the decidua can be stimulated by HLA class I molecules.²⁰

The HLA-G molecule was originally cloned in 1987 and is abundant at the maternal-fetal interface.^{21,22} Based on what was thought to be an almost exclusive expression of HLA-G at the maternal-fetal interface, it was suggested that this molecule maintains a very specialized role in this environment. Another unique feature of the HLA-G genes, which was postulated to be a prerequisite for maintenance of maternal immune tolerance, is the lack of polymorphisms of the HLA-G nucleotide sequence.²³ However, new data show that this may not be the case. Alternative splicing of the HLA-G mRNA yields different membrane-bound and soluble variants of the HLA-G protein and a limited number of variable sites in the DNA sequence of the HLA-G gene.²⁴⁻²⁸ Therefore, the hypothesis that HLA-G is the mediator of fetal-maternal tolerance as a result of its monomorphism and immunologic neutrality needs to be revised.^{23,29,30}

In animal studies, it has been shown that murine trophoblast cells express MHC class I genes and alloantigens at high levels early in gestation. During those times, MHC class I antigens are barely detected on fetal tissues.^{31,32} Therefore, as has been suggested by several investigators, maternal T cells circulating through the murine maternal-fetal interface are highly likely to encounter cells of fetal origin. This pattern of MHC class I

expression at the maternal-fetal interface is incompatible with the hypothesis that fetal tissues at the interface are antigenically immature and therefore do not provoke a maternal T-cell response.

In conclusion, although the apparent lack of classic MHC expression suggests that the preimplantation embryo is protected from direct immunologic attack by MHC-restricted T cells, it could still be vulnerable to a delayed-type hypersensitivity reaction and to adverse effects of antibodies and cytokines produced by non-MHC-restricted effector cells.

LOCAL IMMUNE SUPPRESSION

The final and most recent hypothesis is that specific immune suppressor/regulatory mechanisms are observed during pregnancy. According to this hypothesis, immune cells that specifically recognize paternal alloantigens are deleted from the maternal immune system. This elimination process is thought to be achieved through either deletion of these alloreactive cells or suppression of their activity. One mechanism by which paternal antigen-recognizing T cells may be deleted is through their selective cell death (apoptosis) induced by the Fas/FasL system (Fig. 6-2).³³⁻³⁵ Our studies have indicated that the proapoptotic protein, FasL (a member of the tumor necrosis factor [TNF] ligand superfamily), is not expressed at the cell surface membrane of trophoblast cells; instead, it is secreted via microvesicles which can then act on activated Fas receptor-expressing immune cells at locations away from the implantation site.³⁶ However, the role of this functional secreted FasL is not fully understood and remains under investigation.

Another way in which T cells recognizing paternal antigens may be deleted is through the production of indoleamine 2,3-dioxygenase (IDO) at the maternal-fetal interface.³⁷ IDO is an enzyme that degrades tryptophan, an amino acid that is essential for T cell proliferation and survival.³⁸⁻⁴⁰ A subset of lymphocytes known as T regulatory cells (Tregs) are able to suppress the actions of alloreactive T cells and thereby promote

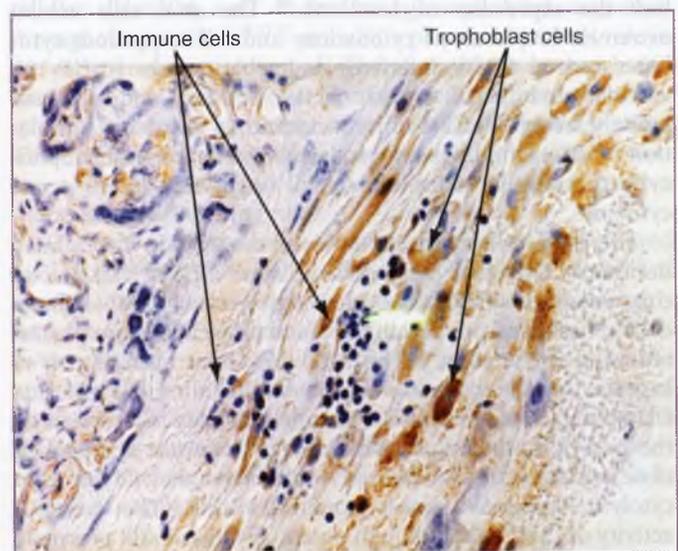

Figure 6-2 Expression of Fas ligand (FasL) in first-trimester trophoblast cells. The proapoptotic protein, FasL, is highly expressed in extravillous trophoblasts, which are in close vicinity to maternal immune cells present at the decidua.

fetal/paternal immunotolerance.^{41,42} These are all potential mechanisms for the immunologic escape of the fetus.

The Role of Immune Cells during Pregnancy

Immune cells represent a major cellular component of the pregnant uterus, and their specific role has been an area of active research. During the first trimester, 70% of decidual leukocytes are NK cells, 20% to 25% are macrophages, and approximately 1.7% are dendritic cells (DCs).⁴³⁻⁴⁵ These cells infiltrate the decidua and accumulate around the invading trophoblast cells. The following sections discuss the main characteristics of four cell types found in the decidua: NK cells, macrophages, DCs, and Tregs.

UTERINE NATURAL KILLER CELLS

NK cells are lymphocytes of the innate immune system that are able to kill various hazardous pathogens and tumors.⁴⁶ It is now widely accepted that NK cells also possess nondestructive functions, as is the case for uterine NK (uNK) cells (for details, see Manaster and Mandelboim⁴⁷). In addition to their classic killing role, uNK cells are major regulatory cells. The uNK cells are identified by their unique phenotype, CD56^{bright}CD16⁻, and can be found in both the pregnant and the nonpregnant uterus. NK cells in the nonpregnant uterus are defined as endometrial NK cells (eNK), and those in the pregnant uterus are referred as decidual NK cells (dNK).

Immunohistochemistry studies have shown that the absolute numbers of eNK cells increases dramatically from the proliferative to the late secretory phase of the menstrual cycle.^{27,47} This occurs as a result of local proliferation of eNK cells rather than migration from circulating NK cells.⁴⁸ The eNK cells have an expression profile of CD56, CD57, CD94, and CD16 similar to that of peripheral blood CD56^{bright} NK cells; however, they have a different profile of killer inhibitor receptor (KIR) receptors CD158b and NKB1, resembling CD56^{dim} NK cells. They also lack the expression of L-selectin.⁴⁹ The eNK cells exhibit extremely low levels of cytotoxicity and fail to produce cytokines such as IFN- γ , interferon-inducible protein 10 (IP-10), vascular endothelial growth factor (VEGF), and placental growth factor (PLGF) without additional cytokine stimulation.^{50,51} These findings suggest that eNK cells are inert lymphocytes that require activation to kill target cells or to secrete cytokines.

The dNK cells represent 40% of the cells in the human decidua.^{52,53} Most of these dNK cells are CD56^{bright}CD16⁺; in contrast, mouse dNK cells express high levels of CD16. Human dNK cells differ from peripheral blood NK cells both in phenotype and in function.⁴⁶ The dNK cells have been shown to express several activating receptors, including NKP44 and CD69, suggesting that dNK cells might already be activated in the local environment of the decidua.^{50,54} However, despite their close contact with fetal-derived trophoblasts, they do not exert cytolytic functions against trophoblast cells. The cytotoxic activity of dNK cells, although potentially low, is still preserved and may be relevant in cases of infection (see later discussion).^{47,51} An important function of dNK cells has been associated with remodeling of the decidual spiral arteries, a process that is vital for the development of a normal pregnancy.⁵⁴⁻⁵⁶

MACROPHAGES

Macrophages are the predominant subset of antigen-presenting cells (APCs) in the human decidua, and they comprise 20% to 25% of the total decidua leukocytes.⁵⁷ The main markers for decidua macrophages are CD14⁺, HLA-DR⁺, and CD68⁺. Macrophages exhibit high levels of phenotypic plasticity and participate in diverse physiologic processes during pregnancy, adapting by marker expression and cytokine production to the local microenvironment. Cumulative evidence suggests the involvement of uterine macrophages in a wide range of gestational processes including implantation, placental development, and cervical ripening.⁵⁸⁻⁶¹

In general, decidua macrophages present a phenotype related to tissue renewal and repair and are also known as M2 macrophages.⁶² Macrophages have been characterized in at least two major subtypes: M1 and M2.^{63,64} M1 macrophages are under the influence of proinflammatory cytokines; they secrete TNF- α and IL-12 and participate in the process of inflammation in response to microorganisms. The M2 polarization is characterized by enhanced expression of scavenger receptors and mannose receptors, secretion of IL-1 receptor antagonist, and reduction of IL-12 expression.⁶⁴ These properties of M2 macrophages are involved in tissue repair and inhibition of inflammation. The M2 phenotype of decidua macrophages supports their role in tissue renewal during trophoblast invasion and placental growth. Appropriate removal of dying trophoblasts prevents the release of paternal antigens that could trigger a maternal immune response against the fetus.⁵⁹ On the other hand, several aspects of parturition, including cervical ripening, onset of labor, and postpartum repair of the uterine cervix, are associated with proinflammatory macrophage activity and an M1 phenotype.⁶⁵⁻⁶⁷

The plasticity of decidual macrophages in response to the local microenvironment is critical for normal pregnancy. Impairment of uterine macrophage function is linked to the pathophysiology of abnormal gestations, including preterm labor and preeclampsia.⁵⁸⁻⁶⁰ Although understanding of the unique characteristics of decidua macrophages has improved, further research is necessary to understand the signals that control normal and abnormal differentiation of macrophages.

T REGULATORY CELLS

The CD4⁺CD25⁺ Tregs were first described as a specific subpopulation of T cells that are responsible for maintaining immunologic self-tolerance by actively suppressing self-reactive lymphocytes.⁶⁸ In the same way as these cells play a central role in preventing autoimmunity, it is thought that Tregs are critical in preventing an immunologic response to fetal antigens released during pregnancy.⁶⁹

During human pregnancy, a systemic expansion of Tregs can already be observed at early stages.⁶⁹⁻⁷¹ There is much evidence to indicate that Tregs are specific to paternal-derived cells, suggesting that their function is to protect fetal cells expressing paternal antigens from immune rejection by the maternal immune system. Infertility has been proposed to be associated with reduced expression of the Treg transcription factor, forkhead box P3 (FOXP3), in endometria.⁷² Similarly, spontaneous abortion has been shown to correlate with lower systemic Treg levels than in normal pregnancies.^{73,74}

Although Tregs have been well studied in various pregnancy models, the factors behind the expansion of Tregs during

pregnancy are not well understood. Some studies have proposed that hormonal changes are involved in Treg expansion independent of paternal antigens, whereas others have suggested that Treg expansion takes place only in the presence of paternal antigens and as early as the time of insemination.^{75,76} In vitro studies have shown that factors released by trophoblast cells induce differentiation of CD4⁺ T cells into Tregs, suggesting an active role for trophoblast cells in the process of immune regulation to paternal antigens in fetal cells.⁷⁷ Although there are numerous questions regarding the regulatory mechanism and potential origin of Tregs, it is clear that they play a central role in preventing a response by the maternal immune system to fetal cells.

DENDRITIC CELLS

DCs are a heterogeneous population of cells that initiate and coordinate the innate adaptive immune response. These cells accumulate in the pregnant uterus before implantation and stay in the decidua throughout pregnancy.⁷⁸⁻⁸⁰ Several lines of evidence point to a pivotal role of DC cells in shaping the cytokine profile at the maternal-fetal interface.⁸⁰⁻⁸³ Depletion of uterine DCs (uDCs) resulted in a severe impairment of implantation and led to embryo resorption.⁸⁴⁻⁸⁶ This effect was not related to tolerance but rather to failed decidualization. In other studies, therapy with DCs significantly decreased the spontaneous resorption rate in a mouse model.^{84,87} These findings suggest that, in addition to their involvement in the immune response, uDCs also play some trophic role in regulating pregnancy.

DECIDUAL CELLS

The pregnant uterine stroma, the decidua, has long been considered only as a supportive environment for the immune cells and trophoblast present at the implantation site. However, recent work has revealed that decidual cells may play a more active role in the regulation of the differentiation, migration, and function of uterine immune cells.^{87a} Animal studies have shown differential expression of chemokines between the pregnant and nonpregnant endometrium. The expression of immune cell chemoattractants was highly expressed in the nonpregnant endometrial stromal cells, as well as in the myometrium and implantation sites of pregnant uteri, but not in the decidua.^{87a} This suggested a change in gene expression during the cellular transformation of endometrial stromal cells into decidual stromal cells. Ex vivo investigation of the promoter region of *CXCL9* and *CXCL10* revealed elevated levels of the repressive histone marker H3K27me3 in decidual versus myometrial stromal cells, which was confirmed in vivo. Furthermore, in response to inflammation, myometrial stromal cells showed upregulation of the marker of active gene transcription H4Ac in the promotion of chemoattractant genes *CXCL9/10*, whereas this was not the case in decidual stromal cells.^{87b} These findings provide a new interpretation of the regulation of the maternal immune system by the pregnant uterus. Contrary to previous studies focused on mechanisms by the placenta (trophoblast cells) inducing either cell death of T cells (e.g., Fas-FasL hypothesis³⁶) or deletion of T cells, these new series of evidences suggest an active role of the decidua controlling the migration of maternal T cells through the implantation site. The fact that the inhibition of certain chemokines in the decidua

is associated with methylation of these genes suggests that epigenetic regulators control the capacity of the decidua to attract T cells. The placenta, and more specifically the trophoblast, could play a critical role in the regulation of decidua chemokine production. The trophoblast secretes cytokines that can regulate the function and differentiation of immune cells. It is plausible that these same factors could induce epigenetic changes in stromal decidual cells, consequently inhibiting their capacity to produce chemokines responsible for T cell recruitment. However, in pathologic conditions such as infection, the inhibitory status may be broken and the same stromal decidual cells might become actively involved in the recruitment and activation of T cells to the implantation site.^{87c} These changes may have detrimental consequences for pregnancy.^{87d}

THE MATERNAL IMMUNE SYSTEM AND ITS ROLE IN PREGNANCY: A DIFFERENT PERSPECTIVE

During normal pregnancy, several of the cellular components of the innate and adaptive immune systems are found at the site of implantation, and this has been taken as conclusive proof that the maternal immune system responds to the allograft fetus. Furthermore, from the first trimester onward, circulating monocytes, granulocytes, and NK cells increase in number and acquire an activated phenotype. What this evidence suggests is that the maternal innate immune system is not indifferent to the fetus. However, where once these observations were thought to support the hypothesis of an immune response *against* the allograft fetus, animal studies using cell-deletion methods have proved quite the opposite. Depletion of NK cells during pregnancy, instead of being protective, has been shown to be detrimental to pregnancy outcome.⁸⁸ Much effort was focused on the susceptibility of the trophoblast to NK cell-mediated cytotoxicity^{20,89} until it was found that uNK cells are not cytotoxic.⁹⁰ Moreover, as discussed earlier, it is now known that uNK cells are important for mediating angiogenesis and trophoblast invasion, two critical events in early pregnancy.⁵⁵ Similar findings have been observed with other immune cells: Macrophages within the decidua are important for clearing apoptotic and cellular debris as well as facilitating trophoblast migration throughout gestation,^{59,91,92} and uDCs play an important role in the early implantation stage.⁹³ Therefore, it can be concluded that the innate immune cells have a critical role to play in fetomaternal immune adjustment and in successful placentation. These findings challenge the whole paradigm of pregnancy that has until now assumed the maternal immune system to be a threat to the developing fetus.

The field of reproductive immunology has always followed mainstream immunology, translating findings from the field of transplantation to explain the immunology of the maternal-fetal relationship. However, these ideas have failed to conclusively prove the principle of semi-allograft acceptance by the mother and have also produced confusion regarding the role of the immune system during pregnancy. It is time to reevaluate the basic underpinnings of the immunology of pregnancy: Does the fetal-placental unit truly act as an allograft that is in continual conflict with the maternal immune system?

REDEFINING MEDAWAR'S HYPOTHESIS

Medawar's original observation was based on the assumption that the placenta is analogous to a piece of skin with paternal

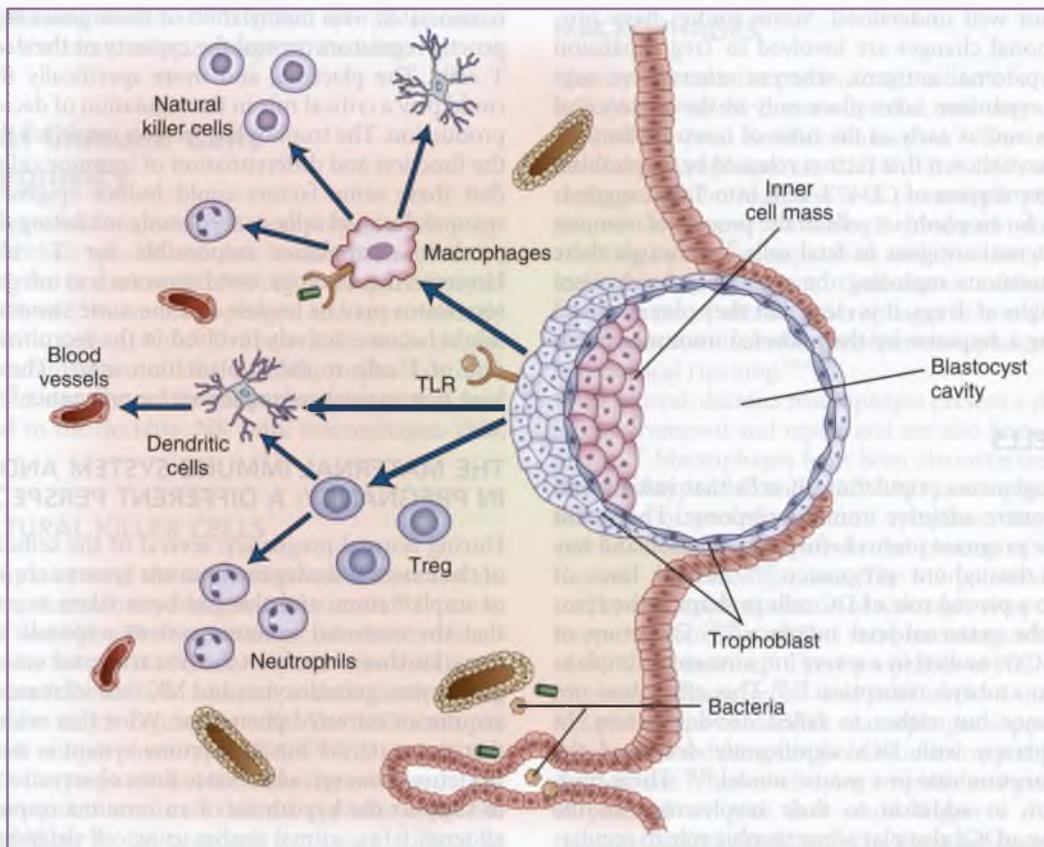

Figure 6-3 Trophoblast-immune interaction. The model summarizes a new perspective on trophoblast-immune interaction wherein the placenta and the maternal immune system positively interact for the success of pregnancy. The trophoblast recognizes, through Toll-like receptors (TLRs), microorganisms and the cellular components at the implantation site and responds to them through the production of cytokines and chemokines. These factors coordinate the migration, differentiation, and function of maternal immune cells. (Modified from Mor G: *Pregnancy reconceived*, Nat History 116:36-41, 2007.)

antigens, which under normal immunologic conditions should be rejected. However, the placenta is more than just a transplanted organ. Knowledge of placental biology has significantly increased over the last 60 years. It is now understood that the placenta is a complex organ that evolved from the original “egg cover.” Unlike graft implantation, pregnancy and implantation of the embryo have been taking place for more than a million years. From an evolutionary point of view, it is difficult to conceive that the placenta and the maternal immune system would still maintain an antagonistic status. Therefore, although there should be an active mechanism that prevents recognition of paternal antigens by the maternal immune system, the trophoblast and the maternal immune system have evolved and established a cooperative status, helping each other against their common enemies, infectious microorganisms.

Our current research is focused on understanding how the trophoblast and the maternal immune system can work together to protect the fetus against infection. The results suggest that the trophoblast functions much like a symphony conductor, and the musicians are the cells of the maternal immune system. The success of the pregnancy depends on how well the trophoblast communicates with each immune cell type and then how all of them work together. At the molecular level, we are investigating how the trophoblast recognizes what is present and, based on that information, what types of signals it sends to

coordinate the activities of each cellular component at the implantation site.

Studies demonstrate that the trophoblast, like an innate immune cell, expresses PRRs that function as sensors of the surrounding environment.⁹⁴⁻⁹⁸ Through these sensors, the trophoblast can recognize the presence of bacteria, viruses, dying cells, and damaged tissue. On recognition, the trophoblast often secretes a specific set of cytokines that act on the immune cells within the decidua (i.e., macrophages, Tregs, NK cells), “educating” them to work together in support of the growing fetus (Fig. 6-3).⁹⁹ Indeed, each immune cell type acquires specific properties related to implantation and placentation, as already discussed. However, a viral or bacterial infection may disturb the harmony of these interactions.

Infection and Pregnancy

Bacterial and viral infections pose a significant threat to a pregnancy and to the well-being of the fetus. These organisms gain access to gestational tissues such as the decidua, the placenta, and the fetal membranes by one of three major routes: ascent into the uterus from the lower tract, descent into the uterus from the peritoneal cavity, or travel through via the maternal circulation.¹⁰⁰ There are strong clinical links between bacterial infection and preterm labor.¹⁰⁰⁻¹⁰³ Indeed, infections are

reportedly responsible for up to 40% of preterm labor cases. Furthermore, in 80% of preterm deliveries occurring at less than 30 weeks' gestation, there is evidence of infection.^{102,103} Other complications of pregnancy, such as preeclampsia, may also have an underlying infectious element.¹⁰⁴⁻¹⁰⁷ Although less is known about how viruses affect pregnancy outcome, their role in complications of pregnancy is being delineated in clinical and experimental studies.¹⁰⁸⁻¹¹⁶ In addition to the potential for fetal infection and developmental complications, viruses such as cytomegalovirus, parvovirus, herpesvirus, influenza, and rubella have been associated with preterm delivery, miscarriage, stillbirth, and preeclampsia.^{107-110,117-121} Therefore, bacterial and viral infections represent an important mechanism of pregnancy complications.

Although many of the pathways involved are undefined, the growing literature suggests that induction of a pregnancy complication (e.g., preterm labor) by a microorganism involves innate immune responses toward the pathogen that lead to excessive inflammation or apoptosis (or both) at the maternal-fetal interface.^{122,123} Moreover, such immune responses triggered by infection that can promote fetal rejection may be initiated by the same cells that under normal conditions promote fetal acceptance—the trophoblast cells.^{14,124,125} Experimental *in vivo* models have demonstrated that delivery of infectious components to a variety of animals triggers preterm labor and delivery.¹²⁶⁻¹²⁸ Clinical studies have correlated placental infection/inflammation with prematurity,^{129,130} and this finding has been supported by experimental studies.^{113,131-134} Studies focusing on the mechanisms involved have implicated the innate immune system PRRs as playing an important role in infection-related pregnancy complications.

PATTERN RECOGNITION RECEPTORS

The innate immune system has the ability to distinguish between self and infectious non-self through a system of pattern recognition.¹³⁵ As described earlier, PRRs recognize and react to conserved sequences, known as pathogen-associated molecular patterns (PAMPs), that are expressed by microorganisms. Some PRRs also sense and respond to host-derived danger signals, or damage-associated molecular patterns (DAMPs).^{136,137} Activation of PRRs by PAMPs or DAMPs typically results in an inflammatory response.¹³⁷ There are two main families of PRRs: the Toll-like receptors and the nucleotide-binding oligomerization domain (NOD)-like receptors.

TOLL-LIKE RECEPTORS

Toll-like receptors (TLRs) are transmembrane proteins that allow for the extracellular and endosomal recognition of microbes or infectious components. Each TLR has a specific ligand-binding domain and therefore senses distinct infectious and host-derived products. Whereas individually the TLRs respond to limited ligands, collectively the family of TLRs can respond to a wide range of PAMPs associated with bacteria, viruses, fungi, and parasites, as well as DAMPs. Eleven mammalian TLRs have been identified and designated TLR1 through TLR12, but only the first 10 have been found to be expressed in humans.¹³⁸ TLR activation by microbial and viral products typically results in an inflammatory response characterized by production of cytokines/chemokines and antimicrobial/antiviral factors.

TLR4 is the specific receptor for gram-negative bacterial lipopolysaccharide (LPS). TLR2 recognizes bacterial lipoproteins, gram-positive bacterial peptidoglycan (PDG) and lipoteichoic acid, and fungal zymosan. Both TLR2 and TLR4 can also sense DAMPs, such as heat shock proteins 60 and 70, surfactant proteins A and D, and high-mobility group protein B1.¹³⁹ TLR2 is unusual because it forms heterodimers with TLR1, TLR6, and TLR10. TLR3 senses viral double-stranded RNA (dsRNA), TLR5 senses bacterial flagellin, TLR8 recognizes viral single-stranded RNA (ssRNA), and TLR9 binds bacterial CpG DNA. Whereas the natural ligand for human TLR7 is unknown, TLR7 in the mouse recognizes the human TLR8 ligand, viral ssRNA.¹³⁸

The TLRs signal through a common pathway; on recognition of a PAMP or DAMP, TLRs recruit the adaptor signaling protein, myeloid differentiation factor 88 (MyD88), initiating a cascade that triggers an inflammatory response (Fig. 6-4A).^{136,140} TLR3 and TLR4 can signal independently of MyD88, through TRIF (Toll/IL-1 receptor domain-containing adaptor protein inducing IFN- β), now known as TICAM1 (TLR adaptor molecule 1), and this alternative pathway generates an antiviral response associated with the production of type I interferons and interferon-inducible genes (see Fig. 6-4A).¹⁴¹ Although the functional capacity of TLRs may, at first glance, appear to be restricted by a high level of homology and shared signaling molecules (discussed later), TLRs have distinct signaling capacities and can trigger varied responses.

NOD-LIKE RECEPTORS

The cytoplasmic-restricted NOD-like receptors (NLRs) contain a NOD domain, a leucine-rich repeat (LRR), and a functionally differentiating domain. NLRs function as intracellular receptors for microbes or microbial components.¹⁴² The NLR family contains two major subgroups involved in microbial recognition: the NOD proteins (NLRs), which contain a caspase recruitment domain (CARD), and the NALP proteins (NLRPs), which contain a pyrin domain (PYD).^{142,143} The NOD proteins, NOD1 and NOD2, recognize peptides derived from the degradation of bacterial PDG that occurs during normal bacterial growth or destruction. PDG from all bacteria contains the NOD2 ligand, muramyl dipeptide (MDP). NOD1 ligand recognition is more selective: The ligand γ -D-glutamyl-meso-diaminopimelic acid (iE-DAP) is found only in gram-negative bacteria.^{144,145} How such bacterial components gain access into the cytoplasmic compartment to activate NLRs such as the NOD proteins is not well defined. Bacterial products may be delivered either from extracellular sites (by endocytosis, pathogen secretion systems, or bacteria pore-forming toxins¹⁴⁶) or from an invasive intracellular bacterium.¹⁴⁷⁻¹⁵¹ Ligand recognition by NOD1 or NOD2 triggers an inflammatory cytokine/chemokine response via the adaptor protein known as RIPK2 (receptor-interacting serine-threonine kinase 2) or RIP2 (receptor-interacting protein 2) (see Fig. 6-4B).^{145,149,152}

The NALP proteins, NALP1 and NALP3, also respond to microbial components, which leads to formation of the inflammasome, a protein platform that specifically mediates the cleavage or processing of intracellular pro-IL-1 β (and pro-IL-18) into its active, secreted form.^{153,154} The NALP1/NALP3 inflammasome contains the adaptor protein, ASC (apoptosis-associated speck-like protein containing a CARD, encoded by the *PYCARD* gene) and caspase-1 (see Fig. 6-4C). NALP3 can be activated by bacterial RNA and toxins, viral RNA, and

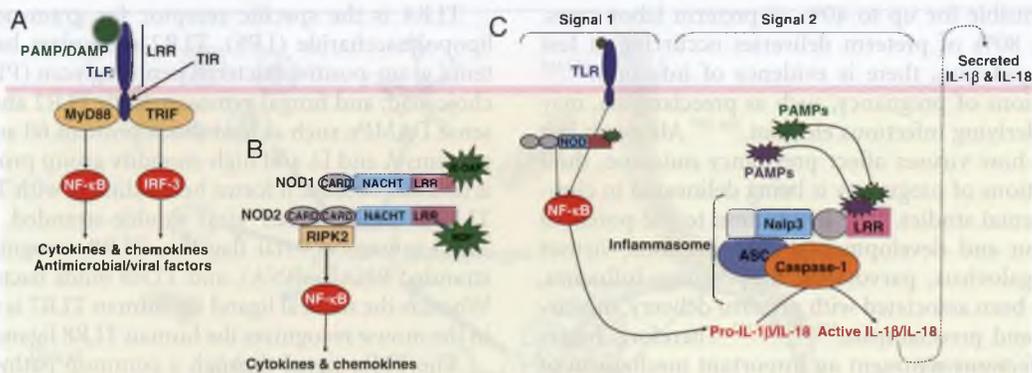

Figure 6-4 Structure of TLRs and NLRs and their signaling pathways. **A**, Toll-like receptors (TLRs) recognize pathogenic PAMPs or host-derived DAMPs via their extracellular domain, which contains leucine-rich repeat (LRR) motifs. On ligand sensing, TLRs recruit to the intracellular Toll/interleukin (IL)-1 receptor (TIR) domain either the adaptor protein myeloid differentiation factor 88 (MyD88) or, for TLR3 and TLR4, the adaptor protein TRIF (TICAM1). Both MyD88 and TRIF can activate the nuclear factor- κ B (NF- κ B) pathway, leading to a cytokine, chemokine, and antimicrobial response. TRIF can also activate interferon regulatory factor 3 (IRF-3), which can trigger an antiviral response. **B**, The NOD proteins, NOD1 and NOD2, contain an LRR domain, which is responsible for ligand recognition, and a central NACHT domain, which facilitates self-oligomerization. NOD1 contains a single caspase recruitment domain (CARD), whereas NOD2 contains two CARD domains. After recognition of their specific ligands—bacterial γ -D-glutamyl-meso-diaminopimelic acid (iE-DAP) and muramyl dipeptide (MDP), respectively—NOD1 and NOD2 recruit to their CARD domains the adaptor protein, RIPK2 (RIP2), which in turn activates the NF- κ B pathway, resulting in the induction of an inflammatory cytokine/chemokine response. **C**, Activation of the NALP3 inflammasome requires two signals. In signal 1, expression of pro-IL-1 β and pro-IL-18 is upregulated by TLR- or NLR-mediated NF- κ B activation. Signal 2 is direct activation of NALP3 by a PAMP or DAMP. On NALP3 activation, ASC and caspase-1 are recruited to the inflammasome. Caspase-1 becomes activated, which results in cleavage of pro-IL-1 β /pro-IL-18 into its active, secreted form. For details, see text.

malarial hemozoin crystals.^{155,156} In addition, NALP3 can be activated by DAMPs such as extracellular adenosine triphosphate (ATP), hyaluronan, and uric acid.¹⁵⁷ To function efficiently, the NALP3 inflammasome is thought to require two signals. The first signal, on being delivered by a microbial product, activates a TLR, leading to upregulation of pro-IL-1 β expression.¹⁵⁶ This is followed by a second signal in the form of a PAMP or DAMP that directly activates NALP3 or NALP3 to trigger inflammasome formation (see Fig. 6-4C).¹⁵⁷⁻¹⁵⁹

THE ROLE OF TLRs AND NLRs IN ADVERSE PREGNANCY OUTCOME

Whereas PRRs are widely expressed throughout the immune system, they are also expressed by nonimmune cells. It is now known that the epithelial and stromal cells of gestational tissues are able to function as components of the innate immune system by recognizing and responding to bacterial and viral components through PRRs, perhaps to prevent pathogens from gaining access to gestational compartments, thus protecting the pregnancy. However, these same innate immune processes may also contribute to poor pregnancy outcome. In vivo animal models have demonstrated that infection or delivery of infectious components during pregnancy triggers adverse pregnancy outcomes, including preterm labor.^{114,126,127,160,161} Moreover, studies using specific PRR agonists and PRR-deficient mice have shown that TLRs and NLRs are involved in the pathogenesis of infection-associated prematurity and pregnancy complications.^{112,113,115,116,134,162-166} The first studies showed that systemic, intrauterine, or intra-amniotic delivery of high-dose LPS triggers inflammation and preterm delivery in animals^{126,164} and that mice deficient for TLR4 are protected against bacterial and LPS-induced preterm birth.¹²⁶ Furthermore, blockade of TLR4 function in nonhuman primates prevents

LPS-induced preterm uterine contractility.^{127,164} Since these discoveries, TLR2, TLR3, TLR9 and NOD1 have also been shown to play a role in infection-associated prematurity in in vivo models.^{112,113,116,134,165,166} In general, an infectious stimulus associated with preterm labor triggers inflammation at the maternal-fetal interface, but bacterial PDG triggers preterm labor¹¹² by inducing placental apoptosis,¹⁶⁵ as do group B streptococci.¹⁶⁷ This highlights the point that different infectious stimuli can have distinct effects at the maternal-fetal interface.

Most pathogen recognition research in the context of pregnancy has focused on the placenta, and a wealth of expression and mechanistic studies have changed the way the function of this organ is viewed. What has become apparent is that the placenta plays an active role in sensing and responding to infections and infectious products and that the expression and functional pattern of TLRs and NLRs in the placental trophoblast changes across normal gestation and in pathology. As discussed earlier, the type of pathogen, and therefore the specific PRR activated, plays a critical role in determining the type of response generated by the placenta.

TLR EXPRESSION IN THE PLACENTA

Normal term placental tissue expresses all 10 TLRs at the mRNA level.^{168,169} At the protein level, placental expression of TLR2 and TLR4 has been very well characterized in normal villous tissue, and the dominant cell type expressing these TLRs is the trophoblast. However, there is differential expression of TLRs by the trophoblast in relation to gestational age. In first-trimester placental tissues, TLR2 and TLR4 proteins are highly expressed by the villous cytotrophoblast and extravillous trophoblast cells, whereas the outer syncytiotrophoblast cells, which are in direct contact with maternal blood, do not express these TLRs. This suggests that the placenta serves as a highly specialized barrier,

protecting the developing fetus against infection.^{124,170,171} A microbe will be a threat to the placenta only if the TLR-negative syncytiotrophoblast cell layer is breached and the pathogen enters either the decidua or the placental villous compartments. Once an infection has gained access to the TLR-positive trophoblast, a response may be mounted. This restricted expression of the TLRs continues into the second trimester.¹⁷² However, by the third trimester, TLR2 and TLR4 expression can be found in the outer syncytiotrophoblast layer as well as in the intermediate and extravillous trophoblast cells,¹⁷³⁻¹⁷⁵ suggesting that the placental villi can readily respond to an infection at its surface. This altered pattern of TLR expression may be a reflection of the changes in placental function as gestation proceeds and a sign of how infection affects a pregnancy at each stage. Indeed, as discussed later, TLR function in the trophoblast also differs with gestational age.

In addition to changes in expression across gestation, studies have found altered TLR expression in pathologic placentas. In preeclampsia, placental expression of TLR2, TLR3, TLR4, and TLR9 is increased.^{176,177} Similarly, in placentas associated with infection and prematurity, there is increased expression of TLR4.^{174,178} Whether this elevation in TLR expression contributes to the inflammatory process or is a consequence of it is still unclear; studies are beginning to suggest that the former hypothesis may be true. Normal parturition is an inflammatory process, and placentas from normal deliveries with labor express elevated TLR5 and TLR2 when compared to placentas delivered

without labor.¹⁷⁹ Similarly, in a mouse model, viral infection during pregnancy was found to increase placental TLR2 and TLR4 expression, which in turn sensitized the animal to LPS-induced preterm labor.¹⁸⁰ Therefore, changes in TLR expression may play a role in the regulation of both normal and preterm labor.¹⁷⁹

TLR FUNCTION IN THE TROPHOBLAST

Studies in human first-trimester trophoblast have shown that TLR2 and TLR4 generate distinct responses. Activation of TLR4 by a high dose of gram-negative bacterial LPS triggers a mild inflammatory chemokine response,^{94,171} whereas activation of TLR2 by gram-positive bacterial PDG inhibits constitutive chemokine production and induces trophoblast apoptosis *in vitro* and *in vivo* (Fig. 6-5A).^{165,171} This unusual TLR2 response depends on the presence of TLR1 and TLR10, and the lack of TLR6.¹⁶⁵ Should TLR6 be expressed, PDG-induced first-trimester trophoblast apoptosis is prevented, and chemokine production is restored (see Fig. 6-5A). Therefore, a gram-positive bacterium may directly promote early trophoblast apoptosis through TLR2.^{165,171} Although TLR2 and TLR4 function differently in response to bacterial components in first-trimester trophoblast, activation of TLR2 by PDG, or of TLR4 by LPS, or both, in third-trimester cells triggers an inflammatory response.^{175,181,182}

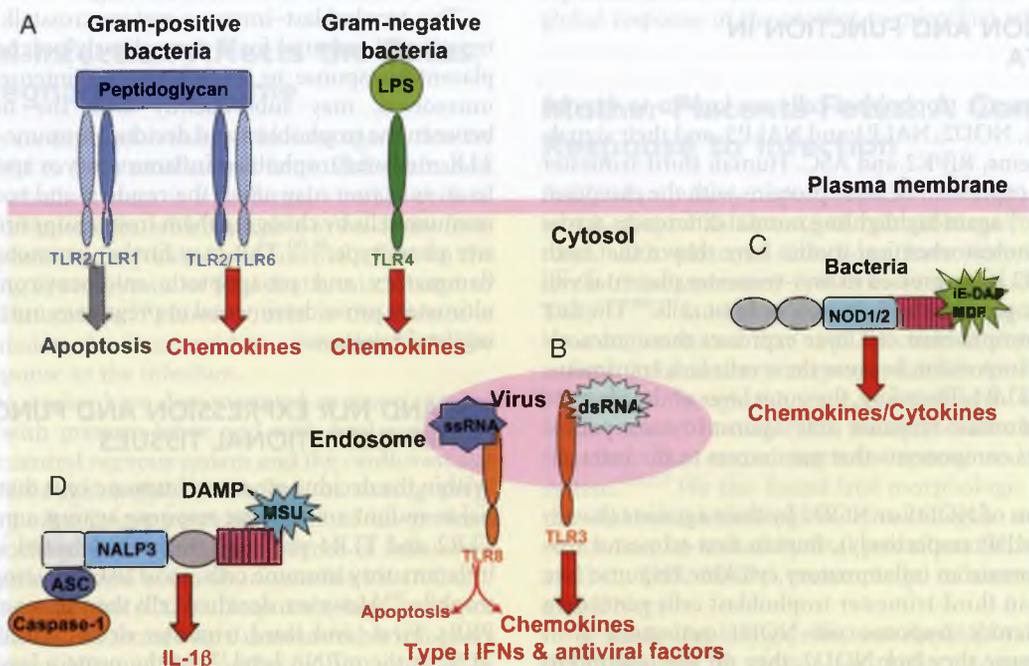

Figure 6-5 Function of Toll-like receptors (TLRs) and NOD-like receptors (NLRs) in the trophoblast. **A**, TLR2 and TLR4 recognize bacterial components at the cell's surface. TLR4 recognition of gram-negative bacterial lipopolysaccharide (LPS) triggers a chemokine response. TLR2 recognition of gram-positive bacterial peptidoglycan, in cooperation with TLR1, triggers apoptosis, whereas TLR2/TLR6 dimers induce a chemokine response. **B**, TLR3 activation by viral double-stranded RNA (dsRNA) within endosomal compartments induces a strong chemokine response as well as the production of type I interferon and antiviral factors. Endosomal TLR8 activation by viral single-stranded RNA (ssRNA) also induces a strong chemokine and type I interferon response, as well as cell apoptosis. **C**, Recognition of the peptidoglycan degradation peptides, glutamyl-meso-diaminopimelic acid (iE-DAP) and muramyl dipeptide (MDP), by the NOD proteins, NOD1 and NOD2, triggers the production of chemokines and cytokines. **D**, Activation of the NALP3 (NLRP3) inflammasome by monosodium urate (MSU), a damage-associated molecular pattern (DAMP), induces interleukin-1 β (IL-1 β) processing and secretion. ASC, apoptosis-associated speck-like protein containing a caspase recruitment domain (CARD); NALP3, NLR family, pyrin domain containing 3 (NLRP3).

In addition to gestational differences in TLR function, the trophoblast responds to viral and bacterial products distinctly. When trophoblast TLR3 is activated by viral dsRNA (simulated by polyinosinic:polycytidylic acid [poly(I:C)]), a highly potent and rapid inflammatory response is triggered,⁹⁴ as well as a specific antiviral and type I IFN- γ response (see Fig. 6-5B).^{94,183} TLR3 activation also induces trophoblast production of IDO, which is known to have antiviral properties.¹⁸⁴ This IDO response by the placenta may provide protection against the infection while maintaining fetal-maternal immunotolerance.¹⁸⁴ In contrast, term trophoblast exposed to cytomegalovirus, which activates TLR2, induces production of TNF, which in turn triggers trophoblast apoptosis in an autocrine manner.^{44,185} Interestingly, TLR8 activation by viral ssRNA also indirectly mediates first-trimester trophoblast apoptosis by upregulating the cell's production of IFN- γ , much more than TLR3 activation does, and it promotes apoptosis in an autocrine/paracrine manner (see Fig. 6-5B).⁴⁴

Together, these studies highlight the ability of the trophoblast to sense and differentially respond to pathogens. This adaptive characteristic of trophoblast TLRs suggests that the placenta has the ability to discriminate between foreign or endogenous danger signals that jeopardize the pregnancy and stimuli that may instead be necessary for success of the pregnancy.^{186,187} Viral infections, and possibly gram-positive bacterial infections, may be more likely to pose a threat to the fetus and to pregnancy outcome than extracellular gram-negative bacterial infections.^{171,188} Indeed, most of the lower tract commensals are of this latter group.¹⁰⁰

NLR EXPRESSION AND FUNCTION IN THE PLACENTA

Human first-trimester trophoblast cells are known to express the NLRs, NOD1, NOD2, NALP1 and NALP3, and their signaling effector proteins, RIPK2 and ASC. Human third-trimester trophoblast cells express all of these proteins with the exception of NOD2,^{98,134,189,190} again highlighting normal differences across gestation. Immunohistochemical studies have shown that both NOD1 and NOD2 are expressed in first-trimester placental villi by the syncytiotrophoblast and cytotrophoblast cells.⁹⁸ The fact that the syncytiotrophoblast cell layer expresses these intracellular receptors is important, because these cells lack transmembrane TLR2 and TLR4. Therefore, the outer layer of the placenta may mount an immune response only against invasive pathogens or infectious components that gain access to the intracellular space.

After activation of NOD1 or NOD2 by their agonists (bacterial iE-DAP or MDP, respectively), human first-trimester trophoblast cells generate an inflammatory cytokine response (see Fig. 6-5C). Human third-trimester trophoblast cells generate a similar inflammatory response on NOD1 activation with iE-DAP, but, because they lack NOD2, they do not respond to MDP.^{98,134,189,190} In an animal model of adverse pregnancy outcome, delivery of the NOD1 agonist, iE-DAP, to pregnant mice induced preterm delivery, reduced fetal weight, altered the placental/decidual cytokine profile, and induced a strong fetal inflammatory response.¹⁹¹ Therefore, PRRs other than the TLRs may be involved in infection-associated preterm labor. This is important because, whereas some of the downstream pathways and outcomes triggered by infections at the maternal-fetal interface are common, the upstream effector mechanisms can

vary. Moreover, some PRRs can function in unique ways by using uncommon signaling pathways and triggering highly specific responses. Indeed, activation of NALP3 by its specific agonist and DAMP, uric acid, induces human first-trimester trophoblast to secrete IL-1 β via activation of the inflammasome¹⁹⁰ (see Fig. 6-5D).

TROPHOBLAST-IMMUNE SYSTEM INTERACTIONS GOVERNED BY PRRs

The expression and function of TLRs and NLRs allow the trophoblast to recognize microorganisms as well as host-derived danger signals so that it may coordinate a local immune response that, in principle, does not jeopardize the success of the pregnancy. The first step of this interaction during the implantation process is the attraction of monocytes by the invading trophoblast. First-trimester trophoblast cells constitutively secrete monocyte chemoattractants such as growth-regulated oncogene- α (GRO- α), monocyte chemoattractant protein 1 (MCP-1), and IL-8, and these chemokines are able to recruit monocytes/macrophages.^{94,99,192}

A second step in this trophoblast-immune system interaction involves a process of immune cell education, by which signals originating from the trophoblast can determine the subsequent cytokine profile generated by the local decidual immune cells. First-trimester trophoblast cells induce the production of chemokines such as GRO- α , MCP-1, IL-8, and regulated on activation, normal T cell expressed and secreted (RANTES) and TNF by monocytes.⁹⁹ Similarly, first-trimester trophoblast cells can also recruit and differentiate Tregs.⁷⁷

This trophoblast-immune system crosstalk may be characteristic and essential for a normal early pregnancy. However, a placental response to an infection, if intense enough or left unresolved, may subsequently alter the normal crosstalk between the trophoblast and decidual immune cells. In this way, TLR-mediated trophoblast inflammatory or apoptotic responses to an infection may affect the resident and recruited maternal immune cells by changing them from a supportive to an aggressive phenotype.^{99,193} This may further promote a strong proinflammatory and proapoptotic microenvironment and may ultimately prove detrimental to pregnancy outcome by facilitating fetal rejection.

TLR AND NLR EXPRESSION AND FUNCTION BY OTHER GESTATIONAL TISSUES

Within the decidua are many immune cells that have the potential to mount an immune response against a pathogen. Indeed, TLR2 and TLR4 protein have been detected in term decidual inflammatory immune cells, most likely macrophages and neutrophils.¹⁹⁴ However, decidual cells themselves also express these PRRs. First- and third-trimester decidual cells express all 10 TLRs at the mRNA level.¹⁹⁵ At the protein level, first-trimester decidual cells have been shown to express TLR2 and TLR4^{195,196} while term decidual cells have been shown to express TLRs 1 to 6.¹⁹⁷ Moreover, stimulation of decidual cells with either LPS, PDG, or Poly(I:C) triggers these cells to produce chemokines and cytokines, and upregulates a number of genes related to the TLR signaling pathway.^{195,197,198} Similarly, the NLRs, Nod1 and Nod2, have also been found to be expressed by the decidualized stroma of first-trimester decidua.¹⁹⁹ More recently, endothelial cells of the endometrial microvasculature have also been

reported to express functional TLRs.²⁰⁰ These studies suggest that the decidual stroma and endothelium can also contribute to the resolution of an infection, and therefore may also play a role in the infection-triggered adverse pregnancy outcome.

The chorioamniotic fetal membranes have also been shown to respond to infectious stimuli. Normal term fetal membranes exposed *in vitro* with various bacteria or bacterial components produce elevated levels of cytokines (IL-1 β , IL-6, IL-8, TNF- α),²⁰¹⁻²⁰⁵ an inflammatory profile also found clinically in preterm fetal membranes.²⁰⁶ Moreover, TLRs are expressed by the fetal membranes.^{194,207,208} At the protein level it is known that both TLR2 and TLR4 are expressed by the amniotic epithelial cells,^{194,207} and TLR2 expression is limited to the basolateral side of these cells.¹⁹⁴ This expression pattern is analogous to previous findings in gut epithelium, supporting the hypothesis that a pathogen must breach certain barriers before a response can be mounted.²⁰⁹ Interestingly, in cases of inflammation, such as in chorioamnionitis, this polarized distribution is lost and TLR2 and TLR4 expression becomes upregulated.^{194,210} Furthermore, exposure of fetal membranes to different types of bacteria generates distinct changes in TLR expression patterns.²¹¹ In a recent study, isolated amniotic epithelial cells were found to express all 10 TLRs at the mRNA level and secrete cytokines in response to TLR5 and TLR2/6 agonists.²¹² TLR stimulation with LPS, however, induced apoptosis, an observation also found using fetal membrane explants.²¹³ Furthermore, no cytokine responses were generated after stimulation of TLRs -3, -7 and -9.²¹² Thus, the fetal membranes may generate distinct responses to different infectious stimuli.

How a Viral Infection Affects the Fetus and the Pregnancy Outcome

Pregnant women are exposed to many infectious agents that are potentially harmful to both mother and fetus. Risk evaluation has focused on whether there is a maternal viremia or fetal transmission. Viral infections, which are able to reach the fetus by crossing the placenta, may have a detrimental effect on the pregnancy, leading to embryonic or fetal death, miscarriage, or major congenital anomalies.²¹⁴ However, even in the absence of placental transmission, the fetus could be adversely affected by the maternal response to the infection.

Epidemiologic studies have demonstrated an association of viral infections with preterm labor and with fetal congenital anomalies of the central nervous system and the cardiovascular system.^{102,215,216} Although some viral infections during pregnancy are asymptomatic, approximately half of all preterm deliveries are associated with histologic evidence of inflammation of the placenta, termed acute chorioamnionitis (ACA)²¹⁷ or chronic chorioamnionitis (CCA). Despite the high incidence of ACA, only a fraction of fetuses have demonstrable infection. Most viral infections affecting the mother do not cause congenital fetal infection, suggesting that the placenta may play an important role as a potent immune-regulatory interface protecting the fetus from systemic infection.^{192,217}

Studies indicate that the placenta functions as a regulator of the trafficking between the fetus and the mother rather than as a barrier.²¹⁸ Fetal and maternal cells move in a bidirectional fashion.^{219,220} Certain viruses and bacteria can reach the fetus by transplacental passage, with adverse consequences. Although viral infections are common during pregnancy, transplacental

passage and fetal infection appear to be the exception rather than the rule. Although there is a paucity of evidence that viral infections lead to preterm labor, there are several areas of controversy and open questions. For example, what effects do initial subclinical viral infections of the decidua or the placenta have on the response to other microorganisms such as bacteria, and what is the effect of a subclinical viral infection of the placenta on the fetus?

Studies from our laboratory suggest that the type of response initiated in the placenta may determine the immunologic response of the mother and, consequently, the pregnancy outcome. A placental infection that is able to elicit the production of inflammatory cytokines such as TNF, IFN- γ , IL-12, and high levels of IL-6, will activate the maternal immune system and lead to placental damage and abortion or preterm labor.¹⁸⁸ On the other hand, a viral infection in the placenta that triggers a mild inflammatory response will not terminate the pregnancy but may be able to activate the immune system, not only from the mother but from the fetus as well. This activation may sensitize the mother to other microorganisms, and therefore increase the apparent risk of infection in pregnant women; it may also promote an inflammatory response in the fetus even though there is no viral transmission.

It is critical to take into consideration the fact that, during pregnancy, it is not only the maternal immune system responding but also the fetal/placental unit. In the past, the placenta and fetus have been considered as nonactive immunologic organs that depend only on the action of the maternal immune system. Our data prove the contrary. The placenta and the fetus together represent an additional immunologic organ, one that affects the global response of the mother to microbial infections.

Mother-Placenta-Fetus: A Complex Response to Infection

Fetal inflammatory response syndrome (FIRS) is a condition in which, despite an absence of cultivable microorganisms, neonates with placental infections have very high circulating levels of inflammatory cytokines such as IL-1, IL-6, IL-8, and TNF.^{122,221-223} Studies in our laboratory using an animal model have demonstrated that viral infection of the placenta triggers a fetal inflammatory response similar to that observed in FIRS, even though the virus is not able to reach the fetus.²²⁴ In the case of human FIRS, these cytokines have been shown to affect the central nervous system and the circulatory system.^{223,225} We also found fetal morphologic abnormalities in the animals, including ventriculomegaly and hemorrhage, which may be caused by fetal proinflammatory cytokines such as IL-1, TNF, MCP-1, macrophage inflammatory protein-1 β and IFN- γ .

Beyond morphologic effects on the fetal brain, FIRS increases the future risk for autism, schizophrenia, neurosensory deficits, and psychosis induced in the neonatal period.²²⁶⁻²²⁸ Moreover, there is evidence that the fetal immune response may predispose to diseases in adulthood.¹²² For this reason, we propose that an inflammatory response in the placenta that alters the cytokine balance in the fetus may affect the normal development of the fetal immune system, leading to anomalous responses during childhood or later in life. Examples are the differential responses in children to vaccination and the development of allergies. Antenatal infections can have a

significant impact on later vaccine responses. This type of outcome may also be observed in other conditions associated with placental infection, such as malaria. A few studies have suggested that surviving infants with placental malaria may suffer adverse neurodevelopmental sequelae and may have abnormal responses to a later parasitic infection.²²⁹ In all of these cases, the parasite did not reach the placenta, but the inflammatory process in the placenta affected the normal fetal development.²³⁰

Are Prophylaxis and Treatment Appropriate and Beneficial for Pregnant Women?

The number of infectious diseases has increased during the past 2 decades and will continue to increase as result of changes in the behavior of the human population.²³¹ As travel to and from different regions of the planet increases, the appearance of new pathogens will also increase. The challenge to determine whether each new pathogen represents a major risk for pregnancy will become more and more difficult if understanding of the immunology of pregnancy does not advance. In addition to evaluating the maternal responses to the pathogen, it is important to evaluate the placental response to the pathogen, because, as described earlier, some microorganisms may not directly affect the pregnancy but could sensitize the mother and the fetus to additional pathogens. In those cases, prophylaxis is required, and the earlier the better. The mantra is, "First, do no

harm." Therefore, the risks and benefits of vaccination during all stages of pregnancy should be carefully evaluated.

Summary

Together, the described studies provide an alternative perspective on the role of the maternal innate immune system and its interactions with the trophoblast during pregnancy. The trophoblast and the maternal immune system act jointly to protect against microorganisms. When the trophoblast identifies potentially dangerous molecular signatures, the maternal immune system responds with coordinate actions. In this way, pregnancy resembles an orchestra in which the trophoblast is the conductor and each immune cell type represents a different musical instrument. The success of the pregnancy depends on how well the trophoblast communicates and works in conjunction with each immune cell.

What was originally proposed to be only a graft-host interaction should now be considered as a supportive regulatory interaction between the trophoblast and the maternal immune system. As more is learned about regulation of the expression and function of uterine immune cells and their regulatory molecules such as TLRs and NOD proteins during pregnancy, a better understanding of the cellular crosstalk that exists at the maternal-fetal interface will be developed.

Maternal Cardiovascular, Respiratory, and Renal Adaptation to Pregnancy

MANJU MONGA, MD | JOAN M. MASTROBATTISTA, MD

Profound physiologic changes occur in the cardiovascular, respiratory, and renal systems during pregnancy. These remarkable adaptations begin soon after conception and continue as gestation advances, yet most are almost totally reversible within weeks to months after delivery. These physiologic adaptations are usually well tolerated by the pregnant patient, but they must be understood so that normal can be distinguished from abnormal.

Cardiovascular System

BLOOD VOLUME

An increase in plasma volume begins at 6 to 8 weeks of gestation, reaching a maximal volume of 4700 to 5200 mL at 32 weeks, an increase of 45% (1200 to 1600 mL) above nonpregnant values.^{1,2} The mechanism of this plasma volume expansion is unclear, but it may be related to nitric oxide–mediated vasodilation, which induces the renin-angiotensin-aldosterone system and stimulates sodium and water retention, protecting the pregnant woman from hemodynamic instability after blood loss.³ As maternal hypervolemia is present with hydatidiform mole, it is unlikely that the presence of a fetus is necessary for this volume expansion to occur.⁴

Red blood cell mass increases by 250 to 450 mL, an increase of 20% to 30% by term compared with pre-pregnancy values. This rise reflects increased production of red blood cells rather than prolongation of red blood cell life.¹ Placental chorionic somatomammotropin, progesterone, and perhaps prolactin are responsible for increased erythropoiesis,⁵ which increases maternal demand for iron by 500 mg during pregnancy. In addition, 300 mg of iron is transferred from maternal stores to the fetus, and 200 mg of iron is required to compensate for normal daily losses during pregnancy, making the total requirement approximately 1000 mg. Erythrocyte 2,3-diphosphoglycerate concentration increases in pregnancy, lowering the affinity of maternal hemoglobin for oxygen. This facilitates dissociation of oxygen from hemoglobin, enhancing oxygen transfer to the fetus.⁶

Because plasma volume increases disproportionately to the increase in red blood cell mass, physiologic hemodilution occurs, resulting in a mild decrease in maternal hematocrit, which is maximal in the middle of the third trimester. This may have a protective function by decreasing blood viscosity to counter the predisposition to thromboembolic events in pregnancy and may be beneficial for intervillous perfusion.⁷

ANATOMIC CHANGES

Histologic and echocardiographic studies indicate that ventricular wall muscle mass and end-diastolic volume increase in pregnancy without an associated increase in end-systolic volume or end-diastolic pressure.^{8,9} Ventricular mass increases in the first trimester, whereas end-diastolic volume increases in the second and early third trimesters.^{8,10} This increases cardiac compliance (resulting in a physiologically dilated heart) without a concomitant reduction in ejection fraction, implying that myocardial contractility must also increase. This is supported by studies of systolic time intervals in pregnancy^{11,12} and echocardiographic demonstration of a decreased ratio of the load-independent wall stress to the velocity of circumferential fiber shortening.¹³ An echocardiographic study of left ventricular function during pregnancy suggests that changes in long-axis performance occur earlier than changes in transverse function and challenges the notion of dominance of circumferential fiber shortening.¹⁴ Left atrial diameter increases in parallel with the rise in blood volume, starting early in pregnancy and plateauing by 30 weeks.¹⁵ A recent study suggests that there is increased left ventricular torsion in pregnancy that may protect against impaired diastolic function despite the increase in preload.¹⁶

A general softening of collagen occurs in the entire vascular system, associated with hypertrophy of the smooth muscle component. This results in increased compliance of capacitive (predominantly elastic wall) and conductive (predominantly muscular wall) arteries and veins that is evident as early as at 5 weeks of the beginning of amenorrhea.¹⁷

CARDIAC OUTPUT

Cardiac output, the product of heart rate and stroke volume, is a measure of the functional capacity of the heart. Cardiac output may be calculated by invasive heart catheterization using dye dilution or thermodilution, or by noninvasive methods such as impedance cardiography and echocardiography. Limited data have been obtained from normal pregnant women by means of an invasive method.¹⁸⁻²⁰ M-mode echocardiography²¹ and Doppler studies²²⁻²⁴ have demonstrated good correlation with thermodilution methods. These validation studies have not been performed in healthy pregnant women, and reports are limited to critically ill patients. Yet to be determined is the most appropriate echocardiographic technique (pulsed-wave or continuous Doppler) and the most reproducible site through which to measure blood flow.²⁵ In contrast, thoracic electrical bioimpedance, which is influenced by intrathoracic fluid volume, hemoglobin, and chest

configuration (all of which change in pregnancy), has had poor correlation with thermodilution techniques, with underestimation of cardiac output during pregnancy.^{23,26,27}

Cardiac output increases by 30% to 50% during pregnancy,^{13,18-20,24,28,29} and half of this increase occurs by 8 weeks of gestation.²⁹ A small decline in cardiac output at term results from a fall in stroke volume.^{8,30-32} Compared with nulliparous women, parous women have a significantly higher median cardiac output and cardiac index as a result of higher median stroke volume, heart rate, left ventricular outflow diameter, and lower total vascular resistance.³³ In normal twin gestations, maternal cardiac output increases to an even greater extent from the mid-trimester of pregnancy.³⁴

Increased maternal cardiac output is caused by an increase in both stroke volume and heart rate. Stroke volume is primarily responsible for the early increase in cardiac output,^{28,35} probably reflecting the increase in ventricular muscle mass and end-diastolic volume. Stroke volume declines toward term.³⁰ In contrast, maternal heart rate, which rises from 5 weeks' gestation to a maximal increment of 15 to 20 beats/min by 32 weeks' gestation, is maintained (Fig. 7-1).^{28,30,36} Therefore, in the late third trimester, maternal tachycardia is primarily responsible for maintaining cardiac output.

Maternal posture significantly affects cardiac output. Turning from the left lateral recumbent to the supine position at term can result in a drop in cardiac output by as much as 25% to 30%.³⁰ This is the result of caval compression by the gravid uterus, which diminishes venous return from the lower extremities, decreasing stroke volume and cardiac output. Although most women do not become hypotensive with this maneuver, up to 8% of women do demonstrate the supine hypotensive syndrome, which is manifested by a sudden drop in blood pressure, bradycardia, and syncope.³⁷ This may result from inadequacy of the paravertebral collateral blood supply in these women, because symptomatic supine hypotensive syndrome does not appear to be associated with a decrease in baroreceptor response.³⁸ This

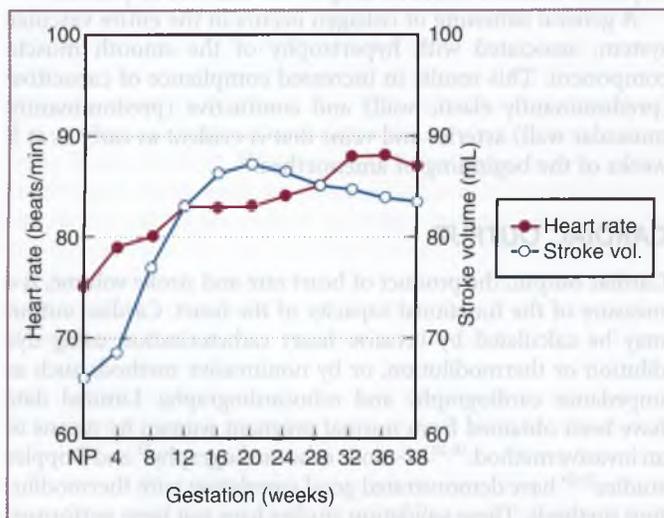

Figure 7-1 Alteration in stroke volume and heart rate during pregnancy. Stroke volume increases maximally during the first half of gestation. There is a slight decrease in stroke volume toward term. A mild increase in heart rate begins early in gestation and continues until term. NP, nonpregnant. (Adapted from Robson SC, Hunter S, Boys RJ, et al: Serial study of factors influencing changes in cardiac output during human pregnancy, *Am J Physiol* 256:H1060, 1989.)

physiologic supine hypotension may affect cardiac hemodynamic parameters and dimensions as measured by cardiac magnetic resonance imaging (MRI), and therefore patients having serial studies should be imaged in a consistent position.³⁹

This physiologic increase in cardiac output has a selective regional distribution. Uterine blood flow increases 10-fold to between 500 and 800 mL/min,⁴⁰ a shift from 2% of total cardiac output in the nonpregnant state to 17% at term. Renal blood flow increases significantly (by 50%) during pregnancy,⁴¹ as does perfusion of the breasts and skin.^{42,43} There does not appear to be any major alteration in blood flow to the brain or liver.

BLOOD PRESSURE

Arterial blood pressure decreases in pregnancy beginning as early as the 7th week.³⁵ This early drop probably represents incomplete compensation for the decrease in peripheral vascular resistance by the increase in cardiac output. When measured in the sitting or standing positions, systolic blood pressure remains relatively stable throughout pregnancy, whereas diastolic blood pressure decreases by a maximum of 10 mm Hg at 28 weeks and then increases toward nonpregnant levels by term.⁴⁴ In contrast, when measured in the left lateral recumbent position, both systolic and diastolic blood pressures decrease to a level 5 to 10 mm Hg and 10 to 15 mm Hg, respectively, below nonpregnant values. This nadir occurs at 24 to 32 weeks' gestation and is followed by a rise toward nonpregnant values at term (Fig. 7-2).⁴⁴ Because diastolic pressures decrease to a greater

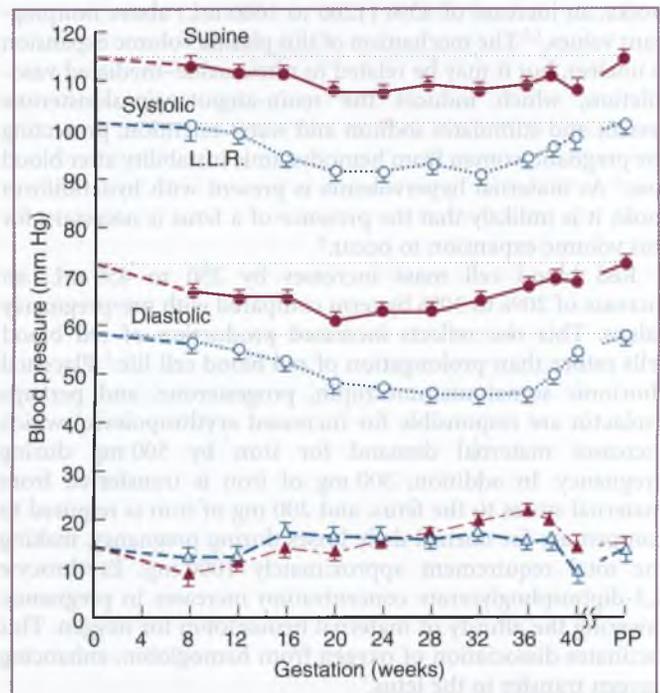

Figure 7-2 Sequential changes in blood pressures throughout pregnancy. The subjects were in supine (closed circles) or left lateral recumbent (L.L.R.) (open circles) positions. At the bottom of the graph, the changes in systolic (open triangles) and diastolic (closed triangles) blood pressures produced by movement from the left lateral recumbent to the supine position are shown. PP, postpartum. (From Wilson M, Morganti AA, Zervoudakis I, et al: Blood pressure, the renin-aldosterone system and sex steroids throughout normal pregnancy, *Am J Med* 68:97, 1980.)

extent than systolic pressures, there is a slight increase in pulse pressure in the early third trimester. Arterial blood pressures are approximately 10 mm Hg higher in the standing or sitting position than in the lateral or supine position; consistency in position during successive blood pressure measurements is essential for the accurate documentation of a trend during pregnancy. Pregnant women who are obese have higher systolic, diastolic, and mean arterial pressures but lower resting heart rates. Additionally, they do not show the normal decline in blood pressure between the first and second trimester of pregnancy and have greater increases in blood pressure between second and third trimester.⁴⁵

Confusion has arisen with regard to the definition of diastolic blood pressure in pregnancy. Measurement of Korotkoff phase IV (the point of muffling) results in mean diastolic pressures 13 mm Hg higher than measurement of Korotkoff phase V (the point of disappearance).⁴⁶ Use of Korotkoff phase IV may be less reproducible.⁴⁷ Intra-arterial measurements of diastolic pressures may be 15 mm Hg lower than manual determinations,⁴⁸ whereas they may be significantly higher than automated cuff diastolic measurements.⁴⁹

The use of ambulatory blood pressure monitoring has been validated in pregnancy.⁵⁰ Monitoring over a period of 24 hours has shown measurements that are either significantly lower⁵¹ or higher⁵² than office measurements. These differences cannot be explained by activity level, although work- and job-related stress have been shown to increase blood pressure in late pregnancy.^{52,53} Ambulatory blood pressure monitoring has shown marked circadian variation in blood pressure during pregnancy, with a nadir of systolic and diastolic blood pressures in the early morning hours and a peak in late afternoon and evening.⁵⁴

SYSTEMIC VASCULAR RESISTANCE

Systemic vascular resistance is calculated by the following equation:

$$\frac{(\text{Mean arterial pressure} - \text{central venous pressure}) \times 80 \text{ dyne-sec cm}^{-5}}{\text{cardiac output}}$$

Systemic vascular resistance decreases from as early as at 5 weeks of pregnancy as a result of the vasodilatory effect of progesterone and prostaglandins and perhaps the arteriovenous fistula-like function of the low-resistance uteroplacental circulation.^{13,55-57} Alternatively, it has been proposed that increased production of endothelium-derived relaxant factors, such as nitric oxide, initiates vasodilation and a drop in systemic vascular resistance.^{3,58} This decrease in systemic vascular tone may be the primary trigger for increasing heart rate, stroke volume, and cardiac output in the first few weeks of pregnancy.^{3,57} The fall in systemic vascular resistance is paralleled by an increase in vascular compliance, which reaches a nadir at 14 to 24 weeks' gestation and then rises progressively toward term.^{17,18}

VENOUS VASCULAR BED

Venous compliance increases progressively during pregnancy as a result of the relaxant effect of progesterone or endothelium-derived relaxant factors on blood vessel smooth muscle, or as a result of altered elastic properties of the venous wall. This results in a decrease in flow velocity and leads to stasis.⁵⁹ Pregnant women are therefore more sensitive to autonomic

TABLE 7-1 Hemodynamic Profiles for Nonpregnant and Pregnant Patients in the Third Trimester

	Nonpregnant	Pregnant	Change
Cardiac output (L/min)	4.3 ± 0.9	6.2 ± 1.0	+43%
Heart rate (beats/min)	71 ± 10	83 ± 10	+17%
SVR (dyne-sec cm ⁻⁵)	1530 ± 520	1210 ± 266	-21%
PVR (dyne-sec cm ⁻⁵)	119 ± 47	78 ± 22	-34%
CVP (mm Hg)	3.7 ± 2.6	3.6 ± 2.5	NS
COP (mm Hg)	20.8 ± 1.0	18.0 ± 1.5	-14%
PCWP (mm Hg)	6.3 ± 2.1	7.5 ± 1.8	NS
COP-PCWP (mm Hg)	14.5 ± 2.5	10.5 ± 2.7	-28%

COP, colloid osmotic pressure; COP-PCWP, gradient between COP and PCWP; CVP, central venous pressure; nonpregnant, at 11 to 13 weeks postpartum; NS, not significant; PCWP, pulmonary capillary wedge pressure; pregnant, at 36 to 38 weeks' gestation; PVR, pulmonary vascular resistance; SVR, systemic vascular resistance. Adapted with permission from Clark SL, Cotton DB, Lee W, et al: Central hemodynamic assessment of normal term pregnancy, *Am J Obstet Gynecol* 161:1439, 1989.

blockade, which results in further venous pooling, decreased venous return, and a fall in cardiac output manifested as a sudden drop in arterial blood pressure.

ANTEPARTUM HEMODYNAMICS

Clark and colleagues studied the effect of pregnancy on central hemodynamics by placing Swan-Ganz catheters and arterial lines in 10 normal primiparous women at 35 to 38 weeks' gestation and again at 11 to 13 postpartum weeks (Table 7-1).²⁰ Late pregnancy was characterized by significant elevations in heart rate, stroke volume, and cardiac output, in concert with significant decreases in systemic and pulmonary vascular resistance and serum colloid osmotic pressure. There was no significant alteration in pulmonary capillary wedge pressure, central venous pressure, or mean arterial blood pressure. The authors suggested that pulmonary capillary wedge pressure does not increase, despite significant increases in blood volume and stroke volume, because of ventricular dilation and the fall in pulmonary vascular resistance. They noted, however, that pregnant women were still at higher risk for pulmonary edema because of the significantly decreased gradient between colloid osmotic pressure and pulmonary capillary wedge pressure (gradient of 10.5 ± 2.7 mm Hg) compared with the nonpregnant state (gradient of 14.5 ± 2.5 mm Hg).

Circulation time demonstrates a slight but progressive decline during pregnancy, reaching a minimal value of 10.2 seconds in the third trimester.⁶⁰ These findings have been interpreted to mean that blood flow velocity increases slightly in pregnancy.

Autonomic cardiovascular control in pregnancy has also been investigated. Although earlier studies indicated a blunted heart rate and blood pressure response to the Valsalva maneuver, possibly because of decreased vagal control of the heart,^{36,61} a study of baroreceptor sensitivity using power spectral analysis of heart rate and blood pressure variability between 28 and 38 weeks' gestation indicated a significant negative correlation between baroreceptor sensitivity and cardiac output, and a

positive correlation with total peripheral resistance. This suggests that baroreceptors respond to changes in cardiac output and peripheral vascular resistance to maintain blood pressure during pregnancy.⁶²

SYMPTOMS AND SIGNS OF NORMAL PREGNANCY

Pregnant women report dyspnea with increased frequency as gestation advances (15% in the first trimester compared with 75% by the third).⁶³ The mechanism for this is unclear, but it may relate to the exaggerated ventilatory response (perhaps progesterone mediated) in response to increased metabolic demand. Easy fatigability and decreased exercise tolerance are also commonly reported, although mild to moderate exercise is well tolerated under normal circumstances.^{64,65} Many women report increased breathlessness during pregnancy, but this is not associated with excessive maternal hyperventilation or absence of adaptive respiratory changes.⁶⁶

Increased lower extremity venous pressure, caused by compression by the gravid uterus and lower colloid osmotic pressure, is commonly manifested as dependent edema—most often found in the distal lower extremities at term. Thigh-high support stockings significantly increase systemic vascular resistance by preventing venous pooling in the lower extremities and may be effective in decreasing peripheral edema in pregnancy.⁶⁷

Cutforth and MacDonald documented clearly the alterations in heart sounds in pregnancy by a phonocardiographic study of 50 normal primigravid women.⁶⁸ Briefly, the first heart sound increased in loudness and was more widely split in approximately 90% of women (30 to 45 msec compared with 15 msec in the nonpregnant state). This results from early closure of the mitral valve, as demonstrated by the shortened interval between the Q wave of the electrocardiogram and the first heart sound. There was no significant change in the second heart sound until 30 weeks' gestation, when persistent splitting that does not vary with respiration may occur. A loud third heart sound was heard in up to 90% of pregnant women, whereas less than 5% had an audible fourth heart sound.

Systolic murmurs develop in more than 95% of pregnant women. These are heard best along the left sternal border and are most often either aortic or pulmonary in origin. Doppler echocardiography demonstrates an increased incidence of functional tricuspid regurgitation during pregnancy that may also lead to a systolic precordial murmur.⁶⁹ Although most of these changes in heart sounds are first audible between 12 and 20 weeks' gestation and regress by 1 week after the birth, nearly 20% have a persistent systolic murmur beyond the 4th week after delivery. Systolic murmurs louder than grade 2/4 and diastolic murmurs of any intensity are considered abnormal during pregnancy. However, 14% of women may have a continuous murmur of mammary vessel origin, which is heard maximally in the second intercostal space.⁶⁸

Uterine growth results in upward displacement of the diaphragm, which is associated with superior, lateral, and anterior displacement of the heart in the thorax. This leads to lateral displacement of the point of maximal impulse and may suggest cardiomegaly on chest radiographs. This appearance is further enhanced by straightening of the left heart border and by prominence of the pulmonary outflow tracts; however, the cardiothoracic ratio is only slightly increased, if at all, in normal pregnancy.⁷⁰

INTRAPARTUM HEMODYNAMIC CHANGES

Labor results in significant alteration in the cardiovascular measurements. The first stage of labor is associated with a 12% to 31% rise in cardiac output, primarily because of a 22% increase in stroke volume.^{71,72} The second stage of labor is associated with an even greater increase in cardiac output (49%). Laboring in the left lateral decubitus position or analgesia decreases the magnitude of this increment, but a left lateral tilt of 15 degrees may be inadequate to prevent aortocaval compression.⁷³ The increase in cardiac output is not completely abolished by relief of pain, because contractions result in the transfer of 300 to 500 mL of blood from the uterus to the general circulation.^{74,75} Systolic and diastolic blood pressures transiently increase by 35 and 25 mm Hg, respectively, during labor.⁷² For these reasons, women who have cardiovascular compromise may experience decompensation with labor, especially during the second stage.

POSTPARTUM HEMODYNAMIC CHANGES

Pregnant women with cardiac disease are perhaps at greatest risk for pulmonary edema in the immediate postpartum period. The immediate puerperium is associated with an 80% increase in cardiac output within 10 to 15 minutes after vaginal delivery with local anesthesia compared with 60% with caudal anesthesia.^{76,77} Whole-body impedance cardiography was used to continuously study maternal hemodynamics and cardiovascular responses in 10 women having cesarean delivery under spinal analgesia.⁷⁸ Within 2 minutes of delivery, there was a 47% increase in cardiac index and a 39% decrease in systemic vascular index without appreciable change in mean arterial pressure. This immediate increase in cardiac output is caused by release of venacaval obstruction by the gravid uterus, autotransfusion of uteroplacental blood, and rapid mobilization of extravascular fluid. All these changes result in increased venous return to the heart and increased stroke volume. Cardiac output returns to prelabor values 1 hour after delivery.⁷⁷

Vaginal delivery is associated with a blood loss of approximately 500 mL, whereas cesarean delivery may cause a loss of 1000 mL.⁷⁹ The pregnant woman is protected from postpartum blood loss in part by the expansion of blood volume associated with pregnancy.

M-mode echocardiographic studies have shown that left atrial dimensions increase 1 to 3 days after the birth, perhaps because of mobilization of excessive body fluids and increased venous return.⁷⁷ Atrial natriuretic levels also increase in the immediate postpartum period, which may stimulate diuresis and natriuresis in the early puerperium.⁸⁰

Whereas left atrial dimensions and heart rate normalize within the first 10 postpartum days, left ventricular dimensions decrease gradually for 4 to 6 months. Cardiovascular measurements, such as stroke volume, cardiac output, and systemic vascular resistance, as measured by M-mode echocardiography, do not completely return to pre-pregnancy values by 12 postpartum weeks and may continue to decrease for 24 weeks before stabilizing.^{28,77}

Respiratory System

There is a moderate decrease in functional residual capacity during pregnancy, attributed to a decrease in both expiratory reserve volume and residual volume (Table 7-2). This is

TABLE 7-2 Respiratory Changes during Pregnancy

Lung Volume (mL)	Nonpregnant	Pregnant	Change
Total lung capacity (vital capacity + residual volume)	4200	4000	-4%
Vital capacity (total lung capacity - residual volume)	3200	3200	No change
Inspiratory capacity (vital capacity - expiratory reserve volume)	2500	2650	+6%
Tidal volume	450	600	+33%
Expiratory reserve volume (vital capacity - inspiratory capacity)	700	550	-20%
Inspiratory reserve volume (inspiratory capacity - tidal volume)	2050	2050	No change
Residual volume (result: decrease in total lung capacity)	1000	800	-20%
Functional residual capacity (residual volume + expiratory reserve volume)	1700	1350	-20%

primarily the result of upward displacement of the maternal diaphragm. Maternal tidal volume increases by 40% in pregnancy, and this increase results in maternal hyperventilation and hypocapnia.⁸¹ Because maternal respiratory rate does not change during pregnancy, the 30% to 50% increase in minute ventilation that is noted as early as the first trimester is attributed to this increase in tidal volume alone.⁸² Increased minute ventilation may be the result of increased progesterone and an increase in basal metabolic rate. Long-term maternal exercise appears to have no effect on pregnancy-induced changes in ventilation or alveolar gas exchange at rest or during standard submaximal exercise; however, ventilatory anaerobic threshold appears to increase with physical conditioning.⁸³

There is a decrease in the partial pressure of carbon dioxide from a pre-pregnancy level of 39 mm Hg to approximately 28 to 31 mm Hg at term. This hyperventilation facilitates the transfer of carbon dioxide from the fetus to the mother and is partially compensated for by an increased renal secretion of hydrogen ions, with a resultant serum bicarbonate level of 18 to 22 mEq/L. A mild respiratory alkalosis is therefore normal in pregnancy, with an arterial pH of 7.44, compared with 7.40 in the nonpregnant state. This mild respiratory alkalosis results in a shift to the left of the oxygen dissociation curve, increasing the affinity of maternal hemoglobin for oxygen (the Bohr effect) and reducing oxygen release to the fetus. This is compensated for by an alkalosis-stimulated increase in 2,3-diphosphoglycerate in maternal erythrocytes, which shifts the oxygen dissociation curve to the right, *facilitating* oxygen transfer to the fetus.⁸⁴

Concomitant with the increase in maternal minute ventilation is a 20% to 40% increase in maternal oxygen consumption caused by increased oxygen requirements of the fetus, placenta, and maternal organs.⁸⁵ Because of the increase in maternal oxygen consumption and the decrease in functional residual capacity, pregnant women with asthma, pneumonia, or other respiratory pathology may be more susceptible to early decompensation.

Kidneys and Lower Urinary Tract

The dramatic changes in renal structure, dynamics, and function that occur during pregnancy have recently been reviewed.⁸⁶

STRUCTURE AND DYNAMICS

Renal size and weight increase during pregnancy as a result of an increase in renal vascular and interstitial volume. Kidney length increases by approximately 1 cm,⁸⁷ and renal volume, as

determined by computed nephrosonography, increases by approximately 30%.⁸⁸ More dramatic, however, is dilation of the urinary collecting system, which occurs in more than 80% of pregnant women by mid-gestation.⁸⁹ Caliceal and ureteral dilations are more common on the right side than on the left,^{90,91} and the degree of caliceal dilation is more pronounced on the right than on the left (15 versus 5 mm).⁹² The prominence of these changes on the right side may result from dextrorotation of the pregnant uterus, the location of the right ovarian vein that crosses the ureter, or the protective "cushion" effect of the sigmoid colon on the left side, or any combination of these. Ureteral dilation is rarely present below the level of the pelvic brim, and sonographic visualization demonstrates tapering of the ureters as they cross the common iliac artery.⁹³ Although obstruction plays a role in the physiologic pyelectasis of pregnancy, an associated increase in renal arterial resistance has not been consistently documented.⁹¹ One reason for this may be the poor reproducibility of pulsed Doppler measurements in the maternal renal circulation as a result of high interobserver and intraobserver variability.⁹⁴ Progesterone, relaxin, and the nitric oxide pathway may play a concomitant role in ureteral smooth muscle relaxation, but there is no consensus on the influence of hormones on these anatomic alterations.^{86,95}

The dilation of the urinary collecting system has several important clinical consequences, including an increase in ascending urinary tract infection, perhaps related to urinary stasis; difficulty in interpreting radiologic examinations of the urinary tract; and interference with evaluation of glomerular and tubular function, because these tests require high urine flow rates. Renal volume returns to normal within the first week after delivery,⁸⁸ but hydronephrosis and hydroureter may persist for 3 to 4 months after the birth.⁹² This should be considered when radiologic or renal function studies on postpartum women are being interpreted. Ureteral peristalsis does not change in pregnancy; however, ureteral tone progressively increases, possibly as a result of mechanical obstruction, and then returns to normal shortly after delivery.⁹⁶ Controversy exists with regard to changes in urinary bladder pressures and capacity. In one study, urinary bladder pressure doubled between the first and third trimesters of pregnancy, implying a decrease in bladder capacity.⁹⁷ Previous studies demonstrated a relatively hypotonic bladder, with decreased pressure and increased capacity near term.⁹⁸ Urethral length and intraurethral closure pressure in pregnancy have also been determined by urodynamic studies and have been found to increase by 20%.⁹⁷ The latter may counter the increase in bladder pressure in an attempt to reduce stress incontinence, which is more common in pregnancy, occurring in 29% to 41% at term.⁹⁹

RENAL FUNCTION

Renal plasma flow, as estimated by para-aminohippurate clearance, increases by 60% to 80% over nonpregnant values by the middle of the second trimester and then falls to 50% above pre-pregnancy values in the third trimester.¹⁰⁰ Renal plasma flow, like cardiac output, is significantly higher when the patient is in the left lateral recumbent position than when she is sitting, standing, or supine. This reflects maximal venous return in the left lateral position.^{101,102}

Glomerular filtration rate (GFR) is estimated by determination of inulin, iothexol, or creatinine clearance. Creatinine clearance, although most commonly used, is the least precise of the determinations because creatinine is secreted by the tubules in addition to being cleared by the glomeruli. Creatinine clearance can be calculated by dividing the total amount of urinary creatinine (in milligrams) by the duration of collection (in minutes). This value is then divided by the creatinine concentration in serum (in milligrams per milliliter). This yields a creatinine clearance in milliliters per minute.

GFR begins to increase by as early as 6 weeks' gestation, with a peak of 50% over nonpregnant values by the end of the first trimester.¹⁰² Although there are few data on the measurement of GFR after 36 weeks of gestation, GFR does not appear to decrease at term. Creatinine clearance is thus moderately increased in pregnancy (to 110 to 150 mL/min). This rate has a circadian variation of 80% to 125%, with maximal creatinine excretion between 2 PM and 10 PM and lowest excretion rates between 2 AM and 10 AM.¹⁰³

The mechanisms behind the changes in renal hemodynamics are unclear, although study of pregnant rats suggests that GFR rises as a result of vasodilation of preglomerular and postglomerular resistance vessels without any alteration in glomerular capillary pressure.¹⁰⁴ This is further supported by the lack of continued increase in GFR after the first trimester of pregnancy despite decreasing serum albumin, implying independence from changes in oncotic pressure.⁵⁷

Because the increase in renal plasma flow is initially greater than the rise in GFR, the filtration fraction (GFR divided by renal plasma flow) decreases until the third trimester of pregnancy, when a fall in renal plasma flow results in the return of the filtration fraction to a pre-pregnancy value of 1/5.¹⁰² This alteration in filtration fraction parallels the change in mean arterial pressure described previously and may be related to circulating progesterone levels.^{100,105}

Filtration capacity, which is estimated by the maximal GFR in response to a vasodilator stimulus, appears to be intact in pregnancy, as documented by studies of amino acid administration in rats⁹⁶ and protein loading in pregnant women.¹⁰⁶ As the resting GFR rises during pregnancy, the functional renal reserve (the difference between the filtration capacity and the resting GFR) decreases. One can therefore accurately assess renal function in pregnant patients with early renal disease by determining filtration capacity, but not by functional renal reserve.¹⁰⁶

The pregnancy-associated rise in GFR (which normally occurs without any concomitant increase in production of urea or creatinine) results in decreased serum creatinine and urea concentrations in pregnancy.¹⁰⁵ Serum creatinine falls from pre-pregnancy values of 0.83 mg/dL to 0.7, 0.6, and 0.5 mg/dL in successive trimesters. Blood urea nitrogen decreases from 12 mg/dL in the nonpregnant state to 11, 9, and 10 mg/dL in the first, second, and third trimesters, respectively.

RENAL TUBULAR FUNCTION

Sodium

Several factors promote sodium excretion in pregnancy. There is an increase in the filtered load of sodium from approximately 20,000 to 30,000 mEq/day as a result of the 50% rise in GFR. Hormones that favor sodium excretion include the following:

Progesterone, a competitive inhibitor of aldosterone¹⁰⁷

Vasodilatory prostaglandins¹⁰²

Atrial natriuretic factor (although increased pregnancy-related production of atrial natriuretic factor has not been universally demonstrated)^{108,109}

Despite these forces, there is a cumulative retention of approximately 950 mg of sodium during pregnancy. This is distributed between the maternal intravascular and interstitial compartments, the fetus, and the placenta.¹¹⁰ The net reabsorption of sodium is one of the most remarkable adaptations of renal tubular function to pregnancy.

Factors that promote this sodium reabsorption include the increased production and secretion of aldosterone, deoxycorticosterone, and estrogen (Fig. 7-3).¹⁰⁷ These hormones may be regulated, in part, by the rise in plasma progesterone and vasodilatory prostaglandins, but they are also mediated by stimulation of the renin-angiotensin system. All components of the renin-angiotensin-aldosterone system increase in the first trimester of pregnancy and peak at 30 to 32 weeks' gestation.³ Hepatic renin substrate is stimulated by estrogens and results in elevated renal production of renin. Renin stimulates increased conversion of angiotensinogen to angiotensins I and II. Sodium retention is also favored by postural changes in pregnancy; the supine and upright positions are associated with a marked decrease in sodium excretion.⁴¹

Potassium

Although the pregnancy-associated increase in plasma aldosterone would favor potassium excretion, a net retention of 300 to 350 mEq of potassium actually occurs. Increased kaliuresis may be prevented by the influence of progesterone on renal

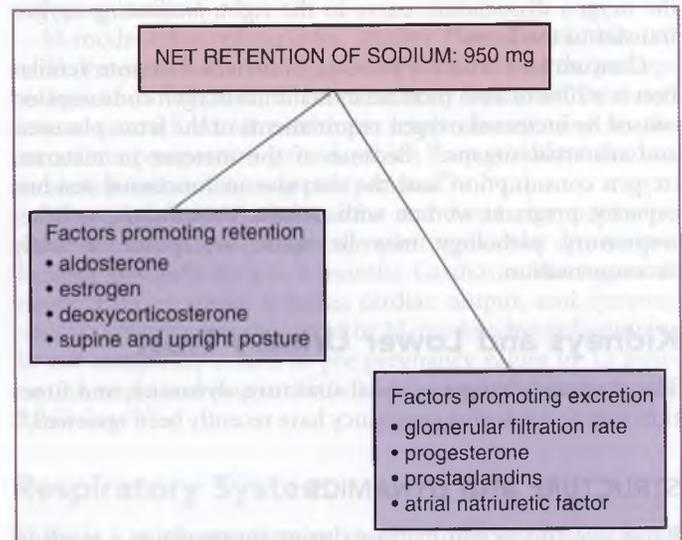

Figure 7-3 Factors influencing the regulation of sodium retention and excretion in pregnancy.

potassium excretion.¹¹¹ Because potassium reabsorption from the distal tubule and the loop of Henle decreases with pregnancy, it has been deduced that a significant increase in proximal tubular reabsorption occurs.¹¹²

Calcium

Urinary calcium excretion increases as a result of increased calcium clearance.¹¹³ This is balanced by increased absorption of calcium from the small intestine, and therefore serum ionic (unbound) calcium levels remain stable. Total calcium levels fall in pregnancy from 4.75 mEq/L in the first trimester to 4.3 mEq/L at term because of a decrease in plasma albumin.¹¹⁴ A rise in calcitriol in early pregnancy is paralleled by suppression of the parathyroid hormone and an increase in renal tubular phosphorus reabsorption.¹¹⁵ This increase in calcitriol promotes reabsorption of calcium and phosphorus from the intestine and may facilitate bone mineralization in the fetus.

Glucose

Glucose excretion increases in pregnant women 10-fold to 100-fold over nonpregnant values of 100 mg/day.¹¹⁶ This glycosuria, which occurs despite increased plasma insulin and decreased plasma glucose levels, is the result of impaired collecting tubule and loop of Henle reabsorption of the 5% of the filtered glucose that normally escapes proximal convoluted tubular reabsorption.¹¹⁷ The clinical significance of this is that glycosuria cannot be accurately used to monitor pregnant women with diabetes mellitus.

Uric Acid

Plasma uric acid levels decrease by 25% at as early as 8 weeks' gestation, reaching a nadir of 2 to 3 mg/dL at 24 weeks' gestation, and then increase toward nonpregnant levels at term.¹¹⁸ This may result from increased GFR and reduced proximal tubular reabsorption.¹¹⁹ Conditions that lead to volume contraction, such as preeclampsia, may be associated with decreased uric acid clearance and increased plasma levels.

Amino Acids

The fractional excretion of alanine, glycine, histidine, serine, and threonine increases in pregnancy.¹²⁰ Excretion of cystine, leucine, lysine, phenylalanine, taurine, and tyrosine increases early in pregnancy but then decreases in the second half of gestation. The excretion of arginine, asparagine, glutamic acid, isoleucine, methionine, and ornithine does not change. The mechanism of this selective amino aciduria is unknown. It is unclear whether renal excretion of albumin increases, decreases, or remains stable¹²¹⁻¹²³ in normal pregnancy. Urinary protein excretion does not normally exceed 300 mg per 24 hours.

Volume Homeostasis

Bodyweight increases by an average of 30 to 35 pounds in pregnancy.¹²⁴ Two thirds of this gain may be accounted for by an increase in total body water, with 6 to 7 L gained in the extracellular space and approximately 2 L gained in the intracellular space. Plasma volume expansion, as outlined previously, accounts for 25% of the increase in extracellular water, with the rest of the increment appearing as interstitial fluid.¹¹⁰ As water is retained, plasma sodium and urea levels fall slightly, from 140.3 ± 1.7 to 136.6 ± 1.5 mM/L, and from 4.9 ± 0.9 to 2.9 ± 0.5 mM/L, respectively.¹²⁵ By 4 weeks after conception, plasma osmolality has decreased from 289 to 280.9. Because water deprivation in pregnant women leads to an appropriate increase in vasopressin and urine osmolality, and water loading results in a proportional decrease, it appears that the osmoregulation system is functioning normally but is "reset" at a lower threshold.¹²⁶ Further evidence to support this conclusion is that the osmotic threshold for thirst is decreased by 10 mOsm/kg in pregnancy.¹¹¹ The mechanism for this readjustment of the osmoregulatory system is unclear but may involve placental secretion of human chorionic gonadotropin.¹²⁷

Endocrinology of Pregnancy

JAMES H. LIU, MD

The concept of the fetus, the placenta, and the mother as a functional unit originated in the 1950s. More recent is the recognition that the placenta itself is an endocrine organ capable of synthesizing virtually every hormone, growth factor, and cytokine thus far identified. The premise that the placenta, composed chiefly of two cell types—syncytiotrophoblast and cytotrophoblast—can synthesize and secrete a vast array of active substances could not even be contemplated until it was recognized in the 1970s that a single cell can, in fact, synthesize multiple peptide and protein factors. This concept is even more remarkable because the placenta has no neural connections to either the mother or the fetus and is expelled after childbirth. Yet the placenta is an integral, functional part of the fetal-placental-maternal unit, and it can be viewed as the most amazing endocrine organ of all. In this chapter, we review the hormonal interactions of the fetal-placental-maternal unit and the neuroendocrine and metabolic changes that occur in the mother and in the fetus during pregnancy and at parturition.

Implantation

The process of embryo implantation was thought to take place between 6 and 7 days after ovulation,^{1,2} but more contemporary studies suggest that in most successful human pregnancies, the embryo implants approximately 8 to 10 days after ovulation.³ This event involves a series of complex steps: (1) apposition of the blastocyst with respect to the endometrial surface; (2) initial adhesion of the blastocyst to endometrium; (3) meeting of the microvilli on the surface of trophoblast with pinopodes, microprotrusions from the apical end of the uterine epithelium; (4) trophoblastic migration through the endometrial surface epithelium; (5) embryonic invasion with localized disruption of the endometrial capillary beds; and finally (6) remodeling of the capillary bed and formation of trophoblastic lacunae.⁴⁻⁶ By day 10, the blastocyst is completely encased in the uterine stromal tissue. A diagrammatic representation of this process is shown in Figure 8-1.

Although recent work with in vitro fertilization (IVF)-related techniques such as embryo donation and frozen embryo transfer has contributed significantly to our understanding of this process, much of our present physiologic information is derived from other mammalian species because human tissue experiments are limited by ethical constraints. This implantation process has been reviewed by Norwitz and colleagues⁵ and Dey and coworkers.⁶

Results from assisted reproductive technologies suggest a window for implantation in which the endometrium is receptive to embryo implantation. In this concept, synchronization between embryonic and uterine receptivity is required for successful nidation. IVF-generated data suggest that implantation is successful usually after embryo transfer into the uterus,

between days 3 and 5 after fertilization. (The embryo is at the eight-cell to blastocyst stage of development.) If the embryo is transferred outside this window or is in a different location, embryo demise or the likelihood of ectopic pregnancy increases. Although the process of embryo implantation requires a receptive endometrium, the process is not exclusive to the endometrium, because advanced ectopic (e.g., abdominal) pregnancies have been reported with a viable fetus. During a typical IVF cycle, embryos are transferred to the uterus on day 3 or day 5 after fertilization. By day 3 of embryo culture, embryo development is at the six- to eight-cell stage. Embryos placed back into the uterus at this stage remain unattached to the endometrium and continue developing to the blastocyst stage, they “hatch” or escape from the zona pellucida, and they implant by day 6 or 7 of embryo life. In IVF programs that transfer on day 3, the chance of each embryo implanting is approximately 17% to 37%.⁷ Thus, to achieve a reasonable chance of overall pregnancy, most women undergoing IVF will have one to two good-quality embryos placed back into the uterus to achieve live birth rates of 25% to 44% per IVF retrieval cycle. Because the implantation potential for each embryo is affected by the age of the mother, and because embryo morphology alone is imprecise for predicting the likelihood of implantation, transfer of multiple embryos can result in higher-order multiple births, such as twins, triplets, or occasionally quadruplets.

Most IVF programs have the capability to culture embryos for up to 5 days. Embryos at this stage are at the blastocyst or morula stage. The overall implantation rate for each good-quality embryo at this stage is between 30% and 50% per embryo. Thus, to achieve a reasonable chance of pregnancy, most women have only one or two good-quality blastocyst-stage embryos transferred to the uterus, reducing the chances of higher-order multiple births. A recent study from population-based control data indicates that the use of assisted reproductive technology accounts for a disproportionate number of low-birth-weight and very-low-birth-weight infants, in part because of multiple births and in part because of higher rates of low birth weight among singleton infants conceived with assisted reproductive technologies.⁸

The cellular differentiation and remodeling of the endometrium induced by sequential exposure to estradiol and progesterone may play a major role in endometrial receptivity. The beginning of endometrial receptivity coincides with the down-regulation of progesterone and estrogen receptors induced by the corpus luteum production of progesterone. It was thought that this process required tight regulation, in that the morphologic development of microvilli (pinopodes) in glandular epithelium⁹ and increased angiogenesis were required for successful embryo nidation. Experience with IVF techniques, however, suggests marked differences in endometrial morphology in different women at the same time of the cycle, or in the same

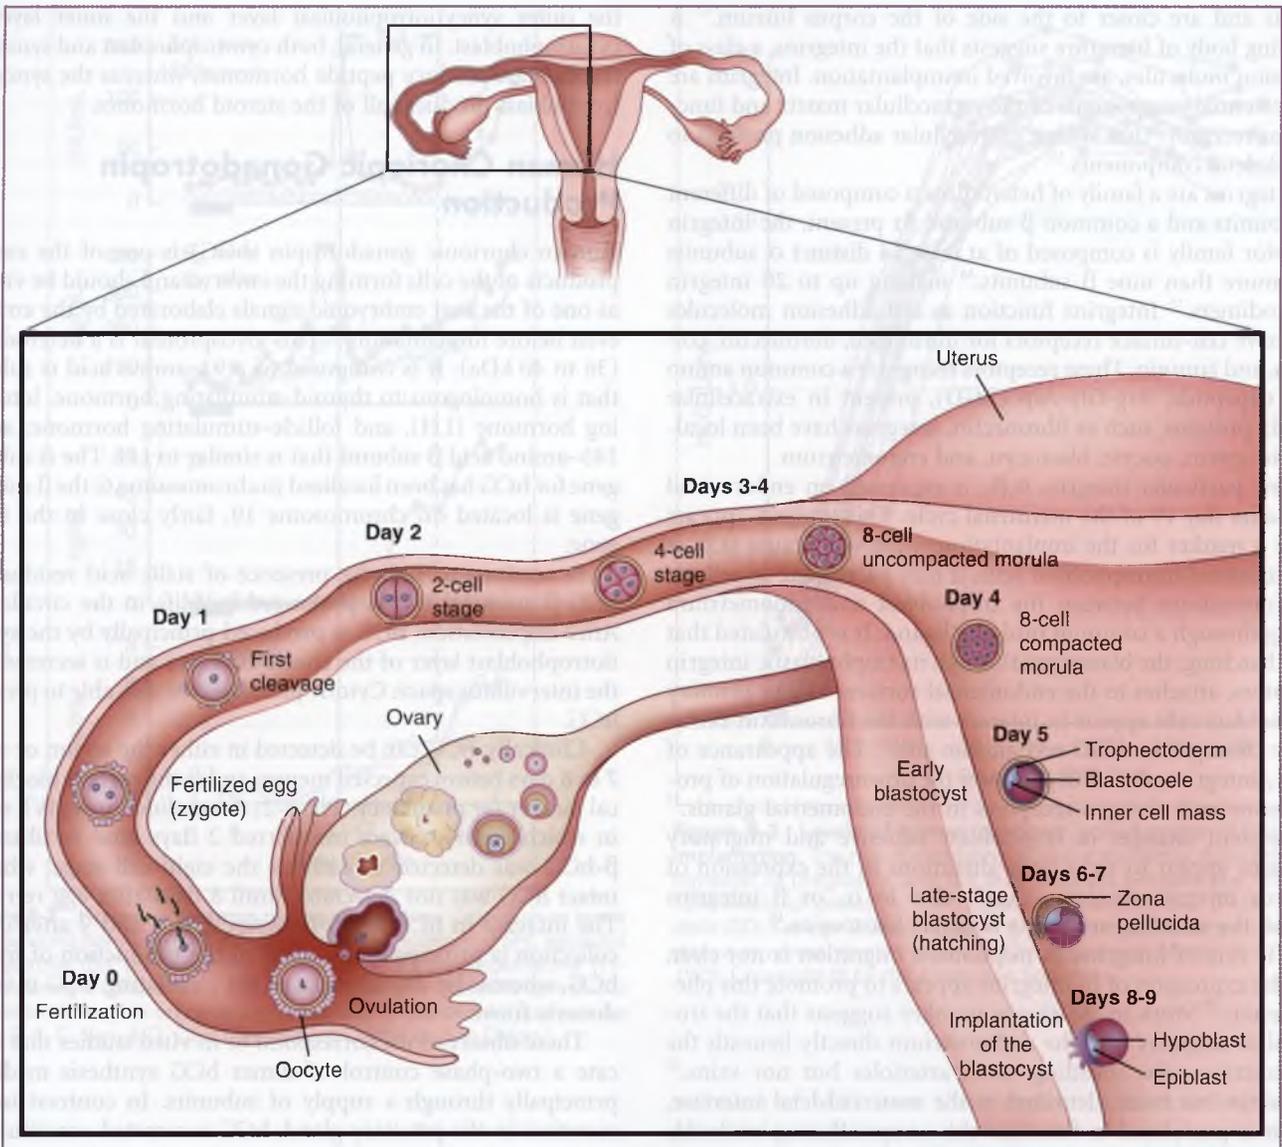

Figure 8-1 Sequence of embryo development from ovulation through the stage of blastocyst implantation in the human.

TABLE 8-1 Growth Factors and Proteins That Play a Significant Role during Embryo Implantation

Factor	Putative Role	Reference
Leukemia inhibitory factor	Cytokine involved in implantation	Cullinan et al, 1996 ¹²¹
Integrins	Cell-to-cell interactions	Stewart et al, 1997 ¹²²

Vascular endothelial growth factor	Mediates implantation	Stewart et al, 1997 ¹²²
L-selectin	Mediates implantation	Genbacev et al, 2003 ²¹

woman from cycle to cycle.¹⁰ Nevertheless, the current concept is that developmental expression of factors by the blastocyst and the endometrium allows cell-to-cell communications so that successful nidation can take place.

Reviews of embryo implantation have identified an increasing number of factors, such as integrins, mucins, L-selectin, cytokines, proteinases, and glycoproteins, localized to either the

embryo or the endometrium during the window of implantation.^{6,11} Much of the information is derived from animal studies, and its application to human implantation is primarily circumstantial. Table 8-1 lists several of the factors believed to mediate embryo implantation.

Ultrasound studies of early human gestation show that most implantation sites are localized to the upper two thirds of the

uterus and are closer to the side of the corpus luteum.¹² A growing body of literature suggests that the integrins, a class of adhesion molecules, are involved in implantation. Integrins are also essential components of the extracellular matrix and function as receptors that anchor extracellular adhesion proteins to cytoskeletal components.¹³

Integrins are a family of heterodimers composed of different α subunits and a common β subunit. At present, the integrin receptor family is composed of at least 14 distinct α subunits and more than nine β subunits,¹⁴ making up to 20 integrin heterodimers.¹⁵ Integrins function as cell adhesion molecules and have cell-surface receptors for fibrinogen, fibronectin, collagen, and laminin. These receptors recognize a common amino acid tripeptide, Arg-Gly-Asp (RGD), present in extracellular matrix proteins, such as fibronectin. Integrins have been localized to sperm, oocyte, blastocyst, and endometrium.

One particular integrin, $\alpha_v\beta_3$, is expressed on endometrial cells after day 19 of the menstrual cycle. This integrin appears to be a marker for the implantation window. Because $\alpha_v\beta_3$ is also localized to trophoblast cells, it may participate in cell-to-cell interactions between the trophoblast and endometrium acting through a common bridging ligand. It is postulated that after hatching, the blastocyst, through its trophoblastic integrin receptors, attaches to the endometrial surface. Mouse primary trophoblast cells appear to interact with the fibronectin exclusively through the RGD recognition site.¹⁶ The appearance of the β_3 -integrin subunit depends on the downregulation of progesterone and estrogen receptors in the endometrial glands.¹⁷ Subsequent changes in trophoblast adhesive and migratory behavior appear to stem from alterations in the expression of various integrin receptors. Antibodies to α_v or β integrins inhibit the attachment activity of intact blastocysts.¹⁸

The role of integrins in trophoblast migration is not clear, but the expression of β_1 integrins appears to promote this phenomenon.¹⁹ Work in the rhesus monkey suggests that the trophoblast migrates into the endometrium directly beneath the implantation site, invading small arterioles but not veins.²⁰ L-selectin has been identified at the maternal-fetal interface, and it is postulated to function also as an adhesion molecule necessary for successful implantation.²¹

Controlled invasion of the maternal vascular system by the trophoblast is necessary for the establishment of the hemochorial placenta. Studies with human placental villous explants suggest that chorionic villous cytotrophoblasts can differentiate along two distinct pathways: by fusing to form the syncytiotrophoblast layer or as extravillous trophoblasts that have the potential to invade the inner basalis layer of endometrium and the myometrium to reach the spiral arteries. Once trophoblasts have breached the endometrial blood vessels, decidualized stromal cells are believed to promote endometrial hemostasis by release of tissue factor and by thrombin generation.²²

Three growth factors have been implicated in the regulation of this process. Epidermal growth factor (EGF)²³ and interleukin-1 β ²⁴ stimulate invasion by the extravillous trophoblast, whereas transforming growth factor- β appears to inhibit the differentiation toward the invasive phenotype and serves to limit the invasiveness of extravillous trophoblast and to induce syncytium formation.²⁵ The process of invasion appears to peak by 12 weeks' gestation.²⁶ These trophoblasts proceed to form the chorionic villi, the functional units of the placenta, consisting of a central core of loose connective tissue and abundant capillaries connecting it with the fetal circulation. Around this core are

the outer syncytiotrophoblast layer and the inner layer of cytotrophoblast. In general, both cytotrophoblast and syncytiotrophoblast produce peptide hormones, whereas the syncytiotrophoblast produces all of the steroid hormones.

Human Chorionic Gonadotropin Production

Human chorionic gonadotropin (hCG) is one of the earliest products of the cells forming the embryo and should be viewed as one of the first embryonic signals elaborated by the embryo even before implantation.²⁷ This glycoprotein is a heterodimer (36 to 40 kDa). It is composed of a 92-amino acid α subunit that is homologous to thyroid-stimulating hormone, luteinizing hormone (LH), and follicle-stimulating hormone, and a 145-amino acid β subunit that is similar to LH. The α subunit gene for hCG has been localized to chromosome 6; the β subunit gene is located on chromosome 19, fairly close to the LH- β gene.

In contrast to LH, the presence of sialic acid residues on hCG- β accounts for its prolonged half-life in the circulation. After implantation, hCG is produced principally by the syncytiotrophoblast layer of the chorionic villus and is secreted into the intervillous space. Cytotrophoblasts are also able to produce hCG.

Clinically, hCG can be detected in either the serum or urine 7 to 8 days before expected menses and is the earliest biochemical marker for pregnancy (Fig. 8-2). In studies during IVF cycles in which embryos were transferred 2 days after fertilization, β -hCG was detected as early as the eight-cell stage, whereas intact hCG was not detectable until 8 days after egg retrieval. The increase in hCG levels between days 5 and 9 after ovum collection is principally the result of the production of free β -hCG, whereas by day 22 most of the circulating hCG is in the dimeric form.

These observations correspond to *in vitro* studies that indicate a two-phase control of dimer hCG synthesis mediated principally through a supply of subunits. In contrast to LH secretion in the pituitary gland, hCG is secreted constitutively as subunits are available and is not stored in secretory granules.²⁸ Initially, immature syncytiotrophoblast produces free β -hCG subunits, whereas the cytotrophoblast's ability to produce the α subunit appears to lag by several days.²⁹ As the trophoblast matures, the ratio of α subunits to β subunits reaches 1:1, and a peak of approximately 100,000 mU/mL is reached by the 9th or 10th week of gestation (Fig. 8-3). By 22 weeks' gestation, the placenta produces more of the α subunit than β -hCG. At term gestation, the ratio of α subunit to hCG release is approximately 10:1.³⁰

The exponential rise of hCG after implantation is characterized by a doubling time of 30.9 ± 3.7 hours.³¹ The hCG doubling time has been used as a characteristic marker by clinicians to differentiate normal from abnormal gestations (i.e., ectopic pregnancy). Most recent studies suggest that the rate of rise of hCG is more variable. An hCG rise of 35% over a 2-day interval will achieve the optimal sensitivity and specificity for differentiation of a normal pregnancy from a pregnancy of unknown location.³² The inability to detect an intrauterine pregnancy (gestational sac) by endovaginal ultrasound when serum hCG levels reach 1100 to 1500 mU/mL suggests an abnormal gestation or ectopic pregnancy. Higher than normal hCG levels may indicate a molar pregnancy or multiple-gestational pregnancies.

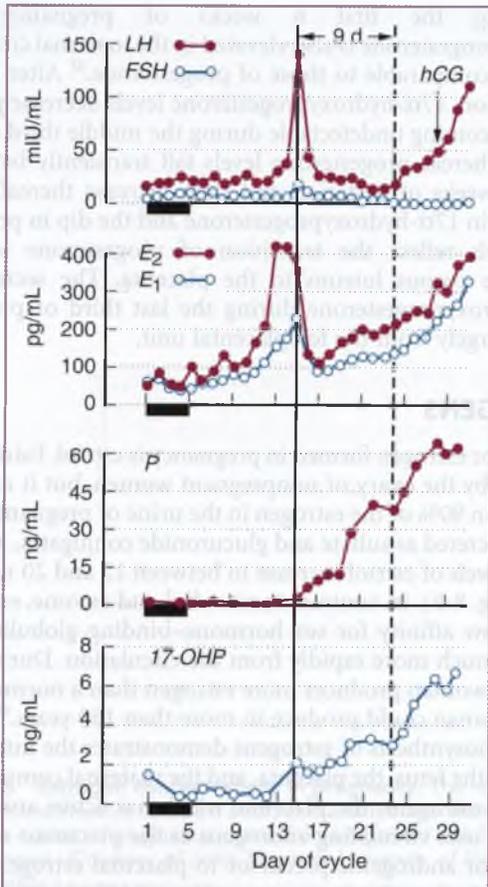

Figure 8-2 Hormone patterns during conception. Graphs show levels of luteinizing hormone (LH), follicle-stimulating hormone (FSH), estradiol (E_2), estrone (E_1), progesterone (P), and 17α -hydroxyprogesterone (17-OHP) during a conception cycle. Human chorionic gonadotropin (hCG) becomes detectable on cycle days 26 and 27. (Adapted with permission from S. S. C. Yen, MD, DSc, University of California, San Diego.)

Levels of hCG in combination with maternal α -fetoprotein and unconjugated estriol have been used as a screening test for detection of fetal anomalies (see Chapter 30).

Maintenance of Early Pregnancy: Human Chorionic Gonadotropin and Corpus Luteum of Pregnancy

The major biologic role of hCG during early pregnancy is to rescue the corpus luteum from premature demise while maintaining progesterone production. Although the secretory pattern of hCG is not well characterized, hCG is required for rescue and maintenance of the corpus luteum until the luteal-placental shift in progesterone synthesis occurs. This concept is supported by observations that immunoneutralization of hCG results in early pregnancy loss.^{33,34}

Studies in early pregnancy show that secretion of hCG and progesterone from the corpus luteum appears to be irregularly episodic with varying frequencies and peaks.^{35,36} In first-trimester explant experiments, intermittent gonadotropin-releasing hormone administration enhances the pulse-like

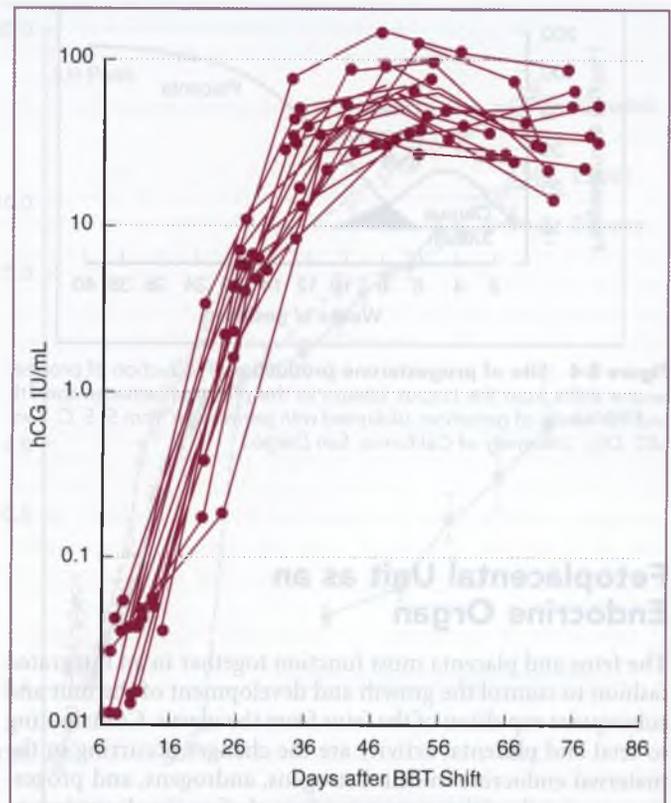

Figure 8-3 Levels of human chorionic gonadotropin (hCG) after implantation. The rise of circulating hCG is exponential during the first trimester of pregnancy, and the level plateaus between the 11th and 12th weeks of gestation. BBT, basal body temperature. (From Braunstein GD, Kamdar V, Rasor J, et al: A chorionic gonadotropin-like substance in normal human tissues, *J Clin Endocrinol Metab* 49:917-925, 1979. Copyright © by the Endocrine Society.)

secretion of hCG from these explants, indirectly implicating placental gonadotropin-releasing hormone as a paracrine regulator of hCG secretion.³⁷ In nonconception cycles, the corpus luteum is preprogrammed to undergo luteolysis, which is regulated through apoptotic mechanisms. Acting through the LH receptor, hCG is also able to stimulate parallel production of estradiol, 17 -hydroxyprogesterone, and other peptides, such as relaxin and inhibin, from the corpus luteum.

Timing of the Luteal-Placental Shift

Ovarian progesterone production is essential for maintenance of early pregnancy. If progesterone action is blocked by a competitive progesterone antagonist, such as mifepristone (RU-486), pregnancy termination results. During later gestation, placental production of progesterone is sufficient to maintain pregnancy. To uncover the timing of this luteal-placental shift, Csapo and colleagues performed corpus luteum ablation experiments. They demonstrated that removal of the corpus luteum before, but not after, the 7th week of gestation usually resulted in subsequent abortion.^{34,38} Removal of the corpus luteum after the 9th week appears to have little or no influence on gestation (Fig. 8-4). Thus, progesterone supplementation is required if corpus luteum function is compromised before 9 to 10 weeks of gestation.

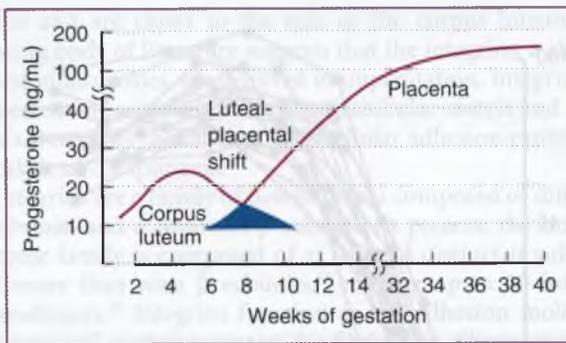

Figure 8-4 Site of progesterone production. Production of progesterone shifts from the corpus luteum to the placenta between the 7th and 9th weeks of gestation. (Adapted with permission from S. S. C. Yen, MD, DSc, University of California, San Diego.)

Fetoplacental Unit as an Endocrine Organ

The fetus and placenta must function together in an integrated fashion to control the growth and development of the unit and subsequent expulsion of the fetus from the uterus. Contributing to fetal and placental activity are the changes occurring in the maternal endocrine milieu. Estrogens, androgens, and progesterins are involved in pregnancy from before implantation to parturition. They are synthesized and metabolized in complex pathways involving the fetus, the placenta, and the mother.

The fetal ovary is not active and does not secrete estrogens until puberty. In contrast, the Leydig cells of the fetal testes are capable of production of large amounts of testosterone, so the circulating testosterone concentration in the first-trimester male fetus is similar to that in the adult man.³⁹ The initial stimulus of the testes is by hCG. Fetal testosterone is required for promoting differentiation and masculinization of the male external and internal genitalia. In addition, local conversion of testosterone to dihydrotestosterone by 5α -reductase localized in situ at the genital target tissues ensures final maturation of the external male genital structures. The maternal environment is protected from the testosterone produced by the male fetus because of the abundance of placental aromatase, which can convert testosterone to estradiol.

PROGESTERONE

During most of pregnancy, the major source of progesterone is the placenta; for the first 6 to 10 weeks, however, the major source of progesterone is the corpus luteum. Exogenous progesterone must be administered during the first trimester to oocyte recipients who have no ovarian function.^{40,41}

Progesterone is synthesized in the placenta mainly from circulating maternal cholesterol.⁴² By the end of pregnancy, the placental production of progesterone is about 250 mg/day, with circulating levels in the mother of about 130 to 150 ng/mL. In comparison, in the follicular phase, production of progesterone is about 2.5 mg/day; in the luteal phase, it is about 25 mg/day. About 90% of the progesterone synthesized by the placenta enters the maternal compartment. Most of the progesterone in the maternal circulation is metabolized to pregnanediol and is excreted in the urine as a glucuronide.

During the first 6 weeks of pregnancy, 17α -hydroxyprogesterone is also elevated in the maternal circulation at levels comparable to those of progesterone.⁴³ After 6 weeks of gestation, 17α -hydroxyprogesterone levels decrease progressively, becoming undetectable during the middle third of pregnancy, whereas progesterone levels fall transiently between 8 and 10 weeks of gestation and then increase thereafter. The decrease in 17α -hydroxyprogesterone and the dip in progesterone levels reflect the transition of progesterone secretion from the corpus luteum to the placenta. The secretion of 17α -hydroxyprogesterone during the last third of pregnancy occurs largely from the fetoplacental unit.

ESTROGENS

The major estrogen formed in pregnancy is estriol. Estriol is not secreted by the ovary of nonpregnant women, but it makes up more than 90% of the estrogen in the urine of pregnant women and is excreted as sulfate and glucuronide conjugates. Maternal serum levels of estriol increase to between 12 and 20 ng/mL by term (Fig. 8-5). In contrast to estradiol and estrone, estriol has a very low affinity for sex hormone-binding globulin and is cleared much more rapidly from the circulation. During pregnancy, a woman produces more estrogen than a normally ovulating woman could produce in more than 150 years.⁴³

The biosynthesis of estrogens demonstrates the interdependence of the fetus, the placenta, and the maternal compartment. To form estrogens, the placenta, which has active aromatizing capacity, uses circulating androgens as the precursor substrate. The major androgenic precursor to placental estrogen formation is dehydroepiandrosterone sulfate (DHEAS), which is the major androgen produced by the fetal adrenal cortex. DHEAS is transported to the placenta and is cleaved by sulfatase, which the placenta has in abundance, to form free unconjugated dehydroepiandrosterone, which is then aromatized by placental aromatase to estrone and estradiol. Very little estrone or estradiol is converted to estriol by the placenta. Near term, about 60% of the estradiol- 17β and estrone is formed from fetal androgen precursors, and about 40% is formed from maternal DHEAS.⁴⁴

The major portion of fetal DHEAS undergoes 16α -hydroxylation, primarily in the fetal liver but also in the fetal adrenal gland (Fig. 8-6). Fetal adrenal DHEAS in the circulation is taken up by syncytiotrophoblast cells, where steroid sulfatase, a microsomal enzyme, converts it back to DHEA that is then aromatized to estriol.⁴⁵ Estriol is then secreted into the maternal circulation and conjugated in the maternal liver to form estriol sulfate, estriol glucosiduronate, and mixed conjugates, which are excreted in the maternal urine.

In the past, maternal estriol measurements were often used as an index of fetoplacental function. However, numerous problems have been documented in interpreting low estriol levels, which has limited the use of estriol. The normal variation of urinary estriol concentrations at any given stage of gestation is quite large (typically, ± 1 standard deviation). A single plasma measurement is meaningless because of moment-to-moment fluctuations. Body position (e.g., bed rest, ambulation) affects blood flow to the uterus and kidney and therefore affects estriol levels. Moreover, numerous drugs, including glucocorticoids and ampicillin, affect estriol levels.

Estetrol is an estrogen unique to pregnancy. It is the 15α -hydroxy derivative of estriol and is derived exclusively from fetal precursors. Although the measurement of estetrol in

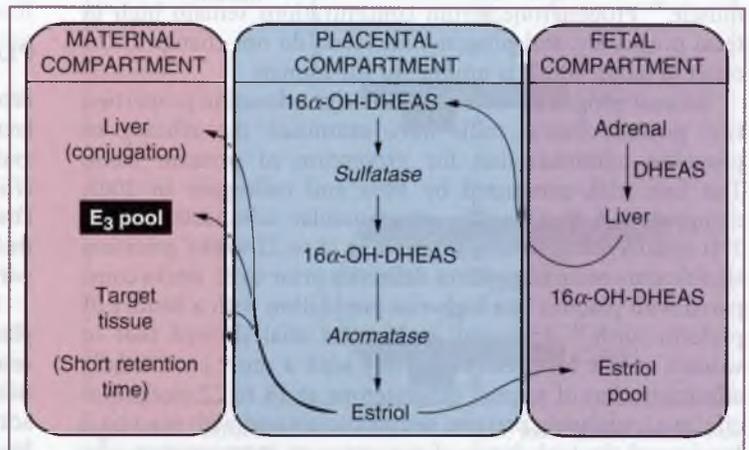

Figure 8-6 Roles of maternal, placental, and fetal compartments in the formation of estriol. Estriol (E₃) is formed in the placenta from the fetal precursor 16α-hydroxydehydroepiandrosterone sulfate (16α-OH-DHEAS). (Adapted with permission from S. S. C. Yen, MD, DSc, University of California, San Diego.)

pregnancy was proposed as an aid in monitoring a fetus at risk for intrauterine death, it has not proved to be any better than measurement of urinary estriol.⁴⁶ Neither estrogenic steroid is currently used in the clinical setting.

Hydroxylation at the C₂ position of the phenolic A ring results in the formation of so-called catecholestrogens (2-hydroxyestrone, 2-hydroxyestradiol, and 2-hydroxyestriol) and is a major step in estrogen metabolism. 2-Hydroxyestrone is excreted in maternal urine in the largest amounts during pregnancy, with marked individual variation (100 to

2500 mg/24 hr). Apparently, 2-hydroxyestrone levels increase during the first and second trimesters and decrease in the third trimester.⁴⁷ The physiologic significance of the catecholestrogens is unclear, particularly because they are rapidly cleared from the circulation; however, they do have the capacity to alter catecholamine synthesis and metabolism during pregnancy (inhibiting catecholamine inactivation via competition for carboxyl-O-methyl transferase and reducing catecholamine synthesis via inhibition of tyrosine hydroxylase). Catecholestrogens also function as antiestrogens, competing with estrogens

for their receptors. Thus, catecholestrogens, present in large quantities, may have significant effects in pregnancy. About 90% of the estradiol-17 β and estriol secreted by the placenta enters the maternal compartment. Estrone is preferentially secreted into the fetal compartment.⁴⁷

Two genetic diseases indicate that placental estrogen synthesis, at least at high levels, is not absolutely required for maintenance of pregnancy. Human gestation proceeds to term when the fetus and placenta lack sulfatase.⁴⁸ In this disorder, the gene has been localized to the distal short arm of the X chromosome, and the resulting male offspring manifest ichthyosis during the first few months of life. Pregnancies also reach term accompanied by severe fetal and placental aromatase deficiency.⁴⁹ Although pregnancy is maintained in both cases despite low placental estrogen synthesis, the changes in the reproductive tract that normally precede parturition, particularly ripening of the cervix, do not occur, revealing a significant role for placental estrogens in preparation for labor and birth. In addition, in the case of aromatase deficiency, both the fetus and the mother are virilized as a consequence of diminished aromatization of androgens.

Low levels of estrogens also occur after fetal demise and in most anencephalic pregnancies, in which fetal signals from the fetal hypothalamic-pituitary unit are diminished and do not stimulate synthesis of fetal adrenal androgens. In the absence of a fetus, as occurs in molar pregnancy and in pseudocyesis, estrogen levels are low as well.

ROLE OF PROGESTINS DURING PREGNANCY AND PARTURITION

Progesterone appears to be important in maintaining uterine quiescence during pregnancy by actions on uterine smooth muscle.⁵⁰ Progesterone serum concentrations remain high in term pregnancy, and progesterone levels do not change at the onset of labor, which is unique for the human.

Because progestins have potent uterine relaxation properties, two pivotal clinical trials have examined the efficacy of progestin administration for prevention of preterm labor. The first trial, conducted by Meis and colleagues in 2003, demonstrated that weekly intramuscular administration of 17 α -hydroxyprogesterone caproate at 18 to 22 weeks' gestation significantly reduced preterm deliveries prior to 37 weeks compared with placebo in a high-risk population with a history of preterm birth.⁵¹ A second multicenter trial showed that in women at risk for preterm delivery with a short cervix, daily administration of vaginal progesterone at 18 to 22 weeks was effective in delaying preterm delivery compared with placebo.⁵² In view of the high levels of progesterone in pregnancy, why would additional progesterone administration modify preterm labor and its attendant risks?

Progesterone regulates uterine contractions by acting through its two major nuclear progesterone receptor (PR) subtypes PR-A and PR-B.⁵³ PR-A appears to repress progesterone actions mediated by the PR-B. At the time of labor, there is an increase in expression of PR-A.⁵⁴ Putting the clinical evidence and the basic science findings together, the current working concept is that the ratio of PR-A to PR-B in myometrial tissue may predict the overall uterine contractile state. When the level of PR-B exceeds that of PR-A, progesterone promotes uterine relaxation and expression of anti-inflammatory genes. When the level of PR-A expression exceeds that of PR-B (such as during parturition),

the proinflammatory pathway genes are activated and the uterine contractile phenotype becomes prevalent.^{55,56}

Progesterone also inhibits uterine prostaglandin production,⁵⁷ presumably promoting uterine quiescence and delaying cervical ripening. Progesterone may also help to maintain pregnancy by inhibiting T-lymphocyte-mediated processes that play a role in tissue rejection.⁵⁸ Thus, the high local concentrations of progesterone appear to contribute to the immunologically privileged status of the pregnant uterus. Progesterone is important in the creation of a cervical mucus barrier that prevents pathogens from penetrating the uterus.

ROLE OF ESTROGENS IN PREGNANCY

Estrogens are important for increasing the uterine capability to be in the contractile mode at the onset of labor. The stimulatory effects of estrogen on phospholipid synthesis and turnover, prostaglandin production, and increased formation of lysosomes in the uterine endometrium, as well as estrogen modulation of adrenergic mechanisms in uterine myometrium, may be the means by which estrogens act to time the onset of labor.⁵⁹ At the cellular level, estrogens promote the uterine contractile state through increased formation of gap junctions. Estrogens also increase uterine blood flow,⁶⁰ which ensures an adequate supply of oxygen and nutrients to the fetus. It appears that estriol, an extremely weak estrogen, is as effective as other estrogens in increasing uteroplacental blood flow.⁶⁰

Estrogens are important in preparing the breast for lactation.⁶¹ Other endocrine systems during pregnancy, such as the renin-angiotensin system,⁶² as well as production of hormone-binding globulins in the liver are increased through estrogen action. Estrogens may play a role in fetal development and organ maturation, including increasing fetal lung surfactant production.⁶³

PLACENTA AND GROWTH FACTORS

From a teleologic perspective, the placenta elaborates growth factors to allow diversion of maternal resources for fetal growth and cellular differentiation. The general processes that are affected include regulation of glucose and amino acid transport, DNA synthesis and cell replication, and RNA and protein synthesis. These processes may be regulated in an autocrine or a paracrine mode in the placenta.

In the absence of sufficient maternal resources (and despite placental mechanisms), fetal growth follows a lower trajectory, resulting in intrauterine growth restriction. This clinical condition has been associated with the "thrifty phenotype" in the adult, a hypothesis first proposed by David J. P. Barker (Barker hypothesis). Individuals with this phenotype are at risk for a variety of chronic diseases, such as type 2 diabetes, coronary vascular disease, hypertension, and stroke.⁶⁴ It is postulated that these associated changes in affected adults involve (1) insufficient maternal resources while the fetus is in utero, (2) effects on the regulation of key placental growth factor mechanisms, and (3) long-term changes thought to represent epigenetic variations in placental growth-factor functions that can be transmitted genetically.

Although much of the research has been conducted in other mammalian systems and may not be directly applicable to humans, major similarities probably exist in the way growth factors operate to ensure continuing growth and development of the fetus.

IFN, interferon; IGF, insulin-like growth factor; IGFBP, insulin-like growth factor-binding protein; IL, interleukin.

For humans, most of our knowledge has been limited to descriptive studies demonstrating localization of many growth factor systems. Our understanding of their functional roles has only begun. Table 8-2 is a partial listing of growth factors that have been identified in the placenta. A detailed description of their respective roles is beyond the scope of this chapter. Only major growth factor systems are discussed.

Insulin-Like Growth Factor, Epidermal Growth Factor, and Transforming Growth Factor- α

In preimplantation embryos, the insulin-like growth factor (IGF) (Fig. 8-7), the transforming growth factor- α , and the EGF systems have been studied extensively. In general, IGF-2 and IGF-1 receptors are primarily responsible for regulation of cell proliferation, whereas cell differentiation is regulated by the transforming growth factor- α and EGF-receptor systems.

IGF-1 appears to be an important modulator of fetal growth. It is normally produced by the liver in response to pituitary growth hormone (GH). In pregnancy, the levels of IGF-1 may be regulated in part by placental GH, a variant of pituitary GH. Fetal cord plasma IGF-1 levels are positively correlated to birth weight and length of the fetus.^{65,66} IGF-2 levels are decreased in animal and human modeling based on data from fetal-growth-restricted pregnancies.⁶⁷

EGF and transforming growth factor- α in the placenta both interact with the EGF receptor. Both growth factors are present in cytotrophoblasts and syncytiotrophoblasts. In the latter cells, EGF stimulates secretion of hCG and human placental lactogen.⁶⁸ The proliferative activities induced by a number of growth factors appear to overlap. These factors include IGF, platelet-derived growth factors, EGF, and fibroblastic growth factors.

Human Chorionic Somatomammotropin

Human chorionic somatomammotropin (hCS), initially named human placental lactogen when it was isolated from the human placenta in the 1960s,⁶⁹ has structural, biologic, and immunologic similarities to both pituitary human growth hormone (hGH) and prolactin. hCS is now known to be a single-chain polypeptide (~22 kDa) containing 191 amino acids and two disulfide bonds. It shares up to 96% homology with GH and about 67% homology with prolactin.^{70,71} The hCS/hGH gene

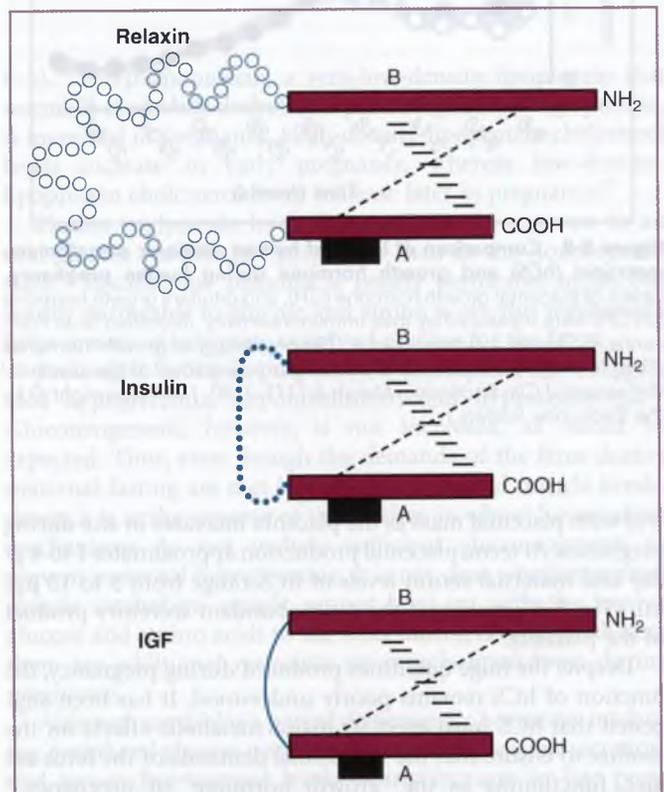

Figure 8-7 Structural similarities of relaxin, insulin, and insulin-like growth factor (IGF). A and B chains are linked by disulfide bonds. (Adapted with permission from S. S. C. Yen, MD, DSc, University of California, San Diego.)

cluster has been localized to the long arm of chromosome 17 and consists of five genes, two coding for hGH and three for hCS.⁷² Two of the three hCS genes are expressed at approximately equivalent rates in term placenta and synthesize identical proteins, and the third gene appears to be a pseudogene.⁷³

hCS is produced only by syncytiotrophoblast cells and appears to be transcribed at a constant rate throughout gestation.^{74,75} As a consequence, serum levels of hCS correlate very

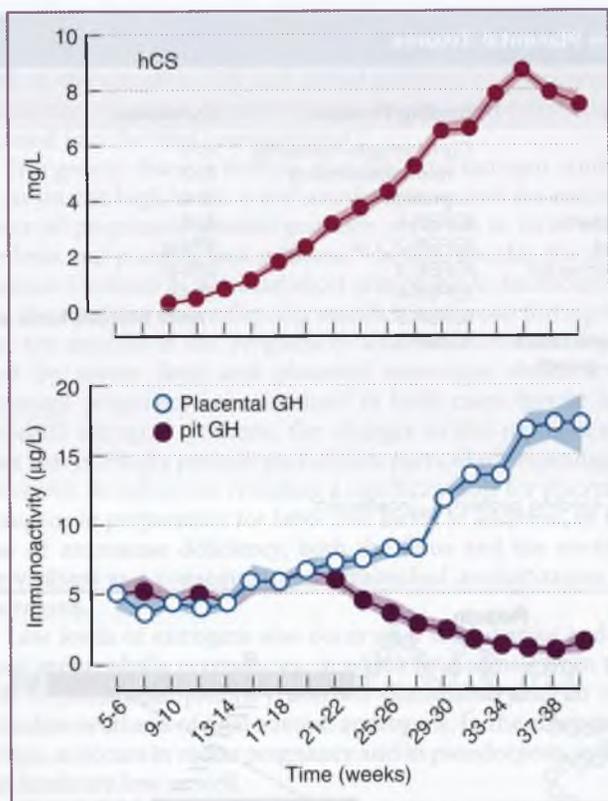

Figure 8-8 Comparison of levels of human chorionic somatomammotropin (hCS) and growth hormone during human pregnancy. Levels of placental growth hormone (GH), and pituitary growth hormone (pit GH) were measured by their immunoreactivity. (Modified from Franckene F, Closset J, Gomez F, et al: *The physiology of growth hormones [GHs] in pregnant women and partial characterization of the placental GH variant*, *J Clin Endocrinol Metab* 6:1171-1180, 1988. Copyright © by the Endocrine Society.)

well with placental mass as the placenta increases in size during pregnancy. At term, placental production approximates 1 to 4 g/day and maternal serum levels of hCS range from 5 to 15 µg/mL (Fig. 8-8), making it the most abundant secretory product of the placenta.

Despite the huge quantities produced during pregnancy, the function of hCS remains poorly understood. It has been suggested that hCS must exert its major metabolic effects on the mother to ensure that the nutritional demands of the fetus are met, functioning as the “growth hormone” of pregnancy.⁷⁶ During pregnancy, maternal plasma glucose levels are decreased, plasma free fatty acids are increased, and insulin secretion is increased with resistance to endogenous insulin as a consequence of the GH-like and contra-insulin effects of hCS (Fig. 8-9). Peripheral glucose uptake is inhibited in the mother but glucose crosses the placenta freely. Amino acids are actively transported to the fetus against a concentration gradient, and transplacental passage of free fatty acids is slow. As a consequence, when the mother is in the fasting or starved state, glucose is reserved largely for the fetus and free fatty acids are used preferentially by the mother. The placenta is impermeable to insulin and other protein hormones.

Despite these observations, the regulation of hCS is poorly understood. Factors that regulate pituitary GH secretion are largely ineffective in altering concentrations of hCS. In

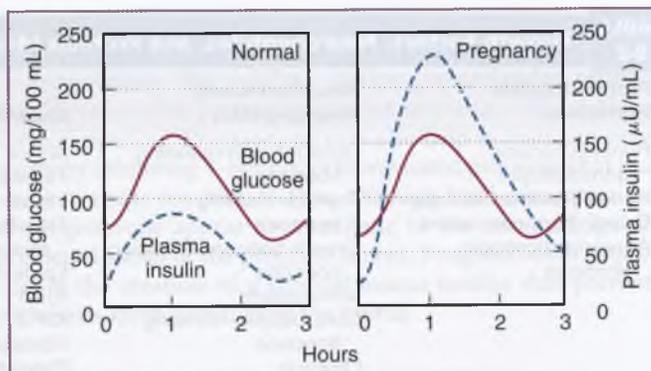

Figure 8-9 Insulin response to oral glucose. Comparison of the plasma insulin response to an oral glucose load (100 g) in nonpregnant (“normal”) women and in women during late pregnancy. (Adapted with permission from S. S. C. Yen, MD, DSc, University of California, San Diego.)

addition, despite its structural homology to GH and prolactin, hCS has very little (although definite) growth-promoting and lactogenic activity in humans.⁷⁶ Moreover, normal pregnancies resulting in the delivery of healthy infants have been reported in individuals with very low to absent production of hCS.^{77,78} Thus, it is possible that hCS is not essential for pregnancy but may serve as an evolutionary redundancy and backup system for pituitary GH and prolactin. Whether pregnancies with diminished hCS production would have good outcomes in the presence of nutritional deprivation, however, remains unknown.

Human Placental Growth Hormone

The two forms of human placental GH are a 22-kDa form and a glycosylated 25-kDa form. Both are encoded by the *hGH-V* gene in the hCS/hGH gene cluster on chromosome 17.^{79,80} Pituitary hCG is encoded by the *hGH-N* gene in the same gene cluster.⁸¹

During the first trimester, pituitary GH is measurable in maternal serum and is secreted in a pulsatile fashion.⁸² Human placental GH levels begin to rise thereafter as pituitary GH levels decrease; human placental GH is secreted in a relatively constant (in contrast to a pulsatile) manner.⁸² It appears that human placental GH stimulates IGF-1 production, which in turn suppresses pituitary GH secretion in the second half of pregnancy.⁸³

Endocrine-Metabolic Changes in Pregnancy

Pregnancy is accompanied by a series of metabolic changes, including hyperinsulinemia, insulin resistance, relative fasting hypoglycemia, increased circulating plasma lipids, and hypoaminoacidemia. All these changes seem intended to ensure an uninterrupted supply of metabolic fuels to the growing fetus, and they are directed by hormones elaborated by the fetoplacental unit.

The insulin resistance associated with pregnancy is accompanied by maternal islet cell hyperplasia (Fig. 8-10). The mechanism responsible for increasing insulin resistance throughout pregnancy is not entirely clear. It appears that hCS and human

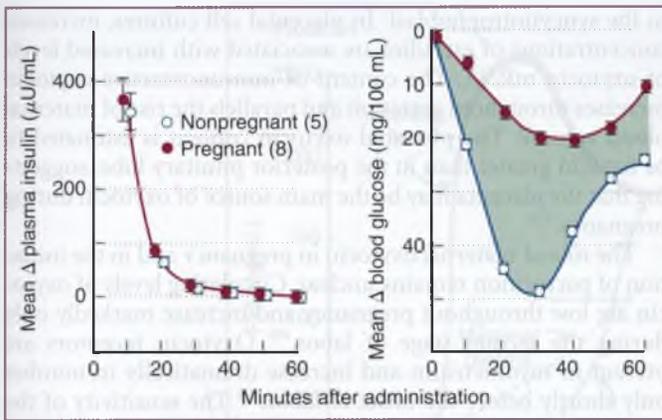

Figure 8-10 Insulin resistance in pregnancy. Left, Almost identical curves show disappearance of circulating insulin after a bolus intravenous insulin injection (0.1 U/kg) in pregnant and nonpregnant women. Right, The marked decline in blood glucose in response to exogenous insulin in nonpregnant as compared with pregnant women suggests increased insulin resistance in the latter group. placental GH in particular reduce insulin receptor sites and glucose transport in insulin-sensitive tissues in the mother (Fig. 8-11).⁸⁴ There is no evidence that glucagon plays a significant role as a diabetogenic factor. The rapid return to normal glucose metabolism after delivery in women with gestational diabetes has been regarded as the best evidence that fetoplacental hormones are largely diabetogenic in the mother.⁸⁵

Total plasma lipids increase significantly and progressively after 24 weeks of gestation, with the increases in triglycerides, cholesterol, and free fatty acids being most marked (Table

TABLE 8-3 Basal Values for Insulin, Glucagon, and Metabolic Fuels in Plasma of Young Women after Overnight Fast

Compound Measured	Nongravid	Late Pregnancy
Glucose* (mg/dL)	79 ± 2.4	68 ± 1.5

Data from Freinkel N, Metzger BE, Nitzan M, et al: Facilitated anabolism in late pregnancy: some novel maternal compensations for accelerated starvation. In Malaisse WJ, Pirart J, editors: *Diabetes. International series no. 312. Amsterdam, 1973, Excerpta Medica, pp 474–488.*

8-3).⁸⁶ Pre-β-lipoprotein, a very-low-density lipoprotein that normally represents a very small percentage of total lipoprotein, is increased in pregnancy. High-density-lipoprotein cholesterol levels increase in early pregnancy, whereas low-density-lipoprotein cholesterol levels increase later in pregnancy.⁸⁷

Plasma triglyceride levels increase more in response to an oral glucose load in late pregnancy than in the nonpregnant state.⁸⁶ Because the placenta is poorly permeable to fat but readily permeable to glucose and amino acids, this mechanism helps ensure an adequate supply of glucose for the fetus.

Prolonged fasting in pregnancy is accompanied by exaggerated hypoglycemia, hypoinsulinism, and hyperketonemia.⁸⁸ Gluconeogenesis, however, is not increased, as would be expected. Thus, even though the demands of the fetus during maternal fasting are met in part by accelerated muscle breakdown, it is at the expense of the mother, in whom homeostatic mechanisms do not include sufficient gluconeogenesis to prevent maternal hypoglycemia. It is not clear whether normal muscle catabolism simply cannot keep up with the loss of glucose and amino acids to the fetus during fasting or whether there are additional restraints on muscle breakdown during pregnancy.

Although cortisol is a potent diabetogenic hormone, inhibiting peripheral glucose uptake and promoting insulin secretion, and serum free cortisol levels clearly increase in late pregnancy,^{89,90} it is unclear just how great a role cortisol plays in the diabetogenic nature of pregnancy. The increased circulating concentrations of estrogen and progesterone in pregnancy may also be important in the altered glucose-insulin homeostasis present during pregnancy.

INHIBIN-RELATED PROTEINS

The human placenta has the capacity to synthesize inhibin, activin, and follistatin.⁹¹ Inhibin is a dimeric protein composed of an α subunit (18 kDa) and a β subunit (14 kDa), originally shown to have an inhibitory effect on pituitary follicle-stimulating hormone release. Two different β subunits have been characterized and have been designated as β_A and β_B. Each different β subunit can thus give rise to two different inhibins

(inhibin A, β_A , and inhibin B, β_B). Activin is a closely related protein that was discovered soon after inhibin and was named because of its ability to stimulate pituitary follicle-stimulating hormone release.

Activin is composed of two β subunits. All three possible configurations of activin have been identified— $\beta_A\beta_A$, $\beta_A\beta_B$, and $\beta_B\beta_B$. Follistatin is a single-chain glycoprotein that can functionally inhibit pituitary follicle-stimulating hormone release by the binding of activin. Besides the human trophoblast, the maternal decidua, amnion, and chorion have been demonstrated to express mRNAs and immunoreactive proteins for inhibin, activin, and follistatin.

High levels of inhibin-like proteins have been reported in patients with fetal Down syndrome⁹² and in patients with hydatidiform mole⁹³; low levels have been observed in women with abnormal gestations, such as ectopic pregnancies,⁹⁴ and pregnancies that end in abortion.⁹⁵ High levels of maternal activin A have been observed in pregnancies complicated by pre-eclampsia, diabetes, and preterm labor.⁹¹

At this point, there are no *in vivo* models to use in studying the functional roles of inhibin-related proteins on placental hormone secretion, so the biologic roles of this system have been derived from *in vitro* cell cultures. In cultured placental cells, activin appears to increase the release of hCG and progesterone,⁹⁶ whereas inhibins decrease hCG and progesterone levels. Follistatin has been reported to reverse the activin-induced release of hCG and progesterone. These regulatory events appear to be parallel to that of the pituitary gland, where activin increases follicle-stimulating hormone release, whereas follistatin and inhibin oppose this effect.

CORTICOTROPIN-RELEASING HORMONE AND CORTICOTROPIN-RELEASING HORMONE-BINDING PROTEIN SYSTEM

The placenta, chorion, amnion, and decidua are all capable of synthesizing corticotropin-releasing hormone (CRH). This 41-amino acid peptide was first isolated from the hypothalamus and is responsible for stimulation of adrenocorticotropic hormone and proopiomelanocortin peptides from the pituitary. CRH is detectable by 7 to 8 weeks' gestation,⁹⁷ and maternal plasma levels of CRH rise progressively throughout gestation.⁹⁸ Maternal CRH levels increase significantly with labor, reaching a peak at delivery; levels remain stable in the absence of labor with cesarean section.⁹⁹ In the term placenta, CRH has been localized to both cytotrophoblast and syncytiotrophoblast.¹⁰⁰ The addition of CRH to human placental cells or amnion stimulates release of prostaglandin E and prostaglandin $F_{2\alpha}$, suggesting that locally elaborated CRH plays a major role in the initiation of myometrial contractility and labor.¹⁰¹

CRH-binding protein has also been identified in the placenta and appears to be produced by syncytiotrophoblast,¹⁰² decidua, and fetal membranes.¹⁰³ This protein conceptually functions as a CRH receptor in the circulation, reduces the biologic activity of CRH, and thus may serve a modulatory role for localized CRH action.

OXYTOCIN

Oxytocin, a nonapeptide produced by the supraoptic and paraventricular nuclei of the hypothalamus, has also been localized

to the syncytiotrophoblast. In placental cell cultures, increased concentrations of estradiol are associated with increased levels of oxytocin mRNA. The content of immunoreactive oxytocin increases throughout gestation and parallels the rise of maternal blood volume. The placental oxytocin content is estimated to be fivefold greater than in the posterior pituitary lobe, suggesting that the placenta may be the main source of oxytocin during pregnancy.¹⁰⁴

The role of maternal oxytocin in pregnancy and in the initiation of parturition remains unclear. Circulating levels of oxytocin are low throughout pregnancy and increase markedly only during the second stage of labor.¹⁰⁵ Oxytocin receptors are present in myometrium and increase dramatically in number only shortly before the onset of labor.¹⁰⁶ The sensitivity of the myometrium, therefore, changes more dramatically in preparation for labor than do the circulating levels of the hormone. Oxytocin also can stimulate the production of prostaglandins by human decidua.¹⁰⁷ These data do not support a major role for oxytocin in triggering the onset of parturition and imply that it is unlikely to be the key initiator of human parturition (see Progesterone, earlier).

RELAXIN

Relaxin, a peptide hormone of approximately 6 kDa, belongs to the insulin family. It is composed of two disulfide-linked chains, A and B (see Fig. 8-7). Relaxin is produced in a number of sites, including the corpus luteum in pregnant and nonpregnant women, the decidua, the placenta, the prostate, and the atria of the heart.

Relaxin first appears in the serum of pregnant women in the same time frame as hCG. Levels during pregnancy are approximately 1 ng/mL. Relaxin concentrations are highest during the first trimester and peak at about 1.2 ng/mL between the 8th and 12th weeks of pregnancy and then gradually decrease to 1 ng/mL for the remainder of the pregnancy.¹⁰⁸ There is no evidence of any circadian rhythm, and no significant changes have been noted during labor.

Available evidence suggests that all relaxin circulating in the mother during pregnancy is of luteal origin. The relaxin concentration is highest in the blood draining the corpus luteum.¹⁰⁹ By immunohistochemistry profiles, relaxin can be detected only in the corpus luteum of the ovary. Luteectomy at term results in a prompt fall in circulating relaxin with a half-life of less than 1 hour. In the absence of luteectomy, relaxin levels fall to undetectable levels within the first 3 days after delivery, consistent with the time frame for postpartum luteolysis. Perhaps most convincing is the observation that relaxin is undetectable in the serum of women pregnant by IVF and egg donation who have no corpora lutea.^{110,111}

Relaxin appears to have a broad range of biologic activities. These include collagen remodeling and the resultant softening of the cervix and lower reproductive tract, and inhibition of uterine contractility.¹¹² However, circulating relaxin does not seem to be necessary for pregnancy maintenance or normal delivery in women. Women who become pregnant by egg donation undergo spontaneous labor at term and are capable of delivery vaginally.¹¹⁰ It is possible, however, that the placenta and decidua may provide sufficient relaxin for normal parturition under such circumstances.

Two conditions associated with an increase in circulating relaxin levels are multiple gestation and ovarian stimulation

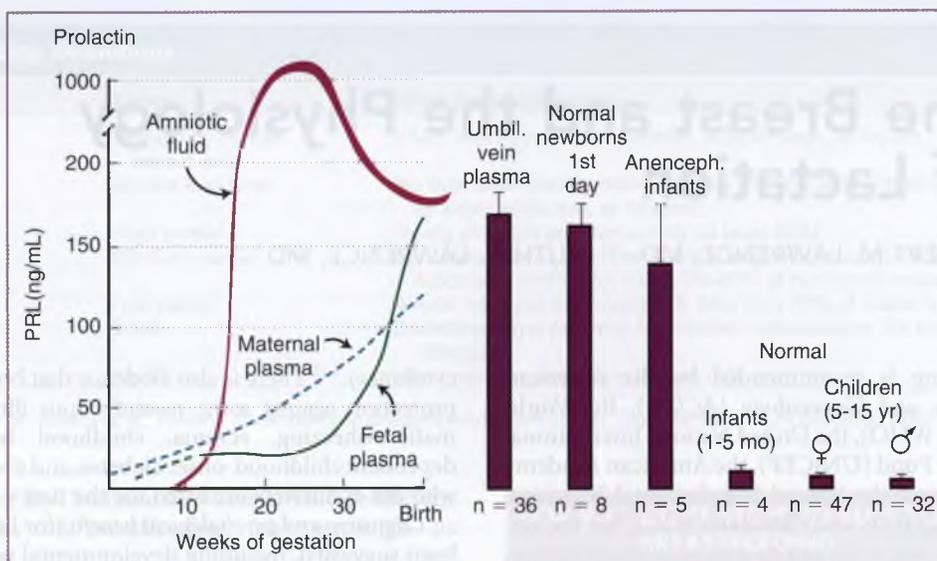

Figure 8-12 Prolactin levels in pregnancy. Approximate levels of prolactin (PRL) in amniotic fluid, maternal plasma, and fetal plasma during the course of pregnancy. Bars allow comparison of prolactin plasma levels in normal and anencephalic newborns with levels in normal infants and children. (Modified from Aubert ML, Grumbach MM, Kaplan SL: *The ontogenesis of human fetal hormones: III. Prolactin*, J Clin Endocrinol Metab 56:155–164, 1975. Copyright © by the Endocrine Society.)

with the use of ovulation-inducing agents. Relaxin concentrations are higher in patients who become pregnant from IVF and exogenous gonadotropin treatment than in untreated pregnant control subjects. In both circumstances, there are multiple ovulation sites with multiple corpora lutea, and multiple gestations each producing an additional increase in serum relaxin concentrations. Multiple gestations are associated with a higher risk of premature delivery, according to one group who suggested that first-trimester hyperrelaxinemia can predict the risk of preterm delivery.¹¹³ This observation, potentially important, warrants further investigation.

PROLACTIN IN PREGNANCY

During the first trimester of pregnancy, maternal serum prolactin levels rise progressively to achieve levels of approximately 125 to 180 ng/mL (Fig. 8-12).¹¹⁴ The dramatic 10-fold increase in prolactin levels is believed to be a reflection of the estrogen-stimulated increase in size of the pituitary lactotropes, which contributes to a two- to threefold enlargement of pituitary volume. Despite the increased magnitude of prolactin concentrations during pregnancy, the normal sleep-associated increase in prolactin remains preserved.¹¹⁵ At delivery, the higher level of prolactin is responsible for priming the breast tissue in preparation for lactation.

After delivery, prolactin levels remain elevated at 200 to 250 ng/mL and fall gradually toward the normal range (<25 ng/mL) during a 3- to 4-week interval in nonbreastfeeding mothers.¹¹⁶ In women who are breastfeeding, prolactin levels remain elevated and increase with each nursing episode. This constant hyperprolactinemic state may be partly responsible for the delay in return of ovulatory function in the breastfeeding woman.

The decidua is the major source of amniotic fluid prolactin. Decidual cells are capable of secretion of prolactin after day 23

of the menstrual cycle. Decidual prolactin is immunologically identical to the 23-kDa prolactin produced by the pituitary gland, and the complementary DNA from decidua appears virtually identical to pituitary prolactin.^{117,118} Unlike the pituitary gland, decidual prolactin is not regulated by dopamine or thyrotropin-releasing hormone. The decidual prolactin synthesis is coupled to progesterone-induced decidualization. Once cells are stimulated to decidualize, prolactin production continues in culture even in the absence of progesterone. Because abnormal levels of amniotic fluid prolactin levels have been found in pregnancies complicated by polyhydramnios or oligohydramnios, it is believed that the biologic role of locally produced prolactin is to regulate solute and water transport in the amniotic compartment.¹¹⁹

PROSTAGLANDINS

Although concentrations of prostaglandin precursors are high in the endometrial compartment during pregnancy, there is a marked decrease in the production of prostaglandins by the endometrial decidua. Levels of cyclooxygenase-1, the constitutively expressed cyclooxygenase enzyme, fall precipitously during the mid-luteal phase of the menstrual cycle at the time of implantation. Under the influence of progesterone, the endometrial decidua produces secretory component, an endogenous inhibitor of prostaglandin synthesis.¹²⁰ The exogenous administration of prostaglandins is capable of inducing abortion or labor in all species, including humans. Taken together, these observations suggest multiple mechanisms that inhibit prostaglandin production during pregnancy. Progesterone may be one factor that suppresses synthesis of prostaglandins.

The Breast and the Physiology of Lactation

ROBERT M. LAWRENCE, MD | RUTH A. LAWRENCE, MD

Universal breastfeeding is recommended by the American College of Obstetrics and Gynecology (ACOG), the World Health Organization (WHO), the United Nations International Children's Emergency Fund (UNICEF), the American Academy of Pediatrics (AAP), and the Special Supplemental Nutrition Program for Women, Infants and Children (WIC), but recommendations alone are not sufficient to promote breastfeeding. It is the responsibility of every physician to recommend and support breastfeeding enthusiastically. This is especially true in obstetrics, where a physician's advice can immediately influence a woman's informed decision concerning breastfeeding and create or diminish barriers to successful breastfeeding.

Benefits of Breastfeeding

Breastfeeding provides significant benefits for both the mother and the infant. A number of these benefits are documented in an evidence-based analysis in the Agency for Healthcare Research and Quality (AHRQ) Report on Breastfeeding in Developed Countries.^{1,2} The benefits are so significant that the AAP and the ACOG recommend exclusive breastfeeding for the first 6 months of life and continued breastfeeding through 12 months or more.

*Breast milk is species specific, made uniquely for the human infant.*³ Protein in breast milk is readily digested and is present in amounts that can be handled by the developing kidney. Various minerals (e.g., iron) and nutrients exist in a form that, in conjunction with other components, make them easily absorbed to meet infants' needs during periods of rapid growth.^{3,4} Cholesterol and docosahexaenoic acid have been shown to play a role in central nervous system development and may contribute to the enhanced intelligence quotient measurements reported in breastfed infants.⁵⁻⁷

Protection against infections, including otitis media, croup, pneumonia, and gastrointestinal infections, is mediated by the more than 50 immunologically active components found in breast milk.^{3,8} These immunologically active components include viable functioning cells (T and B lymphocytes, macrophages), T cell–secreted products, immunoglobulins (especially secretory IgA), carrier proteins such as lactoferrin and transferrin, enzymes (lysozyme and lipoprotein lipase), and nonspecific factors such as complement, bifidus factor, gangliosides, and nucleotides. Other immune factors in breast milk include hormones, hormone-like factors, and growth factors that contribute to the normal maturation of the mucosal barrier of the respiratory and gastrointestinal tracts as well as the infant's developing immune system. Breast milk is a very dynamic fluid, varying with the mother-infant dyad's environment and needs, especially in the face of infection or stress (providing, for example, nucleotides, secretory IgA, interleukin, interferon, and

cytokines).⁹⁻¹² There is also evidence that breastfeeding provides protection against some noninfectious illnesses such as asthmatic wheezing, eczema, childhood lymphoma, insulin-dependent childhood-onset diabetes, and obesity^{8,12-17} in children who are exclusively breastfed for the first 4 to 6 months of life.

Cognitive and psychological benefits for breastfed infants have been suggested, including developmental performance,¹⁸ visual acuity,¹⁹⁻²¹ school performance,²² and performance on standardized²² and intelligence quotient⁶ tests. More recent articles continue to support the impact of breastfeeding on intellectual development while fostering debate over the relative contributions of nutrition, genetics, and environment to the intellectual development of infants and the possible influence on the child's or adult's future cognitive abilities as measured by intelligence quotient testing.^{23,24} The psychological benefits are more difficult to measure but are well described by Newton and Newton,²⁵ and indeed by most mothers who have successfully breastfed their infants. One of the most consistent findings of exclusive breastfeeding is its influence on later intelligence, with a few test point advantages to the breastfed infant.⁷ Reports questioning this effect have been based on *any* breastfeeding, not *exclusive* breastfeeding.²⁶

Potential benefits to the mother include improved postpartum recovery,²⁷ a lower incidence of subsequent obesity,²⁸ a decreased risk of osteoporosis, increased spacing between births, lower cost of providing adequate infant nutrition, and reduced incidence of both breast and ovarian cancers.²⁹ Calcium and phosphorus concentrations are higher in lactating women, and the risk of osteoporosis is measurably less for women who have breastfed their infants.^{30,31} Increasing number of pregnancies, longer oral contraceptive use, and increasing duration of lactation are all protective against ovarian cancer.³²⁻³⁴ The incidence of breast cancer is lower among women who have nursed.^{35,36}

There is a dose-response relationship between the amount of breast milk received by an infant and the benefits or immunologic protection gained. The benefits to the mother from breastfeeding also relate to the duration of breastfeeding. The relative "dose" of breast milk has been described in terms of exclusivity versus the amount of supplementation, by the use of definitions of breastfeeding (Table 9-1).³⁷ The importance of this dose-response relationship is emphasized by ACOG and AAP's recommendation for exclusive breastfeeding in the first 6 months of life, and by the AHRQ Report analysis of the benefits of breastfeeding relative to measured durations of breastfeeding.^{1,2,8}

It is essential that a discussion of the benefits of breastfeeding to infants, mothers, and families (fathers included) be presented alongside any potential risks or contraindications. The benefits of breastfeeding are tremendous, and the risks and

TABLE 9.1 Breastfeeding Definitions

Category	Terms	What the Infant Ingests
Full breastfeeding	Exclusively human breast milk	Infant ingests no other nutrients, supplements, or liquids
	Almost exclusive	No milk other than human milk; only minimal amounts of other substances such as water, juice, tea, or vitamins
Partial breastfeeding	High partial	Nearly all feeds are human milk (at least 80%)
	Medium partial	A moderate amount of feeds are breast milk, in combination with other nutrient foods and nonhuman milk (20%-80% of nutritional intake is human breast milk)
Token breastfeeding	Low partial	Almost no feeds are breast milk (less than 20% of intake is breast milk)
	Token	Breastfeeding is primarily for comfort; non-nutritive, for short periods of time, or infrequent
No breastfeeding	No BF	Infant never ingested any human milk

Adapted from Lobbok M, Krasovec K: Toward consistency in breastfeeding definitions, *Stud Fam Plann* 21:226–230, 1990.

contraindications are few. Summarized here are the conditions in which the risks of breastfeeding may outweigh its benefits.³⁸

- Women who take street drugs or who do not control their alcohol intake.
- A woman who has an infant with galactosemia, because both human and cow's milk may exacerbate the condition. A lactose-free formula is recommended for these infants. In milder forms of galactosemia, partial breastfeeding is possible.
- Women who are infected with the human immunodeficiency virus (HIV) (see Maternal Infections during Breastfeeding, later).
- Women who have active, untreated tuberculosis. Because of the increased risk of airborne transmission associated with the close contact that is typical of breastfeeding, women with active tuberculosis should not feed their infant by any method until treatment is initiated. However, infected women can provide their pumped milk to their infants (see later).
- Women who are known or suspected to be infected with Ebola or Marburg virus or Lassa fever (see later).
- Women who take certain medications (see Medications while Breastfeeding, later).

Medical situations that indicate a potential risk from breastfeeding must be weighed against the benefits of breastfeeding in each mother-infant dyad's unique situation.

ROLE OF THE OBSTETRICIAN IN PROMOTING BREASTFEEDING

Obstetricians have many responsibilities for breastfeeding, including the following:

- Enthusiastic promotion and support for breastfeeding, based on the published literature describing its benefits as advocated by the major pediatric, obstetric, and women's health organizations³⁹
- Imparting clinical information to the lactating mother about the physiology of lactogenesis⁴⁰ and lactation, before and after the birth
- Developing and supporting hospital policies that facilitate breastfeeding and actively remove any barriers to it
- Supporting community efforts to provide women with adequate information to make an informed decision about breastfeeding, including links to community breastfeeding resources

BOX 9-1 EIGHT STEPS TO SUCCESSFUL BREASTFEEDING

1. Drugs used for induction, such as propofol, midazolam, etomidate, or thiopental, enter the milk compartment only minimally because of their extraordinarily brief plasma distribution, and hence their transport to milk is low to nil.
2. Little has been reported on the use of anesthetic gases in breastfeeding mothers, but they also have brief plasma distribution phases, and milk levels are likely to be nil.
3. Mothers with normal term or older infants can generally resume breastfeeding as soon as they are awake, stable, and alert.
4. A single pumping and discarding of the mother's milk after surgery will significantly eliminate any drug retained in milk fat, although this is seldom necessary and not generally recommended.
5. In infants prone to apnea, hypotension, or weakness (premature or very low birth weight), it is appropriate to consider a few hours (12 to 24) of interruption from breastfeeding before resuming nursing.
6. For women undergoing postpartum tubal ligation, interrupting breastfeeding is not indicated because the volume of colostrum an infant would receive is small.
7. Women who receive single doses of medication for sedation and analgesia for short procedures can breastfeed as soon as they are awake and stable.
8. Mothers who undergo plastic surgery, such as liposuction, in which large dosages of local anesthetics (lidocaine) are used should probably pump and discard their milk for 12 hours before resuming breastfeeding.

From 10 Steps to Successful Breastfeeding for Hospitals and Institutions in the USA (website). www.babyfriendlyusa.org/eng/10steps.html. Accessed November 11, 2011.

- Providing balanced anticipatory guidance to mothers and families concerning potential concerns during labor, delivery, postpartum period, and breastfeeding
- Fostering a general acceptance of breastfeeding by promoting a normative portrayal of breastfeeding and supporting the provision of sufficient time and facilities in the workplace
- Performing breast examinations before and after the birth, and emphasizing lactation as the primary function of the breast
- Participating in breastfeeding education in medical and other health profession schools⁴¹
- Supporting breastfeeding in their own medical facilities by instituting the "Ten Steps to Successful Breastfeeding" as outlined by UNICEF and WHO⁴² (Box 9-1)

The mother's plan for infant feeding should be addressed early in prenatal care, with counseling, a medical history focused on breast health and breastfeeding, and a physical examination of the breast. Counseling can be modeled after "The Best Start Three-Step Breastfeeding Counseling Strategy" (available by e-mailing Beststart@mindspring.com),⁴³ a publication that advises beginning with open-ended questions about breastfeeding. An acknowledgment that feelings of doubt about the ability to breastfeed successfully are normal is a good place to begin. Education about breastfeeding then continues with discussion of how others have dealt with these concerns. This conversation will elucidate much about the woman's knowledge of breastfeeding, her previous experiences with breastfeeding, and her own attitudes and those of the infant's father, the extended family, and other potentially supportive persons in the mother's life.

To support breastfeeding adequately throughout the first 6 months of an infant's life, the concerns of family and friends must be addressed actively to foster support for breastfeeding on many levels. Misconceptions and potential barriers must be identified and reasonable solutions developed in partnership with the woman. These often include feelings of responsibility for every unexplained problem the infant displays; conflicts among a woman's several roles as mother, sexual partner, and worker outside the home; and, most commonly, a greater time commitment and fatigue than was expected. It is important to address these and other questions repeatedly throughout pregnancy and not just in the immediate postpartum period, working closely with the infant's pediatrician.³⁹

Examination of the Breast

The medical history related to the breasts should include their development, previous experience with breastfeeding, systemic illnesses, infections, breast surgery or trauma, medications, allergies, self-breast examinations and findings, and any anatomic or physical concerns the mother has about her breasts.

The breast examination at prenatal and postpartum visits should include careful inspection and palpation. Inspection of the breasts is most effective in the sitting position, first with the arms overhead and then with hands on the hips. Skin changes, distortions in shape or contour, and the form and size of the areola and nipple should be noted. Palpation can begin in the sitting position, looking for axillary and supraclavicular adenopathy. Palpation in the supine position is easier for the complete examination of the breast and surrounding anterolateral chest wall. Size, shape, consistency, masses, scars, tenderness, and any abnormalities can be noted in both descriptive and picture form for future comparison. Serial examinations should document maturational changes of pregnancy (size, shape, fullness, enlargement of areola) and nipple position (inversion or eversion).

The changes in the breast during pregnancy provide important prognostic data regarding successful breastfeeding. With the increased frequency of cosmetic breast surgery, it is important to be aware of the nature of any surgery and to examine carefully for the location of the surgical scars. Many women successfully breastfeed after surgery for benign breast disease, breast augmentation, or breast reduction. However, a periareolar incision or "nipple translocation technique" for breast reduction can damage nerves and ducts, making this more difficult. Nipple piercing is another increasingly common procedure, and breastfeeding can be successful after the jewelry is

removed. Such surgeries do not preclude successful breastfeeding but rather remind us that additional early support should be provided to these mothers from physicians, nurses, lactation consultants, and peer support groups.

Perinatal Period

The obstetrician can make important contributions to successful breastfeeding through the conduct of the labor, delivery, and puerperium. A stressful or exhausting labor and delivery has been shown to affect lactation adversely.⁴⁴ A safe delivery for both mother and infant is, of course, the most important outcome. During the delivery and afterward, any medications used should be compatible with breastfeeding and not interfere with the bonding and first feeding. Immediate skin-to-skin contact between mother and infant, and a first feeding within 1 hour of delivery are probably the most important intrapartum steps to increase the likelihood of successful breastfeeding. Having the infant in the mother's room, feeding on demand, and early breastfeeding support (including teaching appropriate techniques) within the first 24 to 36 hours can also help. Supplementation should be avoided unless medically indicated and ordered by the pediatrician.

For the breastfeeding woman, medication choices are very important (see Box 9-4, later in the chapter). Most women and many health professionals assume that no medication can be safely administered to a lactating woman, but the number of contraindicated drugs is in fact quite small. Before assuming a medication is unsafe, expert advice should be consulted, available in texts, via a drug information telephone service (see Suggested Readings), or at carefully selected websites.

Early follow-up (2 to 4 days after discharge) with the infant's health provider should be arranged for all breastfeeding mothers. Continued support of breastfeeding for the mother should occur through the 6-week postpartum visit. Discussions about breastfeeding should cover techniques to ensure adequate emptying of the breast, nipple soreness or trauma, plugged duct (in the form of a small lump), mastitis, breast abscess, breast masses, and bloody nipple discharge, all of which can usually be treated without stopping breastfeeding.

The Breast

To fully understand the process of lactation, one needs to understand the anatomy and physiology of the breast as it applies to this function. The human mammary gland is the only organ that does not contain all the rudimentary tissues at birth. It experiences dramatic changes in size, shape, and function from birth through menarche, pregnancy, and lactation, and ultimately during involution. The three major phases of growth and development before pregnancy and lactation occur in utero, during the first 2 years of life, and at puberty (Fig. 9-1).

EMBRYONIC DEVELOPMENT

The milk streak appears in the 4th week of gestation when the embryo is approximately 2.5 mm long. It becomes the milk line, or milk ridge, during the 5th week of gestation (2.5 to 5.5 mm). The mammary gland itself begins to develop at 6 weeks of embryonic life, and proliferation of the milk ducts continues throughout embryonic growth. The process of forming the nipple in the human embryo begins with a thickened, raised area of ectoderm in the region of the future gland by the 4th

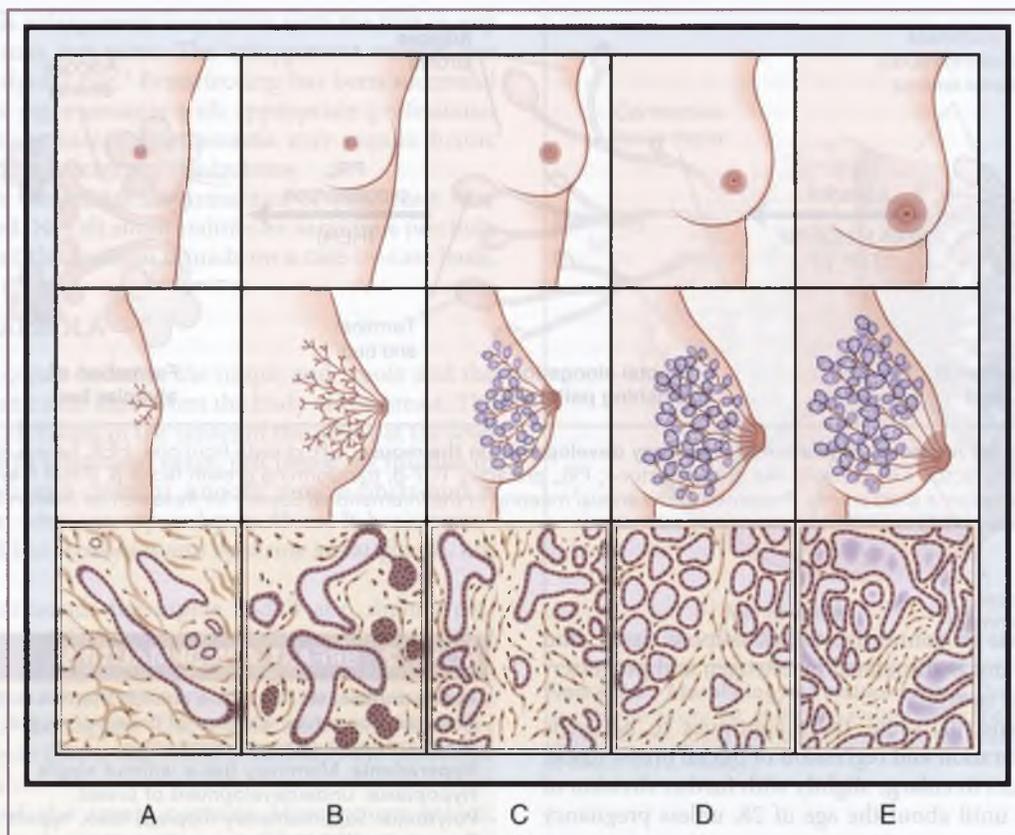

Figure 9-1 Female breast from infancy to lactation, with corresponding duct structure and tissue cross sections. A, B, and C, Gradual development of the well-differentiated ductular and peripheral lobular-alveolar system. D, Ductular sprouting and intensified peripheral lobular-alveolar development in pregnancy. Glandular luminal cells begin actively synthesizing milk fat and proteins near term; only small amounts are released into the lumen. E, With postpartum withdrawal of luteal and placental sex steroids and placental lactogen, prolactin is able to induce full secretory activity of alveolar cells and release of milk into alveoli and smaller ducts. (From Lawrence RA, Lawrence RM: *Breastfeeding: a guide for the medical profession*, ed 7, St Louis, 2010, Mosby.)

week of pregnancy. This thickened ectoderm becomes depressed into the underlying mesoderm, and thus the surface of the mammary area soon becomes flat and finally sinks below the level of the surrounding epidermis. The mesoderm that is in contact with the ingrowth of the ectoderm is compressed, and its elements become arranged in concentric layers that at a later stage give rise to the gland's stroma. By dividing and branching, the ingrowing mass of ectodermal cells gives rise to the future lobes and lobules, and much later to the alveoli.

By 16 weeks' gestation, the branching stage has produced 15 to 25 epithelial strips in the fetus that represent the future secretory alveoli. By 28 weeks' gestation, placental sex hormones enter the fetal circulation and induce canalization in the fetal mammary tissue. The lactiferous ducts and their branches are developed from outgrowth in the lumen. They open into a shallow epidermal depression known as the mammary pit. The pit becomes elevated as a result of mesenchymal proliferation, forming the nipple and areola. An inverted nipple is the failure of this pit to elevate.⁴⁵ At 32 weeks' gestation, the lumen has formed in the branching system, and by term there are four to 18 mammary ducts that form the fetal mammary gland.⁴⁶ Figure 9-2 shows the hormonal regulation of mammary development in the mouse.

The nipple, areola, and breast bud are important landmarks for the determination of gestational age in the newborn. At 40

weeks, the nipple and areola are clearly seen and the breast bud is up to 1.0 cm in diameter. In the first weeks after delivery, the breast bud is visible and palpable; however, the gland then regresses to a quiescent stage as maternal hormones in the infant diminish. After this, the gland grows only in proportion to the rest of the body until puberty.

PUBERTAL DEVELOPMENT

With the onset of puberty in the female, further growth of the breast occurs and the areolae enlarge and become more pigmented. The further development of the breast involves two distinct processes: organogenesis and milk production. The ductal and lobular growth is organogenesis, and this is initiated before and throughout puberty, resulting in the growth of breast parenchyma with its surrounding fat pad. The formation of alveolar buds begins within 1 to 2 years of the onset of menses and continues for several years, producing alveolar lobes. This menarcheal stimulus begins with the extension of the ductal tree and the generation of its branching pattern. The existing ducts elongate. The ducts can develop bulbous terminal end buds that are the forerunners of alveoli. The formation of the alveolar bud begins within 1 to 2 years of the onset of menses. During this ductal growth, the alveoli enlarge and the nipple and areola become more pigmented. This growth

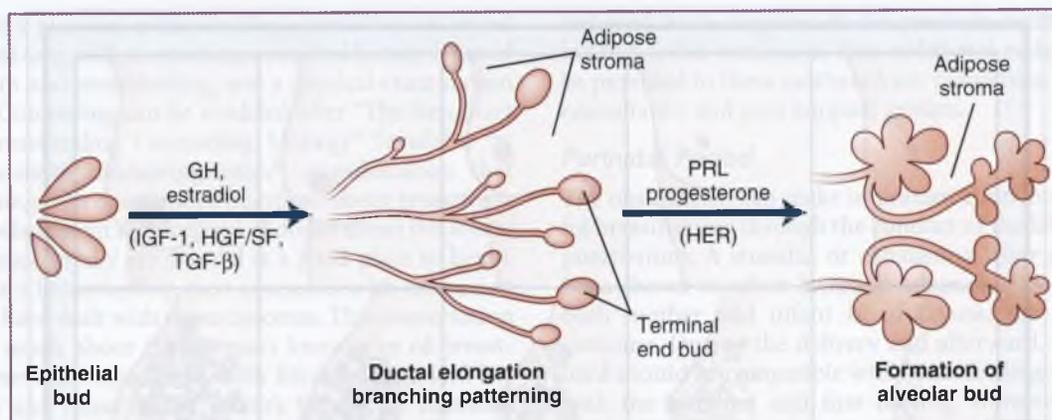

Figure 9-2 Schema for hormonal regulation of mammary development in the mouse. (From Neville MC: *Mammary gland biology and lactation: a short course*. Presented at the annual meeting of the International Society for Research on Human Milk and Lactation, Plymouth, MA, October 1997.)

involves an increase in connective tissue, adipose tissue, and vascular channels and is stimulated by estrogen and progesterone released by the ovary.⁴⁷

During the menstrual cycle, there continues to be cyclic microscopic proliferation and regression of ductal breast tissue. The breast continues to enlarge slightly with further division of the ductal system until about the age of 28, unless pregnancy intervenes.

THE MATURE BREAST

The mature breast is located in the superficial fascia between the second and sixth intercostal cartilages and is superficial to the pectoralis muscle. It measures 10 to 12 cm in diameter. It is located horizontally from the parasternal to the midaxillary line. The central thickness of the gland is 5 to 7 cm. In the nonpregnant state, the breast weighs about 200 g. During pregnancy, however, the size and weight increase to about 400 to 600 g, and to 600 to 800 g during lactation. A projection of mammary tissue into the axilla is known as the tail of Spence and is connected to the central duct system. The breast is usually dome shaped or conic, becoming more hemispheric in the adult and pendulous in the older parous woman.

ABNORMALITIES

In some women, mammary tissue develops at other sites in the galactic band. This is referred to as hypermastia, which is the presence of accessory mammary glands that are phylogenetic remnants. These remnants may include accessory nipples or accessory gland tissue located anywhere along the milk line. From 2% to 6% of women have hypermastia. These remnants remain quiet until pregnancy, when they may respond to the hormonal milieu by enlarging and even secreting milk during lactation. If left unstimulated, they will regress after the birth. Major glandular tissue in the axilla may pose a cosmetic or management problem if the tissue enlarges significantly during pregnancy and lactation, secreting milk. It is distinct from the tail of Spence.

Other abnormalities include amastia (absence of the breast or nipple), amazia, hyperadenia, hypoplasia, polythelia, and

BOX 9-2 BREAST ABNORMALITIES

Accessory breast: Any tissue outside the two major glands

Amastia: Congenital absence of breast or nipple

Amazia: Nipple without breast tissue

Hyperadenia: Mammary tissue without nipple

Hypoplasia: Underdevelopment of breast

Polythelia: Supernumerary nipple(s) (also, hyperthelia)

Symmastia: Webbing between breasts

From Lawrence RA, Lawrence RM: *Breastfeeding: a guide for the medical profession*, ed 7, St Louis, 2010, Mosby.

BOX 9-3 TYPES OF HYPOPLASIA, HYPERPLASIA, AND ACQUIRED ABNORMALITIES IN THE BREAST

HYPOPLASIA

Unilateral hypoplasia, contralateral breast normal

Unilateral hypoplasia, contralateral breast hyperplasia

Unilateral hypoplasia of breast, thorax, and pectoral muscles (Poland syndrome)

Bilateral hypoplasia with asymmetry

HYPERPLASIA

Unilateral hyperplasia, contralateral breast normal

Bilateral hyperplasia with asymmetry

ACQUIRED ABNORMALITIES

Caused by trauma, burns, radiation treatment for hemangioma or intrathoracic disease, chest tube insertion in infancy, and preadolescent biopsy

From Lawrence RA, Lawrence RM: *Breastfeeding: a guide for the medical profession*, ed 7, St Louis, 2010, Mosby.

symmastia (Box 9-2). Abnormalities of the kidneys have been associated with polythelia. Other variations include hyperplasia or hypoplasia in various combinations, as listed in Box 9-3. Gigantomastia is the excessive enlargement of the breasts in pregnancy and lactation, sometimes to life-threatening

proportions. This enlargement may occur with the first or any pregnancy and may not recur. The enlargement recedes but rarely back to original size.³ Breastfeeding has been successful in some cases of gigantomastia with appropriate professional support. In extreme cases, gigantomastia may require heroic measures, including emergency mastectomy.

Mothers with congenital abnormalities of the breast may wish to breastfeed. Not all abnormalities or variations preclude breastfeeding, and the decision is made on a case-by-case basis.

NIPPLE AND AREOLA

The skin of the breast includes the nipple and areola and the thin, flexible, elastic skin that covers the body of the breast. The nipple is a conic elevation in the center of the areola at the level of about the fourth intercostal space, just below the midline of the breast. The nipple contains smooth muscle fibers and is richly innervated with sensory and pain fibers. It has a verrucous surface and has sebaceous and apocrine sweat glands, but not hair.

The areola surrounds the nipple and is also slightly pigmented and becomes deeply pigmented during pregnancy and lactation. The average diameter is 15 to 16 mm, but the range may exceed 5 cm during pregnancy. The sensory innervation is less than that of the nipple. The nipple and areola are very elastic and elongate into a teat when drawn into the mouth by the suckling infant.

The surface of the areola contains Montgomery glands, which hypertrophy during pregnancy and lactation and resemble vesicles. During lactation, they secrete a sebaceous material to lubricate the nipple and areola and protect the tissue while the infant suckles. These glands atrophy after weaning and are not visible to the naked eye except during pregnancy or lactation.

Each nipple contains 4 to 18 lactiferous ducts, of which five to eight are main ducts surrounded by fibromuscular tissue.⁴⁸ These ducts end as small orifices at the tip of the nipple from which the milk flows. The corpus mammae is an orderly conglomeration of a number of independent glands known as lobes. The morphology of the gland includes parenchyma that contains the ductular-lobular-alveolar structures. It also includes the stroma, which is composed of connective tissue, fat tissue, blood vessels, nerves, and lymphatics.

The mass of breast tissue consists of tubuloalveolar glands embedded in adipose tissue, which gives the gland its smooth, rounded contour. The mammary fat pad is essential for the proliferation and differentiation of the ductal arborization (Fig. 9-3). Each lobe is separated from the others by connective tissue, and opens into a duct that opens into the nipple. The extension of ducts is orderly and protected by an inhibitory zone into which other ducts cannot penetrate.⁴⁹

Blood is supplied to the breast from branches of the intercostal arteries and perforating branches of the internal thoracic artery. The main blood supply comes from the internal mammary artery and the lateral thoracic artery. The venous supply parallels the arterial supply.

Lymphatic drainage has been thoroughly studied by researchers of breast cancer. The main drainage is to axillary nodes and the parasternal nodes along the thoracic artery in the thorax. The lymphatics of the breast originate in lymph capillaries of the mammary connective tissue and drain through the deep substance of the breast.

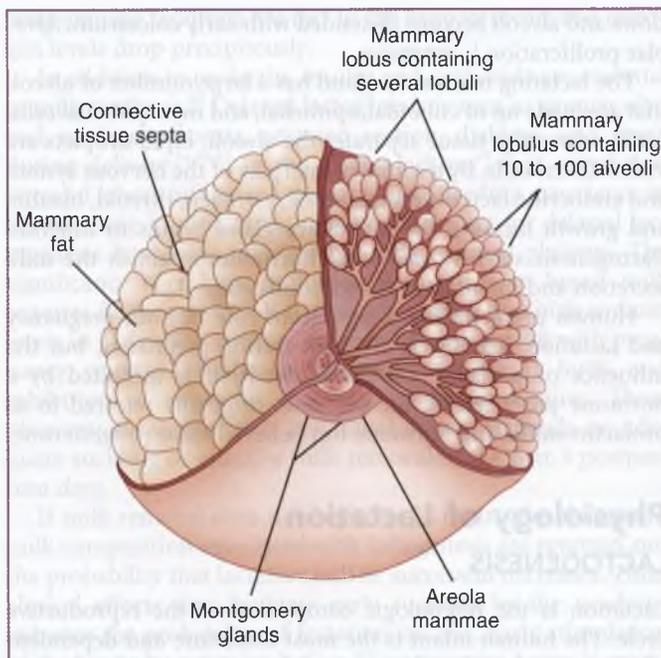

Figure 9-3 Morphology of mature breast. Diagrammatic dissection reveals mammary fat and duct system. (Modified from Lawrence RA, Lawrence RM: *Breastfeeding: a guide for the medical profession*, ed 7, St Louis, 2010, Mosby.)

The breast is innervated from the branches of the fourth, fifth, and sixth intercostal nerves. The sensory innervation of the nipple and areola is extensive and includes both autonomic and sensory nerves. The innervation of the corpus mammae is meager by comparison and is predominantly autonomic. Neither parasympathetic nor cholinergic fibers supply any part of the breast. The efferent nerves are sympathetic adrenergic. Most of the mammary nerves follow the arteries. A few fibers course along the walls of the ducts. They may be sensory fibers that sense milk pressure. No innervation has been identified to supply the myoepithelial cells. Thus, the conclusion is that secretory activities of the acinar epithelium of the ducts depend on hormonal stimulation, such as by oxytocin.

When sensory fibers are stimulated, the release of adeno-hypophyseal prolactin and neurohypophyseal oxytocin occurs. The areola is most sensitive to the stimulus of suckling, the nipple the least, and the skin of the breast is intermediate. The large number of dermal nerve endings results in high responsiveness to suckling. Pain fibers are more numerous in the nipple, with few in the areola. All cutaneous nerves run radially toward the nipple. Breast nerves can influence the mammary blood supply and therefore also influence the transport of oxytocin and prolactin to the myoepithelial cells and the lacteal cells, respectively.

MAMMARY GLAND IN PREGNANCY

During the first trimester, rapid growth and branching from the terminal duct system into the adipose tissue is stimulated by the changing levels of circulating hormones. As epithelial structures proliferate, adipose tissue decreases. There is increased infiltration of the interstitial tissue with lymphatics, plasma cells, and eosinophils. By the third trimester, parenchymal cell growth

slows and alveoli become distended with early colostrum. Alveolar proliferation is extensive.

The lactating mammary gland has a large number of alveoli that are made up of cuboidal, epithelial, and myoepithelial cells. Little connective tissue separates the alveoli. Lipid droplets are visible in the cells. By a complex interplay of the nervous system and endocrine factors (progesterone, estrogen, thyroid, insulin, and growth factors), the mammary gland begins to function (lactogenesis stage I) and other hormones establish the milk secretion and maintain it (lactogenesis stage II).

Human prolactin has a significant role in both pregnancy and lactation. The levels are high during pregnancy, but the influence of prolactin on the breast itself is inhibited by a hormone produced by the placenta, originally referred to as prolactin-inhibiting hormone but believed to be progesterone.

Physiology of Lactation

LACTOGENESIS

Lactation is the physiologic completion of the reproductive cycle. The human infant is the most immature and dependent of all mammals except for marsupials, and thus the breast provides the most physiologically appropriate nutrients required by the human infant at birth. Throughout pregnancy, the breast develops and prepares to take over the role of fully nourishing the infant when the placenta is expelled. The breast is prepared for full lactation after 16 weeks' gestation. The physiologic adaptation of the mammary gland to its role in infant survival is a complex process, only the outline of which is discussed here. There are a number of complete reviews of scientific studies on the physiology of lactation.^{40,46,48,50} Hormonal control of lactation can be described in relationship to the five major changes in the development of the mammary gland: embryogenesis, mammogenesis or mammary growth, lactogenesis or initiation of milk secretion, lactation or full milk secretion, and involution (Table 9-2). Detailed explanation of mammary growth is beyond the scope of this discussion. The two most important

hormones involved in lactation itself are prolactin and oxytocin, and these are described with respect to their impact on lactogenesis.

Lactogenesis is the initiation of milk secretion, beginning with the changes in the mammary epithelium in early pregnancy and progressing to full lactation. Stage I lactogenesis occurs during pregnancy and is achieved when the gland is sufficiently differentiated to secrete milk. It is prevented from doing so by high circulating plasma concentrations of progesterone.⁵¹ Stage II is the onset of copious milk secretion associated with delivery of the infant and the placenta. The progesterone level decreases sharply, by 10-fold in the first 4 days.⁴⁹ This is accompanied by the programmed transformation of the mammary epithelium.⁵² By day 5, the infant has 500 to 750 mL of milk available (Fig. 9-4). The changes in milk composition that occur in the first 10 postpartum days should be

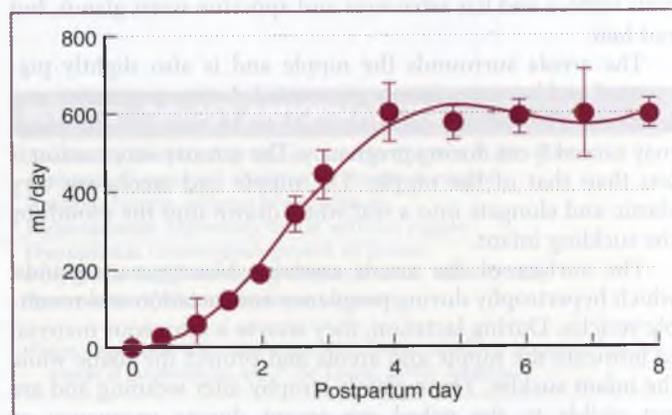

Figure 9-4 Milk volumes during first postpartum week. Mean values from 12 multiparous white women who test-weighed their infants before and after every feeding for the first 7 postpartum days. (Redrawn from Neville MC, Keller RP, Seacat J, et al: *Studies in human lactation: milk volumes in lactating women during the onset of lactation and full lactation*, *Am J Clin Nutr* 48:1375–1386, 1988.)

TABLE 9-2 Stages of Mammary Development

Developmental Stage	Hormonal Regulation	Local Factors	Description
Embryogenesis	?	Fat pad necessary for ductal extension	Epithelial bud develops in 18- to 19-week-old fetus, extending short distance into mammary fat pad with blind ducts that become canalized; some milk secretion may be present at birth Anatomic development
Mammogenesis			
Puberty			
Before onset of menses	Estrogen, GH	IGF-1, hGF, TGF- β ; others?	Ductal extension into mammary fat pad; branching morphogenesis
After onset of menses	Estrogen, progesterone; PRL?		Lobular development with formation of terminal duct lobular unit
Pregnancy	Progesterone, PRL, hPL	HER; others?	Alveolus formation; partial cellular differentiation
Lactogenesis	Progesterone withdrawal, PRL, glucocorticoid	Not known	Onset of milk secretion Stage I: midpregnancy Stage II: parturition
Lactation	PRL, oxytocin	FIL	Ongoing milk secretion
Involution	PRL withdrawal	Milk stasis; FIL?	Alveolar epithelium undergoes apoptosis and remodeling; gland reverts to pre-pregnant state

FIL, feedback inhibition of lactation; GH, growth hormone; HER, heregulin; hGF, human growth factor; hPL, human placental lactogen; IGF-1, insulin-like growth factor 1; PRL, prolactin; TGF- β , transforming growth factor- β .

Modified from Neville MC: *Mammary gland biology and lactation: a short course*. Presented at the biannual meeting of the International Society for Research on Human Milk and Lactation, Plymouth, MA, October 1997.

viewed as part of a continuum in which the rapid changes of the first 4 days are followed by slower changes in various components of milk throughout lactation.⁴⁹ A change in permeability of the paracellular pathways results in a shift from high concentrations of sodium, chloride, and the protective immunoglobulins and lactoferrin, little lactose, and no casein in colostrum, to increasing amounts of all milk components.⁵³

Lactogenesis stage II results in an increase of milk from 100 mL in the first 24 hours to large volumes (500 to 750 mL/day) by day 4 or 5, gradually leveling off at 600 to 700 mL/day by day 8.⁵⁴ These volume changes are associated with a decrease in sodium and chloride concentration and an increase in lactose concentration. The production of lactose drives the production of milk. The early changes in sodium and chloride are a function of the closure of the tight junctions that block the paracellular pathway.^{55,56} Secretory IgA and lactoferrin represent 10% by weight of the milk produced in the first 48 hours, and although their amounts remain the same, the increased volume of milk produced decreases their concentration. At 8 days, secretory IgA and lactoferrin are 1% by weight and 2 to 3 g/day.⁵⁷

At 36 postpartum hours (in multiparas) and at up to 72 hours (in primiparas), milk production increases 10-fold (from 50 to 500 mL/day). Women refer to this as their milk “coming in.” It reflects a massive increase in synthesis and secretion of the components of mature milk, including lactose, protein, and lipid.⁵⁸

During pregnancy, hormones maintain the pregnancy and produce mammary tissue that is prepared to produce milk but does not do so. Progesterone, prolactin, and possibly placental lactogen are credited with the development of the alveoli. Progesterone has been identified as the major inhibitor of milk production during pregnancy.⁵⁹ Prolactin levels in pregnancy are greater than 200 ng/mL. Apparently, the continued high level of prolactin and a decrease in progesterone are necessary for stage II lactogenesis after parturition.⁵⁹ The placenta is the main source of progesterone in pregnancy. After the birth,

progesterone receptors are lost in the human breast and estrogen levels drop precipitously.

In addition to prolactin, insulin and corticoids are essential to milk synthesis.⁶⁰ Delayed lactogenesis is seen in women who had retained placenta, cesarean section, diabetes, and stress during delivery.^{54,60-62} In the 1940s, Jackson⁶³ first noted that stressful labors influenced the early breastfeeding experience in the rooming-in unit. Stress may be the trigger for delayed lactogenesis in the conditions other than retained placenta. The significance of a high sodium concentration in breast milk requires further study.⁵³ It has been observed that high sodium levels in early milk samples are seen in conjunction with pregnancy, mastitis, involution (weaning), premature birth, and inhibition of prolactin secretion by bromocriptine. These observations suggest that junctional closure depends on adequate suckling or effective milk removal in the first 3 postpartum days.

If milk removal does not begin by 72 hours, the changes in milk composition associated with lactogenesis are reversed and the probability that lactation will be successful decreases. Thus, clinical efforts that facilitate early suckling by the newborn enhance the probability of lactation success. Early stimulation of the breast by pumping before 72 postpartum hours is essential when the infant is unable to nurse directly.

LET-DOWN (EJECTION) REFLEX

An effective let-down reflex is key to successful lactation. This reflex, also known as the ejection reflex, was first described in humans by Peterson and Ludwick in 1942,⁶⁴ and it was later demonstrated clinically by Newton and Newton²⁵ to be caused by the release of oxytocin by the pituitary. Since that time, many refinements in the understanding of the process have been published, but the fundamental principles are unchanged (Fig. 9-5).

A mother may produce milk, but if it is not excreted, further production is eventually suppressed. The reflex is a complex function that depends on hormones, nerves, and glandular

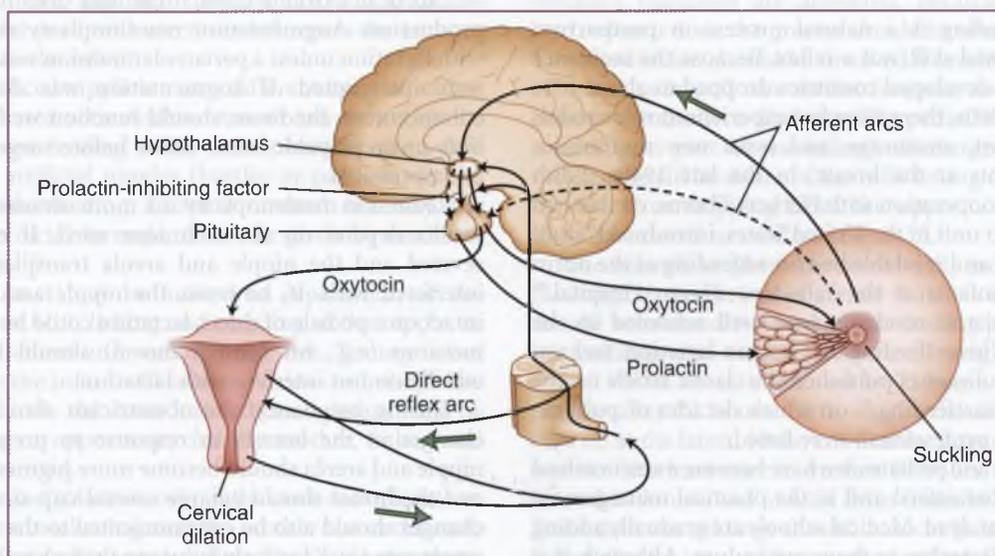

Figure 9-5 Neuroendocrine control of milk ejection. (Modified from Vorherr H: *The breast: morphology, physiology and lactation*, New York, 1974, Academic Press.)

response and can be inhibited most easily by psychological influences.

Oxytocin is the hormone responsible for stimulating the myoepithelial cells to contract and eject the milk from the ductal system. The ducts begin at the alveoli, which are surrounded by a basket-like structure of myoepithelial cells that also surround the ducts all the way to the nipple. When the infant stimulates the breast by suckling, impulses sent to the central nervous system and to the posterior pituitary result in the release of oxytocin, which is then carried by the bloodstream to the myoepithelial cells. This is a neuroendocrine reflex. Oxytocin release can also be stimulated by other pathways of sight, sound, and smell that represent the infant. Oxytocin also stimulates the myoepithelial cells in the uterus, which are very sensitive to oxytocin during parturition and for a week or so after the birth. This causes the uterus to contract, decreases blood loss, and hastens postpartum involution. The uterus of a mother who breastfeeds returns to a pre-pregnant state more rapidly. The uterine cramping experienced while breastfeeding is a result of this stimulus (see Fig. 9-5).

Newton and Newton²⁵ demonstrated that pain and stress interfered with the let-down reflex because it interfered with oxytocin release. In their experimental model, they stimulated stress with pain, loud noises, or pressure to solve mathematical problems. In other species, oxytocin release has been shown to stimulate mothering behaviors.⁶⁵ Levels of adrenocorticotropin and plasma cortisol are decreased in lactating women compared with nonlactating women in response to stress.

Prolactin is central to the production of milk and regulates the rate of synthesis. Its release depends on the suckling of the infant or the stimulation of the nipple by mechanical pumping or manual expression. Prolactin is also released through a neuroendocrine reflex. Its influence is modified, however, by the actual release of milk from the alveoli. Local factors in the ductal system or in the accumulated milk can inhibit milk release and thus inhibit further milk production. Prolactin is not released as a result of sound, sight, or smell of the infant, as is the case with oxytocin, but only by suckling (Fig. 9-6).

INITIATION OF LACTATION

Although breastfeeding is a natural process in postpartum women, it is a learned skill, not a reflex. Because the incidence of breastfeeding in developed countries dropped to about 10% in the 1950s and 1960s, there were few experienced role models available to support, encourage, and assist new mothers in feeding their infants at the breast. In the late 1940s, Edith Jackson at Yale, in cooperation with Herbert Thoms, established the first rooming-in unit in the United States, introduced "child birth without fear," and reestablished breastfeeding as the norm for mothers and infants at the Yale–New Haven Hospital.⁶⁶ Obstetric and pediatric residents were well schooled in the practical aspects of breastfeeding and human lactation. Jackson and her pediatric colleagues published the classic article on the management of breastfeeding,⁶⁷ on which decades of publications, both lay and professional, were based.

The obstetrician and pediatrician have become more involved in the decision to breastfeed and in the practical management of the mother–infant dyad. Medical schools are gradually adding breastfeeding and lactation to their curriculum. Although it is not the physician's role to put the infant to the breast, it is important to understand the process, to recognize problems,

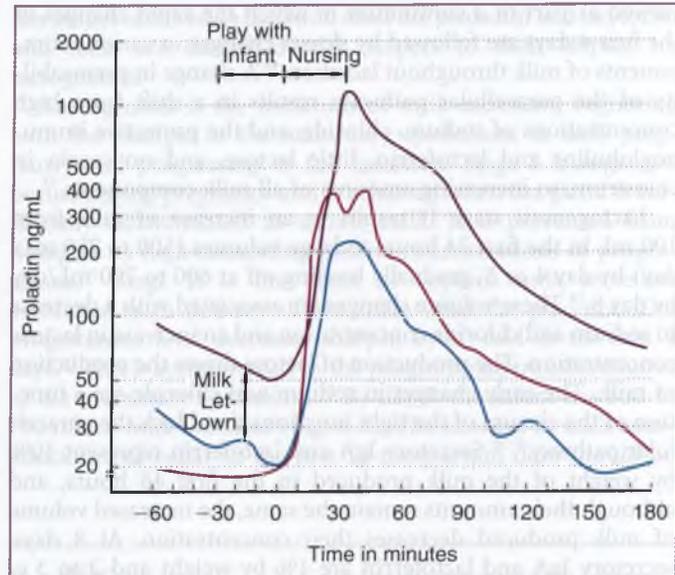

Figure 9-6 Plasma prolactin stimulation. Plasma prolactin levels were measured by radioimmunoassay before, during, and after a period of nursing in three mothers between days 22 and 26 after the birth. The levels rose with suckling but not with infant contact only. (Modified from Josimovich JB, Reynolds M, Cobo E: *Lactogenic hormones, fetal nutrition, and lactation*. In Josimovich JB, Reynolds M, Cobo E, editors: *Problems of human reproduction*, vol 2, New York, 1974, John Wiley & Sons.)

and to know how to solve them. Breastfeeding support is a team effort in which the physician works with many health care professionals, including nurses, midwives, doulas, and dietitians, to provide complete care to the perinatal patient. Lactation specialists may be nurses, dietitians, or nonmedical individuals with special training, or physicians with specialty designation. The physician should be sure that consultants are licensed and board certified by the International Board of Lactation Consultant Examiners, and that other physicians are recognized as fellows of the Academy of Breastfeeding Medicine.

Except in extreme cases, breast size does not influence milk production. Augmentation mammoplasty does not interfere with lactation unless a periareolar incision was made and nerves were interrupted. If augmentation was done for cosmetic enhancement, the tissue should function well, but if there was little or no palpable breast tissue before surgery, lactation may be improbable.

Reduction mammoplasty is a more invasive surgery, and the results depend on the technique used. If many ducts were severed and the nipple and areola transplanted, lactation is interfered with. If, however, the nipple and areola remained intact on a pedicle of ducts, lactation could be successful. Other incisions (e.g., for lump removal) should be discussed but usually do not interfere with lactation.

During pregnancy, the obstetrician should document the changes in the breasts in response to pregnancy, when the nipple and areola should become more pigmented and enlarged and the breast should enlarge several cup sizes. Lack of breast changes should also be communicated to the pediatrician, as it represents a risk for early failure to thrive because of insufficient milk supply. A breast examination should be conducted late in the pregnancy to check for any new findings of masses, lumps,

discharge, or pain. Berens⁶⁸ described the role of the obstetrician throughout pregnancy in detail.

Initiating Breastfeeding

The ideal time to initiate breastfeeding is immediately after birth (the Baby Friendly Initiative recommends within a half hour of birth). When left on the mother's abdomen to explore, the unmedicated newborn will move toward the breast, latch on, and begin suckling. This usually takes 20 to 30 minutes if unassisted.⁶⁹ The infant is ready to feed and has been suckling in utero since about 14 weeks' gestation, consuming amniotic fluid daily (about 1 g protein/kg of fetal weight is received daily from amniotic fluid). The infant at 28 weeks' gestation already has a rooting, sucking, and coordinated swallow while breastfeeding. The ability to coordinate suck and swallow while bottle feeding does not occur until 34 weeks.

Shortly after delivery, the mother should be offered the opportunity to breastfeed and should be assisted to assume a comfortable position, usually lying on her side. The infant can be placed beside her, tummy to tummy facing the breast. The mother should support her breast with her hand, keeping her fingers behind the areola so the infant can latch on. The mother should stroke the center of the lower lip with the breast. The infant should open the mouth wide, extend the tongue, and draw the nipple and areola into the mouth to form a teat. This teat is compressed against the palate by the tongue, and the gums and lips form a seal with the breast. It is the peristaltic motion of the tongue that stimulates the let-down reflex. The continued peristaltic motion travels to the posterior tongue, the pharynx, and down the esophagus as one coordinated motion, so that swallowing is automatically coordinated with suckling during breastfeeding.

Ultrasound imaging of milk ejection in the breast of lactating women has provided a more detailed description of the process compared with the traditional serial sampling of plasma oxytocin levels and measurements of intraductal pressure. A significant increase in milk-duct diameter can be observed during milk ejection. Multiple milk ejections occur during the process and are correlated with milk flow and with the changes in milk-duct diameter, although they are not sensed by the mother.⁷⁰ The number of milk ejections influences the amount of milk available to the infant.

Sucking an artificial nipple is a very different tongue motion that is not coordinated with swallow. A newborn should not be given a bottle to test feeding ability before breastfeeding. It is wise to avoid all artificial nipples (bottles or pacifiers) in the early weeks of breastfeeding. If, for a medical necessity, the infant requires artificial formula, it can be given by medicine cup (cup feeding).^{71,72}

The initial contact may be limited to exploration of the breast by the infant, with licking and nuzzling of the nipple, or the infant may latch on and suck for minutes. Timing is not necessary because the infant will interrupt him- or herself. The first hour after birth, the term unmedicated infant will be quietly alert. It is an opportunity for the mother, father, and infant to get acquainted.

Ideally, mother and infant recover in the same room together. The infant is fed on awakening, and the mother learns the early signs of hunger. Crying is a very late sign. She also learns about caring for her infant. There should be no schedules and no intervention unless an infant does not feed for over 6 hours. A

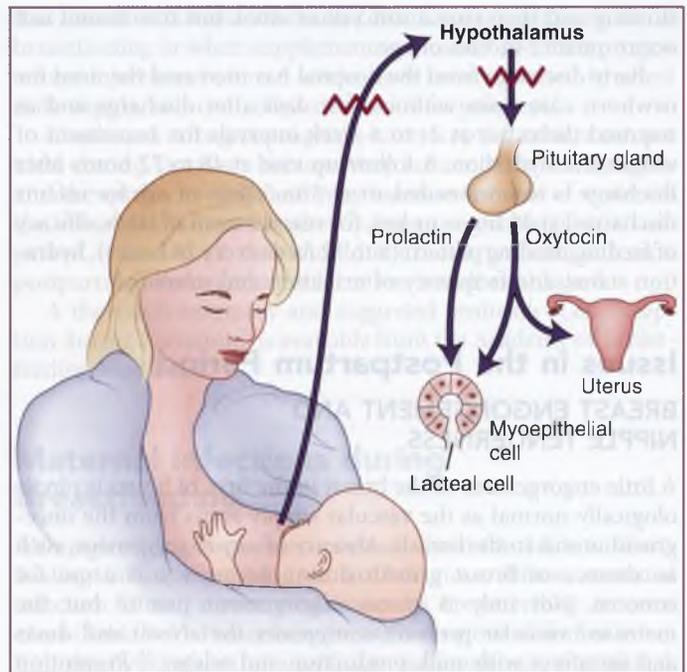

Figure 9-7 Diagram of ejection reflex arc. When the infant suckles the breast, mechanoreceptors in the nipple and areola are stimulated, which sends a stimulus along nerve pathways to the hypothalamus, which stimulates the posterior pituitary gland to release oxytocin. Oxytocin is carried via the bloodstream to the breast and uterus. Oxytocin stimulates myoepithelial cells in the breast to contract and eject milk from the alveolus. Prolactin is responsible for milk production in the lacteal cells lining the alveolus. Prolactin is secreted by the anterior pituitary gland in response to suckling. Stress (e.g., pain, anxiety) can inhibit the let-down reflex. Seeing or hearing the cry of the infant can stimulate the release of oxytocin but not prolactin. (From Lawrence RA, Lawrence RM: *Breastfeeding: a guide for the medical profession*, ed 7, St Louis, 2010, Mosby.)

normal feeding pattern for breastfeeding in early infancy is 8 to 12 feeds every 24 hours until satiety. The nursing staff and lactation consultants ensure that the infant latches on well and the mother's questions are answered. Breastfeeding should not hurt; when it does, the process should be observed and adjusted. The obstetrician should be involved if needed in the evaluation of breast pain and can review frequent and effective feeding prior to the mother's discharge. The pediatrician should observe a feeding as part of the infant's discharge examination. The mother should be aware of the milk letting down by tingling in the breast or dripping from the opposite breast. The infant should be noted to swallow (Fig. 9-7).

The infant's weight is measured daily and again just before discharge. A weight loss of greater than 5% in the first 48 hours should be assessed by checking the feeding process and reviewing voidings and stoolings. Maximal weight loss should not exceed 7% in a breastfed infant by 72 hours. The weight should plateau after 72 hours. Birth weight should be regained by 7 days or, at the latest, 10 days. A healthy infant voids at least once and stools at least once in the first 24 hours, at least twice in the second 24 hours, and at least three times in the third 24 hours. From then on, voidings should occur at least six times daily. An infant should stool at least once (and preferably three times) every day in the first month of life. After 3 to 4 months of age, a perfectly healthy breastfed infant may go a week without

stooling and then pass a soft yellow stool, but this should not occur under 1 month of age.

Early discharge from the hospital has increased the need for newborn care visits within a few days after discharge and as required thereafter at 2- to 4-week intervals for assessment of weight and hydration. A follow-up visit at 48 to 72 hours after discharge is recommended, or at 3 to 5 days of age for infants discharged at 48 hours or less, for reassessment of latch, efficacy of feeding, feeding pattern (8 to 12 feeds every 24 hours), hydration status, and frequency of urination and stooling.⁴¹

Issues in the Postpartum Period

BREAST ENGORGEMENT AND NIPPLE TENDERNESS

A little engorgement of the breast in the first 24 hours is physiologically normal as the vascular supply shifts from the once-gravid uterus to the breasts. Absence of any engorgement, such as absence of breast growth during pregnancy, is cause for concern. Not only is excess engorgement painful but the increased vascular pressure compresses the alveoli and ducts and interferes with milk production and release.⁷³ Prevention of excessive engorgement is the best treatment and involves the following: (1) wearing a well-fitting nursing brassiere even before the breasts are engorged, and around the clock, (2) frequent feedings for the infant, being sure to balance the use of both breasts, (3) gentle massage and softening of the areola before offering the breast to the infant, so that proper latch-on can be accomplished, (4) if necessary, applying cold packs or cold compresses after a feeding, and (5) taking acetaminophen or ibuprofen, which may be safely used by the mother for discomfort.

Peak engorgement usually occurs between 72 and 96 postpartum hours when the mother has arrived home and is on her own. At the peak of discomfort, standing in a warm shower to let milk drip or applying warm compresses before pumping to relieve the pressure and stimulate flow provides relief before the phenomenon subsides.

Sore nipples are a common complaint when early lactation has gone unassisted. It should not hurt to breastfeed. When it does hurt, the infant should be taken off the breast by breaking the suction with a finger and then reattaching the infant carefully, following the steps previously described. The major cause of sore nipples is inadequate latch-on. It is not caused by breastfeeding too long or too frequently. A newborn usually feeds about every 2 hours in the first few weeks of life. Persistent sore nipples, cracks, or oozing may require the assistance of a licensed certified lactation consultant who can take the time and has the experience to work with the mother to identify the cause, determine effective treatment, and assist the dyad in maintaining pain-free breastfeeding.

FALTERING MILK SUPPLY

Many misconceptions lead to the impression that a failing milk supply is a common occurrence. Many women discontinue breastfeeding before 3 postpartum months, believing their milk is diminishing because their breasts are no longer engorged. Once supply and demand have been equilibrated and the breast makes what the infant needs, the breasts are soft and do not constantly drip. The emptying time of the stomach of the infant

fed human milk is 90 minutes, fed formula it is 3 to 4 hours, and fed cow's milk it is 6 hours. Continuing to feed every 3 hours is a testimony to its digestibility, not its inadequacy. Weight gain in the infant is the better barometer of success. The ACOG supports the AAP statement that exclusive breastfeeding should continue for 6 months, with continued breastfeeding while adding weaning foods for the next 6 months, and then as long thereafter as mutually desired by mother and child.^{41,74,75}

Genuine failure to produce enough milk may result from infant causes, such as increased need, increased fluid losses, or lack of adequate suckling, or to maternal causes, such as failure to let down or failure of production. Each case should be carefully reviewed because most situations are remediable. Ideally, the pediatrician is experienced in lactation management or has a staff member who is. Working together with a licensed certified lactation specialist, the issues can be resolved and breastfeeding can continue successfully.

BREASTFEEDING AFTER PREMATURE OR MULTIPLE BIRTHS

Human milk is beneficial in the management of the premature infant according to the Policy Statement of the AAP.⁴¹ The benefits include infection protection; improvement in gastrointestinal function, digestion, and absorption of nutrients; and improved neurodevelopmental outcomes. The psychological well-being of the mother is enhanced when she provides her milk for her compromised infant.⁷⁶ Meeting the intrauterine rates of growth and nutrient accretion requires attention. Although human milk satisfies these needs for larger premature infants, it can be carefully supplemented for smaller infants and still preserve the benefits of human milk. A product created with 100% human milk has been developed to enhance mother's milk and replace supplementation with cow's milk.⁷⁷

Twins and triplets present problems of time management for the mother.⁷⁸ The mother will make enough milk, as supply will meet demand. Twins learn quickly to nurse simultaneously and will continue to do so for months or years. Breastfeeding ensures a mother's interaction with her infants. Helpful friends and relatives can perform the other household duties. The mother can also provide enough milk for triplets. Some mothers prefer to nurse two at a feeding, giving the third a bottle but rotating the three, feeding by feeding. Any breast milk is valuable in this situation. Mothers of multiples need help. It may be necessary for the physician to prescribe help and careful attention to proper rest. Mothers have also breastfed quadruplets and higher. Usually, they nurse several at each feeding and rotate bottle feeding. Exclusive breastfeeding of quadruplets for the first year was reported by Berlin.⁷⁹

Contraception

Lactation suppresses ovulation and thus helps prevent pregnancy for the first several months after delivery but should not be relied on as a sole method of contraception. Many couples resume coitus before the first postpartum visit and should be educated about the effects of breastfeeding on sexual function and fertility. Interest in sex may be reduced, not only by the endocrine environment of lactation but also by maternal fatigue, reduced vaginal lubrication during lactation, and the altered roles of wife and mother. Contraceptive choices are consequently affected by lactation.

Nonhormonal choices are preferred until ovulation resumes. ACOG recommends prelubricated condoms or other lubricated barrier methods such as a diaphragm. Intrauterine devices are appropriate once uterine involution has occurred. Supplemental lubrication may be required.

Use of hormonal contraceptives in breastfeeding women raises questions about maternal-fetal transfer of hormones, but the principal concerns relate to the effect on milk production and risk to the mother. Progestin-only contraceptives, such as the mini-pill tablet, injectable medroxyprogesterone acetate (Depo-Provera, Pharmacia), and levonorgestrel implants, are the hormonal methods of choice when nonhormonal methods are not acceptable. Unlike combined estrogen-progestin pills, the progestin-only methods have no effect on the quantity or quality of milk. The package inserts for progestin-only methods recommend initiation of use at 6 postpartum weeks for women who are breastfeeding exclusively, and at 3 weeks for those who supplement breast milk with formula. The injectable medroxyprogesterone acetate is recommended only at 6 weeks after delivery. The reasons for the delayed use of the progestin-only methods are related to concerns about an immediate effect on the onset of milk production if used within 3 days of birth and about the uncertain ability of the newborn to metabolize progesterone. However, concern about the impact of early initiation of progestin-only pills has been ameliorated by a recent report

that found no adverse effects on continuation rates in exclusive breastfeeding or when supplements are used.⁸⁰ Medroxyprogesterone injections before 6 weeks have been observed to affect milk supply, and controlled studies are in progress.³

Combined estrogen-progestin contraceptive tablets are not ideal during lactation because they reduce both the quantity and the quality of milk and may increase the risk of maternal thromboembolism in the already hypercoagulable postpartum period. If used at all, they should not be started until at least 6 postpartum weeks and after lactation is well established.

A thorough summary and suggested protocol, "Contraception during Lactation," is available from the Academy of Breastfeeding Medicine.⁸¹

Maternal Infections during Breastfeeding

Although often a mother is concerned about the risk to a breastfeeding infant when she has an infectious illness, maternal infection is not a contraindication to breastfeeding in most cases (Table 9-3). Proscribing breastfeeding out of fear of infection deprives infants of significant immunologic, nutritional, and emotional benefits of breastfeeding when they are most needed.³

TABLE 9-3 Breastfeeding Recommendations for Selected Maternal Infections

Organism, Syndrome, or Condition*	Breastfeeding Acceptable†	Medications Compatible with Breastfeeding, Except as Noted‡
CANDIDIASIS		
<i>Candida albicans</i> , <i>Candida krusei</i> : mucocutaneous infection, vulvovaginitis	Yes (simultaneous therapy for infant and mother) [§]	Topical agents, fluconazole, ketoconazole, itraconazole, amphotericin B, flucytosine
<i>Candida tropicalis</i> : invasive infections		
CHLAMYDIA		
<i>Chlamydia trachomatis</i> : Urethritis, vaginitis, endometritis, salpingitis, lymphogranuloma venereum, conjunctivitis, pneumonia	Yes (consider treating the infant)	Erythromycin, azithromycin, clarithromycin, doxycycline, tetracycline, sulfisoxazole
CYTOMEGALOVIRUS		
Asymptomatic infection	Yes (for term infants)	
Infectious mononucleosis	No (for premature or immunodeficient infants); do not give expressed breast milk	
ENDOMETRITIS, PELVIC INFLAMMATORY DISEASE		
Anaerobic organisms	Yes	Clindamycin, metronidazole, cefoxitin, cefmetazole
<i>Chlamydia trachomatis</i>	Yes	Erythromycin, azithromycin, tetracycline
Enterobacteriaceae	Yes	Ampicillin, aminoglycosides, cephalosporins
Group B streptococci	Yes (after 24 hr of therapy, breast milk is okay; observation)	Penicillin, cephalosporins, macrolides
<i>Mycoplasma hominis</i>	Yes	Clindamycin, tetracycline
<i>Neisseria gonorrhoeae</i>	Yes [§]	Ceftriaxone, spectinomycin, doxycycline, azithromycin
<i>Ureaplasma urealyticum</i>	Yes	Erythromycin, azithromycin, clarithromycin, tetracycline
GONORRHEA		
Genital, pharyngeal, conjunctival, or disseminated infection; <i>Neisseria gonorrhoeae</i>	Yes [§]	Ceftriaxone, ciprofloxacin, spectinomycin, azithromycin, doxycycline
HEPATITIS[§]		
A—Acute only	Yes (after immune serum globulin and vaccine)	

Continued

TABLE 9-3 Breastfeeding Recommendations for Selected Maternal Infections—cont'd

Organism, Syndrome, or Condition*	Breastfeeding Acceptable [†]	Medications Compatible with Breastfeeding, Except as Noted [‡]
B —Chronic hepatitis, cirrhosis, hepatocellular carcinoma	Yes (after HBIG and vaccine)	
C —Chronic hepatitis, cirrhosis, hepatocellular carcinoma	Yes	
D —Associated with hepatitis B	Yes (after HBIG and vaccine)	
E —Severe disease in pregnant women	Yes	
G	Inadequate data	
HERPES SIMPLEX TYPES 1, 2		
Mucocutaneous, neonatal, encephalitis	Yes (in the absence of breast lesions)	Acyclovir, valacyclovir, famciclovir
HUMAN IMMUNODEFICIENCY VIRUSES[§]		
Types 1 and 2	No/yes	Little or no information available on antiretrovirals in breast milk
HUMAN T-CELL LEUKEMIA VIRUSES[§]		
Type I (T-cell leukemia/lymphoma virus): myelopathy, dermatitis, adenitis, Sjögren syndrome	No	
Type II: myelopathy, arthritis, glomerulonephritis	No	
LYME DISEASE		
<i>Borrelia burgdorferi</i> : multistaged illness of skin, joints, and peripheral or central nervous system	Yes, with informed discussion	Ceftriaxone, ampicillin, doxycycline
MASTITIS		
<i>Candida albicans</i>	Yes, with simultaneous treatment of the infant	Nystatin, ketoconazole
Enterobacteriaceae	Yes	Fluconazole
<i>Staphylococcus aureus</i>	Yes (after 24 hr of therapy, during which milk must be discarded)	Dicloxacillin, oxacillin, erythromycin, clindamycin, cotrimoxazole, azithromycin, linezolid, vancomycin
Group A streptococci	Yes (after 24 hr of therapy, during which milk should be discarded)	First-generation cephalosporins, penicillin, ampicillin, amoxicillin, erythromycin, azithromycin
<i>Mycobacterium tuberculosis</i>	No breast milk or breastfeeding for 2 weeks of maternal therapy; consider prophylactic isoniazid for the infant	Isoniazid, rifampin, ethambutol, pyrazinamide, ethionamide
Pulmonary or extrapulmonary infection with <i>M. tuberculosis</i>	Yes, expressed breast milk can be used during initial 2 weeks of maternal therapy, then breastfeeding can continue	Antituberculous medications are acceptable during breastfeeding
TRICHOMONAS VAGINALIS		
Vaginitis, urethritis, or asymptomatic infections	Yes	Metronidazole
ADENOVIRUSES		
Conjunctivitis, upper/lower respiratory infections, gastroenteritis	Yes	

*Patients with the syndromes or conditions listed may present with atypical signs and symptoms (e.g., neonates and adults with pertussis may not demonstrate paroxysmal or severe cough). The clinician's index of suspicion should be guided by the prevalence of specific conditions in the community and by clinical judgment. The organisms listed are not intended to represent the complete or even most likely diagnoses but rather possible etiologic agents.

[†]Yes means that if the proposed precautions are followed for a hospitalized mother and infant, breastfeeding is acceptable and may be beneficial to the infant. Any infant breastfed during a maternal infection should be observed closely for signs or symptoms of illness.

[‡]Refer to Suggested Readings for a more complete discussion of medications and compatibility with breastfeeding.

[§]See text for more complete discussion.

^{||}No, in the United States and many other countries where safe alternatives to breast milk are available. Yes, in countries where there is no safe alternative to breast milk available.

[¶]Adenovirus types 4 and 7 have been known to cause severe respiratory disease in premature infants or individuals with immunodeficiency or underlying respiratory disease. In certain situations, feeding expressed breast milk to the infant may not be advisable.

HBIG, hepatitis B immunoglobulin.

Modified from Lawrence RA, Lawrence RM: Breastfeeding: a guide for the medical profession, ed 7, St Louis, 2010, Mosby.

The decision-making process to breastfeed despite maternal infection should involve discussion of the usual route of infection transmission, reasonable infection control precautions, potential severity of the infection in the infant or child, medications to treat the mother that are compatible with breastfeeding, the potential of prophylaxis for the infant, the protective effect of breast milk, and the acceptability of using expressed breast milk temporarily. The discussion should involve the mother (or both parents), weighing the known and potential risks of the infection against the known benefits of breastfeeding.³

For example, diphtheria and active pulmonary tuberculosis in the mother are commonly transmitted via the respiratory route, so contact between infant and mother should be proscribed regardless of how the infant is being fed. In the case of cutaneous diphtheria or tuberculosis mastitis, as long as there are no lesions on the breast, expressed breast milk can be given to the infant during the initial treatment of the mother (probable infectious periods are 5 days for diphtheria, and 14 days or until the sputum is negative for acid-fast tuberculous bacilli). Diphtheria and tuberculosis are not transmitted in the milk. Prophylactic antibiotics for the infant are appropriate in each case—penicillin or erythromycin for diphtheria and isoniazid for tuberculosis.^{3,82,83}

In certain highly infectious and serious infections, such as the hemorrhagic fevers—specifically with Ebola or Marburg virus and Lassa fever—the risk of transmission from any contact with the infected mother is high, and the potential severity of the illness in mother or infant necessitates separation of the infant (breastfed or formula fed) from the mother and prescription of breastfeeding as well as feeding expressed breast milk. For dengue virus or *Hantavirus*, standard precautions are appropriate, along with the temporary use of expressed breast milk and subsequent breastfeeding in the recovering mother.³

Possible West Nile virus (WNV) transmission to an infant through breastfeeding has been reported,⁸⁴ but the data on this infection in pregnant or breastfeeding women and their infants are limited. Hinckley and coworkers reported 10 instances of maternal or infant WNV-related illness while breastfeeding.⁸⁵ In five cases, the transmission of WNV through breast milk could not be confirmed or ruled out, and in the other five cases, there was no evidence of vertical transmission. They concluded that the information they presented does not support a change in breastfeeding practices after infection with WNV, and that more information is needed.

The hepatitis C virus (HCV) is a blood-borne infection. The rate of mother-to-infant transmission is about 6%. Several cohort studies suggest that most infants acquire HCV infection in utero or the peripartum period. HCV has been detected in colostrum and breast milk at low levels. Bhola and McGuire, in their analysis of three large cohort studies involving a total of 1854 mother-infant pairs, concluded that although the studies showed slightly higher percentages of HCV infection among the breastfed children, the proportions were not statistically significant.⁸⁶ Guidelines from the Centers for Disease Control and Prevention and from the AAP state that maternal HCV infection is not a contraindication to breastfeeding. HCV and HIV coinfection in the mother is a contraindication to breastfeeding in high-income countries. Because HCV is a blood-borne virus, some authorities recommend avoiding breastfeeding, at least temporarily, if an HCV-infected mother experiences nipples that are cracked or bleeding.

In the case of infections at specific sites, the management varies with the specific etiologic organism. For example, mastitis caused by *Staphylococcus* or group A *Streptococcus* requires contact precautions—delaying breastfeeding for 24 hours after beginning therapy in the mother and discarding the expressed breast milk for the first 24 hours. For endometritis caused by group B *Streptococcus*, standard precautions, breastfeeding after the initial 24 hours of therapy in the mother, and the use of expressed breast milk in the interim are appropriate. An example of the probable protective effect of breastfeeding is botulism.⁸⁷⁻⁸⁹ *Candida* mastitis is a situation in which breastfeeding should continue while the mother and infant are treated simultaneously for at least 2 weeks to prevent reinfection of the breast from contact with the infant's oral candidiasis.

In mothers with hepatitis, identification of the etiologic agent is required before the appropriate management can be determined. Before the etiologic agent is identified, care must include precautions for all potential organisms. Suspension of breastfeeding (pumping and discarding breast milk) until the etiology is determined may be required. Consultation with an infectious disease specialist is often appropriate. For hepatitis A virus, infection in the newborn or young infant is uncommon and not associated with severe illness. Breastfeeding can continue, and if the diagnosis is made within 2 to 3 weeks of the infant's initial exposure to the infected mother, then immune serum globulin and hepatitis A virus vaccine simultaneously can decrease infection in the infant. With hepatitis B virus, the risk of chronic hepatitis B virus infection and its serious complications is high (up to 90%) when infection occurs perinatally or in early infancy. Simultaneous administration of the hepatitis B immune globulin and the hepatitis B virus vaccine prevents hepatitis B virus transmission in over 95% of cases, regardless of whether the infant is fed by breast or bottle. Therefore, it is very appropriate to continue breastfeeding as soon as effective immune therapy is given.⁸³

No clear data indicate hepatitis C virus transmission via breast milk in HIV-negative mothers (L. S. Barden, personal communication, 2000). However, given the multiple issues involved (e.g., low risk of hepatitis C virus transmission via breast milk, increased risk of transmission in association with HIV infection and high levels of hepatitis C virus RNA in maternal serum, lack of effective preventive treatments [vaccines or immune serum globulin] and the risk of chronic hepatitis C virus infection, and serious liver disease), it is essential to educate the parents about the possible risks of continued breastfeeding. If the mother is symptomatic, breastfeeding may not be indicated. If the mother is not symptomatic, breastfeeding is usually appropriate.

Maternal retroviral infection and breastfeeding is a highly controversial issue that continues to be evaluated and debated. HIV-1 is transmissible via breastfeeding and can significantly increase the risk of HIV infection in infants born to HIV-positive mothers (mother-to-child transmission [MTCT]). One meta-analysis of five studies of infants born to HIV-infected mothers reported the risk of HIV transmission to infants strictly from breastfeeding as 14% (95% confidence interval, 7% to 22%).⁹⁰ Among the many concerns about HIV and breastfeeding are the risk of transmission related to the duration of breastfeeding, the relative risks of exclusive versus nonexclusive breastfeeding, the risk of mortality and morbidity resulting from other infections and malnutrition associated with *not* breastfeeding, the significance of HIV viral loads and CD4

counts in the mother relative to transmission from breast milk, the potential protective effects of breast milk against HIV infection, and the degree to which antiretroviral (ARV) therapy for the mother or infant will be protective against HIV infection. Social issues involved in this debate include the right of the mother to make choices for herself and her infant, the social stigma of not breastfeeding in certain cultures and communities, and the possibility that breastfeeding rates in HIV-negative mothers will be adversely affected by the advice given to HIV-positive mothers. In many countries, neither choice is optimal: breastfeeding risks HIV infection in the infant, but not breastfeeding increases the risks of other infections and malnutrition. The lack of adequate data from controlled trials about the various factors contributing to infection adds to the difficulty of making straightforward recommendations applicable to diverse situations around the world. In the United States, it is appropriate to advise no breastfeeding for infants of HIV-infected mothers to decrease the risk of HIV transmission to the infant.^{3,38}

In resource-poor settings, more recent review of the available data on providing ARV prophylaxis to either the mother or the infant during pregnancy and lactation has led to new recommendations from the WHO.⁹¹ These include specific recommendations for the use of ARV therapy in women who need treatment for their own health; continuing the treatment beyond the postpartum period provides additional protection against MTCT while allowing the infant to receive the other benefits of breastfeeding. The criteria for initiating ARV therapy for pregnant women are the same as for nonpregnant women. All HIV-infected women who are not in need of ARV therapy for their own health should receive an effective ARV prophylaxis regimen to prevent MTCT.

The recommendations include two options related to protection during breastfeeding. The first proposes daily administration of nevirapine to the infant from birth until 1 week after all exposure to breast milk has ended. The second proposes that the mother continue an effective ARV regimen, begun as early as the 14th week of gestation, through 1 week after all exposure of the infant to breast milk has ended. Both options are strong recommendations with a moderate quality of evidence. HIV-infected women should still receive education concerning the choices of infant feeding, with emphasis on the benefits of breastfeeding in combination with ARV prophylaxis for the mother or infant for the duration of breast-milk consumption. Education, support, and medical care throughout lactation for both mother and infant should be provided to achieve the goals of 100% prevention of MTCT, optimal maternal health and survival, and long-term infant health and survival.

Limited reports deal with the risk of HIV-2 transmission via breastfeeding. Studies suggest that HIV-2 transmission via breast milk is less common than HIV-1.⁹² However, until adequate information is available, it is appropriate to use the same guidelines as for HIV-1.

Transmission of human T-cell leukemia virus type I (HTLV-I) infection is associated with breastfeeding, although short-term breastfeeding (<6 months) may pose no greater risk than the risk for formula-fed infants.⁹³⁻⁹⁵ In Japan, where high rates of infection with this virus occur, proscription of breastfeeding is common. In the United States, when the mother has documented HTLV-I infection, it is appropriate to discuss the options, risks, and benefits of breastfeeding and to consider short-term breastfeeding. There are many uncertainties

concerning HTLV-II, related to the diseases associated with infection and to whether transmission occurs via breast milk. Here again, it is appropriate to discuss the available data and to include an infectious disease consultant in the discussion.³

Numerous reviews⁹⁶⁻⁹⁹ and studies^{100,101} attempt to address the many issues of breastfeeding by HIV-positive mothers. The two most helpful resources related to breastfeeding and infection are the AAP's Report of the Committee on Infectious Diseases,⁸³ and *Breastfeeding: A Guide for the Medical Profession* by Lawrence and Lawrence³; the latter contains a chapter and an appendix dedicated to the issue.

Complications of the Breast

PLUGGED DUCTS

Tender lumps in the breast in a mother who is otherwise well are probably caused by plugging of a collecting duct. The best treatment is to continue nursing while manually massaging the area to initiate and ensure complete drainage. Holding the infant in a different position may encourage flow, as may application of hot packs before a feeding. If repeated plugging occurs, a check should be made for possible obstruction from a brassiere strap or other external forces. Some women can actually see small plugs ejected when they massage. For some, reducing polyunsaturated fats in the diet and adding lecithin³ provides relief.

GALACTOCELE

Milk-retention cysts (galactoceles) are uncommon and are usually associated with lactation. The swelling is smooth, rounded, and nontender. The cyst may be aspirated to confirm the diagnosis and to avoid surgery, but it will fill up again. The cyst can be removed with local anesthesia without interruption of the breastfeeding routine. The diagnosis can also be confirmed by ultrasound, by which the cyst and milk look similar but tumor is distinguishable.³

MASTITIS

Mastitis is an infectious process in the breast producing localized tenderness, redness, and heat, together with systemic symptoms of a flulike illness with fever and malaise. It can be distinguished from engorgement and plugged duct (Table 9-4). Usually a red, tender, hot, swollen, wedge-shaped area of the breast is visible, and it corresponds to a lobe (Fig. 9-8). The common organisms are *Staphylococcus aureus*, *Escherichia coli*, and, rarely, *Streptococcus*.

The major points of management are as follows:

- Breastfeeding should continue on both breasts.
- Antibiotics appropriate to the probable cause and relevant sensitivities should be prescribed.
- Antibiotics should be given for no less than 10 days, and preferably 14. The antibiotic should be safe for the infant.
- Bed rest is necessary, and the mother should bring the infant to bed to nurse. She will need assistance for the rest of the household responsibilities.

The most common cause of recurrent mastitis is delayed or inadequate treatment of the initial disease. On recurrence, cultures of a midstream flow of milk should be sent and antibiotics chosen accordingly.

TABLE 9-4 Comparison of Engorgement, Plugged Duct, and Mastitis

Symptom	Engorgement	Plugged Duct	Mastitis
Onset	Gradual, immediately after birth	Gradual, after feedings	Sudden, after 10 days
Site	Bilateral	Unilateral	Usually unilateral
Swelling and heat	Generalized	May shift; little or no heat	Localized, red, hot, swollen
Pain	Generalized	Mild but localized	Intense but localized
Body temperature	<38.4° C (101° F)	<38.4° C	>38.4° C
Systemic symptoms	Feels well	Feels well	Flulike symptoms

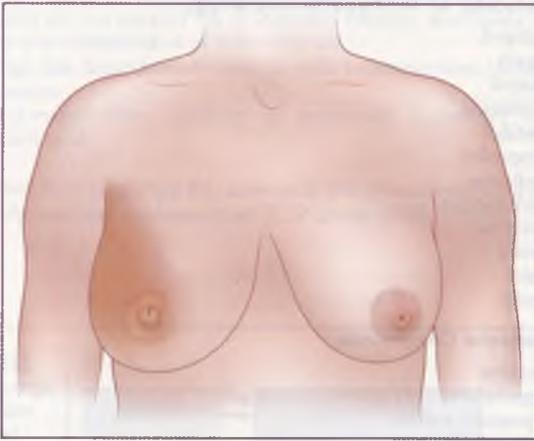

Figure 9-8 Mastitis of right breast, upper outer quadrant. (From Lawrence RA, Lawrence RM: *Breastfeeding: a guide for the medical profession*, ed 7, St Louis, 2010, Mosby.)

CANDIDIASIS OF NIPPLE AND BREAST

Candidiasis of the breast is frequently overdiagnosed because there are several causes for the breast pain that is described by mothers as feeling like “a stab with a hot poker.” On examination, there may be little to see except a pinkish hue to the nipple and central areola. Rarely are white plaques seen on the nipple. If the mother has a history of vaginal candidiasis, the infant’s mouth may have become colonized, and this could have resulted in inoculation of the nipples. The infant should also be examined for both thrush and diaper rash and treated simultaneously with the mother for a full 2 weeks. Nystatin ointment is applied after each feeding to nipples and areolae. The infant receives nystatin drops orally to the oral mucous membranes after each feeding. For a recurrent episode, the mother can be treated with 200 mg oral fluconazole systemically once daily for 3 days. The infant can be given 6 mg/kg on day 1 and then 3 mg/kg per dose every 24 hours orally. Pacifiers and bottle nipples that are put in the mouth should be discarded and new ones sterilized daily. Persistent thrush requires a complete evaluation of the mother and may require treatment for vaginal thrush, decreased sugar in diet, and colonization with lactobacilli by capsule or yogurt.

Ongoing Breastfeeding Support

The duration of lactation will vary significantly by mother-infant dyad. Support should be given to every mother to

maintain her milk supply. This is especially important when the mother and infant are separated for longer periods of time as might occur with maternal hospitalization, surgery, or return to work or school, as some of the more common examples of separation. One of the more effective practices that can assist mothers in maintaining their milk supply involves creating a “breastfeeding-friendly physician’s office.”¹⁰² An office environment that is supportive of breastfeeding can include providing, for example, appropriate written and audiovisual breastfeeding materials, a private lactation room, prenatal and postnatal visits with an emphasis on breastfeeding, access to a lactation consultant, and positive feedback about breastfeeding from the staff and clinicians. Some of the same factors that contribute to successful breastfeeding will facilitate the maintenance of the milk supply during times of separation; early skin-to-skin contact and suckling within the first hour of life, emphasis on early feeding cues and correct technique, encouraging “instinctual breastfeeding behaviors” for both the mother and infant,¹⁰³ and encouraging exclusive and unrestricted (i.e., on-demand) breastfeeding. Mothers should be instructed on how to express their milk, appropriately store it for home use, and maintain lactation. Not every woman needs a pump. Every woman should be trained how to manually express her breasts before she leaves the hospital, as this will facilitate her managing common problems such as a plugged duct or engorgement. Hand pumps, battery-powered pumps, and electrical pumps are available. The most effective method to express milk varies from woman to woman, but it should be comfortable and meet the infant’s and mother’s needs.

As part of the normal discussion of ongoing lactation, the mother should be asked about potential periods of separation from her infant and in particular about her plans for return to work or school as an introduction to the topics of human milk storage for home use and the maintenance of lactation.

Medications While Breastfeeding

Questions about medication during breastfeeding are very commonly asked. The transfer of maternal drugs to the infant during lactation is different from transfer to the fetus during pregnancy. Although it is almost always better to breastfeed, the physician must weigh the benefit and risk of a medication against the substantial benefit of being breastfed for the infant. The risk-to-benefit ratio differs for each drug and clinical setting. Both scientific information and experienced clinical judgment are required to assess the risks and benefits and determine the therapeutic choice.

BOX 9-4 AMERICAN ACADEMY OF PEDIATRICS DRUG GROUPS 1, 2, 3, AND 6**GROUP 1: CYTOTOXIC DRUGS THAT MAY INTERFERE WITH CELLULAR METABOLISM OF THE NURSING INFANT**

Possible immune suppression; unknown effect on growth or association with carcinogenesis; neutropenia

Cyclophosphamide
Cyclosporine
Doxorubicin*
Methotrexate

GROUP 2: DRUGS OF ABUSE FOR WHICH ADVERSE EFFECTS ON THE INFANT DURING BREASTFEEDING HAVE BEEN REPORTED[†]

Amphetamine*
Cocaine
Heroin
Marijuana
Phencyclidine

GROUP 3: RADIOACTIVE COMPOUNDS THAT REQUIRE TEMPORARY CESSATION OF BREASTFEEDING

Copper 64 (⁶⁴Cu)
Gallium 67 (⁶⁷Ga)
Indium 111 (¹¹¹In)
Iodine 123 (¹²³I)
Iodine 125 (¹²⁵I)
Iodine 131 (¹³¹I)
Radioactive sodium
Technetium 99m (^{99m}Tc)
Macroaggregates, sodium pertechnetate (^{99m}TcO₄)

GROUP 6: PARTIAL LIST OF SELECTED MATERNAL MEDICATIONS USUALLY COMPATIBLE WITH BREASTFEEDING**Analgesics**

Acetaminophen
Ibuprofen
Codeine
Antacids

Antibiotics That Can Also Be Given to Infants

Acyclovir
Amoxicillin
Cephalosporins
Erythromycin
Fluconazole
Gentamicin
Kanamycin
Miconazole
Penicillins
Spironolactone
Streptomycin
Vancomycin

Cardiovascular or Antihypertensive Drugs

Captopril
Digoxin
Enalapril
Hydralazine
Labetalol
Metoprolol
Nifedipine
Nitrofurantoin
Quinidine
Quinine
Sotalol
Timolol

Miscellaneous Compounds

Lidocaine
Progesterone-only contraceptive pill
Magnesium sulfate
Prednisolone
Prednisone
Propylthiouracil
Scopolamine
Warfarin
Laxatives (bulk forming and stool softening)
Vaccines

*Drug is concentrated in human milk.

[†]The AAP Committee on Drugs strongly believes that nursing mothers should not ingest drugs of abuse because they are hazardous to the nursing infant and to the health of the mother.

From American Academy of Pediatrics, Committee on Drugs: the transfer of drugs and other chemicals into human milk, *Pediatrics* 108:776, 2001.

The AAP Committee on Drugs has published a list of commonly used drugs and chemicals that may transfer into human milk (Box 9-4).¹⁰⁴ The list is not all-inclusive and is revised intermittently.¹⁰¹ Absence of a drug from the list merely indicates that the committee did not study it in reference to lactation. The categories are as follows:

1. Cytotoxic drugs that may interfere with cellular metabolism of the nursing infant (see Box 9-4, group 1)
2. Drugs of abuse for which adverse effects on the infant during breastfeeding have been reported (see Box 9-4, group 2)
3. Radioactive compounds that require temporary cessation of breastfeeding (see Box 9-4, group 3)
4. Drugs for which the effect on nursing infants is unknown but that may be of concern—for example, bromocriptine, ergotamine compounds, and lithium
5. Drugs that have been associated with significant effects on some nursing infants and should be given to nursing mothers with caution

6. Maternal medication usually compatible with breastfeeding (see Box 9-4, group 6)
7. Food and environmental agents that might have an effect on the breastfeeding infant

A readily available and frequently updated handbook, *Medications and Mothers' Milk*, is published by Hale.¹⁰⁵ This reference provides a scale that is roughly the reverse of the long-established classification system developed by the AAP. The Hale definitions are as follows:

- L1 safest
- L2 safer
- L3 moderately safe
- L4 possibly hazardous
- L5 contraindicated

A lack of information about a drug does not necessarily require cessation of breastfeeding. Understanding the pharmacology of a drug, the dosing schedule, and the stage of growth and development of the infant inform the decision about whether it would affect the infant. Characteristics of the

BOX 9-5 THE PASSAGE OF DRUGS INTO BREAST MILK

1. Mammary alveolar epithelium is a lipid barrier with water-filled pores, and it is most permeable for drugs during the colostrum phase of milk secretion (1st postpartum week).
2. Drug excretion into milk depends on the drug's degree of ionization, molecular weight, solubility in fat and water, and relationship of pH of plasma (7.4) to pH of milk (7.0).
3. Drugs enter mammary cells basally in the nonionized non-protein-bound form by diffusion or active transport.
4. Water-soluble drugs of molecular weight less than 200 pass through water-filled membranous pores.
5. Drugs leave mammary alveolar cells by diffusion or active transport.
6. Drugs may enter milk via spaces between mammary alveolar cells.
7. Most ingested drugs appear in milk; drug amounts in milk usually do not exceed 1% of ingested dosage, and levels in the milk are independent of milk volume.
8. Drugs are bound much less to milk proteins than to plasma proteins.
9. Drug-metabolizing capacity of mammary epithelium is not understood.

Modified from Lawrence RA, Lawrence RM: Breastfeeding: a guide for the medical profession, ed 7, St Louis, 2010, Mosby.

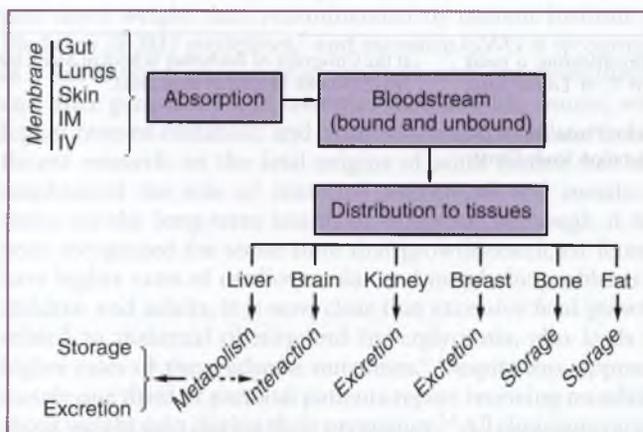

Figure 9-9 Distribution pathways for drugs. Distribution pathways vary with the drug and are relevant to advising the lactating mother about breastfeeding when drugs have been prescribed. IM, intramuscular; IV, intravenous. (Modified from Rivera-Calimlim L: Distribution pathways for drugs, once absorbed during lactation, Clin Perinatol 14:51, 1976.)

drug that influence its passage into milk include the size of the molecule, its solubility in lipid or water, whether it binds to protein, the pH, and the diffusion rates (Box 9-5). The route of administration influences the blood levels and therefore the milk levels. Passive diffusion is the principal transport mechanism. How the drug is metabolized influences whether it is present in the milk in its active form or as an inactive metabolite (Fig. 9-9).

The infant's ability to absorb, digest, metabolize, store, and excrete a drug must be considered when choosing a medication for a nursing mother. A drug that is not orally bioavailable will not be absorbed from the milk by the infant. The ability to absorb and metabolize a drug depends on the infant's developmental age and the chronologic age. An 18-month-old who

nurses briefly about four times a day for comfort will get little medication, has a substantial diet other than mother's milk, and can metabolize and excrete more efficiently than a newborn. In the first weeks of life, the maturation or gestational age should be considered when determining the safety of a medication, because the less mature the infant is, the less mature are the liver and kidneys.

With the exception of radioactive compounds such as iodine 131, there is no drug whose possible presence in the milk would require immediate withholding of breastfeeding because the physician does not know the data. Therefore, the arbitrary interference with breastfeeding until information can be obtained is not justified. Ample references and information lines are available to resolve the issue. For medications used once or for a short time, the time required for the drug to clear the maternal system and her milk can be determined. The mother can pump and discard her milk for that period and return to breastfeeding (usually a few hours or days, not weeks).

MILK-TO-PLASMA RATIO

The *milk-to-plasma ratio*, a term applied to drugs being used by a lactating mother, indicates the level of the drug in the milk compared with the level in the plasma at a given time. The dosage of the drug, including time and route of dosing, must be known to be able to interpret the ratio. If there is a very low level in the plasma and the same very low level in the milk, the ratio is 1. A ratio of 1 means that the level is of concern, even though the actual level in milk is low. Most drugs have a milk-to-plasma ratio of less than 1. It is important to know peak plasma and peak milk levels, and peak plasma and peak milk times, to make appropriate recommendations to avoid feeding the infant when transfer of the drug would be greatest.

ANALGESIA AND ANESTHESIA FOR THE BREASTFEEDING MOTHER

The appropriate use of analgesia and anesthesia in the labor, delivery, and the peripartum period as well as at other times, for the breastfeeding mother is a skill that every obstetrician should master. The use of pharmacologic agents for pain relief during labor and in the postpartum period is appropriate and may improve outcomes for the infant and mother. Their use may influence the course of labor, the neurobehavioral status of the infant, and the initiation of breastfeeding. The effects of such analgesic or anesthetic medications on lactation depends on various factors, such as the age and size of the infant, the ability of the infant to clear the quantity of medication he or she is exposed to, and the stage of lactation. Pain, suffering, fear, and anxiety during labor can affect delivery and have a negative effect on breastfeeding. These issues may necessitate pharmacologic treatment, but continuous support in labor and nonpharmacologic management of pain may decrease the need for medications and facilitate early skin-to-skin contact and initiation of breastfeeding. Appropriately referenced guidelines for analgesia and anesthesia use in lactating women are available from the Academy of Breastfeeding Medicine.¹⁰⁶

Stem Cells and Human Breast Milk

Interest in mammary gland stem cells (MaSC) is focused on two main areas: the search for readily available multipotent

Maternal Nutrition

NAOMI E. STOTLAND, MD | LISA M. BODNAR, PhD, MPH, RD |
BARBARA ABRAMS, DrPH, RD

Despite ample evidence about the importance of nutrition on health in general as well as during pregnancy, the typical American diet is of poor quality. In the United States, diets are far below national recommendations for intake of fruits, vegetables, whole grains, and legumes, and intake of sodium, fats, and added sugars is excessive.¹ Total energy intake has risen, and calories from snacks, soft drinks, and meals eaten away from home (including fast-food restaurants) are higher than ever.^{2,3}

For much of the 20th century, the public health nutrition focus during pregnancy was on the prevention of undernutrition, as inadequate gestational weight gain (GWG) was considered a threat to optimal perinatal outcome. Today, overweight and obesity are the norm, with 32% of reproductive-age women obese and 56% overweight.⁴ Approximately 50% of U.S. women gain more weight than recommended by current Institute of Medicine (IOM) guidelines,⁵ and excessive GWG is recognized as a risk factor for a variety of serious health outcomes during and after pregnancy and over the mother's life course, with higher rates of metabolic and cardiovascular illness later in life. Recent research on the fetal origins of adult disease has also emphasized the role of maternal nutritional and metabolic status on the long-term health of offspring. Although it has been recognized for some time that growth-restricted fetuses have higher rates of cardiovascular and metabolic problems as children and adults, it is now clear that excessive fetal growth, related to maternal obesity and hyperglycemia, also leads to higher rates of these adverse outcomes.⁶ Despite this, approximately one third of prenatal patients report receiving no advice about weight gain during their pregnancy.^{7,8} All clinicians caring for reproductive-age women should educate themselves and their patients about the importance of good nutritional health before, during, and after pregnancy.

Pre-conception Issues

Maternal nutritional and metabolic status at the time of conception may be even more important for fetal development than nutrition during pregnancy. Organogenesis occurs early in the first trimester before many women are aware of the pregnancy. Hence, women who may become pregnant or who are attempting to conceive should optimize their nutritional and metabolic status before pregnancy. Women with pregestational diabetes mellitus should strive to achieve euglycemia before conception, as higher levels of hemoglobin A_{1c} (a marker for hyperglycemia) are associated with progressively higher rates of congenital deformities.⁹

FOLATE

Folate is a term used to describe both folate that occurs naturally in food sources and folic acid, the form of the vitamin

found in fortified foods and dietary supplements. Folate is essential for nucleic acid synthesis, red blood cell synthesis and maintenance, and fetal and placental growth. Maternal folic acid deficiency can cause neural tube defects (NTDs) in the fetus, and other congenital anomalies. The U.S. Centers for Disease Control and Prevention (CDC) recommends 0.4 mg/day of folic acid from diet or supplements for all women capable of becoming pregnant to reduce the risk for NTDs.⁹ Women with a previous pregnancy affected by an NTD should take 4 mg of folic acid beginning 1 month before conception and throughout the first trimester. The United States began mandatory fortification of cereal and grain products with folic acid in 1998. Fortification substantially improved the folate status of U.S. childbearing-age women and reduced the incidence of pregnancies affected by NTDs by 25%.¹⁰ However, there is concern that folic acid supplementation may no longer further reduce risk of NTDs, possibly because fortification may have provided the amount of folic acid required to prevent a majority of folate-sensitive NTDs.^{11,12}

Obese women have been found to have lower serum levels of folate,¹³ and they are also at increased risk for NTDs.¹⁴ The mechanism underlying the association between obesity and NTDs is unclear, and some have suggested it may be related to a higher serum glucose rather than a folic acid deficit.

Folate deficiency has also been associated with a number of adverse birth outcomes, including spontaneous preterm birth.^{15,16} Folic acid supplementation in pregnancy has been shown to lengthen gestation in some^{17,18} but not all studies.¹⁹ Importantly, there has been no decline in the prevalence of preterm birth since nationwide folic acid fortification. It is possible that the relative concentrations of folate species, which mediate the varied biologic effects of folate, may prove more critical than total folate concentration in preventing preterm birth. Indeed, a recent study reported a biologic interaction between two major folate metabolites, serum 5-methyl-tetrahydrofolate and 5-formyl-tetrahydrofolate, on the occurrence of preterm birth.²⁰ Subsequently, investigators found that these folate species were related to maternal inflammation in the lower genital tract,²¹ a potential mediator of preterm birth.²²

BODY MASS INDEX AND OBESITY

According to epidemiologic research, a woman's pre-pregnancy body mass index (BMI) and adiposity have a greater impact on some perinatal outcomes than her GWG.²³ Women who begin pregnancy underweight are at increased risk for both preterm delivery and delivering a small-for-gestational-age (SGA) infant when compared with women of normal pre-pregnancy BMI. However, otherwise healthy but underweight women appear to be at *decreased* risk for multiple adverse outcomes, including macrosomia, cesarean delivery, and preeclampsia.^{24,25} Women

TABLE 10-1 Obesity Class, Body Mass Index (BMI), and Examples

Obesity Class	BMI	Example
I	30-34.9	5'4" woman weighs 175 lb, BMI = 30
II	35-39.9	5'4" woman weighs 205 lb, BMI = 35
III	≥40	5'4" woman weighs 235 lb, BMI = 40

who begin pregnancy obese have increased rates of spontaneous abortion, congenital anomalies (e.g., NTDs, cardiac and gastrointestinal anomalies), gestational diabetes mellitus (GDM), intrauterine fetal death, hypertensive disorders of pregnancy, cesarean birth, failed vaginal birth after cesarean, thromboembolic disease, postoperative complications, and maternal mortality.^{26,27} Higher BMI is associated with lower rates of births involving SGA infants or intrauterine growth restriction (IUGR); however, obese women with chronic hypertension or diabetic vasculopathy may be at increased risk for IUGR. Obese women have lower rates of spontaneous preterm birth; however, there is some evidence that severely obese women have increased rates of medically indicated preterm birth, probably related to the increased rates of preeclampsia and gestational diabetes. Definitions of class I, II, and III obesity can be found in Table 10-1.

Obesity and Pregnancy

POSTCONCEPTION RISKS

The risk for spontaneous abortion in the first trimester is greater for obese women than for women of normal BMI.²⁸ This increased risk is seen among both naturally conceived and in vitro fertilization pregnancies.²⁹ Obesity is associated with an increased risk for congenital anomalies, including NTDs and cardiac malformations, even in the absence of overt diabetes.^{30,31} Although the mechanism linking obesity and congenital anomalies remains unclear, these same anomalies are associated with diabetes, and undiagnosed hyperglycemia early in gestation has been proposed as the mechanism.³² Such malformations are also more difficult to detect in obese women before the birth, because ultrasonography is less sensitive in women with a high BMI.³³

Later in gestation, pre-pregnancy obesity is associated with higher birth weight and macrosomia, even among women who are not diabetic.^{34,35} Additionally, infants born to obese mothers have a higher percentage of body fat than infants born to normal-weight mothers. In a study of 220 infants born to glucose-tolerant mothers, infants born to women with a BMI of 25 or greater were heavier than those born to women with a BMI of less than 25.³⁴ Of note, the increase in birth weights between the two groups was explained by an excess of fat mass rather than lean body mass in the infants. Although overweight and obesity are protective against the birth of an SGA infant, the data (cited earlier) showing decreased lean body mass and increased fat mass among infants born to obese women suggest that this protection may not lead to better health outcomes in children. Obesity increases the risks for hypertension and type 2 diabetes, and if vascular sequelae are present, it increases the risk for IUGR in spite of significant obesity.³⁶

Recent data suggest that the risks of severe and mild forms of preeclampsia and gestational hypertension increase as pre-pregnancy BMI rises.³⁷ Some of this effect may be mediated by inflammation and dyslipidemia in early pregnancy.³⁸

Obesity is also a well-known risk factor for both pre-gestational and gestational diabetes mellitus.³⁹ Body composition may be a better predictor of insulin resistance during pregnancy (and thus GDM risk) than BMI. In a small study of overweight and obese women, visceral fat measured by ultrasound at 20 weeks' gestation was more highly associated with insulin resistance in late pregnancy than was pre-pregnancy BMI.⁴⁰ Maternal race or ethnicity affects the relationship between maternal BMI and GDM risk. In a multiethnic cohort of women, BMI was the least sensitive for predicting GDM risk among Asians and Latinas, compared with white and African-American women.⁴¹ Among Asian women with GDM, 65.3% had a normal BMI and 19.0% had a low BMI. In contrast, 23.2% of African-Americans and 45.4% of whites with GDM had a normal BMI. Because studies among nonpregnant adults have suggested that Asians accumulate central obesity and manifest cardiometabolic abnormalities at a lower BMI than other racial or ethnic groups, waist circumference may be a better predictor of GDM risk than BMI in this group.

Obesity appears to increase the length of gestation, with most studies showing a *lower risk of spontaneous preterm birth* and a *longer gestation* among those delivering at 37 weeks or beyond.^{23,42} Approximately 75% of preterm births are spontaneous, and 25% are medically indicated. Because obese women have higher rates of hypertensive and diabetic disorders of pregnancy, they may be at higher risk for medically indicated preterm birth. A large, population-based cohort study of births in Scotland found that parity altered the relationship between BMI and preterm birth.⁴³ For spontaneous preterm birth, lower BMI was associated with increased risk, and obesity was protective.

Higher BMI is associated with increased risk for cesarean birth,²⁴ and with lower rates of successful vaginal birth after cesarean section among women undergoing a trial of labor.⁴⁴

Overweight and obesity have been associated with increased rates of *intrauterine fetal demise or stillbirth* in large epidemiologic studies.^{45,46} This association persisted even when analysis was restricted to women with early ultrasound dating, ruling out undiagnosed postdatism as the cause. Increased stillbirths are also seen among obese women even when women with overt hypertension and diabetes are excluded from the analyses. The mechanism remains unclear, but some investigators have suggested that subclinical hypertension and hyperglycemia may be the etiology. Fetal monitoring may be more difficult among severely obese women, and obesity has been associated with decreased maternal perception of fetal movement.⁴⁷

MATERNAL OBESITY AND LONG-TERM OFFSPRING OUTCOMES

The relationship between maternal pre-pregnancy obesity and offspring obesity must account for shared genetic, behavioral, environmental, and in utero influences. Animal studies in which animals are fed obesogenic diets during gestation show that there are lifelong adverse changes in body weight, adiposity, and metabolism. Human studies are conflicting as to the role of exposure to maternal obesity in utero as a factor in offspring obesity, but there is a preponderance of evidence that there are

fetal origins of adult obesity as well as cardiometabolic disease.⁴⁸ Optimizing maternal metabolic status with a combination of weight loss and improved diet and exercise behaviors may reduce the risk of obesity in the offspring, but only a randomized trial of a pre-conception intervention would give a definitive answer as to the role of pre-pregnancy obesity in childhood obesity. Of note, an Australian study examined barriers to pre-conception weight loss intervention among obese women, finding that only 16% of obese women self-categorized as obese, and most had already attempted weight loss unsuccessfully.⁴⁹

BARIATRIC SURGERY AND PREGNANCY

Between 1998 and 2005 in the United States, there has been a sixfold increase in the number of bariatric surgery procedures, to about 50,000 procedures annually. Approximately half of these procedures are performed in reproductive-age women.⁵⁰ Although these procedures often result in substantial and sustained weight loss as well as in improvement in diabetes, the data on the effect of bariatric surgery on subsequent pregnancy outcomes are limited. Studies comparing women after bariatric surgery to morbidly obese controls have found reduced rates of GDM and hypertensive disorders of pregnancy.⁵¹ Of concern, a recent case-control study comparing post-bariatric surgery patients to obese and morbidly obese controls found a statistically significant increased risk of SGA, preterm birth, and perinatal mortality among the postsurgical group.⁵² The authors speculated that this may be related to poor nutritional status in the postsurgical group, and they recommended that post-bariatric surgery patients optimize their pre-pregnancy nutritional status. These patients should be followed closely during pregnancy to ensure adequate micronutrient and caloric intake, and maternal weight gain as well as fetal growth should be closely monitored.

WEIGHT GAIN DURING PREGNANCY

In 1990, the IOM established BMI-specific guidelines for GWG for women with singleton pregnancies. Since that time, numerous epidemiologic studies have validated the weight gain ranges provided by the IOM, finding that gain within the guidelines is associated with the lowest rates of numerous adverse maternal and infant outcomes.^{53,54}

In 2009, the IOM issued revised guidelines for weight gain during pregnancy (Table 10-2).⁵ The 2009 IOM Committee expanded the focus of the new guidelines, from preventing low birth weight to also minimizing short- and long-term adverse outcomes for both mother and child. The new guidelines emphasize obesity prevention and reflect new understanding of the developmental origins of disease in utero and the importance of considering a life course perspective in the relationship between pregnancy weight gain and health.

The Committee based the 2009 recommendations on an extensively reviewed evidence base of published research and commissioned studies, including a systematic review conducted by the Agency on Health Quality Research.⁵⁵ e-Table 10-3 shows that the strongest available evidence linked excessive GWG to *cesarean delivery*, *maternal postpartum weight retention*, *macrosomia*, and *large-for-gestational-age fetuses*. Low GWG is linked to *low birth weight* or *SGA fetuses*. There is also strong evidence of a U-shaped relationship between low GWG and preterm delivery in lean women, particularly those with low

TABLE 10-2 Recommended Total Weight Gain Ranges for Pregnant Women by Pre-pregnancy Body Mass Index (BMI)*

Weight Status	Recommended Weight Gain (lb)
SINGLETON PREGNANCY	
Underweight (BMI < 18.5)	28-40
Normal weight (BMI = 18.5-24.9)	25-35
Overweight (BMI = 25-29.9)	15-25
Obese (BMI ≥ 30)	11-20
TWIN PREGNANCY	
Underweight	Insufficient data
Normal weight	37-54
Overweight	31-50
Obese	25-42

Note: For underweight and normal-weight women, these total-weight-gain guidelines are equivalent to a rate of gain of ~1 lb/wk in the second and third trimesters. For overweight women, this rate is ~0.6 lb/wk, and for obese women, it is 0.5 lb/wk.

*BMI is calculated using metric units. To calculate BMI, go to www.nhlbisupport.com/bmi/.

From Institute of Medicine: Weight gain during pregnancy: reexamining the guidelines, Washington, DC, National Academies Press. Posted online, May 28, 2009.

pre-pregnancy BMI, and there is moderate evidence that high gestational gain is also associated with preterm birth. There are too few studies to distinguish spontaneous from medically indicated preterm birth, and important questions remain about biologic plausibility as well as study methods that address the bias that duration of gestation is correlated with both GWG and preterm birth.⁵⁶

Although research relating total GWG and GDM, as well as preeclampsia, is common, the studies are difficult to interpret as the complications themselves may influence total GWG.⁵⁷⁻⁵⁹ Women are screened for GDM at 24 to 28 weeks, and management of the condition involves a diet and lifestyle intervention that often reduces third-trimester weight gain.^{60,61} In general, preeclampsia is clinically evident late in pregnancy, but many of the pathophysiologic changes are present months earlier.⁶² The increased vascular permeability and decreased plasma oncotic pressure in preeclamptic pregnancies can cause significant edema and rapid weight gain that would affect total GWG.⁵ Characterizing the relationship between GWG and the development of GDM and preeclampsia requires studying weight gain before the diagnosis of these conditions. Positive associations between excessive GWG before glucose screening and risk of impaired glucose tolerance have been reported.^{63,64} Excessive gain before screening was associated with GDM among either severely obese women only⁶⁵ or overweight women.^{66,67} We are unaware of any published work that has examined preeclampsia in this regard.

At the time of the writing of the IOM guidelines,⁵ there were only a few large studies suggesting an independent role for excessive GWG in the development of obesity or cardiovascular/metabolic disorders in childhood. Since then, there is a growing consensus that both inadequate and excessive GWG contribute to childhood obesity.^{26,68} For other maternal and child outcomes reviewed, data were missing or insufficient, so the role of GWG was deemed weak. The committee called for new research to fill these gaps in knowledge.

The 2009 IOM Committee considered studies in which relevant outcomes were simultaneously examined to provide evidence-based ranges that balance risks of both low and high GWG for short- and long-term maternal and child outcomes. The resulting 2009 recommendations (see Table 10-2) differ from the 1990 guidelines in several ways. The four pre-pregnancy BMI categories used in 1990 were replaced with the World Health Organization categories now commonly used for adults. The recommendations made in 1990 for short, young, or African-American women have been eliminated because of lack of evidence that they are necessary, and a recent study of women with normal BMI confirms that these groups do not require special guidelines.⁶⁹

The 2009 IOM recommendation for obese women (pre-pregnancy BMI ≥ 30) is a total weight gain of 11 to 20 lb during pregnancy. The Committee was aware that an even lower recommendation could be appropriate for women with severe obesity. Observational studies show that the prevalence of low GWG is more common as pre-pregnancy obesity increases, and data cited in the report provided limited evidence that lower prenatal gains or even weight loss appeared safe and even beneficial in women with class II or III obesity. Several large observational studies published since the report was released confirm that lower amounts of gain than recommended or even weight loss may be consistent with good short-term pregnancy outcome, particularly among the women with class II or III obesity.⁷⁰⁻⁷² However, there are important gaps in knowledge about possible adverse outcomes associated with inadequate weight gain in obese women. In addition to increased incidence of SGA fetuses associated with low gain or loss, the theoretical potential exists for irreversible neurocognitive damage in the fetus resulting from maternal physiologic responses to caloric restriction.⁷³ Data providing evidence that lower weight gain in severely obese women is safe for both short- and long-term health of the fetus are urgently needed to allow tailoring of population-based recommendations by grade of obesity. Ongoing clinical trials of restricted weight gain (0 to 5 kg) among obese women will provide valuable data in the future.⁷⁴

Interventions to Optimize Gestational Weight Gain

Given the high prevalence of both pre-pregnancy obesity and excessive GWG, and the possible long-term implications of weight and nutrition during pregnancy, helping women to achieve optimal weight gain and to learn healthy lifestyle habits during pregnancy is imperative. However, research on effective interventions has provided no clear evidence-based strategy. To date, three meta-analyses and three systematic reviews have been published that investigate behavioral interventions to improve maternal dietary intake or physical activity to reduce excess GWG. One review focused only on women who began pregnancy overweight or obese,⁷⁵ and five included a wider range of pre-pregnancy BMIs.⁷⁶⁻⁸⁰ Researchers used a variety of intervention strategies including counseling and education about weight gain, healthy eating and physical activity, and monitoring of weight gain, with or without feedback. The intensity and frequency of interventions, and the number and combinations of different components, varied. Although all reviews used high-quality methodology to assess the evidence, and all looked at the same accumulation of data, the conclusions varied. Three of the reviews concluded that

interventions can effectively reduce GWG, but the results were inconsistent^{77,79,80}; two concluded that interventions were ineffective^{75,76}; and one concluded that the quality of the studies was too weak to consider their findings for evidence-based guidelines.⁷⁸ Overall, these reviews demonstrated a clear need for more definitive research on which to base clinical practice. Large intervention studies aimed at optimizing weight gain for both obese and normal-weight women are currently ongoing in the United States, the United Kingdom, and Australia, and it is hoped that the results of these studies will provide the evidence base for effective care in the clinical setting.

In the meantime, the 2009 IOM report recommends (1) that women normalize their weight before pregnancy, (2) that clinicians assess pre-pregnancy BMI, recommend the appropriate target weight gain guideline, and track weight gain during pregnancy, ideally plotting on a graph to visualize progress, (3) that individualized assessment and counseling be provided at the beginning of pregnancy and throughout pregnancy as needed, to assist women in following dietary and physical activity patterns that support optimal weight gain, and (4) that women be similarly assisted in returning to their pre-pregnancy BMI after the birth. It is important to recognize that measuring and discussing weight gain alone does not represent adequate care. As a result of normal variability, some women with good diets and lifestyle behaviors gain more or less than recommended for a good outcome, and others with apparently normal GWG have poor nutritional status. Therefore, individualized care, particularly for obese women, is required. Given time constraints and the complexity of changing behaviors, a multidisciplinary team including a perinatal dietitian may be needed. Physical activity should be part of the strategy to prevent excessive GWG. There is evidence that women, including obese women, who exercise or are more physically active during pregnancy gain less weight.^{77,81}

DIETARY GUIDELINES

Because most American women are not meeting current dietary and physical activity guidelines, it is incumbent upon obstetricians and other prenatal care providers to assess diet and exercise behaviors at the start of pregnancy and to counsel women to make healthful behavior changes. The U.S. government offers interactive websites that allow a health professional to estimate energy and nutrient requirements (<http://www.choosemyplate.gov/supertracker-tools/daily-food-plans/moms.html>) or that allow a woman to plan a diet based on the newest dietary guidelines and MYPLATE food plan (www.choosemyplate.gov/supertracker-tools/daily-food-plans/moms.html) according to BMI and reproductive status (nonpregnant, by pregnancy trimester, or lactating). The MYPLATE food plan, in general, recommends that 50% of the plate be devoted to vegetables and fruit, 25% to a lean protein source, and 25% to a whole grain, and it also includes a dairy product. This general food plan is a good basis for dietary guidance in pregnancy, especially if whole, unprocessed foods low in sugar and fat are selected. Another useful resource for general prenatal dietary guidelines is provided by the March of Dimes (www.marchofdimes.com/pregnancy/nutrition_indepth.html).

Furthermore, as pregnancy progresses, most women benefit from dividing food intake into three smaller meals with two to three snacks, each containing a lean source of protein. Finally, although a pregnant woman is “eating for two,” clinicians should emphasize that the extra energy required is not a lot of

food, and that pregnant women require food with high nutritional quality and therefore should substitute healthier foods for processed or fast food. For example, one medium banana + 1½ tablespoons (Tbl) peanut butter + 8 fl oz skim milk provides the extra 340 kcal/day required in the second trimester, and a 12-fl-oz fruit smoothie (fruit, juice, low-fat yogurt) + 2 Tbl trail mix provides the entire 450 extra kcal/day required in the third trimester. Additional details on providing quality nutrition to pregnant women have been published.^{82,83}

EXERCISE/PHYSICAL ACTIVITY

The CDC recommends that healthy pregnant women get at least 150 minutes per week of moderate-intensity aerobic activity.⁸⁴ The American College of Obstetricians and Gynecologists (ACOG) recommends at least 30 minutes of exercise on most days of the week.⁸⁵ Low-impact activities such as swimming, walking, prenatal yoga, and low-impact aerobics are appropriate for most pregnant women. Women who were very active prior to pregnancy can generally continue their exercise routines, but advice must be individualized.

MACRONUTRIENT INTAKE

The following is a general guide for otherwise healthy pregnant women with singleton gestations.

Fruits and Vegetables

Ideally, pregnant women should eat seven or more servings of fruits and vegetables (in any combination) per day, as recommended for nonpregnant individuals. Fruits and vegetables provide fiber as well folic acid, vitamin C, vitamin A, antioxidants, and other nutrients. Consumption of higher-fiber diets is associated with lower risk for excessive GWG among obese women.⁸⁶ One serving of fruit is equal to, for example, one medium apple or one medium banana. One serving of vegetables equals 1 cup raw leafy vegetables or one-half cup of other vegetables (raw or cooked).

Carbohydrates

Carbohydrates should make up between 45% and 65% of a woman's daily calories. Pregnant women should consume six to nine servings of whole grains a day, such as whole wheat bread and whole grain cereals. Whole grains provide fiber as well as B vitamins and minerals. One serving of bread or cereal is equal to one slice of bread, or one-half cup of cooked cereal, rice, or pasta.

Dairy Products

Pregnant women should eat at least four servings of low-fat or nonfat dairy products per day. Dairy products are good sources of calcium, vitamins A and D, protein, and B vitamins. Women who are lactose intolerant can get these nutrients from other food sources: Yogurt and many cheeses are low in lactose, and reduced-lactose milk is commercially available. Women who avoid dairy products can choose other calcium-rich foods such as calcium-fortified citrus juice or soy milk, tofu made with calcium sulfate, canned salmon or sardines (with bones), ground sesame seeds, and leafy green vegetables.

Protein

Pregnant women need about 60 g of protein daily, 10 g above the requirement for nonpregnant women. However, most

Americans consume more protein than necessary, and much of it is from animal sources high in saturated fat. Beneficial sources of protein include lean meats such as chicken without skin, fish, beans, tofu, nuts, and eggs. One serving of protein is equal to 2 to 3 oz of cooked lean meat, poultry, or fish; one-half cup tofu or cooked dried beans; one egg; one-third cup of nuts; or two tablespoons of peanut butter.

Fats

Total fat intake should be between 20% and 35% of daily calories. Beneficial fats include polyunsaturated fatty acids found in fish, nuts, and some vegetable oils. Women should limit their intake of saturated fats (especially from fatty red meat) and avoid trans fats.

Food-Borne Infections

Because pregnant women and fetuses are especially vulnerable to food-borne illnesses such as toxoplasmosis and listeriosis, pregnant women should avoid uncooked and undercooked meats and fish. More information on how to avoid infection with listeriosis can be found on the CDC website, www.cdc.gov/listeria/index.html. General information on food safety can be found on the CDC website, www.cdc.gov/foodsafety/index.html (accessed April 2012).

Fish Consumption: Mercury and Omega-3 Fatty Acids

In 2004, the U.S. government issued health advisories recommending that pregnant women limit their fish consumption to avoid exposure to methyl mercury, a heavy metal and industrial pollutant or contaminant that accumulates in some seafood. Mercury is neurotoxic, and the developing fetus is especially vulnerable. These recommendations were based primarily on data from studies conducted in the Faroe Islands and in New Zealand,^{87,88} which demonstrated worse performance on neurobehavioral tests among children exposed to higher levels of mercury-contaminated fish. However, a similar study from the Seychelles Islands showed no adverse effect of higher maternal fish consumption.⁸⁹ Subsequent to the governmental fish advisories, studies demonstrated that fish consumption dropped among women of reproductive age in the United States.⁹⁰

However, fish is a primary source of omega-3 fatty acids, which are important in fetal neurologic development. Higher consumption of dietary fish oils has also been associated in epidemiologic studies with lower rates of preterm birth, low birth weight, and preeclampsia.⁹¹⁻⁹³ In a large population-based study published in 2007 from the United Kingdom, lower maternal fish consumption was associated with lower verbal intelligence quotient scores and other neurobehavioral measures in children 6 months to 8 years of age.⁹⁴ Thus, controversy persists over the optimal fish intake during pregnancy. It remains unclear whether the benefits of higher seafood consumption outweigh the risks of mercury exposure. Avoidance of fish known to contain higher levels of mercury is prudent (Box 10-1), and more research is needed about the risks related to typical seafood consumption among U.S. women of reproductive age. The U.S. Environmental Protection Agency advisory related to mercury and fish can be found on their website,

Supplementation

MULTIVITAMINS AND PRENATAL VITAMINS

As noted earlier, surveys have shown that a large percentage of pregnant women in the United States consume diets inadequate in several vitamins and minerals. Prescription of prenatal multivitamin supplements during pregnancy is common practice in the United States. Although there are no randomized controlled trials of prenatal multivitamins in U.S. populations, large observational studies suggest a protective effect against preterm birth, SGA birth, preeclampsia, and congenital malformations.^{95,97} Interestingly, recent reports indicate that, for some outcomes, this protective effect may be limited to women who are lean at the start of pregnancy. For example, data from a Pittsburgh-based pregnancy cohort found that lean women who reported regular use of multivitamins in the 6 months around conception had an 81% reduction in the risk of preeclampsia, but no relationship between multivitamins and preeclampsia risk was observed among overweight mothers.⁹⁸ Similar results were found for SGA birth, where multivitamins were associated with a reduced risk in lean but not in obese women.⁹⁷ Subsequent analyses in the Danish National Birth Cohort confirmed these findings for preeclampsia and extended them to preterm birth.^{99,100} These data suggest that some micronutrient interventions aimed at improving outcomes in obese pregnancy may not be effective.

Folate

See Folate under Pre-conception Issues, earlier.

Vitamin D

Vitamin D is a prohormone that either is ingested orally through diet or supplements or is produced photochemically in the skin. Vitamin D has diverse biologic functions, and it has relevance beyond bone health and calcium metabolism.¹⁰¹ However, there is significant controversy surrounding vitamin D in pregnancy, including the ideal concentration of serum 25-hydroxyvitamin D [25(OH)D], the best clinical marker of vitamin D nutritional status.¹⁰² In 2010, the IOM increased the recommended dietary intake for vitamin D in pregnancy from 200 IU to 600 IU, in an effort to ensure a serum 25(OH)D level of about 50 nmol/L in most of the population.¹⁰³ However, the Endocrine Society¹⁰⁴ and many individual experts argue that optimal 25(OH)D concentrations are 75 to 100 nmol/L, and that maintaining these levels requires at least 1000 IU per day in nonpregnant adults^{105,106} and as much as 4000 IU per day for pregnant

women.¹⁰⁷ Regardless of the definition of deficiency, poor vitamin D status is widespread in pregnant U.S. women, affecting 10% to 50% of non-Hispanic whites, 42% to 75% of Hispanics, and 75% to 90% of non-Hispanic blacks.^{108,109} Vitamin D deficiency jeopardizes maternal and fetal bone mass,¹¹⁰ but the association between vitamin D and adverse birth outcomes remains equivocal. A recent randomized, double-blinded, placebo-controlled trial of 350 pregnant mothers in South Carolina showed that supplementation with 4000 IU of vitamin D₃ per day starting at 12 to 16 weeks' gestation is safe and effective at increasing 25(OH)D concentrations to 80 nmol/L within 1 month of delivery, but the study was not powered to detect differences in pregnancy outcomes.¹¹¹ Small clinical trials and some observational studies support a positive relationship between vitamin D deficiency and SGA birth.¹¹² Epidemiologic evidence suggests a role for vitamin D in the development of preeclampsia and gestational diabetes.¹¹² Notably, some studies have suggested U- or reverse J-shaped relationships between 25(OH)D and a number of outcomes, including SGA birth.^{113,114} Large randomized trials are needed to assess the causality of these associations and to determine the optimal 25(OH)D level for pregnancy.

Currently, health authorities and experts disagree as to recommendations for vitamin D screening, the definition of deficiency, and supplementation for pregnant women. ACOG has stated that there is insufficient evidence to support universal screening of pregnant women.¹¹⁵ ACOG says clinicians may consider screening women "at increased risk" for vitamin D deficiency, but it does not recommend universal supplementation. If blood levels reveal deficiency, ACOG states that a dose of 1000 to 2000 IU/day of vitamin D is considered safe. In contrast, the Endocrine Society recommends the screening of all pregnant women as well as universal supplementation with 1500 to 2000 IU/day, and it defines deficiency as a 25(OH)D level of less than 50 nmol/L (in contrast to the IOM, which defines deficiency as <20 nmol/L).^{103,104} Results of ongoing randomized trials of vitamin D supplementation and pregnancy outcomes may help to resolve the controversy.

Vitamin C and Vitamin E

Vitamin C and vitamin E are micronutrients that help to protect against oxidative stress in the body. Oxidative stress is a feature shared by a number of pregnancy complications, including preeclampsia, fetal growth restriction, and premature rupture of fetal membranes. A number of well-designed, double-blinded, placebo-controlled, randomized trials of vitamins C and E have been conducted, but a recent Cochrane Library review notes that there is not enough evidence to determine whether supplementation with vitamin C or vitamin E (alone or in combination with other supplements) benefits pregnant women.^{116,117} Notably, vitamin C supplementation may increase the risk of preterm birth.¹¹⁶

MINERALS AND OTHER SUPPLEMENTS

Iron

Pregnant women are among the groups at highest risk of anemia, and iron deficiency is the most common nutritional cause.¹¹⁸ Epidemiologic data show an association between lower hemoglobin levels and adverse perinatal outcomes, including low birth weight, prematurity, and maternal and

infant mortality.¹¹⁸ Nevertheless, clinical trials of iron supplementation to prevent adverse birth outcomes, including those initiated early in pregnancy, are mixed. Authors of a Cochrane review noted a small (+58 g) increase in birth weight with iron supplementation, but it noted no difference in the incidence of preterm birth, SGA, or low birth weight.¹¹⁹ Some have hypothesized that other deficiencies probably accompany iron deficiency, and that longer periods of supplementation throughout the reproductive years may be needed to prevent poor birth outcomes.¹¹⁸

High hemoglobin, which reflects a failure of normal plasma volume expansion, is associated with maternal hypertension, preeclampsia, or diabetes.¹¹⁹ Therefore, it may be unadvisable to administer 50 to 60 mg iron per day or more to nonanemic women.¹¹⁸

The IOM recommends an iron intake of 27 mg/day during pregnancy, but these needs are difficult to meet with an ordinary diet.⁸² Iron supplements are best absorbed when taken with citrus juices, as the vitamin C enhances absorption. Coffee, tea, milk, and calcium supplements inhibit iron absorption and thus should be consumed separately from iron supplements.

Choline

Choline is a micronutrient required for the synthesis of several metabolites that play key roles in fetal brain development. In animal studies, high choline intake improves attention, learning, and memory in the offspring, and choline deficiency leads to NTDs and poor cognitive development.¹²⁰ Human studies suggest a doubling of NTD risk with maternal dietary choline intake of 290 mg/day or less.¹²¹ The requirement for choline in pregnancy is unknown, but it is estimated to be 450 mg/day during pregnancy.¹²² As the majority of prenatal vitamins and multivitamins do not contain choline, mothers require animal and plant sources of the nutrient.¹²⁰

Iodine

The U.S. recommended dietary allowance (RDA) for iodine is 220 µg/d for pregnant women in order to meet increased demands of maternal and fetal thyroid hormone production and the probable increase in renal iodine clearance.¹²³ Severe iodine deficiency causes significant impairments in cognitive and motor function of children, and correction of the deficiency lessens developmental deficits¹²⁴ (see Chapter 60). The potential adverse outcomes associated with mild-to-moderate iodine deficiency, such as that seen in the United States, remain uncertain.¹²⁴

Calcium

Less than half of U.S. women meet the recommendation for dietary intake of calcium. The recommended daily intake of calcium for women 19 to 39 years old (whether pregnant or not) is 1000 mg/day. For women less than 18 years old, 1300 mg/day is recommended.¹²⁵ For optimal benefit, calcium should be taken with adequate dosages of vitamin D and magnesium. A recent review suggests that calcium supplementation may reduce the risk of preeclampsia (particularly among women at high-risk of the disorder and women with low baseline intakes), and it provides some evidence of a protective effect on preterm birth.¹²⁶ Adequate calcium intake may also be protective against lead toxicity to the fetus, as lead is stored in bone, and increased bone turnover during pregnancy may release lead into the bloodstream.¹²⁷

Fish Oil

Marine oils contain the omega-3 fatty acid docosahexaenoic acid (DHA), which is essential for fetal brain development and many other functions. Because of the observed epidemiologic associations between higher fish consumption and reduced rates of preterm birth, low birth weight, and preeclampsia, large multicenter trials were initiated to study whether fish oil supplements would prevent such adverse outcomes in pregnancy. Unlike dietary fish, supplements can be prepared to minimize mercury and other toxin contamination. A 2006 Cochrane review, and a more recent 2009 review of fish oil supplementation during pregnancy, did not show any significant beneficial effects.^{128,129} However, the author of the Cochrane review¹²⁸ stated that more studies are needed to confirm the role of marine oils during pregnancy in offspring developmental outcome, offspring atopy/allergy, and offspring body composition. On the basis of the available data, some health authorities have recommended that pregnant women aim for an intake of at least 200 mg/day of DHA, either from fish consumption or marine oil supplements.¹³⁰

Vegetarian Diets in Pregnancy

Although the current prevalence of strict vegetarianism in the United States is not reported, data from the population-based National Health and Nutrition Examination Survey (NHANES) cohort (1999 to 2004) showed that 6% were vegetarian.¹³¹ Data are also lacking on the relationship of vegetarian and vegan diets during pregnancy to perinatal outcomes. The primary concern about vegetarian diets is vitamin B₁₂ deficiency, as this vitamin is found primarily in animal food sources. Women who are ovo-lacto-vegetarians (who consume eggs or dairy products, or both) may have adequate B₁₂ intake from dairy products. However, a German cohort study found that 39% of ovo-lacto-vegetarians had low serum levels of B₁₂ during at least one trimester of pregnancy (versus 3% of controls, $P < .001$), although clinical outcomes were not reported.¹³² Vegans (those who consume no animal products) generally require a B₁₂ supplement for adequate intake. Vegans can also increase their B₁₂ intake with B₁₂-fortified vegetarian foods such as soy milk and meat substitutes. The vegan diet may also be so high in fiber and low in fat that caloric intake may be insufficient for pregnancy, and adherents to vegan diets are more likely to have a BMI in the underweight range. Intakes of calcium, vitamin D, riboflavin, and iron may also be inadequate. With dietary assessment and counseling, such women can maintain their diet and have an adequate nutritional intake during pregnancy.

Other Clinical Issues

MULTIPLE GESTATION

Women carrying more than one fetus should increase their caloric intake by 300 kcal/day per fetus. As is true for women carrying singleton gestations, optimal weight gain for twin pregnancies varies by pre-pregnancy BMI (see Table 10-2). Daily caloric intake for women with twins should be 4000 kcal/day for underweight women, 3000 to 3500 kcal/day for normal-weight women, 3250 kcal/day for overweight women, and 2700 to 3000 kcal/day for obese women.¹³³

Women with triplets should aim for a total gain of at least 50 to 60 lb. Eating at least five times a day may help women

achieve this large caloric intake. Vitamin supplementation is especially helpful in multiple gestations, and additional calcium, magnesium, and zinc may improve outcomes.¹³⁴

NAUSEA AND VOMITING

A majority of pregnant women report some nausea and vomiting during pregnancy. Symptoms virtually always appear before 9 weeks of gestation, so a new onset of nausea or vomiting after 9 weeks should prompt a medical workup for other etiologies. Hyperemesis gravidarum (see Chapter 62) is found in only 0.5% to 2% of pregnancies; this is usually defined as severe persistent vomiting with no other clear etiology, accompanied

by large ketonuria or weight loss of at least 5% of pre-pregnancy body weight. Excluding cases of hyperemesis gravidarum, women who experience nausea and vomiting of pregnancy actually have better pregnancy outcomes than women who do not experience these symptoms. First-line therapy should be vitamin B₆, 10 to 25 mg, three or four times per day. Ginger has also been effective in clinical trials. Doxylamine, 12.5 mg three or four times per day, added to the vitamin B₆ regimen, may be of additional benefit.¹³⁵

Developmental Origins of Health and Disease

LUCILLA POSTON, PhD | MARK A. HANSON, MA, DPhil

Environmental agents that affect development at a sensitive or critical period are well recognized to cause teratogenic effects in the embryo or fetus. Obstetricians are also very familiar with the infant mortality and morbidity associated with compromised fetal growth (e.g., the growth restriction of preeclampsia or the macrosomia of maternal diabetes). The more subtle and persistent consequences of perturbations of in utero growth and nutrition are much less widely appreciated. There is now good evidence that even modest changes in growth and development may have unforeseen consequences that extend into adulthood. Although they are not immediately obvious, they can alter an individual's response to the sequential challenges of life, leading, ultimately, to a greater risk of adult disease.

The suggestion that compromised growth in utero may enhance risk of adult disease came from early studies implying that small size at birth conferred greater risk of chronic non-communicable diseases such as cardiovascular disease (coronary heart disease, hypertension, stroke), type 2 diabetes, and osteoporosis.^{1,2} The majority of work in this area has concentrated on perturbations in the nutritional environment during prenatal and early postnatal life. Other environmental influences have been implicated in animal models, including temperature, oxygen tension, fluid balance, and stress,^{3,4} but in this review, we will concentrate largely on the human situation and early nutritional influences, discussing the evidence, the proposed underlying mechanisms, and the scope for possible interventions.

Associations between Low Birth Weight and Adult Disease

HOW THE CONCEPT AROSE: EARLY STUDIES

The concept of the developmental origins of disease dates from the last century, especially in the United Kingdom and Scandinavia in the 1970s and 1980s. Forsdahl recognized from studies of Norwegian populations that chronic adult disease was linked to deficiencies in the early childhood environment, and he stressed that these effects persisted even if circumstances improved in later years.⁵ Similarly, Lucas proposed that detrimental influences in early life increase risk for later disease (for review, see Singhal and Lucas⁶). However, it was the work of Barker and his colleagues in the 1980s that finally established the new field of research initially referred to as “fetal origins of adult disease.” Their early papers described an association between risk of cardiovascular disease and low birth weight in

cohorts of middle-aged men and women in the United Kingdom for whom detailed birth records were available.¹ Subsequent studies showed that low birth weight was associated not only with increased risk of death from cardiovascular disease but also with insulin resistance and obesity—in fact, each of the criteria that define the metabolic syndrome. It was proposed that in utero nutritional status can influence risks of both cardiovascular and metabolic disease in later life.

CONTEMPORARY VIEWPOINTS

Now, more than 20 years since the fetal origins hypothesis was first proposed, it has come to be recognized that birth weight is a weak index of in utero nutrition and growth. Smallness at birth can arise from poor growth beginning in early gestation or from early rapid growth followed by slow growth in late gestation—each likely to arise from a different cause. However, because growth trajectory data usually are not available for historical cohorts, most studies continue to investigate relationships between birth weight and incidence of later disease.

The validity of the hypothesis has been questioned because of the wide variability reported among associations between birth weight and later proxy markers of disease (e.g., blood pressure),⁷ but associations are much stronger, and criticism therefore less warranted, when the outcome measure is clinical disease.⁸ Interpretation must also be influenced by the recognition that pregnancies in the historical cohorts occurred when nutrition and health care were very different from those of contemporary developed societies. The lower-birth-weight individuals in these cohorts, for example, would be unlikely to include fetuses born long before term or those with intrauterine growth restriction. Likewise, the higher-birth-weight group would be unlikely to include fetuses of diabetic mothers, because the survival rate of these infants would have been much lower than it is now.

TESTING THE CONCEPT IN DIFFERENT POPULATIONS

When it became clear that environmental effects that can influence later susceptibility to disease operate over a longer time scale, from before conception through childhood, and that their effects are part of a continuous spectrum, the fetal origins concept was reconstrued as the “developmental origins of health and disease” hypothesis. The strength of this concept lies in its reproducibility in many geographically dispersed cohort studies. Most investigations have replicated the original association

between lower birth weight and death from ischemic heart disease⁹ and also the associations with nonfatal coronary artery disease and stroke.¹⁰ Indeed, a study of 13,830 men and women for whom records were available from the Finnish National Death Register showed an association between low birth weight and *all-cause* mortality among women.¹¹ A follow-up study of 10,803 children born in Aberdeen in the 1950s, at a time when environmental influences were relatively favorable for infants compared with conditions in earlier studies, confirmed an inverse association between birth weight and later coronary artery disease and stroke.¹²

Large cohort studies, such as that of almost 90,000 Swedish army recruits born between 1973 and 1981, have also continued to show that lower birth weight is linked to higher adulthood blood pressure, and the increment in blood pressure, although small in magnitude, is independent of socioeconomic factors or familial effects.¹³ It should also be appreciated that even a small rise in blood pressure is important when viewed from the perspective of risk of later disease.¹⁴ A meta-analysis of data from 198,000 individuals from 20 Nordic studies (1910–1987 cohorts) showed unequivocally an inverse and linear association between birth weight and adult blood pressure in males but a U-shaped relationship in females; those with a birth weight greater than 4 kg had a higher systolic blood pressure in adult life.¹⁵ Similar confirmation of the association between low birth weight and raised systolic blood pressure has been derived from a British birth cohort study of 3157 men and women born in 1946.¹⁶ Some but not all studies correct adulthood outcomes for current body mass index (BMI), an adjustment that has led to a continuing controversy, as have the failure to account for the influence of growth trajectories at different stages of life and the inclusion of subjects taking antihypertensive medication.^{17,18} These criticisms have themselves proved controversial.

Review of the literature investigating associations between low birth weight and insulin resistance shows that people who are light at birth generally have an adverse profile of later glucose and insulin metabolism, which is related to insulin resistance rather than altered insulin secretion.¹⁹ Associations reported between low birth weight and adulthood obesity²⁰ have been challenged in a meta-analysis of the literature.²¹ The use of BMI, which is an inaccurate assessment of central obesity, may confound interpretation, and inverse associations between birth weight and raised adulthood fat mass with reduced lean mass have been described.^{22,23}

Moving beyond birth weight, there is accumulating evidence that body composition at birth and beyond is influenced by a range of prenatal factors. For example, maternal dietary vitamin D status influences neonatal fat mass and adiposity at ages 4 and 6 years,²⁴ and an independent and inverse association has been reported between maternal consumption of n-3 polyunsaturated fatty acids and adiposity in 3-year-olds.²⁵ A comparison of Indian and Caucasian neonates revealed greater abdominal adiposity and lower muscle mass in the former group; this condition is sometimes known as the Indian “thin-fat” phenotype, and it is associated with greater risk of metabolic disease in later life.^{26,27}

OTHER DISORDERS ASSOCIATED WITH LOWER BIRTH WEIGHT

The primary focus in this field has been on developmental origins of cardiovascular disease and disorders of glucose

homeostasis, but associations have also been reported between low birth weight and adulthood reduced bone density,²⁸ schizophrenia,²⁹ breast cancer,³⁰ and asthma.³¹

Associations between Maternal Obesity, Diabetes, Raised Birth Weight, and Adulthood Disease

The rising birth weight in developed countries (with the possible exception of Japan³²) is associated with the prevalence of obesity in pregnancy and related gestational diabetes and may also have potential for detrimental influences on the developing child.^{33,34} This association was originally suggested by a few studies showing a U- or J-shaped relationship between birth weight and later insulin resistance and obesity,^{8,19} especially in populations such as the Pima Indians, where the prevalence of type 2 diabetes is high even among young adults,³⁵ and there is now good evidence that children of women who are diabetic in pregnancy are themselves more likely to develop insulin resistance in later life and to become overweight.^{36,37} Although this relationship may represent in part a genetically inherited disorder, studies of sibling pairs discordant for maternal diabetes show that the association holds only in the offspring prenatally exposed to diabetes, strongly suggesting an acquired diabetic trait.^{38,39}

Infants of mothers with gestational diabetes have a greater neonatal fat mass,⁴⁰ and increased adiposity at the age of 3 years has also been reported,⁴¹ as well as a high rate of childhood metabolic syndrome (central adiposity, insulin resistance, and hypertension) in large-for-gestational-age infants born to mothers with gestational diabetes.⁴² There is some contention as to whether the relationship between maternal diabetes and offspring adiposity is dependent on the infant's being born large for gestational age, but this would seem to be a reasonable assumption, because higher birth weight is generally associated with raised childhood BMI,⁴³ and larger babies tend to become heavier adults. However, some reports infer that this association reflects a direct link between infant lean body mass and lean body mass in later life, rather than between neonatal and adulthood fat mass.²² Nevertheless, several contemporary studies have demonstrated that heavier infants do become fatter children. These include a study from the Avon Longitudinal Study of Parents and Children (ALSPAC) cohort in the United Kingdom showing that birth weight is positively and independently related to both lean body mass and fat mass in 9- and 10-year-old children and, also in the same children, that a higher ponderal index (weight/length³) at birth is associated with greater fat mass.⁴⁴

These findings prompt the pertinent question of whether it is in reality the fatter rather than the heavier child who is predisposed to obesity in later life. Catalano and colleagues exemplified how meaningless the measurement of birth weight can be in estimating the “fatness” of a child by observing that marginally higher birth weights in infants from obese versus lean women can belie highly significant increases in fat mass.⁴⁵ Importantly, most ongoing studies in mother-child cohorts now include measurement of body composition in mother and neonate and, later, in childhood.

In addition to the relationship between maternal diabetes and offspring obesity, many observational studies have shown an association between maternal BMI and the child's BMI that

is unaffected by adjustment for known confounders including maternal smoking, socioeconomic status, and breastfeeding.^{46,47} An unresolved issue, and one of some importance, is whether this maternal/child BMI relationship can explain the observed association between maternal diabetes and offspring adiposity, particularly because adjustment for maternal BMI was not invariably performed in the earlier studies of diabetic women and their children. Some reports (e.g., from Tam and colleagues⁴⁸) have demonstrated that the relationship persists after adjustment for maternal BMI, whereas others have proposed that maternal BMI per se is a predominant determinant of offspring BMI in diabetic pregnancies.^{49,50} Adjusting for maternal BMI could represent an overadjustment (due to common mechanism), but the strong influence of maternal obesity, repeatedly observed, argues against persistent maternal hyperglycemia as a major player in the development of childhood adiposity. Shared genes undoubtedly contribute, but other factors associated with obesity, such as maternal insulin resistance and related maternal hypertriglyceridemia, are also implicated.⁵¹

Some investigators have attempted to define accurately the relationship between maternal and childhood or adulthood body composition over any range of maternal BMI. Whittaker and associates⁵² showed a continuous relationship between maternal BMI and adiposity in the offspring at age 4 years, and Reynolds and colleagues demonstrated the same in offspring at age 28 to 31 years.⁵³ In both studies, it was clear that the relationship operated over the entire normal range of BMI. The latter study is particularly interesting because it reveals a greater effect in primiparous pregnancies, consistent with the suggestion that greater maternal constraint in such pregnancies leads to greater potential “mismatch” in the offspring. Offspring of diabetic pregnancies also appear to grow faster than children from normoglycemic pregnancies from about the age of 4 years.⁵⁴

GESTATIONAL WEIGHT GAIN

Although the topic has been explored only recently, there is remarkable uniformity among the several studies that have addressed the relationship between maternal gestational weight gain and offspring BMI or adiposity.⁵⁵ Some have suggested that the relationship is linear, whereas others have implied nonlinearity, with the gain in childhood weight being apparent only in association with excess maternal weight gain. Women with excessive gestational weight gain have children who are more prone to increased adiposity compared with those whose weight gain is within recommended limits.^{56,57} These associations have been demonstrated after adjustment for confounders such as socioeconomic status, a shared family environment, and hereditary traits for obesity.

CARDIOVASCULAR RISK

Compared to the focus on childhood obesity, relatively little effort has been directed toward assessment of cardiovascular function in the child. In a study from the Southampton Women's Survey, it is clear that the mother's body composition and dietary balance before pregnancy can affect fetal cardiovascular development in late gestation,⁵⁸ and there are several reports of an association between maternal diabetes and offspring blood pressure or biomarkers of cardiovascular risk,^{59,60} including a

relationship between increasing pregnancy glucose concentrations in nondiabetic women and childhood diastolic and systolic blood pressure at the age of 7 years.⁶¹ There are also negative reports, including a recent cross-sectional study from women with gestational diabetes and their children in Germany, showing no association between gestational diabetes in the mother and parameters of cardiovascular function in the children.⁶² As might be anticipated, there is also evidence that tight glycemic control negates any influence of maternal diabetes on cardiovascular and metabolic function in the children.⁶³

Several authors have reported higher blood pressure and an adverse cardiovascular biomarker profile in children born to obese women,^{56,64} as well as a relationship between gestational weight gain and blood pressure in the offspring; these topics were recently reviewed.⁶⁵ Because obesity is associated with increased blood pressure, it is not clear whether these associations are explicable by an associated increase in childhood adiposity or whether cardiovascular risk in the child has independent origins. However, a recent report from a cohort in Israel, the Jerusalem Perinatal Study, showed that associations of maternal gestational diabetes with higher blood pressure in offspring are independent of childhood body weight.⁶⁶

MODE OF DELIVERY AND EARLY ANTIBIOTIC EXPOSURE

Some investigators have explored the intriguing hypothesis that the mode of delivery of a child may influence the risk of later obesity, with the suggestion that children born by cesarean section may be at greater risk.^{67,68} Although more studies are needed to confirm or refute this association, a study in a Danish cohort of 28,354 mother-child dyads demonstrated that the use of antibiotics during the first 6 months of life is associated with childhood overweight in children of normal-weight mothers but not obese mothers. This finding raises interesting questions regarding the role of the gut microbiota in early life and the risk of later obesity. In relation to mode of delivery, the infant gut flora profile is known to be influenced by vaginal delivery, which is associated with colonization by microbes from the maternal vaginal and gastrointestinal tracts.⁶⁸

BREASTFEEDING

Longitudinal studies tracking height and weight of participants have suggested that those children who demonstrate rapid growth in early infancy or in early childhood are at risk for adulthood cardiovascular and metabolic disease, with children who are small at birth being the most vulnerable.

Investigations among cohorts of very premature children have shown that rapid growth in the first weeks or even days of neonatal life associated with formula feeding may lead to increased risk for cardiovascular disease in adolescents.⁶⁹ Rapid weight gain in infancy has been linked to childhood obesity in many studies.^{34,70,71} Formula feeding promotes rapid growth in early infancy⁷² and has been associated with increased risk for obesity in childhood and adolescence.⁷³ A study from a U.S. cohort suggested that obesity in adults (aged 20 to 32 years) may be linked to rapid growth during only the first 8 days of life in normal birth-weight infants fed formula milk⁷⁴; moreover, a meta-analysis of 61 studies showed that breastfed babies have a reduced incidence of childhood or adulthood obesity compared with those whose mothers opted to feed their infants

with formula milk.⁷⁵ However, the protection against obesity afforded by breastfeeding remains controversial, and the magnitude of the effect, when one is demonstrated, is modest. In a recent commentary, Beyerlein and von Kries suggested that the inconsistency in results could potentially be explained by different effects of breastfeeding in normal weight compared with overweight children.⁷⁶

If formula feeding does predispose to obesity, as some suggest, then the dietary composition requires scrutiny. A randomized trial of high-protein versus lower-protein feed in 1138 formula-fed infants revealed that 2-year-olds who were fed the lower-protein formula as infants had reduced weight-for-length z scores compared with those who had been fed the higher-protein formula, and that z scores in the lower-protein group were similar to those in a breastfed reference group.⁷⁷ In further support of a protective role for breastfeeding, a recent study found an association between greater cardiorespiratory fitness in late childhood and the duration of breastfeeding in children who were exclusively breastfed, and this association was unaffected by adjustment for birth weight, physical activity, and maternal educational level.⁷⁸ These observations fit into the broader framework of greater risk associated with greater “mismatch” between the environment during development and that in later life.⁷⁹

CHILDHOOD GROWTH

One of the largest cohort studies linked coronary events to birth weight and early life growth trajectories.⁸⁰ Among 8760 Finnish men and women born between 1934 and 1944, those who suffered coronary events were more likely to have been small at birth and thin at 2 years and to have subsequently experienced a greater increase in BMI by 11 years of age. Lower BMI at 2 years and increased BMI from 2 to 11 years of age were also associated with a highly significant elevation of fasting insulin concentrations. A lowered risk of coronary events with higher weight at 3 months was noted, but no analysis was presented of weight gain in the earliest weeks of life (see earlier discussion), although graphic representation suggested a rapid growth trajectory during the first few weeks in those who had coronary events. Nonetheless, the overall growth trajectory closely resembled that found in India among men and women who developed insulin resistance or diabetes in adulthood.⁸¹

Importantly, the influence of birth weight and the critical period of childhood weight gain remain to be fully established in contemporary cohorts. The different conclusions drawn by Singhal and Lucas⁶ and by Barker and coworkers⁸⁰ regarding the relative importance of postnatal growth may relate to the different historical periods studied but also to differences in the subjects (e.g., preterm versus term). Preterm birth itself is associated with increased risk for type 2 diabetes independent of size for gestational age.⁸² Studies such as those from Finland and the United Kingdom investigated adults who were born in times when nutrition was not abundant and may have been unbalanced, particularly for those born in Finland around the time of the Second World War. However, the rapid postnatal growth hypothesis was shown to hold in three contemporary studies. A study from the ALSPAC cohort of children born in the 1990s reported that increased insulin resistance and raised abdominal girth were evident in 8-year-olds who were born small and demonstrated greater weight gain between birth and age 3 years.⁸³ A report from a young U.K. cohort (22 years of age)

showed that systolic blood pressure was highest in those who were born small but demonstrated rapid weight gain between the ages of 1 and 5 years.⁸⁴ And in the recent study by Taveras and colleagues, crossing 2 or more weight-for-length centiles in the first 2 years was associated with greater adiposity at age 5 and age 10 years.⁸⁵ Of course, growth from conception onward lies on a continuum, so it is difficult in all these studies to determine the time at which environmental influences induce effects, some of which manifest only later. Longitudinal studies are particularly important here, because small shifts in the timing of the adiposity rebound, which all children show, can give a misleading impression in cross-sectional studies.

DEVELOPMENTAL EFFECTS OF ANTENATAL GLUCOCORTICOIDS

In view of the widespread use of antenatal steroids to hasten fetal lung maturation in cases of threatened premature delivery, the obstetrician should be aware that antenatal administration of steroids in experimental animals evokes persistent and deleterious effects in the developing offspring that become manifest only in adulthood. The administration of an exogenous glucocorticoid such as dexamethasone during a critical window of early development is detrimental to cardiovascular and renal function and to glucose homeostasis in several species⁸⁶⁻⁸⁸; it has also recently been shown to affect learning and attention behaviors in juvenile nonhuman primates.⁸⁹ How much this reflects exaggeration of naturally occurring prenatal processes that induce a change in the offspring phenotype or whether it represents a disruption of *normal* development is not known.

Understandably, concern has arisen regarding the prolonged effects of antenatal glucocorticoids given to pregnant women at risk of preterm delivery, despite the uncontested improvement in neonatal respiratory outcome. One report showed elevation of neonatal blood pressure 2 standard deviations above the normal range in 67% of children exposed to multiple courses and 24% of those exposed to a single course.⁹⁰ However, in a randomized, controlled trial (RCT), 31-year-olds who had been exposed to a single course of betamethasone in utero showed no difference in psychological functioning or health-related quality of life when compared with those antenatally randomized to placebo.⁹¹ A report from the same cohort at age 30 years showed a higher plasma insulin concentration 30 minutes after a 75-g oral glucose tolerance test, possibly indicative of insulin resistance, although cardiovascular indices were unaffected.⁹² This modest influence on adulthood risk factors was suggested by the authors not to contraindicate the use of a single course of betamethasone.

More recently, RCTs have been undertaken to assess the influence of repeated doses of antenatal glucocorticoids, and despite some evidence for reduced infant weight, length, and head circumference at birth, a recent Cochrane review of 10 trials, 4 of which provided information on follow-up of children age 2 to 3 years, concluded that benefit was obtained from multiple versus single doses for neonatal outcomes, without any evidence for either significant benefit or harm at follow-up.⁹³ The authors recommended the use of more than one dose of glucocorticoids when indicated. In the absence of any longer-term follow-up studies from these trials, it must be concluded at present that the gain from administration of antenatal corticosteroids, preferably a single dose, outweighs the potential disadvantage.

The pronounced consequences of maternal glucocorticoid administration described in the animal studies has logically led to concern over the potential effects of maternal stress on the fetus. Several studies in rodents showed that stress in pregnancy can lead to altered behavior of the offspring and also to altered biochemical responses to stress.⁹⁴ Cardiovascular function in adult offspring may also be compromised.⁹⁵ Studies in humans also strongly indicate a deleterious and persistent effect of maternal stress in the offspring, with many prospective studies showing a link between antenatal maternal anxiety or stress and cognitive, behavioral, and emotional problems in the child.^{96,97}

Animal Models

The developmental origins of health and disease concept has stimulated wide-ranging investigations in animal models.^{37,98-102} Studies in rats, mice, sheep, guinea pigs, and nonhuman primates have lent strong support to the hypothesis. Most notably, several characteristics of the offspring phenotypes arising from a range of nutritional interventions are shared across species. Indeed, it has proved remarkably easy to demonstrate characteristics equivalent to human disease, particularly features of the metabolic syndrome, through experimental manipulation of the diet of the pregnant animal or the offspring. The effects include aspects of cardiovascular function and glucose homeostasis in the offspring. Adulthood adiposity, insulin resistance, and hypertension have also been induced by maternal nutritional intervention, both undernutrition and overnutrition. In addition, behavioral effects are apparent, including reduced exploratory behavior and activity levels and even impaired learning behavior.^{89,103,104} These animal models offer the potential for investigation of mechanisms and suggestions for intervention. Interventions recently reviewed¹⁰⁵ include, in rats, supplementation of a low-protein diet during pregnancy with glycine or folate^{106,107} and prenatal and gestational weight loss in obese dams¹⁰⁸; in mice, pharmacologic therapy with a statin has been investigated.¹⁰⁹

Mechanistic Insights

We are perhaps now beginning to get some clear leads on mechanisms. The fact that sustained effects in the offspring can be produced in very early pregnancy, even by the preimplantation environment, focuses attention on the early embryo^{110,111} and raises potential concern regarding the possible long-term effects of in vitro fertilization (IVF). Embryo transfer, with or without culture to blastocyst stage in vitro, produces elevated blood pressure in offspring.¹¹¹ This is worrying because changes in the test-tube milieu could potentially explain the increased rate of abnormalities associated with defects of genomic imprinting reported in IVF infants.¹¹⁰

Sustained epigenetic changes are proposed to occur in fetal/neonatal nuclear DNA as a result of alterations in nuclear DNA methylation, in histone structure, or in small noncoding RNAs. These changes subsequently affect subsequent gene expression in response to stimuli (e.g., transcription factors) that can be affected by factors such as diet and hormone levels. The effects can be reversed by dietary supplements that promote the provision of methyl groups.¹¹² More recently, epigenetic changes have been demonstrated in nonimprinted genes in the livers of rat offspring, effects that were inversely related to gene expression and reversed by maternal dietary folate supplementation.¹¹³

Epigenetic changes in response to maternal interventions have also been reported in the pancreas¹¹⁴ and hypothalamus.¹¹⁵ These effects are associated with changes in DNA methyltransferase activity¹¹⁶ and can be passed to grand-offspring.¹¹⁷

The first studies are now emerging showing similar epigenetic observations in humans, including effects on DNA methylation of candidate genes in the placenta, umbilical cord, and cord blood. One study showed a link to maternal nutrition in pregnancy, epigenetic state at birth, and the child's adiposity at 6 to 9 years of age.¹¹⁸ In another, there was a link with a range of genes measured in cord blood and with the child's adiposity.¹¹⁹ A third study reported an association between maternal glucose homeostasis in later pregnancy and epigenetic effects on placental adiponectin.¹²⁰

Permanent alteration to mitochondrial DNA (mtDNA) offers a plausible hypothesis^{121,122} and may be additive to effects on nuclear DNA. Persistent alterations to mtDNA have been proposed to explain the transgenerational transmission of disorders observed in several animal models^{123,124} and the development of metabolic disorders.

Induction of a phenotype with greater risk of later disease does not have to involve an overall reduction in somatic growth, as has been suggested by some of the epidemiologic studies and many of the animal models. It appears, therefore, that reduced body growth per se does not lie directly on the causal pathway to such disease. This observation does not preclude changes in the growth or structure of individual organs, especially if the environmental challenge occurs during sensitive developmental windows. A prime candidate is the kidney. Children with lower birth weight have a reduced nephron complement, and a deficiency in nephron number has also been linked to the development of hypertension in humans.^{125,126} Animal studies of unbalanced nutrition during pregnancy or glucocorticoid treatment have reported reduced nephron number in the offspring.⁹⁹ Moreover, reduction in fetal growth produced by uterine artery ligation in the rat produced epigenetic effects on expression of genes associated with apoptosis in the kidney.¹²⁷

Almost all nutritional models and a model of reduced uterine blood flow have shown persistent alteration in the pancreatic structure, including a reduction in pancreatic beta cell density.^{128,129} This may contribute to early pancreatic failure in the face of peripheral insulin resistance and to the development of overt diabetes later in life. Intriguingly, many studies have suggested that altered development of the neural networks within the appetite regulatory centers of the hypothalamus could permanently alter central pathways of energy balance and play a role in inducing later hyperphagia and food preference in the offspring, thereby contributing to obesity. From studies in rodents, it is known that leptin and insulin have potent modulatory roles in hypothalamic neurodevelopment, and it is hypothesized that early life exposure to either high (overnutrition) or low (undernutrition) levels of these hormones could permanently modify hypothalamic function.^{37,101,130-132}

Therefore, permanent alteration to nuclear or mitochondrial DNA or to organ structure provides plausible mechanisms whereby an early-life nutritional challenge can translate into heightened or indeed reduced risk of disease in adult life. Animal models have contributed much to understanding of these pathways and are providing important models to interrogate disease processes in humans. For example, a paradigm of nonalcoholic fatty liver disease can be induced by feeding a fat-rich diet to rodents during pregnancy. The liver in the

offspring shows marked similarities to the human condition, with fat deposition, mitochondrial dysfunction, and an increase in expression of inflammatory mediators. This phenotype is worsened when the offspring themselves are challenged by a fat-rich diet, suggesting that early life exposure to the influences of the diet increases the vulnerability of the liver to a later challenge.^{133,134} Similarly, animal models demonstrating hypertension in the offspring have shown marked similarity in mechanism, centering on increased sympathetic outflow and the kidney. This is apparent as a result of maternal undernutrition or obesity, and these models may potentially provide intriguing insights into potential mechanisms of early-onset hypertension.^{135,136}

Time for Intervention?

NUTRIENT SUPPLEMENTATION

In light of the clinical and cohort studies, and indeed of all that is already accepted in relation to infant morbidity and mortality in small-for-gestational-age (SGA) children, low birth weight should obviously be prevented whenever possible. Balanced energy/protein supplementation may reduce the risk of SGA delivery in undernourished women,¹³⁷ but prevention of low birth weight has proved to be an intractable problem in developed countries.¹³⁸ Nutritional interventions with micronutrients may have small effects, but they have largely failed to show a significant impact on maternal or neonatal mortality.¹³⁹ Although it has been argued that the majority of studies have been of inadequate design and that well-conducted RCTs of adequate sample size and appropriate outcome measures are still required. Such a study is now underway in Mumbai. The Pune nutritional trial¹⁴⁰ has shown that birth weight is strongly related to maternal folate status and green vegetable intake at 28 weeks' gestation.

MATERNAL BODY COMPOSITION

Optimization of maternal pre-pregnancy body composition and nutrition is likely to minimize the developmental origins problem and therefore may improve antenatal and maternal health care in developing countries. The animal models are beginning to provide specific direction for effective intervention. For example, maternal administration of the amino acids taurine and glycine have been shown to have potential for reversal of disorders of cardiovascular function and glucose metabolism induced by unbalanced maternal nutrition. Importantly, prospective cohort studies are moving away from birth weight as a primary outcome and toward more accurate indices of body composition such as dual-energy x-ray absorptiometry (DEXA). Longitudinal studies of fetal growth trajectories—not just of the fetal body but of organs such as the liver, kidneys, and placenta—are also underway, and these measurements will be linked to maternal pre-pregnancy characteristics and pregnancy outcome. The studies will then have to be continued into childhood with measures of body composition, metabolism and physical activity, cardiovascular function, and glucose and lipid homeostasis. This will be expensive, but it will be an investment that pays great dividends when translated into public health policy to identify in early life individuals who will be susceptible to later chronic disease and give them more individually based advice and interventions.

MATERNAL OBESITY: AN IMPORTANT PUBLIC HEALTH MESSAGE

Obesity in pregnancy can now be added to the concern about the long-term effects of the nutritional environment on the risks of cardiovascular disease and obesity in the developing child. The numerous studies linking maternal obesity, gestational diabetes, and high gestational weight gain to suboptimal health in the offspring provide a clear and immediate public health message. Despite the carefully considered recommendations of the U.S. Institute of Medicine in 2009¹⁴¹ for women with normal or high pre-pregnancy BMIs, there remains the need to identify ideal weight gain in pregnant women, not only for improvement of maternal and neonatal outcomes but also for longer-term outcomes in the child. Attention needs to be paid to parity and ethnicity as well as pre-pregnancy BMI. Most importantly, we need to know how best to achieve the desired weight gain through safe intervention.

The Southampton Women's Survey has already made clear that maternal thinness, as judged by skinfold thicknesses, and imprudent diet produces effects on the circulatory adaptations of the late-gestation fetus.⁵⁸ A range of maternal characteristics, including body composition, smoking, and strenuous exercise in pregnancy, are also associated with lower neonatal bone mineral density.¹⁴² Because it may be unwise to recommend caloric restriction in pregnant women, and given the central role of insulin resistance in adverse pregnancy outcome, dietary and exercise interventions that aim to improve insulin sensitivity rather than reduce caloric intake may prove most efficacious for improvement of pregnancy outcome. Recent reviews of the intervention studies that have aimed to reduce gestational weight gain in obese pregnant women have demonstrated a modest reduction but no convincing evidence for improved pregnancy outcome.¹⁴³ To date, little information is available on longer-term follow-up of the children.

NEONATAL FEEDING REGIMENS

Optimal neonatal feeding strategies clearly need better definition in relation to subsequent risk for obesity and cardiovascular disease. Large RCTs are underway to define the optimal constituents of formula milk for babies of mothers who are unable or unwilling to breastfeed. These will also evaluate relationships between neonatal growth rate and risk for later disease.

DEVELOPMENTAL EFFECTS ON THE HUMAN PHENOTYPE: PATHOLOGY OR SURVIVAL?

The acquisition of disease risk in utero as a result of imbalances in the nutritional environment likely confers advantage in terms of Darwinian fitness (i.e., survival to reproduce), or the underlying mechanisms would not have been selected during human evolution. The "thrifty phenotype" hypothesis of David Barker and the late Nicholas Hales¹⁴⁴ concerns a rather special case of this broader phenomenon, in which fetal phenotypic changes are induced in response to nutritional imbalance in utero. These changes confer an immediate survival advantage, but the individual also has to cope with later detrimental effects in terms of increased risk of disease. If disease were to occur only in the postreproductive phase of life, then it would have no impact on fitness. Fetal blood flow, for example, is directed to areas of the body where nutrient delivery is prioritized (e.g., brain), thus

depriving the skeletal muscle, which grows less. In later life, the lack of skeletal muscle would confer the advantage of reducing glucose consumption when food is in poor supply—often thought to have been a valuable adaptive response in our hunter-gatherer ancestors. However, should nutritional status be surprisingly good, the poor capacity of the muscle to take up glucose could eventually contribute to development of the insulin resistance of type 2 diabetes. In the case of placental insufficiency, the fetus would be “tricked” into the need to prepare for a life of nutritional inadequacy when in reality the postpartum life is one of nutritional plenty.

THRIFTY PHENOTYPE AND PREDICTIVE ADAPTIVE MODELS

The thrifty phenotype hypothesis seems valid in the case of the SGA infant, but it becomes problematic when one considers the graded relation between, for example, size at birth and risk of later disease, which is manifest across the entire normal range of size at birth. The “predictive adaptive response” hypothesis proposed by Gluckman and Hanson¹⁴⁵ suggests that aspects of the prenatal environment are able to induce phenotypic changes in the embryo and fetus that confer advantage in terms of Darwinian fitness because they predict aspects of the postnatal environment. According to this view of the phenotype, the offspring has not been set to cope with a prenatal challenge but to be best able to respond to predicted postnatal challenges. An accurate prediction would confer greater likelihood of health in the predicted environment, but an inaccurate or inappropriate prediction or a change in the environment resulting from socioeconomic change or migration would be associated with greater risk of disease. Therefore, it is the mismatch between the predicted and the actual environment that raises risk of disease.⁷⁹ There are now several lines of experimental evidence in animals that support this concept,^{124,146,147} and evidence is emerging in humans in terms of reproductive function.¹⁴⁸ Recently, prenatal induction of phenotype (as judged by birth weight) has been shown to influence the effect of severe undernutrition in childhood in terms of whether the child develops marasmus or kwashiorkor.¹⁴⁹

Conclusions

Epidemiologic studies from contemporary and historical cohorts implicate a role for prenatal influences on the risk of later development of adult disease. The influences considered to date have focused largely on maternal diet and body composition, but there is increasing evidence for effects of maternal smoking, strenuous exercise, stress, drugs such as steroids, pathogens, and environmental pollutants that can act as endocrine disruptors. These may act in part via epigenetic effects on the developing offspring. Many studies have linked lower birth weight with greater risk of adulthood cardiovascular morbidity, obesity, and insulin resistance. There are also considerable data supporting an association of maternal obesity or gestational diabetes with acquisition of risk of type 2 diabetes in the offspring. There is a need to conduct prospective cohort studies, to define the prenatal and postnatal phenotypic characteristics that are associated with later risk, and then to develop prognostic intermediate outcome markers and pilot potential interventions. A few such investigations are now underway.

It is as yet too early to suggest any specific intervention in pregnancy or in the neonate, except to recommend that obese women achieve a normal BMI before considering becoming pregnant. The concepts discussed support a focus for public health measures that aim to optimize nutrition for mother and child as a strategy to prevent obesity and insulin resistance in the population. A new focus on development as part of a life-course perspective is likely to have a very substantial effect in reducing the burden of chronic noncommunicable disease in both developed and developing societies.

Fetal Cardiovascular Physiology

JEFFREY R. FINEMAN, MD | RONALD CLYMAN, MD

Blood Flow Patterns and Oxygen Delivery

In the mammalian adult, oxygenation occurs in the lungs, and oxygenated blood returns via the pulmonary veins to the left side of the heart to be ejected by the left ventricle into the systemic circulation. In the fetus, gas exchange occurs in the placenta, and the fetal lungs are nonfunctional as far as the transfer of oxygen and carbon dioxide is concerned. For oxygenated blood derived from the placenta to reach the systemic circulation, the fetal circulation is so arranged that several sites of intercommunication (shunts) are present. In addition, preferential flow and streaming occur to limit the disadvantages of intermixing the oxygenated and deoxygenated blood that returns to the heart. The patterns of blood flow to and from the fetal heart are shown diagrammatically in Figure 12-1. With fetal stress, these preferential streaming patterns may be modified even more to mitigate the adverse effects of disorders such as reduced umbilical blood flow and fetal hypoxemia. Little quantitative information regarding primate fetal circulation is available; the data presented here were obtained mainly from fetal lambs.

VENOUS RETURN TO THE HEART

About 40% of total fetal cardiac output (i.e., about 200 mL/kg of fetal body weight per minute) is distributed to the placental circulation; a similar amount returns to the heart via the umbilical venous system. Because umbilical venous blood is the most highly oxygen-saturated blood in the fetal circulation, distribution of umbilical venous return is most important in determining oxygen delivery to fetal tissues. After entering the intraabdominal portion of the umbilical vein, a portion of umbilical venous blood flow supplies the liver; the remainder passes through the ductus venosus, which directly connects the umbilical vein–portal sinus confluence to the inferior vena cava (IVC) (see Fig. 12-1). Unlike the umbilical and portal veins, the ductus venosus has no direct branches to the liver. Umbilical venous blood can enter the ductus venosus directly. Portal venous return, however, can reach the ductus venosus only through the portal sinus.¹ Approximately 50% of umbilical blood flow passes through the ductus venosus; the remainder enters the hepatic–portal venous system and passes through the hepatic vasculature.²

The fetal liver receives its blood supply not only from the umbilical vein but also from the portal vein and hepatic artery. In normal fetal lambs in utero, umbilical venous blood flow contributes approximately 75% to 80% of total blood supply of the liver.²⁻⁴ Portal venous blood flow accounts for about 15%, and hepatic arterial blood flow from the aorta represents only

4% to 5%. The blood from these sources is distributed differently to the various parts of the liver. Hepatic arterial blood flow to the liver is equally distributed to the right and left lobes, but the left lobe is supplied almost exclusively (>95%) by umbilical venous blood. In contrast, the right lobe receives both umbilical venous blood (approximately 60%) and portal venous blood (approximately 30%). Because umbilical venous blood supplies a major portion of flow to the right liver lobe by traversing the portal sinus, little if any portal venous blood reaches the ductus venosus. The blood in the ductus venosus therefore has pH, blood gas, and hemoglobin oxygen saturation values similar to those of umbilical venous blood. The portion of umbilical venous blood flow that passes via the ductus venosus directly into the IVC meets the systemic venous drainage from the lower body.

Blood flow through the thoracic IVC represents approximately 65% to 70% of venous return to the heart; flow from the ductus venosus accounts for about one third of this amount.^{2,5} The two streams (one from the abdominal IVC and one from the ductus venosus) do not mix, and they demonstrate definite streaming in the thoracic IVC; the well-oxygenated blood derived from the ductus venosus occupies the dorsal and leftward portion of the IVC.⁶ This separation of the more highly saturated umbilical venous stream and the desaturated IVC stream returning from the lower body produces preferential flow of umbilical venous return into the left atrium and then into the left ventricle and ascending aorta.⁶⁻⁸ Of particular importance is preferential streaming of umbilical venous blood to the brain and myocardium.

The preferential streaming of umbilical venous return to the left lobe of the liver and portal venous return to the right lobe also affects the distribution of oxygenated blood to the fetal body. The left hepatic lobe is perfused with umbilical venous blood, which has an oxygen saturation of 80% to 85%; the right lobe is perfused by a mixture of umbilical and portal venous blood, which has a much lower oxygen saturation (approximately 35%). The oxygen saturation of blood in the hepatic veins reflects this difference in perfusion saturation.^{1,4} The oxygen saturation in left hepatic venous blood is about 10% lower than that in umbilical venous blood but about 10% higher than that in right hepatic venous blood, in which the saturation more closely approximates that in the descending aorta.

In fetal lambs, the ductus venosus and left hepatic vein drain into the IVC, essentially at a common point; partial valves are seen over the entrance of the hepatic vein and ductus venosus into the IVC.¹ Similarly, the entrance of the right hepatic vein into the IVC has a valvelike membrane overlying the ostium. This arrangement probably allows left hepatic venous blood to be distributed in a manner similar to that of ductus venosus

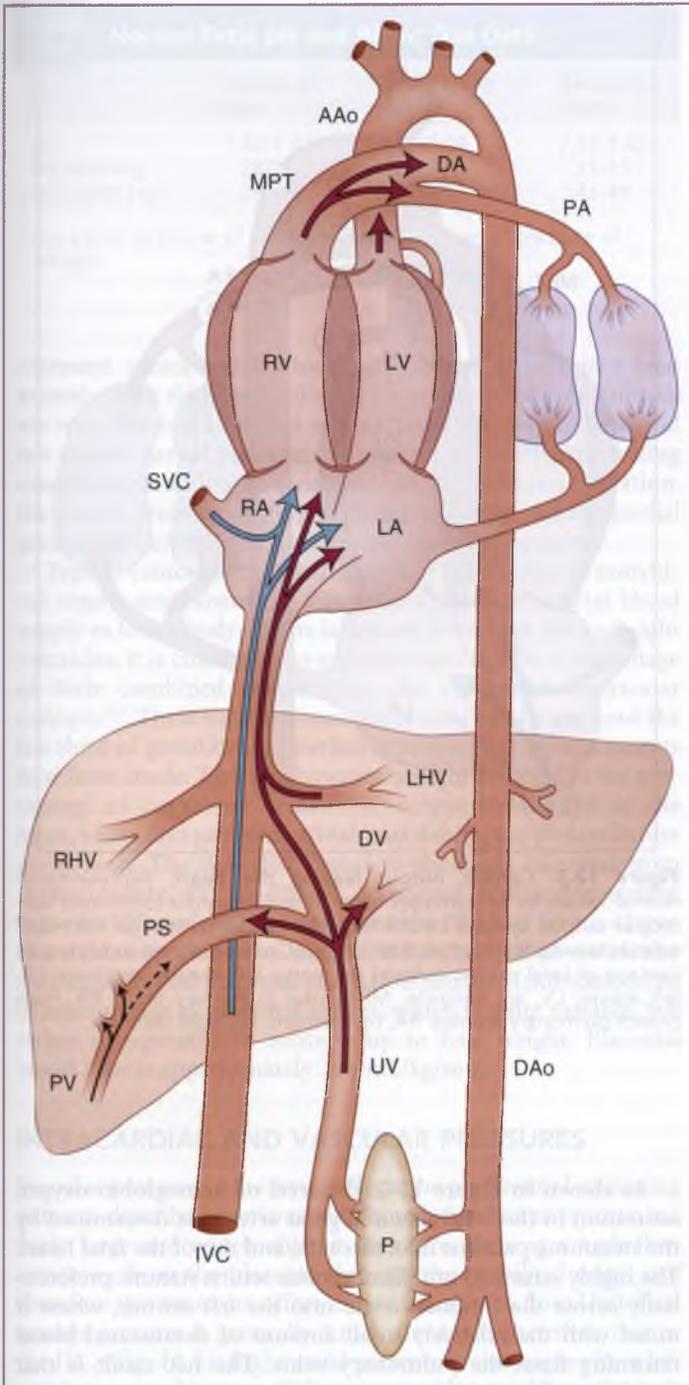

Figure 12-1 Diagrammatic representation of the normal fetal circulation and major fetal blood flow patterns. AAo, ascending aorta; DA, ductus arteriosus; DAo, descending aorta; DV, ductus venosus; IVC, inferior vena cava; LA, left atrium; LHV, left hepatic vein; LV, left ventricle; MPT, main pulmonary trunk; P, placenta; PA, main branch pulmonary arteries; PS, portal sinus; PV, portal vein; RA, right atrium; RHV, right hepatic vein; RV, right ventricle; SVC, superior vena cava; UV, umbilical vein.

blood, whereas right hepatic venous blood is distributed similarly to the abdominal IVC stream. This is particularly important because about half of umbilical venous return passes through the liver, accounting for about 20% of total venous return to the heart. In fetal lambs, left hepatic venous blood flow

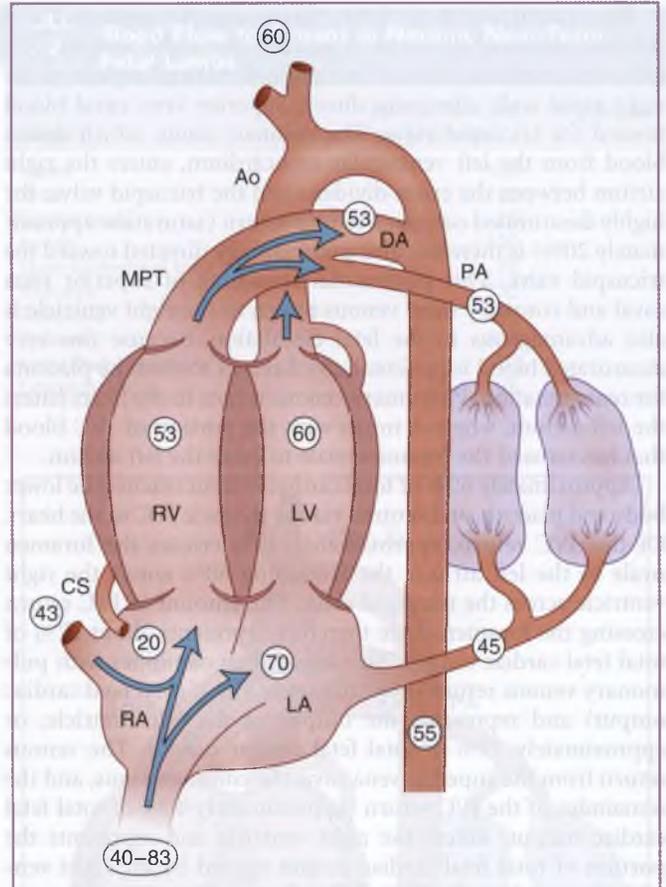

Figure 12-2 Hemoglobin oxygen saturation. Representative normal hemoglobin oxygen saturation data in the heart and major vascular channels in fetal lambs. (Circled numbers indicate percent saturation.) Ao, aorta; CS, coronary sinus; DA, ductus arteriosus; LA, left atrium; LV, left ventricle; MPT, main pulmonary trunk; PA, main branch pulmonary arteries; RA, right atrium; RV, right ventricle.

follows the same pattern as ductus venosus flow, with preferential streaming to the brain and heart.⁴ Similarly, right hepatic blood flow follows the distribution pattern of abdominal IVC blood flow.

The IVC blood then enters the right atrium, and because of the position of the foramen ovale, more preferential streaming occurs. The foramen ovale is situated low in the interatrial septum, close to the IVC. The cephalad margin of the foramen, formed by the lower margin of the septum secundum, lies on the right side of the atrial septum; it is called the crista dividens and is positioned so that it overrides the orifice of the IVC. The crista dividens therefore splits the IVC bloodstream into an anterior and rightward stream that enters the right atrium and a posterior and leftward stream that passes through the foramen ovale into the left atrium. It is this latter stream that has the more highly saturated blood returning from the umbilical circulation through the ductus venosus and left hepatic lobe. Despite this anatomic arrangement and the preferential streaming in the IVC, some mixing of blood does occur; a portion of the more highly saturated umbilical venous blood passes directly into the right atrium, and some desaturated abdominal IVC blood passes into the left atrium. The net result, however, is still a significantly higher saturation in the left atrium than in the right (Fig. 12-2).

Blood returning to the heart via the superior vena cava also streams preferentially once it reaches the right atrium. The crista interveniens, situated in the posterolateral aspect of the right atrial wall, effectively directs superior vena caval blood toward the tricuspid valve. The coronary sinus, which drains blood from the left ventricular myocardium, enters the right atrium between the crista dividens and the tricuspid valve; the highly desaturated coronary venous return (saturation approximately 20%) is therefore also preferentially directed toward the tricuspid valve. This preferential streaming of superior vena caval and coronary sinus venous return to the right ventricle is also advantageous in the fetal circulation, because this very desaturated blood is preferentially directed toward the placenta for reoxygenation. Pulmonary venous return to the heart enters the left atrium, where it mixes with the portion of IVC blood that has crossed the foramen ovale to enter the left atrium.

Approximately 65% of total cardiac output reaches the lower body and placenta and returns via the thoracic IVC to the heart. Of this IVC return, approximately 40% crosses the foramen ovale to the left atrium; the remaining 60% enters the right ventricle across the tricuspid valve. The amount of IVC return crossing the foramen ovale therefore represents about 27% of total fetal cardiac output. This blood then combines with pulmonary venous return (approximately 8% of total fetal cardiac output) and represents the output of the left ventricle, or approximately 35% of total fetal cardiac output. The venous return from the superior vena cava, the coronary sinus, and the remainder of the IVC return (approximately 40% of total fetal cardiac output) enters the right ventricle and represents the portion of total fetal cardiac output ejected by the right ventricle (approximately 65% of total fetal cardiac output).

CARDIAC OUTPUT AND ITS DISTRIBUTION

In the fetus, because of the blood flow across the ductus arteriosus into the descending aorta, lower body organs are perfused by both the right and left ventricles (across the aortic isthmus). For this reason and because of intracardiac shunting, it is customary to consider fetal cardiac output as being the total output of the heart, or the combined ventricular output. In fetal lambs, this is about 450 mL/kg/min. Unlike in the adult, and because of the various sites of intracardiac and extracardiac shunting, the left and right ventricles in the fetus do not eject in series and therefore do not need to have the same stroke volume. In fact, as shown in Figure 12-3, the right ventricle ejects approximately two thirds of total fetal cardiac output (approximately 300 mL/kg/min), whereas the left ventricle ejects only a little more than one third (approximately 150 mL/kg/min).⁹

Echocardiographic studies in human pregnancy have suggested that in humans also, the right ventricle dominates the left.¹⁰⁻¹⁴ Of the 65% of cardiac output ejected by the right ventricle, only a small amount (8%) flows through the pulmonary arteries to the lungs. The remainder (57%) crosses the ductus arteriosus and enters the descending aorta. Because right ventricular output contains all superior vena caval and coronary sinus return, it allows this unoxygenated venous blood to be preferentially returned to the placenta. Left ventricular output (approximately 35% of cardiac output) enters the ascending aorta; in the fetal lamb, approximately 21% reaches the brain, head, upper limbs, and upper thorax. About 10% of cardiac output traverses the aortic isthmus and joins the blood flowing across the ductus arteriosus to perfuse the descending aorta.

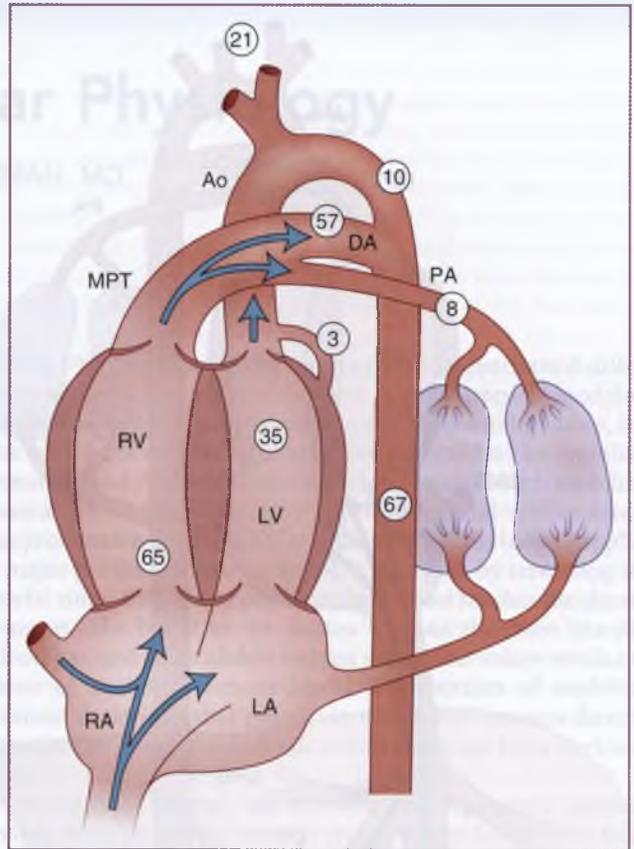

Figure 12-3 Cardiac output leaving the heart. Representative normal values for percentages of total cardiac output (combined ventricular output) ejected by the heart and passing through the major arteries leaving the heart in fetal lambs. (Circled numbers indicate percentage of total cardiac output.) Ao, aorta; DA, ductus arteriosus; LA, left atrium; LV, left ventricle; MPT, main pulmonary trunk; PA, main branch pulmonary arteries; RA, right atrium; RV, right ventricle.

As shown in Figure 12-2, the level of hemoglobin oxygen saturation in the ventricles and great arteries is determined by the streaming patterns into, through, and out of the fetal heart. The highly saturated umbilical venous return streams preferentially across the foramen ovale into the left atrium, where it mixes with the relatively small amount of desaturated blood returning from the pulmonary veins. The net result is that blood ejected by the left ventricle to the ascending aorta is relatively well oxygenated (saturation about 60%). On the other hand, the extremely desaturated coronary sinus venous return and the desaturated blood returning from the brain and upper body flow almost exclusively across the tricuspid valve into the right ventricle. This blood mixes with the IVC stream, which is primarily composed of desaturated blood returning from the lower body but also contains some umbilical venous return. The net result is that the oxygen saturation of blood in the right ventricle is lower than that in the left. This blood perfuses the fetal lungs and traverses the ductus arteriosus to the descending aorta, from which it perfuses lower body organs and reaches the placenta for reoxygenation.

Blood gas and pH values in the fetus also reflect the preferential streaming patterns. The data shown in Table 12-1

TABLE 12-1 Normal Fetal pH and Blood Gas Data

	Umbilical Vein	Descending Aorta	Ascending Aorta
pH	7.40-7.43	7.36-7.39	7.37-7.40
PO ₂ (mm Hg)	28-32	20-23	21-25
PCO ₂ (mm Hg)	38-42	43-48	41-45

PCO₂, partial pressure of carbon dioxide; PO₂, partial pressure of oxygen.

represent values usually found in healthy catheterized fetal animals. Both daily variability and variability between animals are seen. During a normal uterine contraction, arterial blood has a lower partial pressure of oxygen than under truly resting conditions. In addition, during the last 7 to 10 days of gestation, the partial pressure of oxygen declines slightly and the partial pressure of carbon dioxide increases commensurately.

Typical values for the distribution of blood flow to individual organs are shown in e-Figure 12-4. Because arterial blood supply to lower body organs is derived from both left and right ventricles, it is customary to express organ flow as a percentage of their combined output (i.e., the combined ventricular output).^{5,15} These values remain fairly constant throughout the last third of gestation, the period in which such measurements have been made. There is, however, a slight increase in the percentage of combined ventricular output distributed to the heart, brain, and gastrointestinal tract during the 10 days before parturition. The flow distributed to the lungs increases from approximately 4% to 8% of combined ventricular output between 125 and 130 days of gestation (0.85 of term). Organ blood flows are shown in Table 12-2. Like combined ventricular output, umbilical placental blood flow usually is not considered in relationship to placental weight, which is quite variable, but rather is expressed in relationship to fetal weight. Placental blood flow is approximately 200 mL/kg/min.

INTRACARDIAC AND VASCULAR PRESSURES

Vascular pressure in the fetus reflects the preferential streaming patterns described previously. Although the ductus venosus is a fairly large and widely dilated structure, there is a high flow returning from the placenta through the umbilical veins, and therefore this structure offers some resistance to flow. Umbilical venous pressure is generally 3 to 5 mm Hg higher than that in the IVC (Fig. 12-5). Right atrial pressure is also higher than left atrial pressure because of the greater volume of flow through the right atrium. Although the ductus arteriosus is widely patent, it too offers a small resistance to flow. Therefore, systolic pressures in the main pulmonary trunk and right ventricle are slightly higher (1 to 2 mm Hg) than those in the aorta and left ventricle.

The representative pressure data shown in Figure 12-5 would be expected in a fetus close to term. Arterial pressures increase slowly and progressively over the last third of gestation, reaching these values shortly before parturition. Measurement of intravascular pressures in the fetus reflects the additional amniotic pressure not found after birth. Because intra-amniotic pressure is used as the zero reference point, the values presented exclude this additional pressure and are therefore true vascular pressures.

TABLE 12-2 Blood Flow to Organs in Normal, Near-Term Fetal Lambs

Organ	Blood Flow (mL/100 g organ weight/min)
Heart	180
Brain	125
Upper body	25
Lungs	100
Gastrointestinal tract	70
Kidneys	150
Adrenals	200
Spleen	200
Liver (hepatic arterial)	20
Lower body	25

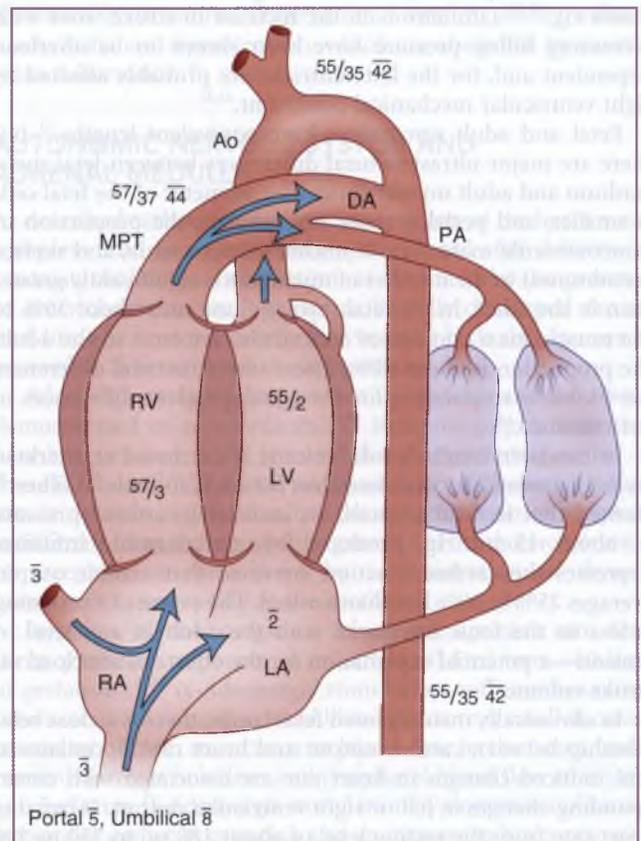

Figure 12-5 Normal vessel and chamber pressures. Representative normal pressures (systolic/diastolic) in millimeters of mercury (mm Hg) in various vessels and cardiac chambers in fetal lambs. (Mean pressures are indicated by numbers with an overbar.) Ao, aorta; DA, ductus arteriosus; LA, left atrium; LV, left ventricle; MPT, main pulmonary trunk; PA, main branch pulmonary arteries; RA, right atrium; RV, right ventricle.

Myocardial Function

Cardiac output is determined by the interrelationships of preload, afterload, myocardial contractility, and heart rate. Preload (ventricular filling pressure) reflects the initial muscle length, which by the Frank-Starling principle influences the development of myocardial force. Afterload (the impedance to ejection from the ventricles) is reflected basically by arterial pressure. Contractility reflects the intrinsic inotropic capability of the myocardium.

Studies of fetal myocardium show immaturity of structure, function, and sympathetic innervation relative to the adult myocardium.^{16,20} At all muscle lengths along the curve of length versus tension, the active tension generated by fetal myocardium is lower than that generated by adult myocardium.¹⁶ In addition, resting, or passive, tension is higher in fetuses than in adults, suggesting lower compliance of fetal myocardium.

Studies in chronically instrumented intact fetal lambs showed that after volume loading by the infusion of blood or saline, the right ventricle is unable to increase stroke work or output to the same extent as in the adult.¹⁷ This is particularly true in less-mature fetuses, in whom right ventricular end-diastolic pressure is markedly elevated without any obvious change in right ventricular stroke work. Similar results are found for both the left and right ventricles but with some ability to increase output or work at lower pressures, between 2 and 5 mm Hg.¹⁸⁻²⁰ Limitations in the increase in stroke work with increasing filling pressure have been shown to be afterload dependent and, for the left ventricle, are probably affected by right ventricular mechanical constraint.^{21,22}

Fetal and adult sarcomeres have equivalent lengths,²³ but there are major ultrastructural differences between fetal myocardium and adult myocardium. The diameter of the fetal cells is smaller, and perhaps more importantly, the proportion of noncontractile mass (i.e., of nuclei, mitochondria, and surface membranes) to the number of myofibrils is significantly greater than in the adult. In the fetal myocardium, only about 30% of the muscle mass consists of contractile elements; in the adult, the proportion is about 60%. These ultrastructural differences are probably responsible for the age-dependent differences in performance.¹⁶

In newborn lambs, stroke volume is decreased at afterload levels that would be considered low for adult animals.²⁴ Gilbert²⁰ showed that in fetal animals, an increase in arterial pressure of about 15 mm Hg, produced by methoxamine infusion, depresses the cardiac function curve so that cardiac output averages 25% to 30% less than normal. The extent of shortening is less in the fetus compared with the adult at any level of tension—a potential explanation for the effects of afterload on stroke volume.¹⁶

In chronically instrumented fetal lambs, there is a close relationship between cardiac output and heart rate. Spontaneous and induced changes in heart rate are associated with corresponding changes in left or right ventricular output. Increasing heart rate from the resting level of about 180 up to 250 to 300 beats/min increases cardiac output by 15% to 20%. Likewise, decreasing heart rate below the resting level significantly decreases ventricular output.

The fetal heart normally appears to operate near the top of its cardiac function curve. An increase in heart rate results in only a modest increase in output; however, bradycardia can reduce output significantly. At an atrial filling pressure greater than approximately 8 mm Hg, there is little or no increase in output because the length-to-tension relationship has reached a plateau. In addition, the fetal heart is sensitive to changes in afterload.

SYMPATHETIC AND PARASYMPATHETIC INNERVATION

Isolated fetal cardiac tissue has a lower threshold of response to the inotropic effects of norepinephrine than does adult cardiac

tissue and is more sensitive to norepinephrine throughout the dose-response curves.¹⁶ Because isoproterenol, a direct β -adrenergic agonist that is not taken up and stored in sympathetic nerves, has similar effects on fetal and adult myocardium, the supersensitivity of fetal myocardium to norepinephrine is probably the result of incomplete development of sympathetic innervation in fetal myocardium. Myocardial concentrations of norepinephrine in the fetus within several weeks of term are significantly lower than in newborn animals, and activity of tyrosine hydroxylase, the intraneuronal enzyme responsible for the first transformation in catecholamine biosynthesis, is also reduced.¹⁶ In contrast, adrenal gland tyrosine hydroxylase activity at the same gestational age is not suppressed, possibly because the decrease in myocardial activity is related to delayed sympathetic innervation rather than to a generalized immaturity.

Monoamine oxidase, the enzyme responsible for oxidative deamination of norepinephrine, is also present in lower concentrations in the fetal heart than in the adult. Histochemical evaluation of the development of sympathetic innervation using the monoamine fluorescence technique has further substantiated the delayed development of sympathetic innervation of the fetal myocardium. At term, sympathetic innervation is incomplete. Patterns of staining indicate a progression of innervation, starting at the area of the sinoatrial node and progressing toward the left ventricular apex.^{25,26}

Although sympathetic nervous innervation appears to begin developing in the fetal heart by about 0.55 of term, β -adrenergic receptors seem to be present much earlier and can be stimulated by appropriate agonists before 0.4 of term.²⁷ Before about 0.55 of term (80 days of gestation in the lamb), fetal myocardium may be affected by circulating catecholamines, but local reflex activity through the sympathetic nervous system is not likely to play a major role in circulatory regulation.

Vagal stimulation at about 0.85 of term produces bradycardia. Administration of atropine at 0.55 of term produces a modest increase in fetal heart rate,²⁸ indicating that vagal innervation is present by this stage of development. Histochemical staining for acetylcholinesterase in close-to-term fetuses has shown that the concentrations of this enzyme, which is responsible for metabolism of acetylcholine, are similar to those found in adults.

ENERGY METABOLISM

In the normal unstressed fetus, myocardial blood flow is about 180 mL/min per 100 g of tissue, approximately 80% greater than in the adult. Fetal myocardial oxygen consumption, as measured in the left ventricular free wall, is about 400 mM/min per 100 g, similar to that in the adult. In adult sheep, free fatty acids provide the major source of energy for the myocardium, and carbohydrate accounts for only about 40% of myocardial oxygen consumption.²⁹ In fetal sheep under normal conditions, however, free fatty acid concentrations are extremely low, and almost all the oxygen consumed by the left ventricular wall can be accounted for by carbohydrate metabolism: 33% by glucose, 6% by pyruvate, and 58% by lactate metabolism.

Adenosine triphosphatase (ATPase) activity in fetal myocardium is equal to that in adult myocardium, suggesting that energy utilization by the contractile apparatus is similar in the two tissues.¹⁶ Mitochondria from fetal myocardium demonstrate higher oxidative phosphorylation than those from adult

myocardium. The higher oxygen consumption in fetal mitochondria uncoupled by deoxyribonucleoprotein suggests that the augmented respiratory rate in mitochondria is a reflection of increased electron transport.¹⁶ This is consistent with the greater cytochrome oxidase activity in fetal mitochondria.

Control of the Cardiovascular System

Maintenance of normal cardiovascular function, blood pressure, heart rate, and distribution of blood flow represents a complex interrelationship among local vascular and reflex effects. These effects are initiated by the stimulation of various receptors, and they are mediated through the autonomic nervous system as well as through hormonal influences. Although some information is available about how these mechanisms affect the circulation after stress, little is known about their role in normal fetal cardiovascular homeostasis. To complicate the situation, other factors, such as sleep state, electrocortical activity, and uterine activity, transiently affect the circulation. As a result, this area of fetal physiology is difficult to study, and the data are difficult to interpret.

LOCAL REGULATION

As the oxygen content of blood perfusing the fetus falls, blood flow to the brain, myocardium, and adrenal glands increases; on the other hand, pulmonary blood flow falls as oxygen content of the blood decreases. Local effects of changes in oxygen environment are less clearly established for other organs.

Many adult organs exhibit autoregulation, the ability to maintain constant blood flow over a fairly wide range of perfusion pressures. In the fetus, the umbilical-placental circulation does not exhibit autoregulation, and blood flow changes in relation to changes in arterial perfusion pressure.³⁰ On the other hand, the cerebral circulation in fetal lambs does show autoregulatory capability.³¹

BAROREFLEX REGULATION

In chronically instrumented fetal lambs, the fetal heart rate slows after an acute increase in systemic arterial pressure.^{32,33} This baroreflex response, although present by 0.55 of term (80 days of gestation), is poorly developed early on; the sensitivity of the reflex to induced changes in pressure increases with advancing gestation. Carotid denervation partially inhibits the response, and combined carotid and aortic denervation abolishes it. Parasympathetic blockade with atropine also abolishes the reflex. Although the existence of the arterial baroreflex is established, Dawes and associates³⁴ suggested that the threshold for fetal baroreflex activity is above the range of the normal fetal arterial blood pressure and that this reflex is not important in controlling cardiovascular function in utero.

Carotid sinus and vagus nerve activity are synchronous with the arterial pulse, suggesting continuous baroreceptor activity.^{35,36} Marked fluctuations in arterial blood pressure and heart rate are observed after sinoaortic denervation, although the average arterial blood pressure and heart rate are not different from those in controls.³⁷

The baroreflex in fetal animals requires fairly marked changes in pressure to produce relatively minor responses. Sinoaortic denervation increases heart rate and blood pressure variability, however. Under normal circumstances, therefore, baroreceptor

function acts to stabilize the heart rate and blood pressure. In the fetus, as in the adult, baroreflex control is also influenced by hormonal systems.³⁸

CHEMOREFLEX REGULATION

In general, chemoreceptor stimulation by sodium cyanide injection induces hypertension and bradycardia.^{39,40} Central or carotid chemoreceptor stimulation causes hypertension and mild tachycardia with increased respiratory activity, whereas aortic chemoreceptor stimulation produces bradycardia with modest increases in arterial blood pressure. Because the carotid chemoreceptors are less sensitive than the aortic chemoreceptors, hypertension and bradycardia usually result. In chronically instrumented fetal lambs, sodium cyanide produces bradycardia with variable blood pressure changes, responses that are abolished by sinoaortic denervation.⁴¹ Fetal hypoxia produces bradycardia and hypertension, which are abolished by carotid sinus denervation.⁴²

AUTONOMIC NERVOUS SYSTEM AND ADRENAL MEDULLA

As described earlier, sympathetic innervation of the heart is not complete until term or, in some species, until after delivery. In contrast, cholinergic innervation, as measured by the presence of acetylcholinesterase, appears to be fully developed during fetal life. The innervation of other vascular beds also appears to proceed at different rates during gestation.⁴³

Adrenergic receptors are present in the fetus and have been demonstrated in myocardium.⁴⁴⁻⁴⁶ Receptor populations that have been studied in the fetus exhibit characteristics similar to those in adults.^{47,48} The fetus possesses mature adrenergic receptors fairly early in gestation, but the concentration of receptors is different from that in adult organs.⁴⁴ The fetal concentration of receptors can be altered by administration of thyroid hormone or isoxsuprine to the mother.

Injection of cholinergic or adrenergic agonists into fetal sheep produces responses at as early as 0.4 of term (60 days of gestation).^{27,49} α -Adrenergic stimulation with methoxamine produces an increase in arterial blood pressure, a small decrease in cardiac output, an increase in blood flow to the lungs, and a marked decrease in kidney and peripheral blood flow at as early as 0.5 of term. β -Adrenergic stimulation by isoproterenol causes a response earlier in gestation and an increase in heart rate with little or no change in arterial blood pressure and cardiac output. Blood flow to both the myocardium and the lungs is increased. Administration of acetylcholine decreases blood pressure and heart rate and increases pulmonary blood flow markedly, particularly in fetuses close to term.

Although receptor affinity is well developed during fetal life, the response to a specific agonist is blunted relative to that in the adult. The maximal constrictor response to norepinephrine or nerve stimulation increases throughout the latter part of gestation, and even more after birth.⁵⁰ The increase might result from gestational differences in neurotransmitter release in the fetus. During the last trimester of gestation, there is a progressive increase in maximal pressor response to ephedrine, which exerts its effect indirectly through neurotransmitter release; phenylephrine has a direct pressor effect.⁵¹ In addition, neurotransmitter reuptake in sympathetic nerve terminals is not fully mature in the fetus.⁴⁸ Similarly, the differences between

fetal and adult myocardium with respect to threshold and sensitivity to norepinephrine indicate an immature reuptake mechanism for norepinephrine in the fetus.¹⁶

As gestation progresses, these variable rates of maturation of different components of the autonomic nervous system modify control mechanisms relating to the autonomic nervous system. The role of β -adrenergic stimulation in resting circulatory regulation has been evaluated by pharmacologic blockade of β -adrenergic receptors with propranolol. This component of the sympathetic nervous system exerts a positive influence over fetal heart rate that first appears at about 0.6 of term (80 to 90 days),²⁸ but this influence is relatively small.⁵² During stress such as hypoxia or hemorrhage, however, β -adrenergic activity appears to be increased because propranolol produces much greater changes in heart rate.

α -Adrenergic control of the circulation has a somewhat clearer developmental pattern. α -Adrenergic blockade with phentolamine or phenoxybenzamine reduces arterial blood pressure very little, if at all, before 0.75 of term (100 to 110 days); thereafter, there is a progressive increase in response, indicating a progressive increase in resting vascular tone attributed to α -adrenergic nervous activity. The parasympathetic nervous system exerts an inhibitory influence over fetal heart rate that is present by 0.55 of term (80 days).^{28,52} Parasympathetic blockade with atropine produces small changes at this age, and there is a progressive increase in parasympathetic control as gestation advances. After approximately 0.85 of term (120 to 130 days), no further increase is evident.

Hypoxemia or asphyxia increases circulating plasma catecholamine concentrations in fetal sheep.⁵³⁻⁵⁵ In fetuses younger than about 120 days' gestation, when the adrenal gland becomes innervated, extremely low fetal blood oxygen concentrations are required to stimulate the adrenal gland; thereafter, catecholamine secretion can be induced by more moderate hypoxemia.⁵³ Infusing catecholamines to reach plasma concentrations that mimic those observed during hypoxemia produces circulatory changes similar to those seen during hypoxemia.⁵⁶ Adrenal medullary responses to stress appear to play a role in circulatory adjustments; whether catecholamine secretion exerts a continuous regulatory function is not clear.

HORMONAL REGULATION OF THE CIRCULATION RENIN-ANGIOTENSIN SYSTEM

The renin-angiotensin system is important in regulating the normal fetal circulation and its response to hemorrhage. The juxtaglomerular apparatus in the kidneys is well developed in fetuses and is present by 0.6 of term (90 days).⁵⁷ Plasma renin activity, as well as circulating angiotensin II, is present in fetal plasma as early as about 0.6 of term.⁵⁸⁻⁶⁰ The effects of fetal stress (e.g., hemorrhage, hypoxia) on the renin-angiotensin system are not absolutely clear. In some studies, small amounts of hemorrhage increased plasma renin activity,^{57,58} but other studies have shown little effect.⁶¹ Similarly, the effects of hypoxemia on the renin-angiotensin system in the fetus are controversial, but most likely hypoxemia is of little consequence.

When angiotensin II is infused to achieve plasma concentrations similar to those that occur after a moderate (15% to 20%) hemorrhage, there are broad cardiovascular effects.⁶² Arterial blood pressure increases markedly, and after an initial abrupt bradycardia, heart rate increases. Combined ventricular output increases, as does blood flow to the lungs and myocardium.

Renal blood flow decreases, but umbilical placental flow is unchanged; this latter phenomenon indicates vascular constriction in the umbilical-placental circulation because arterial blood pressure increases but flow does not. The increase in myocardial blood flow is probably caused by an increase in stroke work, and the large increase in pulmonary blood flow probably reflects the release of some other local pulmonary vasodilating substance, such as one of the prostaglandins.⁶³

Inhibition of the action of angiotensin II by specific inhibitors, such as saralasin, has somewhat variable effects. In general, in unstressed fetal animals, a fall in mean arterial pressure and a slight decrease in heart rate occur.⁵⁹ Combined ventricular output is unaltered, but umbilical-placental blood flow falls, probably in association with the fall in systemic arterial pressure. Blood flow to the peripheral tissues, adrenal glands, and myocardium increases. During hemorrhage, the effects of saralasin are markedly accentuated and result in profound hypotension and bradycardia.

Under normal resting conditions, endogenous angiotensin II appears to exert a tonic vasoconstriction on the peripheral vascular bed, thereby maintaining systemic arterial blood pressure and umbilical-placental blood flow. In response to hemorrhage, angiotensin II is released; it produces more vasoconstriction in the periphery and has other cardiovascular effects, thereby maintaining systemic arterial blood pressure and umbilical blood flow.

Vasopressin

Arginine vasopressin (antidiuretic hormone) has been detected at as early as 0.4 of term (60 days) in fetal lambs.⁶⁴ Although hypoxia and hemorrhage, as well as many other stimuli such as hypotension and hypernatremia, induced a marked increase in plasma vasopressin concentrations,^{64,65} it is unlikely that vasopressin plays a major role in normal circulatory regulation. Maximal antidiuresis in adults occurs with vasopressin concentrations that have no discernible effects on systemic blood pressure. Fetal vasopressin concentrations are below this level.

Infusing vasopressin into fetal sheep to produce concentrations similar to those observed during fetal hypoxemia produces hypertension and bradycardia.⁶⁰ Combined ventricular output decreases slightly, but the proportion distributed to the gastrointestinal tract and peripheral circulations falls, whereas that distributed to the umbilical-placental, myocardial, and cerebral circulations increases. These findings indicate that vasopressin probably participates in fetal circulatory responses to stress not only directly but also by enhancing pressor responses to other vasoactive substances. Under resting conditions, however, vasopressin apparently has little regulatory function.

Natriuretic Peptides

Atrial natriuretic peptide (ANP) and B-type natriuretic peptide (BNP) belong to a potent volume-regulating family of cardiac hormones released from the atria and ventricles in response to myocyte stretch and other stimuli such as α -agonist stimulation, endothelin 1 (ET-1), and cytokines.⁶⁶ These peptides have potent vasodilatory, diuretic, natriuretic, and growth inhibitory actions via the secondary messenger, cyclic guanosine monophosphate (cGMP). The natriuretic system appears to be functional by mid-gestation, and it is able to regulate systemic and pulmonary blood pressures as well as salt and water balance in the fetus. In addition, these peptides are regulated during heart

development, suggesting an important role for the natriuretic peptides in the developing cardiovascular system. Finally, both ANP and BNP have potent vasodilating properties in the placenta and therefore may be important regulators of placental blood flow.^{67,68}

Arachidonic Acid Metabolites

Although prostaglandins typically are locally active substances that do not normally circulate in adult blood, relatively high concentrations do normally circulate in the fetus.^{69,70} It is likely that these prostaglandins are derived from the placenta. The fetal vasculature is also capable of producing prostaglandins, and the umbilical vessels, ductus arteriosus, and aorta produce significant amounts of prostaglandin E (PGE) and prostacyclin (also known as PGI₂).

Prostaglandins administered to the fetus have diverse and extensive cardiovascular effects. PGE₁ and PGE₂ constrict the umbilical-placental circulation.^{71,72} PGF_{2α} and thromboxane also cause constriction, whereas PGI₂ dilates the umbilical-placental circulation. PGE₁, PGE₂, PGI₂, and PGD₂ produce pulmonary vasodilatation in the fetus, whereas PGF_{2α} produces constriction.⁷³ Infusion of PGE₁ into fetal sheep has no effect on cardiac output or systemic pressure, but, in addition to a reduction in umbilical-placental blood flow, there are increases in flow to the myocardium, adrenals, gastrointestinal tract, and peripheral tissues.⁷⁴

Of great interest is the role of prostaglandins in maintaining patency of the ductus arteriosus in the fetus. Circulating prostaglandins, as well as PGE₂ and PGI₂ produced locally in the ductus arteriosus, play a major role in maintaining the ductus arteriosus in a dilated state in utero.⁷⁵⁻⁷⁷ Details of the overall physiologic regulation of the ductus arteriosus are discussed in a later section.

The role of endogenous prostaglandin production in regulating other fetal vascular beds has been elucidated by administering inhibitors of prostaglandin synthesis to the fetus. Although PGE₂ produces umbilical-placental vasoconstriction, inhibition of prostaglandin synthesis has little effect on umbilical-placental vascular resistance, suggesting that prostaglandins do not normally regulate the umbilical-placental circulation. When prostaglandin synthesis is inhibited, the proportion of blood flow to the gastrointestinal tract, kidneys, and peripheral circulation decreases, indicating an increase in vascular resistance in these tissues. Vascular resistances in other tissues are essentially unchanged.

Although prostaglandins do not appear to be central to regulation of the resting fetal pulmonary circulation, PGI₂ may act to modulate tone and thereby maintain pulmonary vascular resistance relatively constant. However, leukotrienes, also metabolites of arachidonic acid and potent smooth muscle constrictors, may play an active role in maintenance of the normally high fetal pulmonary vascular resistance. In newborns,⁷⁸ leukotriene inhibition attenuates hypoxic pulmonary vasoconstriction. In fetal lambs, leukotriene receptor blockade⁷⁹ or inhibition of leukotriene synthesis⁸⁰ increases pulmonary blood flow about eightfold, suggesting a role for leukotrienes in maintenance of the normally high fetal pulmonary vascular resistance; the presence of leukotrienes in fetal tracheal fluid supports this hypothesis.⁸¹

Endothelial-Derived Factors and Endothelin

In addition to PGI₂, vascular endothelial cells can be stimulated to produce other important vasoactive factors, including potent

vasoconstrictors such as ET and potent vasodilators such as endothelium-derived nitric oxide (NO).⁸² NO is produced by most endothelial cells in response to various stimuli, usually involving specific receptors or changes in shear stress. Smooth muscle relaxation is produced through several messenger systems, such as guanylyl cyclase/cGMP, K channels, or PGI₂/cyclic adenosine monophosphate. In the human fetus, NO is produced by umbilical vascular endothelium^{83,84}; nitroso-compounds reduce umbilical vascular resistance in vitro,⁸⁵ and NO modulates resting umbilical vascular tone in fetal sheep in utero.⁸⁶ Disturbances in normal NO production may also be involved in the genesis of preeclampsia⁸⁷ and persistent pulmonary hypertension of the newborn (PPHN).⁸⁸

NO clearly is involved in regulation of vascular tone in the fetal pulmonary circulation, although it plays a far more important role in the postnatal transition to air breathing.⁸⁹ Superfused fetal sheep pulmonary arteries release endothelium-derived relaxing factor when stimulated with bradykinin.⁹⁰ In fetal lambs, the vasodilating effects of bradykinin are attenuated by methylene blue, and resting tone increases with Nω-nitro-L-arginine, an inhibitor of NO that is synthesized by NO synthase from precursor L-arginine,⁹¹ suggesting that a cGMP-dependent mechanism, such as NO production, continuously modulates or offsets the increased tone of the resting fetal pulmonary circulation. Inhibition of endothelial-derived NO synthesis also blocks the pulmonary vasodilatation with oxygenation of fetal lungs in utero and markedly attenuates the increase in pulmonary blood flow with ventilation at birth.^{91,92}

ET-1, a 21-amino-acid polypeptide also produced by vascular endothelial cells, has potent vasoactive properties.⁹³ The hemodynamic effects of ET-1 are mediated by at least two distinct receptor populations, ET_A and ET_B, the densities of which are different depending on the vascular bed studied. The ET_A receptors are located on vascular smooth muscle cells and mediate vasoconstriction, whereas the predominant subpopulation of ET_B receptors is located on endothelial cells and mediates vasodilation.⁹⁴⁻⁹⁶ However, a second subpopulation of ET_B receptors is located on smooth muscle cells and mediates vasoconstriction.⁹⁷ The vasodilating effects of ET-1 are associated with the release of NO and potassium channel activation.⁹⁸⁻¹⁰² The vasoconstricting effects of ET-1 are associated with phospholipase activation, the hydrolysis of phosphoinositol to inositol-1,4,5-triphosphate and diacylglycerol, and the subsequent release of Ca²⁺.¹⁰³ In addition to its vasoactive properties, ET-1 has mitogenic activity on vascular smooth muscle cells and may participate in vascular remodeling.¹⁰⁴

The predominant effect of exogenous ET-1 in the fetal and newborn sheep pulmonary circulation is vasodilation, mediated via ET_B receptor activation and NO release. However, the predominant effect in the juvenile and adult pulmonary circulations is vasoconstriction, mediated via ET_A receptor activation. In fetal lambs, selective ET_A receptor blockade produces small decreases in resting fetal pulmonary vascular resistance. This suggests a potential minor role for basal ET-1-induced vasoconstriction in maintaining the high fetal pulmonary vascular resistance.^{99,101} Although plasma and urinary concentrations of ET-1 are increased at birth,^{105,106} in vivo studies suggest that basal ET-1 activity does not play an important role in mediating the transitional pulmonary circulation.¹⁰⁷ ET-1 causes fetal renal vasodilation¹⁰⁸ and therefore may be involved in the regulation of fetal renal blood flow. An upregulation of ET-1 has been implicated in PPHN.¹⁰⁹

Other factors, such as calcitonin gene-related peptide and a related substance, adrenomedullin, have vasodilatory effects on the fetal pulmonary circulation and may play a role in the regulation of pulmonary vascular tone in the fetus.^{110,111} The effects of these substances probably also are mediated by NO release.¹¹²

Ductus Arteriosus

Patency of the fetal ductus arteriosus is regulated by both dilating and contracting factors. The factors that promote ductus arteriosus constriction in the fetus have yet to be fully identified. The ductus arteriosus maintains a tonic degree of constriction in utero that appears to be both dependent and independent of extracellular calcium.¹¹³ ET-1 also appears to play a role in producing the basal tone of the ductus arteriosus.¹¹⁴

The factors that oppose ductus arteriosus constriction in utero are better understood. The vascular pressure within the ductus arteriosus lumen opposes ductus arteriosus constriction.¹¹⁵ Vasodilator prostaglandins appear to be the most important factors opposing ductus arteriosus constriction in the latter part of gestation.^{113,116} Inhibitors of prostaglandin synthesis (e.g., indomethacin) constrict the fetal ductus arteriosus both in vitro and in vivo.^{76,117,118} Their vasoconstrictive effects appear to be most pronounced beyond 30 weeks' gestation in humans. Both the type 1 and type 2 isoforms of cyclooxygenase (COX) are present within the fetal ductus arteriosus and are responsible for synthesizing the prostaglandins that maintain ductus arteriosus patency.¹¹⁹ Inhibitors of both COX-1 and COX-2 individually produce fetal ductus arteriosus constriction in vivo.¹¹⁹ Conversely, PGE₂ dilates the constricted ductus arteriosus both in vitro and in vivo. PGE₂ produces ductus arteriosus relaxation by interacting with several of the PGE receptors (i.e.,

EP₂, EP₃, and EP₄).¹²⁰ The EP₄ receptor appears to play a prominent role in ductus arteriosus vasodilation.^{121,122} NO also is made by the fetal ductus arteriosus and appears to play an important role in maintaining ductus arteriosus patency in rodent fetuses.¹¹⁶ Although NO is made in the ductus arteriosus of larger species, its importance in maintaining ductus arteriosus patency under normal conditions has not been conclusively demonstrated.¹²³

Although pharmacologic inhibition of prostaglandin synthesis produces ductus arteriosus constriction in utero, genetic interruptions of either prostaglandin synthesis (i.e., homozygous combined COX-1 and COX-2 knockout mice)¹²⁴ or signaling (i.e., homozygous EP₄ receptor knockout mice)¹²² do not lead to ductus arteriosus constriction in utero. Contrary to expectations, both of these genetic interruptions produce newborn mice in which the ductus arteriosus fails to close after birth. The mechanisms through which the absence of prostaglandins early in gestation alters the normal balance of other vasoactive factors in the ductus arteriosus have yet to be elucidated. Pharmacologic inhibition of prostaglandin synthesis in human pregnancy also is associated with an increased incidence of patent ductus arteriosus after birth.¹²⁵ When the fetus is exposed to indomethacin in utero, the ductus arteriosus constricts. Ductus arteriosus constriction in utero produces ischemic hypoxia, increased NO production, and smooth muscle cell death in the ductus arteriosus wall. These factors prevent the ductus arteriosus from constricting normally after birth and make it resistant to the constrictive effects of indomethacin administered postnatally.¹²⁵⁻¹²⁷

Behavioral States in the Fetus: Relationship to Fetal Health and Development

BRYAN S. RICHARDSON, MD | RICHARD HARDING, PhD, DSc | DAVID W. WALKER, PhD, DSc

Studies in human adults more than 50 years ago first demonstrated that sleep occurs in two distinct phases or states—rapid eye movement (REM) sleep and slow-wave sleep (SWS), or non-rapid eye movement (NREM) sleep—that are recognized by temporal patterns in various electrophysiologic and behavioral parameters. These sleep states have also been shown to exist in apparently healthy newborn infants, although they are not evident in preterm infants born much before 36 weeks of gestation. Over the past 3 decades, the use of chronic catheterization techniques in fetal animals, primarily sheep, and the use of high-resolution ultrasound equipment for the study of the human fetus have firmly established the existence of activity or behavioral states in utero that have similarities to postnatal sleep states. From such study, it has become evident that fetal behavioral activities play an important role in normal growth and development of the lungs and musculoskeletal system. These activities also serve to characterize the healthy fetus, since they become altered when oxygenation is compromised, providing a basis for the use of activity parameters in the biophysical assessment of fetal health. Moreover, a developmental process is evident whereby the emergence of behavioral state activity across species is related to the anatomic maturation of the brain, supporting a functional role in the brain's growth and development.

Fetal Behavioral State Activity

ANIMAL STUDIES

Studies involving chronic placement of electrodes and pressure sensors in unanesthetized fetal animals near term, primarily in sheep, have identified the equivalents of behavioral or sleep states with similarities to those described after birth in neonates and adults. Behavioral state classification is based for the most part on electrophysiologic recordings (cortical activity with an electrocorticogram [ECoG], eye movements with an electrooculogram [EOG], and neck muscle activity with a nuchal electromyogram [EMG]) (Fig. 13-1), with the following states recognized¹⁻³:

- HV/LF ECoG-NREM—high-voltage, low-frequency ECoG activity, eye movements absent, nuchal muscle tone mainly present
- LV/HF ECoG-REM—low-voltage, high-frequency ECoG activity, rapid eye movements, nuchal muscle atonia
- Awake—low-voltage, high-frequency ECoG activity, eye movements present or absent, nuchal muscle tone present

The HV/LF-NREM and LV/HF-REM behavioral states described for the ovine fetus are directly comparable to these same states seen after birth and thus are seen to represent in utero sleep state activity.¹⁻³ The third behavioral state (resembling wakefulness) can also be characterized using criteria used to identify postnatal wakefulness. Direct observations of exteriorized sheep fetuses, behavioral responses to external stimuli, and the different effects of evoked potentials in skeletal muscles provide further support for the existence of a fetal awake-like state.¹⁻⁴

As seen with sleep state activity after birth, additional physiologic parameters are recorded as consistent concomitants to fetal behavioral state activity, although species differences may be evident. In the ovine fetus, rapid irregular breathing movements, as identified in recordings of tracheal pressure, occur only during the LV/HF-REM state.⁴ They are not continuous, however, as approximately one third of LV/HF-REM time is not associated with breathing movements, and thus this parameter cannot be used as a criterion for defining the presence or absence of this state. Similarly, in the ovine fetus, wakefulness or arousal is generally associated with higher blood pressure and heart rate, whereas heart rate is lower during HV/LF-NREM and further decreased during LV/HF-REM, which is thought to be mediated by a decrease in sympathetic activity.⁴⁻⁶ On the other hand, fetal heart rate variability is generally increased during LV/HF-REM in association with the presence of breathing movements, and this can be attributed in part to a respiratory sinus arrhythmia.⁴ In fetal sheep, episodes of repeated swallowing (resembling postnatal feeding episodes) and bladder contractions (indicative of bladder emptying) are also influenced by behavioral state. Near term, both of these activities occur mainly during LV/HF ECoG activity in association with eye movements and increased nuchal muscle activity, suggesting a state of heightened arousal resembling wakefulness.^{7,8}

Detection of temporal patterns in individual state criteria as well as concomitant physiologic parameters, as noted, that are relatively stable and repeat over time provide evidence for the existence of fetal behavioral states in other animal species, including the rhesus monkey,⁹ baboon,¹⁰ and guinea pig.¹¹

HUMAN STUDIES

Body movement and heart rate patterns in the human fetus near term reveal a cyclicity that, when compared with postnatal patterns, appears to have a state-related basis (Fig. 13-2).^{12,13} One set of widely used state definitions was introduced by

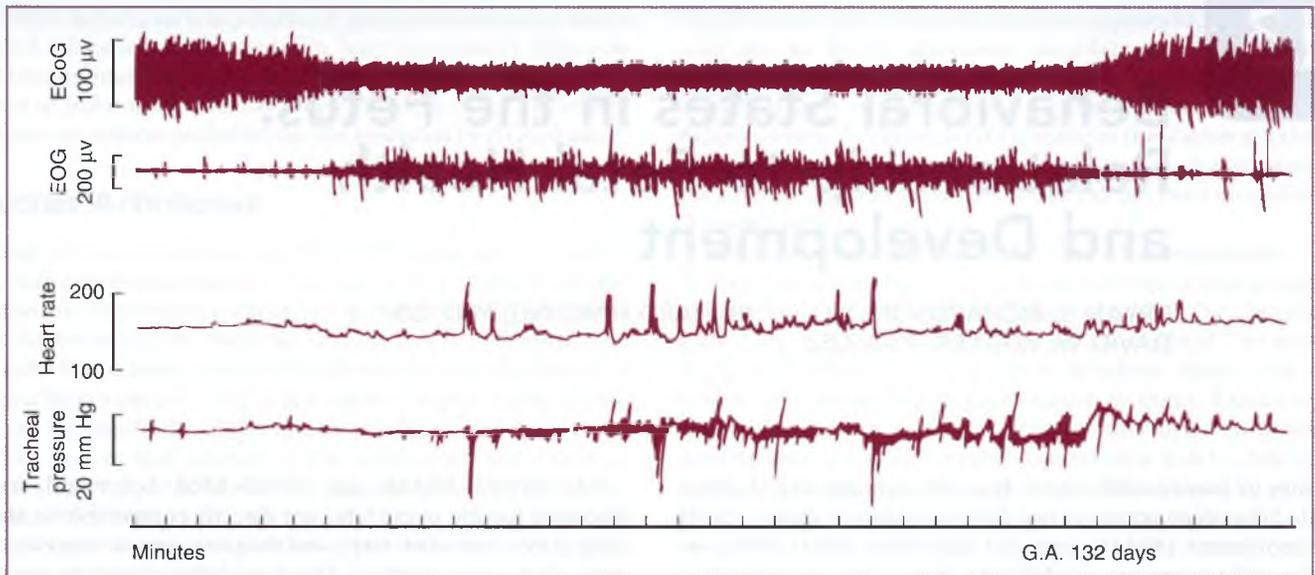

Figure 13-1 Electro-ocular activity and fetal breathing movements. Electrophysiologic recordings demonstrate that electro-ocular activity (EOG) and fetal breathing movements normally occur during times of low-voltage electrocortical activity (ECoG). G.A., gestational age.

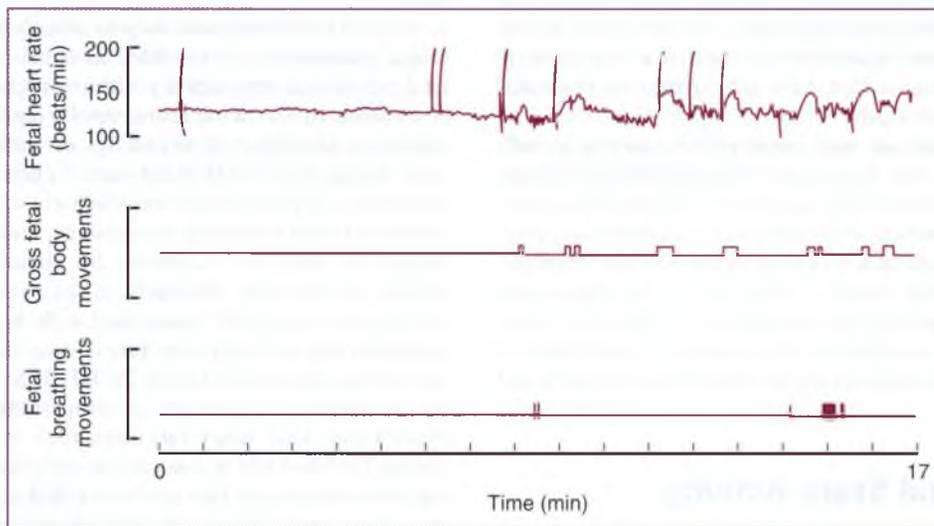

Figure 13-2 A chart recording of behavioral parameters from a healthy human fetus near term. For the first 8 minutes, there are no gross body movements and the heart rate pattern demonstrates no accelerations. From 8 to 17 minutes, a normal episode of gross body movements accompanied by accelerations in the heart rate occurs. (From Richardson BS, Campbell K, Carmichael L, et al: *Effects of external physical stimulation on fetuses near term*, Am J Obstet Gynecol 139:344–352, 1981.)

Nijhuis and colleagues¹⁴ and is based on parameters observed with ultrasound and the simultaneous recording of fetal heart rate patterns. Following Prechtl's¹⁵ strategy for the newborn infant, four distinct behavioral states were recognized from the stability of the temporal association of parameters over prolonged periods, and from the simultaneous changes in these parameters at state transition:

State 1F (fetal)—quiescence (occasional brief gross body movements), eye movements absent, fetal heart rate stable with a narrow oscillation bandwidth

State 2F—frequent gross body movements, eye movements continually present, fetal heart rate with a wider

oscillation bandwidth and frequent accelerations during body movements

State 3F—no gross body movements, eye movements continually present, fetal heart rate stable but with a wider oscillation bandwidth than for state 1F

State 4F—frequent and vigorous gross body movements, eye movements continually present, fetal heart rate unstable with large and long-lasting accelerations

When eye movements, body movements, and heart rate patterns are compared, states 1F and 2F appear to be directly comparable to NREM (or quiet sleep) and REM (or active sleep), respectively, in the newborn. However, comparisons between

fetal states 3 and 4 and postnatal states are less clear, as state 3F is seldom seen after birth, and the frequency of body movements for state 4F is somewhat less than that seen in active wakefulness after birth. Nonetheless, the behavioral response of the human fetus to external stimuli, including vibroacoustic stimulation, supports the existence of a fetal awake-like state near term,^{16,17} in keeping with comparable findings in the ovine fetus.

Additional behavioral parameters are evident as state-related concomitants, but as they are not continuously present they are unsuitable for use as state-defining criteria. Fetal breathing movements are more regular during state 1F than state 2F, whereas their incidence is increased during 2F.^{18,19} Fetal micturition detected by ultrasound recognition of bladder emptying appears to be inhibited during episodes of low heart rate variation suggestive of state 1F, but it appears to be facilitated when heart rate variation is high and rapid eye movements and fetal breathing movements are present, suggesting state 2F or possibly 4F.²⁰ On the other hand, regular mouthing movements, as seen in the neonate, occur only during periods of quiescence and can be considered a concomitant of state 1F.²¹

Developmental Changes

For the ovine fetus (term, approximately 145 days), well-differentiated ECoG patterns are evident from approximately 120 days of gestation onward, with a temporal relationship to episodic muscle and breathing activity that is indicative of behavioral states.³ Initially, there is a high proportion (>50%) of time in the LV/HF-REM state, with approximately 30% of the time in the HV/LF-NREM state and only brief periods of apparent wakefulness (Fig. 13-3). Thereafter, there is a progressive decrease in the incidence of LV/HF-REM, to approximately 40% by term, because of an increase in periods of wakefulness and HV/LF-NREM.³ Postnatally, there is a marked falloff in the incidence of LV/HF-REM sleep, to less than 10%, primarily because of an increase in time spent awake.^{1,3} The durations of both HV/LF-NREM and LV/HF-REM also show a developmental increase with advancing gestation (see Fig. 13-3), although the scoring of these depends on the means of assessment and the minimal duration cutoff values selected.^{3,22} The ovine fetus also has a cycling of behavioral parameters before the appearance of a differentiated ECoG, but these are not well synchronized, and episodic breathing and ocular movements are initially associated with increased, rather than decreased, activity in the neck muscles.²³

The human fetus first demonstrates clearly defined behavioral states at approximately 36 weeks of gestation with stable alignment of behavioral parameters and synchrony of change at state transitions.¹⁴ At this time, state 2F (or REM sleep) predominates, occurring approximately 40% of the time (Table 13-1). State 1F (or NREM sleep) occurs approximately 25% of the time, and state 4F (or wakefulness) occurs but briefly. Approximately 20% of the time, behavioral states cannot be identified. With advancing gestation, the incidences of NREM sleep and wakefulness increase, the incidence of the REM state remains little changed, and the percentage of time with no identifiable state decreases. This time course of behavioral state development in utero is qualitatively similar to that observed in healthy preterm neonates.¹⁵ Moreover, although the NREM and REM states are observed more frequently in the fetus at term (approximately 80%) than in the neonate during early infancy

TABLE 13-1 Coincidence* of Human Fetal States 1F and 2F

State	Gestational Age (wk)			
	25-30 [†]	32 [‡]	36 [‡]	40 [‡]
1F (%)	6	15	20	36
2F (%)	17	46	38	42
No coincidence (%)	77	29	22	9

*Shown as percentage of total recording time.

[†]Data (mean values) from Drogtop AP, Ubels R, Nijhuis JG: The association between fetal body movements, eye movements and heart rate patterns in pregnancies between 25 and 30 weeks of gestation, *Early Hum Dev* 23:67-73, 1990.

[‡]Data (median values) from Nijhuis JG, Precht HFR, Martin CB Jr, et al: Are there behavioural states in the human fetus? *Early Hum Dev* 6:177-195, 1982.

(approximately 70%), the ratios of these two states remain similar.^{14,15} Before 36 weeks of gestation, periods of activity and quiescence are evident, but although the coinciding behavioral parameters may mimic states, they lack stability in temporal relationship and synchrony of change at transition of states (see Table 13-1).^{14,24} Of note, the duration of this activity-quiescence cycle also shows a maturational change, with a progressive increase from about 20 minutes at 28 weeks' gestation to about 60 minutes by term, and this length is similar to that of the REM-NREM cycle of the newborn infant.^{14,15}

Observations on the maturation of ECoG patterns in utero and of behavioral state activity after birth provide insights into the development of sleep-wake states in other species. The organization of ECoG activity in the guinea pig fetus is similar to that in the ovine fetus, with the onset of cyclic differentiation occurring prenatally and with progressive maturation in ECoG waveforms thereafter.¹¹ Likewise, fetal baboons show well-differentiated ECoG patterns near term with maturational changes thereafter.¹⁰ Newborn guinea pigs, monkeys, baboons, and sheep clearly demonstrate the behavioral state aspects of NREM sleep, REM sleep, and wakefulness at the time of birth.^{1,10,11,25} On the other hand, the adult-like ECoG aspects of sleep and wakefulness are not fully developed until several postnatal days in the rat, rabbit, and cat, with an associated delay in the appearance of delineated sleep states.^{26,27} Although comparison between the immature of several species of animals indicates considerable differences in the rate of development of sleep-wake patterns, all demonstrate a similarly high proportion of the REM state with the establishment of well-defined behavioral states.

HYPOXIA AND INTRAUTERINE GROWTH RESTRICTION

In the near-term ovine fetus, moderate hypoxemia of short-term duration²⁸ and graded reductions in fetal oxygenation over several days²⁹ result in minimal change in ECoG activity until hypoxemia is severe enough to result in metabolic acidosis. This then leads to a decrease in the incidence of the LV/HF ECoG state, whereas forelimb, eye, and breathing movements are variably decreased with lesser degrees of hypoxemia (Fig. 13-4). This hierarchical response of fetal activity to hypoxia can be seen to be protective, as ECoG activity that may be important for brain development is initially minimally changed, whereas behavioral activities that result in increased energy

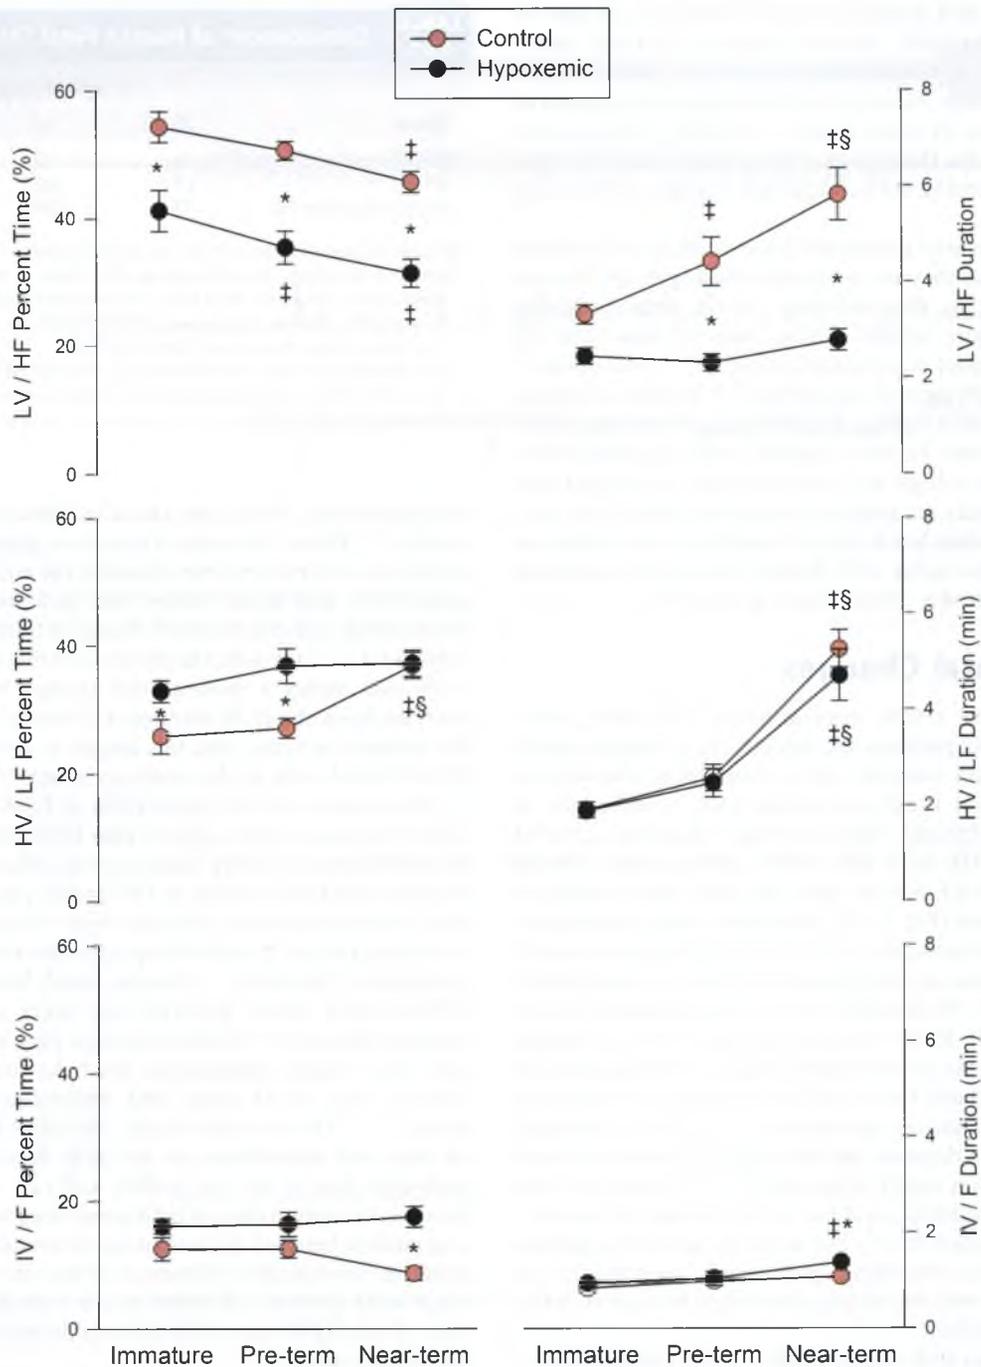

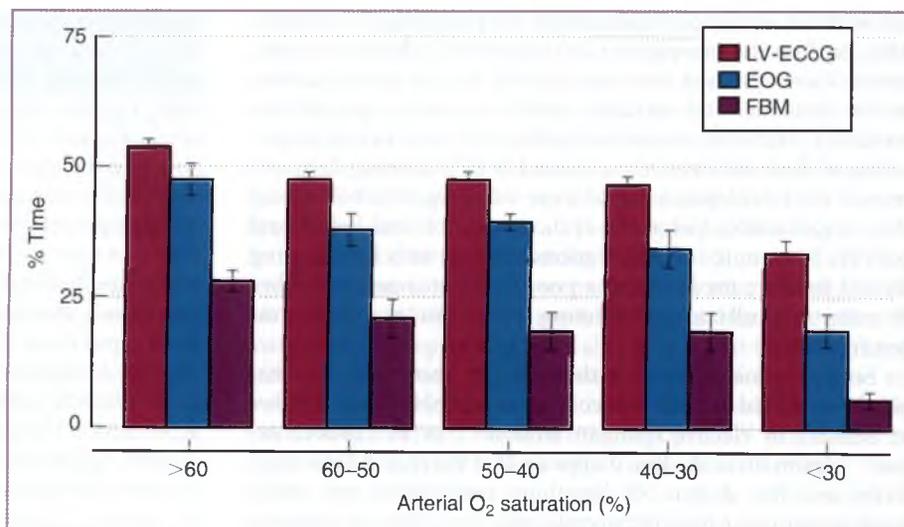

Figure 13-3 Percent time and duration of ECoG low-voltage/high-frequency (LV/HF), high-voltage/low-frequency (HV/LF) and indeterminate voltage/frequency (IV/F) epochs/activity in normoxic control and chronically hypoxic fetal sheep with advancing gestational age. Data presented as grouped means \pm SEM; * P < .05 for control group versus hypoxic group, † P < .05 for control group versus immature within group, § P < .05 for control group versus pre-term within group. (From Keen AE, Frasch MG, Sheehan MA, et al: *Maturational change and effects of chronic hypoxemia on electrocortical activity in the ovine fetus*, Brain Res 1402:38–45, 2011.)

expenditure^{30,31} are decreased. However, it should be noted that a marked decrease in fetal movement activity with graded hypoxemia is seen only at the level at which acidemia becomes apparent.²⁹ Thus, clinical assessment of fetal movements should be used as a marker for moderate to severe hypoxemic change.

In the ovine fetus subjected to moderate hypoxemia chronically over the latter part of pregnancy and sufficient to result in

growth restriction,^{32,33} LV/HF ECoG state activity is seen to be decreased by approximately 30%, whereas HV/LF ECoG state activity shows a modest increase (see Fig. 13-3).³³ This reciprocal decrease in LV/HF and increase in HV/LF state activities with chronic hypoxemia supports the concept that these ECoG changes are adaptive and regulated as the brain shifts its operational time to a state with lower oxidative needs.^{34,35} However,

Figure 13-4 Percentage of time with graded reductions in fetal arterial oxygen saturation over 5 days of study as measured by low-voltage electrocortical (LV-ECoG), electro-ocular (EOG), and fetal breathing movement (FBM) activities. (From Richardson B: *Metabolism of the fetal brain: biological and pathological development*. In Hanson M: *The fetal and neonatal brain stem*, Cambridge, 1991, Cambridge University Press.)

ECoG state transition times are also longer in these chronically hypoxemic animals when studied near term. Additionally, the transition times no longer differ as in normoxic animals in which ECoG state transition from LV/HF to HV/LF is significantly longer than that from HV/LF to LV/HF.³³ These findings suggest that chronic hypoxemia has affected the development of ECoG control circuitries in the brainstem, which may then have longer-term implications for sleep-wake control postnatally. Fetal breathing movements have also been shown to be marginally decreased to approximately 20% of the time in the ovine fetus subjected to chronic hypoxemia with resultant intrauterine growth restriction (IUGR),³⁶ consistent with the related decrease in LV/HF-REM state activity and providing a decrease in oxidative needs.

In human pregnancies with IUGR and presumed chronic fetal hypoxemia,³⁷⁻³⁹ the incidence of fetal breathing movements and gross body movements is generally decreased, but it appears to depend on the severity of the IUGR and the conditions of study.⁴⁰⁻⁴⁵ Although the related decrease in energy expenditure is likely to be biologically important, there is considerable overlap with population norms, which limits the clinical usefulness of these movement parameters as markers for IUGR. When behavioral state organization was assessed in growth-restricted fetuses during the latter part of human pregnancy, little difference was noted in the incidence of the coincidence of states 1F and 2F when compared with that of appropriately grown fetuses.⁴⁶ However, subtle differences have been noted, with IUGR fetuses showing a delay in the appearance of well-delineated behavioral states resulting from longer transition periods with decreased synchrony of behavioral parameters and indicating a disturbance in state organization and thereby in brain development.^{46,47}

Assessment of Fetal Health: Breathing and Body Movements

The present use of fetal breathing and body movements in the assessment of fetal health is largely confined to their component parts in biophysical profile (BPP) scoring (see Chapter 32). As

used in the BPP, fetal movement activity has been scored in an all-or-none manner and related to a number of outcomes, including subsequent intrauterine demise, fetal distress in labor requiring operative intervention, abnormal 5-minute Apgar score, abnormal umbilical cord gases or pH, and IUGR. Although these end points differ somewhat, the physiologic basis for the use of fetal activity in the biophysical assessment of fetal health is the same; that is, with a compromise in oxygenation leading to hypoxemia with or without associated acidosis, fetal movement activity will decrease as an adaptive response whereby energy expenditure is also decreased.

As currently scored in the BPP, fetal breathing movements are more likely to be falsely abnormal at 26 to 33 weeks' gestation than at 34 to 41 weeks.⁴⁸ This is not surprising given the lower incidence of breathing activity in younger fetuses, and it emphasizes the need to establish population norms reflecting the biologic patterns and known factors affecting this activity. Likewise, nonstress testing is more likely to be falsely nonreactive before 32 weeks' gestation,⁴⁹ again reflecting well-described maturational changes where the amplitude of fetal heart rate (FHR) accelerations associated with body movements is normally less before 32 weeks than at later gestational ages.⁵⁰ Assessment of FHR reactivity has therefore included the use of objective computerized FHR analysis to take into account gestational age and to identify the lower-amplitude FHR accelerations expected in healthy, normally growing preterm fetuses as well as the accelerations seen in growth-restricted fetuses, in addition to providing a more accurate assessment of FHR variability.^{51,52}

The negative predictive value for a normal perinatal outcome is high, it is similar among the three dynamic biophysical variables (fetal breathing movements, gross body movements, and nonstress heart rate testing), and it is on the order of 95% with little improvement when test results are combined.^{53,54} However, the positive predictive value for an abnormal perinatal outcome is improved when test results are combined. For the dynamic fetal variables, the monitoring of body movements appears to improve the positive predictive value of the BPP more than the monitoring of breathing movements or nonstress testing.^{55,56} As noted by Devoe and colleagues,⁵⁷ however, such comparisons

are without statistical relationship to physiologic incidence data, because the unweighted and somewhat arbitrary scoring system currently used does not provide for the quantification of the dynamic fetal variables and their normal population standards. Moreover, sequential rather than concurrent monitoring of these fetal activities, as used in BPP scoring, does not respect the interdependence of these variables with behavioral state organization. Given the cyclic nature of fetal behavioral activity, 70 minutes of observational testing with BPP scoring should be more predictive of a poor fetal outcome than either 30 minutes of ultrasound scanning or 40 minutes of nonstress testing alone.

Fetal movement activity in the high-risk obstetric patient has also been related to umbilical cord gases and pH obtained either at delivery by elective cesarean section⁵⁸⁻⁶⁰ or by cordocentesis.^{61,62} From these studies, it appears that decreased FHR reactivity and the absence of breathing movements are earlier manifestations of fetal hypoxemia with the onset of acidemia and therefore more sensitive markers, but with higher false positive rates.^{63,64} On the other hand, the absence of body movements and fetal tone are late markers and therefore can be expected to have better positive predictive value.^{63,64} This implies a hierarchy in the fetal brain for the control of these activities in response to the onset of hypoxemia or acidemia. Although this may be true, as suggested by studies in the ovine fetus,²⁹ the clinical evidence to date shows considerable overlap of blood gas and pH values among test groupings and is largely based on arbitrary standards without relation to population norms.

Although the negative predictive value for a normal perinatal outcome is high with BPP scoring, there continue to be a small number of patients with adverse perinatal outcomes that are not predicted by dynamic fetal monitoring.⁶⁵ This serves to emphasize that the monitoring of fetal movement activity provides an assessment of fetal health only at the time of testing, from which a probability of continued health may be formulated. An improved negative predictive value might occur with more frequent testing, but the time course over which these fetal variables become abnormal before fetal death is not known and may well change with the severity and vagaries of the assorted disease processes. Clinical reports indicate that in some instances, deterioration in scoring profiles may occur over intervals as short as 2 to 3 days.^{54,65} The marked decrease in fetal movement activity required for an abnormal BPP score with the all-or-none criteria appears to be a marker for moderate to severe hypoxemic change with the onset of acidemia, as determined by related changes in umbilical cord gases and pH. This is similar to the study of movement activity in the ovine fetus with graded reductions in oxygenation²⁹ and suggests the need for heightened surveillance in the extremely high risk pregnancy because metabolic deterioration may occur rapidly as acidemia worsens.

Fetal Growth and Development

BRAIN

Brain growth and development are characterized by a series of events that include the proliferation and migration of nerve cells, gliogenesis, the growth of axons and dendrites, the formation of functional synapses, cell death, myelination of axons, and the fine tuning of neuronal specificity. These events proceed in a temporally and regionally dependent manner that is well

coordinated. For the most part, the sequence of developmental events is similar across mammalian species, albeit with considerable variance in the degree of advancement by the time of birth. In sheep, the increase in brain weight during early development occurs in two phases: one up to 90 days after conception, and the second, a more rapid and longer increase after 90 days that continues to birth,⁶⁶ leading to the classification of sheep as prenatal brain developers. These two phases appear to reflect an increase in neuroblast multiplication followed by neuroglial multiplication and myelination.^{66,67} For monkeys, neurogenesis is also largely complete well before birth, although the most rapid phase of synaptogenesis occurs thereafter in a time-window of approximately 40 days, centered on birth.⁶⁸ Although early neuronal connectivity with synaptogenesis and dendritic arborization is largely mediated by an intrinsic growth program, specific refinement occurs later on to generate class-specific dendritic morphologies regulated in part by patterns of synaptic activity.⁶⁹ Sensory-driven activity contributes to these processes during postnatal brain development.⁷⁰ Recent study has pointed to a similar requirement for endogenous neural activity generated by the nervous system itself before sensory input is widely available, and presumably more so for those species whose development is extensively prenatal.⁷⁰ From a comparative standpoint using the timing for peaks in growth velocity of brain development, guinea pigs as well as monkeys can also be classified as prenatal brain developers, humans as perinatal brain developers, and cats and rats as postnatal brain developers.⁶⁶

The anatomic development of the brain as studied across species thus appears to correlate with its electrophysiologic development as indicated by behavioral state maturation. Whereas sheep and guinea pigs, as prenatal brain developers from a neuroanatomic standpoint, have relatively mature electrocortical patterns at birth, rats, as postnatal brain developers, have a poorly differentiated ECoG. This neurodevelopmental correlation, along with the high proportion of REM sleep or REM-like behavioral activity during early life, indicates that the immature being has a high requirement for such activity and that the REM state itself might play a role in the brain's development. The concept of a functional role for the REM state in brain development is further supported by the finding in the ovine fetus of an increase in cerebral metabolic rate at this time, which is most pronounced in midbrain and pontine structures (Table 13-2),^{34,35,71} presumably reflecting increased neuronal activity associated with the REM state. Doppler flow velocity studies in the human fetus suggest a similar REM state effect, given the tight flow-metabolism coupling reported for the brain.⁷² There is also a maturational increase in the cerebral metabolic rate of the ovine fetal LV/HF-REM state³⁵ (see Table 13-2); this increase, along with the reported maturational change in the power spectrum of the ECoG waveform,⁷³ may reflect increasing endogenous stimulation of and by the brain during the REM state, as proposed by Roffwarg and coworkers.⁷⁴ The cerebral metabolic rate of the LV/HF-REM state in fetal sheep at term is similar to that of the awake state at 24 hours after birth, a time of increasing exogenous stimulation for the brain's functional activity (see Table 13-2).³⁵ Thus, it is not surprising that drug-induced REM sleep deprivation in rat pups results in disturbed sleep-wake patterns during later life and a significant reduction in the size of the cerebral cortex.⁷⁵ Although these findings are not conclusive, collectively they support a role for the REM state during early brain

TABLE 13-2 Cerebral Oxygen Consumption ($\mu\text{mol}/100 \text{ g}/\text{min}$) in the Ovine Fetus

development, in which endogenous stimulation promotes synapse refinement and the formation of orderly connections during the critical period of synaptic plasticity.^{70,76}

Although most study and speculation has been directed at the REM state, there is reason to believe that the NREM state may also be important for the brain's development. The developmental change in NREM sleep coincides with the formation of thalamocortical and intracortical patterns of innervation and thereby with periods of heightened synaptogenesis, and it may also be associated with important processes in synaptic remodeling.^{77,78} Furthermore, study in the near-term ovine fetus with infusion of an amino acid tracer has shown that leucine uptake by the brain is increased during the HV/LF-NREM state, indicating that protein synthesis and degradation must also be increased at this time.⁷⁹ This finding is consistent with that in adult animals, where higher rates of cerebral protein synthesis have been shown to be positively correlated with the occurrence of NREM sleep.^{80,81} These studies also indicate that the decrease in the brain's metabolic demand during NREM sleep as seen in the ovine fetus^{34,35} and in other species postnatally, including humans,⁸² does not result from a decrease in biosynthetic activity and may, in fact, favor the synthesis of new proteins. This would support the restorative theory of sleep,⁸³ whereby energy conservation during NREM sleep favors the anabolic restoration of tissues. Thus, REM and NREM sleep state activity may both have an impact on the brain's development, with the former providing a degree of endogenous stimulation through neuronal activity leading to synaptic remodeling with increased protein synthesis or degradation,⁸⁴ which occurs during the subsequent NREM period when energy needs for neuronal activity are lower. An interaction between sleep states and the brain's development is also supported by the finding in the near-term ovine fetus that HV/LF-NREM episode duration is positively correlated with the duration of the previous LV/HF-REM episode,⁸⁵ in keeping with a homeostatic model of REM/NREM sleep control as proposed for the adult rat.⁸⁶

LUNGS

Evidence from animal experimentation and from observations of human fetuses has indicated that fetal breathing movements are important for the normal development of the fetal lungs.

Studies in fetal sheep have eliminated phasic respiratory movements by reversible blockade of the phrenic nerves,⁸⁷ thereby avoiding atrophy of the diaphragm muscle that results from section of the spinal cord or phrenic nerves. Prevention of fetal breathing by reversible blockade of the phrenic nerves leads to a marked reduction in the amount of liquid in the future air-spaces of the lung, and it is considered that this reduction in lung expansion is the cause of the lung hypoplasia that occurs in the absence of fetal breathing.⁸⁸ Thus, it appears likely that fetal breathing is necessary to maintain an adequate degree of lung expansion, which is essential for normal lung growth and maturation. Sheep studies have also shown that fetal breathing movements oppose the inherent tendency of lung tissue to recoil; if unopposed, lung recoil in the fetus would result in the loss of lung fluid and eventual lung hypoplasia.⁸⁸ In addition to maintaining adequate lung expansion, fetal breathing also causes phasic distortion of lung cells, and in vitro evidence indicates that this may stimulate cell division and hence lung growth.⁸⁹ Of interest, the experimental induction of growth restriction in fetal sheep leads to altered lung development that affects the conducting airways and alveoli.^{90,91} However, the extent to which these effects are the result of the associated decrease in fetal breathing activity or of the related chronic hypoxemia or hypoglycemia, and the longer-term consequences for pulmonary function, remain to be determined.

Because fetal breathing movements are important for lung growth, they have been studied in patients with oligohydramnios in relationship to the subsequent development of pulmonary hypoplasia.^{92–95} Although fetal breathing movements appear to be variably decreased or absent in fetuses who are subsequently shown to have pulmonary hypoplasia,^{94,95} this may depend on the gestational age studied. Fetuses with preterm rupture of the membranes and oligohydramnios, as studied during the latter half of pregnancy, are certainly capable of making breathing movements.^{96,97} Moreover, fetuses with renal agenesis and oligohydramnios and who are subsequently shown to have pulmonary hypoplasia, but who are studied after 29 weeks of gestation, are also seen to make breathing movements.⁹² Thus, fetal breathing movements may appear to be decreased or absent in the younger fetus with oligohydramnios because of the developing pulmonary hypoplasia and increased "lung stiffness." With advancing gestation and an increase in the stimuli for respiratory movements and chest wall excursion, breathing movement activity may become evident despite the underlying pulmonary hypoplasia. Studies in sheep have shown that the lung hypoplasia associated with oligohydramnios is primarily a result of chronically decreased lung expansion, rather than inhibition of fetal breathing. Experimental oligohydramnios reduces thoracic dimensions⁹⁸ as well as the degree of fetal lung expansion and hence lung growth.⁹⁹ Further experiments demonstrated that the reduction in lung expansion was reversible,¹⁰⁰ and that the effects of oligohydramnios on fetal breathing could not account for lung hypoplasia.¹⁰¹

MUSCULOSKELETAL SYSTEM

In normally grown newborn infants, lean body mass is 87% of total body weight at term, but it increases to 98% in growth-restricted infants, suggesting a reduction in fat deposition with fetal growth restriction.¹⁰² Padoan and colleagues¹⁰³ used ultrasound estimation of fetal body fat and lean mass to demonstrate that growth-restricted fetuses have reduced subcutaneous fat

and lean mass compared with control fetuses, particularly in the presence of adverse perinatal outcome. However, it is unknown whether this relative loss of muscle mass (sarcopenia) persists into adulthood, although several studies have demonstrated a positive association between birth weight and muscle mass at different stages of life. Furthermore, there is evidence that small size at birth is associated not only with reduced muscle mass and strength but also with changes in metabolic function, with a small study showing that impaired fetal growth was associated with reduced muscle glycolysis in adult life as revealed by phosphorus 31 magnetic resonance spectroscopy.¹⁰⁴ However, the link between the mechanical and metabolic functions of muscle remains unclear, and there was no evidence in this study for differences in skeletal morphology according to size at birth. Although evidence from animal models suggests that early influences on the growth and development of muscle fibers may underlie the relationship between size at birth and adult muscle mass and function, the concept that there is a fixed number of skeletal muscle fibers at birth appears outdated. Recent evidence suggests that postmitotic myonuclei in mature myofibers might be able to reform myoblasts or stem cells, and there is increasing recognition of the role that satellite cells play in postnatal muscle growth and regeneration.¹⁰⁵

De Vries and Fong¹⁰⁶ recently described the changes in the pattern of fetal body movements and motility associated with several genetic fetal anomalies. Hypokinetic fetal movement patterns were associated with several autosomal recessive disorders, whereas other chromosomal anomalies were associated with hyperkinetic gross fetal body movements but with restriction in distal joint mobility resulting in clenched wrists. Therefore, abnormal fetal body movement patterns or the quality of those movements may contribute to abnormal neuromuscular development. However, although the neural activity of fetal motility and its motor effects may contribute to the development of muscles, joints, and even the fine structure of the central nervous system itself,¹⁰⁷ there has been little study, either clinical or animal based, in this area to date.

During development, all embryonic and fetal myotubes initially appear to possess slow myosins, and fetal and neonatal muscle fibers initially contract slowly. The embryonic form of myosin is replaced by a fetal (or neonatal, depending on the species and length of gestation) myosin that is immunologically distinct but shares similarities of ATPase properties with adult "slow" myosins; in some of these fibers, the myosin is then replaced with an adult "fast" isoform. The factors controlling this sequential expression of myosin genes are not fully understood, but they include hormones (especially thyroid hormone), stretch and muscle loading, and the pattern of activity in the motor nerves.¹⁰⁸

For species that are immature at birth (e.g., rats), all muscles initially contract slowly but differentiate into typical "fast" and "slow" muscles under the influence of neural input determined by the development of the neonate's behavioral repertoire. Other evidence that muscle fiber phenotype is under neural control comes from cross-innervation experiments—when a slow muscle is innervated by a foreign fast nerve it atypically expresses fast myosins and physiologically becomes a fast-twitch

muscle.¹⁰⁹ However, fast- and slow-twitch leg muscles develop normally in fetal sheep even if the spinal cord is sectioned,¹⁰⁸ suggesting that expression of particular myosin isoforms also depends on interactions between the muscle and nerve and possibly fast and slow trophic factors, rather than solely on centrally generated motor activity.

Fetal movements, which are evident in many species from early pregnancy, may also be important in the development of joints and the myotendinous junction. However, in the fluid-filled amniotic cavity, it is unlikely that limb and trunk muscles experience resistance and loading sufficient to influence expression of the different myosin isoforms; this may explain the expression of predominantly fast myosin heavy chain (MHC) isoforms before birth. Postnatally, stretch and load have the effect of increasing expression of slow MHC isoforms in skeletal muscle, a response that remains a fundamental property of skeletal muscle into adult life.^{110,111}

These considerations of minimal load and stretch may not apply to the fetal diaphragm, the principal muscle that supports ventilation, and which is involved in a reasonable amount of work before birth. As noted, fetal breathing movements are important for adequate growth and development of the fluid-filled lungs, and they are likely to place a workload on the diaphragm that influences expression of the myosin isoforms. Although other muscle groups (e.g., intercostals) may assist, efficient diaphragm function is essential from the moment of birth. Muscle fibers in the diaphragm can be categorized as slow or fast, but functionally individual fibers appear to possess hybrid characteristics in the sense that they express both slow and fast isoforms of muscle proteins and have contractile properties typical of both slow- and fast-twitch fibers.^{112,113} In fetal sheep, this hybrid phenotype emerges near the end of gestation, and it is further induced by the increased longitudinal tension on the diaphragm that arises with the transition from liquid to air breathing.¹¹⁴

The mechanical effort associated with the initiation of air breathing at birth is high because of the high compliance of the chest wall and the low compliance of the fluid-filled lungs. This also means that the diaphragm must be resistant to fatigue, particularly in infants born prematurely with immature lungs, which are commonly surfactant deficient. The extra stretch imposed on the diaphragm at the transition to air breathing may also cause modification of the tertiary structure of some proteins, which then changes the elastic properties of the diaphragm. Perhaps the most important of these structural proteins is titin, a very large, muscle-specific protein that spans half the length of a sarcomere and, during contraction, controls the structure and stability of the sarcomere by keeping myosin in a central position to maximize attachment of the myosin head to actin.^{115,116} Diaphragm dysfunction that arises after passive mechanical ventilation, such as increased muscle stiffness, has been associated with loss of titin.¹¹⁷ These are likely to be important considerations for preterm neonates, who often need ventilating for considerable periods of time.

Placental Respiratory Gas Exchange and Fetal Oxygenation

GIACOMO MESCHIA, MD

Knowledge of respiratory gas exchange across the human placenta depends on integrating observations in pregnant patients with experimental findings in laboratory animals. This integration is necessary because data on the physiology of the human fetus are scant and cannot be interpreted correctly in the absence of experimental evidence. The evidence in laboratory animals consists of a fairly comprehensive set of data in sheep with chronically implanted vascular catheters in the maternal and fetal circulations and a more limited but important set of data in nonhuman primates and other mammals.

Transport of Atmospheric Oxygen to the Gravid Uterus

The transport of oxygen (O_2) from the atmosphere to fetal tissues can be visualized as a sequence of six steps that alternate bulk transport with transport by diffusion (Fig. 14-1). The first three steps of this process are part of general physiologic knowledge and therefore are presented here briefly.

In step 1, transport of oxygen from the atmosphere to the alveoli occurs by action of the respiratory muscles, which move air in and out of the maternal lungs. This action maintains the partial pressure of oxygen (PO_2) in the alveoli at a level that is regulated by several physiologic mechanisms, some of which are driven by sensors that detect the PO_2 , the partial pressure of carbon dioxide (PCO_2), and maternal blood pH. During pregnancy, the maternal organism is set to regulate arterial PCO_2 at a lower level than in the nonpregnant state.

In step 2, oxygen diffuses from the alveoli into the maternal red blood cells that circulate through the lungs. In the normal organism at sea level, the diffusion rate is so rapid that the PO_2 at the venous end of the pulmonary capillaries becomes virtually equal to the PO_2 in the adjacent alveoli. Nevertheless, the PO_2 of maternal arterial blood is somewhat less than the PO_2 in a sample of alveolar air, in part because some deoxygenated blood bypasses the lungs and in part because ventilation and perfusion of the alveoli are not matched evenly throughout the lungs. Under pathologic conditions that prevent equilibration of PO_2 between alveoli and blood, increase the degree of uneven ventilation-perfusion, or shunt more deoxygenated blood directly into the arterial system, the PO_2 difference between alveolar air and arterial blood is larger.

In step 3, maternal blood, propelled by action of the maternal heart, transports oxygen from the lungs to the gravid uterus via the pulmonary veins, left atrium, left ventricle, aorta, uterine arteries, and branches of the ovarian and vaginal arteries. Oxygen is transported by blood in two forms: free and bound to hemoglobin. In any blood samples, these two forms are in

reversible equilibrium. The special nomenclature for the components of this equilibrium is summarized in Table 14-1.

Measurement of Uterine and Umbilical Oxygen Uptakes

The study of fetal physiology in sheep has led to the development of a method for measuring simultaneously, under normal steady-state conditions, uterine and umbilical blood flows and the concentrations of metabolites in maternal arterial, uterine venous, umbilical venous, and umbilical arterial blood.¹ This method allows the calculation of uterine and umbilical oxygen uptakes as two separate entities. The rationale for this calculation, commonly known as the Fick principle, is as follows. Each milliliter of maternal blood in passing through the pregnant uterus gives up a certain amount of oxygen, which can be calculated by measuring the difference in oxygen content between maternal arterial and uterine venous blood. The quantity of oxygen lost by each milliliter of blood is then multiplied by the milliliters of blood flowing through the pregnant uterus to obtain the uterine oxygen uptake. To calculate the rate at which the umbilical circulation takes up oxygen, exactly the same reasoning is applied to the umbilical blood data.

In mathematical terms, uterine O_2 uptake ($\mu\text{mol}\cdot\text{min}^{-1}$) is given by the following equation:

$$\text{Uterine } O_2 \text{ uptake} = F \times (AO_2 - VO_2)$$

where F is uterine blood flow ($\text{mL}\cdot\text{min}^{-1}$) and $(AO_2 - VO_2)$ is the arterial-venous difference in O_2 content across the uterine circulation ($\mu\text{mol}\cdot\text{mL}^{-1}$).

Similarly,

$$\text{Umbilical } O_2 \text{ uptake} = f \times (\gamma O_2 - \alpha O_2)$$

where f is umbilical blood flow, and $(\gamma O_2 - \alpha O_2)$ is the difference in O_2 content between umbilical venous and arterial blood. The instruments that can measure blood O_2 content directly are rarely used. Instead, measurements of blood O_2 saturation, O_2 capacity, and PO_2 are commonly used to calculate O_2 content:

$$O_2 \text{ content} = (S \times [O_2 \text{ CAP}]) + \alpha \text{ sol } PO_2$$

where $\alpha \text{ sol}$ is the solubility coefficient of oxygen in blood. Because oxygen solubility in blood is very low, it is important to note that ordinarily the $\alpha \text{ sol } PO_2$ term is much smaller than the product of O_2 saturation and O_2 capacity. Table 14-2 gives a numerical example of these calculations in a near-term ewe breathing atmospheric air. It shows that setting the $\alpha \text{ sol } PO_2$ term to zero would reduce the uterine oxygen uptake estimate

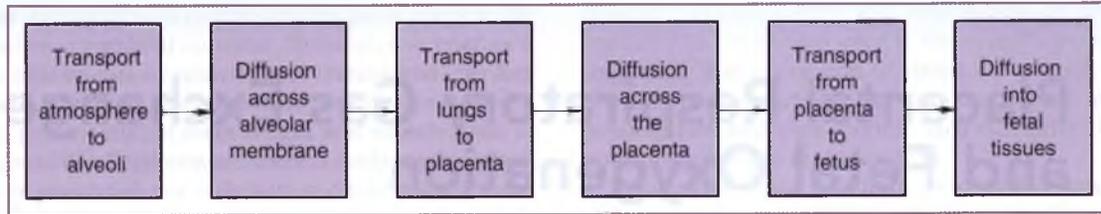

Figure 14-1 Transport of oxygen from the atmosphere to the fetal tissues in a sequence of steps that alternate bulk and diffusional transport. (From Meschia G: Supply of oxygen to the fetus, J Reprod Med 23:160, 1979.)

TABLE 14-1 Blood Oxygen Transport: Terminology, Measurement, and Relationships

Nomenclature	Symbol	Units
Free O ₂	[O ₂]	mM*
O ₂ bound to hemoglobin	[HbO ₂]	mM*
O ₂ content		mM*
O ₂ pressure	PO ₂	mm Hg
Hemoglobin	[Hb]	mM*
O ₂ capacity	[O ₂ CAP]	mM*
O ₂ saturation	S	—
O ₂ saturation × 100	% S	—

CALCULATIONS
 O₂ content = [HbO₂] + [O₂]
 [O₂ CAP] = 4 [Hb][†]
 S = [HbO₂] + [O₂ CAP]
 [O₂] = α sol PO₂ (where α sol is the solubility coefficient of O₂ in blood)

*Another unit used often in reporting quantities of O₂ is mL_{STP} (1 millimole = 22.4 mL_{STP}).
[†]Each hemoglobin molecule can combine with four molecules of oxygen. The [Hb] used in the calculation of [O₂ CAP] is total hemoglobin minus carboxihemoglobin and methemoglobin.

TABLE 14-2 Calculation of the Uterine and Umbilical Oxygen Uptakes: Numerical Example

MEASURED QUANTITIES	
Maternal arterial O ₂ saturation (%)	95.0
Uterine venous O ₂ saturation (%)	77.0
Maternal blood O ₂ capacity (mM)	7.0
Maternal arterial PO ₂ (mm Hg)	72.0
Uterine venous PO ₂ (mm Hg)	40.0
Uterine blood flow (mL•min ⁻¹)	1263
Umbilical venous O ₂ saturation (%)	82
Umbilical arterial O ₂ saturation (%)	57
Fetal blood O ₂ capacity (mM)	6.8
Umbilical venous PO ₂ (mm Hg)	28
Umbilical arterial PO ₂ (mm Hg)	19
Umbilical blood flow (mL•min ⁻¹)	600
O ₂ solubility (mM•mm Hg ⁻¹)	0.0013

CALCULATIONS
 Uterine O₂ uptake (μmol•min⁻¹) = 1263 [7.0 (0.95 – 0.77) + 0.0013 (72 – 40)] = 1591 + 53 = 1644
 Umbilical O₂ uptake (μmol•min⁻¹) = 600 [6.8 (0.82 – 0.57) + 0.0013 (28 – 19)] = 1020 + 7 = 1027
 Uteroplacental O₂ consumption (μmol•min⁻¹) = 1644 – 1027 = 617

by about 3% (1591 versus 1694 μmol•min⁻¹) and the umbilical oxygen uptake estimate by less than 1% (1020 versus 1027 μmol•min⁻¹).

The uterine-umbilical oxygen uptake difference defines the oxygen consumption rate of a tissue mass that includes, in

TABLE 14-3 Umbilical Oxygen Uptake and Uteroplacental Oxygen Consumption Values (Mean ± SEM) in Mid-gestation and Near-Term Ewes*

	Mid-gestation	Near-Term
Number of animals	11	47
Gestational age (days)	75	132
Fetal weight (g)	209 ± 14	3150 ± 93
Placental weight (g)	409 ± 25	328 ± 10
Umbilical O ₂ uptake (μmol•min ⁻¹)	94 ± 7	1117 ± 37
Uteroplacental O ₂ consumption (μmol•min ⁻¹)	420 ± 36	611 ± 31
Umbilical O ₂ uptake per kilogram of fetal weight (μmol•min ⁻¹ •kg ⁻¹)	464 ± 25	356 ± 7

*Term = 147 ± 3 days.

addition to the placental villous tree, the myometrium and the endometrial glands. This tissue mass is called the *uteroplacenta*.

Umbilical Oxygen Uptake

Measurements of umbilical oxygen uptake define the rate of fetal oxygen consumption. From mid-gestation to term, fetal O₂ consumption increases exponentially, correlating with the exponential increase in fetal weight. However, the consumption does not increase in exact proportion to weight. As shown in Table 14-3, the fetal lamb at mid-gestation has an oxygen consumption rate per unit of body mass that is about 30% higher than at near-term.

The relationship between oxygen consumption and body weight of adult mammals at rest is described fairly accurately by the Brody-Kleiber equation²:

$$\dot{V}O_2 = 440 \times BW^{0.75}$$

where $\dot{V}O_2$ is the O₂ consumption rate in μmol•min⁻¹ and BW is the body weight in kilograms. This equation summarizes three important aspects of mammalian physiology. First, adult mammals of similar body size, such as sheep and humans, have similar basal oxygen consumption rates despite differences in body composition. Second, small mammals have an enormously higher oxygen consumption per unit of body weight than large mammals. For example, the resting oxygen consumption rate of a 20-g mouse and that of a 600-kg cow are approximately 1100 and 85 μmol•min⁻¹•kg⁻¹, respectively.² Third, at comparable body weight and temperature, homeotherms consume about five times more oxygen than poikilotherms.² This information provides a basis for exploring the physiologic meaning of fetal oxygen consumption.

The oxygen consumption rates of near-term bovine³ and guinea pig⁴ fetuses have been estimated to be 300 and 392 $\mu\text{mol}\cdot\text{min}^{-1}\cdot\text{kg}^{-1}$, respectively. Because the guinea pig fetus weighs much less than the bovine fetus (approximately 0.08 versus 25 kg), the Brody-Kleiber equation predicts a four times greater oxygen consumption per unit of fetal body weight in the guinea pig. Clearly, however, this is not the case. This type of evidence has led to the conclusion that oxygen consumption per unit body weight is much less variable in prenatal than in postnatal life.⁵ Data on fetal heart rates agree with this conclusion. Heart rate is a correlate of O_2 consumption per unit body weight. The heart rates of immature fetuses are virtually equal among mammals, irrespective of large differences in body weight.⁶

These data imply a fundamental difference in the comparative physiology between small and large mammals. In small mammals (adult body weight <1 kg), adaptation to postnatal life requires an increase in oxygen consumption per unit of body weight. In large mammals, it requires a decrease. The fetus represents a rate of relatively low energy metabolism within the maternal body of small animals and a rate of relatively high energy metabolism in the maternal body of large animals.

It is not clear why adaptation to postnatal life requires small-size mammals to increase the intensity of resting oxygen consumption to well above the fetal value. By contrast, there is some understanding of why in large mammals this adaptation entails a decrease in the oxygen consumption per kilogram of body weight. The postnatal environment requires large animals to develop a heavy bone and muscle structure. In fetal life, the development of this structure is delayed in favor of developing the internal organs. The internal organs have a much higher oxygen consumption rate per unit weight than do bones and resting muscle. The data in Table 14-4 demonstrate that this organ-specific difference in intensity of oxidative metabolism is already present in fetal life. According to this evidence, one of the reasons why the fetus of a large mammal has a higher oxygen consumption per unit weight than the resting adult is that in the fetus the internal organs are a larger fraction of body weight.

A difference in body composition is the explanation that is generally given for the fact that oxygen consumption per unit of body weight in a newborn baby at rest in a thermoneutral environment is about twice the adult value (approximately 300 versus 150 $\mu\text{mol}\cdot\text{min}^{-1}\cdot\text{kg}^{-1}$). As a percentage of body weight, the brain is about 12% in the newborn and 2% in the adult human. Notice that this figure for oxygen consumption in a newborn human (300 $\mu\text{mol}\cdot\text{min}^{-1}\cdot\text{kg}^{-1}$) is within the range of

values for fetal oxygen consumption that have been measured in experimental animals. This indicates that in humans, the transition from prenatal to postnatal life is not associated with any immediate and large change in the rate of energy metabolism.

Included in the rate of fetal energy metabolism is the energy cost of growth. The energy cost of protein turnover and accretion in the fetal lamb has been estimated to account for about 18% of oxygen consumption.⁷ In a study of severely hypoxic, growth-restricted fetal lambs,⁸ umbilical oxygen uptake per kilogram of body weight was reduced only 24% below normal, despite evidence that at the time of measurement the growth rate was virtually zero. Among fetal organs, there is no correlation between oxygen consumption and growth rate (see Table 14-4). These findings indicate that the energy cost of growth represents a relatively small fraction of fetal oxidative metabolism. Most of the oxygen consumed by the fetus is used to fuel the rapid ionic and metabolic fluxes that characterize the life of homeotherms.

Normal Fetal Oxygenation

An important aspect of fetal physiology is that during the last third of gestation, fetal blood has much lower oxygen saturation and PO_2 values than maternal blood. At sea level, maternal arterial blood is 96% saturated with oxygen and has a PO_2 of about 100 mm Hg. By contrast, the blood that carries oxygen to the fetus via the umbilical vein has normal oxygen saturation and PO_2 values equal to about 81% and 35 mm Hg, respectively. Similarly low values characterize the normal oxygenation of umbilical venous blood in sheep (Table 14-5). Furthermore, the structure of the fetal vascular tree is such that all fetal organs are perfused by blood having lower oxygen saturation and PO_2 values than umbilical venous blood. The only exception is the left hepatic lobe, which is perfused almost exclusively by umbilical venous blood.

In the near-term ovine fetus, the normal umbilical arterial oxygen saturation and PO_2 values are approximately 55% and 19 mm Hg, respectively (see Table 14-5). Umbilical arterial oxygenation is identical to that of the blood that supplies oxygen to all the organs perfused via the fetal abdominal aorta. The normal umbilical arterial oxygenation of the human fetus is unknown. However, a simple calculation demonstrates that it must be similar to that of the fetal lamb. If we assume a human fetal oxygen consumption rate of 300 $\mu\text{mol}\cdot\text{min}^{-1}\cdot\text{kg}^{-1}$ and an umbilical flow rate of 110 $\text{mL}\cdot\text{min}^{-1}\cdot\text{kg}^{-1}$,⁹ application of the Fick principle to the human data in Table 14-5 yields an arterial

oxygen saturation of 47%. The human fetal oxyhemoglobin dissociation curve can then be used to estimate an umbilical arterial PO₂ of 20 mm Hg.

The blood that perfuses the fetal upper body has a greater oxygenation level than umbilical arterial blood. This difference is caused by a preferential streaming of umbilical venous blood into the left ventricle.¹⁰ In near-term fetal lambs, the difference in oxygen content across the aortic isthmus is 0.45 ± 0.02 mM.¹¹ This means that, given the normal umbilical arterial content and capacity values shown in Table 14-5, the oxygen saturation in the fetal ascending aorta is about 63%. At this saturation, the PO₂ of ovine fetal blood is about 22 mm Hg.

In conclusion, the oxygenation of a third-trimester fetus would define a state of severe hypoxia in postnatal life. How is it possible, then, for the human and the ovine fetus to have an oxygen consumption rate per kilogram that is about twice the basal adult value? The factor that makes this possible is the output of the fetal heart, which is about 460 mL·min⁻¹·kg⁻¹,^{12,13} much higher than that of the adult heart at rest. For example, in a 50-kg adult human, the output of each ventricle would have to be 11.5 L·min⁻¹ to match the fetal output, rather than the normal resting cardiac output of about 5 L·min⁻¹.

Fetal cardiac output compensates for the low level of fetal oxygenation by maintaining a high ratio of blood flow to oxygen consumption through the circulation of individual fetal organs. Table 14-6 compares the fetal and adult values of this ratio for the brain and the hind limbs of sheep. For each of these organs, the blood flow that is used to maintain a given oxygen consumption rate is about 2.5 times greater in the fetus than in the adult. This difference in blood flow is not caused by differences in oxygen capacity. In near-term ovine pregnancies, the hemoglobin contents of maternal and fetal blood are not significantly different.

The mean PO₂ and oxygen saturation values of human umbilical venous blood are significantly higher at mid-gestation than at term.¹⁴⁻¹⁶ A common interpretation of this evidence is that during pregnancy there is a progressive decline of fetal oxygenation, but experimental data in sheep suggest otherwise. Like the human fetus, the fetal lamb has higher mean umbilical venous and arterial oxygen saturations at mid-gestation than at term.¹⁷ However, there is also evidence that the PO₂ and oxygen saturation of umbilical venous blood in a given fetus can be remarkably stable during the last third of gestation.¹⁸ This evidence indicates that in the course of a normal pregnancy, instead of a progressive decline, there is a shift in the level of umbilical blood oxygenation, from the high plateau that characterizes the first half of gestation to the lower plateau that characterizes the last third.

In 10 mid-gestation fetal lambs, the mean umbilical venous oxygen saturation was 90%, with a standard deviation (SD) of ±3.5%.¹⁷ If we assume 2 SDs to define the normal range of variability, the lower limit of umbilical venous oxygen saturation at mid-gestation would be about 80%. A larger number of observations is needed to provide a more precise definition of this limit. In 93 near-term fetal lambs, the umbilical venous oxygen saturation (mean ± SD) was 81% ± 7%. This puts the lower limit of normal umbilical venous oxygen saturation in the last third of gestation at about 67%. In the human fetus, an oxygen saturation of 67% at the normal umbilical venous pH of 7.37 corresponds to a PO₂ of 27 mm Hg.¹⁹

However, two studies of the human fetus have estimated the lower limit of normal umbilical venous PO₂ at 38 weeks to be 20 mm Hg instead of 27 mm Hg.^{14,16} At PO₂ 20 mm Hg and pH 7.37, the oxygen saturation of human fetal blood is about 47%.¹⁹ This level of umbilical venous oxygenation is too low to be in the normal range (see later discussion). The unreliably large

normal limits of third-trimester fetal PO_2 that are reported in the literature may be the result of a statistical analysis that assumes a linear decrease of PO_2 from mid-gestation to term and a PO_2 variability that is independent of age.

UMBILICAL VENOUS PO_2 IS A FUNCTION OF UTERINE VENOUS PO_2

In any given near-term, normal ovine pregnancy, umbilical venous PO_2 varies as a function of uterine venous PO_2 , and the uterine-umbilical venous PO_2 difference remains virtually constant in response to wide PO_2 changes. Figure 14-2 shows the umbilical venous PO_2 response to variations in uterine venous PO_2 induced by changing the percentage of oxygen in maternal inspired air or by shifting the oxyhemoglobin dissociation curve of maternal blood to the right via a decrease in the pH of maternal blood. Figure 14-3 shows the results of experiments in five animals in which the uterine venous PO_2 was decreased by decreasing uterine blood flow. The two figures demonstrate a similar umbilical-versus-uterine venous PO_2 relationship despite the different means that were used to vary uterine venous PO_2 . Changes in the percentage of oxygen in maternal inspired air cause changes in the PO_2 and oxygen content in maternal arterial blood, but they have virtually no effect on uterine blood flow.²⁰ In contrast, a decrease of uterine blood flow does not change the oxygenation of maternal arterial blood. A detailed analysis of the PO_2 versus blood flow experiment can be found in the original publication.²¹

In an attempt to explain this basic information, it is useful to address two questions: (1) Why does umbilical venous PO_2 vary as a function of uterine venous PO_2 ? and (2) Why is umbilical venous PO_2 so much less than uterine venous PO_2 ?

Venous Equilibration Model of Transplacental Exchange

Studies in sheep on the transplacental diffusion of molecules that rapidly cross the placental barrier (e.g., tritiated water, ethanol) have established that the maternal and fetal placental circulations form an exchange system that tends to equilibrate the venous concentrations of any molecule that diffuses across the barrier.²²

The physiologic concept of venous equilibration is easy to grasp by considering the hypothetical model shown in Figure 14-4. This model assumes that the basic unit of transplacental exchange consists of a membrane that separates two bloodstreams flowing in the same direction. At the arterial end of the exchanger, the maternal bloodstream enters with a higher PO_2 than fetal blood (72 versus 19 mm Hg), thus establishing a PO_2 gradient that drives O_2 molecules across the membrane into fetal blood. As the two streams flow concurrently past the membrane, transfer of oxygen into the fetal circulation causes a progressive decrease of PO_2 in the maternal stream and a progressive increase of PO_2 in the fetal stream, so that the transmembrane PO_2 difference at the venous end tends toward zero. This model explains why, in a venous equilibration system, umbilical venous PO_2 depends directly on uterine venous PO_2 , but has no direct relation to maternal arterial PO_2 .

Placental Oxygen Consumption Prevents Transplacental PO_2 Equilibration

Placental O_2 consumption is one of the factors that maintains umbilical venous PO_2 at a lower level than uterine venous PO_2 .

The placenta consumes oxygen. Because oxygen transport into the placenta is by diffusion, the placenta has no intrinsic mechanisms by which it could utilize oxygen drawn from the

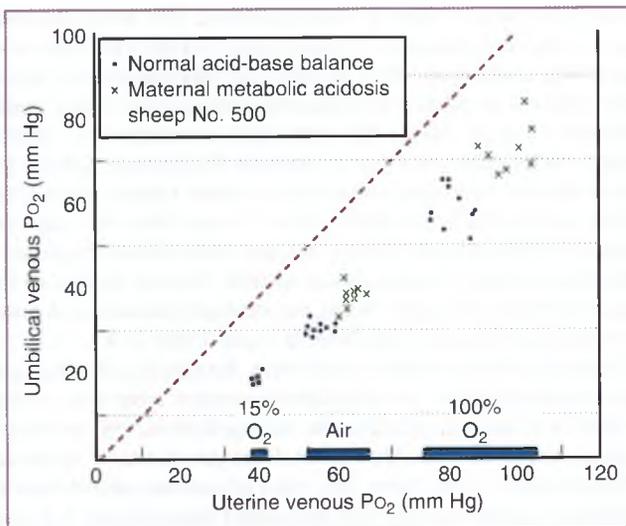

Figure 14-2 Relationship of umbilical venous PO_2 to uterine venous PO_2 in a near-term pregnant sheep. The partial pressure of oxygen (PO_2) in uterine venous blood was varied by administration of different gas mixtures to the mother and by displacement of the maternal hemoglobin dissociation curve to the right via a decrease of maternal blood pH. The dashed line is the identity line. (From Rankin JHG, Meschia G, Makowski EL, et al: Relationship between uterine and umbilical venous PO_2 in sheep, *Am J Physiol* 220:1688, 1971.)

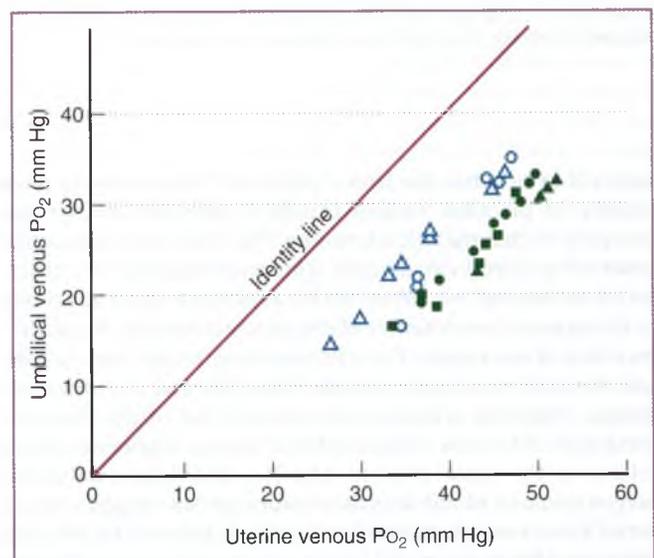

Figure 14-3 Relationship of umbilical to uterine venous PO_2 in five near-term sheep. The partial pressure of oxygen (PO_2) in uterine venous blood was decreased by decreasing uterine blood flow. Each animal is represented by a different symbol. (From Wilkening RB, Meschia G: Fetal oxygen uptake, oxygenation, and acid-base balance as a function of uterine blood flow, *Am J Physiol* 244(6):H749, 1983.)

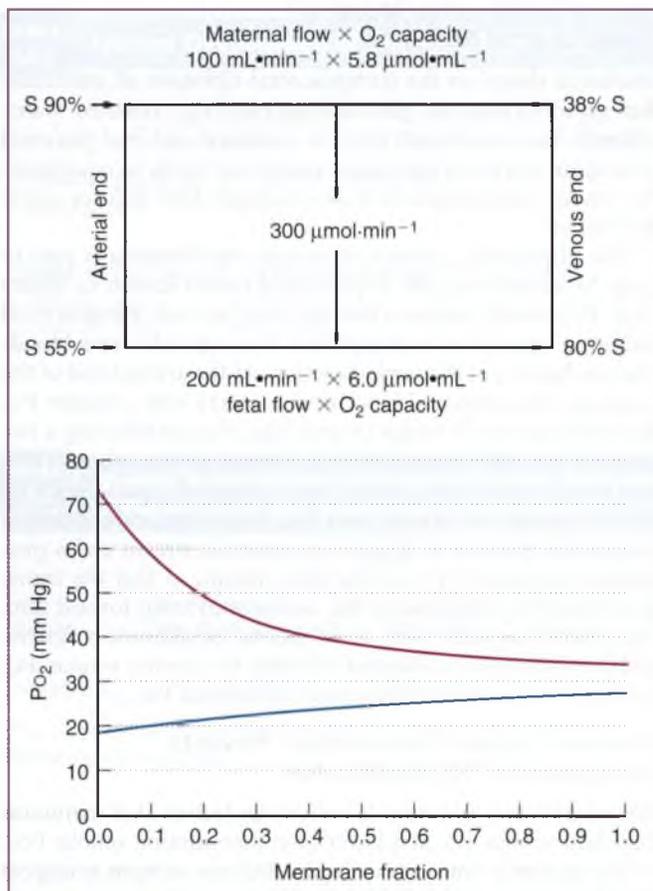

Figure 14-4 Concurrent blood flow model of oxygen (O_2) transport across a structurally homogeneous membrane that does not consume any oxygen. In this model (upper diagram), the fetal O_2 saturation (S), blood flow, and O_2 capacity values are representative of normal values at two-thirds gestation. The membrane is assumed to have an O_2 -diffusing capacity that provides almost complete equilibration of the partial pressure of oxygen (PO_2) at the venous end of the exchanger. The graph of PO_2 versus membrane fraction (lower diagram) shows the PO_2 changes from the arterial to the venous end within the maternal (red line) and fetal (blue line) vascular channels.

maternal rather than the fetal circulation. The mother-to-fetus polarity of placental oxygen transport depends on extrinsic mechanisms that maintain a positive PO_2 difference between the maternal and fetal circulations. This transplacental PO_2 difference is the sum of two terms: the PO_2 difference that is generated by the oxygen consumption of the placenta and the PO_2 difference that draws oxygen from the maternal to the fetal circulation. If we try to imagine how the transplacental PO_2 difference changes from the arterial to the venous end of the placental circulation, it becomes apparent that its two components do not behave in the same manner. The PO_2 difference that draws oxygen into fetal blood decreases toward zero as oxygen is transferred from one circulation to the other. In contrast, the PO_2 difference that is generated by the oxygen-consuming placenta does not change systematically from the arterial to the venous end. Placental mitochondria, like those in other organs, do not appreciably change their oxygen utilization rate in response to changes in PO_2 , as long as the PO_2 is kept above a critical level, which is generally quite low. As a consequence, the PO_2

difference generated by placental oxygen consumption is a larger fraction of the transplacental PO_2 difference at the venous end than at the arterial end of the placental circulation. These theoretical considerations agree with the experimental evidence that umbilical PO_2 does not equilibrate with maternal PO_2 if the fetus is removed by cesarean section and the umbilical circulation is perfused by means of a pump.²³

DEVELOPMENT OF PLACENTAL OXYGEN TRANSPORT IN SHEEP

Table 14-3 shows that at mid-gestation, the uteroplacental tissues consume about 4.5 times more oxygen than the fetal lamb. Approximately 70% to 80% of uteroplacental oxygen consumption is used by the placental villous tree.²⁴ The major mechanism that allows the umbilical circulation to extract oxygen from such an organ is uterine hyperemia. Table 14-7 shows that the mid-gestation uterine blood flow is almost five times greater than umbilical flow^{17,24} and that the ratio of uterine flow to uterine oxygen uptake is about $0.9 mL \cdot \mu mol^{-1}$. This ratio is high in comparison to that of other organs in the maternal body. The adult brain, for example, has a blood flow-to-oxygen uptake ratio of about 0.3 (see Table 14-6).

Table 14-8 shows that by near term the placenta has become much more effective in transporting oxygen from the uterine to the umbilical circulation. At mid-gestation, $490 mL \cdot min^{-1}$ uterine blood flow satisfies a fetal oxygen demand of about $90 \mu mol \cdot min^{-1}$. Near term, the ratio of uterine blood flow to umbilical oxygen uptake has decreased from about 5.4 (i.e., $490/90$) to about 1.2 (i.e., $1250/1030$). At mid-gestation, about 18% of the oxygen taken up by the pregnant uterus enters the fetal circulation (i.e., $90/510$). Near term, umbilical oxygen uptake has become about 63% of uterine oxygen uptake (i.e., $1030/1630$). To understand what causes this change in the effectiveness of placental oxygen transport, we must turn our attention to the histology of human placental development.

TABLE 14.8 Growth from Mid-gestation to Near Term: Fetal Weight, Umbilical and Uterine Oxygen Uptake, Umbilical and Uterine Blood Flow, and Uteroplacental Oxygen Consumption in Ewes Carrying a Single Fetus*

*Comparison of representative numbers. The compared variables are ordered according to the magnitude of the multiplier.

DEVELOPMENT OF OXYGEN TRANSPORT ACROSS THE HUMAN PLACENTA

Histologic studies of the human placenta have provided basic information about the mechanism that makes the near-term placenta more effective than the mid-gestation placenta in transporting oxygen from the uterine to the umbilical circulation. In the near-term placenta (39 weeks), the villous tree is subdivided into stem, intermediate, and terminal villi. Within the terminal villi, some of the capillaries are separated from maternal blood by a very thin trophoblastic layer. According to morphometric analysis,²⁵ the 39-week terminal villi have a much larger surface area than the intermediate villi (9.99 ± 0.45 versus 1.68 ± 0.11 m²) and contain a greater capillary volume (52.63 ± 3.55 versus 10.53 ± 1.31 cm³). However, capillary diameter is greater in the intermediate villi (28.58 ± 1.68 versus 17.26 ± 0.86 μm). The stem villi contain much less capillary volume than the intermediate and terminal villi (1.22 ± 0.16 cm³). The terminal villi begin to be formed at about 23 weeks and grow exponentially in the third trimester.²⁶ As a result, umbilical O₂ uptake at mid-gestation occurs almost exclusively via the intermediate villi, and up to the beginning of the third trimester, a large fraction of the oxygen that the fetus consumes is transported via these villi. The placenta is an organ with multiple functions. Placental respiratory gas exchange is essential to fetal survival and growth, but, in contrast to the lungs, it never becomes the dominant function. This explains why, in the human placenta, the development of a thin, well vascularized epithelial layer that facilitates transplacental diffusional exchange is confined to the terminal villi. The exponential growth of these villi occurs at a stage when fetal oxygen demand is increasing exponentially, requiring the placenta to become more effective in transporting oxygen from the uterine to the umbilical circulation. However, even in the term placenta, about 18% of the total umbilical capillary volume is in the intermediate villi. The observation that capillary diameter is greater in the intermediate villi suggests that the capillaries in these villi may be perfused by more than 20% of umbilical blood flow even near term.

For this reason, it would be erroneous to assume that virtually all the oxygen consumed by the near-term fetus enters the umbilical circulation via the terminal villi. It is more realistic to assume that umbilical oxygen uptake occurs via a set of capillaries that are unevenly perfused, are embedded in villi having different oxygen consumption rates, and extract oxygen from maternal blood through a barrier with uneven thickness. We cannot exclude the possibility that capillaries perfusing the stem villi have a net loss of oxygen to the surrounding tissues. Umbilical venous blood is the confluence of bloodstreams with different oxygen saturations.

CHRONIC REGULATION OF PLACENTAL OXYGEN TRANSPORT

Several studies of placental respiratory gas exchange in healthy, near-term ewes have described the effect of selective change in one of the relevant variables. There have been studies on the effects of decreasing uterine blood flow,²¹ decreasing umbilical blood flow,²⁷ shifting the oxyhemoglobin dissociation curve of either fetal blood²⁸ or maternal blood²⁹ to the right, ventilating the maternal lungs with different gas mixtures,²⁹ decreasing the fetal oxygen demand,³⁰ and reducing the placental exchange surface by 50%.³¹ The results all point to the conclusion that placental respiratory gas exchange is not controlled by short-term homeostatic mechanisms that would minimize the effect of any of these changes on fetal oxygenation. Uterine blood flow does not change significantly in response to acute changes in maternal Po₂, umbilical blood flow, or fetal oxygen demand. A decrease of Po₂ in either the uterine or the umbilical circulation does not evoke a compensatory decrease in the uterine-umbilical venous Po₂ difference.

In sharp contrast to these results, there is a set of data showing that placental oxygen transport can adapt remarkably well to chronic differences in Po₂ in the uterine circulation.

Adult sheep carry either one or both of two hemoglobin types (i.e., hemoglobin A and B) that are controlled by two autosomal co-dominant genes. The blood of ewes homozygous for hemoglobin A has markedly higher oxygen affinity than the blood of ewes homozygous for hemoglobin B. For most of gestation, the fetuses of these ewes produce only one hemoglobin type, hemoglobin F, and have a single oxyhemoglobin dissociation curve. Under the sheltered conditions of domestication, ewes carrying either the A or B hemoglobin coexist in the same flock and are so similar that there have been no attempts to selectively breed for either one of the two hemoglobin types.

Figure 14-5 shows a comparison of the arterial and venous Po₂ and oxygen saturation values in the uterine and umbilical circulation of ewes homozygous for adult A or B hemoglobin.³² All the ewes carried a single fetus. The A carriers had a lower uterine venous Po₂ than the B carriers (41.7 ± 0.6 versus 47.6 ± 0.8 mm Hg, $P < .001$), despite a significantly higher uterine venous oxygen saturation ($78.1\% \pm 0.5\%$ versus $67.5\% \pm 1.4\%$, $P < .001$).

The higher uterine venous saturation of A carriers was due, in part, to a significantly smaller oxygen content difference across the uterine circulation (1.19 ± 0.05 versus 1.47 ± 0.07 mM, $P < .01$). This indicates a higher ratio of uterine blood flow to oxygen uptake in the A sheep (0.84 versus 0.68 mL•μmol⁻¹ O₂). Placental development had compensated for the lower uterine venous Po₂ of the A sheep by producing a smaller uterine-umbilical venous Po₂ difference (14.2 ± 1.2 versus

20.4 ± 1.2 mm Hg, $P < .01$). The end result of these two compensatory changes (higher uterine flow and lower vein-to-vein PO_2 difference) was that the fetuses of the A carriers had the same level of oxygenation as the fetuses of the B carriers. There was no significant difference in fetal weight (3000 ± 170 versus 3070 ± 270 kg) between the two groups. For more detailed information, see the original publication.³²

The relevance to human placental physiology of this set of data is demonstrated by an old observation showing that maternal blood with oxygen affinity equal to that of fetal blood is compatible with normal fetal growth and development.³³ These data are relevant also to a discussion of fetal oxygenation at high altitude. High-altitude residents have a higher risk of delivering low-birth-weight infants than sea-level residents do.³⁴ However, in populations of highland origin, the risk is said to be smaller than in populations of lowland origin.³⁴

Hypoxia of Fetal Growth Restriction

Human fetal growth restriction (FGR) is often associated with significantly low umbilical venous oxygen saturation and PO_2

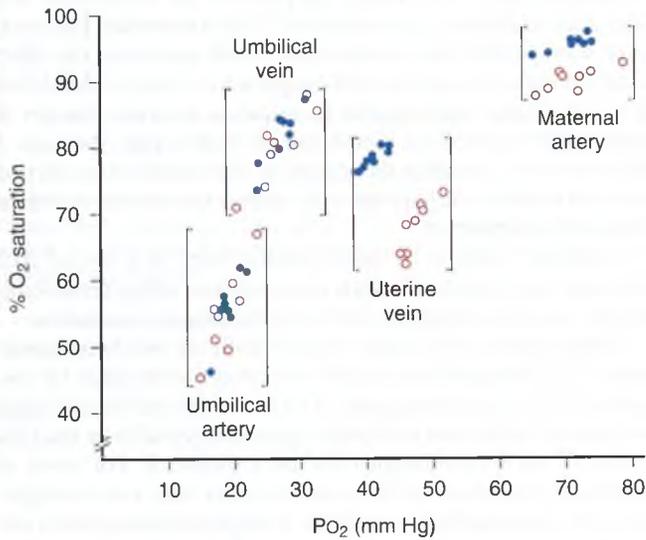

Figure 14-5 Plot of maternal and fetal blood oxygen (O_2) saturation versus partial pressure of oxygen (PO_2) in pregnant ewes homozygous for adult hemoglobin A or hemoglobin B. The blood of eight sheep homozygous for adult hemoglobin A (filled circles), which has a high affinity for O_2 , has an oxyhemoglobin dissociation curve to the left of the curve obtained from eight sheep homozygous for hemoglobin B (open circles), which has a low affinity for O_2 . Fetuses of hemoglobin A and hemoglobin B sheep have overlapping oxyhemoglobin dissociation curves because, at the gestational age of the study, most hemoglobin present in fetal blood is fetal hemoglobin. (From Wilkening RB, Molina RD, Meschia G: Placental oxygen transport in sheep with different hemoglobin types, *Am J Physiol* 254[4 Pt 2]:R585, 1988.)

values. In fetuses with an umbilical pulsatility index greater than 2 SDs above normal and an abnormal heart rate pattern, umbilical venous oxygen saturation and oxygen content are close to the limits for fetal viability. Table 14-9 presents two examples taken from the literature. In this FGR type, the placenta is small and demonstrates a reduction in the volume ratio of terminal compared with intermediate villi (2.97 versus 3.82).²⁵ This finding shows underdevelopment of the process that shifts a progressively larger fraction of umbilical oxygen uptake from the intermediate to the terminal villi. Therefore, the small FGR placenta is not simply a scaled-down version of a normal placenta; it is abnormal with respect to both size and differentiation. This evidence suggests that in the FGR syndrome, a large fraction of the oxygen that the fetus consumes is drawn across the thick, oxygen-consuming barrier of the intermediate villi.

In favor of this explanation is a study showing an enlargement of the uterine-umbilical venous PO_2 difference in human FGR.³⁵ Because the maternal and fetal blood could not be sampled simultaneously, the results of this study are not entirely persuasive. However, in sheep, a type of FGR in which severe hypoxia results from an enlargement of the transplacental PO_2 difference can be produced experimentally by exposing pregnant ewes to a hyperthermic environment from about the 38th to the 120th day of a 147-day gestation.⁸ In this FGR model, the uterine-umbilical venous PO_2 difference is inversely related to placental weight (Fig. 14-6). FGR hypoxia is associated with a significantly low umbilical blood flow per kilogram of fetal weight.⁸ However, a low umbilical flow does not explain why, in

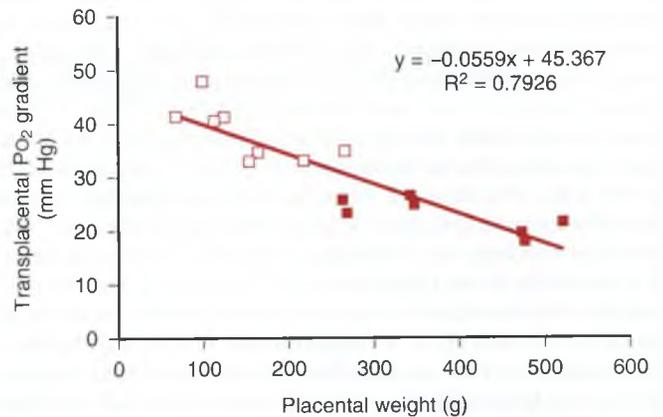

Figure 14-6 Correlation of the uterine-umbilical venous PO_2 difference versus placental weight in fetal sheep. Open squares indicate growth-restricted fetal sheep; filled squares indicate normal fetal sheep. PO_2 , partial pressure of oxygen. (From Regnault TRH, deVrijer B, Galan HL, et al: Development and mechanisms of fetal hypoxia in severe fetal growth restriction, *Placenta* 28:714, 2007.)

PO₂, partial pressure of oxygen.

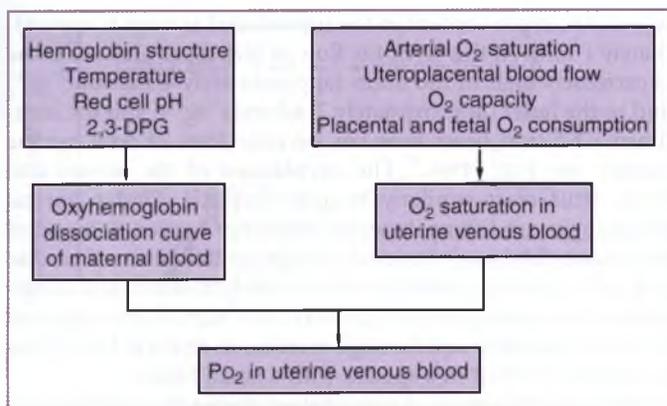

Figure 14-7 Factors that determine uterine venous partial pressure of oxygen (PO_2). 2,3-DPG, 2,3-diphosphoglycerate.

FGR, the umbilical venous blood PO_2 is below normal. In theory, a decrease in the rate at which fetal blood flows through the umbilical vessels tends to increase, rather than decrease, umbilical venous PO_2 , because the slow flow increases the chance of transplacental PO_2 equilibration. Experimental evidence agrees with this theoretical consideration.²⁷ It seems likely that in FGR, the decrease in umbilical flow results from structural changes in the placental vascular tree that increase the impedance to flow and cause an enlargement of the umbilical pulsatility index. In addition, it is likely that the decrease in umbilical flow is due also to a redistribution of fetal cardiac output that increases the cerebral and cardiac blood flow in response to hypoxia.

Is Placental Oxygen Transport Blood Flow Limited?

It is fairly common to find in the literature the statement that placental oxygen transport is blood flow limited. I have found an example in which this statement is made without any reference to a source, as if it were a well-established scientific fact. The basis for this claim is measurement of the placenta diffusing capacity for carbon monoxide (CO). This measurement defines the ratio between the transplacental CO diffusion rate and the transplacental CO pressure difference. It is called “diffusing capacity” because it includes, in addition to the permeability of the placental barrier, the rates at which CO is released from maternal hemoglobin and bound to fetal hemoglobin. The CO diffusing capacity measurement has been used to construct a mathematical model of the placenta.³⁶ This model visualizes the placenta as an aggregate of exchange units. In each unit, the maternal and fetal bloodstreams run concurrently and are separated by a highly permeable membrane that allows PO_2 equilibration between the venous effluents of the two streams. In other words, the entire placental barrier is thought to be so permeable to oxygen that the maternal and fetal blood flow rates are the only factors that limit the rate of transplacental oxygen diffusion.

Since the publication of this model in 1972, the evidence concerning placental oxygen transport (reviewed in this chapter) has made this assumption untenable. The hypothesis that best fits the new evidence is that in the stem and intermediate villi

of the human placenta there is no transplacental PO_2 equilibration, because the maternal and fetal bloodstreams are separated by a thick epithelial membrane and because either this membrane or the villous stroma (or both) have an oxygen consumption rate that is comparable in magnitude to the oxygen uptake by the capillaries that perfuse these villi. In the first two thirds of gestation, a high maternal placental blood flow rate compensates for this hindrance to umbilical oxygen uptake. In the last third of gestation, a second compensatory mechanism becomes prominent in the form of terminal villi development. In the terminal villi, maternal and fetal blood are separated by a thin membrane that may allow local, blood flow–limited exchange. Although there is no doubt that these villi are a more effective diffusional exchanger than the stem and intermediate villi, their effectiveness may be short of ideal. One reason is that the blood flow in and out of these villi occurs via capillary loops that bring in close proximity the input of deoxygenated blood with the output of oxygenated blood. This structural arrangement creates a countercurrent exchange system that decreases the PO_2 of the blood exiting the villi. A second reason is that the ratio of capillary blood flow in the intermediate villi to that in the terminal villi may be substantially higher than indicated by the capillary volume ratio.

In any case, the third-trimester placenta can be visualized as an organ that takes up oxygen in part via a high-diffusional-resistance pathway (intermediate villi) and in part via a low-resistance pathway (terminal villi). The factors, largely unknown, that control placental growth and differentiation modulate the relative contributions of the two pathways to umbilical oxygen uptake and determine the magnitude of the PO_2 difference between the uterine and umbilical venous effluents. According to this view, development of the low-resistance pathway can compensate for a low PO_2 in the maternal placental circulation and maintain a normal level of fetal oxygenation. Underdevelopment of the terminal villi would do the opposite, causing an enlargement of the transplacental PO_2 difference and resulting in the type of fetal hypoxia that characterizes FGR. The answer to the question of whether placental O_2 transport is blood flow limited should be that it is flow dependent but not flow limited.

Factors That Determine Uterine Venous PO_2

At any one time, uterine venous PO_2 is the primary determinant of umbilical venous blood PO_2 in the ovine or human fetus. The factors that determine uterine venous PO_2 are shown in Figure 14-7. Of these, the immediate causative factors are the oxygen saturation and the oxyhemoglobin dissociation curve of venous blood. The position of the oxyhemoglobin dissociation curve is shifted by pH, so that at any given saturation, the PO_2 is inversely related to pH (Bohr effect). Because of the Bohr effect, maternal alkalosis can be detrimental to fetal oxygenation through its effect on uterine venous PO_2 .

The oxygen saturation of uterine venous blood, S_v , is a function of four variables and can be calculated with the following equation:

$$S_v = S_A - \dot{V}O_2 / (F \times [O_2 \text{ CAP}])$$

where S_A is the oxygen saturation of maternal arterial blood, $[O_2 \text{ CAP}]$ is the oxygen capacity of maternal blood, F is the uterine blood flow, and $\dot{V}O_2$ is the oxygen consumption rate of

the gravid uterus. This equation, an application of the Fick principle, is an approximation that neglects the small contribution of free oxygen to the oxygen content of blood. Implicit in the equation are the three main types of hypoxia listed in textbooks of physiology:

- Low saturation of arterial blood (hypoxic hypoxia)
- Reduced oxygen capacity (anemic hypoxia)
- Reduction in blood flow (circulatory hypoxia)

Fetal Response to Hypoxia

The circulation of a nonanesthetized, otherwise healthy fetus reacts to an acute decrease in umbilical venous and arterial PO_2 in a predictable manner.^{11,37} As the PO_2 falls, blood flow is increased to the central nervous system (CNS) and the heart, although cardiac output and placental blood flow tend to remain constant. As a consequence, acute fetal hypoxia is characterized by a redistribution of cardiac output favoring the CNS and the heart at the expense of other parts of the fetal body. The fraction of cardiac output directed toward the CNS and heart increases hyperbolically as the arterial oxygen content decreases (Fig. 14-8).¹¹ The functional meaning of this relationship is that to mount a successful defense against hypoxia, the fetus must keep the flow of oxygen to the CNS and heart (i.e., the product of blood flow times the oxygen content per milliliter of arterial blood) at a constant or nearly constant level. The limit of a successful circulatory defense against acute hypoxia is reached when the perfusion rate of the CNS and heart has reached its maximum. In the fetal lamb, this limit is attained

when the oxygen content in the supraductal arteries is approximately 1 mM. At this level, the flow of blood per gram of tissue is extremely high in the brain (approximately $4 \text{ mL} \cdot \text{min}^{-1} \cdot \text{g}^{-1}$) and in the heart (approximately $7 \text{ mL} \cdot \text{min}^{-1} \cdot \text{g}^{-1}$), and the combined CNS and heart flow has become 26% of fetal cardiac output (see Fig. 14-8).¹¹ The circulations of the human and ovine fetus react similarly to acute hypoxia. Under normal physiologic conditions, however, the large oxygen demand of the human fetal brain requires a larger contribution of cardiac output to cerebral perfusion than in the fetal lamb. As a consequence, in response to acute hypoxia, the human fetus may not be able to produce a percentage increase in cerebral blood flow as dramatic as that in a species with a small brain.

Between the region of oxygenation that defines physiologic hypoxia (i.e., the normally low level of fetal oxygenation) and the limit below which there is an insufficient oxygen supply to the CNS and heart, there is a broad range (approximately 1 to 2.5 mM arterial oxygen content in the fetal lamb) in which the supply of oxygen to some parts of the fetal body other than the CNS and heart (e.g., skeletal muscle) cannot sustain a normal level of oxygen consumption.³⁸

Oxygen Therapy

Inhalation of oxygen by a pregnant patient can dramatically increase the PO_2 of the maternal arterial blood but causes only a small increase in fetal PO_2 (Table 14-10). This observation seems to contradict the empiric knowledge that oxygen therapy can be an effective measure for the improvement of fetal oxygenation. Indeed, some investigators have claimed that maternal oxygen inhalation cannot ameliorate fetal hypoxia because its effect on fetal PO_2 is “negligible.” Others have claimed that the discrepancy between PO_2 changes in mother and fetus is the consequence of severe placental vasoconstriction in response to the high PO_2 of maternal blood. To dispel these misconceptions, it is necessary, first, to understand why fetal PO_2 increases much less than maternal arterial PO_2 and then to focus attention on the effect that oxygen therapy has on the oxygen content of fetal blood.

The venous equilibration model of placental exchange and the characteristics of the maternal and fetal oxyhemoglobin dissociation curves readily explain the “small” effect of oxygen

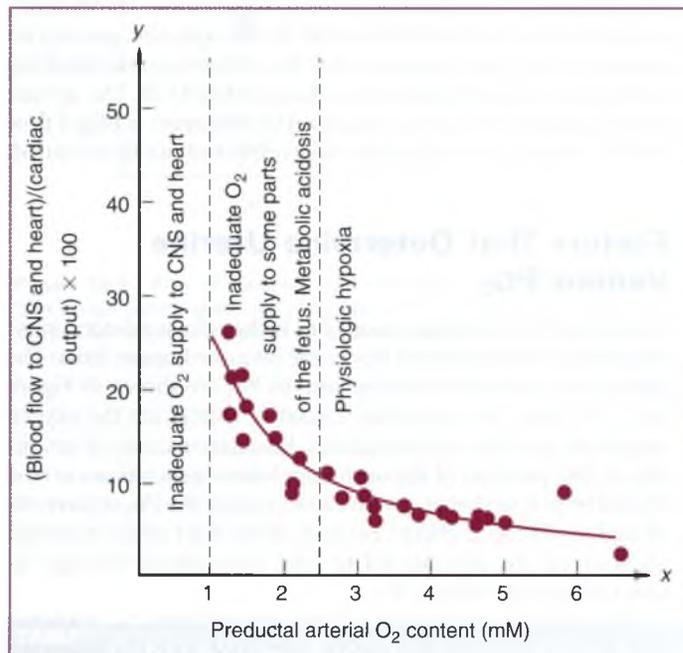

Figure 14-8 Hyperbolic relationship between oxygen (O_2) content in the preductal arteries of a fetal lamb and percentage of cardiac output directed to the heart and the central nervous system (CNS). The curve was drawn according to the equation, $y \cdot x = 0.26$. In Gluck L, editor: *Intrauterine asphyxia and the developing fetal brain*, Chicago, 1977, Year Book Medical.)

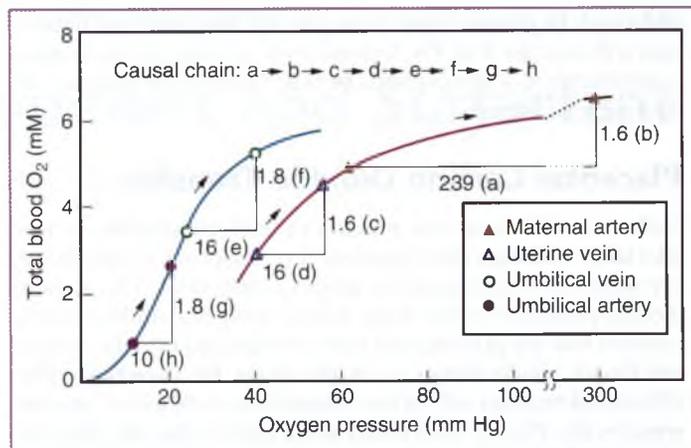

Figure 14-10 Example of the pronounced effect of oxygen therapy on fetal blood oxygen content in a case of fetal hypoxia secondary to maternal hypoxia. Red line indicates maternal blood; blue line indicates fetal blood. The steps in the causal chain are the same as in Figure 14-9. (From Meschia G: *Transfer of oxygen across the placenta*. In Gluck L, editor: *Intrauterine asphyxia and the developing fetal brain*, Chicago, 1977, Year Book Medical.)

therapy on fetal P_{O_2} . In the example shown in Figure 14-9, the oxygen contents of maternal and fetal blood are plotted against P_{O_2} :

- Inhalation of 100% oxygen by the mother causes the P_{O_2} of maternal arterial blood to increase from 90 to 500 mm Hg (step a).
- This increase in P_{O_2} causes an increase of maternal arterial oxygen content equal to 1 mM (step b). These changes in arterial P_{O_2} and oxygen content do not cause any appreciable change in the uterine blood flow.
- If we assume that these changes do not increase the uterine oxygen consumption rate—a correct assumption if fetal oxygen supply was already adequate before oxygen therapy—the law of conservation of matter requires that uterine venous oxygen content must increase also by 1 mM (step c).
- The increase in uterine venous oxygen content causes the uterine venous P_{O_2} to increase by 11.5 mm Hg (step d). Notice that the “S” shape of the maternal oxyhemoglobin dissociation curve and the different positions of the arterial and venous points on this curve determine that a given change of oxygen content is associated with a markedly smaller change of P_{O_2} in the uterine vein than in the maternal arteries. Notice also that the assumption of a constant oxygen consumption rate maximizes the increase in venous P_{O_2} . If the oxygen consumption of the gravid uterus were to increase in response to oxygen therapy, the increase in venous P_{O_2} would be less than indicated.
- Given an increase of 11.5 mm Hg in the uterine venous P_{O_2} , the umbilical venous P_{O_2} will increase by an approximately equal value (step e).
- The increase in umbilical venous P_{O_2} is associated with an increase in umbilical venous oxygen content (step f), the magnitude of which is dictated by the slope of the oxyhemoglobin dissociation curve and by the position of the umbilical venous point on that curve.

- In this example (see Fig. 14-9), the oxygen content of umbilical venous blood increases by 0.7 mM. If we assume no appreciable change in umbilical blood flow or oxygen uptake, it follows (again by application of the law of conservation of matter) that the oxygen content in the umbilical artery must increase also by 0.7 mM (step g).
- Because the arterial point is positioned on the steep part of the fetal oxyhemoglobin dissociation curve, an increase of 0.7 mM in oxygen content is associated with a P_{O_2} increase of only 4 mm Hg (step h).

The conclusion of this chain of events is that a P_{O_2} change of 410 mm Hg in maternal arterial blood results in a P_{O_2} change of 4 mm Hg in umbilical arterial blood.

If we focus our attention on fetal P_{O_2} changes by excluding other considerations, we might be tempted to conclude that maternal oxygen therapy has no appreciable effect on fetal oxygenation. However, oxygen therapy can cause similar increments in the oxygen content of maternal and fetal blood. In the example, an increase of 1 mM in maternal blood was associated with an increase of 0.7 mM in fetal blood. Under somewhat different circumstances, the oxygen content of fetal blood can actually increase more than that of maternal blood (Fig. 14-10).

Oxygen therapy is commonly used in the treatment of acute fetal hypoxia. It may be valuable also in the treatment of chronic fetal hypoxia. In one study, 55% oxygen was administered for several days to pregnant patients with intrauterine growth restriction.³⁹ There were significant increases in umbilical venous P_{O_2} and oxygen saturation and a significant improvement in Doppler flow patterns.

Finally, it is important to consider the issue of oxygen toxicity. Breathing oxygen at high concentrations can be harmful to the lungs of the mother. Because of this concern, breathing of 100% oxygen at atmospheric pressure must be limited to a few hours only. Breathing of 50% oxygen at atmospheric pressure is considered safe, although the question of whether pregnancy alters the tolerance of the mother to hyperoxia has not been

addressed. In general, there is no concern that maternal hyperoxia will increase fetal PO_2 to toxic levels, as long as the oxygen is administered at atmospheric pressure and for the purpose of treating fetal hypoxia.

Placental Carbon Dioxide Transfer

Carbon dioxide is an end product of fetal metabolism. In the fetal lamb, the respiratory quotient (i.e., moles of CO_2 produced per mole of O_2 consumed) is approximately 0.94. The carbon dioxide produced by the fetus diffuses from the umbilical circulation into the placenta and from the placenta into the maternal blood, which brings it to the lungs for excretion. The diffusional transfer of carbon dioxide from fetus to mother requires the PCO_2 of fetal blood to be higher than the PCO_2 of maternal blood. In chronic sheep preparations, umbilical venous PCO_2 is approximately 3 mm Hg higher than uterine venous PCO_2 . The factors responsible for determining the magnitude of the PCO_2 gradient between fetal and maternal blood have not been analyzed in detail. A consequence of the high diffusibility of carbon dioxide across the placenta is that respiratory disturbances of acid-base balance in the mother cause—with a delay of a few minutes only—analogue disturbances in the fetus, as long as the two organisms are in communication via a well-perfused placenta. An abnormally low fetal PCO_2 (fetal

respiratory alkalosis) is always secondary to a low maternal PCO_2 . To the contrary, an abnormally high fetal PCO_2 (fetal respiratory acidosis) can be caused by a high maternal arterial PCO_2 , inadequate gas exchange across the placenta, or a combination of these two conditions.

There are probably substantial differences among mammals in the permeability of the placental barrier to bicarbonate ions. The epitheliochorial placenta of sheep has a very low permeability to bicarbonate and to other small anions, such as chloride ions and ketoacids. If maternal metabolic acidosis or alkalosis develops, the bicarbonate concentration of fetal blood remains normal for several days. However, the hemochorial placenta of the rabbit or rhesus monkey is much more permeable to chloride ions than an epitheliochorial placenta. This suggests that the hemochorial placenta is permeable to bicarbonate and other ions, in which case metabolic disturbances of acid-base balance in the mother would cause analogous disturbances in the fetus. Information is lacking for humans and other species with a hemochorial placenta concerning the rate at which a metabolic disturbance of acid-base balance in the maternal compartment is transmitted to the fetal compartment.

Fetal Lung Development and Surfactant

ALAN H. JOBE, MD, PhD | BEENA D. KAMATH-RAYNE, MD, MPH

Overview of Lung Development

The development of the fetal lung is timed to achieve in the normal infant a smooth transition to breathing air at term. This complex organ development can be disrupted or interrupted by pregnancy abnormalities primarily related to prematurity. The effects of pregnancy-associated abnormalities on the fetal lung can either increase or decrease the probability of good lung function at delivery. Clinicians have a number of treatments to improve lung function after these abnormal deliveries, so lung function no longer limits survival for most preterm infants.¹ The most remarkable success stories in perinatal medicine include the use of antenatal corticosteroids to decrease the incidence of respiratory distress syndrome (RDS), surfactant treatments for RDS, and improved respiratory care strategies. These successes resulted from studies of lung development and maturation that began with the correlation of decreased surfactant levels with respiratory failure in preterm infants by Avery and Mead in 1959.² The first direct clinical benefit was the development by Gluck and colleagues in 1971 of the lecithin-to-sphingomyelin ratio using amniotic fluid to predict the risk of RDS in preterm infants.³ Another surfactant component, phosphatidylglycerol, was then developed for lung maturity testing.⁴ On the basis of studies with fetal sheep, Liggins and Howie demonstrated a decreased incidence in RDS with maternal corticosteroid treatments in 1972.⁵ Many investigators then developed surfactant treatment for RDS and other neonatal lung diseases.⁶ Recent progress with less injurious approaches to ventilatory support has also contributed to improved outcomes.⁷ Future progress with more intractable problems resulting from very preterm birth, such as abnormal lung growth and lung injury resulting in bronchopulmonary dysplasia (BPD), will depend on understanding the signaling pathways at the molecular level that regulate normal and abnormal lung development. This chapter will outline normal lung development and then introduce concepts related to the clinically relevant induced lung maturation in late gestation.

Normal Lung Development

EMBRYONIC STAGE (3 TO 7 WEEKS AFTER CONCEPTION)

The lung primordium appears as an outgrowth from the foregut endoderm at about 22 days after conception (Fig. 15-1). A lung bud appears by 26 days and grows into the mesenchyme surrounding the foregut parallel to the primitive esophagus. Lung bud-derived epithelial cells form tubules that bifurcate on day 28 into the eventual right and left mainstem bronchi, and branching continues with the initiation of lung vascular

development. By the end of the embryonic stage, the separation of the trachea and esophagus is complete, with vascular connections to the left and right atria. Transcription factors and signaling molecules regulate these processes, as identified with transgenic and other model systems (Table 15-1). Deletion of fibroblast growth factor-10 (FGF-10) or compound deletions of the zinc finger DNA-binding proteins Gli2 and Gli3 will disrupt tracheal development. Retinoic acid deprivation can disrupt early lung branching morphogenesis, as can deletion of retinoic acid receptors. Retinoic acid signaling regulates the spatial and temporal expression of homeobox (HOX) genes in the embryonic lung. FGF family members acting through specific FGF receptors also modulate airway branching, as demonstrated by structural abnormalities resulting from disrupted signaling or deletions. Of clinical relevance, abnormalities in embryonic lung development result in esophageal and tracheal atresia, tracheal esophageal fistula, pulmonary agenesis, and lung lobation defects.

PSEUDOGLANDULAR STAGE (5 TO 17 WEEKS)

The pseudoglandular period is characterized by progressive division to 15 to 20 generations of airways, depending on airway segment length and lobar position.⁸ The developing airways are lined with simple cuboidal cells that contain large amounts of glycogen. Epithelial differentiation is centrifugal, so the most distal tubules are lined with undifferentiated cells, with progressive differentiation from the more proximal to the distal airways.

Pulmonary arteries grow in conjunction with the airways, and the principal arteries are present by 14 weeks of gestation. The pulmonary microvasculature develops in the mesenchyme around the developing airways by the processes of angiogenesis (the sprouting of new vessels from preexisting vessels) and of vasculogenesis (fusion of primitive vascular plexuses, which then connect with vessels). These processes are under control of factors such as vascular endothelial growth factor⁹ (VEGF). Pulmonary veins develop in parallel by both angiogenesis and vasculogenesis, but with a different pattern that demarcates lung segments and subsegments. By the end of the pseudoglandular stage, airways, arteries, and veins have developed in a pattern corresponding to that found in the adult. The diaphragm separates the chest from the abdomen during this stage of lung development, and failure of the diaphragm to close results in diaphragmatic hernia and lung hypoplasia.

CANALICULAR STAGE (16 TO 26 WEEKS AFTER CONCEPTION)

The canalicular stage represents the transformation of the pre-viable lung to the potentially viable lung that can exchange

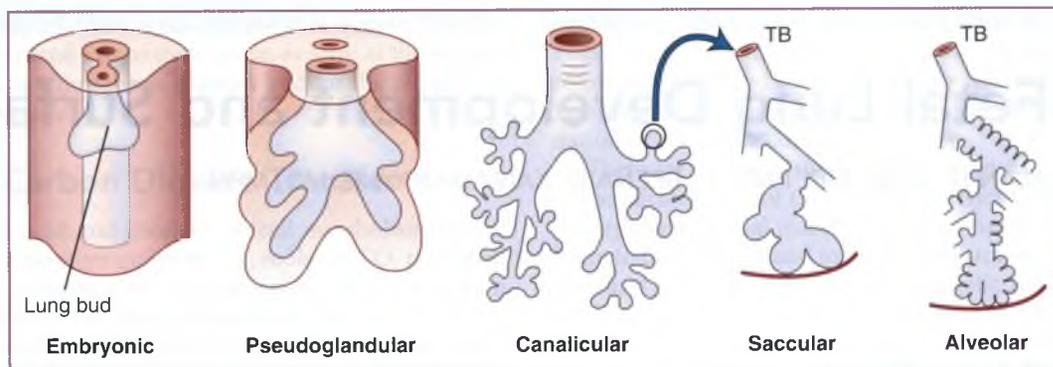

Figure 15-1 Morphologic development of the human lung. Schematic representations of stages of development. TB, terminal bronchiole. (Courtesy of Jeffrey Whitsett, Cincinnati Children's Hospital.)

TABLE 15-1 Lung Development in the Human Fetus

Stage of Development	Fetal Age (wk)	Structural Events	Regulators of Lung Growth and Differentiation	Associated Abnormalities
Embryonic	3-7	Lung bud formation, trachea, lobar and segmental bronchi	TTF-1, FGF-10, Gliogenes, retinoic acid, HOX genes	Tracheoesophageal fistula, pulmonary agenesis, lobation defects
Pseudoglandular	5-17	Subsegmental bronchi, terminal bronchi, mucous glands, cartilage, smooth muscle, early vasculature and epithelial differentiation, diaphragm formation	TTF-1, FGFs, FOXa1/a2, TGF- β , VEGF	Sequestration, cystic adenomatoid malformation, lymphangiectasias, congenital diaphragmatic hernia
Canalicular	16-26	Respiratory bronchioles, acinar saccules, thinning of capillary-epithelial space, type I and type II epithelial cells	Glucocorticoids, VEGF	Pulmonary hypoplasia, alveolar-capillary dysplasia
Saccular	26-36	Division of acinar saccules, microvascular expansion, increase in gas-exchange surface area	Glucocorticoids, VEGF	Pulmonary hypoplasia, pulmonary hypertension
Alveolar	32 wk through childhood	Septation of alveoli, maturation of type II cells, surfactant	Elastin, glucocorticoids, retinoic acids, inflammatory mediators	SP-B, SP-C, and ABCA3 transporter deficiencies, pulmonary hypertension

FGF-10, fibroblast growth factor-10; FOXa1/a2, forkhead box a1/a2; SP, surfactant protein; TGF- β , transforming growth factor- β ; TTF-1, thyroid-specific transcription factor 1; VEGF, vascular endothelial growth factor.

gases. The three major events during this stage are the appearance of the acinus, the development of the potential air-blood barrier, and epithelial differentiation with the start of surfactant synthesis in recognizable alveolar epithelial type II cells.¹⁰ The acinus is the tuft of distal airways originating from a terminal bronchiole. Its initial development is the critical first step for the development of the future gas exchange surface of the lung. The initially poorly vascularized mesenchyme surrounding the airways becomes more vascular and more closely aligned with the airway epithelial cells. The capillaries initially are a double capillary network between future airspaces. These capillaries then fuse to form a single capillary bed between the future gas exchange surfaces. If the double capillary network does not fuse, the infant will have severe hypoxemia and the histopathologic findings of alveolar-capillary dysplasia. With close vascular apposition to the saccular walls and involution of the mesenchyme, the alveolar-capillary respiratory membrane begins to form by about 21 weeks. The total surface area occupied by the air-blood barrier increases exponentially through the canalicular stage, with a resultant fall in the mean wall thickness and

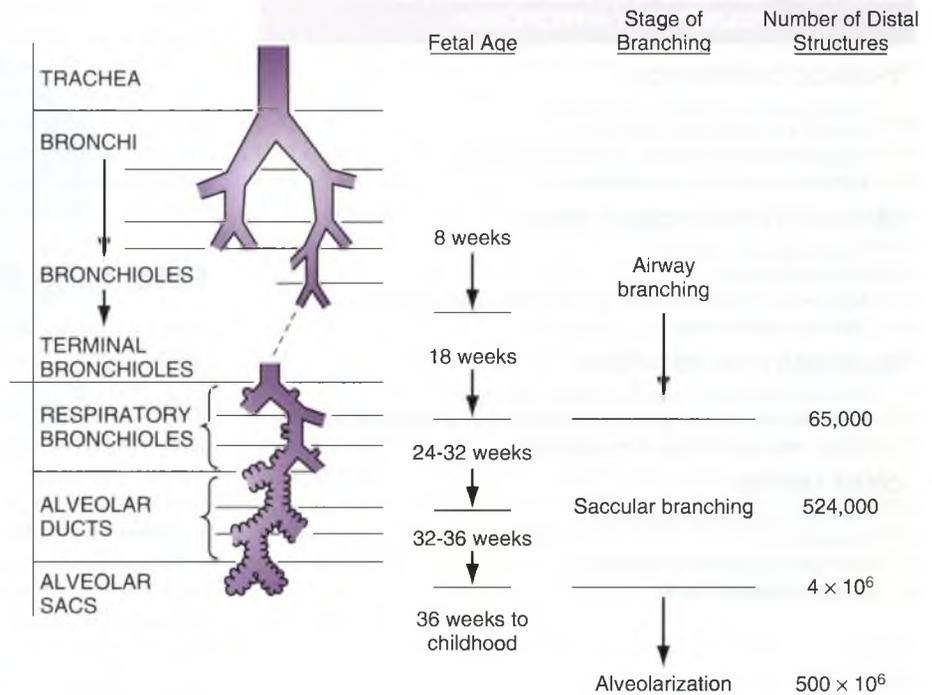

with an increased potential for gas exchange. Epithelial differentiation is characterized by proximal-to-distal thinning of the epithelium by transformation of cuboidal cells into thin cells that line wide tubes. The tubes grow both in length and in width with attenuation of the mesenchyme, which is simultaneously vascularized. After about 20 weeks' gestation in the human fetus, immature type II cells containing glycogen begin to have lamellar bodies in their cytoplasm, indicating the initiation of surfactant production.

SACCULAR STAGE (24 TO 36 WEEKS AFTER CONCEPTION)

The saccular stage is the period of lung development when potentially viable preterm fetuses are delivered. The sacculle is the terminal structural element of the fetal lung, which divides or septates through perhaps three generations with the formation of respiratory bronchioles, and a further three generations to form alveolar ducts before the initiation of "secondary" septation of the saccules to become alveoli.¹¹ During this saccular

BRANCHING DEVELOPMENT OF THE HUMAN LUNG

Figure 15-2 Airway branching, fetal age, and distal structures during lung development. Airway branching results in about 16 generations of airways by about 18 weeks' gestation. Branching of distal saccular structures yields respiratory bronchioles and alveolar ducts in the saccular lung by about 32 weeks' gestation. Alveolarization continues from 32 to 36 weeks' gestation and through childhood. (Concept from Burri P: *Development and growth of the human lung*. In Fishman AP, Fisher AB, editors: *Handbook of physiology: the respiratory system*, Bethesda, MD, 1986, American Physiology Society.)

stage of lung development, airspace number increases from about 65,000 at 18 weeks to 4 million by 32 to 36 weeks of gestation (Fig. 15-2). The lung microvasculature continues to increase, as does the gas-exchange surface area of the lung. The fetal lung is sensitive to maternal glucocorticoid treatments and can respond with increased surfactant synthesis and with mesenchymal attenuation. The lung is also sensitive to the development of pulmonary hypoplasia. Saccular septation and the associated vascularization are critical stages of lung development that can be influenced by pregnancy abnormalities and can affect lung function after preterm birth.

ALVEOLAR STAGE

Alveolarization is initiated at 32 to 36 weeks from the terminal saccules by the appearance of septa containing capillaries, elastin fibers, and collagen fibers. The new alveoli rapidly septate to generate about 100 million alveoli at term and about 500 million alveoli in the adult human.^{12,13} The rate of alveolar formation is maximal between about 36 weeks' gestation and several months after birth, and it continues to increase slowly through childhood.¹⁴ The important concept is that alveolar development begins late in fetal development and continues after term delivery in the human. The process of alveolar septation requires an elastin fiber to bud from the distal alveolar-capillary respiratory membrane along with a double capillary network to form a new septation. The double capillaries then become a single capillary with a loss of mesenchyme to form a new, thin, alveolar capillary membrane. The process requires orchestrated elastin, collagen, and extracellular matrix regulation by fibroblast growth factor and receptors and transcription factors such as FOXA2, TTFI, and GATA6. A theme of lung development is that regulatory elements that were essential for embryonic and canalicular lung development are also critical

during terminal lung development with alveolar septation, although with different roles and localizations.

The surfactant system is fully mature by late gestation because surfactant sufficiency is essential for survival of the newborn. In rodents, surfactant maturation is complete in the saccular lung, as alveolarization occurs after birth. In mouse models, both the mother and the fetus contribute to the synchronization of lung maturation with term delivery.¹⁵ Genetic-based abnormalities of surfactant can present as RDS after term birth because of poor respiratory adaptation. These include abnormalities in the surfactant proteins (SPs) SP-B and SP-C and of an intracellular transporter ABCA3 that is integral to surfactant storage in lamellar bodies. There is no information in the human on the variability of timing between individuals for the stages of lung development in the population.

Pulmonary Hypoplasia

Although embryonic developmental anomalies occasionally result in unilateral pulmonary atresia and abnormal lung segmentation syndromes, pulmonary hypoplasia syndromes are much more common. In an unselected autopsy series, pulmonary hypoplasia was diagnosed by low lung weight in 15% to 20% of the infants who had died.¹⁶ Diagnosing pulmonary hypoplasia by the rigorous anatomic criteria of decreased airway numbers and decreased radial alveolar counts is time consuming and not routine, as are measurements of decreased lung DNA content relative to body weight. Pulmonary hypoplasia in the fetus can be predicted by ultrasound and magnetic resonance imaging (MRI). The diagnosis is made after birth on the basis of the severity of respiratory failure and the clinical associations.

The fetus must maintain the appropriate volume of fetal lung fluid in the airspaces and have the normal frequency and

BOX 15-1 CLINICAL ENTITIES ASSOCIATED WITH PULMONARY HYPOPLASIA**THORACIC COMPRESSION**

- Renal agenesis (Potter syndrome)
- Urinary tract outflow obstruction
- Oligohydramnios before 28 weeks' gestation
- Extra-amniotic fetal development

DECREASED INTRATHORACIC SPACE

- Diaphragmatic hernia
- Pleural effusions
- Abdominal distention sufficient to limit chest volume
- Thoracic dystrophies

DECREASED FETAL BREATHING

- Intrauterine central nervous system damage
- Fetal Werdnig-Hoffmann syndrome (or spinal muscular atrophy)
- Other neuropathies and myopathies

OTHER ENTITIES

- Primary pulmonary hypoplasia
- Trisomy 21
- Multiple congenital anomalies
- Erythroblastosis fetalis

amplitude of fetal breathing movements for the lung to grow normally.¹⁷ Fetal lung fluid volume can be decreased either by external chest compression (e.g., oligohydramnios) or by space occupation in the chest cavity (e.g., diaphragmatic hernia). Conditions associated with pulmonary hypoplasia are listed in Box 15-1. Thoracic compression syndromes are most destructive to lung growth during the canalicular period of human lung development, after 16 to 26 weeks' gestation. Oligohydramnios not associated with renal anomalies does not invariably result in pulmonary hypoplasia. However, the earlier in gestation it occurs, the more severe it will be, the longer the oligohydramnios will last, and the more likely it will be that severe pulmonary hypoplasia will occur.¹⁸ However, some infants delivered after many weeks of oligohydramnios resulting from premature or preterm rupture of membranes can have good lung function.¹⁹ Pulmonary hypoplasia, despite maintenance of apparently normal fetal lung fluid and amniotic fluid volumes, can occur in infants with severe central nervous system damage from infections or developmental neuropathies and myopathies. Infants with trisomy 21 or other syndromes may have anomalous lung development or may have abnormal fetal breathing patterns that contribute to pulmonary hypoplasia.

Diaphragmatic hernia is the most common cause of the pulmonary hypoplasia that results from lung compression. The lung on the side of the diaphragmatic hernia is often severely hypoplastic, and the contralateral lung is also hypoplastic but less so. In animal models, maturation of the surfactant system is delayed in hypoplastic lungs that resulted from diaphragmatic hernia. Surfactant components are decreased in amniotic fluid from infants with diaphragmatic hernia.²⁰ Interventions to obstruct the fetal trachea will cause the fetal lung to distend with fetal lung fluid. This lung distention will stimulate lung growth, but it may decrease the number of type II cells and the amount of surfactant.²¹ As a general rule, the fetal lung develops abnormally if it is compressed, if it is collapsed because of loss of fetal lung fluid, or if it is overstretched.

Infants with diaphragmatic hernia and with less severe degrees of pulmonary hypoplasia can be supported with mechanical ventilation. Attempts to achieve normal gas exchange and oxygenation with excessive mechanical ventilation will cause severe lung injury. Gentle approaches to mechanical ventilation, together with the selective use of extracorporeal membrane oxygenation, and delayed surgical correction of diaphragmatic hernias are resulting in survivals of 80% for infants without other anomalies.

Fetal Lung Fluid

The fetal airways are filled with fluid until delivery and the initiation of ventilation. Quantitative information about fetal lung fluid has come from studies with the fetal lamb; sonographic and pathologic correlates are available for humans. The fetal lung close to term contains enough fluid to maintain the airway expanded to approximately 25 mL/kg body weight, which is similar to the functional residual capacity once air breathing is established. The composition of fetal lung fluid is unique relative to other fetal fluids.²² The chloride content is high, the bicarbonate is low, and protein is low because the fetal epithelium is essentially impermeable to protein. Active chloride transport by epithelial cells with passive water movement causes a 4 to 5 mL/kg/hr production of fetal lung fluid in later gestation.²³ The net production of fetal lung fluid is about 400 mL/day for a 4-kg sheep fetus. In humans, about half of the fluid is swallowed and half mixes with the amniotic fluid with fetal breathing. The pressure in the fetal trachea exceeds that in the amniotic fluid by about 2 mm Hg, generating an outflow resistance that maintains the fetal lung fluid volume. The secretion of fetal lung fluid is primarily an intrinsic metabolic function of the developing alveolar and airway epithelium, because changes in vascular hydrostatic pressures, tracheal pressures, and fetal breathing movements do not greatly affect fetal lung fluid production.

Although fetal lung fluid is essential for normal lung development, its clearance is equally essential for normal neonatal respiratory adaptation. Fetal lung fluid production can be completely stopped and fluid adsorption initiated in near-term fetal sheep by infusions of epinephrine at concentrations that approximate the levels of epinephrine present during labor.²⁴ The epinephrine-responsive change in the airspace epithelium from fluid secretion to fluid absorption is absent in preterm fetal sheep, but it can be induced by short-term cortisol and triiodothyronine infusions.²⁵ Thus, the clearance of fetal lung fluid is maturation dependent and inducible. In term guinea pigs, inhibition of sodium channel function delays fluid clearance and causes respiratory distress, demonstrating that sodium transport is essential for the clearance of airway fluid after birth.²²

In fetal sheep, lung fluid volume decreases in the days just before labor to about 65% of the maximal volumes present during fetal life.²³ During active labor and delivery, another 30% of the fluid is cleared from the airways and alveoli, leaving only about 35% of the fetal lung fluid to be adsorbed and cleared from the lungs with breathing. Most of the fluid moves rapidly into the interstitial spaces and then directly into the pulmonary vasculature, with clearance of less than 20% of the fluid by pulmonary lymphatics. Clearance of the fluid from the interstitial spaces occurs over many hours. Pre-labor, labor, and delivery are important regulators of the amount of lung fluid that

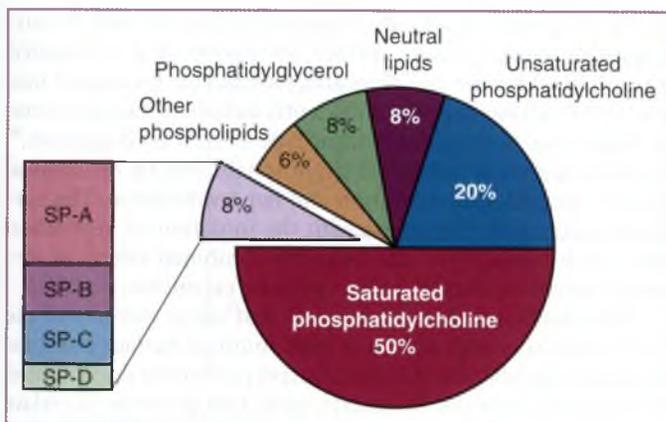

Figure 15-3 Composition of surfactant. The major component is saturated phosphatidylcholine. The surfactant proteins (SP) contribute about 8% to the mass of surfactant.

will be present at the initiation of air breathing. Alveolar fluid volume in the normal air-breathing lung is only about 0.3 mL/kg.

Surfactant

SURFACTANT COMPOSITION

Surfactant in the lungs of all mammalian species is 70% to 80% phospholipids, about 8% protein, and about 8% neutral lipids, primarily cholesterol (Fig. 15-3). The phosphatidylcholine species of the phospholipids contribute about 70% by weight to surfactant.²⁶ The composition of the phospholipids in surfactant is different from the lipid composition of the lung tissue or other organs. About 50% of the phosphatidylcholine species are saturated, in that the fatty acids esterified to the glycerol-phosphocholine backbone are the 16-carbon saturated fatty acid palmitic acid. This saturated phosphatidylcholine is the principal surface-active component of surfactant. The acidic phospholipid phosphatidylglycerol makes up 4% to 15% of the phospholipids in surfactant from different species. The composition of the phospholipids in the surfactant lipoprotein complex changes during late gestation. Surfactant phospholipids from the immature fetus or newborns contain relatively large amounts of phosphatidylinositol, and these amounts decrease as phosphatidylglycerol appears with lung maturity.²⁷ Although phosphatidylglycerol is a convenient marker for lung maturity, its presence is not necessary for normal surfactant function.

Many of the proteins isolated with surfactant from alveolar lavage are serum proteins that are not specific to surfactant. However, four SPs have been characterized and their functions partly elucidated.²⁸ The proteins SP-A and SP-D have related structures and are classified as collectins, because they bind carbohydrate lectins in a calcium-dependent manner. The 26-kDa monomer of SP-A, which is heavily glycosylated, is assembled as a six-tetramer complex of about 650 kDa. The protein has a collagen-like domain that facilitates tetramer formation, and a carbohydrate recognition domain. SP-A is expressed predominantly in type II cells and Clara cells in the late-gestation and mature lung. SP-A appears in fetal lung fluid and in amniotic fluid in parallel with the surfactant phospholipids during late gestation.²⁹ SP-A associates with surfactant and is required for tubular myelin formation. SP-A may

contribute to the biophysical function of surfactant primarily by making surfactant less sensitive to inactivation by edema fluid and inflammatory products in the injured lung. Mice that lack SP-A have essentially normal surfactant function and metabolism, unless the lung is injured.

SP-A functions primarily as an innate host defense protein that binds carbohydrates and interacts with immune cells in the lungs. SP-A binds endotoxin, a wide range of gram-positive and gram-negative organisms, fungi, and other organisms such as mycobacteria and *Pneumocystis carinii*. SP-A promotes phagocytosis and killing of microorganisms by alveolar macrophages. SP-A also acts as an opsonin for the phagocytosis of viruses, such as herpes simplex, influenza A, and respiratory syncytial virus. Mice that lack SP-A are less effective at clearing and killing bacteria and viruses, and infections are more likely to become systemic.³⁰ The defect in host defenses can be corrected by treating SP-A-deficient mice with SP-A. Genetic polymorphisms in SP-A have been linked to an increased risk of RDS.³¹ Infants born with low ratios of SP-A to surfactant phospholipid are at increased risk for death and bronchopulmonary dysplasia.³² SP-A levels are also low in preterm baboon models of BPD, in infants with respiratory syncytial virus pneumonia, and in patients with acute RDS.

SP-D is similar in structure and function to SP-A, but there are distinct differences.³³ The 43-kDa monomer of SP-D forms tetramers that associate into a 560-kDa multimer. SP-D, which is minimally associated with surfactant lipids, is expressed in the lung in type II cells, Clara cells, and other airway cells and glands. Its expression in the lung increases from late gestation, and glucocorticoids and inflammation can increase its expression. It is an innate host defense protein that binds bacteria and fungi, and it aggregates viruses with specificities that overlap with those of SP-A. SP-D promotes opsonization and phagocytosis by macrophages and modulates the proinflammatory responses of leukocytes in the lung. In contrast to SP-A, SP-D increases with acute lung injury. Mice that lack SP-D have increased tissue and alveolar pools of surfactant lipids and develop emphysema as they age.³⁴ SP-D-deficient mice have increased inflammatory responses to respiratory syncytial virus. No state of SP-D deficiency has been identified in humans, and its contribution to the pathogenesis of BPD and lung infections in newborns has not been defined.

SP-B is a small, 79-amino-acid homodimer of about 18 kDa that is about 2% of surfactant by weight.²⁸ It is required for normal packaging of the surfactant phospholipids into lamellar bodies for secretion. In the absence of SP-B, type II cells have no lamellar bodies and SP-C is incompletely processed. Therefore, functionally, SP-B deficiency also results in SP-C deficiency. Mice and humans that lack SP-B die soon after birth with a severe RDS-like syndrome.³⁵ Surfactant treatment is not effective, presumably because there are no pathways for reprocessing the surfactant components. Deficiency of SP-B most frequently occurs because of a frame-shift mutation, with a gene frequency of 1 per 1000 to 3000 individuals.³⁶ There are also many other mutations in SP-B, and the SP-B deficiency mutations account for about 30% of term infants who die at birth from probable genetic causes of respiratory failure. An antenatal diagnosis of SP-B deficiency can be made using amniotic fluid. Some mutations result in low expression of SP-B that may increase with glucocorticoid treatment. Infants with low expression may have a chronic progressive lung disease indistinguishable from bronchopulmonary dysplasia.

SP-C is a highly conserved, 35-amino-acid protein that is about 2% surfactant by weight.²⁸ SP-C messenger RNA is expressed in the developing tips of the branching airways during early lung development. During late gestation, SP-C is expressed, processed, and secreted by type II cells, with SP-B and the surfactant lipids in lamellar bodies. This extremely hydrophobic protein promotes surfactant film adsorption. SP-C deficiency in mice causes no lung developmental abnormalities or striking abnormalities in surfactant function.³⁷ However, the mice get a progressive interstitial lung disease as they age. SP-C deficiency in humans can also cause a progressive interstitial lung disease that can present in infancy and may make the individual susceptible to developing acute RDS.³⁸ Acute lung injury will decrease the expression of SP-C.

Deficiency of the ABCA3 transporter causes surfactant deficiency and severe lethal RDS in term infants.³⁹ ABCA3 localizes to the limiting membranes of lamellar bodies in type II cells. Its deficiency disrupts lipid transport and lamellar body formation, resulting in severe surfactant deficiency. This genetically based deficiency disease is more common in term infants than are SP-B or SP-C deficiencies.

SURFACTANT METABOLISM

Type II cells and macrophages are the cells responsible for the major pathways involved in surfactant metabolism (Fig. 15-4). The synthesis and secretion pathways in type II cells are complex sequences of biochemical events that result in the exocytosis of lamellar bodies (containing surfactant lipids, SP-B, and SP-C) to the alveolus. Specific enzymes in the endoplasmic reticulum of type II cells use glucose, phosphate, and fatty acids as substrates for phospholipid synthesis. The major phospholipid in surfactant is synthesized by type II cells as a 2-acyl unsaturated molecule, which is minimally surface active. This phosphatidylcholine is then remodeled to yield a phosphatidylcholine with palmitic acids in the 1-acyl and 2-acyl positions, referred to as saturated phosphatidylcholine. This lipid is very surface active but is a solid at body temperature. Other phospholipids, such

as phosphatidylinositol and phosphatidylglycerol, and the surfactant proteins facilitate surface adsorption of the saturated phosphatidylcholine and thus affect surfactant function. Once the type II cell has matured sufficiently to have surfactant stores, secretion can be stimulated from type II cells by β -agonists,⁴⁰ by purines such as adenosine triphosphate, and by mechanical stimuli, such as lung distention and hyperventilation. The surfactant secretion that occurs with the initiation of ventilation after birth probably results from the combined effects of elevated catecholamines, purines, and lung expansion.

After Avery and Mead² observed that saline extracts of the lungs of infants with RDS had high minimal surface tensions, decreased alveolar and tissue surfactant pools were documented in developing animals. In general, surfactant pool sizes correlate with lung compliance during development, although other factors, such as structural maturation, also influence compliance measurements. Surfactant from infants with RDS is less surface active and more susceptible to inactivation by proteinaceous edema fluid than surfactant from the mature lung.⁴¹ Maturation of the surfactant system involves the appearance of the surfactant storage and secretory organelle, the lamellar body in type II cells, normally after 22 to 24 weeks' gestation. The changes that occur when an immature surfactant matures include an increase in saturated phosphatidylcholine, a decrease in phosphatidylinositol, an increase in phosphatidylglycerol (normally after about 35 weeks' gestation), and large increases in surfactant proteins. With maturation, the amount of surfactant exceeds the amount in the adult lung by about 10-fold.

Surfactant metabolism after preterm birth helps explain the clinical course of RDS. In ventilated preterm monkeys with RDS, the pool size of alveolar surfactant increases from about 5 mg/kg at preterm birth, to close to the 100 mg/kg measured in term monkeys, within 3 to 4 days.⁴² Although there are no comparable pool size measurements for humans, the concentration of saturated phosphatidylcholine in airway samples from infants recovering from RDS increased over a 4- to 5-day period to become comparable to values for normal or surfactant-treated infants.³² This slow increase in pool size explains why

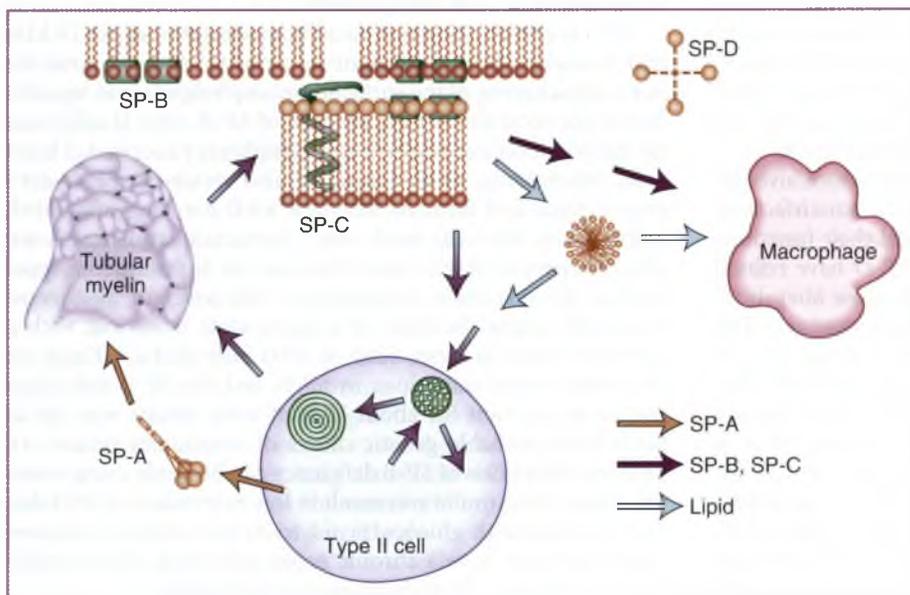

Figure 15-4 Surfactant metabolism. The lipid-associated surfactant proteins B (SP-B) and SP-C (solid red arrows) track with the lipid from synthesis to secretion of lamellar bodies. SP-A is secreted and combines to form tubular myelin with SP-B, SP-C, and the lipids. The surface film is shown as a monolayer of lipids with SP-B. The hypo-phase of bilayer lipids is a reservoir of surfactant that can add to the monolayer. SP-B and SP-C leave the monolayer without lipids and are catabolized by macrophages. Lipids leave the monolayer as vesicles and are either catabolized or recycled back to type II cells.

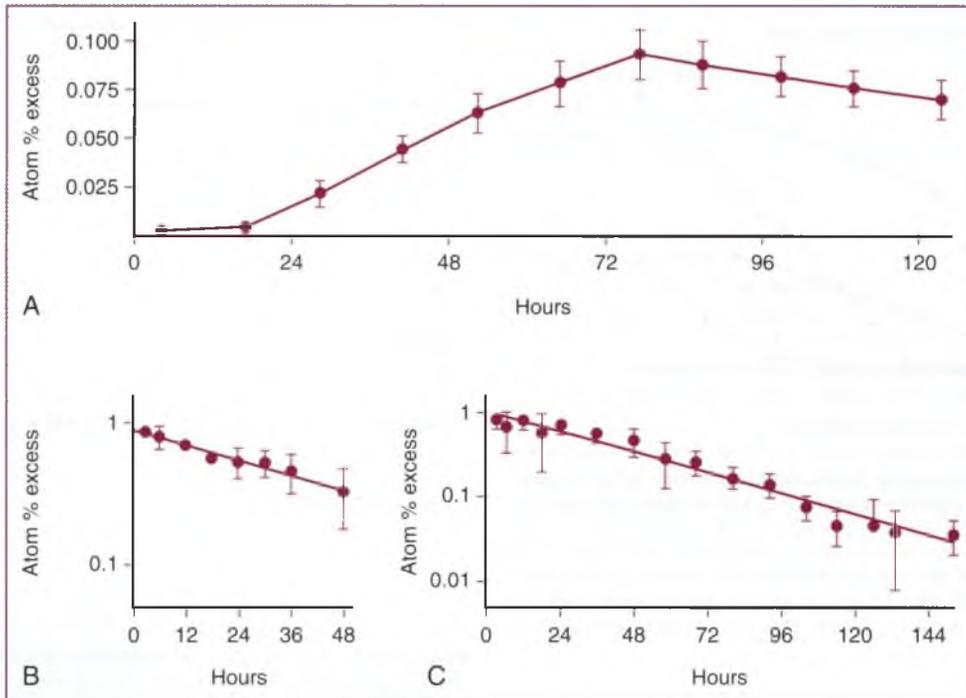

Figure 15-5 Measurements of surfactant metabolism in preterm infants with respiratory distress syndrome using stable isotopes. **A**, Curve for the carbon 13 labeling of palmitate in phosphatidylcholine recovered from airway aspirates of 11 preterm infants who received ^{13}C -glucose infusion for the first 24 hours of life. The time to maximal enrichment (expressed as atom % excess ^{13}C) was 77 ± 8 hours. The half-life after peak enrichment was about 100 hours. **B** and **C**, Loss of ^{13}C -dipalmitoyl phosphatidylcholine from treatment doses of surfactant given to eight preterm infants at a mean age of 4.6 hours (**B**), and for a second dose of surfactant given at a mean age of 37 hours (**C**). The half-life of the label in the airway aspirates was about 34 hours. (Data in **A** from Bunt JE, Carnielli VP, Darcos Wattimena JL, et al: *The effect in premature infants of prenatal corticosteroids on endogenous surfactant synthesis as measured with stable isotopes*, *Am J Respir Crit Care Med* 162:844, 2000; data in **C** from Torresin M, Zimmermann LJ, Cogo PE, et al: *Exogenous surfactant kinetics in infant respiratory distress syndrome: a novel method with stable isotopes*, *Am J Respir Crit Care Med* 161:1584, 2000.)

the uncomplicated clinical course of RDS lasts from 3 to 5 days. Measurements of the kinetics of surfactant secretion and clearance in the newborn explain the slow increases in surfactant pool sizes after preterm birth.⁴³ Although incorporation of precursors into lung phosphatidylcholine is rapid, there are long delays between synthesis and the movement of surfactant components to lamellar bodies for secretion. The peak time for secretion of surfactant lipids labeled with carbon 13 (from ^{13}C -glucose) was about 70 hours in infants with RDS (Fig. 15-5A).⁴⁴ The slow increase in the alveolar surfactant pool from de novo synthesis is balanced by slow catabolism and clearance.⁴⁵ Radiolabeled surfactant phospholipids administered into the airspaces of term lambs were cleared from the lung with a half-life of about 6 days. The biologic half-life of surfactant lipids in infants with RDS was about 35 hours (see Fig. 15-5B).⁴⁶ The preterm lung requires a number of days to achieve normal surfactant pool sizes and metabolism.

Surfactant does not remain static in the airspaces. The surfactant phospholipids move from the airspaces back to type II cells by endocytosis into multivesicular bodies (see Fig. 15-4).⁴⁵ In the term and preterm lung, about 90% of the phospholipids are recycled back to the lamellar bodies for re-secretion to the airspaces. In the adult lung, this process is about 25% efficient. The phospholipids are recycled as intact molecules without degradation and resynthesis. In the adult lung, macrophages catabolize about 50% of the surfactant. There are few macrophages in the preterm lung at birth, but macrophage numbers increase with postnatal age, inflammation, and injury. The

dynamics of surfactant metabolism are further complicated by transitions of surfactant aggregate forms in the alveolar space.⁴⁵ Surfactant phosphatidylcholine transitions from being secreted by lamellar bodies to a tubular myelin pool, which is the reservoir in the hypo-phase from which the surface film is maintained. SP-A participates in this transition. Area compression of the surface film is thought to then concentrate saturated phosphatidylcholine by squeezing out other lipids and surfactant proteins. New surfactant adsorbs into the surface film, and used surfactant leaves as small vesicles, which are cleared from the airspaces.

PHYSIOLOGIC EFFECTS OF SURFACTANT

The effects of surfactant on the preterm surfactant-deficient lung are illustrated by the pressure-volume relationships during quasi-static inflation and deflation.⁴⁷ The pressure needed to open a lung unit is related to the radius of curvature and surface tension of the meniscus of fluid in the airway to that unit. With surfactant deficiency, surface tensions are high and variable. The uninflated lung contains fluid-filled airways with different radii. In surfactant-deficient lungs, the units distal to airways with larger radii and with lower surface tensions pop open first, making lung inflation nonuniform. Preterm surfactant-deficient rabbit lungs do not inflate until pressures exceed 25 cm H_2O (Fig. 15-6). Surfactant treatment decreases the opening pressure to about 15 cm H_2O . Because the treatment does not alter the radii of the airways, the decreased opening pressure results from

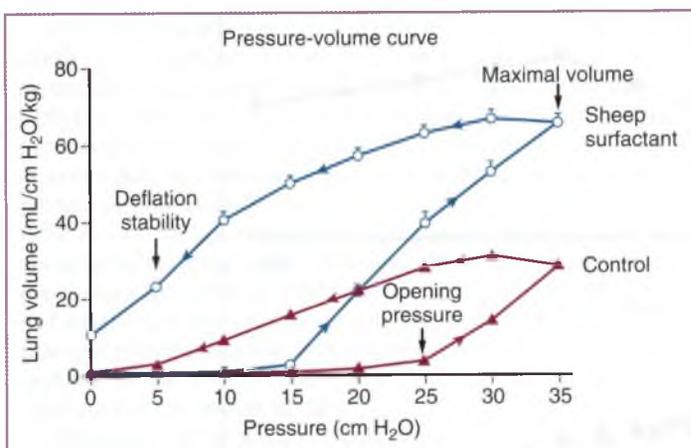

Figure 15-6 Pressure-volume relationships for the inflation and deflation of surfactant-deficient and surfactant-treated 27-day-old preterm rabbit lungs. Surfactant deficiency in the control is indicated by the high opening pressure, the low maximal volume at a distending pressure of 35 cm H₂O, and the lack of deflation stability at low pressures on deflation. In contrast, treatment of 27-day-old preterm rabbits with a natural (sheep) surfactant strikingly alters the pressure-volume relationships.

adsorption of the surfactant to the menisci. Inflation is more uniform because low surface tensions make aeration of airways less dependent on airway size. More units open at lower pressures, and there is less overdistention of the units that do open. Inflation is more uniform with surfactant sufficiency or surfactant treatment. A striking effect of surfactant on the surfactant-deficient lung is the 2.5-times increase in maximal volume at 35 cm H₂O airway pressure. This difference in the lung gas volume caused by surfactant treatment translates to increased surface area for gas exchange. Surfactant also stabilizes the lung on deflation. The surfactant-deficient lung collapses at low transpulmonary pressures. The surfactant-treated lung retains about 36% of the lung volume with deflation to 5 cm H₂O pressure. This stability on deflation explains the increased functional residual capacity in the surfactant-sufficient lung.

SURFACTANT FOR RESPIRATORY DISTRESS SYNDROME

Fujiwara and associates first reported in 1980 that instillation of the airway with surfactant improved oxygenation in infants with severe RDS.⁴⁸ Surfactant prepared for animal lungs became available for the treatment of RDS in 1990 after extensive clinical trials.⁴⁹ The metabolic characteristics of surfactant in the preterm are favorable for surfactant treatment.⁴⁵ In the infant with RDS, alveolar and tissue pool sizes are small, and the alveolar pool increases slowly after birth. Treatment acutely increases both the alveolar and tissue pools because the exogenously administered surfactant is taken up into type II cells and processed for re-secretion. The surfactant given as treatment becomes a metabolic substrate for the preterm lung, which can improve its function.⁵⁰ The treatment surfactant remains in the lungs and is not rapidly degraded. Treatment dosages of surfactant do not inhibit the endogenous synthesis of saturated phosphatidylcholine or the surfactant proteins by feedback mechanisms. No adverse metabolic consequences of

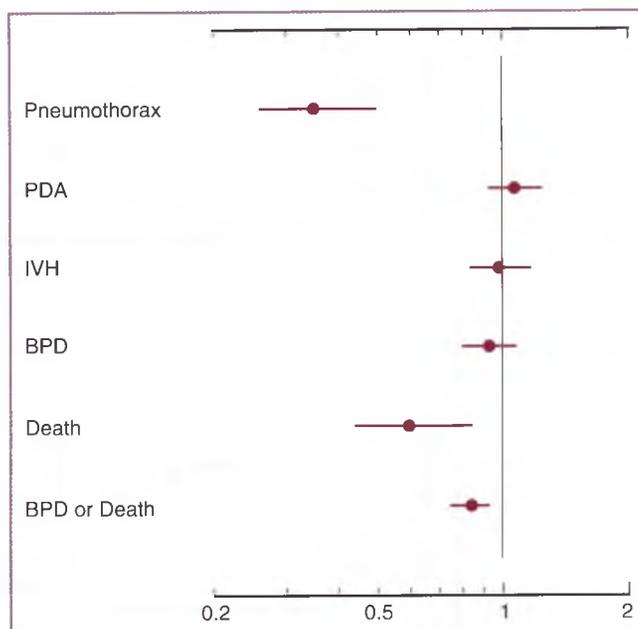

Figure 15-7 Results of a meta-analysis of eight randomized controlled trials of surfactant for the treatment of respiratory distress syndrome. Results are given as odds ratios and 95% confidence intervals for 988 randomized patients. BPD, bronchopulmonary dysplasia; IVH, intraventricular hemorrhage; PDA, patent ductus arteriosus. surfactant treatment on the endogenous metabolism of surfactant or other lung functions have been identified.

The clinical trials of patients with RDS consistently showed that mortality from RDS and overall infant mortality rates decreased with surfactant treatment (Fig. 15-7).⁴⁹ The treatments also decreased the incidence of pneumothorax, oxygen requirements, and ventilatory requirements over the first several days of life. A disappointment has been the lack of a consistent decrease in the incidence of BPD in surfactant-treated survivors of RDS. Presumably, infants whose lives are saved by surfactant treatment are those most likely to develop BPD. Fortunately, the severity of BPD has decreased as more immature infants have survived. Surfactant treatments do not seem to affect the non-pulmonary complications of prematurity, such as patent ductus arteriosus and intraventricular hemorrhage,

Surfactant was originally evaluated for treating infants at risk for RDS as soon as possible after birth, generally during resuscitation, or for treating established RDS in infants at 6 to 24 hours after delivery.⁴⁹ In clinical practice, surfactant treatments are delayed for at-risk infants until there are early signs of RDS. More recent trials demonstrated that using symptoms to time the treatment does not change outcomes such as BPD and intraventricular hemorrhage.⁵¹ A newer use of surfactant treatment is to allow the preterm infant to initiate ventilation without intubation or positive pressure ventilation. In a number of trials, this approach has decreased the need for surfactant treatment or mechanical ventilation while achieving equivalent or slightly better outcomes.^{52,53}

Infants with primarily surfactant deficiency should respond well to surfactant. Reasons for poor responses include injury to

the preterm lung by inflammation or ventilatory injury before surfactant treatment, unrecognized pulmonary hypoplasia, or very immature lung structure. Antenatal corticosteroid treatments before preterm birth seem to act synergistically with surfactant to improve outcomes for infants by improving respiratory function and decreasing pneumothorax and intraventricular hemorrhage.⁵⁴ Multiple beneficial interactions between antenatal corticosteroids and postnatal surfactant treatments can be demonstrated in experimental models.⁵⁵ The corticosteroid exposure makes the endogenous surfactant more resistant to inhibition by proteins and inflammatory mediators. The corticosteroid-induced increase in airspace volume and decrease in permeability of the airway epithelium decreases the dosage of exogenous surfactant needed to improve lung function and decreases surfactant inactivation. Other effects of corticosteroids on fluid clearance and inflammation probably also contribute to improved clinical responses. The availability of surfactant treatments is not a reason to withhold antenatal corticosteroid treatment of women at risk for preterm delivery.

Induced Lung Maturation and Pulmonary Outcomes

FREQUENCY OF INDUCED LUNG MATURATION

It is difficult to identify the point at which the normal human fetal lung matures and becomes able to transition to air

breathing without assistance. There is biologic variability—female fetuses mature about a week before male fetuses, as estimated by the incidence of RDS—and there is probably genetic variability. Furthermore, abnormalities associated with pregnancy affect the timing of lung maturation. Based on the lecithin-to-sphingomyelin (L/S) ratio for amniotic fluid from normal pregnancies, lung maturation (also defined by the absence of RDS) should occur after about 35 weeks' gestational age (Fig. 15-8).³ As seen in Figure 15-8, only about 10% of infants born at 35 weeks' gestation have RDS.⁵⁶ About 50% of infants at 30 weeks' gestation and close to 100% of infants younger than 28 weeks' gestation had RDS. Of 9575 infants born at less than 29 weeks' gestation from 2003 to 2007 reported by the NICHD Neonatal Research Network, 93% had RDS.⁵⁷ However, recent trials of infants of similar gestational ages treated with continuous positive airway pressure reported the use of mechanical ventilation or surfactant treatments in only 30% to 60% of the infants.^{52,53} Thus, many very preterm infants have either no RDS or mild RDS, indicating that the great majority of these infants have some degree of induced lung maturation. The variation in the number of diagnoses of RDS resulted from how the infants were initially managed. Induced lung maturation may be the most important fetal adaptation that facilitates survival in infants born before term.

On the other hand, very preterm births can result in children with abnormalities (Fig. 15-9). Two major associations with very preterm birth are abnormal vascular developmental

Figure 15-8 Occurrence of respiratory distress syndrome (RDS) compared with lecithin-to-sphingomyelin (L/S) ratio relative to gestational age. The incidence of RDS is high at early gestational ages, but it is only about 10% when the amniotic-fluid L/S ratio in normal pregnancies exceeds 2 (represented by the box), which indicates lung maturation. The curves demonstrate a divergence in the incidence of RDS and the L/S ratio as a predictor of RDS, indicating that induced early lung maturation is frequent. (RDS data from Chang EY, Menard MK, Vermillion ST, et al: *The association between hyaline membrane disease and preeclampsia*, Am J Obstet Gynecol 191:1414–1417, 2004; L/S data from Gluck L, Kulovich M, Borer RC, et al: *Diagnosis of the respiratory distress syndrome by amniocentesis*, Am J Obstet Gynecol 109:440–445, 1971.)

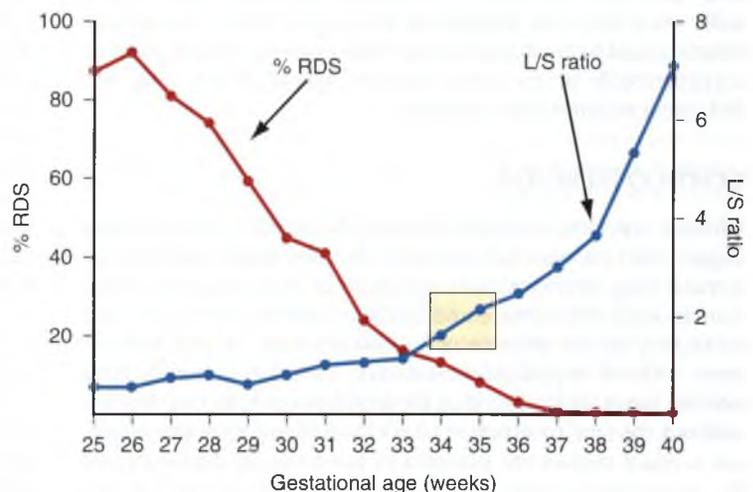

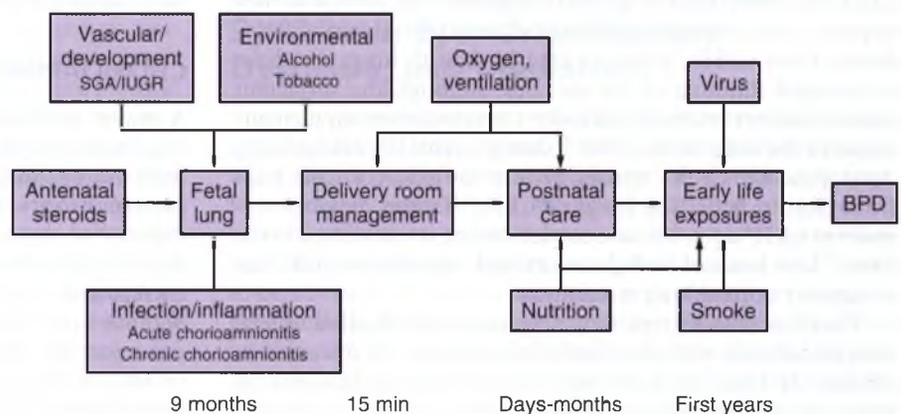

Figure 15-9 Major fetal and neonatal factors that contribute to lung outcomes such as bronchopulmonary dysplasia (BPD) in preterm infants. The ages at which these factors are pertinent are indicated. IUGR, intrauterine growth restriction; SGA, small for gestational age.

syndromes, frequently associated with preeclampsia and fetal growth restriction, and chorioamnionitis or fetal exposure to inflammation.⁵⁸ The fetal lung is also influenced by maternal exposures to, for example, tobacco and alcohol. Although an understanding of fetal exposures and responses that alter postnatal acute (e.g., RDS) and more prolonged (e.g., BPD) lung outcomes is incomplete, clinical experiences with induced lung maturation and the results from animal models provide useful insights.

ABNORMAL VASCULAR DEVELOPMENT AND GROWTH RESTRICTION

Although the vascular abnormalities associated with prematurity are primarily placental in origin, the development of the fetal lung also can be altered to promote RDS or BPD. Preeclampsia is associated with an increased risk for RDS in very preterm deliveries⁵⁶ but with a decreased risk for RDS for late-preterm deliveries.¹⁵ This divergent outcome suggests gestationally dependent fetal responses. Intrauterine growth restriction and preeclampsia are major predictors of increased respiratory morbidity and BPD.⁵⁹⁻⁶¹ These very preterm fetuses also do not have a mortality benefit from antenatal corticosteroid treatments. These clinical observations are consistent with a number of experimental results that demonstrate abnormal lung development in growth restriction models. Fetal growth restriction in sheep decreases alveolar numbers and vessel development, both effects that could promote the subsequent development of BPD after preterm birth.⁶² This abnormal lung development, with what must be substantial fetal stress from the growth failure, could be mediated in part from increased production of corticosteroids by the fetus, but the increased RDS does not indicate a maturational response.

CORTICOSTEROIDS

Clinical experience and results with transgenic mouse models suggest that endogenous cortisol is not absolutely required for normal lung development.⁶³ Explants of mid-gestational fetal human lung differentiate and develop mature type II cells and surfactant in the absence of glucocorticoids. Infants born at term without hypothalamic-pituitary function generally have normal lungs, indicating that the fetal human lung can develop without the fetal production of cortisol. However, some maternal cortisol crosses the placenta to the fetus, as demonstrated by experiments with transgenic mice. Disruption of the corticotropin-releasing hormone (CRH) gene (*Crh*^{-/-}) results in adult mice with very low plasma corticosterone levels, and they require corticosterone supplementation to reproduce.⁶⁴ CRH^{-/-} fetuses from CRH^{-/-} mice die after birth with lungs that have an arrested thinning of the saccules, although the surfactant system matures relatively normally. Corticosterone supplementation in the water of the CRH^{-/-} dam prevents the delayed lung development in CRH^{-/-} fetuses, because the glucocorticoid leaks from dam to fetus. The lungs of CRH^{-/-} fetuses develop normally in CRH⁺ dams because corticosterone is transferred to the fetus.⁶⁵ Low levels of fetal glucocorticoid exposure are sufficient to support normal lung maturation.

The clinical issues regarding diagnosis and induction of fetal lung maturation with antenatal corticosteroids are discussed in Chapter 34. However, a few points about basic mechanisms are pertinent at this juncture. Pharmacologic induction of early

BOX 15-2 EFFECTS OF ANTENATAL CORTICOSTEROIDS ON FETAL LUNGS

ANATOMY AND BIOCHEMISTRY

- Thinning of the mesenchyme of the alveolar-capillary structure

- Decreased incidence of respiratory distress syndrome
- No effect on incidence of bronchopulmonary dysplasia
- Decreased mortality

lung maturation is the rationale for the clinical use of antenatal glucocorticoids in women at risk for preterm delivery. Numerous animal models and clinical trials demonstrate that glucocorticoids can induce maturation of lung and other organs. The numerous effects of antenatal corticosteroids include changes in lung structure and increased surfactant synthesis (Box 15-2). These changes favorably improve lung function after preterm birth and the effects of surfactant treatments on more structurally mature lungs. Maternal treatment with corticosteroids changes lung structure of fetal sheep within 24 hours, but surfactant does not increase for several days.⁶⁶ Clinically, the net effect is a decrease in RDS and infant death, but there is no decrease in BPD, presumably because of the increased survival of infants at the highest risk of BPD.⁶⁷ However, antenatal corticosteroid treatments decrease alveolar septation in fetal sheep and primates, and postnatal corticosteroid treatments blunt alveolar and microvascular development in rodents whose lungs alveolarized after birth.^{68,69} These changes are similar to the arrest of lung development with BPD. In fetal sheep, the adverse effects of maternal corticosteroids reverse with further fetal development, but prolonged and high-dosage fetal exposures could affect lung outcomes.

CHORIOAMNIONITIS AND FETAL INFLAMMATION

A major association with very preterm labor and delivery is chorioamnionitis, which is often “silent” and apparent only from histopathology of the fetal membranes. About 50% of preterm infants with birth gestations of less than 30 weeks are exposed to chorioamnionitis. These infants often do not have RDS, but they may have an increased risk for BPD.⁷⁰ The clinical correlations with histologic chorioamnionitis are confounded because severe inflammatory exposures caused by pathogens can injure the fetal lung, whereas the more frequent exposures to low-virulence pathogens such as *Ureaplasma* and *Mycoplasma* may mature the fetal lungs and thus decrease RDS. In

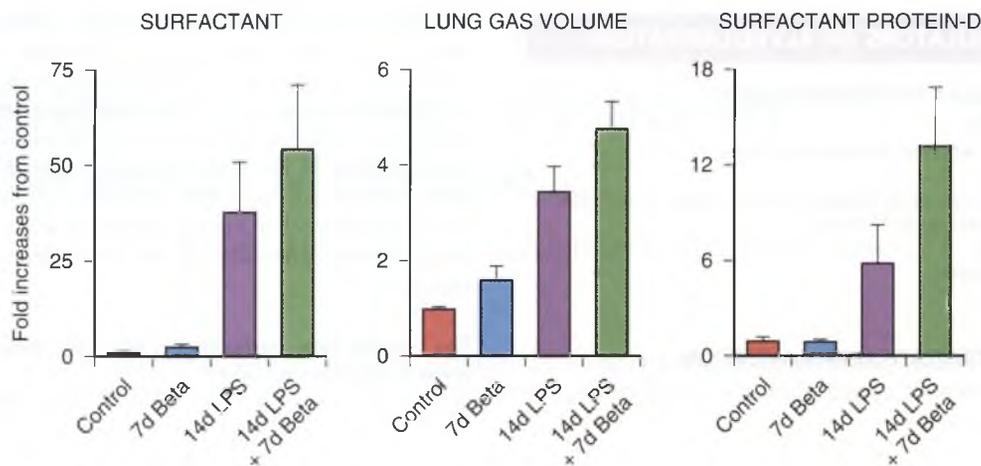

Figure 15-10 Fetal exposures to intra-amniotic lipopolysaccharide (LPS) and maternal betamethasone (Beta). Fetal sheep were exposed to maternal betamethasone and/or intra-amniotic LPS before preterm delivery at 120 days' gestation. The exposures were 7 or 14 days (7d and 14d) before the delivery. Surfactant was measured as saturated phosphatidylcholine, lung gas volume was measured at a distending pressure of 40 cm H₂O, and surfactant protein D was measured by enzyme-linked immunosorbent assay. All values are expressed as fold increases relative to control values of 1. Beta had modest effects alone, LPS increased the measurements, and the combined exposures resulted in the largest increases. (Data from Kuypers E, Collins JJ, Kramer BW, et al: *Intra-amniotic LPS and antenatal betamethasone: inflammation and maturation in preterm lamb lungs*, *Am J Physiol Lung Cell Mol Physiol* 302:L380–L389, 2012.)

fetal sheep models, chronic colonization of the amniotic fluid with *Ureaplasma* induces lung maturation without other adverse fetal effects.⁷¹ This lung maturation requires the contact of the proinflammatory agonist with the fetal lung and the subsequent recruitment of inflammatory cells to the fetal lung.⁷² The potent proinflammatory cytokine interleukin-1 is a major mediator of lung maturation induced by *Escherichia coli* lipopolysaccharide.⁷³ The maturational responses to intra-amniotic inflammation are more consistent and greater than are the responses to maternal corticosteroids. In clinical practice, fetuses exposed to chorioamnionitis in preterm labor are then exposed to antenatal corticosteroids. The effects of these two exposures on fetal lung gas volumes, surfactant, and the innate host defense protein SP-D in fetal sheep demonstrate interactive effects that improve lung function (Fig. 15-10).⁷⁴

LATE GESTATIONAL LUNG MATURATION

Increased rates of respiratory morbidity are now seen in late preterm (34 to <37 weeks) and early term (37 to <39 weeks) infants. This increase correlates with increased rates of scheduled cesarean deliveries without labor. With each progressive week of gestation, rates of respiratory morbidity decrease.⁷⁵ The explanation for the respiratory morbidity has at least two components that are part of the continuum of lung maturation as the human fetus approaches term. First, although lung maturation probably occurs in most normal fetuses by about 36 weeks' gestation,³ it is subject to a large variability in timing, which extends to term. Second, normal labor and delivery are preceded by a pre-labor phase, during which fetal cortisol increases, and fetal lung fluid secretion may slow or cease. Labor and delivery increase fetal catecholamines and promote adsorption of fetal lung fluid. The net effects are physiologic adaptations that facilitate the transition to breathing air. Late preterm and unlabored cesarean-delivered infants can have respiratory morbidities that include surfactant-deficiency respiratory distress syndrome, transient tachypnea of the newborn (thought to

represent delayed clearance of fetal lung fluid), and nonspecific tachypnea syndromes.⁷³ The magnitude of the potential problem can be appreciated by the following estimates. Assume the apneic term newborn born without labor has a fetal lung fluid volume of 25 mL/kg, a normal blood volume of 80 mL/kg, and a hematocrit of 50%. The fetal lung fluid, which contains essentially no protein, would be equivalent to 62% of the plasma volume. Cesarean delivery, intubation, and ventilation could result in a crystalloid volume challenge of 25 mL/kg, which could destabilize cardiopulmonary function. Although this scenario is extreme, many subtle abnormalities and a few severe difficulties of neonatal adaptation result from large amounts of alveolar and interstitial fluid in the lungs of infants. These respiratory problems are a continuum, as infants with severe transient tachypnea can have indicators of surfactant deficiency.⁷⁶ Furthermore, late preterm and early term infants can have neonatal morbidities despite tests indicating lung maturity.⁷⁷ One trial found no benefit of antenatal corticosteroids to prevent the respiratory complications,⁷⁸ but antenatal corticosteroids for elective cesarean section were beneficial in another trial.⁷⁹

Overview of Respiratory Distress Syndrome, Bronchopulmonary Dysplasia, and Mediators

The major adverse pulmonary outcomes after preterm birth are RDS and BPD. With current obstetric and neonatal management, the survival of infants of gestations of 24 weeks and older is remarkable. Some degree of lung maturation is critical to the survival of infants after delivery at very early gestational ages. Remarkably, the human lung often matures sufficiently to permit survival—sometimes without surfactant or mechanical ventilation—10 weeks or more before lung maturation would normally occur. The human fetus has remarkable plasticity in organ responses to the abnormalities causing preterm labor and delivery, which include chorioamnionitis and

maternal corticosteroid treatments. Other fetal effects of pregnancy-related abnormalities remain to be identified. Adverse outcomes such as BPD result from the simultaneous and sequential assaults on lung development from fetal exposures, resuscitation, and postnatal management. For example, the modulators of alveolarization are the exposures of the preterm fetus and newborn (Box 15-3). The successes of perinatal medicine related to very preterm deliveries depend on the extraordinary plasticity of the fetal lung for the frequent survivors.

Evidence-Based Practice in Perinatal Medicine

GEORGE A. MACONES, MD, MSCE | METHIDIUS G. TUULI, MD, MPH

All those who drink of this remedy recover in a short time, except those whom it does not help, who die. Therefore, it is obvious that it fails only in incurable cases.

—Galen (circa 100 AD)

Evidence-Based Medicine in Perspective

Many of the improvements in medical care for women in the past 30 years have come about as a result of carefully designed studies of interventions aimed at improving health. Before that time, physicians relied on anecdote and personal experience to guide patient care.

Evidence-based medicine is a style of practice best described as “integrating individual clinical expertise with the best-available external clinical evidence from systematic research.”¹ Therefore, contrary to what many believe, evidence-based medicine combines understanding of the literature with individual expertise. It is this blend of evidence and clinical intuition that makes evidence-based medicine so attractive and essential to the practice of modern medicine.

Why is evidence-based medicine important in maternal-fetal medicine? First, the practice of evidence-based medicine allows us to provide the best care to our patients. Instances in obstetrics are easily found where an incomplete or improper assessment of the evidence has led to problems with care. The classic example is the emergence of electronic fetal heart rate monitoring (see Chapter 33). This device, novel when it was introduced, generated new information that was widely expected to lead to improved perinatal outcomes. Unfortunately, electronic fetal monitoring was widely implemented before evidence of benefit existed, and it became firmly rooted in obstetrics in the United States and many other countries. As has been well documented, it is uncertain whether continuous electronic fetal monitoring confers any benefit beyond that of intermittent auscultation in low-risk patients, and it has been a major contributing factor in the rise in the rate of cesarean delivery.

Second, clinical research is growing exponentially, as evidenced by the number of medical journals, research publications, and scientific societies. Some have estimated that 1000 articles are added to MEDLINE per day. In addition, clinical research has gained in importance, with programs at the National Institutes of Health and other funding agencies focused on clinical research. Because there is so much information, and because both physicians and patients can access it so rapidly, it is essential for practicing clinicians to be able to assess the medical literature to determine a best course of action for an individual patient.

Finally, in perinatal medicine we are today faced with many important yet unanswered questions, such as these:

- Should universal cervical length screening be offered? If so, should women with a short cervix be treated with vaginal progesterone, cervical cerclage, or a pessary?
- Can preeclampsia be detected, prevented, or reduced through prenatal screening and treatment programs?
- Should we screen women for inherited thrombophilias if they have a history of poor pregnancy outcome? If so, how should we treat those who are positive?

How do we, as physicians and researchers, reach sound decisions for such questions? We start by learning to assess the quality of available medical evidence. In this chapter, we review the principles that serve as a basis for learning to interpret clinical research, including clinical research study designs, measures of effect, sources of error in clinical research (systematic and random), and screening and diagnosis. This will provide the reader with the information that will advance the journey toward becoming an evidence-based medicine practitioner.

Types of Clinical Research Studies

Several study designs are reported in the medical literature. Figure 16-1 illustrates how the design of a study is determined.

DESCRIPTIVE STUDIES

Case reports and case series are simply descriptions of either a single case or a number of cases, and these are termed descriptive studies.² Often they focus on an unusual disease, an unusual presentation of a disease, or an unusual treatment for a disease. In case reports and case series, there is no control group. Therefore, drawing any inference on causality is impossible. Such studies are useful mainly for hypothesis *generation* rather than hypothesis *testing*. However, case reports and case series can be very valuable in the scientific process, because many important observations were initially made by a single case or series of cases. For example, in the early 1980s, physicians in California noted an unusual respiratory illness in homosexual men. The astute observation of these physicians led to the discovery of the acquired immunodeficiency syndrome epidemic in the United States.

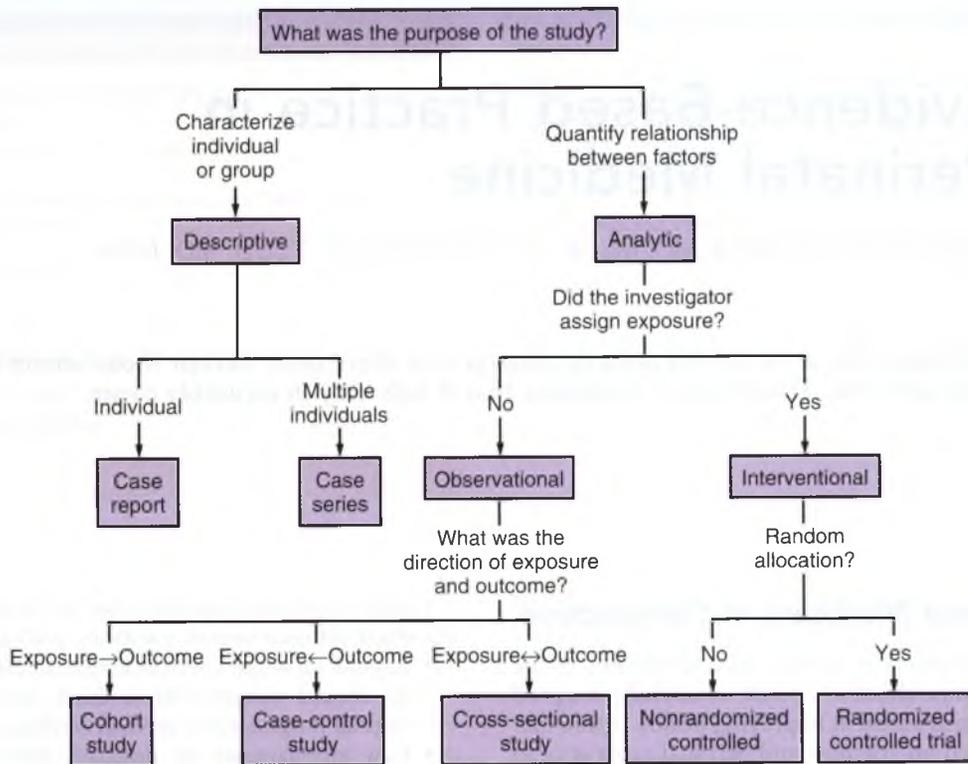

Figure 16-1 Algorithm for classifying types of clinical research design. The classification of study design is based on the purpose of the study, whether or not the investigator assigned the exposure, and the conceptual direction of the exposure and outcome.

ANALYTIC STUDIES

Analytic studies, unlike descriptive studies, involve two or more comparison groups. This permits inferences to be drawn by quantifying the relationship between factors. Analytic studies may be observational or interventional, depending on whether the investigator assigns the exposure.

Observational Studies

The two main types of observational studies are case-control studies and cohort studies.²⁻⁴ These study designs attempt to assess the relationship between an exposure and an outcome (Table 16-1).

Case-Control Studies. In case-control studies, subjects are identified on the basis of disease rather than exposure. Groups of subjects with and without disease are identified, and then exposures of interest are retrospectively sought. Comparisons of the distribution of exposures are then made between cases and controls. Case-control studies are useful for the study of rare conditions. Advantages of case-control studies include efficient use of time, low cost, and the ability to assess the impact of multiple exposures. However, case-control studies cannot be used to calculate an incidence of disease for a particular exposure, and they carry substantial potential for confounding and bias.

A *nested case-control study* is a modification of the case-control design. In this design, cases and controls are drawn from a defined cohort of subjects. Because all subjects in the cohort are disease free at entry into the study, those who go on to develop the outcome of interest become the cases, and a random

TABLE 16-1 Comparison of Case-Control Studies and Cohort Studies

Case-Control Studies	Cohort Studies
Good for rare disease	Good for common disease
Study multiple exposures	Study multiple outcomes
Done quickly	Long follow-up
Inexpensive	Expensive (prospective)
No incidence data	Can directly calculate incidence
Prone to bias	Less prone to bias

sample of the remaining subjects who do not develop the outcome become the controls. To reduce confounding, controls are often matched to cases on the basis of the presence or absence of one or more variables. This unique study design reduces potential selection bias of controls coming from a population that is different from that of the cases. This design is also useful when measurements of interest are costly or time consuming. Rather than performing the measurement on all patients in the cohort, archived samples are analyzed only for subjects selected as cases and controls.⁵

Cohort Studies. *Cohort studies* identify subjects on the basis of exposure and then assess the relationship between the exposure and the clinical outcome of interest. Cohort studies can be either retrospective or prospective. In a retrospective cohort study, the exposed population is identified after the event of interest has occurred. In a prospective cohort study, exposed

and unexposed subjects are followed over time to see if the outcome of interest occurs. Cohort studies are useful in the study of rare exposures. The advantages of cohort studies are that the incidence of disease in exposed and unexposed individuals can be assessed, and there is less potential for bias (especially if prospective). The main disadvantage of prospective cohort studies is that they can be time consuming, sometimes requiring years to complete (if prospective), and are therefore often expensive.

A clinical example may help to contrast these study designs. The relationship between anticonvulsant use in pregnancy and the occurrence of neural tube defects could be assessed with either a case-control or a cohort study. In a case-control study, one would identify a group of cases of fetuses or neonates with neural tube defects and a group of controls (i.e., children without a neural tube defect). The maternal record could be reviewed to determine whether exposure to anticonvulsants has occurred. To study this question with a cohort study, one would first identify a population of women taking anticonvulsants in pregnancy and a group not taking anticonvulsants, and then follow both groups through pregnancy and delivery to determine the frequency of neural tube defects in each group.

Cohort studies can be either prospective or retrospective, whereas case-control studies are almost always retrospective. The advantage of a prospective cohort study is that the type and amount of data being collected can be determined by the investigator on the basis of the research question. In a retrospective cohort study, one almost always relies on inpatient or outpatient records for data collection, so the study is limited by the type and quality of the data included in these sources. For example, suppose an investigator is interested in the relationship between maternal cocaine use and fetal growth restriction. In a prospective cohort study, one would have the opportunity for a very accurate assessment of this exposure, perhaps by obtaining a hair sample. A retrospective study would have to rely on what was recorded in the medical record, which is most likely based on patient self-report.

There is a common misconception that an analysis performed using data collected prospectively and contained in a database is equivalent to a prospective cohort study. In fact, unless the research question was defined a priori (i.e., before the start of data collection), this is best termed a *retrospective secondary analysis of prospectively collected data*. In many cases, such analyses are more similar to a retrospective cohort study, because important clinical information may not have been collected as completely or systematically as it could have been had the research question been specified in advance (see Types of Data for Clinical Research, later).

Interventional Studies

Unlike observational studies, where the investigator has no control over the exposure, interventional studies involve assignment of the exposure by the investigator. The ability to assign exposure provides a level of investigator control over interventional studies that cannot be achieved in observational studies. However, interventional studies may not be feasible for all research questions. For example, it may not be ethical for an investigator to expose subjects to a factor likely to cause a deleterious outcome. Similarly, outcomes with a long lag time (often associated with high costs) may make the interventional design unsuitable for a particular question. Interventional studies involving human subjects are termed clinical trials. Depending

on whether subjects are randomly or nonrandomly assigned to the comparison groups, clinical trials may be randomized or nonrandomized.

The randomized clinical trial is the gold standard of clinical research design.⁶ In this type of clinical trial, eligible consenting participants are randomly allocated to receive different therapies. Differences in clinical outcomes are then compared on the basis of the treatment assignment. Clinical trials are powerful because the likelihood that confounding and bias will influence the results is minimized. *Randomization* is the hallmark of randomized controlled trials. It is the method of assigning subjects to groups in such a way that characteristics of the subjects do not affect the group to which they are assigned. To achieve this, the investigator allows chance to decide which group each subject is assigned to. Randomization ensures that differences in outcomes between comparison groups are attributable to the intervention alone and not to known or unknown confounding characteristics. Although randomization does not guarantee that the groups will be identical in all baseline characteristics, it does ensure that any differences between them are the result of chance alone. Randomization also facilitates concealment of intervention from subjects and investigators to further reduce bias. Finally, randomization leads to groups that are random samples of the study population, permitting the use of standard statistical tests that are based on probability theory.

However, clinical trials are logistically difficult and expensive, and they can take years to complete. There are also concerns about whether the results of clinical trials can be generalized—that is, applied to clinical practice with the expectation that the same results will occur. Specifically, people who consent to be part of a trial may differ from those who do not consent in that they may be more likely to comply with an intervention or have a generally healthier lifestyle than persons who decline to enter the study. In addition, well-performed clinical trials often have strict inclusion and exclusion criteria, with strict follow-up procedures. In real-life clinical situations, such rigor in follow-up rarely occurs. Standards for reporting prospective randomized trials have been developed to ensure that results from all trial participants are reported. These have been published as the CONSORT statement.⁷

Despite these concerns, clinical trials provide the best evidence to guide practice. An excellent example of a practice-guiding clinical trial was the screening and treatment study of bacterial vaginosis (BV) in pregnancy performed by the Maternal-Fetal Medicine Units (MFMU) Network.⁸ A variety of studies from around the world suggested that both symptomatic BV and asymptomatic BV were associated with spontaneous preterm birth.⁹⁻¹¹ In addition, secondary analyses of data from clinical trials with high-risk women suggested that screening and treating BV in pregnancy might reduce the occurrence of spontaneous preterm delivery.^{11,12} Many assumed that screening and treating pregnant women might reduce the incidence of preterm birth if applied to *all* pregnant women. To answer this question, the MFMU Network performed a placebo-controlled clinical trial comparing placebo to treatment with metronidazole for pregnant women who screened positive for BV.⁸ This study demonstrated that treating pregnant women with asymptomatic BV did not affect the occurrence of preterm birth.

Another benefit of randomized clinical trials is that subgroup analyses from such data can be used to generate hypotheses for future research. One example is the study cited earlier

by Hauth and colleagues.¹² After the primary analysis of their randomized clinical trial of metronidazole and erythromycin to reduce the risk for preterm birth in women with a prior preterm birth or other historical risk factors demonstrated a reduction of preterm birth, a secondary analysis found that the benefit was limited to women with BV. This secondary analysis (and a similar secondary analysis of another randomized clinical trial¹³) should have prompted a new randomized trial of antibiotic treatment, into which women would be enrolled if they had both BV and a historical risk for preterm birth.

OTHER STUDY DESIGNS

Two other study designs deserve mention: systematic review and meta-analysis, and decision analysis. Both are valuable tools for the evidence-based medicine practitioner.

Systematic Review and Meta-analysis

Systematic review and meta-analysis are two related but different terms, and they are often confused. A systematic review is a scientific investigation that focuses on a specific question and uses explicit, planned methods to identify, select, assess, and summarize the findings of similar but separate studies. It may or may not include a quantitative synthesis of the results from separate studies.¹⁴ A meta-analysis, on the other hand, is the process of using statistical methods to quantitatively combine the results of similar studies identified in a systematic review, in an attempt to allow inferences to be made from the sample of studies. In a meta-analysis, the results of a series of randomized clinical trials (or observational studies) can be statistically combined to obtain a *summary estimate* for the effect of a given treatment.¹⁵ Systematic reviews and meta-analyses should be differentiated from other, less data-driven review articles in which authors present their own interpretation of data. The strength of a meta-analysis comes from its being an analysis of

combined results from multiple studies, thereby increasing the power to detect differences. This is an especially important methodology in obstetrics, as here there are few large randomized clinical trials to guide treatments. Numerous meta-analyses have been performed for topics in obstetrics,^{16,17} and many appear in the Cochrane Database of Systematic Reviews.¹⁸ Two such analyses (Figs. 16-2 and 16-3) are taken from the Cochrane Library meta-analysis of the effect on neonatal outcome of antibiotics given antenatally to women with preterm prematurely ruptured amniotic membranes.¹⁹ In Figure 16-2, a comparison of neonatal infectious complications between those who received antibiotics and those who did not is made, and the data are pooled for all available studies. Each of 11 randomized trials that met inclusion criteria for this analysis is listed, with the number of subjects and the frequency of the outcome in the treatment and control groups noted. The relative risk and 95% confidence interval (see Assessing Random Error, later) for each study, weighted for their sample size, are shown. The total number of subjects with the outcome of interest is summed and the combined relative risk and 95% confidence interval calculated. In this example, a number of small trials show a nonsignificant trend in favor of antibiotic treatment. The pooled (i.e., statistically combined) relative risk was 0.67, with a 95% confidence interval from 0.52 to 0.85. The point estimate (i.e., the relative risk) suggests that the "best guess" is that antibiotics reduce the risk for neonatal infection by 33%. The confidence interval suggests that the data are consistent with as much as a 48% reduction in risk ($1 - 0.52$) or as little as a 15% ($1 - 0.85$) reduction in risk. Even the upper bound of the confidence interval suggests a protective effect of antibiotics on neonatal infection.

Compare this summary graph with that for the effect of antibiotics on perinatal death in women with preterm premature rupture of membranes (see Fig. 16-3). Here, the pooled estimate yields a point estimate relative risk of 0.89, with a 95%

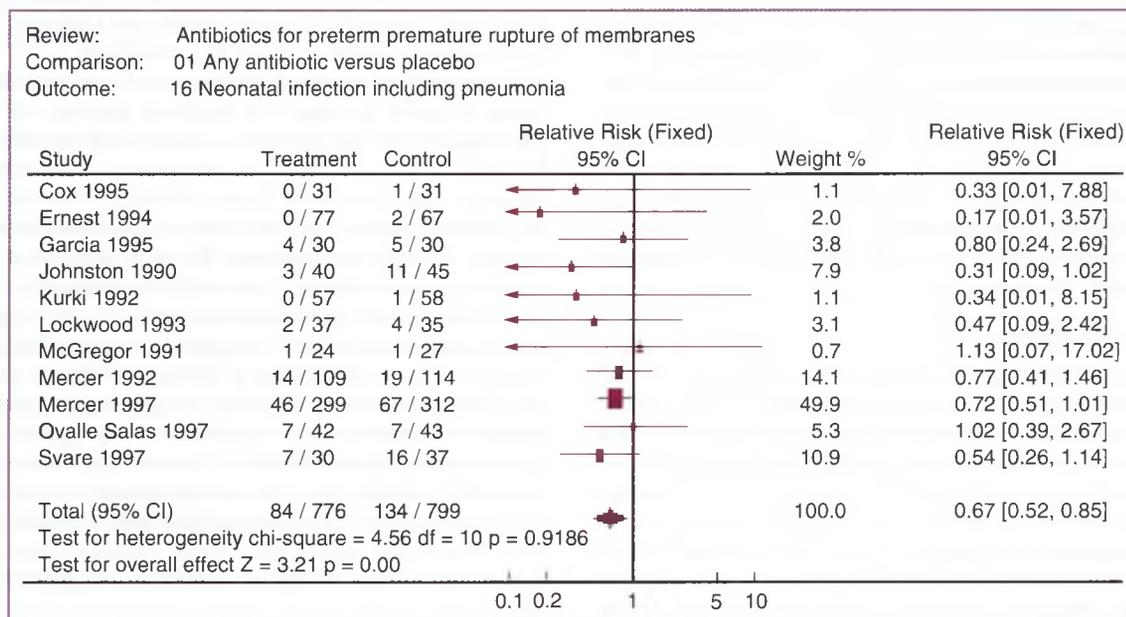

Figure 16-2 Meta-analysis summary graph for neonatal infection. The effect of maternal antibiotic administration on the occurrence of neonatal infection in women with preterm premature rupture of membranes. 95% CI, 95% confidence interval. (From Kenyon S, Boulvain M, Neilson J: *Antibiotics for preterm premature rupture of membranes*, Cochrane Database Syst Rev (4):CD001058, 2001.)

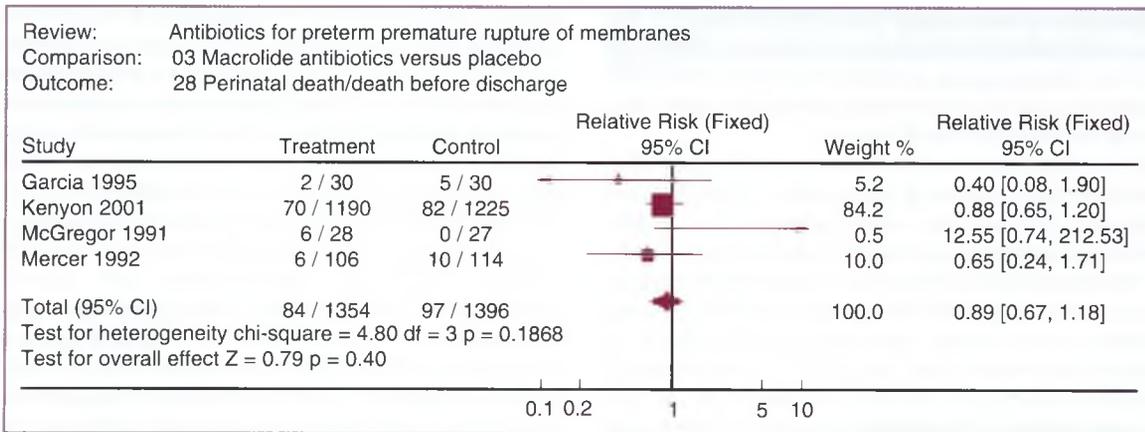

Figure 16-3 Meta-analysis summary graph for perinatal death. The effect of maternal antibiotic administration on the occurrence of perinatal death or death before discharge in women with preterm premature rupture of membranes. 95% CI, 95% confidence interval. (From Kenyon S, Boulvain M, Neilson J: *Antibiotics for preterm premature rupture of membranes*, Cochrane Database Syst Rev (4):CD001058, 2001.)

confidence interval from 0.67 to 1.18. The point estimate suggests that the best estimate is that antibiotics reduce the occurrence of perinatal death by 11%. The confidence interval suggests that the data are consistent with as much as a 33% reduction in perinatal death or an 18% increase in perinatal death with antibiotics. Because the confidence interval crosses a relative risk of 1.0, the data are consistent with “no difference” between the groups.

A notable limitation of meta-analysis is that clinical trials on the same general topic seldom enroll populations or employ treatments that are the same. Therefore, at times, meta-analysis can seem like mixing apples and oranges.^{15,20-22} It is incumbent on the reader to make such a determination. Guidelines for publication of quality meta-analyses have been promulgated by the QUOROM statement, proposed by a consortium of journal editors,²³ and, like the CONSORT statement, they are subscribed to by the *American Journal of Obstetrics and Gynecology*, *Obstetrics and Gynecology*, and general medical journals such as *Lancet*, *New England Journal of Medicine*, and *Journal of the American Medical Association*.

Two other issues are pertinent to the subject of meta-analyses. First, performing a meta-analysis requires significant methodologic skill, so not all meta-analyses are of the same quality. The Cochrane Library, for example, includes very high quality meta-analyses on a number of obstetric topics. Second, there is debate about the role of meta-analyses when large clinical trials are available. This issue was raised in a meta-analysis of antiplatelet agents for the secondary prevention of preeclampsia.²⁴ The authors suggested that antiplatelet agents may reduce the risk for preeclampsia and for birth before 34 weeks of gestation. In this meta-analysis, out of five studies that enrolled over 1000 women in each treatment arm, four did not show a reduction in the risk for preeclampsia with antiplatelet therapy. How do we reconcile the role of large clinical trials with the role of meta-analyses in guiding our practice? Although opinions vary, we believe that a single, well-performed randomized clinical trial in a generalizable population provides stronger evidence than a meta-analysis (where heterogeneous studies must be combined). On the other hand, meta-analyses that include large studies may provide insight into the efficacy of treatment in subgroups of subjects. For example, a more recent meta-analysis of antiplatelet agents

for the prevention of preeclampsia, stratified by timing of initiation of intervention, demonstrated over 50% risk reduction when aspirin was initiated prior to 16 weeks' gestation and no significant effect when aspirin was initiated at 16 weeks or later.²⁵

Decision Analysis

Decision analysis is a methodology in which the component parts of a complex decision are identified and analyzed in a theoretical model. Decision models often use the existing literature to compare different therapeutic strategies for a clinical dilemma. The ultimate goal of any decision analysis is to reach a clinical decision. Importantly, decision models are often the foundation for formal economic analysis, such as cost-effectiveness analysis.²⁶ Decision and economic analyses are fairly common in the obstetric literature. Such analyses have been published on screening for group B streptococci,²⁷ indomethacin use for preterm labor,²⁸ tocolysis at advanced gestational ages,²⁹ thromboprophylaxis at cesarean delivery,³⁰ and universal cervical length screening to prevent preterm birth.^{31,32} Interested readers should consider reading review articles on this subject.^{26,33}

Types of Data for Clinical Research

Data for clinical research may be primary or secondary. Primary data are information collected specifically for the purpose of answering a given research question. For example, information collected during a clinical trial to test the stated trial hypothesis is primary data. Such data are tailored to the specific question, and important variables are systematically collected.

Secondary data, on the other hand, are data collected for another purpose and then used for clinical research. Most of these are institutional or administrative databases. Analysis of data collected as part of a different research question is a secondary data analysis. There are advantages and disadvantages of secondary data.³⁴ Because such data are already available, the expense and time needed to collect them are circumvented. Furthermore, national databases tend to be population or representative samples, increasing generalizability of research findings. The sample sizes are often large, facilitating the evaluation of even rare outcomes. For example, the national birth

certificate data sets include greater than 99% of births in the United States, with sample sizes of over 4 million.³⁵ They can be linked to other data sets, such as infant death data, for further analyses. Finally, because they have been collected for years, they are an excellent resource for trend analysis.

Despite these advantages, several limitations of existing data must be considered when assessing such studies.³⁴ First, because they are collected primarily for other purposes (e.g., public health surveillance or billing) and not for clinical research, the specifics of the information collected and the method by which it is collected may be suboptimal for research purposes. Second, there are validity and accuracy concerns as well as issues of misclassification and missing data. In particular, when missing data are related to whether the outcome of interest is present or absent (i.e., not missing at random), use of such data can produce biased results. Furthermore, although the large sample sizes of secondary data are often an advantage, they may also result in statistically significant differences that mean the data are of limited clinical value.

Therefore, although secondary data have important uses and several advantages, there are also significant limitations. Researchers should know the data source well, including how the information was collected, what the accuracy is, and what proportion of data is missing. Research using secondary data should capitalize on the strengths of the particular data set and avoid analyses that are dependent on the weakest aspect of the data. The main goal of studies based on secondary data should be hypothesis *generation* and not definitive hypothesis *testing*.

Error in Clinical Research

SOURCES OF ERROR IN CLINICAL RESEARCH

Broadly speaking, two types of error can occur in clinical research studies: *systematic* error and *random* error.^{3,4} Random error is assessed using various methods for hypothesis testing, as described later. Systematic error is generally introduced into the study design by the investigator. Sources of systematic error include confounding and bias.³⁶⁻³⁸ As readers of clinical research, our goals are to understand and try to interpret the role of these errors in the studies we read.

Confounding

Confounding is a type of systematic error that can be present in observational research studies.^{36,38,39} Confounding occurs when two factors are associated with each other, and the effect of one factor on a given outcome is distorted by the effect of the other factor. Randomized clinical trials of sufficient size generally cannot be confounded, because randomization itself should lead to an equal distribution of confounding factors between various treatment groups.⁶

An example that illustrates possible confounding comes from observational studies of indomethacin for tocolysis. Norton and colleagues⁴⁰ performed a matched retrospective cohort study of infants delivered at less than 30 weeks of gestation. The authors identified 57 infants delivered at or before 30 weeks' gestation whose mothers were exposed to indomethacin for preterm labor, and 57 infants whose mothers did not receive indomethacin. Infants born to mothers treated with indomethacin before delivery had a higher rate of necrotizing enterocolitis and grades II to IV intraventricular hemorrhage, an observation also noted in other observational studies.⁴¹⁻⁴³ However, the

proper interpretation of observational studies requires that potential sources of systematic error such as confounding and bias be considered. In this example, it is possible that confounding may explain the association between indomethacin and the neonatal morbidity observed in this observational study.⁴⁴ Specifically, because indomethacin is generally not a first-line tocolytic in practice, it is likely that this drug was used mainly in subjects who failed first-line tocolysis. If failing first-line tocolysis is itself a risk factor for adverse neonatal outcome, then the association between indomethacin and adverse neonatal outcome can be confounded. Thus, a principal question in the interpretation of these studies is whether patients who are failing first-line tocolysis are themselves at higher risk for adverse neonatal outcomes (whether exposed to indomethacin or not) than those who respond to first-line tocolysis. Existing data suggest that women whose labor does not stop after first-line tocolysis have an increased risk for adverse neonatal consequences because of the well-established relationship between tocolytic failure and subclinical and intra-amniotic infection, both of which are associated with adverse neonatal outcome.

Because of the relationships between refractory preterm labor and subclinical infection, and between subclinical infection and major neonatal morbidity,⁴⁵⁻⁴⁷ it is uncertain whether the association between indomethacin and adverse neonatal outcome in these retrospective observational studies is a true association or a spurious association resulting from confounding. We hypothesize that in the observational studies, exposure to indomethacin may be nothing more than a sign of inflammation-driven preterm labor, which itself is associated with major neonatal complications.⁴⁴

Bias

Bias is defined as a "process at any stage of inference tending to produce results that depart systematically from true results."⁴⁸ Bias usually occurs at the study design stage.^{37,38} There are two main types of bias to consider. *Selection* bias occurs when an error is made in the selection of a study population. For example, a study by Nicholson and colleagues⁴⁹ sought to determine the association between "preventive" induction and a reduced rate of cesarean birth. The authors designed a retrospective cohort study, comparing outcomes for women managed by physicians who use preventive induction, to outcomes of women managed by physicians who do not use preventive induction. The results suggest that those cared for by physicians who use preventive induction have, surprisingly, lower cesarean rates. However, the physicians who practiced preventive induction in this study were trained in family medicine, whereas those who practiced without preventive induction were trained as obstetric/gynecologic specialists. Because it is likely that these two groups of physicians cared for different types of patients and probably had differences in clinical management, the possibility of selection bias exists. Such bias cannot be controlled for analytically. In this example, the authors correctly acknowledged the possibility of selection bias as an explanation for their findings.

Information bias occurs when a systematic error is made in the measurement of exposure or outcome information. *Recall* bias is a type of information bias that occurs when subjects recall past events differently, and the difference is related to the exposure status or the disease outcome. Recall bias occurs commonly in observational studies of teratogenesis. In a case-control study to assess whether exposure to medications is associated with cleft lip,⁵⁰ cases of cleft lip were ascertained after

delivery occurred. Controls were women who delivered children without a birth defect. Mothers of cases and controls were asked about medication use during the pregnancy. The question that should be asked when reading such a study is whether women who delivered a child with a birth defect are more likely to recall medication use than women who delivered a normal child. If there is differential recall, a significant recall bias could lead to an inflated estimate of the relationship between medications and cleft lip.

ASSESSING THE ROLE OF SYSTEMATIC ERROR IN CLINICAL RESEARCH

Clinicians must be able to assess the role of systematic error in clinical research. Although a detailed discussion is beyond the scope of this chapter, there are several useful maxims for reading clinical research:

1. Systematic error is of greater concern for observational studies than for clinical trials. Because of randomization, confounding seldom occurs in clinical trials.⁵¹
2. Retrospective observational studies are more likely to be biased than prospective studies (although bias can still occur in prospective observational studies).
3. For any observational study, one should carefully read the methods section and consider whether there is the potential for bias.
4. Even when one believes a study to have a serious bias, the study should not automatically be discarded. It is important to consider not just the *presence* of bias but also the *direction* of the bias.⁵⁸ Consider again the example of the case-control study of medications and cleft palate just described. Now assume that the results of the study suggested no association between medications and cleft palate. Given the study design, concern about recall bias is appropriate, but in this case the recall bias would have led to an overestimate of the association between medications and cleft lip. Because the study showed *no* association, it is unlikely that the recall bias would lead to a change in the overall interpretation of the results of the study.
5. Likewise, confounding should always be considered as an explanation of observed results. Readers should consider whether relevant confounding factors were measured and, if they were unmeasured, the direction of the possible confounding. Statistical techniques that can be used to adjust for measured confounding factors include multivariable linear and logistic regression.⁵² In modern observational clinical research, it is unacceptable to report only unadjusted associations when measured confounders can be adjusted for with appropriate statistical techniques.

ASSESSING RANDOM ERROR: HYPOTHESIS TESTING AND MEASURES OF EFFECT IN CLINICAL RESEARCH

In clinical research, one is often interested in whether an exposure is significantly associated with an outcome, or whether an intervention can improve a given outcome. Commonly, interpretation of the results of clinical research is focused on the assessment of a significance test, such as a probability value. This type of testing provides information on the role of chance

TABLE 16-2 Vitamins C and E to Prevent Preeclampsia

	Preeclampsia		Total
	Yes	No	
Vitamins C and E	56	879	935
Placebo	47	895	942
Total	103	1774	1877

Data from Rumbold AR, Crowther CA, Haslam RR, et al: Vitamins C and E and the risks of preeclampsia and perinatal complications, *N Engl J Med* 354:1796–1806, 2006.

(i.e., random error) to explain the observed results in a given study. Although assessing the role of random error is important when reading medical literature, it is equally important to assess the role of systematic error (i.e., bias and confounding) in clinical research.

Let us consider a randomized trial that was designed to assess whether supplementation with vitamins C and E in pregnancy would reduce the incidence of preeclampsia and perinatal complications.⁵³ To answer this question, the authors randomly allocated 935 women to active treatment with vitamins, and 942 to placebo (Table 16-2). The association between treatment with vitamins C and E and preeclampsia can be expressed in several ways: by probability value, by relative risk with 95% confidence intervals, and by several other measures of effect, including odds ratio and risk difference.

Probability Value

A probability value is defined as the likelihood of obtaining the observed differences in the sample if there is no true difference in the population. For example, a probability value of 0.05 means that there is a 5% probability of achieving the observed difference if in fact the null hypothesis of no true difference is true. Thus, the smaller the probability value, the smaller is the possibility of chance as the explanation for an observed difference. In the MFMU Network example⁸ (in which treatment with metronidazole was compared to placebo for women who screened positive for BV in pregnancy), the probability value was 0.95, indicating a high likelihood that chance explained the small difference in the rates of preterm birth between the groups.

Traditionally, a probability value of less than 0.05 has indicated “significance,” whereas a probability value of more than 0.05 has indicated “no significance.” In fact, many journals still allow probability values to be reported in this way. However, with the definition of a probability value in mind (see preceding paragraph), readers should wonder whether a probability value of 0.049 is different from a probability value of 0.051. Clearly, there is more to the interpretation of a probability value than the absolute number.

Relative Risk with 95% Confidence Intervals

A relative risk is defined as the incidence of the outcome in the exposed group divided by the incidence of disease in the unexposed (untreated) group. Therefore, in the vitamin study (see Table 16-2), the relative risk was as follows:

$$\text{Relative risk} = \frac{56/935}{47/942} = \frac{0.06}{0.05} = 1.20$$

A relative risk of 1.0 means that the incidence of the outcome is identical in the exposed and unexposed subjects. A relative risk of less than 1.0 means that the incidence of the outcome is less in the exposed group, whereas a relative risk of more than 1.0 means that the incidence is greater in the exposed group.

The point estimate is the best estimate of the association between an exposure and an outcome, but it does not give information about the stability or statistical precision of the estimate. Clearly, the precision of such an estimate is related to the power of the study. The precision of a relative risk or other measure of effect is often described as a 95% confidence interval.⁵⁴ A 95% confidence interval is interpreted as follows: If a study is without bias, there is a 95% chance that the true point estimate lies within the bounds of the confidence interval. The narrower the confidence interval is, the greater is precision in the estimate. The wider the confidence interval is, the less certainty there is in the estimate.

Confidence intervals also provide information about statistical significance. In general, if a relative risk of 1.0 falls within the bounds of the 95% confidence interval for a given association, then the corresponding probability value will be greater than 0.05. Likewise, if a relative risk of 1.0 is *not* included in the bounds of a 95% confidence interval, then the corresponding probability value will most likely be less than 0.05.

Other Measures of Effect

An odds ratio is another popular measure of effect that can be calculated from either observational studies or clinical trials.⁵⁵ Odds ratios are good approximations of relative risks when the disease of interest is rare. They are most commonly calculated in case-control studies when the calculation of a relative risk is impossible because the denominator is not known. Odds ratios are also the output for most statistical packages when multivariable logistic regressions are performed. In general, relative risks are preferred over odds ratios when data are available to calculate a relative risk, such as in cohort studies or clinical trials.

Using the example from Table 16-2, the odds ratio for the association between vitamin treatment and preeclampsia is as follows:

$$\text{Odds ratio} = \frac{56 \times 895}{879 \times 47} = 1.21$$

An odds ratio is interpreted in exactly the same manner as a relative risk. Thus, an odds ratio of 2.0 would be interpreted as a twofold increase in risk, whereas an odds ratio of 0.5 would mean a 50% reduction in risk. The 95% confidence intervals are also interpreted in the same fashion as those for relative risks. Remember that the preferred measure of effect to calculate in clinical trials and cohort studies is a relative risk (or risk difference). Odds ratios can be used as surrogates for relative risks when the disease in question is rare.

The risk difference is the simple arithmetic difference in incidence between groups and can be calculated from clinical trial data or from cohort studies (but not from case-control studies). In the case of the vitamin study data (see Table 16-2), the risk difference is $0.06 - 0.05 = 0.01$.

A risk difference is interpreted differently from a relative risk or an odds ratio. A risk difference of zero means that there is no difference in the incidence of disease between groups. A positive risk difference means that the incidence of the outcome is greater in the experimental group, whereas a negative risk

difference means that the incidence of the outcome is greater in the control group. In the example of vitamin C and E treatment to prevent preeclampsia, the risk difference means that there is a 1.0% increase in the risk for preeclampsia in those exposed to vitamins C and E. The 95% confidence interval includes zero, which signifies that the data are consistent with there being no difference in the incidence between groups (and corresponds to a probability value of more than 0.05).

The measure of effect that is appropriate is largely determined by the aims of the study and the study design.⁵⁵

APPROACH TO ASSESSING RANDOM ERROR

Approaching the analysis of research data can seem daunting. However, apprehension can be minimized by forming a clear plan at the start or in the planning phase of a research study. The following are some key steps to consider in the analysis of clinical research data.

Step 1. Graph and Summarize

Graph and summarize (e.g., means, range, standard deviation) all outcomes and exposures. This simple process allows the researcher to see a snapshot of the data to appreciate the distribution of a variable (e.g., is it a normal distribution?) and to identify implausible data elements.

Step 2. Perform Univariable Data Analyses

This critical step provides the foundation for the next steps: stratified and multivariable analysis. Univariable analysis allows assessment of associations between any given single exposure and outcome. The choice of the statistical test (or tests) in univariable analysis will vary with the design of the study and the type of outcome and exposure. An important design criterion that influences the univariable statistical test employed is whether or not the study is matched. *Matching* refers to the process of making a study group and comparison group comparable with respect to extraneous factors. A matched study design must be followed by a matched analysis.

There are several commonly used univariable statistical tests:

- Chi-square and Fisher's exact tests: These tests are used when both the outcome and the exposure of interest are binary (yes/no). These tests compare the observed distribution of numbers in the cells of a 2×2 table, and they compare them to the expected distribution. Chi-square and Fisher's exact tests are used when data are unmatched. If the study is matched, then the appropriate test is the McNemar test.
- Student *t* test: A *t* test is used to compare means between two groups. For example, if one wished to compare the mean maternal age of women who develop preeclampsia with the age of those who do not, a *t* test would be appropriate. A *t* test can be either paired (for matched data) or unpaired (for unmatched data).

Step 3. Perform Stratified Analysis

Stratified analysis is a way to assess confounding factors and effect modification. This can help to identify the variables to be included in multivariable analysis. The following is an example of a stratified analysis for a hypothetical case-control study to assess the association between alcohol use and preeclampsia. Table 16-3 is a 2×2 table generated from this case-control study.

TABLE 16-3 2×2 Table from Case-Control Study to Assess Relationship between Alcohol Use and Preeclampsia

	Preeclampsia +	Preeclampsia –	Total
Alcohol +	71	52	—
Alcohol –	29	48	—
Totals	100	100	200

TABLE 16-4 Association between Alcohol and Preeclampsia in Nulliparous Subjects

	Preeclampsia +	Preeclampsia –	Total
Alcohol +	8	16	—
Alcohol –	22	44	—
Totals	30	60	90

Odds ratio = 1.0 (95% confidence interval, 0.33 to 2.9).

TABLE 16-5 Association between Alcohol and Preeclampsia in Multiparous Subjects

	Preeclampsia +	Preeclampsia –	Total
Alcohol +	63	36	—
Alcohol –	7	4	—
Totals	70	40	110

Odds ratio = 1.0 (95% confidence interval, 0.23 to 4.2).

The unadjusted odds ratio is 2.26; 95% confidence interval (CI), 1.2 to 4.2. This unadjusted analysis suggests that alcohol use increases the risk for preeclampsia, but in an observational study, confounding factors that may distort the relationship between alcohol and preeclampsia must be considered. One possible confounding factor is parity, because it may be associated with both alcohol use and preeclampsia. To assess whether parity confounds the association between alcohol use and preeclampsia, a stratified analysis can be performed to assess the alcohol-preeclampsia association separately in multiparous and in nulliparous women. This stratified analysis of this hypothetical data set generates Tables 16-4 and 16-5.

In addition to these stratum-specific odds ratios, a stratified analysis also generates a Mantel-Haenszel summary odds ratio, which in this case is 1.0; 95% CI, 0.42 to 2.34. The proper interpretation of this summary odds ratio is that it represents the association between alcohol use and preeclampsia, after adjusting for the effect of parity. Thus, in this hypothetical example, although the unadjusted odds ratio suggested an association, the adjusted results did not. Stated differently, parity confounds the association between alcohol and preeclampsia.

A stratified analysis is thus a key step in assessing potential confounders, but it is limited because one can stratify only one or two factors simultaneously. Therefore, stratified analysis is more useful to assess potential confounders that should be included in multivariable models.

Step 4. Perform Multivariable Analysis

A multivariable analysis is essential for observational studies, and it can be used occasionally in interventional studies. It allows assessment of the independent effects of many exposures

on an outcome, while controlling for confounding factors. The performance of a multivariable analysis is complex and beyond the scope of this chapter. It is generally useful to consult with a biostatistician or with someone who has significant expertise in this area.

SAMPLE SIZE AND POWER

So far, we have focused mainly on the assessment of type I (or alpha) error in clinical research, defined as the probability of rejecting the null hypothesis when in fact the null is correct. Type II (or beta) error is defined as the probability of accepting the null hypothesis when in fact it is false. In a study with type II error, the results are falsely reported as negative, and thus a true difference is missed. This typically occurs when the sample size is insufficient.

This concept of a false-negative study emphasizes the importance of sample size estimation and statistical power (*power* is defined as 1 minus the beta error). Sample size estimates should be performed prior to any observational or interventional study. The following are the key components of a sample size estimate for cohort studies or clinical trials, and for case-control studies (that have a binary outcome).

Sample size estimate for cohort study or clinical trial

Alpha error
Beta error
Incidence of outcome in unexposed subjects
Ratio of exposed to unexposed subjects
Minimum detectable relative risk

Sample size estimate for case-control study

Alpha error
Beta error
Prevalence of exposure in controls
Ratio of controls to cases
Minimum detectable odds ratio

Some of these components deserve discussion. First, alpha error, by tradition, is set at 0.05, reflecting the intent to perform a study whose results will be falsely declared to be positive less than 5% of the time. Second, beta error is usually set somewhere between 0.05 and 0.20, reflecting the intent to identify a true relationship at least 80% of the time when a relationship truly exists, and, simultaneously, a willingness to miss finding a true relationship 20% of the time. This means that such a study is described as having 80% to 95% power. Third, the incidence of exposure or the prevalence of exposure can generally be estimated from the literature or from pilot data. Last, the minimum detectable odds ratio or relative risk is that meant to be clinically relevant. In practice, there is a tradeoff between wanting to detect as small a difference as possible and wanting to maintain a reasonable sample size (from a logistical and cost perspective).

Sample size estimates should be performed before beginning a research study and should be reported as part of the study's design. As readers of the literature, we should be especially cognizant of sample size and statistical power in cases of a negative study.

Assessing Research on Screening and Diagnosis

Screening and diagnostic tests are an integral part of clinical medicine. For example, measurement of fundal height, a

screening test for fetal growth disturbances and amniotic fluid abnormalities, is a routine part of prenatal care. If the fundal height measures significantly less than anticipated, a diagnostic test, in this case an ultrasound examination, is performed. In obstetric practice, certain screening sequences are commonly followed by particular diagnostic tests—for example, a family history (screening test) can lead to a targeted ultrasound (which may be diagnostic for some disorders or a screening test for others) and eventually to amniocentesis (diagnostic test). Because such sequences are so common, physicians must understand the principles of screening and diagnostic tests⁵⁶ so that they can properly interpret the test results and decide whether a new test should be incorporated into their clinical practice.

SCREENING VERSUS DIAGNOSIS

Screening has been defined as “the presumptive identification of an unrecognized disease or defect by the application of tests, examination or other procedures which can be applied rapidly. ... A screening test is not meant to be diagnostic. Persons with positive or suspicious findings must be referred to their physicians for diagnosis and treatment.”⁴⁸ Thus, screening tests are those that are widely applied to a population and require follow-up with a diagnostic test (if an individual screens positive). In general, a successful screening program must meet the following criteria:

- The condition screened for must have a significant burden on health.
- There must be effective early treatment for those who screen positive.
- The screening test must be valid (accurate) and reliable (reproducible).
- The test must be sufficiently sensitive and specific (see later).
- The screening test must be inexpensive and easy to perform.
- The screening test must be safe and acceptable to patients.
- The screening program must be cost-effective.

Cervical cytology screening for premalignant lesions of the cervix is an example of a successful screening program that fulfills all of these criteria. In contrast, although cytomegalovirus infection of the fetus and neonate creates a significant burden of disease, a screening program for this virus has no value because there is no successful intervention. Similarly, although cervicovaginal fetal fibronectin screening can identify as many as 60% of women destined for preterm birth before 28 weeks,⁵⁷ there is currently no effective intervention that could be applied to screen-positive women to reduce the risk for preterm delivery.⁵⁸

SENSITIVITY, SPECIFICITY, AND PREDICTIVE VALUES

It is critical to understand the characteristics of both screening and diagnostic tests. Sensitivity and specificity are characteristics inherent in the test and are independent of the prevalence of the disease.^{56,59} Sensitivity is the probability, expressed as a percentage, that if the disease is present, the test is positive. The numerator is the number of patients with the disease who have a positive test, and the denominator is the total number of diseased patients tested.

Specificity is the probability, expressed as a percentage, that if the disease is absent, the test is negative. The numerator is the number of subjects without disease who have a negative test, and the denominator is the total number of nondiseased subjects tested. Although the sensitivity and specificity of a test are important considerations when deciding whether or not to order a test, we become more interested in the predictive values when the test results have returned. Predictive values, unlike sensitivity and specificity, depend on the prevalence of the outcome in the population tested.

A positive predictive value (PPV) is the probability that if the test is positive, the subject has the disease. The numerator is the number of subjects with the disease who have a positive test, and the denominator is the total number of those with a positive test. A negative predictive value (NPV) is the probability that if the test is negative, the subject does not have the disease. The numerator is the number of subjects without disease who have a negative test, and the denominator is the total number of those with negative tests. Given the same sensitivity and specificity, the PPV will increase and the NPV will decrease as the prevalence rises. Likewise, as the prevalence decreases, the PPV decreases and the NPV increases.

These abstract concepts are best demonstrated with a clinical example. Peaceman and colleagues⁶⁰ performed a prospective cohort study at multiple centers to assess whether cervicovaginal fetal fibronectin could be used as a diagnostic test in women with symptoms of preterm labor; fetal fibronectin has also been assessed in other studies as a screening test.⁵⁷ In the Peaceman study, women with symptoms of early preterm labor were enrolled, and cervicovaginal swabs for fibronectin testing were obtained. Treating physicians and patients were blinded to the results of the fibronectin test, a strength of the study. The outcomes assessed were the occurrence of delivery within 7 days, within 2 weeks, and before 37 weeks' gestation. The results of the analysis of delivery within 7 days (Table 16-6) may be used as an example to illustrate sensitivity, specificity, and PPV and NPV.

Some would look at these results and the high NPV and suggest that fetal fibronectin testing is a useful tool in this setting to rule out an imminent delivery. Another way of looking at these same data would be to look closely at the low prevalence of delivery within 7 days (3%). After reading this article, the following questions emerge: Is it appropriate to use a diagnostic test in such a low-prevalence group? And, more importantly,

TABLE 16-6 Fetal Fibronectin (FFN) as Predictor of Delivery within 7 Days of Testing

	Delivery, <7 Days		Totals
	Yes	No	
FFN +	20	130	150
FFN -	3	610	613
Totals	23	740	763

Prevalence = $23/763 = 3\%$.

Sensitivity = $20/23 = 87\%$; specificity = $610/740 = 82\%$.

Positive predictive value = $20/150 = 13\%$; negative predictive value = $610/613 = 99.5\%$.

Data from Peaceman AM, Andrews WW, Thorp JM, et al: Fetal fibronectin as a predictor of preterm birth in patients with symptoms: a multicenter trial, *Am J Obstet Gynecol* 177:13, 1997.

TABLE 16-7 Fetal Fibronectin (FFN) as Predictor of Delivery within 7 Days of Testing: Hypothetical Analysis of a High-Prevalence Group

	Delivery, <7 Days		Totals
	Yes	No	
FFN +	99	117	216
FFN -	15	532	547
Totals	114	649	763

Prevalence = $114/763 = 15\%$.

Sensitivity = $99/114 = 87\%$; specificity = $532/649 = 82\%$.

Positive predictive value = $99/216 = 45\%$; negative predictive value = $532/547 = 97\%$.

what would be the impact of testing a higher-prevalence population (i.e., a population with a greater chance of preterm birth within 7 days)?

Physicians may look at these results differently. Some may argue that the treatment for preterm labor has risk, is of questionable efficacy, and is overused. Thus, a test that could avoid overtreatment with tocolytics might be helpful. Others could argue that the very high NPV with fetal fibronectin was obtained only when testing patients with a very low prevalence of preterm delivery and that no diagnostic test is needed in such a low-prevalence population. Furthermore, when this test is used in a higher-prevalence group, the NPV will decrease, making it much less useful. The value of a test with these characteristics is thus population dependent, according to the prevalence of preterm birth and the prevailing pattern of clinical care regarding tocolytic drugs for women with minimal symptoms.

For example, let us assume the population tested could be selected by adding clinical data to define a group with a higher prevalence of delivery within 7 days. Table 16-7 illustrates the effect of the increased prevalence on PPV and NPV. Remember that the sensitivity and specificity stay constant regardless of the disease prevalence. As expected, the PPV increases somewhat, and the NPV is decreased to 97%. Another way of looking at the NPV is that 3% of those with a negative test will go on to deliver within 7 days. Is this rate of false-negative testing acceptable for a patient who presents at 24 weeks with symptoms of preterm labor? Once again, the answer is determined by patient- and physician-related factors that are unique to the clinical setting.

LIKELIHOOD RATIOS

Likelihood ratios, another method to describe test performance, can be used to calculate post-test probabilities, just like predictive values. In literature from the United States, predictive values are commonly reported, whereas likelihood ratios are preferred in many European and South American journals. A likelihood ratio is defined as the probability of the test result in the presence of outcome, divided by the probability of the result in those without the outcome. Separate likelihood ratios are calculated for positive tests and negative tests. Likelihood ratios express how many times more (or less) likely a test result is to be found in those with the outcome compared with those without the outcome.

As an example, the positive likelihood ratios from the data on delivery within 7 days in the previously cited Peaceman

study⁶⁰ can be calculated as shown here, by dividing the proportion of women with a positive test who did deliver within 7 days, by the proportion of women with a positive test who did not deliver within 7 days:

$$\text{Positive likelihood ratio} = \frac{20/23}{130/740} = \frac{0.87}{0.18} = 4.8$$

Likelihood ratios can also be used to calculate a post-test probability (PPV), which is what we use in clinical practice. To do this, however, the pretest probability (prevalence) must be converted to pretest odds using the following formula:

$$\text{Odds} = \text{probability of event} / (1 - \text{probability of event})$$

$$\text{Probability} = \text{odds} / (1 + \text{odds})$$

Using the Peaceman data for a positive test, the prevalence of delivery within 7 days is 3%. In odds, this translates to 0.031. Then, we can calculate the post-test odds using the following formula:

$$\text{Pretest odds} \times \text{likelihood ratio} = \text{post-test odds}$$

In this case, the post-test odds are $0.031 \times 4.8 = 0.1488$. When the post-test odds are converted to a post-test probability (i.e., a PPV), the result is $0.1488 / 1.1488 = 13.0\%$, the same as the PPV calculation we saw in Table 16-6.

Looking at the positive and negative likelihood ratios is another way to assess the utility of a test, and these ratios can be used to convert pretest probabilities to post-test probabilities. For the latter, this can be somewhat cumbersome, and many individuals prefer to simply use a 2×2 table to calculate predictive values.

RECEIVER OPERATING CHARACTERISTIC CURVES

Although test results may be categorical (i.e., positive or negative), they are more often expressed in clinical medicine as a point on a continuum. Clinicians evaluate test results and try to discriminate “normal” from “abnormal.” Although it would be ideal to have tests that are simultaneously very sensitive and specific, this is seldom the case, so we are faced with selecting thresholds that trade between degrees of sensitivity and specificity. A graphic method that makes these tradeoffs explicit and aids in the selection of cut points is the *receiver operating characteristic (ROC) curve*. The sensitivity is placed on the y axis versus 1 minus the specificity (the false-positive rate) on the x axis for the entire range of cut points. Tests that discriminate well tend to generate a curve that occupies the upper left corner of the graph. Poorly discriminating tests generate a curve that falls along the diagonal that follows from the lower left corner to the upper right corner. A 45-degree line along this diagonal describes a nondiscriminating test, which is one that has no threshold value.

ROC curves have three primary uses: to select a cut point for an individual test, to assess the overall accuracy of the individual test, and to compare the overall accuracy of two tests for the same condition. The last is most often done by calculating and comparing the area under the ROC curve.

An example of the clinical use of ROC curves in selecting an appropriate cut point was published by Owen and colleagues⁶¹ and focused on mid-trimester transvaginal cervical

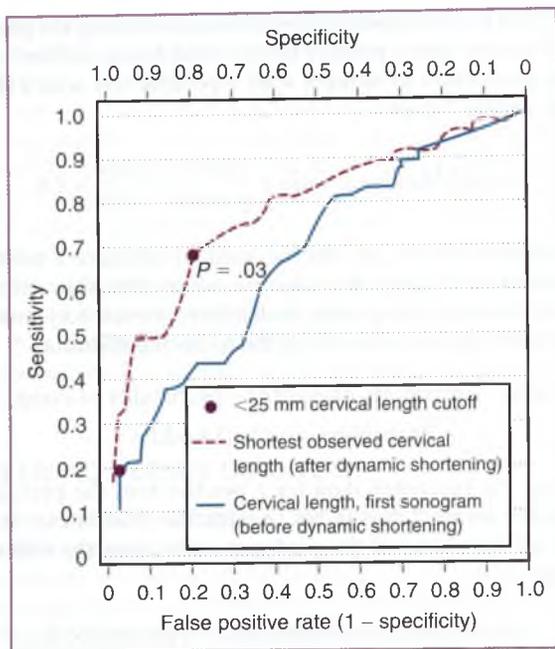

Figure 16-4 Comparison of receiver operating characteristic (ROC) curves for cervical length. ROC curves of cervical length cutoffs for the prediction of spontaneous preterm birth before 35 weeks' gestation. (From Owen J, Yost N, Berghella V, et al: *Mid-trimester endovaginal sonography in women at high risk for spontaneous preterm birth*, JAMA 286:1340-1348, 2000.)

length measurements to predict preterm birth before 35 weeks' gestation in high-risk women. To assess this question, the authors performed a multicenter prospective study of transvaginal ultrasound cervical measurements every 2 weeks in 183 women with a prior birth at less than 32 weeks. Figure 16-4 shows a comparison of ROC curves for shortest observed cervical length to the cervical length at the first examination, for the prediction of spontaneous preterm birth before 35 weeks' gestation. Figure 16-4 suggests the following:

1. The shortest observed cervical length is a better discriminator than the initial cervical length for the prediction of spontaneous preterm birth at less than 35 weeks.
2. Although the shortest observed cervical length is better than the initial examination, neither test is particularly discriminating (as evidenced by the fact that neither curve is very close to the left upper corner of the graph).
3. The optimal cut point for the shortest observed cervical length is 25 mm. At this level, however, the sensitivity is only about 70%, with a false-positive rate of about 20%.

Iams and colleagues⁶² reported a study of several tests to predict preterm birth in pregnant women. Cervical examinations by digital examination (expressed as a Bishop score) and

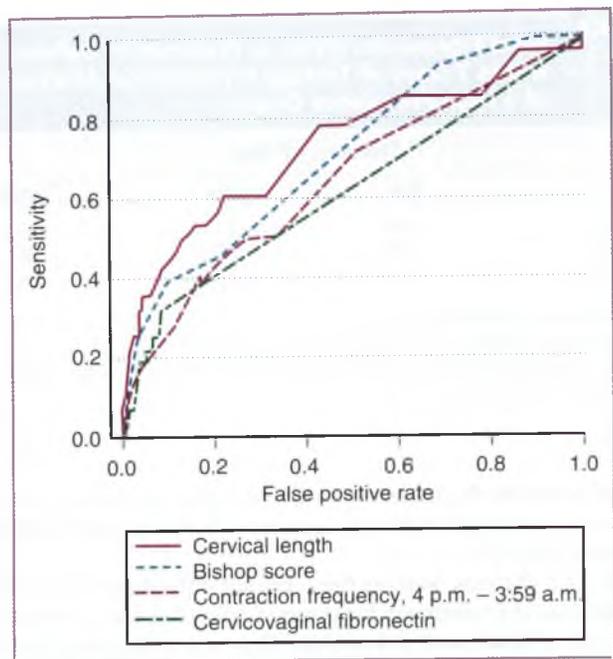

Figure 16-5 Comparison of tests to predict preterm birth. Receiver operating characteristic curves for cervical length, Bishop score, frequency of contractions, and presence or absence of fetal fibronectin in cervicovaginal secretions at 27 to 28 weeks' gestation in the prediction of spontaneous preterm delivery (less than 35 weeks). (From Iams JD, Newman RB, Thom EA, et al, for the National Institute of Child Health and Human Development Network of Maternal-Fetal Medicine Units: *Frequency of uterine contractions and the risk of spontaneous preterm delivery*, N Engl J Med 346:250-255, 2002.)

by ultrasound (expressed as the length of the cervical canal) were compared with monitored uterine contraction frequency and fetal fibronectin in cervicovaginal secretions using ROC curves. The performance of each test was displayed on a common graph of their ROC curves (Fig. 16-5). Cervical length by ultrasound, although far from an ideal test, had the best performance, as the uppermost line of the curves displayed.

Summary

This overview of study design and methods to analyze and report data in perinatal medicine can serve as a starting point to integrate research data appropriately into clinical care. As any skill, it is mastered by frequent repetition and especially by analyzing and presenting one's own data with one of the methods described.

Obstetric Imaging

JOSHUA A. COPEL, MD | THOMAS R. MOORE, MD

Performing and Documenting the Fetal Anatomy Ultrasound Examination

THOMAS R. MOORE, MD | JOSHUA A. COPEL, MD

The mid-trimester fetal ultrasound examination (“anatomy scan”) serves as an important checkpoint for evaluation of the pregnancy and its potential risks. It affords an opportunity to compare obstetric dating with fetal biometric measures, and it permits, prior to fetal viability, identification of important structural abnormalities that may significantly alter neonatal prognosis and management. Finally, it allows identification of maternal abnormalities such as uterine fibroids and placenta previa that may require major alterations in the obstetric management plan before delivery.

The mid-trimester fetal anatomy scan is commonly performed to screen for fetal structural anomalies.¹ The Eurofetus study,² which assessed the accuracy of mid-trimester sonography in identifying fetal anomalies in a large unselected population examined after birth, reported that slightly more than half of the structural defects identified postnatally had been detected on ultrasound.

Subsequently, Gagnon and colleagues³ evaluated the existing literature regarding the accuracy of second-trimester sonography to identify fetal anomalies and reported that a prenatal ultrasound examination at 18 to 20 weeks’ gestation can detect major structural anomalies in approximately 60% of cases.

Categorizing Types of Obstetric Ultrasound Examinations

The content of each obstetric ultrasound examination, and its report, depend on the level of detail required to address the specific clinical indication that occasioned the request for evaluation. The various types of examinations are categorized by the Current Procedural Terminology (CPT) Code Set, which is maintained by the American Medical Association through its CPT Editorial Panel.⁴ The CPT Code Set describes a host of medical, surgical, and diagnostic services provided in virtually every area of medicine and is designed to facilitate reliable and uniform communication regarding medical and diagnostic services among providers, patients, and accreditation organizations. The currently sanctioned and utilized CPT codes and their descriptions are listed in Table 17-1. CPT code books are published annually with updates in every edition. New versions become active each calendar year, and practitioners should review changes to codes they use each year. CPT codes are also required for all electronically submitted health care bills.

All ultrasound examinations require a report in the patient’s medical record, including the indication for the study, relevant findings, and their interpretation.^{5,6} The content of the report depends on the indication for the ultrasound study, and it should include enough information for other clinicians to incorporate the findings into the patient’s care.

In the case of obstetric imaging, the CPT guidelines for each examination type provide very specific elements that must be evaluated and reported in the fetus, placenta, and uterus (Box 17-1).

Basic Mid-Trimester Fetal Anatomy Scan

The “Standard Examination” or basic mid-trimester fetal anatomy scan⁶ (CPT 76805) should include an evaluation of the following⁵:

- Fetal cardiac activity
- Fetal number (and chorionicity if multifetal pregnancy)
- Fetal structural dimensions and corresponding gestational age estimates
- Anatomy of major organ structures
- Placental appearance and location
- Amniotic fluid
- Uterine and adnexal anatomy including lower uterine segment and cervix

The examination should begin with an overview of the uterine contents taken in successive sagittal and transverse sections so that fetal number, viability, lie, placental position, and amniotic fluid can be determined. This information will guide successive transducer placements to facilitate obtaining targeted images to demonstrate specific anatomic features and measurements.

Next, fetal biometry should be obtained for comparison with existing pregnancy dating. The specific fetal structural dimensions to be obtained for gestational age estimation are summarized in Box 17-2.⁷

Having collected the fetal biometric measurements, the next task is to demonstrate fetal anatomy for the major organ systems. The specific features appropriate to a mid-trimester standard examination are summarized in Box 17-3.⁷

In addition to sequential examination of the fetal anatomy, examination of the placenta, umbilical cord, and amniotic fluid facilitates risk estimation for potential obstetric problems such as third-trimester hemorrhage and poor fetal growth. Box 17-4 summarizes the placenta, cord, and amniotic fluid elements that should be evaluated.⁷

Finally, the ovaries, uterus, and cervix should be evaluated. This assessment should include imaging of both adnexal areas with particular attention to cysts and masses. The contour of the uterus should be imaged with particular attention to the presence of müllerian anomalies (e.g., arcuate, bicornuate, septate) and masses such as myomata. The configuration of the lower uterine segment should be assessed, especially for the presence of placenta previa, vasa praevia and obstructing fibroids. The cervix should be visualized transabdominally, and if images are suboptimal or abnormal, endovaginal scanning should be performed.⁶

TABLE 17-1
CPT Codes for Obstetric Ultrasound Examinations*

Code	Type of Examination	Description
76801	First trimester	Ultrasound, pregnant uterus, real time with image documentation, fetal and maternal evaluation (<14 weeks 0 days), transabdominal. This code is applied for first-trimester ultrasound scans.
76802	Routine obstetric screening after first trimester	76801 plus each additional gestation
76805		Ultrasound, pregnant uterus, real time with image documentation, fetal and maternal evaluation (≥14 weeks 0 days), transabdominal. This code is used for fetal size and anatomy screening if there are no suspected abnormalities or high-risk conditions.
76811	Fetal and maternal evaluation plus detailed fetal anatomic examination	Ultrasound, pregnant uterus, real time with image documentation, fetal and maternal evaluation plus detailed fetal anatomic examination, transabdominal. This code is used only once per pregnancy and is applied when abnormalities are suspected by patient history or by finding during a prior ultrasound examination.
76812	Limited	76811 plus each additional gestation.
76815		Ultrasound, pregnant uterus, real time with image documentation, limited (e.g., fetal heartbeat, placental location, fetal position, and/or qualitative amniotic fluid volume), one or more fetuses. This code is applied for scanning to establish fetal or placental position and for biophysical or amniotic fluid assessment.
76816	Repeat	Ultrasound, pregnant uterus, real time with image documentation, follow-up (e.g., reevaluation of fetal size by measuring standard growth parameters and amniotic fluid volume, reevaluation of organ systems suspected or confirmed to be abnormal on a previous scan), transabdominal. This code is applied for all follow-up or repeat examinations.
76817	Transvaginal	Ultrasound, pregnant uterus, real time with image documentation, transvaginal. This code is applied for all transvaginal scanning during pregnancy.
76818	Fetal BPP with NST	Fetal well-being is assessed via the fetus' movements, tone, and breathing and amniotic fluid volume. An NST is also performed.
76819	BPP without NST	BPP only: movements, breathing, tone, amniotic fluid.

*Note: Nonvisualization of any of the required fetal or maternal components due to fetal position, gestational age, or maternal body habitus must be clearly noted in the ultrasound report.
BPP, biophysical profile; NST, nonstress test.

BOX 17-1 ELEMENTS FOR OBSTETRIC ULTRASOUND PERFORMANCE AND REPORTING REQUIRED BY MAJOR CPT CODE

76801: PREGNANCY LESS THAN 14 WEEKS

Number of gestational sacs and fetuses
Gestational sac or crown-rump measurement appropriate for gestational age
Description of the maternal uterus and adnexa
Qualitative assessment of amniotic fluid volume and gestational sac shape

76805: PREGNANCY OF 14 WEEKS OR MORE

Number of gestational/chorionic sacs and fetuses
Amniotic fluid
Four-chamber heart
Intracranial, spinal, abdominal anatomy
Placenta location
Umbilical cord insertion site
Maternal adnexa if visible

76811: PREGNANCY, WITH DETAILED MATERNAL AND FETAL EVALUATION

All elements specified for 76805 (see Box 17-2)
PLUS description of:
Third and fourth cerebral ventricles
Cerebellar lobes with measurement
Cerebellar vermis
Cisterna magna with measurement
Nuchal thickness measurement (15 to 20 weeks)
Palate
Thorax: any masses, effusions, integrity of the diaphragm
Ribs
Abdominal cavity: presence of ascites

Documentation of Ultrasound Examinations

The requisite images required for the level of the examination performed should be obtained, labeled, and stored. Images should remain available as required by local statutory regulations but usually for at least 5 years.

A report summarizing the study should be prepared which contains the following⁸:

- Patient identifying information
- Date of the examination
- The indication for the procedure
- The type of examination
- The referring provider
- Gestational age by established dates
- Number of fetuses and chorionicity, if appropriate
- Fetal biometry with predicted gestational age
- Principal findings, normal, abnormal, and poorly visualized
- Differential diagnosis for any abnormalities
- Recommendations for pregnancy management or further ultrasound examinations

It is important for documentary completeness and reporting consistency that the required elements for each ultrasound procedure, as specified in the CPT Code Set, be obtained and provided in the summary report. If some elements were not obtained, that fact should be reported along with any relevant technical factors (e.g., gestational age, maternal body habitus).

BOX 17-2 MID-TRIMESTER FETAL BIOMETRY AND GESTATIONAL AGE ASSESSMENT (CPT 76805)**BIPARIETAL DIAMETER (BPD)**

Imaging elements:

- Cross-sectional view at the level of the thalami
- Linear midline falx cerebri interrupted by the cavum septi pellucidi and thalami
- Insonation angle of 90 degrees to the falx
- No cerebellum visible

Measurements: from the outer table of the proximal parietal bone to the inner table of the distal parietal bone, bisecting the intervening thalami.

HEAD CIRCUMFERENCE (HC)

Imaging elements: uses the same plane as for BPD.

Measurements: If a machine-generated ellipse is used, the caliper is employed to trace the outer edges of the cranial bones visible at the level of the BPD, and the machine calculates the circumference from the caliper trace. Alternatively, the two largest diameters are obtained with 90 degrees between them; the transverse diameter should extend from the outer table of the proximal parietal bone to the outer table of the distal parietal bone; the longitudinal diameter should extend from the outer edges of the occipital to the frontal bone along the midline falx (occipital frontal diameter [OFD]).

The HC is calculated as the product of $1.62 \times (\text{BPD} + \text{OFD})$.

ABDOMINAL CIRCUMFERENCE (AC)

Imaging elements:

- A circular, cross-sectional view is obtained at a level cephalad of the umbilical vein entry into the abdomen and cephalad

of the kidneys but caudad of the thoracic structures (e.g., heart and lungs).

The umbilical vein should be visible at the level of the portal sinus.

The stomach bubble should be present.

The kidneys and the umbilical cord insertion should not be visible.

Measurements: If used, a machine-generated ellipse is obtained by tracing the outer edges of the abdominal skin visible in the image, and the machine calculates the circumference from the caliper trace. Alternatively, the two largest diameters are obtained with 90 degrees between them: The longitudinal diameter (LAD) should bisect the circular plane from the outer aspect of the fetal spine to the skin edge anteriorly; the transverse diameter (TAD) should extend from outer skin to outer skin.

The AC is calculated as the product of $1.57 \times (\text{LAD} + \text{TAD})$.

FEMUR LENGTH

Imaging elements:

The femur can be seen at an angle extending 45 degrees from the fetal spine. Using an insonation angle of 90 degrees, both ends of the ossified femoral metaphysis should be visible.

Measurements: The maximum length of the ossified diaphysis is measured without including the distal femoral epiphysis.

Adapted from International Society of Ultrasound in Obstetrics and Gynecology Clinical Standards Committee: Practice guidelines for performance of the routine mid-trimester fetal ultrasound scan, Ultrasound Obstet Gynecol 37:116–126, 2011.

BOX 17-3 MID-TRIMESTER FETAL ANATOMY ASSESSMENT ELEMENTS (CPT 76805)

Head and face

- Cranial bones
- Falx cerebri

The Detailed Maternal and Fetal Evaluation Study

The standard mid-trimester fetal anatomy scan should be performed and reported in accordance with the requirements of CPT 76805. However, there are circumstances when targeted and more detailed fetal evaluation study is necessary. Because this type of examination requires significantly more time and technical expertise, a separate CPT code, 76811, is available (see Table 17-1). Implicit in the assignment of CPT 76811 is that detailed fetal, placental, and the uterine imaging will be obtained and that these findings will be evaluated in the context of maternal and fetal risk profiles.

The “Level II Scan,” using the detailed fetal and maternal evaluation code of 76811, should not be applied to routine anatomy scans that are typically performed in general obstetric providers’ offices during most pregnancies⁹; nor is it intended for routine use by imaging specialists who may be asked to scan women who are without increased risk of a fetal anomaly. Rather, this code and its required components are intended for use in cases in which there is a known or strongly suspected fetal anatomic or genetic abnormality or increased risk for fetal abnormality on the basis of family history, maternal age, or maternal medical conditions (e.g., diabetes, teratogen exposure, abnormal aneuploidy). Simply doing a more thorough job than that prescribed for a Standard Examination is not sufficient to utilize this code; there must be an indication beyond routine fetal anatomy screening.

In general, this specialized ultrasound and medical evaluation should be performed only once per pregnancy by any practice. After a detailed fetal anatomic examination and maternal

risk assessment is completed, all subsequent procedures should be considered “follow-up” and coded as CPT 76816.

The typical imaging elements required for CPT 76811 are listed in Box 17-1. Although these elements are usually included in every examination, they are not necessary or sufficient for all. For example, if there is a family history of polydactyly, counting fingers and toes is essential.

Typical Images Obtained in a Level II Scan

Typical images obtained in a detailed fetal and maternal ultrasound examination (CPT 76811) are presented in Figures 17-1 through 17-38.

Doppler Ultrasound: Select Fetal and Maternal Applications

MERT OZAN BAHTIYAR, MD | JOSHUA A. COPEL, MD

Gray-scale ultrasound is one of the most important tools in contemporary obstetric practice. Despite its frequent use, gray-scale ultrasound is limited in assessing the fetal hemodynamic status. Addition of color, power, and pulsed Doppler ultrasound functions greatly improves understanding of fetal circulation and fetal hemodynamic status.

Frequency shifts from moving targets is detected by Doppler ultrasound. Each vessel has a unique blood flow velocity waveform (FVW). FVWs can be analyzed mathematically by computing certain ratios. Commonly used computed ratios include the ratio of systolic to diastolic blood flow velocity (S/D), the pulsatility index (PI), and the resistance index (RI) (Fig. 18-1).

This chapter reviews four of the most commonly assessed fetal and maternal blood vessels in regard to optimal technique to obtain FVWs and briefly discusses their utility in clinical practice.

Umbilical Artery

ANATOMY

The umbilical cord inserts to the placenta, usually near the center of its fetal surface, but it may attach at any point. At term, the umbilical cord is usually 1 to 2 cm in diameter and 30 to 90 cm in length (average, 55 cm). The umbilical cord usually has two arteries and one vein, which are surrounded by mucoid connective tissue (Wharton jelly) (Fig. 18-2).

TECHNIQUE

Number of Vessels

The number of umbilical arteries (UAs) should routinely be documented during ultrasound examination. There are several different techniques. One of the most common methods is to document two UAs traveling around the fetal bladder. To achieve this image, the umbilical cord insertion to the fetus is visualized in a cross section of the fetal abdomen. The color Doppler box is then placed over the fetal abdomen, and the ultrasound probe is angled toward the fetal pelvis while the cord insertion is kept in view. Two UAs are visualized with color Doppler traveling around the fetal bladder. UAs arise from the anterior branch of the internal iliac arteries; if the wrong angle is used, both internal iliac arteries may be visualized and can be mistaken for UAs (Fig. 18-3).

Doppler Flow Pattern

A freely floating loop, portion, or segment, located approximately at the middle of the umbilical cord, is identified.

Attention should be paid to avoid compression of the umbilical cord between the extremities or against the uterine wall. Such external compression may affect the flow pattern by changing the vascular resistance.

Once a target loop is identified, the color Doppler box is placed over the umbilical cord. The UAs can be visually identified based on their number, pulsatile color flow pattern, caliber, and direction of blood flow. The color flow scale and gain are adjusted appropriately to ensure that the velocity of the flow in question is within the scale. A pulsed Doppler gate is placed over the UA. The gate size is adjusted appropriately to sample only the UA (unless the intent is to sample both the UA and the umbilical vein). Most of the indices are calculated ratios (e.g., S/D, RI, PI) and do not require calculation of absolute flow velocities. However, the angle of insonation (i.e., the angle between the ultrasound beam and the direction of flow) should still be kept as low as possible during Doppler assessment to maximize the sizes of both systolic and diastolic flow components (see Fig. 18-1 and Video 18-1).

CLINICAL USE

Single Umbilical Artery

Single UA is the most common congenital abnormality of the umbilical cord. The prevalence of single UA ranges from 0.2% to 11%, depending on the population studied.¹⁻⁵ In a recent population-based retrospective cohort analysis⁶ of 203,240 fetuses and neonates, 0.44% were found to have single UA, and 0.37% had isolated single UA. Single-UA fetuses and neonates had a 6.77 times greater risk of congenital anomalies and a 15.35 times greater risk of chromosomal abnormalities. The most common congenital anomalies in chromosomally normal fetuses and neonates were genitourinary (6.48%), followed by cardiovascular (6.25%) and musculoskeletal (5.44%). With isolated single UA, placental abnormalities (odds ratio [OR] = 3.63, 95% confidence interval [CI], 3.01 to 4.39), hydramnios (OR = 2.80; CI, 1.42 to 5.49), and amniocentesis (OR = 2.52; CI, 1.82 to 3.51) occurred more frequently than with three-vessel cords. Neonates with single UA or isolated single UA had increased rates of prematurity, growth restriction, and adverse neonatal outcomes.⁶

Fetal Growth Restriction

During normal pregnancy, there is a progressive increase in end-diastolic velocity in the UA due to decreasing downstream impedance to flow as the placental vessels grow. This causes all of the UA Doppler indices to become progressively lower across the third trimester (Fig. 18-4).

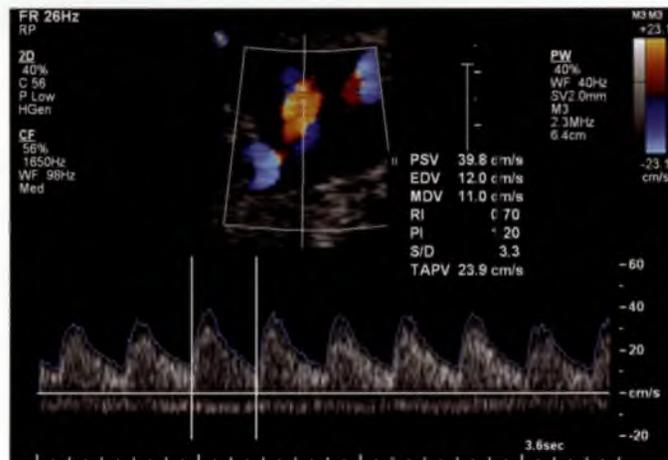

Figure 18-1 Measured and calculated Doppler ultrasound indices. Where PSV = peak systolic velocity, EDV = end-diastolic velocity, MDV = mean diastolic velocity, RI = resistance index, PI = pulsatility index, S/D = ratio of systolic to diastolic blood pressure, and TAPV = time-averaged peak velocity, the following equations apply:

$$\frac{S}{D} = \frac{PSV}{EDV}$$

$$RI = \frac{PSV - EDV}{PSV}$$

$$PI = \frac{PSV - EDV}{TAPV}$$

Figure 18-2 Placental cord insertion.

There is a progressive worsening of the UA FVW due to increasing systemic resistance in growth-restricted pregnancies with risk of stillbirth and asphyxia. Use of UA Doppler studies in small-for-gestational-age pregnancies and in pregnancies with preeclampsia has been associated with reduction in perinatal mortality.⁷ However, these changes should be seen as a marker of a high-risk condition and an indication for further surveillance and should not be used in isolation as an indication for delivery (Fig. 18-5).

Middle Cerebral Artery

ANATOMY

The middle cerebral artery (MCA) is the larger terminal branch of the internal carotid artery. It arises from the circle of Willis, a roughly shaped heptagon of arteries located on the ventral

Figure 18-3 A and B, Documentation of two umbilical arteries. 3V cord, three-vessel cord.

surface of the brain (see Fig. 18-1). Arteries forming the circle of Willis give rise to numerous perforating branches, which serve structures located deep to their origins, and to the large cortical branches (anterior, middle, and posterior cerebral arteries) (Fig. 18-6).⁸

TECHNIQUE

Correct technique is critical in determining the MCA peak systolic velocity (PSV). An axial section of the brain, including the thalami and cavum septum pellicidum, should be obtained. The color or power Doppler box is placed over the midline anterior to the thalami, allowing identification of the circle of Willis. The MCA is examined with a small, pulsed Doppler sample volume as close as possible to its origin. It does not matter whether the near- or far-side vessel is interrogated, as long as the angle between the ultrasound beam and the direction of blood flow is kept as close as possible to 0 degrees. For standardization and reliability purposes, the point of measurement is very important, because the PSV decreases as the distance from the origin increases. The highest point of the waveform is measured (Fig. 18-7 and Video 18-2).^{9,10} The peak velocity and the shape of the PVW become highly variable during episodes of fetal breathing, so sampling during fetal breathing is unreliable. Excessive amount of pressure to the fetal head through the ultrasound probe may also change the waveform, reducing apparent end-diastolic flow.

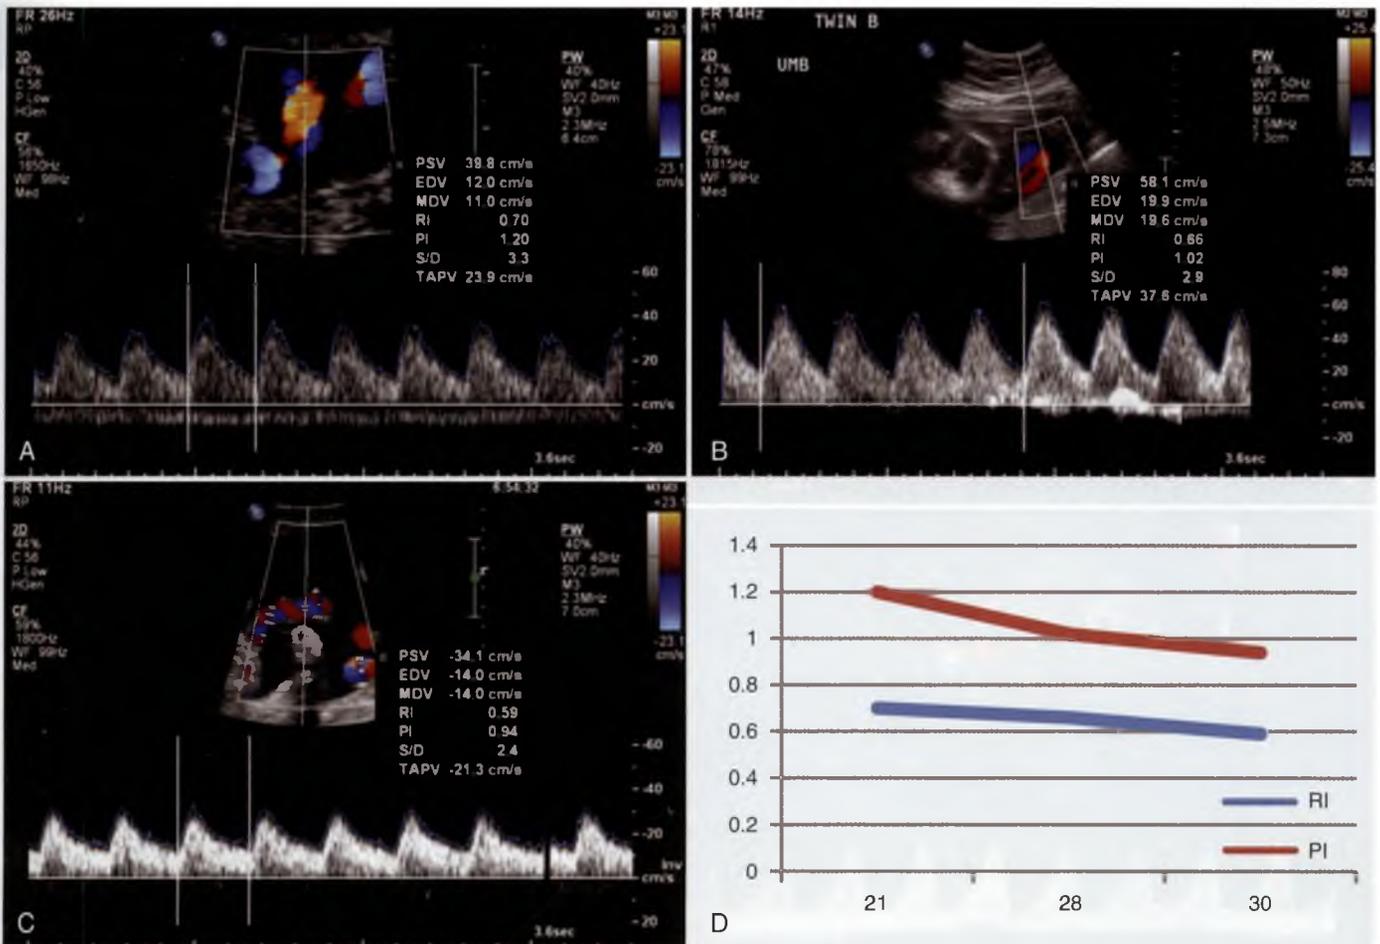

Figure 18-4 Umbilical artery S/D ratio during normal pregnancy. A, 21 weeks. B, 28 weeks. C, 30 weeks. D, Resistance index (RI) and pulsatility index (PI) values from 21 to 30 weeks. See Figure 18-1 for list of definitions for remaining abbreviations.

CLINICAL USE

The MCA is commonly used to assess suspected fetal anemia and to determine presence of “brain sparing” in intrauterine growth restriction (IUGR).

Fetal Anemia

The PSV in the MCA is a precise, noninvasive way to detect fetal anemia.⁹ Moderate or severe anemia is predicted by values of PSV in the fetal MCA greater than 1.5 times the median for gestational age, with a sensitivity of 100% and a false-positive rate of 12% in fetuses with red blood cell alloimmunization (Table 18-1). Increased MCA PSV can also reliably predict anemia in fetuses with parvovirus B19 infection.¹¹ If velocimetry indicates fetal anemia, a cordocentesis should be performed to determine the fetal hematocrit (Video 18-1). An intrauterine blood transfusion should be performed once anemia has been confirmed. It has been shown that MCA PSV can be reliably used even in fetuses with two previous transfusions.¹²

Intrauterine Growth Restriction

The diagnosis of intrauterine growth restriction (IUGR) is most commonly established by obtaining an ultrasound estimated fetal weight (EFW), based on multiple fetal biometric measurements, that falls below the 10th percentile for the particular

gestational age. Fetal growth restriction has multiple etiologies, including genetic and syndromic causes, viral infection, and placental dysfunction.¹³

Increases in placental blood flow resistance and perceived fetal hypoxemia lead to brain sparing. This is associated with a decrease in the Doppler cerebroplacental ratio (CPR),¹⁴ which is defined as the MCA RI divided by the UA RI¹⁵ (Fig. 18-8), or with increased end-diastolic velocity in the cerebral circulation manifested as decreased MCA PI (Fig. 18-9),¹⁶ or both.

Ductus Venosus

ANATOMY

The ductus venosus (DV) is a small vessel that connects the intraabdominal umbilical vein with the inferior vena cava (IVC). It is approximately 0.7 mm in diameter at 18 weeks and 1.7 mm at 40 weeks of gestation.

TECHNIQUE

The DV may be identified in various planes. The most common approaches are the sagittal and oblique parasagittal views and the cross-sectional abdominal view. In sagittal views, the umbilical cord insertion to the abdomen is identified first. The UAs

Modified from Mari G, Deter R, Carpenter R, et al: Noninvasive diagnosis by Doppler ultrasonography of fetal anemia due to maternal red-cell alloimmunization. Collaborative Group for Doppler Assessment of the Blood Velocity in Anemic Fetuses, *N Engl J Med* 342:9-14, 2000.

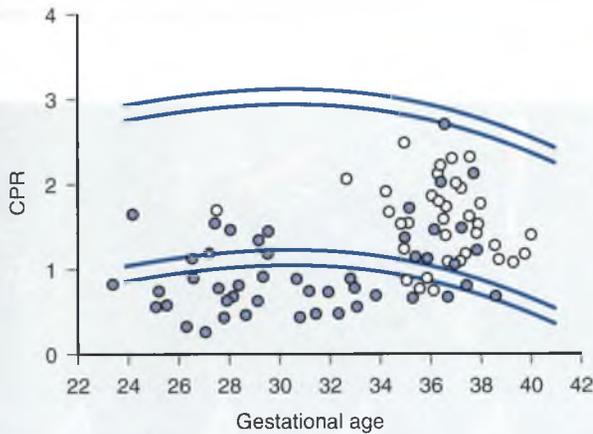

Figure 18-8 Cerebroplacental ratio (CPR) in relation to gestational age. The curves indicate the 5th, 10th, 90th, and 95th percentile values for pregnancies with and without morbidity and perinatal complications. The interval between Doppler imaging and delivery was less than 2 weeks. Open circles, <10th percentile, no morbidity; filled circles, <10th percentile, with morbidity. (From Bahado-Singh R, Kovanci E, Jeffres A, et al: *The Doppler cerebroplacental ratio and perinatal outcome in intrauterine growth restriction*, *Am J Obstet Gynecol* 180:750-756, 1999.)

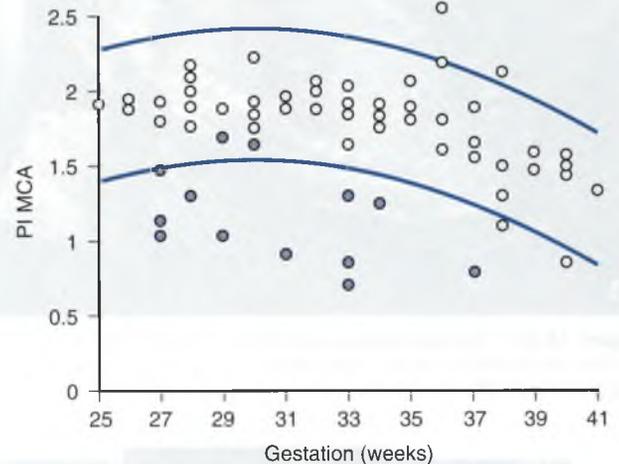

Figure 18-9 Middle cerebral artery pulsatility index (PI MCA) as a function of gestational age in weeks. Open circles, pregnancies with normally grown fetuses. Filled circles, pregnancies with growth-restricted fetuses. (From van den Wijngaard JA, Groenenberg IA, Wladimiroff JW, et al: *Cerebral Doppler ultrasound of the human fetus*, *Br J Obstet Gynaecol* 96:845-849, 1989.)

travel caudally, whereas the umbilical vein initially travels cephalad and then, following the liver contour, turns sharply posteriorly, toward the IVC. The DV arises from the apex of the umbilical vein, where it is traveling posteriorly, and is directed toward the insertion of the IVC and the right atrium (Figs. 18-10 and 18-11, and Video 18-3).

Because of the fetal position, it may not be possible to obtain the DV signal in sagittal views. The DV can also be identified with color Doppler imaging in a cross-sectional view of the abdomen at the level of the stomach. However, in this approach, visual confirmation of the DV is often challenging, and the operator must often rely on a combination of color flow mapping and the blood flow pattern.

The DV has a triphasic blood flow pattern, with persistent forward flow throughout the cardiac cycle. Because there is no intervening valvular structure, the DV flow pattern directly reflects pressure changes within the right heart. The hepatic

vein and IVC, which are in close proximity, have biphasic blood flow patterns. Blood normally flows retrograde during end diastole in the hepatic vein and IVC, but would be an abnormal finding for the DV (Fig. 18-12).

The DV signal should be obtained during fetal rest and in the absence of fetal breathing movements. Because there is no intravascular valvular structure at the DV-IVC junction, changes in intrathoracic pressures are directly reflected in DV flow patterns.

CLINICAL USE

First Trimester

Doppler ultrasound assessment of the DV in the first trimester, between 10 and 14 weeks' gestation, has been suggested as a tool to identify fetuses at increased risk for chromosomal anomalies. In approximately 90% of fetuses with chromosomal anomalies,

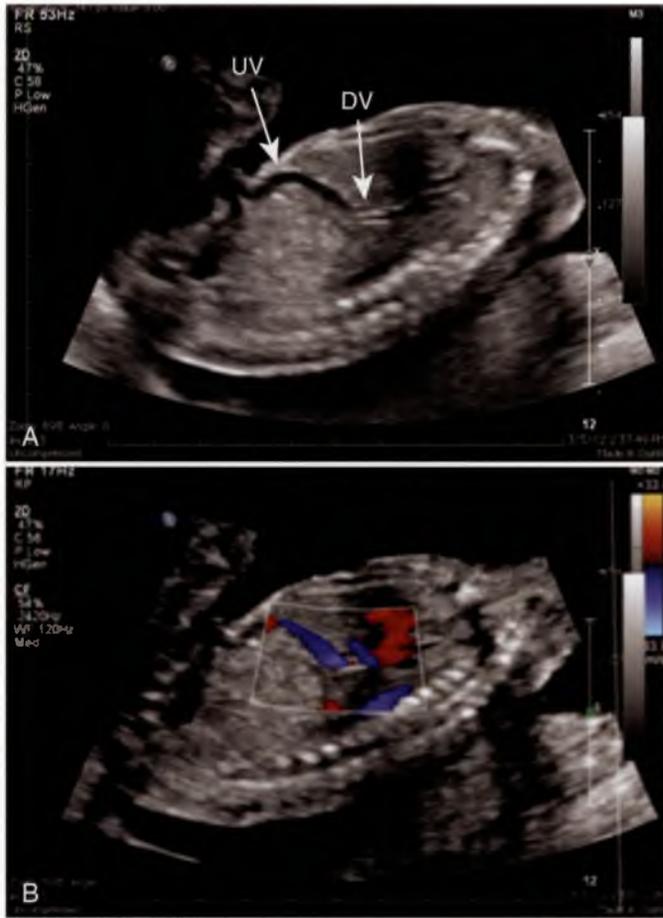

Figure 18-10 Ductus venosus (DV). Umbilical vein (UV) and DV can be visualized in midline sagittal view in gray scale (A) or color Doppler mode (B).

Figure 18-11 Hepatic vein (HV), ductus venosus (DV), and inferior vena cava (IVC) merge immediately before draining in to the right atrium.

reverse or absent flow during atrial contraction has been reported. A similar blood flow pattern is seen in only 3.1% of chromosomally normal fetuses.¹⁷

Abnormal DV blood flow in chromosomally normal fetuses with increased nuchal translucency has also been suggested to identify those with an underlying major cardiac defect in 31% to 63% of cases.^{18,19}

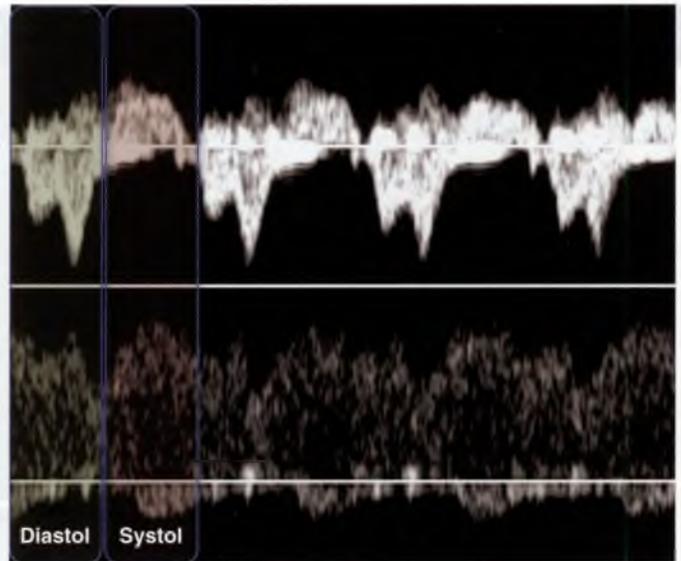

Figure 18-12 Doppler blood flow velocity waveforms at the atrio-ventricular valve (top) and ductus venosus (bottom) synchronized for the cardiac cycle.

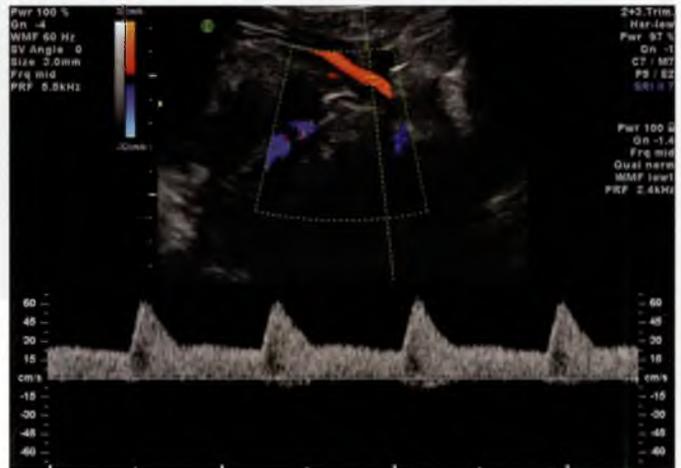

Figure 18-13 Uterine artery Doppler blood flow velocity waveform.

Second and Third Trimester

Growth-restricted fetuses with absent or reverse DV flow during atrial systole have worse perinatal outcomes.²⁰ Absent or reverse flow during atrial systole in the DV is a very strong indication of a pending fetal demise within 1 week.²¹ In most IUGR fetuses, sequential deterioration of venous flow precedes biophysical profile score deterioration.²²

Uterine Artery

ANATOMY

The uterine arteries arise from the anterior division of the internal iliac artery. They cross the ureter anteriorly and travel in the cardinal ligament, then through the inferior portion of the broad ligament, to reach the uterus. Eventually, the uterine artery typically anastomoses with the ovarian artery.

TECHNIQUE

The ultrasound probe is placed above the inguinal canal and directed into the parauterine area in the region of the lower uterine segment. The iliac artery and vein can be seen running obliquely along the pelvic side wall. Using color Doppler for guidance, the operator can then rotate the probe, moving the upper end medially until the uterine artery is recognized as it crosses the iliac vessels (Fig. 18-13 and Video 18-4).

Impedance to flow in the uterine arteries decreases with gestation. The initial fall (until 24 to 26 weeks) is thought to be caused by trophoblastic invasion of the spiral arteries, but a continuing fall in impedance may be explained in part by a persisting hormonal effect on elasticity of arterial walls. Impedance in the uterine artery on the same side as the placenta is lower than on the contralateral side.

CLINICAL USE

Uterine artery Doppler studies reflect flow impedance in the uteroplacental circulation, although measurement has not been proven to reduce perinatal morbidity or mortality. In conditions such as preeclampsia and fetal growth restriction, abnormal uterine artery Doppler studies indicate inadequate placentation and have been correlated with histologic evidence of defective replacement of spiral arteries by maternal trophoblast.

Clinical Applications of Three-Dimensional Sonography in Obstetrics

DOLORES H. PRETORIUS, MD | SEERAT AZIZ, MD |
DEBORAH A. D'AGOSTINI, RDMS | REENA MALHOTRA, MD |
TRACY L. ANTON, RDMS | LORENE E. ROMINE, MD

Three-dimensional (3D) and four-dimensional (4D) ultrasonography (US) have developed significantly over recent years, and both radiologists and obstetricians have contributed to the large body of work in the medical literature.¹ 3D and 4D US are also referred to as volume sonography.

Two-dimensional (2D) US remains the backbone of sonographic imaging, to which 3D and 4D US have contributed an additional layer of problem-solving tools. This chapter addresses the obstetric applications of 3D US.

Volume Sonography: Basics

Volume data sets are typically obtained with a 3D mechanical probe by performing an automated volume sweep at a constant speed. This volume information is displayed on the 2D screen in three perpendicular planes—the X, Y and Z planes. Manipulation of the images in these planes is then performed, focused at the appropriate anatomic level of concern. A reference dot facilitates multiplanar localization in the three planes. In addition, a 3D rendered image may be displayed from the volume in the area of concern (Fig. 19-1). This 3D image can be further manipulated and edited for more targeted information. Measurements can also be made from the multiplanar images, and some US machines allow for measurements from the rendered images as well.

As with all new imaging tools, much emphasis is placed on the 3D surface-rendered image. However, it is the multiplanar data that often contributes the most information diagnostically. A significant advantage of 3D over 2D US is that once the data are acquired, the image can be reviewed and manipulated in different planes for diagnostic clarification, even after the patient has left the ultrasound examination suite.

Routine use of 3D US is not recommended for primary evaluation of the fetus. Rather, targeted 3D acquisition should be performed once an abnormality has been identified by 2D US or indicated clinically. For example, if the question of a cleft lip or cleft palate is raised on the initial 2D examination or if there is a pertinent family history, then targeted 3D US study of the face and palate should be performed.^{2,3} 3D US is often used to obtain an image of the fetal face to give to mothers as a part of their diagnostic examination.

Conventional 2D imaging is sometimes limited by interobserver and intraobserver variation in image interpretation. This limitation is minimized considerably by volume acquisition, because all three planes are available for review by different clinicians and can be manipulated with the 3D software for a

comprehensive evaluation. Questions raised while viewing one plane can often be addressed and resolved by examining the same region in the other two planes.

3D US and its clinical application are limited by various factors, including gestational age, maternal obesity, fetal motion, and imaging technique. Imaging technique covers a wide range of parameters, from sonographer expertise to transducer and equipment type. With increasing experience among sonographers and sonologists, as well as more user-friendly 3D and 4D software programs, 3D US is expected to provide an important additional layer of information that will impact clinical management.

Imaging Tools in Volume Sonography

The type of 3D US imaging tools used depends on the specific clinical question that needs to be answered (Table 19-1). For example, when evaluating bony abnormalities, the use of maximum intensity projection (MIP) would be appropriate. Conversely, surface rendering would be most helpful in the assessment of soft tissue pathology, such as cleft lip.

Excellent initial image acquisition technique is crucial for optimal 3D US imaging. This is achieved by imaging the fetus in a position that is most favorable for the clinical issue at hand. For example, when evaluating cleft lip and palate, a supine fetal position with the face directed toward the anterior uterine wall is most desirable. However, in cases of fetal spine anomalies, fetal prone position is more optimal for a detailed spine evaluation.

Other technical considerations, such as focal zone, system gain, region of interest, and the use of harmonics, all play a significant role in achieving the best results. Many factors that can adversely affect image quality are beyond the examiner's control, including fetal motion, maternal body habitus, early gestation, and polyhydramnios or oligohydramnios.

Table 19-2 lists the commonly used 3D US tools for evaluating specific fetal abnormalities.

The electronic scalpel, like the multiplanar display, is a very useful tool for most areas of interest, because it allows controlled removal of undesired echoes.

Stereographic displays of bony structures have also been studied in the research arena and show promising results with the use of enhanced depth perception. Nelson and colleagues found that stereoscopic viewing improved the conspicuity of complex bony structures and added structural detail information in 14% of fetal skull and 26% of fetal spine cases reviewed.⁴

Figure 19-1 Images of normal fetal faces. **A**, Multiplanar and rendered imaging of fetal face at 27 weeks. *Top left*, Sagittal image of the face. *Top right*, Axial image through the fetal orbits. *Bottom left*, Coronal image of the face. *Bottom right*, Surface-rendered image of the fetal face en face. **B**, Rendered imaging of fetal face at 16 weeks. New algorithms for rendering are providing a skin-like appearance to the fetus.

Use of Three-Dimensional Ultrasound in the First Trimester

Advances in 3D US have enabled fetal imagers to diagnose a spectrum of anomalies, once difficult to detect, at an early stage during pregnancy. The question is not whether 3D is better than 2D, but rather, in which situations can 3D be used as an adjunct to 2D US to yield maximum information. Traditional 2D US is sufficient with respect to many diagnoses; however, in those cases where findings are equivocal or may change management, adjunctive 3D techniques have proved to be valuable⁵ and can often reduce the duration of exposure to the US beam.⁶ Key

TABLE 19-1 Applications of 3D Ultrasound Imaging Tools

Type of Tool	Specific Use
MP	Palate, spine, brain, uterine anomalies

advantages of 3D imaging include the ability to rotate the image of the embryo limitlessly (see Fig. 19-1B) with arbitrary planar evaluation and more precise volumetric measurements. In addition, selective surface and skeletal rendering is made possible by 3D US. In the first trimester, 3D US has also been used to describe details of fetal embryologic development *in vivo* for comparison with magnetic resonance imaging (MRI) microscopy on human embryo specimens.⁷

Bhaduri and colleagues evaluated the fetal anatomic survey using 3D US in conjunction with first-trimester nuchal translucency (NT) screening and found that 3D US was adequate for assessment of the head, abdominal wall (Fig. 19-2), stomach, limbs, and vertebral alignment but was less effective in assessing the kidneys, the heart, and the intactness of the skin over the spine.⁸ Although they thought that acquiring multiple volumes could assist in excluding gross abnormalities, they also acknowledged the disadvantage of the slightly inferior resolution of 3D images compared with 2D in this gestational age group. Nicolaides' group evaluated the feasibility of obtaining NT measurements from 3D volumes in 40 women and concluded that reslicing of stored 3D volume data could be used to replicate NT measurements only when nuchal skin could clearly be seen

on 2D US. Compared with 2D US, the NT measurements using the 3D volume data set could be repeated in 95% of sagittal volumes but in only 60% of random volumes.⁹

Major benefits of 3D US in the first trimester include improved ability to detect and decipher uterine anomalies (e.g., differentiating an interstitial ectopic pregnancy from a normal intrauterine pregnancy in a uterine malformation), to assess

congenital anomalies (see Fig. 19-2), and to obtain accurate NT measurements.

UTERINE MALFORMATIONS

The importance of detecting uterine anomalies is particularly pertinent in pregnant women because some carry an increased incidence of spontaneous or recurrent abortion.¹⁰ Simon and associates reported that müllerian duct anomalies have a prevalence of approximately 3.2% in the general healthy population,¹¹ with septate uterus being the most common anomaly and the one that carries the highest risk of recurrent first-trimester spontaneous abortions. The distinction between septate and bicornuate uterus is important, because these conditions carry different risks for pregnancy loss and require different types of surgical management.

Several methods have been used to evaluate the uterus and endometrium, including hysterosalpingography, sonohysterogram, and MRI. Hysterosalpingography offers high-resolution imaging of the endoluminal content of the uterus (i.e., the endometrial canal), but the study is done at the expense of exposing the patient to ionizing radiation. Additionally, because this study does not evaluate the outer contours of the uterus, seeing two distinct uterine cavities does not allow differentiation between septate, bicornuate, and didelphys uteri. Although 2D US can identify two horns of a uterus, it is usually not possible to differentiate between septate and bicornuate uterus because the outer myometrial contour cannot be visualized in traditional planes.

A distinct advantage of 3D US is the ability to view the uterus and endometrium in the coronal plane, which usually cannot be obtained in 2D US. This view offers the ability to evaluate the serosal surface as well as the endometrial cavity; rendering displays can provide additional information to the multiplanar images to distinguish among different anomalies (Fig. 19-3). At times, subtle differences in the configuration of the uterus may make the distinction between arcuate, septate, and bicornuate

Figure 19-2 Omphalocele at 13 weeks 5 days. The omphalocele (arrow) had bowel and liver within it.

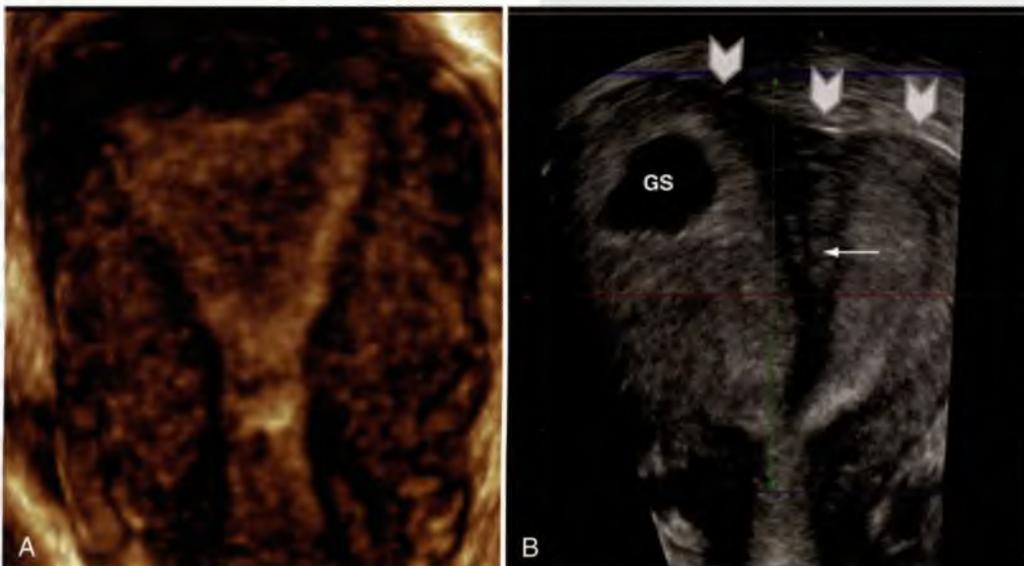

Figure 19-3 Multiplanar coronal images through normal and abnormal uteri. A, Normal endometrium and normal outer uterine contour. B, Septate uterus with a 6-week gestational sac (GS) in the right horn. Notice the normal external uterine contour (arrowheads). A thin, fibrous septum is seen in the uterine cavity (arrow).

uteri difficult. Parameters such as the height of the fundal cleft, the distance between the uterine cornua, and the indentation of the endometrium all contribute to the differentiation of anomalies.

A 3D US image in the coronal plane can be used to measure the intercornual distance, the length of a septum, and the depth of the external fundal indentation.^{12,13} In the case of a complete septate uterus, a separate volume focused on the cervix allows for the coronal plane to confirm or exclude the presence of a septate cervix as well.¹⁴ The sensitivity and specificity of 3D US in the detection of a septate uterus are 98.4% and 100.0%, respectively, and the positive and negative predictive values are 100.0% and 96.0%, respectively.¹⁵

ECTOPIC PREGNANCY

An important potential application of 3D US is in the transvaginal diagnosis of an ectopic pregnancy. Scanning in different spatial planes allows for thorough evaluation of the adnexae, assisting in the diagnosis of tubal ectopic pregnancies. As an extension of the previous discussion on uterine malformations, the importance of 3D US must be stressed when evaluating for possible interstitial ectopic pregnancy. In patients with a uterine malformation, the gestational sac may be located laterally within the uterus. This is of diagnostic importance, because the sonologist must decide whether the pregnancy is a

laterally located intrauterine pregnancy or an interstitial ectopic pregnancy.

Regardless of whether there is a uterine anomaly, the diagnosis of an interstitial ectopic pregnancy can be difficult. Interstitial pregnancies are surrounded by a myometrial layer that is difficult to visualize by traditional 2D US. Ackerman and coworkers described a sonographic sign for interstitial ectopic pregnancies, the so-called interstitial line (Fig. 19-4).¹⁶ Using data based on a retrospective study of 12 interstitial ectopic pregnancies, they determined that visualization of a hyperechoic line extending from the lateral aspect of the uterine cavity into the midsection of the gestational sac corresponds to the interstitial portion of the fallopian tube. This finding, along with a mantle of myometrium surrounding the ectopic gestational sac, is highly specific for diagnosing an interstitial ectopic pregnancy, and visualization of both is facilitated by 3D US. Jurkovic and Mavrellos used two signs to diagnose interstitial ectopic pregnancies in their patient population: visualization of the interstitial line connecting the gestational sac to the endometrial cavity and a continuous mantle of myometrium surrounding the sac.¹⁷

Harika and colleagues suggested that 3D US may be useful in early diagnosis of tubal ectopic pregnancies in asymptomatic patients.¹⁸ In a study of 12 patients, all of whom were asymptomatic and were at less than 6 weeks' gestation, both 2D and 3D US was performed. The 2D images showed no

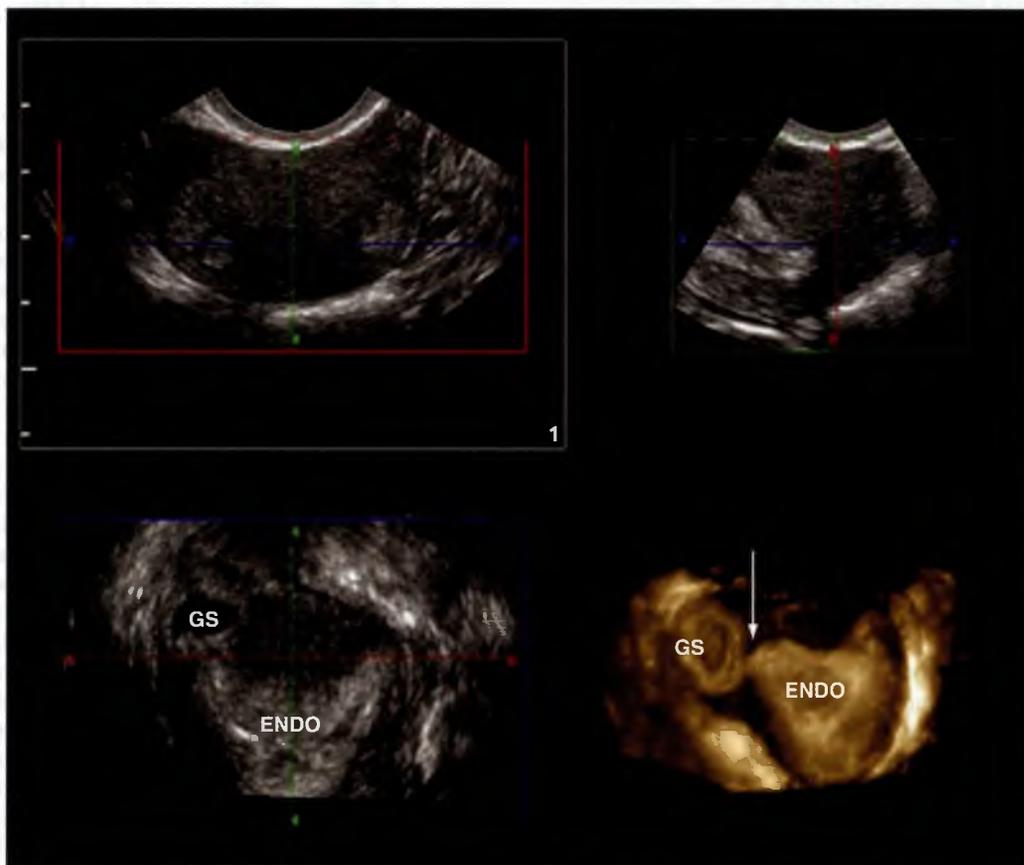

Figure 19-4 Multiplanar display of an interstitial ectopic pregnancy at 5 weeks 4 days. *Upper left*, Axial plane through the uterus. *Upper right*, Sagittal plane through the uterus. *Lower left*, Coronal plane demonstrating the endometrium (ENDO) of the uterus adjacent to the gestational sac (GS). *Lower right*, Rendered image. The arrow is pointing to the thin line between the endometrium and the gestational sac, consistent with the "interstitial line sign."

feature of intrauterine or extrauterine pregnancy. In four patients, however, 3D transvaginal US demonstrated ectopic, small gestational sacs in the fallopian tube. Visualization of the fallopian tube was possible because of a feature noticed on 3D US not previously described: The fallopian tube was surrounded by a fine hypoechoic border.

EARLY DETECTION OF CENTRAL NERVOUS SYSTEM ABNORMALITIES

The advent of 3D US has enabled first-trimester detection of central nervous system anomalies that heretofore were diagnosed in the second trimester by 2D US.

Acrania/Anencephaly

Some degree of brain tissue degeneration results as the tissue comes in contact with amniotic fluid. The US diagnosis of anencephaly is made when no osseous structures are seen above the orbit, irrespective of the degree of neural tissue present.¹⁹ The lack of calvarium is well demonstrated with multiplanar or surface-rendered 3D US images. Benoit and associates⁶ reported that anencephaly could be visualized at 11 weeks and acrania could be seen at 12 weeks.

Hydrocephalus

Hydrocephalus, or the abnormal accumulation of cerebrospinal fluid in the ventricular system of the brain, can be detected during the first trimester with the use of high-resolution scanning techniques. In a normally developing brain, choroid plexus almost fills the ventricle initially. Visualization and measurement are possible at 11 weeks. With hydrocephalus, the choroid has a suspended appearance in the fluid-overloaded ventricle. The “dangling choroid” sign can easily be demonstrated with multiplanar imaging.⁵

Encephalocele

A defect in the rostral portion of the neural tube leads to the development of an encephalocele. The use of 3D US in this regard applies to the ability to depict the abnormal configuration of the fetal head using both surface rendering and multiplanar imaging.⁵

Evaluation of the fourth ventricle to assess for Chiari malformation has been studied with 2D US, but no studies using 3D US have been published as yet. However, in our experience, it has been useful to evaluate the intracranial anatomy using multiplanar displays, including obliteration of the fourth ventricle, in first-trimester fetuses with Chiari malformation.

FETAL FACE

Nasal Bone Assessment

Many investigators have studied the association of absent nasal bone ossification and increased risk of trisomy 21 using 2D US in the first trimester. A study by Rembouskos and coworkers, in 2004, evaluated 120 stored volumes of fetuses of 11 to 14 weeks' gestation; the ideal plane for measuring the nasal bone was found to be the midsagittal plane at a 45-degree angle.²⁰ The researchers concluded that the nasal bone could always be demonstrated with 3D US in the midsagittal plane when the acquisition angle was between 30 and 60 degrees. However, outside that range, the images of the nasal bone were unsatisfactory.

Retronasal Triangle Assessment for Facial Clefing

Sepulveda and associates described the normal first-trimester appearance of the anterior facial bones in the coronal plane and termed this sonographic landmark the *retronsal triangle* (i.e., the three echogenic lines formed by the two frontal processes of the maxilla and the primary palate) (Fig. 19-5).²¹ They showed that the normal retronsal triangle could be consistently imaged using 3D US from 11 + 0 to 13 + 6 weeks' gestation and that cleft palate could be identified retrospectively using this sign.²¹ The retronsal triangle sign appears to be a first-trimester 3D US correlate of the 2D US second-trimester premaxillary sign described by Suresh and colleagues.²² A follow-up study showed that seven cases of orofacial clefing could be identified prospectively.²³ The same group recently reported identification of micrognathia in the first trimester, using the same view, by showing an absent mandibular gap inferior to the retronsal triangle; normal fetuses have a gap in the midaspect of the mandible on this view.²⁴

FETAL EXTREMITIES

Fetal limb abnormalities detected before 15 weeks' gestation can have a broad differential diagnosis, including syndromal or chromosomal conditions such as trisomies 18, 13, and 21. Rice and colleagues showed that 3D US was useful as an adjunct to 2D US in assessing three of nine limb abnormalities.²⁵

Use of Three-Dimensional Ultrasound in the Second Trimester

FETAL FACE

Evaluation of the fetal face for craniofacial dysmorphism involves the identification of several features, including the forehead, nose, lips, palate, jaw, and eyes. Among the craniofacial malformations, cleft lip/palate is the most common. Detection of an abnormality in any one of these areas directs a dedicated search for other associated anomalies in the fetus. In one study of 460 infants with clefts, almost 37% had other anomalies; the incidence of these anomalies was higher in infants with cleft palate (46%) than in those with cleft lip and palate (36%) or cleft lip alone (13%).²⁶

Cleft Lip and Palate

Anatomically, the palate is comprised of the anterior hard palate and the posterior soft palate. Two bones contribute to the hard palate on each side: the palatine process of the maxilla in the front and the horizontal plate of the palatine bone in the back. Together, they form the transversely oriented palatomaxillary suture in the posterior two thirds of the palate.²⁷ A midline interpalatal suture between these bones completes the hard palate. The smaller anterior portion of the hard palate is the primary palate, and the larger posterior segment is the secondary palate. The soft palate extends back from the posterior margin of the hard palate between the oropharynx and the nasopharynx.

Embryologically, the hard palate and upper lip have separate origins. The central part of the upper lip (the philtrum), the alveolar ridge of the upper four incisors, and the triangular primary palate are formed by the fused medial nasal segments, whereas the lateral parts of the upper lip and the secondary

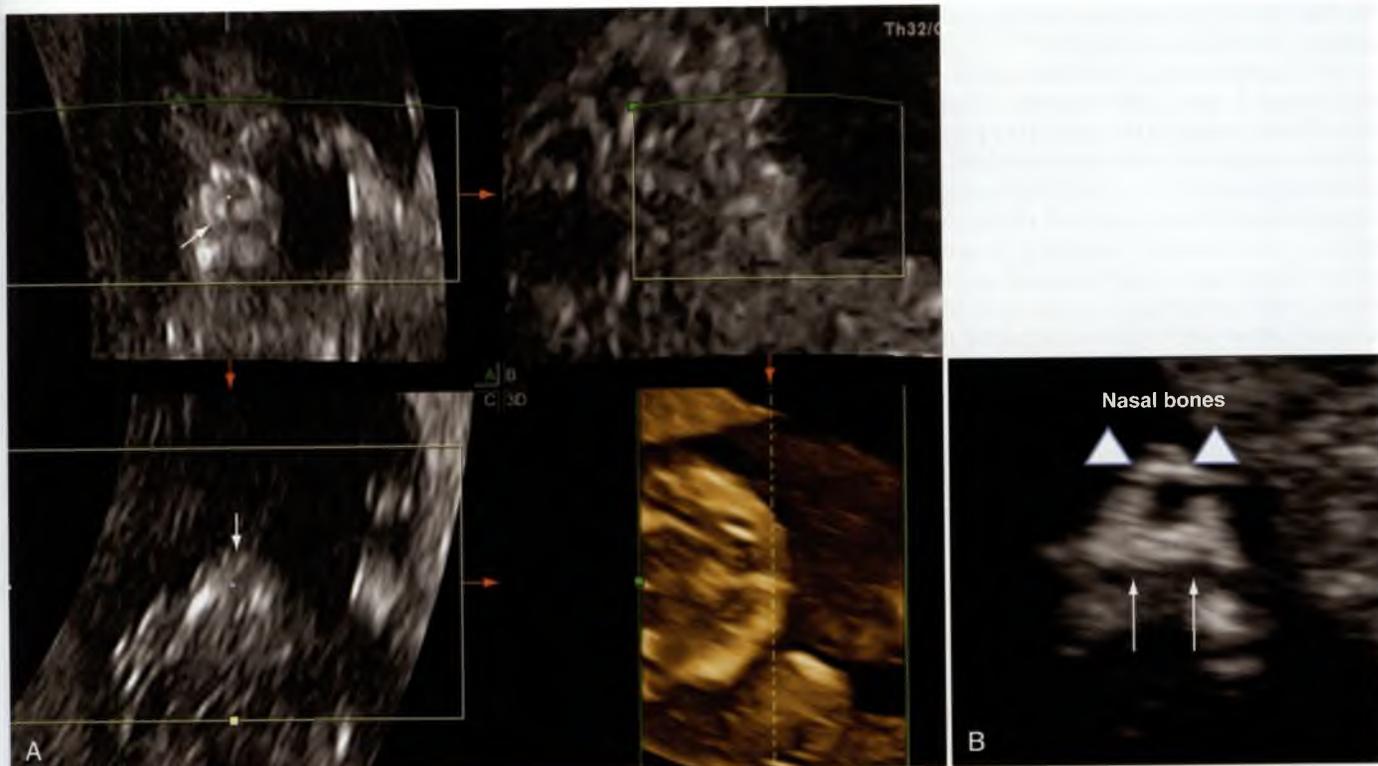

Figure 19-5 Midline cleft lip and palate at 12 weeks 4 days. **A**, Multiplanar image of midline cleft palate (arrow) seen in upper left image (coronal) and lower right image (axial). Upper right image is a profile image, and lower right image is an axial image that is rendered. **B**, Normal retronasal triangle showing normal maxilla (palate) (arrows) at the bottom of the triangle and the nasal bones (arrowheads) at the top of the triangle.

palate are formed by the maxillary swelling. The incisive foramen lies at the junction of the primary and secondary palate and represents the dividing landmark between anterior and posterior cleft deformities.

Cleft lip and cleft primary palate results from failure of fusion of the medial nasal segment with the ipsilateral maxillary swelling. *Cleft of the secondary palate*, however, is the result of nonfusion of the palatine shelves in the midline. Anterior lip/palate anomalies include cleft lip (CL) and cleft lip and alveolus (CLA), which can be unilateral or bilateral. Posterior or secondary cleft palate defects (CP) are midline or paramedian. There is a higher likelihood of a cleft palate in those fetuses who have a severe cleft lip, and, conversely, the cleft lip is more severe when there is a cleft palate.²⁸

Before the advent of 3D US, sonographic imaging described clefts of the hard palate without distinction between primary and secondary clefts. For example, a cleft lip involved the lip alone, but a cleft lip extending to the alveolus was usually classified as “cleft lip and palate”; no further differentiation between primary and secondary clefts could be made on the basis of 2D US imaging. With multiplanar and rendered imaging provided by 3D US, it is now possible to identify the posterior extent of clefts and also some isolated clefts of the secondary palate (without a CLA).

The standard 2D US coronal oblique view of the fetal face is used to assess for the presence of *cleft lip/alveolar ridge*. This method fares poorly in the diagnosis of *cleft palate*, with the evaluation being greatly impaired by bony shadowing on the standard oblique face view. Despite these drawbacks, Sherer and colleagues were able to view the hard palate on axial 2D views.²⁹

They provided the only available complete nomogram on palatal measurements (width, length, and area), between 15 and 41 weeks, based on 2D US. A nomogram for the anterior alveolar ridge between 14 and 32 weeks' gestation using 2D US was presented by Goldstein and coworkers.³⁰ More recently, Captier and colleagues³¹ performed a series of measurements of the postmortem fetal palate including the velopalatal angle and the soft/hard palate ratio, using 18 formalin-fixed fetuses in the second and third trimesters. The length of the soft palate is about half that of the bony palate.

Although 2D US has been the mainstay for the diagnosis of cleft lip and palate, adjunctive 3D US imaging improves the diagnostic accuracy.^{32,33} However, these results are applicable only to high-risk, referred patients; they have yet to be proved similarly effective in the screening of low-risk populations. Until recently, the diagnosis of isolated cleft palate (secondary palate) was elusive by both 2D and 3D US. Several new 3D US methods have now evolved targeting evaluation of this area. Faure and coworkers³⁴ presented a case report of an isolated V-shaped cleft palate (secondary palate and soft palate cleft) using a new 3D US technique, and Benacerraf and associates reported on an isolated cleft of the soft palate in association with Fryn syndrome.³⁵

A standardized imaging approach is most helpful in improving diagnostic accuracy. This includes initial 2D imaging followed by 3D volume acquisition, multiplanar display methods, and image manipulation and reconstruction with various rendering techniques for accurate diagnosis. Ramos and colleagues reported the benefits of using a systematic approach to evaluate the fetal face with 3D US; their technique was based on rotating

the fetal face into a standardized orientation using the orbits to assist in determining symmetry.³⁶

For diagnosis of palatal abnormalities, the initial 3D volume acquisition is best performed in the sagittal plane with the transducer centered at the level of the palate or in the axial plane with the transducer centered at the level of the maxilla. In the ideal situation, the fetus should be facing up with the face presenting toward the anterior wall of the uterus. But fetal presentation, fetal motion, anteriorly located shadowing limbs, oligohydramnios or polyhydramnios, and operator inexperience can all contribute to a less than ideal plane for volume imaging. Most sonologists would agree that the middle to late second trimester is the best time to assess for cleft lip or palate; however, the palate has been identified as early as 11 weeks' gestational age.³⁷

The sonographic appearance of the various types of clefts was well described by Rotten and Levaillant, who performed a retrospective evaluation of 96 cases of CL, CLA, and CP with 2D and 3D US and then correlated their findings with postnatal evaluation.³⁸ They found that, when there is a cleft of the secondary palate (CP) with a unilateral CLA, the CP defect is not strictly midline but is slightly asymmetrical. However, in cases of bilateral CLA associated with CP, the residual palate is seen only as a small structure located far laterally on each side of the defect, and the vomer appears to be suspended in the midline with no palatal bone to attach to.³⁸ On the midline sagittal view, this suspended vomer can be mistaken for the palate. This artifact emphasizes the need for evaluation in all three planes when a cleft is suspected.

For multiplanar display and postprocessing of the volume data, the three planes are generally viewed such that the plane of initial acquisition is displayed on the top left box with the other two orthogonal planes displayed in the other two boxes; the fourth box in the right lower corner is for the surface-rendered image.¹ When the rendered images are used for diagnosis, it is recommended that the findings be confirmed on the planar images, to avoid pitfalls such as pseudoclefts, which can result from shadowing artifact.³⁹

The crucial step in postprocessing involves placing the central cursor in each image at the area of concern, in this case the palate. This is performed for each of the three planes—sagittal, axial, and coronal—and helps to achieve a more precise, symmetrical, and detailed evaluation. Additionally, tomographic ultrasound imaging (TUI) can be performed to gain more information. This is particularly helpful in the axial plane. TUI can be performed in the axial, sagittal, or coronal plane (Fig. 19-6A,B).

With the use of the multiplanar display and image manipulation, a surface-rendered image can be generated. Surface rendering typically has been used for image generation to assist the parents (and the physician) in their understanding of the anatomic and clinical issues involved (Fig. 19-7). As a general rule, this capability is not routinely thought to enhance diagnostic efficiency or accuracy, although it may increase diagnostic confidence for normal versus abnormal studies.⁴⁰

Nevertheless, recent reports in the literature have described skillful use of surface-rendered images to reveal additional information. Campbell and colleagues⁴¹ published a review of eight cases in which they utilized a "reverse face" (RF) view of the palate. Briefly, this involves a 180-degree rotation of the frontal view of the face around a vertical axis so that the surface-rendered palate and face can be sequentially viewed from back

to front, thus avoiding the shadowing caused by the hard palate. A true coronal plane is necessary for successful palatal evaluation by this technique. A limitation of this method, as described by Campbell and colleagues,^{41,42} is the inability to measure the width of the cleft on rendered images. However, a gross evaluation of mild versus severe clefting can easily be made: A significant tongue protrusion through the CP defect suggests a large lesion. These distinctions of severity of disease are helpful for surgical planning.

Another approach used for evaluating the fetal lip and palate, called the "flipped face" (FF) view, was described in detail by Platt and coworkers.⁴³ In this view, the jaw, lips, alveolar ridge, palate, and maxilla are observed sequentially in a plane parallel to the palate but as if looking at the palate from below; in contrast, in the RF view, the palate is examined in a coronal plane and is viewed from back to front, as if looking at the palate from behind. In both techniques, the primary objective is to avoid shadowing from the facial bones, including the palate, because such an artifact would severely limit diagnostic accuracy. Currently we use a modified FF view to evaluate the hard palate that is more intuitive: The face is upright, and the viewing plane is from inferior rather than superior (see Fig. 19-6C,D).³⁹

An angled insonation technique was described by Pilu and Segata.⁴⁴ With the fetus facing up (i.e., toward the anterior uterine wall), the midsagittal plane is displayed. The US beam is then insonated at an angle of about 45 degrees to the palate with the beam looking obliquely up at the hard palate from below. Static 3D volume is acquired and then analyzed later. Pilu and Segata⁴⁴ found that, for diagnosis of CP by their method, the multiplanar evaluation, volume contrast imaging (VCI), and TUI were the most helpful imaging techniques. Whereas CP could be identified on the axial planes, precise delineation of the margins of the palatal defect was to some extent hindered by the tongue extending into the defect. In this case, the coronal plane was found to be more helpful.

To overcome some of these limitations, Faure and colleagues^{34,45} used a slightly different approach to imaging the fetal palate. Their work was focused on establishing an easy and rapid method to image the normal hard palate and to identify its anatomic landmarks. Its practical application and use in cleft cases has not yet been clearly established, and the soft palate cannot be evaluated by this method. The technique that they described involves initial volume imaging in the axial plane. This is contrary to most other methods, which prescribe initial volume acquisition in the midsagittal plane. Using their described approach and a postprocessing procedure of viewing the palate from the underside, Faure and coworkers were able to consistently identify six of seven anatomic landmarks of the palate from 17 to 32 weeks' gestation, with the alveolar ridge and the horizontal plate of the palatine bone being visualized 100% of the time.³⁴

Whereas all of these methods have a potential to improve assessment of the palate, some fetuses may still not be able to be evaluated by any of the described techniques.

In summary, when faced with suspected craniofacial malformations, detection of cleft of the secondary palate without cleft lip and alveolus is still difficult in the best hands.

Forehead

The facial angles are best measured in the midsagittal plane. In this plane, the fetal profile, including the frontal bone, is evaluated and the nasal bone length is measured. Merz and

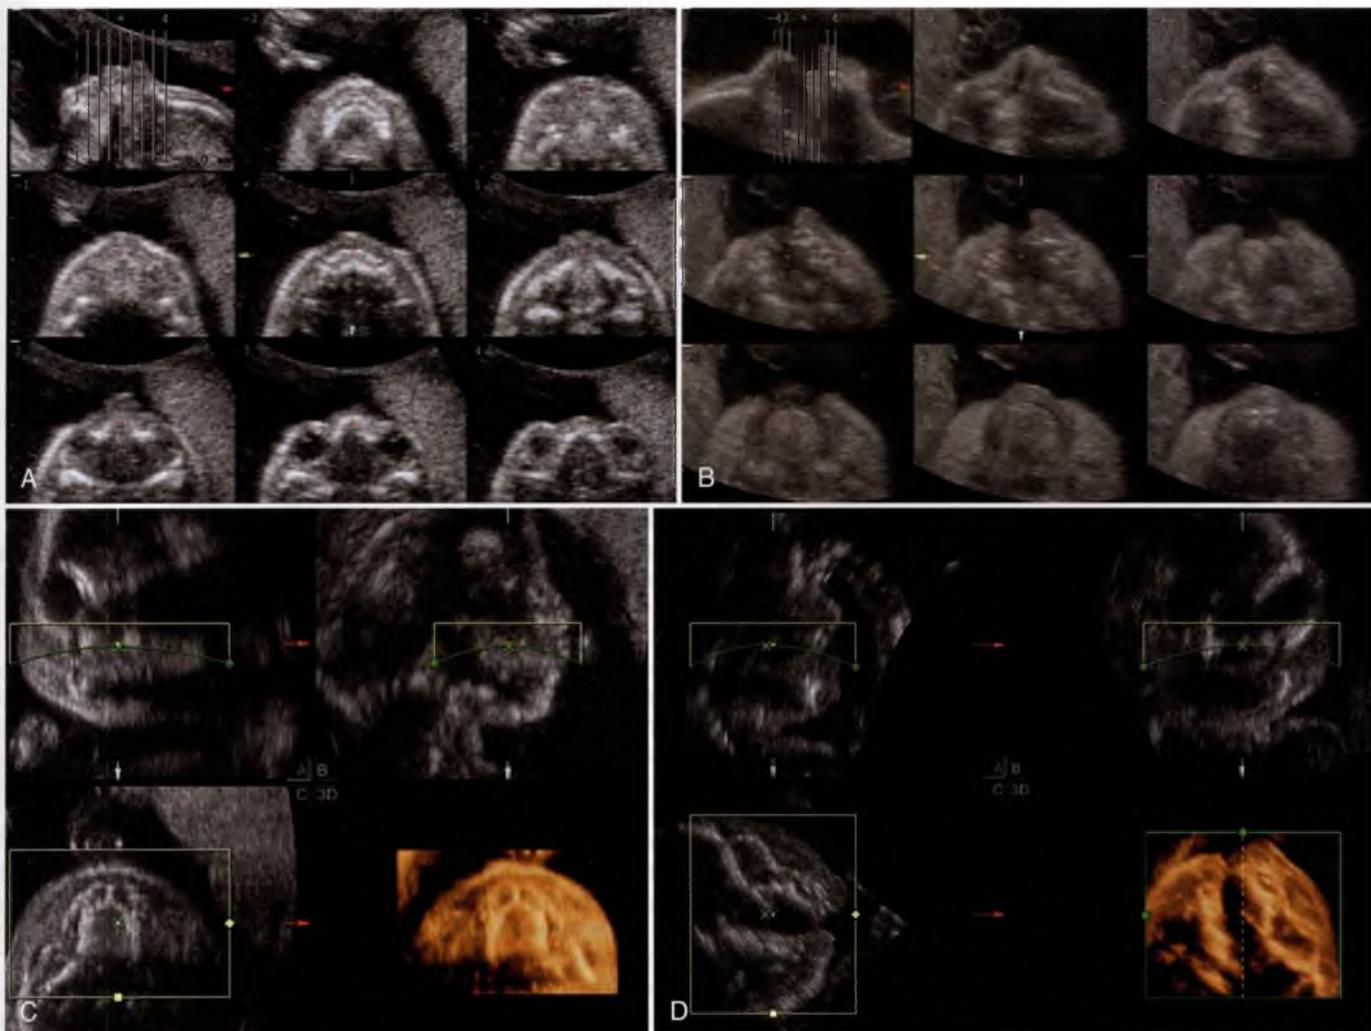

Figure 19-6 Evaluation of the fetal primary and secondary palate. *A*, Multislice display of the normal primary palate at 20 weeks. *Upper left*, Reference image showing where the other eight images are positioned in relation to the profile. The middle image in the upper row is of the mandible. The middle image in the middle row is of the primary palate. The lower images are of the orbits. *B*, Multislice display of a cleft primary and secondary palate at 28 weeks. *Upper left*, Reference image showing where the eight images are positioned in relation to the profile. The middle image in the upper row demonstrates the nostrils. The middle image in the middle row shows the cleft in the palate extending from the primary (alveolar ridge) palate through the secondary (hard) palate. The middle image in the bottom row shows the normal fetal tongue. *C*, Multiplanar display of the normal primary and secondary palate at 23 weeks. *Upper left*, Fetal face in coronal plane with a narrow rendering box overlying palate. *Upper right*, Image in the sagittal plane. Notice that the green region-of-interest viewing line is slightly curved upward to follow the contour of the palate more closely. *Lower left*, Axial plane through the palate with the primary palate well visualized. *Lower right*, A rendered image displaying the normal primary (alveolar ridge) and secondary (hard) palate. *D*, Multiplanar display of a cleft primary and secondary palate at 21 weeks. *Upper left*, Fetal face in profile with the narrow rendering box overlying the palate. *Upper right*, Image in the coronal plane. Notice that the green region-of-interest viewing line is slightly curved upward to follow the contour of the palate more closely. *Lower left*, Axial plane image clearly demonstrating the cleft through the primary and secondary palate. *Lower right*, A rendered image displaying the large primary (alveolar ridge) and secondary (hard) cleft palate.

coauthors⁴⁶ studied 618 pregnant women and found that with 2D US the true midline sagittal plane was achieved in only 69.6% of cases, whereas with 3D US this plane could easily be imaged by manipulating the image volume in all three planes. Faro and colleagues⁴⁷ studied the frontal bones and metopic sutures with 3D US in 16 fetuses at 9 to 34 weeks' gestational age. Early on, the frontal bones appear as small ossification centers on either side. Subsequent growth defines the development of the metopic suture that then starts undergoing fusion by about 32 weeks.

Profile abnormalities, such as frontal bossing seen in achondroplasia (Fig. 19-8), are easily demonstrated on the midsagittal

plane and the surface-rendered images. Moeglin and Benoit⁴⁸ described two case reports of achondroplasia diagnosed with the use of 3D US. They found that the typical craniofacial features, pointed proximal femur, and abnormal appearance of the hands, previously described in achondroplasia, could be easily evaluated with 3D US. Tsai and coworkers diagnosed a case of frontal encephalocele using 3D US.⁴⁹

A recent 3D US assessment of nasal bone length (NBL), prenatal thickness (PT), and frontomaxillary facial (FMF) angle was performed by Vos and colleagues in healthy second- and third-trimester fetuses.⁵⁰ They presented normal reference ranges for these landmarks using 3D US but found that their

normative 3D NBL measurements were smaller than the previous NBL published data. Additionally, they found that, whereas NBL and PT were readily measurable and reproducible by 3D US, the FMF angle remained technically more challenging. Their normative data will likely be of particular value in the evaluation for Down syndrome markers in late-to-care gestations.

Figure 19-7 Rendered image of bilateral cleft lip and palate at 35 weeks 5 days. Premaxillary mass (black arrow) is seen between the bilateral clefts (white arrows).

Orbits

Evaluation of the orbits is part of high-risk obstetric sonography. The best plane for evaluation of the orbits is the axial plane. This is usually accomplished with 2D US, but with complex facial anomalies, 3D US provides additional information. Nomograms for the interorbital and interocular distances have previously been established by 2D US.⁵¹ These distances can also be measured on the axial plane in the 3D reconstructed images. A true axial plane is easier to identify with 3D US, because the volume can be manipulated after the patient has left the examination room to obtain the optical plane.

Metopic Suture

Abnormal cranial sutures and fontanelles can be seen in cases of chromosomal abnormalities or syndromes. Early fusion of sutures leads to craniosynostosis. The metopic suture is a fetal structure that separates the two fetal frontal bones (Fig. 19-9A). Normally, the metopic suture fuses by the 32nd week. Early fusion of the frontal bones results in cranial shape anomalies causing underlying parenchymal issues. Pretorius and Nelson⁵² recognized early on that 3D US could aid in improving visualization of cranial sutures and fontanelles. This was also demonstrated by Dikkeboom and coauthors,⁵³ who found that, except for the sagittal suture and the posterior fontanelle, all dominant cranial sutures and fontanelles can reliably be evaluated by volume acquisition in the sagittal and transverse planes. Advanced gestational age and cephalic presentation decreased visualization of these structures. Surface rendering and transparent maximum mode were considered most helpful by Faro and colleagues during their assessment of the metopic suture and frontal bones.⁴⁷

Abnormal metopic suture pattern and early obliteration of the metopic suture are both associated with other anomalies.⁵⁴ In their 3D US review of 11 fetuses with metopic suture abnormalities, Chaoui and colleagues identified four abnormal appearances, including a V-Y shape, a U shape, premature

Figure 19-8 Evaluation of fetal profiles. **A**, Normal fetal profile in a fetus at 28 weeks. Rendered image demonstrates normal forehead, nose, and lips. **B**, Rendered image shows frontal bossing in a fetus with achondroplasia at 29 weeks. Notice the prominent forehead. **C**, Rendered image of micrognathia in a fetus with campomelic dysplasia at 31 weeks.

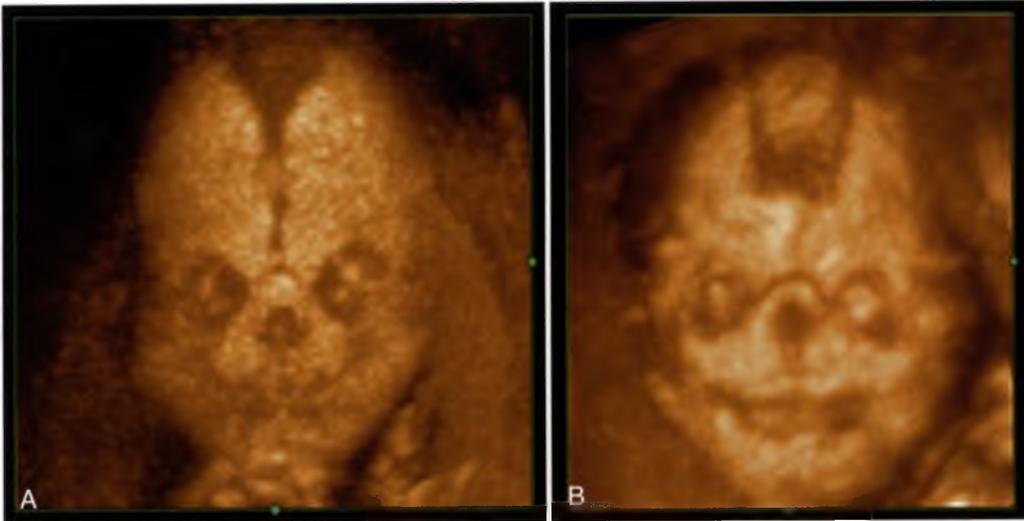

Figure 19-9 Rendered images of metopic suture. A, Rendered image of a normal metopic suture using skeletal settings. B, Rendered image of an abnormal metopic suture in a fetus with Apert syndrome at 20 weeks' gestational age.

closure, and bone interposed in the suture line. The latter two conditions were associated with holoprosencephaly and callosal abnormalities, whereas sutural shape abnormalities were found in fetuses with facial defects without holoprosencephaly or callosal issues (Fig. 19-9B).

Fetal Mandible

Fetal mandible abnormalities such as micrognathia (small jaw) and retrognathia (receding jaw, see Fig. 19-8C) are associated with several syndromes and chromosomal disorders, including Treacher Collins syndrome, Pierre Robin sequence, Turner syndrome, and trisomies 8, 9, 13, and 18. 3D US has been found to be useful as an additional imaging tool when a fetal mandible abnormality is suspected on the initial 2D examination, and it can aid in the diagnosis of other facial dysmorphisms.⁵⁵

Rotten and coworkers used 3D US to evaluate the fetal mandible.⁵⁶ They established normative data for two new indices—the ratio of mandibular to maxillary width (MD/MX), for use in the diagnosis of micrognathia, and the inferior facial angle (IFA), which helps in establishing the diagnosis of retrognathia. Retrognathia is diagnosed when the IFA is less than 50 degrees. Micrognathia is defined by a MD/MX ratio less than 0.785. The three planes required for these measurements include the midsagittal plane and two axial planes. These images can also be obtained by using 2D US, but 3D imaging allows greater accuracy in defining the measurement planes. These authors reemphasized that retrognathia can occur with or without micrognathia and that one should avoid the general practice of grouping these two abnormalities under the single heading of micrognathia.

The 3D methods described by Rotten, Chen, and their colleagues were successfully used to diagnose retrognathia in a case report of a fetus with pyelectasis and chromosomal duplication.⁵⁷ Both Rotten and Chen have used 3D multiplanar imaging and surface-rendering techniques in fetal jaw evaluation. As with 2D imaging, 3D US can lead to misdiagnosis of micrognathia if only the sagittal view is used for diagnosis. In such a case, careful review of the multiplanar images will reveal that an erroneous obliquity of the sagittal plane resulted in the false diagnosis of micrognathia. This error is easily corrected by

manipulating all three planes for a perfectly symmetrically positioned face.⁵⁵

Fetal Ear

The fetal ear can be displayed on rendered surface images to evaluate for morphologic detail as well as orientation to the face.^{58,59} Shih and associates reported successful 3D reconstruction of fetal ears in 105 cases.⁵⁹ Of these, 18 fetuses with anomalous ears were identified, demonstrating the benefits of 3D US.⁵⁹

FETAL HEART AND VASCULAR SYSTEM

The four-chamber view of the heart has been established as an important part of the routine fetal anatomic survey. However, as this view became incorporated into the routine survey, many examiners noted that outflow tract abnormalities were being missed. This occurs because many outflow tract abnormalities do not affect the appearance of the four-chamber view. The American College of Radiology (in 2003) and the American College of Obstetricians and Gynecologists (in 2004) suggested that there is a benefit in incorporating the right and left ventricular outflow tracts into the fetal survey to detect more cardiac anomalies. The examination of the outflow tracts is suggested by both organizations if “technically feasible”—a caveat that illuminates a real limitation, the technical difficulty in obtaining these views in the hands of inexperienced sonographers.

Obtaining these views requires freehand sweeping of the transducer in a plane transverse and parallel to the four-chamber view of the heart. This can be difficult, and small deviations in transducer position will alter the displayed anatomy. TUI is a method of simultaneously displaying multiple sequential cardiac images with the ability to rotate the image in any plane desired. It can be thought of as being analogous to computed tomographic imaging. TUI images can be displayed with either static or gated cardiac motion⁶⁰ (spatiotemporal image correlation [STIC]) volume acquisitions. A major benefit of TUI is the ability to evaluate the heart either in real time (i.e., at the time of scanning) or offline at a later time, using the data acquired during scanning. DeVore and

Polanko demonstrated that TUI decreases the time spent evaluating cardiac anatomy.⁶¹ Other techniques, such as color Doppler, power Doppler, high-definition Doppler, B-flow, and various rendering techniques were used by Gindes and coworkers to assess 81 fetuses with cardiac anomalies and were found to make a major contribution in classifying cardiac anomalies from volume data.⁶² Turan⁶³ and Yagel⁶⁴ and their colleagues also reviewed the benefits of these various techniques in assessing cardiac anomalies.

Goncalves and coauthors⁶⁵ described a method for examining the fetal heart using 4D US and STIC. STIC allows acquisition of a fetal heart volume and its visualization as a 4D cine sequence. Only one satisfactory volume data set needs to be obtained. Acquisition is performed with an automated slow sweep, and frames are sequentially acquired at a rapid rate. This method also proves valuable for 3D surface rendering of structures such as cardiac valves. This technology allows the entire volume of the heart to be evaluated. It is useful for diagnosis as well as teaching (Fig. 19-10). The STIC technology allows for the heart to be rotated using the cursor dot in any plane. For example, in transposition of the great vessels (Fig. 19-11), the bifurcation of the pulmonary artery can be seen in one plane and its relationship to the left ventricle (i.e., abnormal outlet) in another plane.

According to Sklansky and colleagues, real-time 3D fetal echocardiography allows continuous volume data acquisition, making the need for cardiac and respiratory gating minimal.⁶⁶ Furthermore, cardiac activity can be viewed in real time at its actual speed, or the speed can be slowed down or even stopped. One drawback of 3D fetal echocardiography is that one third of the cardiac structures, such as cardiac valves, are not well visualized due to limits in resolution. Application of 3D

technology in the setting of a rapid fetal heartbeat is limited because of motion artifact.^{66,67} The artifacts can be minimized by using various gating methods. With 3D technology and gated techniques, fetal cardiac anatomy is actually better depicted than with 2D US. The current limitations are expected to be overcome with further technical advances in this field.

The fetal venous system, including the umbilicoportal venous connections, cardinal veins, umbilical veins, vitelline veins, and anomalous pulmonary venous connections, have also been studied with 3D US.^{68,69} Achiron and colleagues showed that fetuses with Down syndrome have an increased prevalence of abnormal umbilical vein connections to the inferior vena cava,⁶⁸ which are optimally displayed with 3D US.⁶⁸

Umbilical cord knots have been shown to be optimally displayed by 3D US, particularly with high-definition color flow⁷⁰ and power Doppler flow.⁷¹

THORAX

Anomalies of the thoracic cavity have been studied with 3D US by Achiron and coworkers, who found that 3D US enhances diagnostic precision and provides better spatial visualization.⁷² They found that different 3D modalities were better suited in the detection of different thoracic anomalies. For example, the TUI mode was particularly helpful in assessing diaphragmatic hernias and lung dysplasia, but VCI was more effective in distinguishing liver from lung tissue in fetuses with diaphragmatic hernia. Measurement of lung volumes in fetuses with suspected lung hypoplasia has been studied by many authors. Peralta and colleagues performed 3D US automatic volume assessment with the Virtual Organ Computer-Aided Analysis (VOCAL) program, using various angles and compared them to MRI

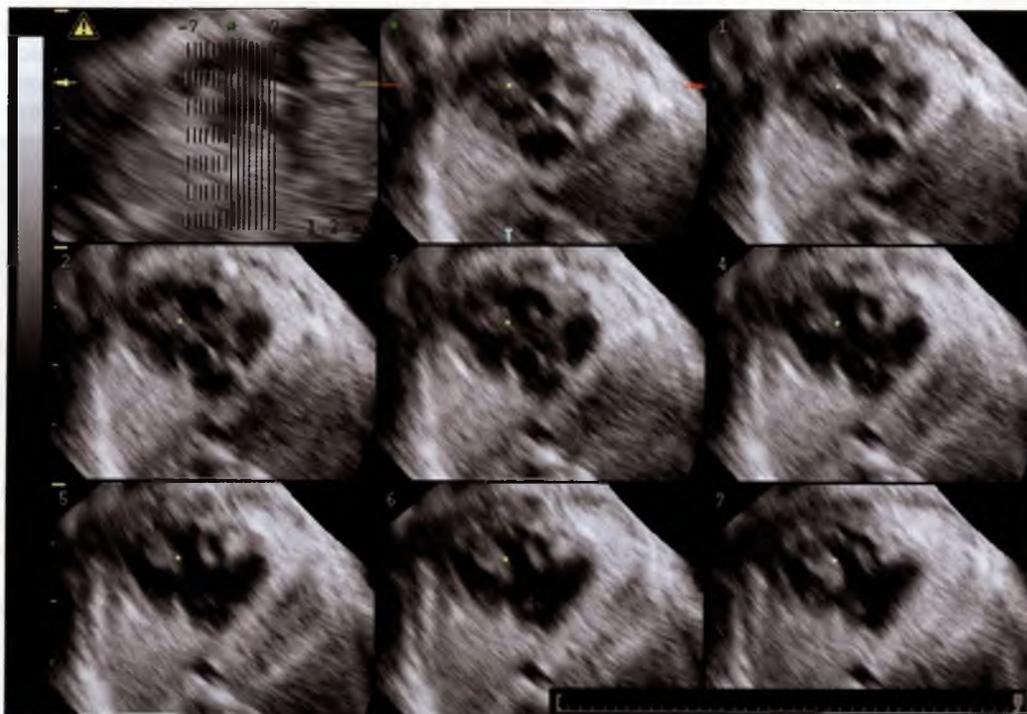

Figure 19-10 Multislice display of fetal heart with atrial ventricular canal defect at 25 weeks. *Upper left*, Reference image showing where the other eight images are positioned in relation to the heart in the sagittal plane. The upper right image shows what could be misinterpreted as a normal four-chamber view. The middle and lower rows demonstrate the four-chamber view with absence of the crux of the heart, characteristic of an atrial-ventricular canal defect.

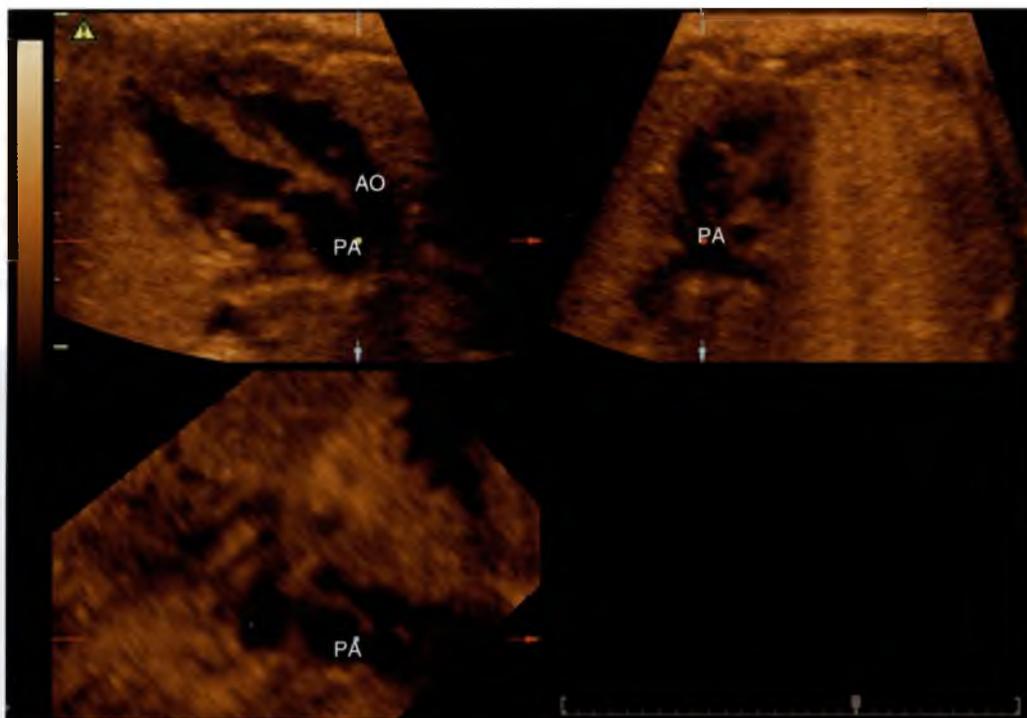

Figure 19-11 Evaluation of heart in a fetus with transposition of great arteries at 24 weeks using spatiotemporal image correlation. The cursor dot is located in the pulmonary artery in each image. *Upper left*, Axial plane showing the aorta (AO) and the pulmonary artery (PA) coming off the ventricles in parallel. *Upper right*, Branching of the pulmonary arteries in a sagittal plane. *Lower image*, Pulmonary artery in a coronal plane. (Courtesy of Greg Devore.)

Figure 19-12 Gastroschisis at 19 weeks. *A*, Surface-rendered image in sagittal plane shows herniation of bowel outside the fetal abdomen. *B*, Surface-rendered image in coronal plane. The *arrow* points to the umbilical cord insertion to the right of the herniation.

estimations.⁷³ They found that, compared with MRI, 3D US consistently underestimated the size of the lungs and that lung measurements acquired with the 30-degree rotation were significantly less than those measured with the smaller angles.⁷³

ABDOMEN

Many authors have shown that 3D US is a useful complementary tool to 2D US when evaluating for abdominal

wall defects. When a mass protrudes from the fetal abdomen, the differential diagnosis includes omphalocele, gastroschisis, and prune-belly syndrome, to name a few. Differentiation is important because the clinical outcome and management may be different. Some authors found that 3D US offered additional information that 2D US did not and that this allowed refinement of the differential, thus affecting the outcome with respect to management and prenatal counseling (Fig. 19-12).⁷⁴

Gender assignment using 3D US has been successful in the first trimester, primarily because it allows the sagittal plane to be obtained easily.^{75,76} It has also been studied in the second and third trimesters.⁷⁷ The diagnosis of ambiguous genitalia can be difficult, and although 3D US may be beneficial as an adjunct to 2D US in assessing gender anomalies and acquiring measurements, it has not been proven to be superior to 2D US in assigning fetal gender.^{77,78}

CENTRAL NERVOUS SYSTEM

3D US is useful in evaluating midline brain anatomy, particularly in the sagittal plane. Some authors have advocated that 3D US imaging of the fetal brain should, when necessary, be done transvaginally.⁷⁹ 3D US has been used to confirm the presence of normal midline structures such as the corpus callosum (CC) (Fig. 19-13) and cavum septi pellucidi (CSP) (Fig. 19-14), particularly in the setting of mild ventriculomegaly. The development of these structures is closely related. The normal CSP should be seen in all fetuses between the 17th and 37th weeks of gestation.⁷⁹ The presence of the CSP implies the presence of a CC; however, the absence of the CSP does not always indicate agenesis of the CC.

Gindes and colleagues⁸⁰ identified the normal hippocampus-fornix structure with 3D US. They found 3D US to be necessary for sonographic depiction and measurement because of the obliquity of this C-shaped structure, and they were able to identify this structure bilaterally in 94% of fetuses beyond 14 weeks' gestational age using this method. 3D US may play an important role in future fetal imaging, because abnormal development of this structure is associated with various congenital brain anomalies and disorders.

3D US has been shown to accurately demonstrate measurements of the cerebellar vermis starting at the 18th gestational week, regardless of fetal position (Fig. 19-15).⁸¹ Measurement of the vermian length and detection of the primary fissure are important in the evaluation of the cerebellum, particularly in fetuses at risk for inferior vermian hypoplasia.⁸¹ VCI has been helpful in enhancing visualization of the cerebellar vermis. In a study comparing fetuses with abnormalities of the cerebellum to normal fetuses, no difference was found in the superoinferior measurement of the vermis before 22 weeks, and the perimeter

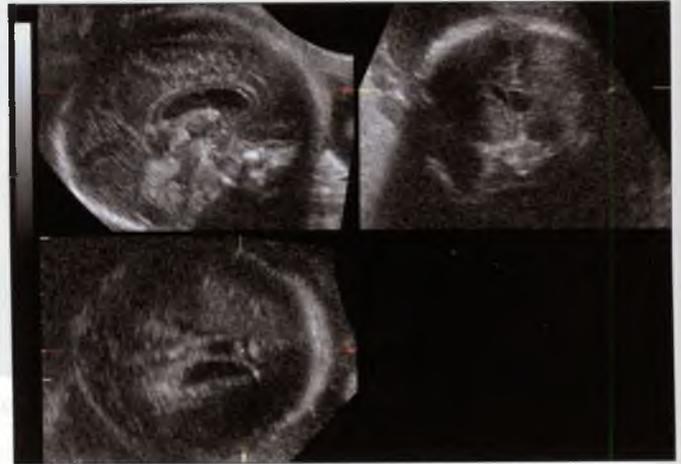

Figure 19-13 Multiplanar image of the normal corpus callosum at 30 weeks. Upper left, Sagittal plane through the fetal brain. The dot on the image is on the normal, hypoechoic corpus callosum, which is located above the septum pellucidi in all three images. Upper right, Coronal view. Lower image, Axial view.

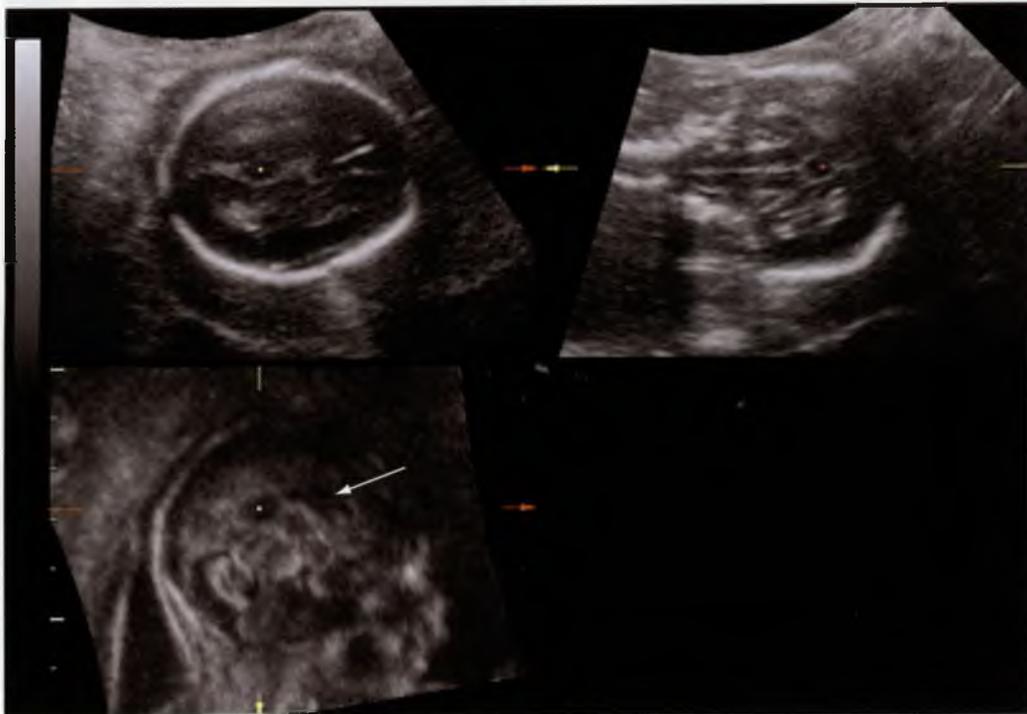

Figure 19-14 Multiplanar images of the normal cavum vergae at 19 weeks. Upper left, Axial view. Upper right, Coronal view. Lower image, Sagittal view demonstrating the normal cavum vergae as a posterior extension of the cavum septi pellucidi (arrow). The cursor dot is on the cavum vergae in all three images.

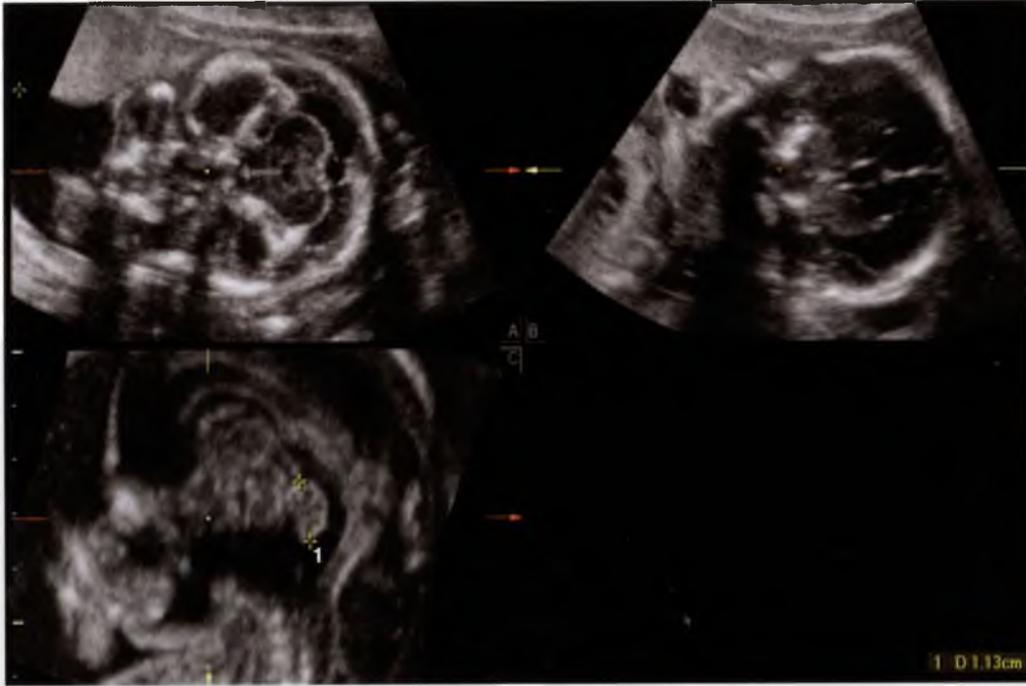

Figure 19-15 Multiplanar images of cerebellar vermis. *Top left*, Axial image through the posterior fossa. *Top right*, Coronal image through the brain. *Bottom left*, Calipers are measuring the craniocaudal length of the vermis in a sagittal plane as 1.1 cm, which is within normal limits for gestational age.

Figure 19-16 Neural tube defect at 21 weeks. *Upper left*, Coronal plane showing an open neural tube defect on the distal spine (dot on image). *Upper right*, Axial view. *Bottom*, Sagittal view.

was not affected before 28 weeks; however, the cross-sectional area of the vermis was smaller than that of normal fetuses earlier in gestation.⁸²

3D US is a valuable adjunct to 2D US imaging in the evaluation of neural tube defects (Fig. 19-16). Several features of 3D US allow more accurate determination of the exact level of myelomeningoceles of the spine, including the ability to magnify the rendered and planar images after scanning and the ability to accurately count vertebral levels using the 3D rendered images.⁸³ The combination of multiplanar and rendered imaging increases the likelihood of detecting the appropriate level of the anomaly.⁸⁴

FETAL EXTREMITIES AND SKELETON

3D US has proved to be the adjunctive imaging modality of choice in evaluation of fetal skeletal anomalies detected on 2D US. Maximum intensity, surface rendering, and x-ray modes are the display modalities best suited to evaluate fetal skeletal structures. The MIP is particularly helpful to visualize curved structures, such as the spine and ribs, in a single rendered image. The volume-rendered images can then be rotated along the vertical axis, improving identification of anomalies.

The fetal spine is sonographically visible at approximately 12 weeks' gestation. In younger fetuses the entire spine can be evaluated in a single volume data set, whereas in older fetuses multiple volumes are needed. The rotational ability afforded by 3D US allows easier recognition of structures. Benoit described the value of using 3D imaging to evaluate the fetal skeleton.⁸⁵ He postulated that 3D US is the investigation modality of choice to study the fetal skeleton at any gestational age. The posterior view of the fetus allows excellent visualization of the spine and is helpful in determining whether there are segmentation anomalies. According to Benoit, the posterior view, in combination with the multiplanar views, can accurately demonstrate the level of the conus medullaris.⁸⁵ Anomalies such as spina bifida, hemivertebrae, and sacral agenesis can be diagnosed.

The posterior view is also suitable to visualize the posterior ribs, aiding in counting ribs when there is a question of too many or too few ribs. Rib abnormalities can be associated with other minor and severe abnormalities. Gindes and associates⁸⁶ reported that imaging of fetal ribs is best acquired with static 3D volumes in the sagittal plane if the fetus is at rest. In this case, the spine is best visualized with the fetus in a prone position with respect to the transducer. However, if the fetus is moving, a thick slice method is better suited.

Garijan and Pretorius demonstrated that 3D US allows clarification of the spatial relationships of deformed limbs in skeletal dysplasias in ways that are not possible with 2D US (Fig. 19-17).⁸⁷ Their study demonstrated the ability to detect scapular anomalies that were undetected on conventional 2D US. A volume-rendered MIP technique enables detection of anomalies such as limb shortening and scoliosis. Surface rendering is very good at demonstrating entities such as clubfoot (Fig. 19-18) and supernumerary digits (Fig. 19-19).

Figure 19-17 Evaluation of fetal skeletal dysplasia. Rendered display of ectrodactyly (lobster claw) of the foot in a fetus with DiGeorge syndrome at 36 weeks.

3D US has also aided in the prenatal diagnosis of cleidocranial dysplasia (CCD).⁸⁸ The multiple skeletal features associated with CCD, including clavicular hypoplasia, absent nasal bones, and wide, nonmineralized midline calvarial areas, can all be readily identified with 3D US.

Early second-trimester identification of amniotic band syndrome using 3D US has been reported in two fetuses.⁸⁹ The amniotic bands and associated abnormal features such as acrania, cleft lip, and digit amputations can be shown with

Figure 19-19 Polydactyly at 23 weeks. Rendered image shows post-axial polydactyly (arrow) on the hand on the left side of the image. The other hand is seen on the right.

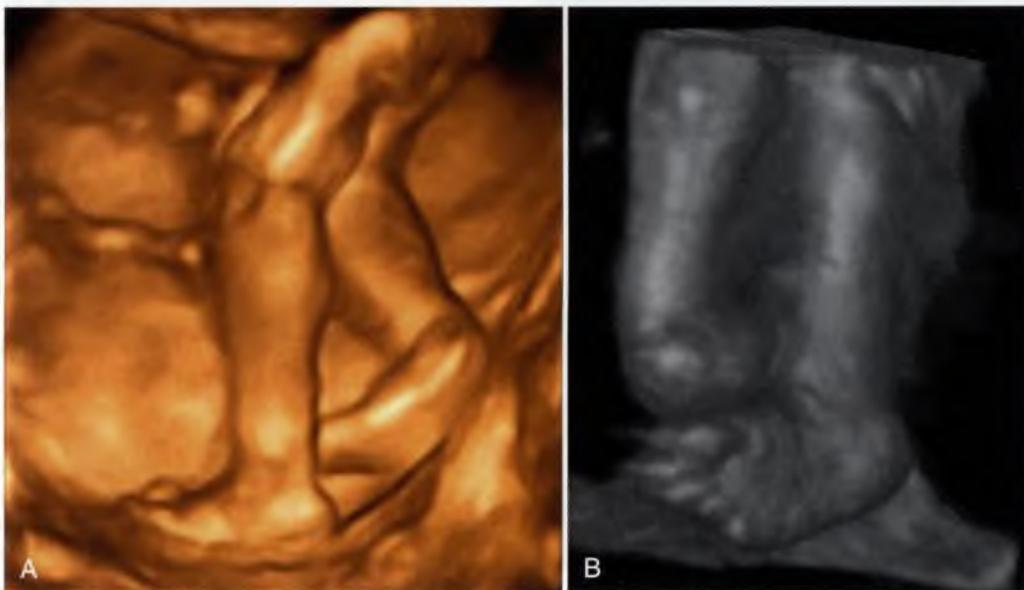

Figure 19-18 Evaluation of fetal ankles. A, Normal ankles at 19 weeks. Rendered image demonstrates normal ankle alignment in a sagittal plane. B, Clubfoot at 20 weeks. Rendered image demonstrates abnormal ankle alignment in a patient with bilateral clubfoot.

surface-rendered 3D images and can help in parental comprehension. However, the role of 3D US in such circumstances remains adjunctive in nature, with no definite evidence of altered outcome.

Parental Bonding

For the parents, any sensory link to the fetus carries significant importance. Until the stethoscope was invented, this connection took the form of fetal movements felt by the mother and sometimes by the father if the hand was placed on the mother's abdomen at the time that the fetus kicked. This association became vastly improved when the heartbeat could be heard with the stethoscope and then heard and seen with ultrasound imaging. 2D imaging brought its own form of parental bonding, with parents taking home sonographic images of the fetus as keepsakes or to show to family and friends. Increasingly, the father now accompanies the mother at routine obstetric sonogram appointments, and both parents usually watch the imaging screen with focused attention.

3D rendering of the fetal face has added another dimension to parental bonding (see Fig. 19-1). Many parents expect 3D imaging to be performed as a routine, especially since the advent of commercial 3D fetal rendering. Several studies have looked at the issue of parental bonding and have tried to determine scientifically whether 3D US promotes the bonding process. Ji and colleagues⁹⁰ questioned 50 mothers who had a 2D US study and 50 who had both 2D and 3D US. They concluded that 3D US promoted bonding between pregnant women and their developing fetus; 82% of women who had 2D and 3D US formed a mental picture of their baby, compared with 39% of women who had 2D US imaging alone. In addition, more women in the former group shared their 3D pictures with others.

3D US can provide important information to the expectant parents and help them in their decision-making process. For example, in a study by Johnson and associates³³ that was performed to review 3D versus 2D US in the diagnosis of cleft lip and cleft palate, seven patients found 3D imaging useful. Of these, three fetuses with suspected cleft lip on 2D US were found to have normal lip and palate on 3D. One family who had been considering termination based on 2D imaging decided to continue the pregnancy after viewing the extent of the cleft on 3D US. Three families decided to continue with termination after observing the cleft lip/palate on 3D US.

Pretorius and associates⁹¹ included 100 parents (both male and female) and asked them to draw a fetal picture before and after seeing a 3D US view of their fetus. The drawings were significantly different after 3D US in 23% to 56%, slightly different in 41% to 64%, and not significantly different in 2% to 22%. Overall, a more practical image was drawn of both the fetus and its surroundings (uterus and placenta). Among the medical professional community, Lee and coworkers⁹² found that, whereas doctors and sonographers expected 3D US to affect future diagnostic imaging, undergraduate students also thought that 3D US would affect parental bonding positively.

In contrast to these studies, Lapaire and colleagues⁹³ performed a prospective study on 60 patients and found that,

whereas 3D US improved identification of the fetus, it did not have an increased influence on maternal-fetal bonding when compared with 2D US. They recommended that 3D US be used only for medical indications and not for standard screening purposes.

Medicolegal Issues

Basic medicolegal issues do not change with 3D imaging, but certain complexities do arise. For example, medical care providers must determine whether the volumes or only still images will be stored and whether multiplanar or volume-rendered images will be saved in the archives. In general, we recommend that only still images be saved unless the volumes are being used for research, teaching, or quality assurance purposes.

Future of Volume Sonography in Obstetrics

Over the last 2 decades, it has become clear that 3D US is here to stay. How much of an influence it has on routine imaging protocols remains to be seen. There is no doubt that 2D imaging is the mainstay of obstetric sonography. Clinical indication and the detection of areas of concern on 2D US may direct further evaluation with 3D. Even with 3D volume acquisition, however, the primary diagnostic information lies in the multiplanar data, and the surface-rendered images are derived from these multiplanar sources.

3D and 4D US remains a challenge to the uninitiated. In particular, when this new technique was introduced more than 2 decades ago, very few sonologists, sonographers, and obstetricians were inclined to use it. A large measure of this reluctance came from new machines and display features that appeared overwhelming and time-consuming (slow software) and were at the time nonintuitive. Different types of keyboards and display buttons or knobs also limited enthusiasm and hindered wider use of this technique.

Recent upgrades have resulted in the development of a more user-friendly postprocessing software that is no longer daunting to those who have limited or no 3D experience. This enhanced image manipulation capability, together with newer ultrasound probes with vastly improved resolution, has greatly aided in the expansion of 3D application in obstetrics. As the trend continues, an increasing number of sonologists and sonographers will approach 3D US with greater confidence and decreased trepidation. Continued targeted application of 3D US to solve specific diagnostic issues is expected to greatly increase knowledge, understanding, and expertise in the management of fetal disorders. Finally, given the volume of 3D US research in the last decade, it is quite probable that the demand for 3D US from both the professional and the patient community will increase as understanding and expertise in the field expand.

SECTION II

Lesions

Microbiological Features

The microbiological features of the lesion are characterized by the presence of a dense infiltrate of inflammatory cells, predominantly neutrophils, within the epidermal and dermal layers. The infiltrate is often organized into well-defined abscesses, which are typical of bacterial infections. The organisms themselves are often difficult to identify due to their small size and the presence of host cell debris.

Immunohistochemical Findings

Immunohistochemical studies of the lesion reveal a strong positive reaction for markers associated with acute inflammation, such as CD68 (macrophages) and CD15 (neutrophils). The presence of these markers supports the diagnosis of an acute bacterial infection. Additionally, the absence of significant staining for markers associated with chronic inflammation or specific fungal organisms further narrows the differential diagnosis.

The histological findings, including the presence of neutrophilic abscesses and the immunohistochemical profile, are highly suggestive of a bacterial etiology. The clinical presentation of a rapidly developing, painful, and erythematous lesion further supports this diagnosis.

The clinical presentation of the lesion is characterized by a rapidly developing, painful, and erythematous nodule on the skin. The patient reports a history of recent trauma to the area, which may have facilitated the entry of bacteria. The absence of systemic symptoms and the localized nature of the lesion are consistent with a primary cutaneous infection.

The clinical and histological findings are consistent with a diagnosis of bacterial abscess. The patient should be treated with appropriate antibiotics and surgical drainage of the abscess. A follow-up examination should be scheduled to ensure resolution of the lesion.

Parental Involvement

Parental involvement is a critical component of the management of the child's condition. The parents should be educated about the signs and symptoms of the infection and the importance of adherence to the treatment regimen. Regular communication with the healthcare provider is essential to monitor the child's progress and address any concerns.

The parents should be encouraged to actively participate in the child's care, including monitoring for any changes in the lesion or the child's overall health. They should be instructed on proper wound care and the use of prescribed medications. Additionally, the parents should be advised to avoid activities that could further irritate the lesion or increase the risk of infection. The healthcare provider should provide clear instructions and answer any questions the parents may have.

The parents should be informed of the potential complications of the infection and the importance of seeking medical attention if the lesion worsens or if the child develops any systemic symptoms. The healthcare provider should provide the parents with contact information for the clinic and a clear understanding of the follow-up schedule.

The parents should be reassured that the infection is treatable and that the child's prognosis is generally good with appropriate management. The healthcare provider should provide the parents with written instructions and a copy of the child's medical records. The parents should be encouraged to ask any questions they may have and to express their concerns. The healthcare provider should provide the parents with the necessary support and resources to ensure the best possible outcome for the child.

Figure 18-18. Evaluation of skin lesion. The histological findings, including the presence of neutrophilic abscesses and the immunohistochemical profile, are highly suggestive of a bacterial etiology. The clinical presentation of a rapidly developing, painful, and erythematous lesion further supports this diagnosis.

Central Nervous System Imaging

ANA MONTEAGUDO, MD | ILAN E. TIMOR-TRITSCH, MD

20A CEPHALOCELE

Diagnosis

DEFINITION

Cephaloceles are cranial defects, along bony sutures, in which there is a herniation of the brain or the meninges, or both. Cephaloceles can be occipital, parietal, or frontal; in the Western Hemisphere, 80% are occipital. If the cephalocele sac contains brain tissue, it is termed an *encephalocele*; if only cerebrospinal fluid (CSF) is present, it is termed a *meningocele*.

INCIDENCE AND PATHOGENESIS

- Incidence ranges from 1 in 3500 to 1 in 5000 live births.¹ Occipital encephalocele is most common.²
- Usually isolated, but in a small percentage of cases may be a part of a chromosomal or nonchromosomal syndrome.
- The exact pathogenesis of cephalocele is unclear. However, there is failure of closure of the neural tube no later than 26 days after conception, at the time when the anterior neural tube closes.³

DIFFERENTIAL DIAGNOSIS

- Midline scalp masses such as cysts, hemangiomas, nuchal tumors, cephalhematomas, cystic teratomas, scalp edema, cystic hygromas, branchiogenic cysts, and fetal hair (during the third trimester)
- Amniotic band syndrome
- Autosomal recessive syndromes that feature a cephalocele: Meckel (cephalocele, renal cystic dysplasia, and postaxial polydactyly); Walker-Warburg or HARD \pm E (hydrocephaly, agyria, retinal dysplasia, with or without encephalocele); Knobloch (vitreoretinal degeneration and occipital encephalocele)

KEY DIAGNOSTIC FEATURES

- Sac-like structure adjacent or posterior to the fetal head
- Brain tissue seen in the sac covered by skin
- Skull defect
- Hydrocephaly in 80% of occipital encephaloceles
- Microcephaly (20%)

ASSOCIATED ANOMALIES

- Approximately 65% of fetuses and infants with cephalocele have at least one major malformation, and 35% have isolated cephalocele.⁴
- Extracranial malformations: cardiovascular (ventricular septal defect [VSD], coarctation of the aorta, single umbilical artery); urogenital tract (pyelectasis, ureteral agenesis); malformations of the extremities (talipes equinovarus); malformations of the thorax and abdominal wall (gastroschisis, diaphragmatic hernia, costal malformations)⁵
- CNS anomalies include microcephaly (up to 25%), hydrocephaly (30%-50%), agenesis of the corpus callosum, Dandy-Walker malformation, holoprosencephaly (lobar), Arnold-Chiari type II malformation,⁴ and cerebral dysgenesis.
- Trisomy 18, trisomy 13, mosaic trisomy 20; various deletions and duplications also described

Imaging

Figure 20-1 Cephalocele: axial view.

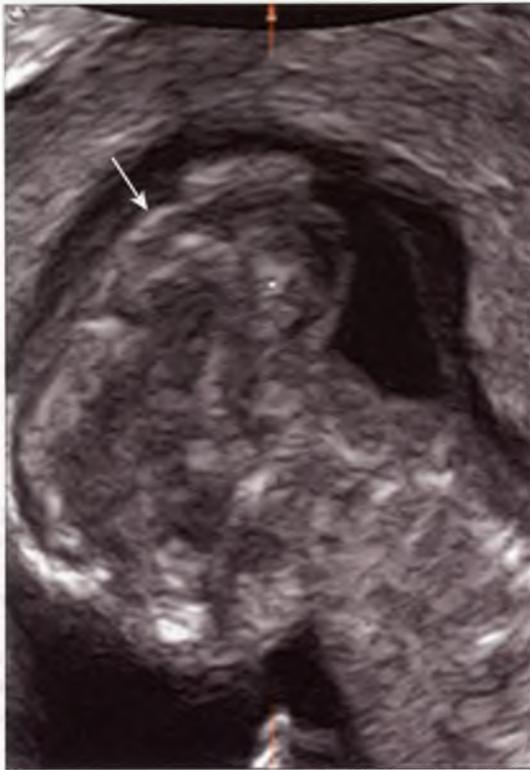

Figure 20-2 Cephalocele: sagittal view. The cephalocele sac is seen protruding from the posterior aspect of the fetal head (*arrow*) in this fetus at 12 weeks' gestation.

Figure 20-4 Cephalocele: sagittal view. Anterior encephalocele at 16 weeks' gestation (*arrow*). There is a mass superior to the nose. A bony defect is also seen.

Figure 20-3 Cephalocele: 3D reconstruction. A fetus at 20 weeks with a posterior encephalocele (*arrow*).

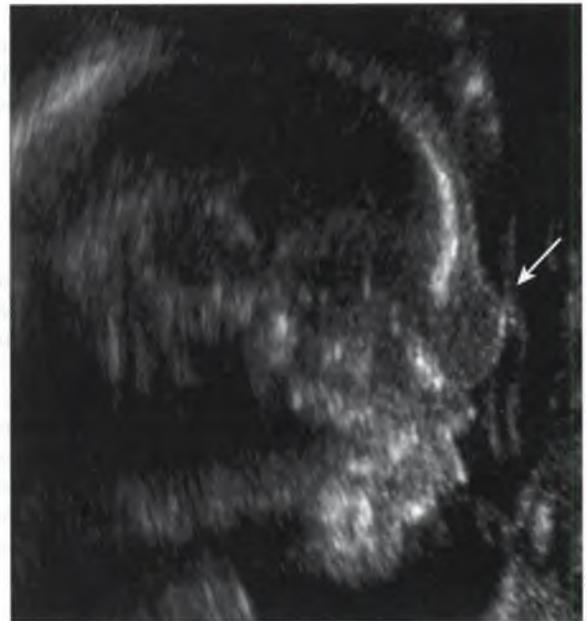

Figure 20-5 Cephalocele: sagittal view. Anterior encephalocele at 25 weeks' gestation (*arrow*).

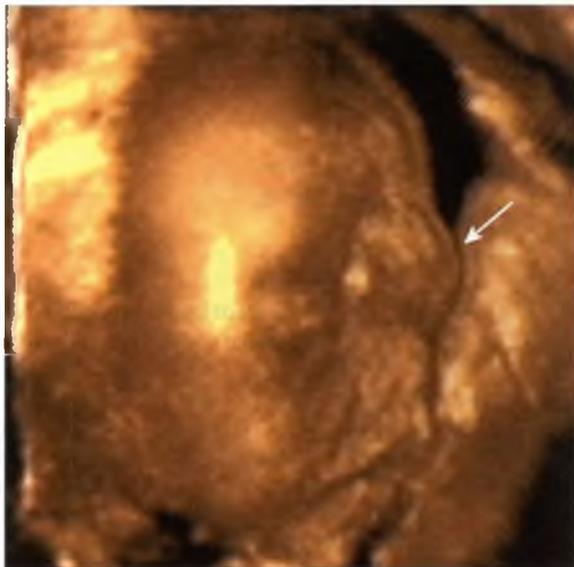

Figure 20-6 Cephalocele: 3D reconstruction. Anterior encephalocele located between the eyes and superior to the nose (arrow). Large posterior encephalocele at 12 weeks' gestation (arrow).

Management

ANTENATAL MONITORING

- Detailed anatomic survey, fetal echocardiography
- Genetic counseling, chorionic villus sampling (CVS), and/or amniocentesis; may consider microarray if chromosomes are normal
- Consultation with maternal-fetal medicine, pediatric surgery, pediatric neurology, and neonatology

- Consider MRI if diagnosis is not clearly established by ultrasound.
- Offer termination of pregnancy.
- Repeat ultrasound during the third trimester.

OBSTETRIC MANAGEMENT

- Delivery in a tertiary care hospital
- Delivery route needs to be individualized after consultation with the appropriate specialists, such as maternal-fetal medicine, neonatology, pediatric neurology, and neurosurgery.

NEONATAL MANAGEMENT

- Depends on the presence of associated anomalies, size and contents of the cephalocele
- Postnatal surgical resection and closure of the defect

PROGNOSIS

- High mortality rate—as high as 80% in prenatally diagnosed cases
- Among the survivors: normal development in 48%, mild developmental delay in 11%, moderate developmental delay in 16%, severe developmental delay in 25%, and death in 5%⁶
- Meckel and Walker-Warburg syndrome have a poor prognosis with a significant number of fetuses stillborn or dying shortly after birth.
- In Knobloch syndrome, severe visual deficits eventually leading to blindness
- Normal intelligence has been reported.

20B CHOROID PLEXUS CYSTS

Diagnosis

DEFINITION

Choroid plexus cysts (CPCs) are well-demarcated, anechoic, fluid-filled structures within the choroid plexus of the lateral ventricles of the brain.¹ They are not true cysts in the pathologic sense. CPCs are often called “soft sonographic signs” or “markers” of aneuploidy, because some studies have found an association between them and fetal chromosomal abnormalities. However, as more knowledge has accumulated, the initial importance attributed to this common sonographic finding has diminished. When the CPCs are isolated, some consider them an anatomic variant.^{2,3}

INCIDENCE AND PATHOGENESIS

- Incidence ranges from 0.18% to 3.6% of fetuses scanned in the second trimester.^{1,4,5}
- Pathogenesis is not clear but may be caused by filling of the neuroepithelial folds with cerebrospinal fluid. The CPC results from fluid trapped within this spongy layer of cells.

DIFFERENTIAL DIAGNOSIS

- Ventriculomegaly
- Choroid plexus papilloma

- Intraventricular hemorrhage
- Periventricular leukomalacia

KEY DIAGNOSTIC FEATURES

- Unilateral or bilateral sonolucent cystic structures within the glomus of the choroid plexus of the lateral ventricles
- Borders are well delineated.
- Size, shape, and number are variable.
- Usually small, measuring <10 mm in diameter (range, 3–20 mm); should be at least >2 mm to meet criteria. Therefore not every “dropout” seen in the choroid plexus is a true CPC.
- They regress, spontaneously disappearing during the third trimester.^{3,6,7}

ASSOCIATED ANOMALIES

- CPCs may be an isolated finding or associated with fetal anomalies.
- Associated anomalies are typically those seen with trisomy 18 and include congenital heart disease, clenched hands, single umbilical artery, intrauterine growth restriction, and rocker bottom feet.
- Chromosomal aneuploidy: trisomy 18
- Rare cause of obstructive hydrocephaly

Imaging

Figure 20-7 Choroid plexus cyst: axial view. A-C, Axial view of three different fetuses at the time of the anatomic survey (19 to 21 weeks) with bilateral choroid plexus cyst (CPC). The CPCs were isolated findings in all three fetuses. Notice that the appearance is slightly different in each fetus.

Figure 20-8 Choroid plexus cyst: sagittal view. The CPC is clearly seen within the choroid plexus.

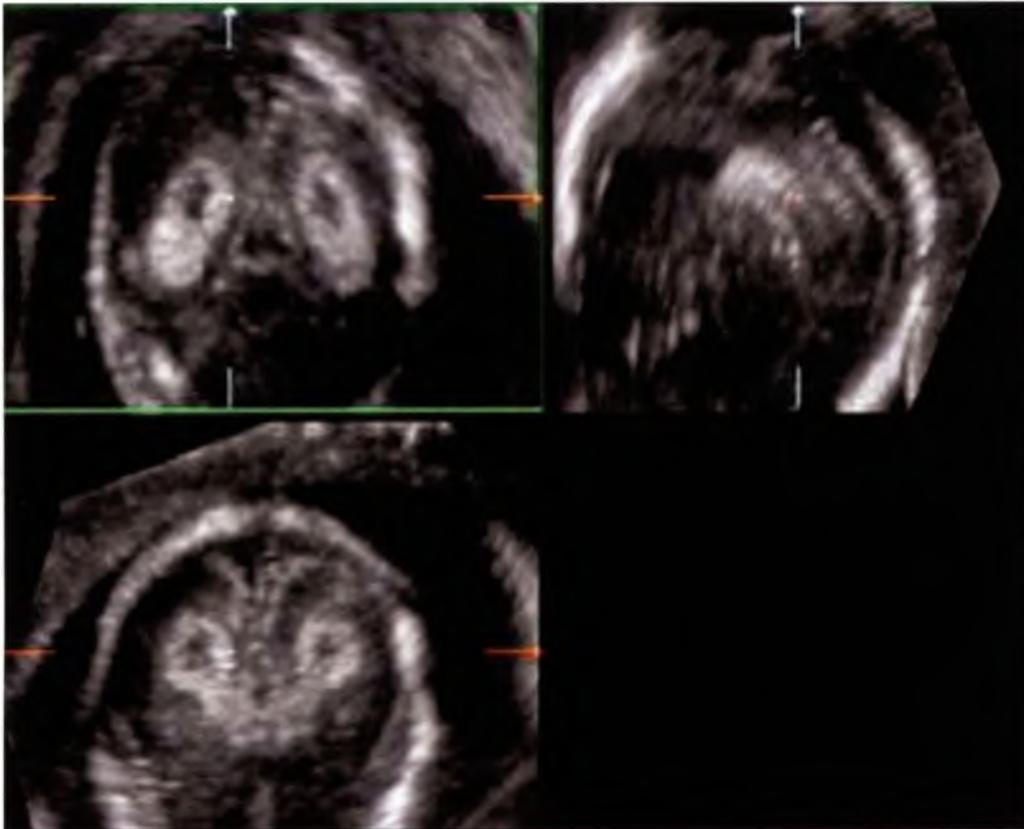

Figure 20-9 Choroid plexus cyst: 3D view. This 3D multiplanar display shows the appearance of bilateral choroid plexus cysts in all three planes.

Management

ANTENATAL MONITORING

- Anatomic survey. Document bilateral open hands, normal fetal cardiac views, and three vessels in the umbilical cord.
- Consider fetal echocardiography if unable to adequately image the fetal heart.
- Maternal serum screen, if not already done, or review first-trimester nuchal translucency (NT) screen result. Consider an integrated screen.
- If CPCs are isolated findings and the maternal serum screen suggests low risk, couple can be counseled that amniocentesis is unlikely to find any abnormality.
- If CPCs are associated with other findings (e.g., ventricular septal defect [VSD], clenched hands) or the maternal serum screen shows increased risk, offer genetic counseling and amniocentesis.
- After normal fetal anatomy is established, no sonographic follow-up is considered necessary, because isolated as well as nonisolated CPCs resolve spontaneously.⁵
- Further sonography is not necessary unless severe parental anxiety is present.

OBSTETRIC MANAGEMENT

- In patients with isolated CPC, routine obstetric management is indicated.

- Cesarean section only for the usual obstetric indications
- If associated with other findings, the delivery method may be dictated by the concurrent fetal anomaly.

NEONATAL MANAGEMENT

- No special management is necessary for neonates who had isolated CPCs as fetuses.
- However, if there are other anomalies, management of the neonate is dictated by the findings.
- If trisomy 18 is present: comfort care, genetic consultation, and perinatal hospice if available.

PROGNOSIS

- The prognosis of isolated CPC is good; almost all resolve by 32 weeks.^{3,6,8}
- Isolated CPCs in fetuses with normal karyotypes do not affect child development after birth.⁹
- Guarded prognosis if associated with anomalies, depending on results of karyotyping and/or severity of the associated anomalies
- The concurrent anomaly dictates the prognosis.

20C HOLOPROSENCEPHALY

Diagnosis

DEFINITION

Holoprosencephaly (HPE) encompasses a spectrum of brain abnormalities in which there is failure of the forebrain to properly divide along the midline. The three “classic forms” are alobar, semilobar, and lobar; a fourth mild form, middle interhemispheric variant (MIHV), is also recognized. In alobar, the most severe type, there is complete lack of division of the forebrain with absent midline structures. In semilobar, there is some posterior separation. In lobar, there is lack of separation of the ventral neocortex and agenesis of the corpus callosum. In MIHV, the mildest form, the failure of separation involves the posterior frontal and parietal lobes, with incomplete separation of the thalami and caudate nuclei and absent body of the corpus callosum.¹ HPE is associated with a spectrum of facial abnormalities, with the more severe abnormalities seen with the most severe types (e.g., alobar).

INCIDENCE AND PATHOGENESIS

- Holoprosencephaly (HPE) is the most common malformation involving the forebrain. It occurs in 1:250 embryos and 1:10,000 live births. It is estimated that in more than 90% of affected embryos, spontaneous demise and abortion will occur.¹⁻³
- HPE is a primary defect of induction and patterning that leads to partial or complete failure of division of the prosencephalon into two separate hemispheres between the 18th and 28th day after conception.² However, no splitting actually occurs; instead, there is budding of the telencephalon.³
- Genetic and environmental factors play a role in the development of HPE.²

DIFFERENTIAL DIAGNOSIS

In alobar and semilobar HPE:

- Hydrocephaly
- Schizencephaly
- Arachnoid cyst
- Agenesis of the corpus callosum

In lobar HPE:

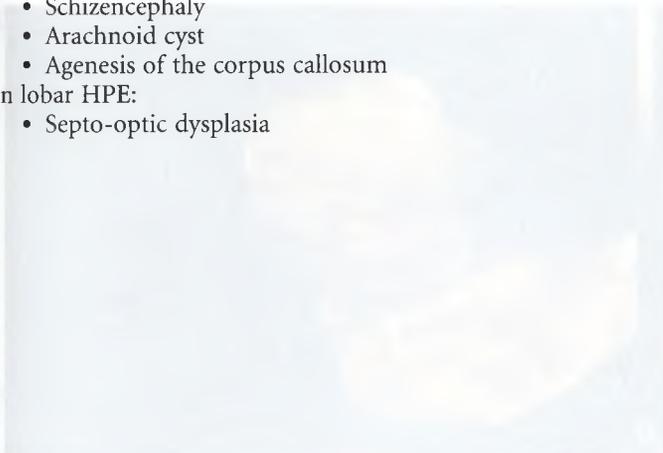

- Septo-optic dysplasia

KEY DIAGNOSTIC FEATURES

- In alobar HPE, there is a monoventricle; absence of the interhemispheric fissure, falx cerebri, corpus callosum, and cavum septi pellucidi; fusion of the thalami and cerebral hemispheres, and possibly various facial anomalies (e.g., cyclopia, proboscis, median clefts).
- In semilobar HPE, there is absence of the interhemispheric separation, but posteriorly there is some separation. The anterior horns are fused; the septi pellucidi and the anterior part of the corpus callosum are absent; and there is partial separation of the thalami, a rudimentary third ventricle, and facial anomalies (e.g., hypotelorism).
- In lobar HPE, there is an absent cavum septi pellucidi and corpus callosum in the affected area.
- In middle interhemispheric variant (MIHV), there is incomplete separation of the thalami and caudate nucleus, absent body of the corpus callosum, and brain heterotopias.
- Microcephaly is commonly seen.

ASSOCIATED ANOMALIES

- CNS abnormalities: most commonly neural tube defects (exencephalies, meningoencephalocoles, myelomeningocele, and myelocoles), Dandy-Walker malformation (DWM), rhombencephalosynapsis.
- Face abnormalities seen with the most severe cases may include cyclopia, synophthalmia, or microphthalmia; proboscis; severe hypotelorism; midline cleft lip and palate; flat nasal bridge; and single or barely separated nostrils.^{1,4}
- 25%-45% of newborns with HPE have a karyotype abnormality (trisomy 13, trisomy 18, triploidies). Mutations in 21q22.3, sonic hedgehog (*SHH*), *Zic2*, *SIX3*, and *TGIF* genes are also seen.¹
- About 25% have syndromes such as Smith-Lemli-Opitz and Pallister-Hall.

Imaging

Figure 20-10 Normal axial view. This is an axial view in a normal fetus. It is included to compare it with the pathology in Figures 20-11 and 20-12.

Figure 20-11 Holoprosencephaly: axial view. A, Fetus at 11 5/7 gestational weeks with holoprosencephaly. The midline falx is absent, and the choroid plexuses appear to be fused. B, A fetus at 14 weeks' gestation with alobar holoprosencephaly. Absence of all midline structures is evident.

Figure 20-12 Holoprosencephaly: 3D rendering of the face. A 17-week fetus with alobar holoprosencephaly. A, The face is dysmorphic with a proboscis between the eyes. B, The profile in this fetus is flat, and the proboscis is prominent.

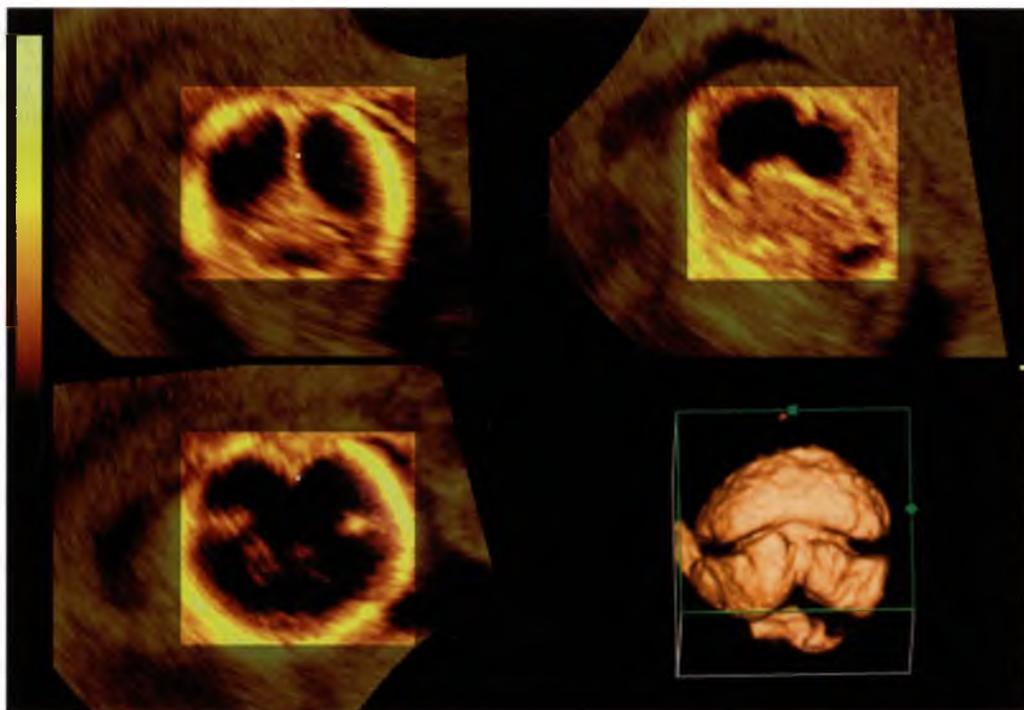

Figure 20-13 Semilobar holoprosencephaly. 3D ultrasound with an inversion rendering of the fluid in the dilated and fused anterior horns and the posterior horns divided by a midline falx.

Management

ANTENATAL MONITORING

- Anatomic survey, fetal neuroscan, consider 3D to assess degree of facial abnormalities. Fetal echocardiography.
- Offer genetic counseling, karyotyping, and microarray studies.
- Consultations with neonatology, pediatric neurology, and genetics are suggested.
- Offer termination of pregnancy.
- In the lobar form of HPE and in ongoing pregnancies, consider fetal MRI to better define the brain anomaly and look for gray matter abnormalities.
- In ongoing pregnancies, repeat scan in the third trimester.

OBSTETRIC MANAGEMENT

- Delivery should be at institution with an NICU as well as services such as pediatric neurology, genetics, and radiology.
- Vaginal delivery is not contraindicated. Delivery route should be individualized depending on the severity of the brain and facial abnormalities. In alobar HPE, if macrocephaly or severe hydrocephaly is present, consider cephalocentesis.
- In milder forms of HPE, cesarean delivery should be performed for the usual obstetric indications. In alobar HPE, cesarean section should be offered only for maternal indications.

NEONATAL MANAGEMENT

- Newborns with the most severe brain anomalies and facial dysmorphism supportive should be given comfort care due to the high mortality rate.

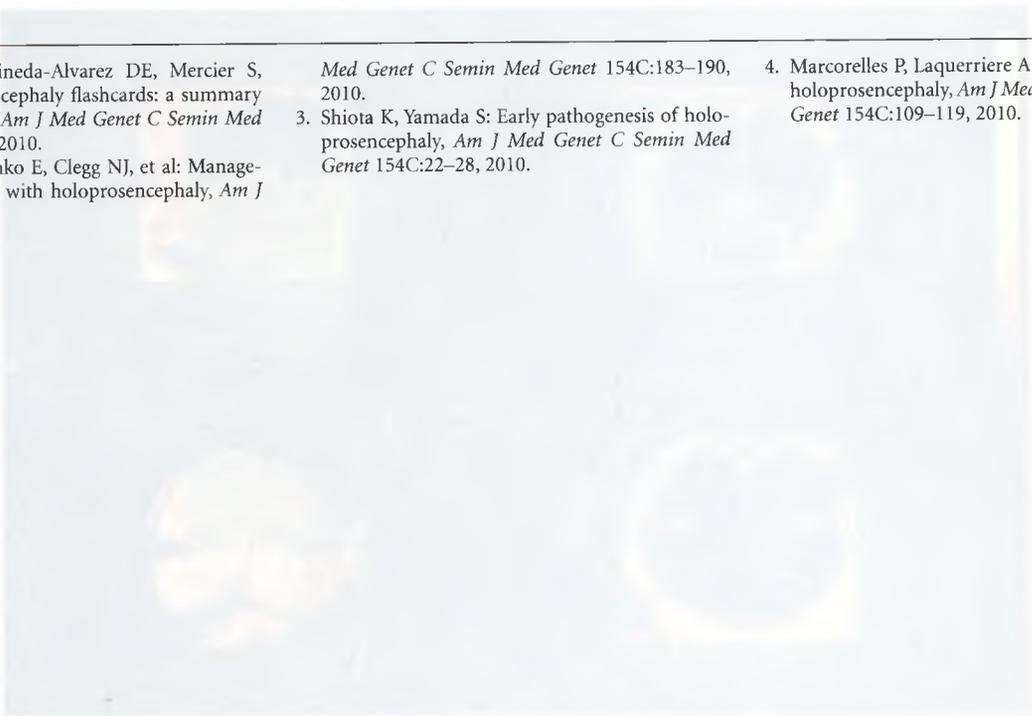

- Refer parents to perinatal hospice program, if available.
- In neonates with milder forms of HPE, consultation with genetics and neurology as well as repeat brain ultrasound and/or MRI are recommended to reassess the in utero findings.
- Karyotyping and/or microarray testing should be performed if not previously done.

PROGNOSIS

- Mortality rate for neonates with HPE is high. Some survive beyond the neonatal period, and a small number survive for many years.³ Approximately 33% die within the first day, 58% within the first month; only 29% survive 1 year.²
- Survival depends on the severity of the brain and facial abnormalities, the presence of aneuploidy, and other congenital anomalies.
- Alobar HPE has the highest mortality; however, children with milder forms of HPE (lobar and MIHV) may live for many years. Isolated HPE has the best survival; 54% live beyond the first year.²
- All children with HPE have developmental disabilities. The degree of developmental disability typically correlates with the severity of the brain malformation. Alobar HPE has the worst neurologic outcome.²

20D PORENCEPHALIC CYST

Diagnosis

DEFINITION

Porencephalic cyst is a pathologic brain cavity filled by cerebrospinal fluid (CSF); it is not a true cyst because it does not have a cyst wall. The cyst is the end result of an insult occurring between the second trimester of pregnancy and the early postnatal period. Areas affected by the insult undergo tissue necrosis and resorption, leaving behind a cavity in the brain (porencephalic cavity). Schizencephaly and porencephaly may share similar pathologies.

INCIDENCE AND PATHOGENESIS

- Porencephaly is a rare disorder that is the end result of a prenatal or perinatal ischemic stroke caused by an arterial or venous infarction, intraparenchymal hemorrhage, or in utero infection. These insults result in focal or multifocal areas of brain necrosis that subsequently undergo dissolution and cavity formation.
- The fetal incidence is unknown; however, in term neonates the estimated incidence of a perinatal arterial ischemic stroke (PAIS) is 1:2500 to 1:5000.

DIFFERENTIAL DIAGNOSIS

- Unilateral schizencephaly
- Arachnoid cysts
- Hydranencephaly

- Ependymal cyst
- Encephalomalacia
- Brain tumor

KEY DIAGNOSTIC FEATURES

- “Cyst” or cavity within the brain parenchyma that communicates with the ventricles and/or subarachnoid space
- Ventriculomegaly on the same side as the cyst
- No mass effect present
- Cyst seen along the distribution of the middle cerebral artery or other arteries
- Typically seen late in the pregnancy

ASSOCIATED ANOMALIES

- Ventriculomegaly
- Polymicrogyria may border the “cysts.”
- Thrombophilias, high rate when compared to the general population
- In one study, 64% of infants with perinatal arterial stroke had at least one thrombophilic marker and 68% of the mothers were carriers of a thrombophilia.
- Factor V Leiden mutation, protein C deficiency, and the presence of antiphospholipid antibodies were significant factors for perinatal stroke.
- A mutation in collagen IV A1 (*COL4A1*) gene in autosomal dominant porencephaly

Imaging

Porencephalic Cyst

Fetal

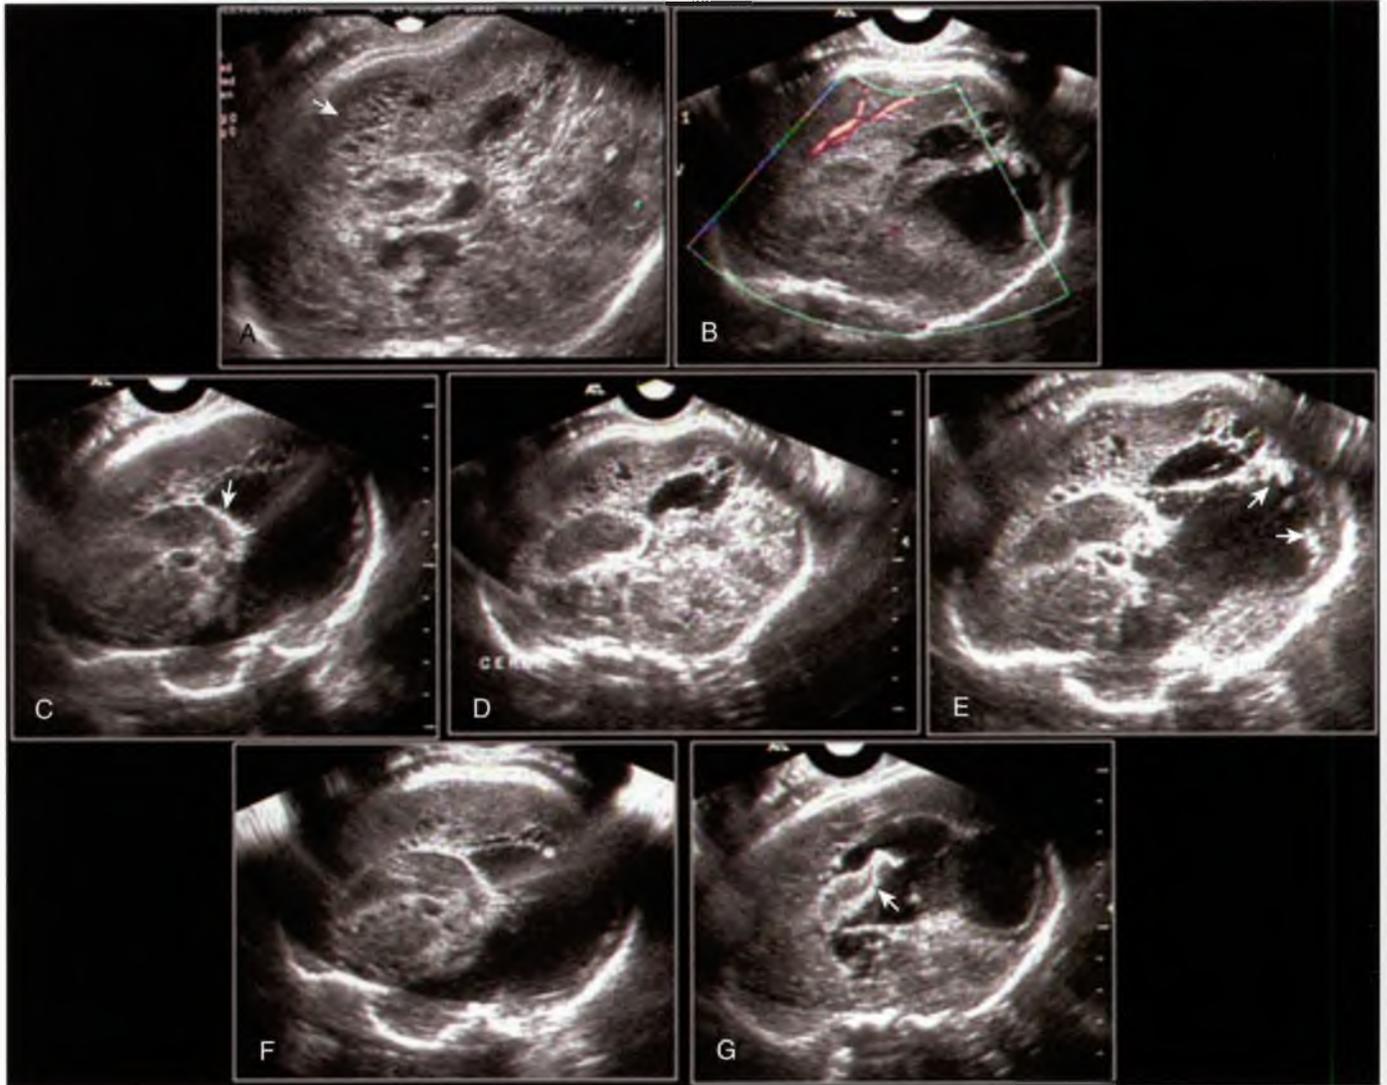

Figure 20-14 Porencephalic cyst: serial sagittal view. A, The brain parenchyma in this median section shows multiple cystic structures (*arrow*) consistent with areas of brain that have undergone a destructive in utero insult. Note that the corpus callosum cannot be identified. B, Color Doppler demonstrates remnants of the pericallosal artery. C, A more lateral view of the brain shows a large cystic structure, likely a dilated posterior horn of the lateral ventricle. The *arrow* points to a thin choroid plexus. D, A median section of the fetal brain. Note that neither the corpus callosum nor the vermis of the cerebellum can be clearly identified due to the brain insult, which has resulted in multiple cystic areas in the brain. E shows the dilatation of the posterior horn of the lateral ventricle. The *arrows* point to two of the multiple brightly echogenic structures surrounding the ventricle; these are areas of brain destruction. F, Similar view of E. G, The *arrow* points to a thin and dysmorphic choroid plexus.

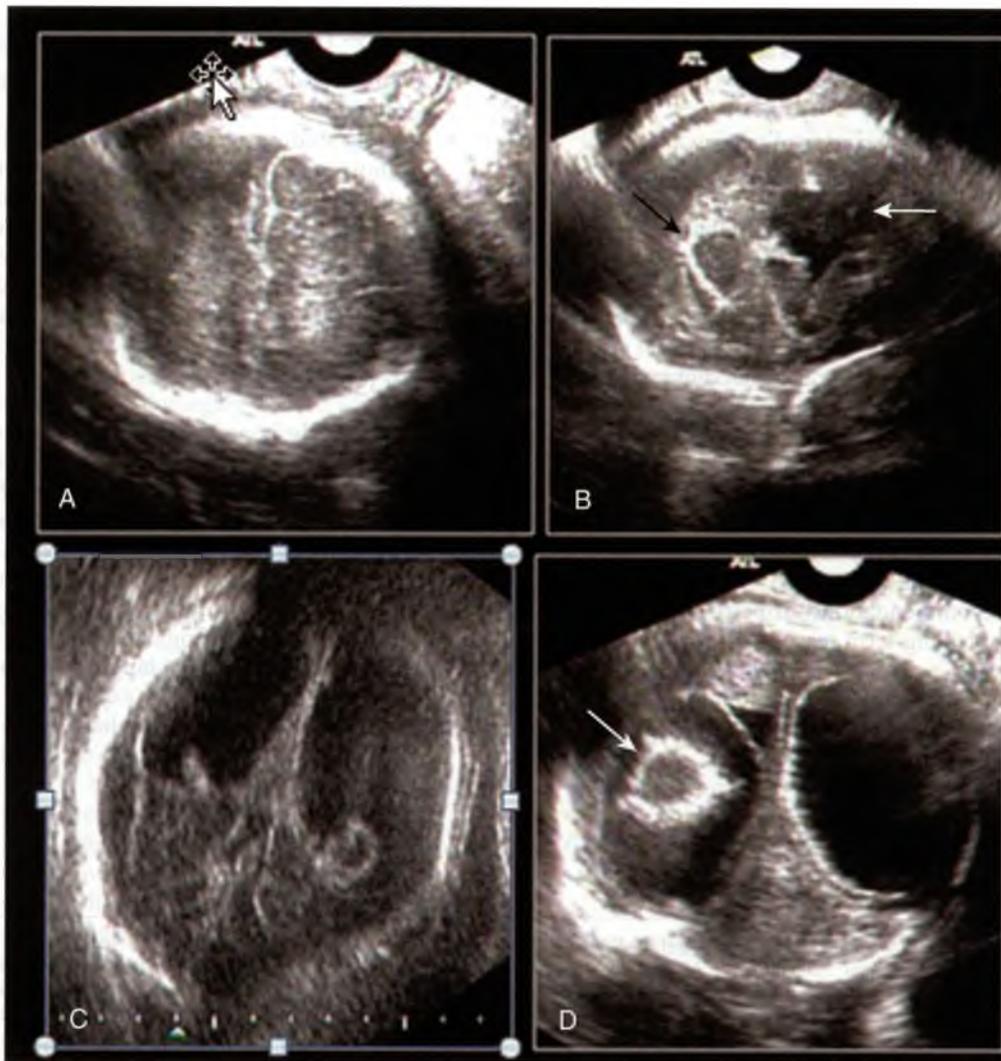

Figure 20-15 Porencephalic cyst: coronal view. Fetus with an intracranial hemorrhage, four serial coronal sections from anterior to posterior. A, Anterior coronal showing a normal brain. B, A slightly more posterior section shows blood (echogenic mass) within the anterior horn and extending into the brain parenchyma (black arrow); the white arrow shows the porencephalic cyst. C, Bilateral hydrocephaly. D, Posterior coronal sections with blood within the posterior horn (arrow).

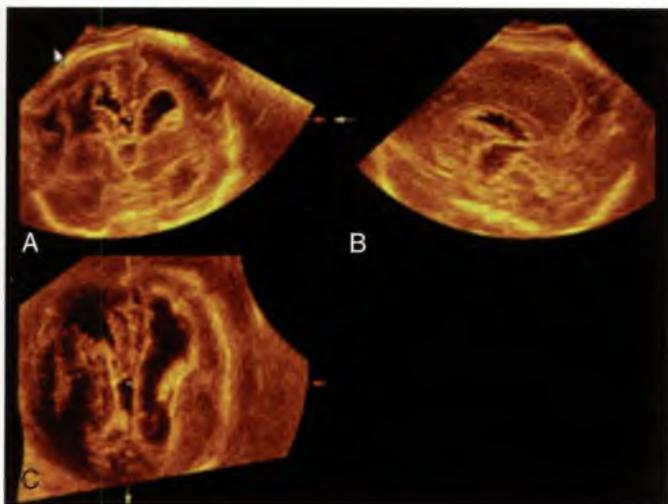

Figure 20-16 Porencephalic cyst: 3D orthogonal view. Coronal (A), sagittal (B), and axial (C) sections of this fetus that has suffered an intracranial hemorrhage are shown. In the coronal section, a porencephalic cyst is seen within the brain parenchyma (A). The borders of the lateral ventricles are irregular with a moth-eaten appearance due to the destruction of the brain tissue secondary to the hemorrhage (C).

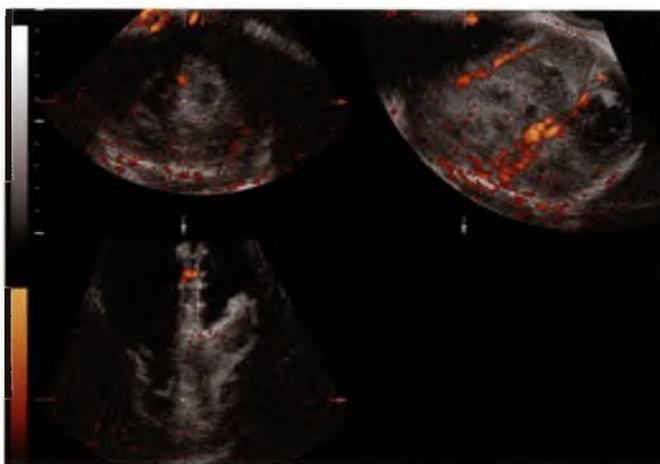

Figure 20-17 Porencephalic cyst: 3D color Doppler angiogram. Minimal vascularity is seen in the brain of this fetus with porencephaly.

Management

ANTENATAL MONITORING

- Detailed anatomic survey and fetal neuroscan
- Genetic counseling and testing
- Thrombophilia workup of both parents (factor V Leiden mutation, protein C deficiency, antiphospholipid antibodies)
- Fetal infection workup (TORCH titers)
- Consultations with neonatology, pediatric neurology, and neurosurgery
- Fetal MRI to look for other intracavitary and extracavitary anomalies
- Offer termination of pregnancy.
- For ongoing pregnancies, ultrasound to monitor ventriculomegaly

OBSTETRIC MANAGEMENT

- No standard recommendations for best route of delivery
- Given the poor long-term prognosis, vaginal delivery should be offered.
- Cesarean section should be performed for routine obstetric indications.

NEONATAL MANAGEMENT

- At birth evaluation by neonatologist, may need NICU admission
- Imaging studies such as ultrasound and MRI to confirm diagnosis and search for additional anomalies
- Evaluation by geneticist to exclude familial porencephaly
- Neurology and neurosurgery consultations
- Evaluation and control of seizures, which may begin shortly after birth
- Shunt if severe or progressive hydrocephaly

PROGNOSIS

- Porencephaly is associated with considerable morbidity and mortality. The prognosis varies according to the location, extent of the lesion, and timing of the insult. Most prenatally diagnosed cases have a poor outcome.
- Among survivors, porencephaly is the leading cause of cerebral palsy and congenital hemiplegia.
- Hemiparesis and/or motor deficits are seen in >80%.
- 50%-75% have neurologic deficits or epilepsy.
- 20%-60% have deficits in language, vision, cognition, and behavior.
- A small number of children have mild to no neurologic symptoms.

20E VENTRICULOMEGALY: AQUEDUCTAL STENOSIS

Diagnosis

DEFINITION

The terms *ventriculomegaly* (VM) and *hydrocephaly* are used interchangeably in the literature, but they are different entities. *Ventriculomegaly* should be preferred, because it identifies the abnormal sonographic finding, independently from the etiology. Most commonly, “ventriculomegaly” is used when the ventricles are mildly enlarged, and “hydrocephaly” is used when they measure >15 mm. Aqueductal stenosis (AS) results from the narrowing of the aqueduct of Sylvius, which connects the third and fourth ventricles. VM is a common cause of noncommunicating obstructive hydrocephaly.

INCIDENCE AND PATHOGENESIS

- The incidence of congenital dilation of the lateral ventricles is 0.3 to 1.5 per 1000 births.¹
- AS is the most common cause of fetal VM, accounting for 30%-40% of the cases.²
- The aqueduct may become stenotic as a result of mass effect or from intrinsic pathology.³
- In approximately 75% of patients, the etiology for the disorder is not known (idiopathic AS).^{3,4} Causes of AS include genetic (X-linked syndrome or L1 syndrome), MASA syndrome (*mental retardation, aphasia, shuffling gait, adducted thumbs*), and spastic paraplegia 1 (SPG1) syndrome; bacterial and viral infections (e.g., cytomegalovirus [CMV], influenza A); hemorrhage (direct obstruction of the aqueduct by blood or clot); and CNS anomalies (e.g., Chiari I, Dandy-Walker malformation).^{3,4}
- Incidence of X-linked hydrocephaly is 1:30,000 males.⁵

KEY DIAGNOSTIC FEATURES

- AS is a diagnosis of exclusion, and other causes of VM need to be ruled out.³

- Severe bilateral VM with lateral ventricles measuring >15 mm with dangling choroid plexus and dilation of the third ventricle
- VM is usually progressive.
- Macrocephaly
- The brain mantle may be thin or compressed.⁶
- The corpus callosum may be thin or undetectable due to compression from the dilated ventricles.
- Agenesis of the corpus callosum
- Absent or fenestrated cavum septi pellucidi
- The posterior fossa structures (cerebellum, vermis, and cistern magna) are normal.
- Periventricular calcification if AS is caused by intracranial infection
- Hemorrhage or masses
- Abducted thumbs⁷
- Male fetuses

DIFFERENTIAL DIAGNOSIS

- Holoprosencephaly
- Porencephaly
- Schizencephaly
- Hydranencephaly

ASSOCIATED ANOMALIES

- Extracranial abnormalities (30% of cases)
- 25% of cases have multiple anomalies.
- Anomalies include macrocephaly, agenesis of the corpus callosum, and bilateral abducted thumbs (up to 50%-60% of cases) (Online Mendelian Inheritance in Man [OMIM] database #307000)
- Can be part of the MASA syndrome
- Chromosomal aberrations (11% of cases)
- *LICAM* mutation
- In utero infection (e.g., CMV)

Imaging

Figure 20-19 Aqueductal stenosis: coronal view. Coronal view of mild, borderline ventriculomegaly.

Figure 20-20 Aqueductal stenosis: 3D view. Ventriculomegaly in a case of agenesis of the corpus callosum.

Figure 20-21 Aqueductal stenosis: coronal view. Cytomegalovirus caused this ventriculomegaly. Note the hyperechoic lining of the ventricle caused by the infection.

Figure 20-22 Aqueductal stenosis: coronal view. The lateral ventricles and the third ventricle are dilated.

Figure 20-23 Aqueductal stenosis: coronal section. Mild, asymmetric ventriculomegaly.

- Cephalocentesis for cephalopelvic disproportion to enable vaginal delivery is controversial.
- Cesarean section should be reserved for standard obstetric indications.

NEONATAL MANAGEMENT

- Evaluation by neonatology, pediatric neurology, and neurosurgery
- Repeat head ultrasound and/or MRI to reassess in utero findings
- Serial head measurements to assess progression of the hydrocephaly
- Surgical management in cases of progressive ventriculomegaly
- Treatment of AS is surgical; there are two procedures: shunts (ventriculo-peritoneal or ventriculo-atrial) and endoscopic third ventriculostomy (ETV). In ETV, a window is created in the floor of the third ventricle³ to drain the cerebrospinal fluid (CSF).
- ETV is gaining popularity and is becoming the primary treatment for AS, because the risk of infection is low and there are fewer shunt complications.³

Management

ANTENATAL MONITORING

- Anatomic survey
- Fetal neuroscan
- Fetal echocardiography
- Genetic counseling and amniocentesis for karyotype and infection studies (toxoplasmosis and CMV polymerase chain reaction [PCR]), and if X-linked hydrocephaly is suspected, microarray for *LICAM* gene mutation at Xq28
- MRI to look for associated brain anomalies
- Before viability, the option of pregnancy termination should be offered to the parents.
- For ongoing pregnancies, serial follow-up of the brain anatomy and its measurement
- Congenital ventriculomegaly may develop late in gestation, and a normal mid-trimester examination does not exclude this condition.

OBSTETRIC MANAGEMENT

- In the absence of macrocrania, a trial of labor is indicated in vertex presentation.

PROGNOSIS

- Prognosis for AS is difficult to predict. Prognosis depends on the specific cause of the hydrocephaly and the presence of associated anomalies. Poorest prognosis is found among cases of X-linked AS because of the associated anomalies.
- In idiopathic AS, despite postnatal treatment, the outcome is guarded and most children have varying degrees of neurodevelopmental delays.⁸ Of 14 children, 4 (29%) developed normally, 5 (36%) had minimal impairment, and 5 (36%) had abnormal development.⁸ In a study of children with AS followed from 5 to 25 years, at age 3 years 44% were normal, 28% had moderate disability, and 28% had severe disability.⁹
- In X-linked hydrocephaly with severe VM, intellectual disability is usually severe and is independent of shunting procedures.⁵ There is progressive, usually severe, lower-extremity spasticity.
- In MASA syndrome, intellectual disability ranges from mild (IQ 50-70) to moderate (IQ 30-50). The degree of intellectual impairment does not necessarily correlate with head size or severity of hydrocephaly.⁵

20F VENTRICULOMEGALY: ARNOLD-CHIARI MALFORMATION

Diagnosis

DEFINITION

Arnold-Chiari malformation (Chiari II) is a complex congenital anomaly resulting from the presence of open spinal defect (myelomeningocele) in which there is herniation of the cerebellar vermis and brainstem through the foramen magnum.^{1,2} Ventriculomegaly (noncommunicating) develops in most of the cases as a result of the abnormal position of the posterior fossa structures.

INCIDENCE AND PATHOGENESIS

- The incidence of the Chiari II malformation is essentially the same as that of spina bifida: 1.90 per 10,000 live births.³
- The onset of myelomeningocele is approximately the fourth week of gestation, at the time of closure of the posterior neural tube.
- Four theories have been proposed, but the most widely accepted is the “unified theory,” in which failure of closure of the neural tube results in amniotic fluid leakage through the open spinal defect, leading to lack of development of the posterior fossa and abnormalities of neural and calvarial development.⁴

DIFFERENTIAL DIAGNOSIS

- Spinal abnormalities such as scoliosis, kyphosis, caudal regression syndrome
- VACTERL (vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula and/or atresia, renal agenesis, and limb defects)
- Sacrococcygeal teratoma
- Aqueductal stenosis

Imaging

Figure 20-24 Arnold-Chiari malformation: axial view. Axial section of the fetal brain demonstrates hydrocephaly.

KEY DIAGNOSTIC FEATURES

- Elevated maternal serum α -fetoprotein (AFP)
- Spinal findings: “U-shaped” spine, bulging mass or irregularities of the posterior contour of the spine in the sagittal section⁵
- Classic cranial findings: “lemon” and “banana” signs seen in >95% of cases between 16 and 24 weeks⁶
- Ventriculomegaly or hydrocephaly
- First trimester: a proposed new cranial finding is lack of visualization of the intracranial translucency (IT) on ultrasound.⁷

ASSOCIATED ANOMALIES

- Anomalies affecting the skull, such as a small posterior fossa, low-lying tentorium cerebelli, and enlarged foramen magnum
- Anomalies of the cerebral hemispheres, such as polymicrogyria, cortical heterotopias, and dysgenesis of the corpus callosum
- Posterior fossa anomalies, such as descent of the cerebellar vermis through the foramen magnum, displacement of the superior cerebellum through the tentorium, and aqueductal stenosis
- Hydrocephaly (noncommunicating) is seen in 80%-90% of the cases.⁸
- Spinal anomalies: scoliosis or kyphosis
- Hip deformities and clubfoot^{8,9}
- Chromosomal abnormalities in about 10% of cases of spina bifida (trisomy 13 and 18); rare 22q deletion syndrome⁹

Figure 20-25 Arnold-Chiari malformation: sagittal view. Sagittal view of the fetal spine demonstrates a sacral meningocele (arrow).

Figure 20-26 Arnold-Chiari malformation: transverse view of the spine. In this view, the meningomyelocele sac is seen protruding through the spinal defect.

Figure 20-27 Arnold-Chiari malformation: axial view. The lemon and banana sign can be appreciated.

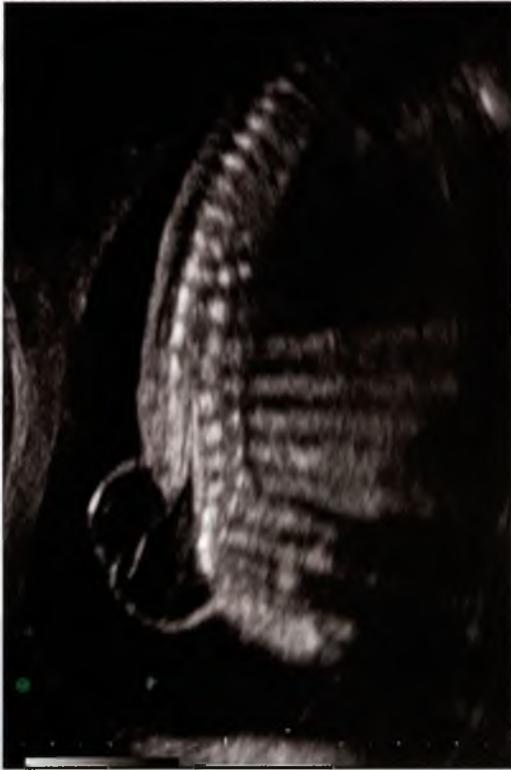

Figure 20-28 Arnold-Chiari malformation: sagittal view. In the sagittal view of the spine, the sac is seen protruding in the lumbar sacral area.

Figure 20-29 Arnold-Chiari malformation: 3D image of the meningomyelocele. 3D surface rendering demonstrates the meningomyelocele sac.

Management

ANTENATAL MONITORING

- Detailed anatomic survey, fetal echocardiogram
- Genetic counseling, chorionic villus sampling (CVS) and/or amniocentesis
- Discuss pregnancy options, such as termination of pregnancy, and in utero fetal surgical treatment of the spinal defect (19-25 weeks).
- Consultations with maternal-fetal medicine, neonatology, pediatric neurology, and neurosurgery
- Consider MRI if diagnosis is not clearly established by ultrasound.
- Serial scans to monitor hydrocephaly
- Consider antenatal surveillance in the third trimester.

OBSTETRIC MANAGEMENT

- Delivery in a tertiary care facility with access to NICU and pediatric neurosurgery
- Vaginal delivery is possible.
- Cesarean section is indicated for breech presentation, severe hydrocephaly, and obstetric indications.
- One study demonstrated better neurologic outcomes when cesarean delivery was performed before the onset of labor.¹⁰

NEONATAL MANAGEMENT

- Myelomeningocele has to be covered with sterile wet dressing to prevent infection and damage through excoriation or desiccation.

- Prophylactic antibiotic coverage
- Imaging studies (ultrasound and/or MRI) to reassess myelomeningocele and brain.
- Surgery to close the defect within the first 1-3 days of life. With severe hydrocephaly, a shunt is placed at the time of the spinal repair.
- In mild to moderate ventriculomegaly, serial physical and imaging monitoring to assess progression of the ventriculomegaly is suggested.

PROGNOSIS

- Nonlethal anomaly associated with morbidity and mortality
- Cognitive outcome is related to the hydrocephaly and shunt complications.
- About 70% have IQ >80.
- Only about half of patients are able to live independently as adults.
- Independent mobility is related to the level of the defect; with lesions above L2, there is loss of quadriceps and iliopsoas muscle and a wheelchair existence should be anticipated.
- Social continence can be achieved in as many as 80% of these children.
- Approximately 14% die within the first 5 years due to shunt complications (malfunction and infection).
- Among those with brainstem dysfunction leading to respiratory and swallowing problems, the mortality rate rises to 35%.¹¹⁻¹³

20G VENTRICULOMEGALY: BORDERLINE LATERAL CEREBRAL VENTRICULOMEGALY

Diagnosis

DEFINITION

Ventriculomegaly (VM) is defined as the diameter of one or both lateral ventricles measuring 10 mm or larger. VM is further divided according to the severity of the dilation; in borderline or mild VM, the lateral ventricles measure 10-12 mm; in moderate VM, 12.1-14.9 mm, and in severe VM, ≥ 15 mm.¹ However, in many articles, fetuses with mild to moderate lateral ventricles (10-14.9 mm) are grouped together. They may be symmetric or asymmetric. Ventriculomegaly is not a diagnosis; it is a sign caused by a variety of pathologies.

INCIDENCE AND PATHOGENESIS

- The overall incidence of VM is 1:1000 to 2:1000 births.² However, the reported incidence of borderline or mild VM ranges from 1.4/1000 births in the low-risk population to 22/1000 births in the high-risk population.³
- In a study of mild to moderate VM between 18 and 24 weeks, the incidence was 7.8 per 10,000 births.⁴
- The pathogenesis of isolated mild VM has not been clearly elucidated and often remains unknown. It most likely is multifactorial and frequently associated with other brain anomalies, chromosomal aneuploidy, or fetal infections.⁵

DIFFERENTIAL DIAGNOSIS

- Open spina bifida
- Early hydrocephaly

- Agenesis of the corpus callosum
- Normal variant

KEY DIAGNOSTIC FEATURES

- Lateral ventricle measuring ≥ 10 but < 12 mm
- Choroid plexus may appear dangling.
- Resolution of mild isolated VM occurs in as many as 62% of the cases before 24 weeks' gestation.⁴
- Males are more commonly diagnosed with mild VM than females.^{1,4}

ASSOCIATED ANOMALIES

- Associated structural and/or chromosomal malformation in about 41%.¹
- In a study of 355 cases of confirmed mild to moderate VM, chromosomal aneuploidy was seen in approximately 11%. Trisomy 21 was most common, followed by trisomies 18 and 13. Structural anomalies (with normal karyotype) were seen in 43% with brain anomalies being the most common (e.g., Chiari II, agenesis of the corpus callosum, microcephaly). Other anomalies included heart, diaphragmatic hernia, omphalocele, and limb reduction. Congenital infection was seen in 0.8% (cytomegalovirus [CMV], toxoplasmosis).
- A systematic review showed that for mild VM the overall aneuploidy rate was 3% and the rate of infection 0.4%.⁶

Imaging

Figure 20-30 Borderline lateral cerebral ventriculomegaly: axial view. with transabdominal scanning, the hemisphere closest to the transducer may not be clearly imaged.

Figure 20-33 Bilateral moderate ventriculomegaly: axial view. Bilateral moderate ventriculomegaly. The ventricles measure 12.9 and 13 mm.

Figure 20-31 Borderline lateral cerebral ventriculomegaly: axial view. Bilateral mild ventriculomegaly is seen in this fetus at 22 6/7 gestational weeks.

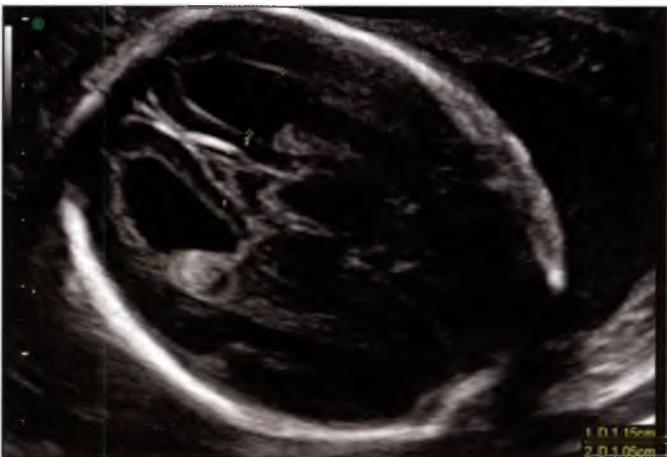

Figure 20-32 Borderline lateral cerebral ventriculomegaly: axial view. The ventricles measure 11.5 and 10.5 mm.

Figure 20-34 Bilateral severe ventriculomegaly: axial view. The ventricles are dilated, measuring 25 and 30 mm; there is minimal amount of brain tissue.

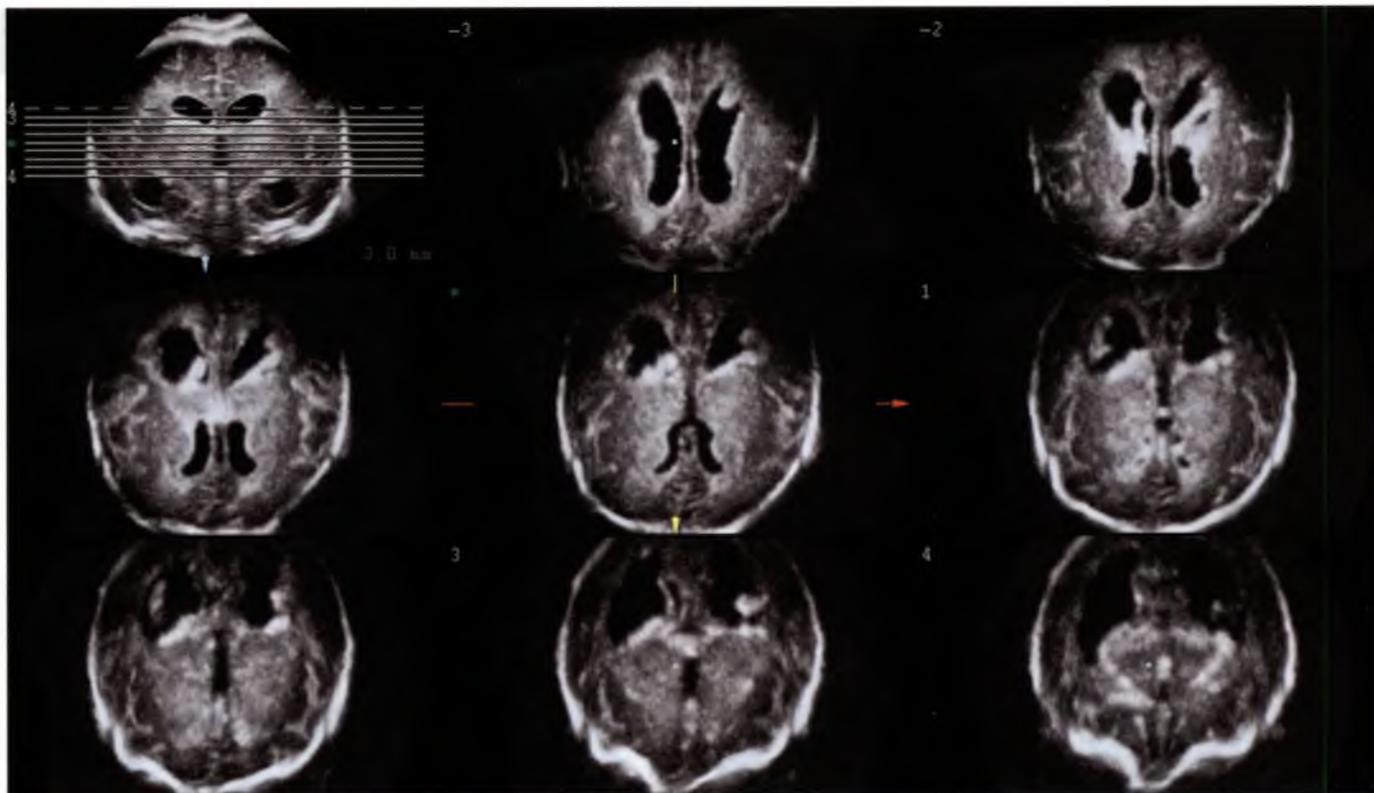

Figure 20-35 Borderline lateral cerebral ventriculomegaly after intracranial hemorrhage: 3D serial axial sections. The tomographic feature is used for the 3D volume.

Management

ANTENATAL MONITORING

- Detailed anatomic survey
- Fetal neuroscan to look for additional anomalies. If the fetus is a vertex with the head in the pelvis, transvaginal scan is helpful.
- Fetal echocardiography
- Genetic counseling and amniocentesis, especially if the mild VM is not an isolated finding or if maternal aneuploidy screening suggests risk
- Consider sending amniotic fluid for infection studies (toxoplasmosis and CMV polymerase chain reaction [PCR]).
- MRI of the brain to look for additional brain anomalies
- Pediatric neurology consultation
- Serial ultrasound to monitor the progression of the VM

OBSTETRIC MANAGEMENT

- Vaginal delivery is not contraindicated in cases of mild VM.
- Cesarean delivery for routine obstetric indications. However, each case needs to be individualized, especially those with associated malformations.

NEONATAL MANAGEMENT

- Evaluation by neonatology
- Head ultrasound and/or MRI to reassess intrauterine findings
- Consider chromosomal studies with microarray if neonate appears dysmorphic or other anomalies are discovered in the neonatal period and these studies were not performed prenatally.
- Consultation with pediatric neurology

PROGNOSIS

- In cases of mild VM associated with other anomalies, the prognosis is influenced by the anomaly (e.g., trisomy 21 or agenesis of the corpus callosum).
- In utero progression of the VM is associated with increased neurologic sequelae.^{6,7}
- In a review, the pooled prevalence of neurodevelopmental delay in isolated mild VM with normal karyotype was 4.9% (relative risk [RR] = 3.507; 95% confidence interval [CI], 1.718-7.155; $P < .001$). 10.7% of females had neurodevelopmental delay, compared with 5.6% of males; however, this difference was not statistically significant.⁷

20H VENTRICULOMEGALY: DANDY-WALKER MALFORMATION AND VARIANT

Diagnosis

DEFINITION

The term *Dandy-Walker malformation* (DWM) refers to a spectrum of malformations that include enlargement of the posterior fossa with an elevated cerebellar tentorium and torcular, dilation of the fourth ventricle, and malformed cerebellar vermis.¹ In as many as 70% to 80% of the cases, some degree of ventriculomegaly or hydrocephaly is present, with progressive postnatal ventriculomegaly.

INCIDENCE AND PATHOGENESIS

- DWM is a rare disease with an estimated incidence of 1 per 30,000 births. It is present in 4%-12% of all cases of infantile hydrocephaly.²
- It results from a developmental arrest in the hindbrain that occurs between the fourth and sixth weeks of gestation.³

DIFFERENTIAL DIAGNOSIS

- Posterior fossa arachnoid cysts
- Blake's pouch cyst
- Mega cisterna magna
- Vermian hypoplasia

KEY DIAGNOSTIC FEATURES

- Large cisterna magna that communicates with the fourth ventricle
- Absent or hypoplastic vermis
- Cerebellar hemispheres splayed apart with varying degrees of dysplasia
- Elevated tentorium and torcular herophili
- Ventriculomegaly

ASSOCIATED ANOMALIES

- Present in as many as 60% of the cases of prenatally diagnosed DWM.⁴
- In postnatal studies, the frequency of associated malformations has ranged from 50% to 70%.²
- Central nervous system (CNS) anomalies are the most common and include hydrocephaly, agenesis or dysgenesis of the corpus callosum, holoprosencephaly, cephaloceles, migrational disorders, and heterotopias.²
- Non-CNS anomalies: congenital heart disease, craniofacial, renal, limbs, abdominal wall, diaphragmatic hernia, and ambiguous genitalia.^{5,6}
- Intrauterine growth restriction⁶
- Chromosomal anomalies such as trisomy 9, 21, 18, and 13; triploidy; 6p and 3q22-q24 deletion^{1,7}
- Nonchromosomal syndromes such as Meckel, Walker-Warburg, and Cornelia de Lange

Imaging

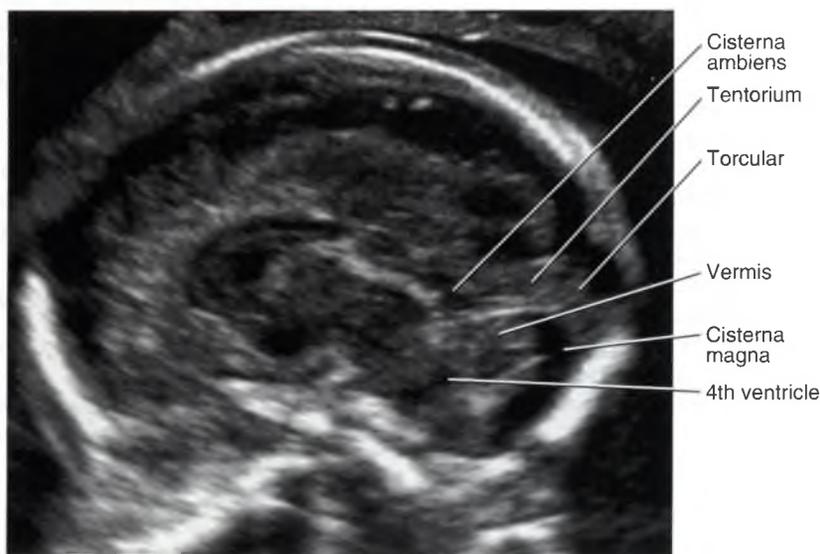

Figure 20-36 Normal brain: median view. The normal anatomy of the posterior fossa is depicted for comparison.

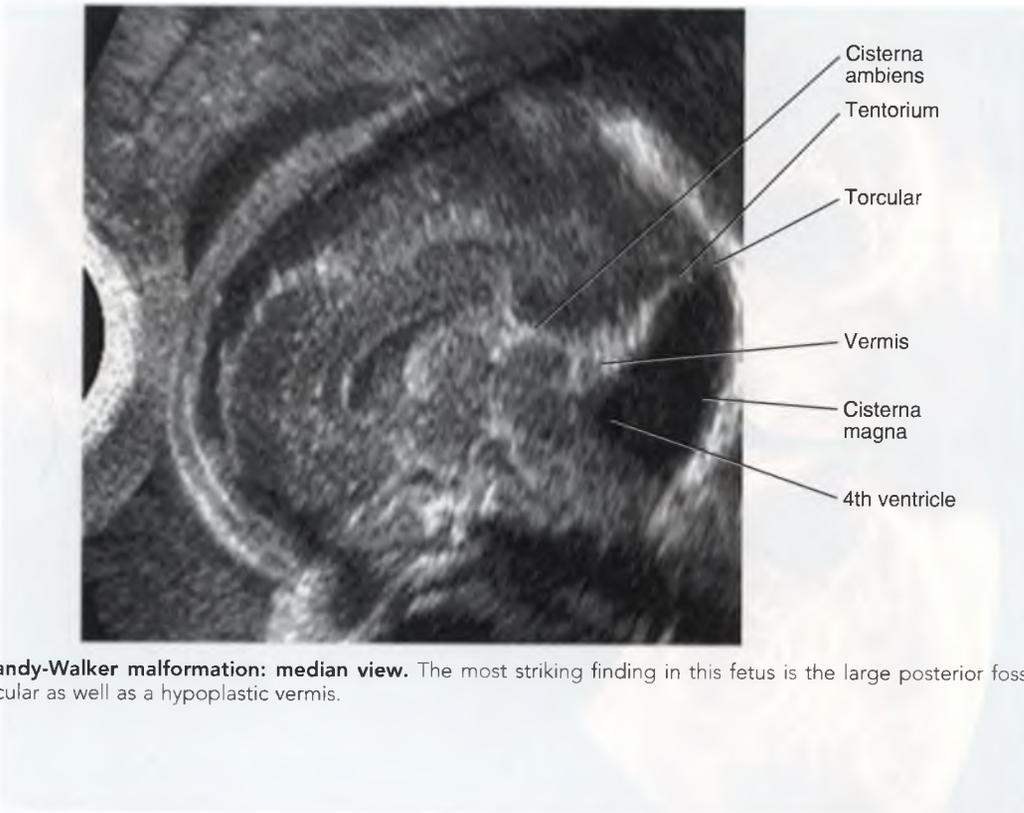

Figure 20-37 Dandy-Walker malformation: median view. The most striking finding in this fetus is the large posterior fossa with an elevated tentorium and torcular as well as a hypoplastic vermis.

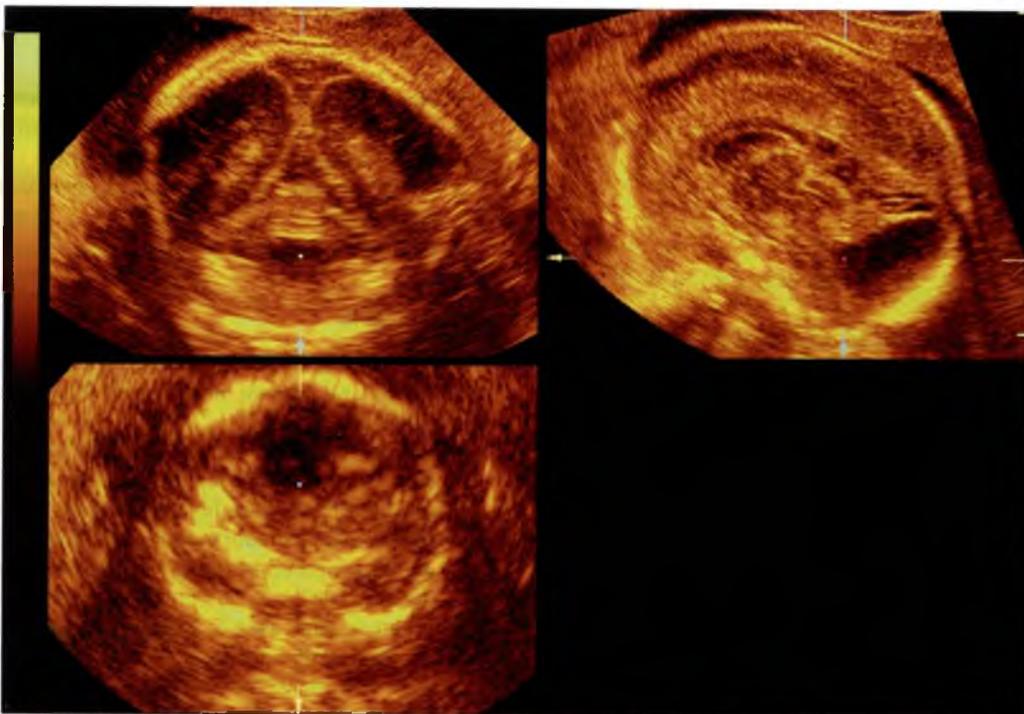

Figure 20-38 Dandy-Walker malformation: 3D view. All three scanning planes are seen in this fetus. The median section (*upper right*) depicts the large cisterna magna, the elevated tentorium and torcular, and the hypoplastic and upwardly turned vermis.

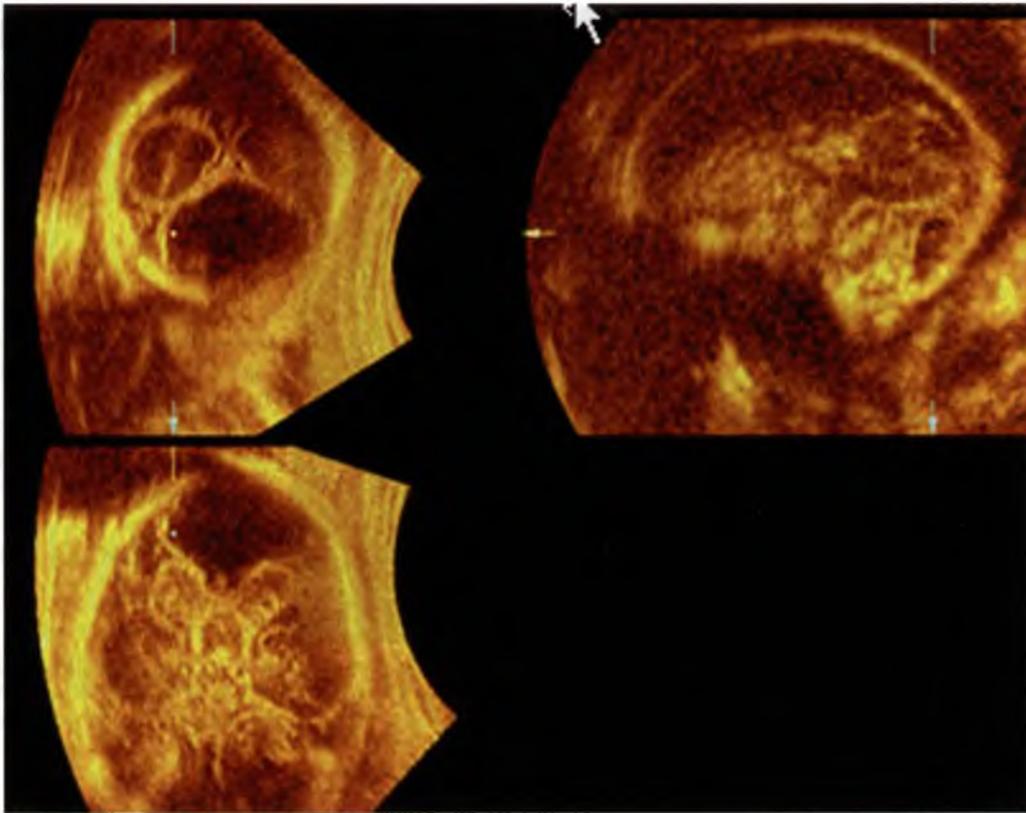

Figure 20-39 Dandy-Walker malformation: 3D view. The coronal image (upper left) shows the large cisterna magna. In the lower left image, the fourth ventricle is seen communicating with the cisterna magna, and the cerebellar hemispheres are splayed by the large posterior fossa.

Management

ANTENATAL MONITORING

- Anatomic survey
- Fetal neuroscan
- Fetal echocardiography
- Genetic counseling, karyotype, test for 3q24 deletion, microarray studies
- Consider MRI to rule out associated anomalies
- Consultation with maternal-fetal medicine, neonatology, and pediatric neurology
- Offer termination of pregnancy
- For ongoing pregnancies, serial scans to monitor the degree of ventriculomegaly

OBSTETRIC MANAGEMENT

- Vaginal delivery is not contraindicated in cases of DWM.
- Cesarean section for the routine obstetric indications or macrocephaly
- However, in cases of severe hydrocephaly, cephalocentesis can be performed to decompress the head and achieve vaginal delivery.

NEONATAL MANAGEMENT

- At birth, the neonates may be asymptomatic or mildly symptomatic; symptoms typically develop within the first year of life.
- Macrocephaly may be present at birth if severe ventriculomegaly is present.

- Hydrocephaly is progressive and is seen in up to 80% of cases. Shunt placement is the treatment of choice.⁸
- Head ultrasound and MRI to confirm in utero findings
- Offer genetic testing if not performed during the pregnancy.
- Pediatric neurology consultation

PROGNOSIS

- Motor deficits such as delayed motor development, hypotonia, and ataxia; about half have mental retardation (OMIM #220200)
- Intrauterine fetal demise in about 14%⁶
- 80% develop hydrocephaly by 3 months.⁸
- Overall infant mortality ranges from 10% to 66%.⁵ Infants with multiple malformations have higher death rates (63%) when compared to those with isolated Dandy-Walker syndrome (DWS) (37%).⁵ Infants with two or more affected organ systems were 6 times as likely to die than those with isolated DWS and those with one additional finding were 2.27 times as likely to die than those with the isolated DWM.
- The major causes of death are infection, uncontrolled hydrocephaly, and shunt complications.⁸
- A systematic review concluded that up to one third of survivors (children) with DWM can develop normally.⁹ Favorable neurodevelopmental outcome is seen in children with no associated CNS or extra-CNS anomalies and with a normal lobulated vermis.⁹

Imaging of the Face and Neck

21A CLEFT LIP AND PALATE

ANTONETTE T. DULAY, MD

Diagnosis

DEFINITION

- Common malformation that typically runs between the nostrils and may involve the central part of the posterior palate¹⁻⁴
- Linear defect extending from upper lip to the nostril¹⁻⁵
- Midline clefts often associated with brain malformations (e.g., holoprosencephaly⁶)
- Majority of cases have a multifactorial etiology and inheritance.⁷
- Four types¹:
 - Type 1: Unilateral cleft lip (CL), no cleft palate (CP)
 - Type 2: Unilateral CL, with CP
 - Type 3: Bilateral CL/CP
 - Type 4: Midline CL/CP

INCIDENCE AND PATHOGENESIS

- Incidence about 1/1000 for cleft lip with or without cleft palate¹⁻⁷
- Incidence about 5/1000 for isolated cleft palate¹⁻⁷
- Male predominance^{1,6}
- Variation between ethnic groups:
 - Asians, 1/600; whites, 1/1000; African Americans, 1/2500¹
- 60% of facial clefts are isolated.⁵
- Upper lip and primary palate normally fuse by week 7.
- Secondary palate forms by fusion of palatal shelf by week 12.^{1,5,6}
- CL or CP occurs if the frontonasal process of the face does not join the lateral maxillary prominences at about week 7.^{1,5,6}
- Normally developing fetal brain induces frontonasal development. Abnormality in the underlying brain can be associated with a midline facial cleft by week 4.^{1,5,6}
- Risk factors: hyperthermia, chronic steroids, methotrexate, alcohol, hydantoin, trimethadione, and aminopterin, maternal rubella, phenylketonuria, folic acid deficiency, and zinc deficiency^{1,6}

DIFFERENTIAL DIAGNOSIS

- Facial teratoma
- Frontonasal dysplasia
- Premaxillary agenesis, associated with alobar holoprosencephaly

- Normal variant with delayed maxillary fusion
- Bilateral orofacial clefting:
 - Holoprosencephaly
 - Anterior meningocele
 - Frontal encephalocele
 - Macroglossia
 - Hemangioma
 - Proboscis
 - Rhabdomyosarcoma
- Amniotic band syndrome
- More than 400 syndromes associated with facial clefting,^{1,7,8} including trisomy 13 and 18, Treacher Collins, Pierre Robin, Goldenhar, DiGeorge, Crouzon, Waardenburg^{1,7,8}

KEY DIAGNOSTIC FEATURES

- Typically not detectable until about 18 weeks^{4,5}
- Lips best seen in coronal view; palate best visualized from axial view.¹⁻⁵ Three-dimensional (3D) ultrasound can help.^{1,9,10}
- Unilateral CL with or without CP:
 - Most cases of CL are left-sided and unilateral.
 - Obliquely aligned gap in the lip extends to the nose.
 - Profile view may demonstrate a hooked nose.
 - A gap between the maxilla and palate may be present.
- Bilateral CL with or without CP:
 - Central mass protrudes below the nose.
 - Profile view may show an infranasal, premaxillary mass.
 - Standard view of the lips may be difficult to obtain.
 - If anterior palate is involved, a gap in the alveolar ridge of the maxilla may be visualized.
- Midline CL and CP:
 - Absent central maxilla and upper lip
 - Deformed nose, possibly even absent and replaced by a proboscis. The nose may also be small or have a single nostril.
- 3D ultrasound may demonstrate the interior of the mouth better, enabling better visualization of the fetal palate: alveolar ridge disruption or premaxillary protrusion suggests presence of bilateral cleft lip and palate. Better assessment of the posterior palate is also possible.^{1,9,10}
- The amniotic fluid and placenta are usually unaffected. However, if swallowing is affected by CL or CP, polyhydramnios may result. With an isolated CL or CP, fetal growth is typically normal.

ASSOCIATED ANOMALIES

- Lumbar and cervical spine (33%)⁴⁻⁸
- Cardiac (24%)⁴⁻⁸
- Chromosomal (10%), especially trisomy 13^{7,8}
- Polyhydramnios if defective swallowing⁶

Imaging

Figure 21-1 Ultrasound image of cleft lip in a fetus.

Figure 21-3 2D ultrasound image of midline cleft lip.

Figure 21-2 2D ultrasound image of large lateral cleft lip and palate.

Figure 21-4 2D ultrasound image of large midline cleft lip (arrow).

- Central CL or CP is typically associated with other facial findings, such as hypotelorism or cyclops.³⁻⁸ Holoprosencephaly should also be suspected, as well as trisomy 13.³⁻⁸
- Other associated syndromes include frontonasal dysplasia, and premaxillary agenesis, which typically is associated with alobar holoprosencephaly.³⁻⁸

Figure 21-5 3D ultrasound image of midline cleft lip.

Figure 21-6 3D ultrasound image of unilateral cleft lip (arrow).

Management

ANTENATAL MONITORING

- Antenatal studies and consultations to offer:
 - Chromosomal study
 - Fetal echocardiogram
 - Prenatal genetics consultation
 - Consider neonatal intensive care unit (ICU) consultation.
 - Pediatric craniofacial consultation to address postnatal care
- Monthly serial ultrasound follow-up because of risk for other anomalies
- Supplementation: folic acid (4 mg daily) before any future conception

OBSTETRIC MANAGEMENT

- The intrapartum course is typically unaffected.
- Because of the potential for difficulties that may arise in securing the airway of a neonate with CL or CP, delivery at a facility with experience in this is recommended. (Not necessary for neonates with simple clefts, which can be delivered wherever planned.)

NEONATAL MANAGEMENT

- Examination by a pediatric dysmorphologist. In up to 25% of infants with orofacial clefting, an associated malformation is discovered postnatally.
- Timing of repair depends on the nature of anatomic malformation.^{1-3,6}
 - CL usually repaired at 2-3 months^{1-3,6}
 - CP usually repaired at 9-18 months^{1-3,6}
 - If defects are wide, repair is often delayed, requiring increased use of presurgical nasal alveolar molding.^{1-3,6}

- In some cases, surgical procedures may take place into the teenage years, at the end of craniofacial growth period.^{1-3,6}
- Multidisciplinary approach:
 - Plastic, maxillofacial surgery
 - ENT, speech therapy, audiology
 - Orthodontics, dentistry
 - Genetics
 - Feeding evaluation, nutrition consultation
 - Psychological support

PROGNOSIS

- Surgical results usually excellent, with most patients achieving aesthetic restoration
- Speech development is typically excellent.^{1-8,11}
- All children require speech and language evaluation annually until 4 years of age.¹⁻⁸
- Hearing abnormalities may be identified early, largely related to conduction deafness.
- Chronic otitis media may become an issue.²⁻⁴
- In some cases, dental abnormalities or poor olfaction can exist, despite repair.²⁻⁴
- Serial cognitive development screening¹⁻⁸
- Recurrence risk:
 - Up to 4% in the next pregnancy if the parents unaffected and no family history⁶⁻⁸
 - If one parent is affected, and no prior child has had CL or CP, risk is 4%.
 - 12% if one prior child is affected and 25% if two children are affected⁶⁻⁸
 - When both parents have CL or CP, recurrence risk is much higher, ranging from 35% (no prior children affected), to 45% (one child affected), to 50% (two children affected).⁶⁻⁸

21B CYSTIC HYGROMA

CHRISTINA S. HAN, MD

Diagnosis

DEFINITION

- Congenital thin-walled cysts that contain lymphatic fluid
- Septated or nonseptated, commonly located in the soft tissue at the posterior neck region, but may extend cephalad to engulf the fetal head or caudad to cover the dorsum of the fetus, or may be found in the mediastinum and axilla
- Alternative or historical names include cystic lymphangioma, lymphatic hamartoma, jugular lymphatic obstructive sequence, and hygroma colli cysticum.

INCIDENCE AND PATHOGENESIS

- 1 in 100 pregnancies in first trimester.¹ The subclassification of septated cystic hygroma occurs in 1 in 285 pregnancies.²
- Arise from failure of primitive lymphatic tree to connect to the venous system. Blind lymphatic pouch results in dilation of the lymphatic sac.³

KEY DIAGNOSTIC FEATURES

- Anechoic fluid-filled cavities that are encircled by soft tissue, usually located in the posterior neck
- May be multiloculated with septations, or simple in appearance
- May involve the fetal head, back, axilla, or mediastinum
- A thick midline band may be present posteriorly, formed by the nuchal ligament separating the bilateral jugular lymphatic sacs.

DIFFERENTIAL DIAGNOSIS

- Thickened nuchal translucency
- Neural tube defects (posterior encephalocele, cervical meningocele)
- Cystic teratoma
- Hemangioma
- Thyroglossal duct cysts
- Branchial cleft cysts
- Laryngocele
- Twin-twin transfusion syndrome in monochorionic-diamniotic twin gestations

ASSOCIATED ANOMALIES

- Associated structural anomalies seen in 33.8% of cases of first-trimester cystic hygromas²
- Aneuploidy (50%): Trisomy 21 (37.3%) is the most common chromosomal abnormality associated with cystic hygromas, followed by Turner syndrome (28.3%), trisomy 18 (19.4%), trisomy 13 (9.0%), and triploidy (4.5%).² Mosaic deletion of chromosomes has also been reported.²
- Cardiac anomalies account for 72.7% of the associated structural abnormalities. Reported cardiac anomalies include hypoplastic left or right heart syndrome, tetralogy of Fallot, ventricular septal defect, and other complex cardiac anomalies.² In euploid fetuses, the incidence of major congenital heart disease was 4.3%.⁴
- Syndromes reported in fetuses with cystic hygroma include Roberts, Cornelia de Lange, multiple pterygium, and Noonan syndromes, and fetal akinesia sequence.
- Skeletal abnormality
- Fetal hydrops
- Intrauterine fetal demise

Imaging

Figure 21-7 Fetal Turner syndrome. Large bilateral cystic mass is seen at level of fetal neck in axial view, with thick midline nuchal ligament. Fetal Turner syndrome, diagnosed on amniocentesis, resulted in demise of the fetus at term.

Figure 21-8 Large bilateral cystic mass at the level of the fetal head. Axial view shows thin midline nuchal ligament.

Figure 21-9 Cystic hygroma. Cystic hygroma seen on ultrasound performed for first-trimester aneuploidy screening.

Figure 21-10 Cystic hygroma. A cystic hygroma may extend cephalad to engulf the fetal head and scalp.

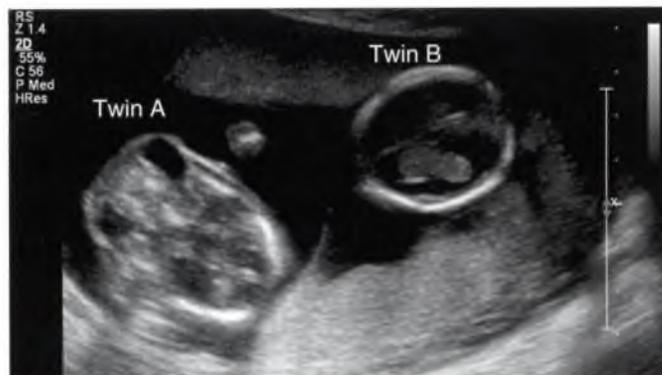

Figure 21-11 Cystic hygroma. A cystic hygroma was seen in twin A of a dichorionic twin gestation.

Management

ANTENATAL MONITORING

- Detailed fetal anatomic survey is necessary to identify potential associated anomalies and to determine the relationship between the hygroma and the upper airway, as obstruction can occur at birth.
- Fetal echocardiogram for associated cardiac anomalies
- Serial fetal ultrasounds to evaluate for fetal growth, progression of hygroma, polyhydramnios from esophageal compression, and development of fetal hydrops
- Antenatal fetal testing should be considered in late third trimester because of risk for fetal demise.

OBSTETRIC MANAGEMENT

- Pregnancy termination is an available management option.
- In the patient electing pregnancy continuation, definitive fetal karyotype testing is strongly indicated.
- Antenatal consultations with pediatric subspecialists, neonatologists, and geneticists may be necessary.
- Fetal MRI may help with differential diagnoses and may better delineate anatomic relationship with airway structures, particularly in cases of giant cystic hygromas.⁵
- If tracheal impingement is suspected, ex utero intrapartum treatment (EXIT) may allow an orotracheal airway or tracheostomy to be established before disconnection of the neonate from the uteroplacental vasculature.⁶

NEONATAL MANAGEMENT

- Extensive involvement of airway may be present, requiring management by otolaryngologists, neonatologists, anesthesiologists, and pediatric surgeons.
- Thorough evaluation by a pediatrician is indicated.
- Pterygium colli (webbed neck) may be present.
- Neonatal evaluation by a geneticist may be necessary to rule out genetic syndromes.

PROGNOSIS

- Compared with nonseptated cystic hygromas, septated cystic hygromas confer an increased risk for aneuploidy (odds ratio [OR] = 5.2), cardiac malformations (OR = 12.4), and fetal or neonatal death (OR = 6.0).²
- On the basis of older studies, the mortality rate associated with cystic hygromas diagnosed before 30 weeks' gestation is high (93%), and most deaths (84%) are associated with progressive nonimmune fetal hydrops.⁷ In the FASTER trial, which reported termination rates of 59.8%, spontaneous intrauterine fetal demise was reported in 37.7% of continuing pregnancies.² Three fourths of fetal demises were reported in chromosomally or structurally abnormal fetuses.²
- Resolution may occur spontaneously in utero and is associated with improved survival and normal outcomes. In the FASTER trial, normal pediatric outcome is reported in 16.7% of fetuses with first-trimester cystic hygroma and in two thirds of live births.

21C MICROGNATHIA

SONYA S. ABDEL-RAZEQ, MD

Diagnosis

DEFINITION

Micrognathia is characterized by the presence of a hypoplastic mandible and receding chin. Retrognathia is a posteriorly displaced mandible. In either instance, the typical sequence includes displacement of the tongue posteriorly and superiorly, leading to both abnormal closure of the palatine process—resulting in either a clefted or a high-arched palate—and glossoptosis.

INCIDENCE AND PATHOGENESIS

- Epidemiology
 - Actual incidence unknown
 - Seen in association with a heterogeneous group of conditions, including, trisomy 13, Goldenhar syndrome, Pierre Robin sequence, Treacher Collins syndrome
- Genetics
 - Autosomal dominant: recurrence risk is 50% (Treacher Collins syndrome)
 - Autosomal recessive: recurrence risk 25% (Smith-Lemli-Opitz syndrome)
- Embryology
 - Defect in first and second branchial arches
 - Abnormal migration or proliferation of neural crest cells
 - Mandibular hypoplasia: superior displacement of the tongue and failure of palate fusion as a result of mechanical effect on hard palate

KEY DIAGNOSTIC FEATURES

- General
 - Receding chin on true sagittal image of face
 - Wide spectrum of severity

- Ultrasound findings
 - Jaw index: the ratio of anteroposterior (AP) diameter mandible/biparietal diameter $\times 100$
 - AP diameter from symphysis mentis to line drawn between bases of mandibular rami
 - Normative data available:
 - Jaw index < 23 : 100% sensitivity, 98.7% specificity for micrognathia
 - Jaw index < 21 : 100% positive predictive value
 - Polyhydramnios present in up to 70% of cases
 - Impaired swallowing is the likely cause

DIFFERENTIAL DIAGNOSIS

- Pseudo-micrognathia
 - Incorrect imaging plane
 - True midline sagittal view necessary
 - Abnormal head shape may cause small-appearing chin
 - Thanatophoric dysplasia
 - Achondroplasia
- Amniotic band sequence
 - Destructive defects
 - Band from fetus to uterine wall or placenta

ASSOCIATED ANOMALIES

- Micrognathia often associated with limb abnormalities:
 - Oral-facial-digital syndromes
 - Oral-mandibular-limb hypogenesis syndromes
- Teratogens:
 - Isotretinoin
 - Penicillamine
 - Valproate
 - Maternal diabetes

Imaging

Figure 21-12 Normal mandible. Fetal mandible should be measured in a plane, with the main portion of one ramus of the jaw visible between the temporomandibular joint and the junction of the mandibular rami. The distance between them is measured to obtain the mandibular length. The temporomandibular joint is visualized just below the level of the orbits in axial view.

Figure 21-13 Micrognathia. Sagittal view shows nasal bone and forehead.

Figure 21-14 Micrognathia. Sagittal view shows micrognathia.

Figure 21-15 Extreme case of micrognathia. Nasal bone and forehead are seen in this true sagittal image.

Figure 21-16 Micrognathia. 3D ultrasound image.

Figure 21-17 Micrognathia. 3D ultrasound image.

Management

ANTENATAL MANAGEMENT

- Genetic counseling, including detailed family history and teratogen exposure
- Offer karyotype study, including 22q11.2 deletion detection
 - 66% have abnormal chromosomes
- Detailed survey for fetal anomalies
- Fetal echocardiogram
- Consultations
 - Neonatology
 - Consider ENT consultation when ex utero intrapartum treatment (EXIT) may be used.
- Because of possibility of polyhydramnios, monthly sonographic evaluations should be performed to detect changes in amniotic fluid index.

OBSTETRIC MANAGEMENT

- Delivery in a tertiary care center
 - Possibility of severe respiratory complications and difficult intubation
 - Consider EXIT procedure for airway management at delivery before cutting umbilical cord

NEONATAL MANAGEMENT

- Major care objectives are to establish a definitive diagnosis, a stable airway, and an adequate feeding mode.

- Airway support for onset of respiration may be necessary because of airway obstruction from mandibular hypoplasia and glossoptosis.
 - Support can vary to include nasal trumpet, oral airway with bag and mask ventilation, tracheostomy.
- Thorough physical examination to confirm presence or absence of other abnormalities and need for further diagnostic testing
- ENT consultation
 - Flexible endoscopy to determine most appropriate management approach

PROGNOSIS

- Outcome depends on final diagnosis.
- Series of sonographically “isolated” micrognathia:
 - 54% with airway difficulties at birth requiring intervention
 - 31% with feeding difficulties
 - 38% with developmental delay, varying severity
- Intellectual outcome with wide variation
- Recurrence risk
 - Aneuploidy: 1% in maternal-age-related cases
 - Syndromes are often sporadic new mutations, although several have autosomal dominant or recessive inheritance.

22A CONGENITAL DIAPHRAGMATIC HERNIA

ANNA KATERINA SFAKIANAKI, MD, MPH

Diagnosis

INCIDENCE AND PATHOGENESIS

- Incidence is 2.4-4.9/10,000. Most are sporadic.
- 75% left-sided, 15% right-sided, 10% bilateral; in fetal demises, 47% left-sided, 27% right-sided, 27% bilateral
- Results from abnormal diaphragm development at 6-10 weeks with incomplete closure of the pleuroperitoneal folds
- Associated with smoking, alcohol, vitamin A deficiency, thalidomide, anticonvulsants
- Herniated viscera cause decreased bronchial branching, alveolar number, and pulmonary vascularization, and overmuscularization of pulmonary arterial tree, leading to pulmonary hypoplasia, pulmonary hypertension.

DIFFERENTIAL DIAGNOSIS

- Cystic lesions of the lung, specifically congenital cystic adenomatoid malformation (CCAM), especially types 1 and 2, and bronchopulmonary sequestration (BPS)
- In left-sided congenital diaphragmatic hernia (CDH): bronchogenic cyst
- In right-sided CDH: type 3 CCAM
- Mediastinal teratomas tend to be more vascular, and the abdominal contents are in situ.
- In CDH, the mass is commonly made up of intestines, and prolonged imaging may allow visualization of peristalsis.

KEY DIAGNOSTIC FEATURES

- Major finding is a thoracic mass accompanied by mediastinal shift.
- In left-sided CDH, the stomach appears as a cystic mass and is not seen in its normal position; liver is herniated in 50%.
- In almost all right-sided CDHs, the liver herniates; liver and lung have similar echogenicities, so a discrete mass is not always seen; diagnosis is suspected because of a mediastinal shift to the left. Doppler can show hepatic vascularity; gallbladder may be seen; MRI may be useful.
- Abdominal circumference may be small, and the abdomen may appear scaphoid.

- Polyhydramnios results from esophageal compression; hydrops may follow.
- Depending on size of defect, herniated contents may change position over time.

ASSOCIATED ANOMALIES

- Has been associated with an increased nuchal translucency (NT) in the first trimester¹
- Associated anomalies in 40%-60% of liveborn infants (complex CDH or CDH positive), and in 95% of cases of intrauterine fetal demise²
- Cardiac anomalies in 40%, most commonly ventricular septal defects and atrial septal defects
- Gastrointestinal anomalies second most common, including Meckel diverticulum and anal atresia
- Chromosome anomalies in 10%-20%, most commonly trisomy 21, trisomy 18, and trisomy 13
- Syndromic etiology in 10%

Imaging

Figure 22-1 Congenital diaphragmatic hernia. Parasagittal view, taken at the same time as Figure 22-2. The heart (HRT) and stomach (STO) are seen superior to the diaphragm in the same plane.

Figure 22-2 Left-sided congenital diaphragmatic hernia. Axial (transverse) view of the fetus in Figure 22-1. The heart (HRT) is displaced to the right side of the chest, and the left side is occupied by loops of bowel, the stomach (STOM), and part of the left lobe of the liver. The right lung-to-head circumference ratio is 0.8. No other anomalies identified.

Figure 22-3 Left-sided congenital diaphragmatic hernia. Transverse view of the patient seen in Figures 22-1 and 22-2, 1 week later. The heart is displaced to the right side of the chest, and the left side is occupied by loops of bowel and the stomach. Fetal liver is not in the thorax. The lung-to-head circumference ratio is 0.81.

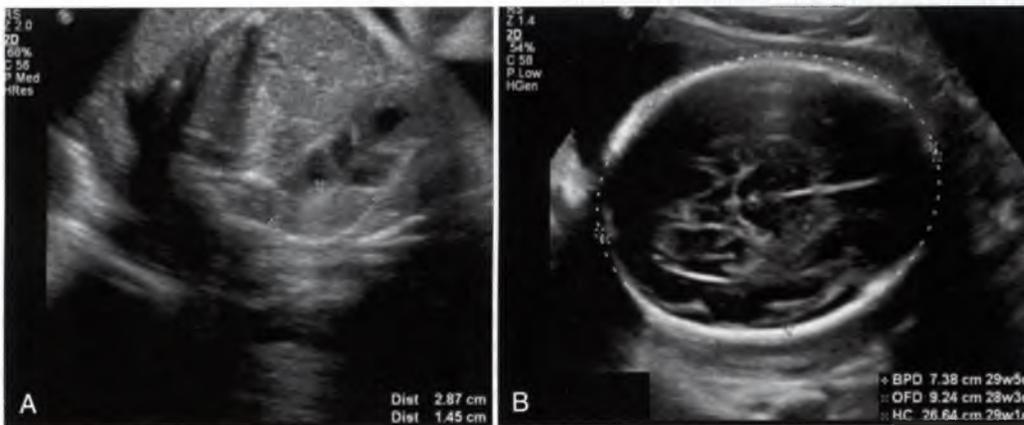

Figure 22-4 Left-sided congenital diaphragmatic hernia (CDH). Ultrasound at 29 weeks' gestation demonstrating a left-sided CDH that was first diagnosed at 18 weeks. Bowel and liver occupy the majority of the thoracic cavity. The heart is displaced to the right and the stomach is in the right hemithorax, posterior to the heart. The lung-to-head circumference ratio, calculated using the measurements in A and B, was 0.5-0.8, a range indicating a poor prognosis.

Figure 22-5 Fetus with multiple anomalies associated with congenital diaphragmatic hernia. On this transverse view, the liver and stomach are seen in the thoracic cavity and the heart is displaced to the right. A large ventricular septal defect is seen. The lung-to-head circumference ratio is 0.4. The patient underwent amniocentesis, which demonstrated trisomy 18.

Management

ANTENATAL MONITORING

- Detailed ultrasound and fetal echocardiogram
- Karyotype, array comparative genomic hybridization (aCGH)
- Consultation with departments of genetics, neonatology, pediatric surgery
- Most important prognostic signs are liver herniation, right-sided lesion, and fetal lung volume as assessed by the lung-to-head-circumference ratio (LHR).^{3,4}
- Serial ultrasounds for growth, amniotic fluid, size and quality of the intestine
- Antenatal testing started at 32-33 weeks, or earlier if severe

OBSTETRIC MANAGEMENT

- When gestation < 24 weeks, termination of pregnancy can be considered.
- With abnormal testing, especially after 34 weeks, delivery should be strongly considered.
- Antenatal steroids if <34 weeks; giving steroids at >34 weeks has not been associated with improved outcomes.
- Delivery is preferably at a tertiary care facility with extracorporeal membrane oxygenation (ECMO) capabilities.
- Cesarean delivery is reserved for usual obstetric indications.
- Fetal endoscopic tracheal occlusion is offered in Europe but still investigational in United States.

NEONATAL MANAGEMENT

- ECMO is frequently used, although the literature is inconclusive about its effect on survival. Pulmonary hypertension may require vasodilator therapy.
- Management ultimately involves reduction of the herniated viscera and surgical repair of the diaphragmatic defect, which is usually delayed until the newborn is clinically stable.
- Traditional repair was via an open surgical approach, but minimally invasive techniques have been introduced.

PROGNOSIS

- Spontaneous intrauterine fetal demise occurs in 2%.⁵
- Among fetuses who survive to delivery, survival of those with isolated CDH is 60%-80%.⁷
- Survival is improved in prenatally diagnosed infants and infants born at a tertiary care facility.⁷
- Worse outcomes are seen in blacks, other minorities, and those with public insurance.⁸
- Long-term complications in pulmonary, musculoskeletal, gastrointestinal and neurodevelopmental systems in 20%-30%

22B CYSTIC LUNG LESIONS, CCAM, SEQUESTRATION

ANNA KATERINA SFAKIANAKI, MD, MPH

Diagnosis

INCIDENCE AND PATHOGENESIS

- The incidence of congenital cystic adenomatoid malformation (CCAM) ranges from 1/11,000 to 1/35,000 live births; mid-trimester incidence is higher because of spontaneous resolution.^{1,2} Bronchopulmonary sequestration (BPS) is even more rare.
- Both result during pseudoglandular phase of lung development (7-17 weeks); they may have common origin.
- CCAM is a hamartomatous lesion containing tissue from different pulmonary origins.
- BPS involves extraneous, nonfunctioning lung tissue that has separated from the normal pulmonary structure.
- Both have oncogenic potential.
- Hybrid lesions exist.

DIFFERENTIAL DIAGNOSIS

- Congenital diaphragmatic hernia (CDH); presence of peristalsis suggests CDH.
- Congenital lobar emphysema
- Bronchogenic cyst is usually isolated and originates from the upper airway, with which a direct connection can sometimes be visualized.
- Intraabdominal BPS is usually on the left; distinguish from neuroblastoma and mesoblastic nephroma, enteric duplication cysts.
- Mediastinal masses, such as cystic hygroma and teratoma: Teratoma has more vascularity and shadowing.

KEY DIAGNOSTIC FEATURES

- CCAM classified as microcystic (<5 mm) vs. macrocystic (>5 mm).
- There are five histologic types of CCAM.
 - Type 1 (50%-70%): small number of large cysts, 3-10 cm or single dominant cyst
 - Type 2 (15%-30%): smaller cysts, 0.5-2 cm, and solid areas
 - Type 3 (5%-10%): microcystic; mass appears solid, echogenic, well circumscribed.
- BPS can be intralobar sequestration (ILS) or extralobar sequestration (ELS).
- ELS is more common in fetuses; it may be extrathoracic, with 10% of lesions below the diaphragm, usually on left.

ASSOCIATED ANOMALIES

- CCAM is usually isolated and sporadic; other anomalies (in 15%-20%) are most commonly cardiac and renal.³
- Exception is type 2 CCAM, with ~60% associated anomalies.
- BPS is more commonly associated with other anomalies than CCAM is.
 - Associated anomalies in 40%-50% of ELS, in 15% of ILS
 - Connections to gastrointestinal tract are most common and increase risk for infection.⁴
- No known association with chromosome abnormalities in either
- Depending on severity, we may see polyhydramnios, mediastinal shift, pleural effusions, and hydrops, which are more common in type 3 CCAM (up to 40%).

Imaging

Figure 22-6 Type 2 congenital cystic adenomatoid malformation (CCAM). Sagittal view of a fetus at 24 weeks' gestation with type 2 CCAM located in the posterior chest. I, inferior vena cava; S, superior vena cava.

Figure 22-7 Type 2 congenital cystic adenomatoid malformation (CCAM). Axial (transverse) view of the fetus seen in Figure 22-6. The mass is multicystic and located posterior to the heart. The patient underwent left upper lobe lobectomy at 4 months of life.

Figure 22-8 Type 3 congenital cystic adenomatoid malformation (CCAM). Sagittal image of a fetus at 20 weeks demonstrating the position of the CCAM above the diaphragm and on the left side. Note the fetal diaphragm and the stomach beneath it.

Figure 22-9 Severe congenital cystic adenomatoid malformation (CCAM). Sagittal image of a fetus at 22 weeks with type 2 CCAM and ascites. Fluid surrounds the liver. The ascites resolved 3 weeks later, and the mass was resected on day 2 of life because of persistent mediastinal shift.

Figure 22-10 Bronchopulmonary sequestration. Transverse view, 26 weeks' gestation. Color flow Doppler demonstrates blood supply from the descending aorta, confirming that this is a sequestration rather than a congenital cystic adenomatoid malformation.

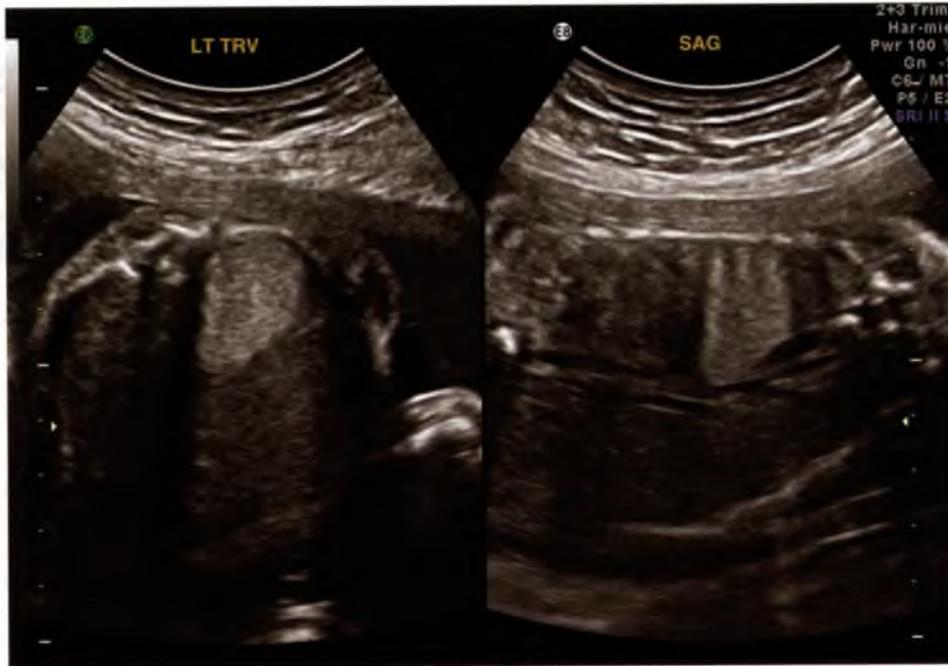

Figure 22-11 Bronchopulmonary sequestration. Transverse (left) and sagittal (right) images of the same fetus as in Figure 22-10 at 26 weeks' gestation. The fetus never developed hydrops and the mass was resected electively.

Management

ANTENATAL MANAGEMENT

- Detailed ultrasound and fetal echocardiogram
- Karyotype, array comparative genomic hybridization (aCGH)
- Pulmonary hypoplasia cannot be predicted by antenatal imaging at this time.
- Natural course of CCAM is for growth until 25 weeks, after which growth may plateau or even regress.⁵
- Monitor at 1- to 3-week intervals until stability of the lesion has been established, looking for hydrops in Type 3 CCAM.
- Antenatal testing protocols have not been studied prospectively.

OBSTETRIC MANAGEMENT

- With small lesions, can deliver in usual facility; otherwise, transfer to tertiary care center with pediatric surgery department, extracorporeal membrane oxygenation (ECMO).
- Consider intervention during pregnancy if hydrops: rare for BPS, more often found in Type 3 CCAM.
- Options for antenatal intervention include thoracentesis, shunt, and laser ablation or injection of feeding artery.
- Open fetal surgery for poorest prognosis if at <32-34 weeks' gestation
- Steroids may help if other fetal interventions not available.^{6,7}
- Cesarean for usual obstetric indications

NEONATAL MANAGEMENT

- Lesions may regress prenatally, but neonatal follow-up is always suggested.
- 50% of cases of CCAM are asymptomatic at birth; in case of respiratory compromise, immediate resection is indicated; in stable patients, timing is controversial.
- Surgical management: lobectomy or nonanatomic segmentectomy; lobectomy suggested for CCAM or ILS because of risk for incomplete resection.
- ELS is not associated with infection or malignant transformation and can be managed expectantly with serial imaging.

PROGNOSIS

- Prognosis depends on specific histology, associated anomalies, hydrops, degree of residual lung function, and presence or absence of pulmonary hypoplasia.
- Survival to delivery in >95%, or ~100% if no hydrops^{6,8}
- Risk of pulmonary hypoplasia is highest with type 3 CCAM (microcystic), with its tendency for growth and mass effect.
- Outcomes for patients with intraabdominal ELS seem to be improved over those with ILS because of decreased risk for pulmonary hypoplasia.

Fetal Cardiac Malformations and Arrhythmias: Detection, Diagnosis, Management, and Prognosis

MARK SKLANSKY, MD

Despite the increasing recognition of the importance of prenatal detection of congenital heart disease (CHD), and despite the availability of increasingly sophisticated three- and four-dimensional (3D and 4D) technology, screening for fetal heart disease remains one of the most challenging and least successful aspects of fetal ultrasonography.¹⁻³ The rate of prenatal detection of even severe forms of CHD remains disappointingly low.^{1,3-9} Moreover, when a fetal heart defect or arrhythmia is suspected, many professionals still feel uncomfortable with doing much more than referring the patient to someone else for further evaluation.

This updated and expanded chapter aims neither to make everyone involved with fetal ultrasonography into an expert fetal echocardiographer nor to provide an exhaustive, encyclopedic review of the field of fetal cardiology; such detailed reviews can be found elsewhere.^{10,11} Instead, the chapter maintains a distinctive clinical bent, aiming to help those involved with fetal cardiac imaging (1) to become better at screening the fetal heart for CHD, (2) to become better at diagnosing and evaluating common forms of fetal cardiac malformations and arrhythmias, (3) to understand the basic approach to fetal and neonatal management of the most common forms of fetal cardiac malformations and arrhythmias, and (4) to understand the general prognosis associated with the most common forms of fetal heart disease.

After a brief discussion of the epidemiology of fetal heart disease, this chapter reviews the basic approach to screening in low-risk pregnancies for fetal heart disease. The next section reviews the more detailed technique of formal fetal echocardiography in pregnancies at high risk for fetal CHD, including a description of the fetal presentation of fetal congestive heart failure (CHF) and a discussion of the potential role of 3D fetal echocardiography. The last two sections discuss the diagnosis, management, and prognosis of the most common and clinically important forms of fetal cardiac malformations and arrhythmias.

Incidence of Congenital Heart Disease in the Fetus

Congenital heart disease is by far the most common major congenital malformation.^{12,13} Although most studies suggest an incidence of approximately 8 in 1000 live births,¹³⁻¹⁵ this figure includes many forms of disease (e.g., secundum atrial septal defect [ASD], mild valvar pulmonary stenosis, and small

muscular or membranous ventricular septal defects [VSDs]) that will never require either medical or surgical attention. In fact, three or four of every 1000 live newborn infants have some form of CHD that is likely to require medical, if not surgical, intervention.¹ Because cases of fetal heart disease, particularly those associated with aneuploidy or extracardiac malformations, may end in fetal demise, and because many VSDs may close spontaneously before birth,¹⁶ the incidence of CHD during the first and second trimesters should be considerably higher than the incidence at term.

At the same time, some forms of CHD probably have a higher incidence at term than during the first or early second trimesters. Many forms of CHD evolve dramatically from first trimester to term.^{17,18} Mild aortic or pulmonary valve stenosis, for example, may evolve prenatally into severe forms of critical pulmonary or aortic stenosis or may even adversely affect ventricular development to the point of manifesting as hypoplastic left or right heart syndrome at term. Similarly, cardiac tumors such as cardiac rhabdomyomas or intrapericardial teratomas may not develop significantly until the second trimester,¹⁹ and they may continue to enlarge dramatically from mid-gestation to term. Ductal constriction or closure of the foramen ovale may not develop until late in gestation,²⁰ and the same may be said for fetal arrhythmias, valvar regurgitation, myocardial dysfunction, and CHF.¹⁸

Risk Factors for Congenital Heart Disease in the Fetus

Inasmuch as most cases of CHD occur in pregnancies not identified as being at high risk,^{21,22} effective screening for CHD in low-risk pregnancies remains tremendously important. Nevertheless, many risk factors (fetal, maternal, and familial) for fetal heart disease have been identified (Boxes 23-1, 23-2, and 23-3).²³⁻³⁸ The familial recurrence of CHD remains well described³⁹ but incompletely understood. Pregnancies conceived via in vitro fertilization may be at risk for congenital heart disease.⁴⁰ Some anomalies, such as omphalocele with diaphragmatic hernia and tracheoesophageal fistula,²⁸ cleft lip/palate,²⁷ aneuploidies such as trisomy,^{23,25,32} or maternal CHD,^{26,29,30,33,34} carry significantly increased risks for fetal heart disease. Other associations, such as a family history of CHD,^{26,36} many cases of maternal diabetes,^{25,38} fetal exposure to many of the known teratogens,^{25,31,37} and fetal ureteral obstruction or gastroschisis,²⁸ carry only moderately increased risks for CHD.

BOX 23-1 RISK FACTORS FOR FETAL HEART DISEASE**FETAL**

Abnormal visceral/cardiac situs
 Abnormal four-chamber view or outflow tract evaluation
 Arrhythmia
 Aneuploidy
 Two-vessel umbilical cord
 Extracardiac structural malformation
 Intrauterine growth restriction
 Polyhydramnios
 Pericardial effusion/pleural effusion/ascites
 Twins
 Increased nuchal translucency thickness

MATERNAL

Systemic erythematosis
 Diabetes mellitus
 Phenylketonuria
 Viral syndrome (mumps, Coxsackie virus, influenza, rubella, cytomegalovirus)
 Congenital heart disease
 Teratogen exposure
 In vitro fertilization?

FAMILIAL

First-degree relative with congenital heart disease
 First-degree relative with cardiac syndrome
 DiGeorge syndrome
 Long QT syndrome
 Noonan syndrome
 Marfan syndrome
 Tuberous sclerosis
 Williams syndrome

BOX 23-2 EXTRACARDIAC STRUCTURAL MALFORMATIONS ASSOCIATED WITH FETAL HEART DISEASE**CENTRAL NERVOUS SYSTEM**

Neural tube defect
 Hydrocephalus
 Absent corpus callosum
 Arnold-Chiari malformation
 Dandy-Walker malformation

THORACIC

Tracheoesophageal fistula
 Cystic adenomatoid malformation of the lung
 Diaphragmatic hernia

SKELETAL

Holt-Oram syndrome
 Apert syndrome
 Thrombocytopenia/absent radii
 Ellis-van Creveld syndrome
 Fanconi syndrome

GASTROINTESTINAL

Omphalocele
 Duodenal atresia
 Imperforate anus
 Gastroschisis

UROGENITAL

Dysplastic/absent kidney
 Horseshoe kidney
 Ureteral obstruction

BOX 23-3 SUBSTANCES BELIEVED TO CAUSE FETAL HEART DISEASE

Anticonvulsants
 Valproic acid
 Carbamazepine
 Phenytoin
 Phenobarbital
 Warfarin
 Aspirin/ibuprofen
 Tricyclic antidepressants
 Lithium
 Alcohol
 Recreational drugs (including cocaine)
 Isotretinoin

A single umbilical artery has been associated with CHD, as well.⁴¹ Many syndromes (familial, sporadic, or related to known teratogens) convey variable risks for CHD.²⁵ Finally, increased nuchal translucency thickness in the first trimester (10 to 14 weeks) represents an important, relatively recently described risk factor for fetal heart disease, even in the presence of normal fetal chromosomes.^{24,35}

A distinction should be recognized between *fetal risk factor for CHD* and *indication for fetal echocardiography*. Because not all risk factors for fetal heart disease are equal, the primary obstetrician or perinatologist should weigh the likelihood of fetal heart disease when considering whether further evaluation is indicated. However, the expertise of primary obstetricians, perinatologists, and radiologists, as well as of pediatric cardiologists, in evaluating the fetal heart varies tremendously. Therefore, the determination of which pregnancies to refer for formal echocardiography should depend on the perceived degree of added expertise in fetal cardiac imaging, management of fetal heart disease, and counseling for fetal heart disease offered by the consultant.^{42,43} Ultimately, the decision of whom to refer for formal fetal echocardiography should reflect both the perceived likelihood of fetal heart disease and the additional expertise anticipated from referral.

Screening for Congenital Heart Disease in the Fetus

The prenatal detection of CHD in the low-risk pregnancy has long represented the fetal sonographer's Achilles' heel.⁴⁴ Although CHD occurs more frequently than any other major congenital anomaly, the rate of detection has remained disappointingly low.^{1,3-9} This weakness in fetal screening sonography is a real problem. Not only is CHD responsible for most neonatal mortality from congenital malformations¹² but also prenatal detection and diagnosis can improve the outcome of fetuses and neonates with CHD.⁴⁵⁻⁵⁰ For these reasons, more improvement needs to be made in the prenatal detection of the patient at low risk than in the detailed fetal diagnosis of CHD.^{5,21,51}

For years, those involved with fetal imaging have attempted to improve the prenatal detection of CHD. Soon after the development of two-dimensional (2D) fetal cardiac imaging, investigators proposed the four-chamber view (4CV) as an effective approach to screening the fetus for CHD.⁵²⁻⁵⁴ To this day, the 4CV (Video 23-1) has remained the standard of care for the screening fetal ultrasound evaluation of low-risk pregnancies,

although probably not for much longer.^{2,55,56} In practice, the 4CV has not resulted in the high rates of detection initially anticipated.^{1,4,6,57-59}

To improve detection further, some have demonstrated that color flow imaging, performed along with the 4CV, could improve detection rates.^{60,61} More importantly, others have emphasized the importance of evaluating outflow tracts along with the 4CV.^{8,62-68} In fact, many forms of ductal-dependent CHD (e.g., double-outlet right ventricle [DORV], tetralogy of Fallot [TOF], transposition of the great arteries, truncus arteriosus) have abnormal outflow tracts but generally normal-appearing 4CVs, and it is these ductal-dependent forms of CHD that most commonly require early intervention after delivery. Routine evaluation of the outflow tracts has been somewhat problematic, however, in part because the outflow tracts do not reside in a single plane (Video 23-2), which is what is seen in the 4CV. Nevertheless, evaluation of outflow tracts along with obtaining the 4CV for the low-risk standard fetal ultrasound evaluation makes sense and is swiftly becoming the standard of care.^{2,55,56} Although current guidelines for screening for heart disease during the second trimester include the 4CV and an attempt, when feasible, to evaluate the outflow tracts, there has been an increasing recognition of the importance of routine evaluation of the outflow tracts along with the 4CV.

More recently, multiple investigators have suggested that 3D imaging, wherein volumes may be acquired within seconds and then interactively reviewed, allowing the display of virtually any plane, may facilitate and improve the evaluation of both the 4CV and the outflow tracts.⁶⁹⁻⁷¹ Algorithms to automate the display of conventional fetal cardiac views from a single volume data set offer promise.^{72,73} Many investigators have suggested that 3D and 4D volume data sets may improve prenatal detection because they can be sent electronically to experts at distant sites for review.⁷⁴ However, image resolution with 3D imaging remains low, and considerable expertise is currently required to evaluate volume data sets, despite a wealth of evolving algorithms and display techniques aimed at facilitating and improving analysis.^{69-72,75}

Given the limitations of ultrasound in evaluating the fetal heart, some investigators have pursued the application of magnetic resonance imaging to the fetal heart.⁷⁶ However, this application has been limited because of the lack of a readily available means to gate the acquired images to the cardiac cycle.

Despite these developments, second-trimester screening for major forms of CHD remains ineffective, for several reasons that have been well described previously.⁷⁷ First, the practice of prenatal screening for CHD remains heavily dependent on both the expertise of the sonographer^{3,78} and the quality of the equipment. Second, effective screening requires an experienced reviewer to evaluate the fetal heart.⁶³ And third, although it makes sense to evaluate static fetal structures as still-frame images, it does not make sense—and does not work—to evaluate the heart as a single still-frame image of the 4CV, or even as a series of still-frame images of the 4CV and outflow tracts.⁴⁴

For these reasons, the beating 4CV⁴⁴ and outflow tracts⁸ should supplant the motionless 4CV as the centerpiece of screening the fetus for CHD. Visualization of valve and myocardial motion facilitates and enhances the evaluation of cardiac structure^{4,79} and makes missing major CHD less likely. Ideally, screening should also include evaluation of both outflow tracts; however, the addition of just the left ventricular outflow tract (LVOT) would probably effectively detect most major anomalies typically missed with 4CV imaging alone.⁶⁴

However, one additional consideration may be the single most important reason for the failure of current screening approaches to detect a greater percentage of cases of major forms of CHD. Those who scan fetal hearts understand that optimal visualization of the heart requires something at least as important as expertise and high-quality equipment. Screening for fetal CHD requires high-quality windows, appropriate angles of interrogation, and satisfactory fetal lies. To obtain these elements requires variable amounts of not only expertise but also time. Whereas finding the way around the fetal spine to evaluate the crux of the heart may be easier to do with greater scanning expertise, obtaining satisfactory fetal lies still commonly requires extended periods of time to be spent performing various maternal maneuvers aimed at optimizing the fetal lie. The importance of time spent in this way cannot be overstated.

The following paragraphs describe the routine (second-trimester) evaluation of low-risk pregnancies for fetal heart disease. Descriptions of first-trimester evaluation of the fetal heart (now performed increasingly because of the identification of nuchal translucency as a risk factor for CHD, and because of increasing sophistication and resolution of ultrasound transducers and software)^{17,80-83} may be found elsewhere.

TECHNIQUE

Extracardiac Evaluation

Prenatal screening for CHD should begin with an evaluation for extracardiac abnormalities associated with CHD. The umbilical cord should have three vessels, the heart and stomach should both be on the fetal left (above and below the diaphragm, respectively), and there should be no ascites (Fig. 23-1) or pericardial or pleural effusions. A trivial amount of pericardial fluid may normally be seen adjacent to the right and left ventricular free walls.⁸⁴ Abnormalities of any of these findings should raise the level of suspicion for CHD and prompt more than just a routine evaluation.

Figure 23-1 Transverse image of the fetal abdomen demonstrating marked ascites. This finding, in combination with thoracic effusions, indicates fetal hydrops.

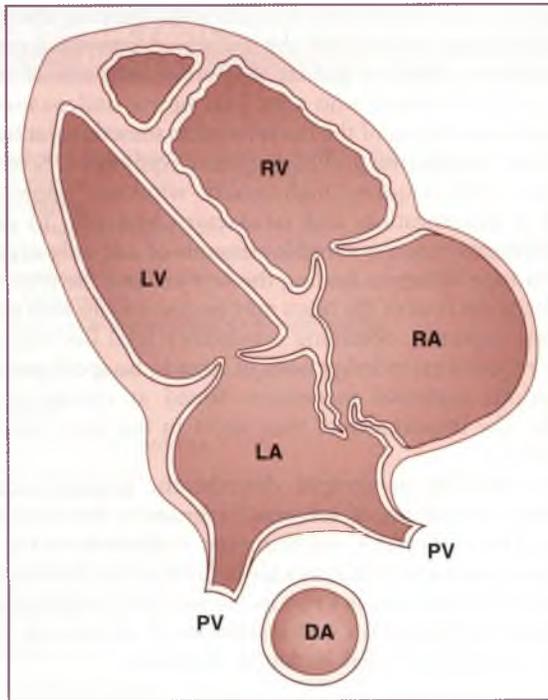

Figure 23-2 Schematic diagram of fetal four-chamber view. The right side of the heart appears slightly larger than the left side. The pulmonary veins (PV) enter the left atrium (LA). The flap of the foramen ovale resides in the left atrium. The tricuspid valve inserts onto the ventricular septum slightly apical to the mitral valve insertion. The moderator band characterizes the right ventricular apex. Both ventricles contribute to the cardiac apex. DA, descending aorta; LV, left ventricle; RA, right atrium; RV, right ventricle. (Courtesy of Irving R. Tessler, MD.)

Figure 23-3 Fetal echocardiographic image of four-chamber view. Compare with Figure 23-2. The right side of the heart appears slightly larger than the left. A right-sided pulmonary vein (PV) drains into the left atrium (LA). The tricuspid valve inserts onto the ventricular septum slightly more apically than does the mitral valve. The moderator band characterizes the right ventricular apex. Both ventricles contribute to the cardiac apex. DA, descending aorta; LV, left ventricle; RA, right atrium; RV, right ventricle.

Beating Four-Chamber View

The 4CV (Figs. 23-2 and 23-3; see Video 23-1) always deserves a close, detailed evaluation, even as part of a general screening fetal ultrasound study. In fact, because of the current low rates of prenatal detection of CHD,^{1,3-7} the 4CV probably deserves more attention than it has been receiving. Evaluation of the beating 4CV should assess situs, size, symmetry, structure, and squeeze.

Situs. The heart should be located in the left thorax, with the apex directed approximately 45 degrees to the left. Hearts on the right (dextrocardia), in the middle (mesocardia), or with the apex directed toward the left (left axis deviation)⁸⁵ have all been associated with CHD. Moreover, should the space around the heart be filled with fluid, either circumferentially or with a depth of greater than 2 mm, further evaluation may be indicated.⁸⁴

Size. The heart should occupy no more than approximately one third of the cross-sectional area of the thorax.⁸⁶ Alternatively, the circumference of the fetal heart should be no more than approximately half the transverse circumference of the thorax. However, no quantitative threshold outperforms an experienced eye. An enlarged fetal heart, by any means of measurement, should be considered a strong indicator of CHD and should prompt a more detailed evaluation.

Symmetry. The right and left sides of the fetal heart should appear generally symmetric, with the right side slightly larger.

During the third trimester, this right-sided predominance may become more pronounced.⁸⁷ If the left side of the heart appears larger than the right, or if the right side appears substantially larger than the left, further evaluation may be prudent.

Frequently, there is a question as to whether the right side is enlarged or the left side is small. Commonly, it may be a little of both, with fetal cardiac output simply redistributing. In other cases, however, the pathology is truly one-sided. The more important questions to consider may be (1) why is there an abnormal ratio between the right and left sides of the heart, and (2) what is the primary lesion?

Structure. Even for the purposes of screening for CHD, several aspects of the structure of the 4CV should be evaluated. First, the flap of the foramen ovale should be visualized as being deviated into the left atrium. This flap may not be well visualized, but certainly a flap that is deviated toward the right atrium should raise the concern for right-sided volume or pressure overload and prompt further evaluation. Second, the lowest portion of the atrial septum, just above the insertion point of the mitral valve, should always be visualized. Third, the septal leaflet of the tricuspid valve should attach to the ventricular septum slightly more toward the apex than the septal leaflet of the mitral valve does. In practice, this normal offset may be subtle, difficult to appreciate, and, if we are to be honest, not critical to note for the purposes of screening for CHD. Fourth, the mitral and tricuspid valves should be thin and delicate, with

the tricuspid valve slightly larger than the mitral valve, and the valves should open symmetrically during diastole. Fifth, the left ventricle (aligned with the left atrium) should be smooth walled and should extend to the apex. The right ventricle should appear more heavily trabeculated and should extend toward the cardiac apex along with the left ventricle. Finally, the ventricular septum should appear intact with 2D imaging.

Commonly, the coronary sinus is seen in circular cross-section in the left atrium, just above the lateral aspect of the mitral valve. When the imaging plane has been shifted to just inferior and posterior to that of the true 4CV, the coronary sinus may be seen longitudinally just above the mitral valve annulus, and draining directly into the right atrium. In this plane, the mitral valve does not appear to open, and the coronary sinus may be mistaken for an ostium primum defect.

Squeeze. The 4CV (as well as the outflow tracts), even for the purposes of screening for CHD, should be evaluated with the heart beating. The heart rate should range roughly between 120 and 160 beats/min, with no pauses and no skipped or extra beats, other than transient bradycardia during deep transducer pressure. The mitral and tricuspid valves should open and close symmetrically, and both ventricles should squeeze well. Abnormalities of rhythm, valvar function, or myocardial motion may reflect important forms of fetal heart disease and may be overlooked with evaluation of only still-frame images.⁴⁴

Outflow Tracts

Prenatal screening for CHD should include visualization of both outflow tracts (Videos 23-3 and 23-4; see Video 23-2). In practice, appropriate evaluation of the outflow tracts may be more challenging than visualization of the 4CV, in part because, unlike the 4CV, the outflow tracts do not lie in a single plane. Nevertheless, because of the ability of the outflow tract views to detect major forms of CHD not visualized with the 4CV, evaluation of both outflow tracts is appropriately becoming the standard of care.^{2,55,56}

Slight angulation of the transducer cephalad from the 4CV should demonstrate the aortic valve and ascending aorta arising from the left ventricle (Figs. 23-4 and 23-5; see Videos 23-2 and 23-3). The aortic valve should appear thin and delicate. The ventricular septum should be noted to extend, uninterrupted, from the cardiac apex all the way to the lateral aspect of the ascending aorta. The ascending aorta, or aortic root, should point toward the right of the spine. The left ventricular

long-axis view should allow detection of most forms of CHD involving the outflow tracts.⁶⁴ However, with just slight further cephalic angulation of the transducer, the right ventricular outflow tract (RVOT) (pulmonary valve and pulmonary artery) can be visualized arising from the right ventricle and crossing the aortic root (Figs. 23-6 and 23-7; Video 23-5). The pulmonary valve should be thin and delicate, and the pulmonary valve and main pulmonary artery should be slightly larger than the aortic valve and aortic root. The main pulmonary artery should point to the left of the spine.

PRENATAL SCREENING USING THREE-DIMENSIONAL IMAGING

Although the current standard for screening the low-risk pregnancy for CHD uses 2D imaging, 3D imaging may ultimately facilitate the prenatal detection of CHD by allowing virtual⁶⁹ or automated^{72,73} evaluation of the entire fetal heart after a simple, short acquisition. When desired, volume data sets may be transmitted electronically to experts at remote locations, who can

perform a virtual examination as if actually scanning the patient themselves.^{74,88} Ultimately, 3D fetal cardiac imaging may make acquisition of fetal cardiac data sets less dependent on time and operator skill and facilitate evaluation of the 4CV and outflow tracts offline.^{69,89} However, 3D and 4D data sets of high quality appear to be more challenging to acquire than previously appreciated. Fetal 3D cardiac imaging is discussed later, and fetal echocardiography in high-risk pregnancies will be covered.

Technique of Fetal Echocardiography

Detailed fetal echocardiography in the pregnancy at high risk for CHD provides an in-depth and comprehensive evaluation of fetal cardiovascular structure and function.⁹⁰⁻⁹² In experienced hands, and particularly when performed beyond 18 weeks' gestation, fetal echocardiography has been shown to have high sensitivity for almost all forms of fetal heart disease.^{21,93,94}

First-trimester fetal echocardiography, performed between 10 and 14 weeks' gestation either transvaginally or transabdominally, does not have the same degree of sensitivity for CHD as second-trimester imaging, in part because of resolution considerations when imaging the smaller first-trimester heart, and in part because many forms of CHD (e.g., aortic and pulmonary valvar stenosis, ventricular hypoplasia, valvar regurgitation, arrhythmias, cardiac tumors, restriction of the ductus arteriosus or foramen ovale) evolve significantly between the late first trimester and term.^{18,95,96} Nevertheless, in experienced hands, the clinical role of first-trimester fetal echocardiography has increased along with first-trimester nuchal translucency screening and improvements in image resolution.^{17,80-83,97,98} Early fetal echocardiography provides early reassurance in cases of normal-appearing hearts, the opportunity for early fetal interventions for the small subset of fetal cardiac conditions that may benefit from early invasive intervention, and the

opportunity for early termination in cases of severe disease.⁹⁹ However, the technique requires specialized training and expertise.¹⁰⁰

Further discussion of first-trimester fetal cardiac imaging will not be pursued in this chapter. Instead, this section reviews the technique of fetal echocardiography as performed transabdominally beyond 16 to 18 weeks' gestation. Solely to optimize image quality, fetal echocardiography should optimally be performed between 22 and 28 weeks' gestation. However, because earlier diagnosis may be desired for various management and emerging therapeutic options, fetal echocardiography should be performed generally between 18 and 22 weeks' gestation.

Formal fetal echocardiography involves evaluation of the fetal heart and cardiovascular system using several modalities: 2D imaging, color flow imaging, spectral or continuous wave Doppler evaluation, quantitative assessment of ventricular function, and 3D imaging. In practice, the fetal heart and cardiovascular system is probably best evaluated in an anatomically systematic fashion, using various modalities in combination for each anatomic component of the evaluation. However, the order in which individual components of the evaluation are performed may vary with case-specific clinical and imaging considerations.

Various quantitative measurements^{10,11,101-113} may be performed if an abnormality is suspected, if doubt remains regarding normalcy, or if measurements for a database are desired. Spectral Doppler echocardiography should routinely be used to assess flow across vessels or valves with suspected pathology.^{101,103,108-111} Any structure that appears small or large should be measured several times, with the best-guess measurement plotted on nomograms according to gestational age.¹¹³⁻¹¹⁹ Color flow imaging, which is exquisitely sensitive to valvar regurgitation, flow through small VSDs, and pulmonary and systemic venous returns, should be used routinely to demonstrate normalcy and to assess pathology. More sophisticated tissue Doppler studies^{106,120,121} or other quantitative means of evaluation of ventricular diastolic¹⁰⁸⁻¹¹¹ or combined diastolic and systolic^{104,105} function may be used in special circumstances.

This section describes a clinical approach to the formal fetal echocardiographic evaluation, with an emphasis on the importance of routine 2D and color flow imaging. Although admittedly less rigorous and comprehensive than guidelines recommended by the American Society of Echocardiography,⁹⁰ this approach to fetal echocardiography is consistent with guidelines recommended by the International Society of Ultrasound in Obstetrics and Gynecology,⁹² and more stringent than those recently recommended by the American Institute of Ultrasound in Medicine, which do not require evaluation of cardiac motion or the use of color flow imaging.⁹¹ In response to concerns regarding the adequacy of its most recent guidelines, the American Institute of Ultrasound in Medicine is revising its most recent set of guidelines for fetal echocardiography.¹²²

GENERAL IMAGING

The formal fetal echocardiogram begins with a determination of the number of fetuses, their levels of activity, their respective positions, and their gestational ages. The number of fetuses and their respective positions matter because the lie, late in the third trimester, may affect delivery plans. With multiple-gestation pregnancies, each fetus should undergo its own detailed fetal echocardiogram, and noting the fetal lie or position helps to

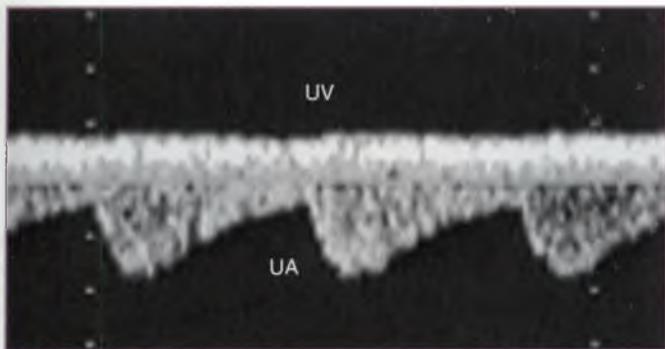

Figure 23-8 Spectral Doppler display of flow in a free-floating umbilical cord. UA, umbilical artery; UV, umbilical vein.

distinguish one fetus from another. Gestational age determination (1) enables assessment of fetal growth, (2) may affect counseling or management strategies, and (3) allows assessment of cardiac structures that vary in appearance with gestational age.

UMBILICAL CORD

Next comes evaluation of the umbilical cord (Fig. 23-8). Spectral Doppler evaluation of the umbilical artery provides information on placental resistance, which may affect fetal cardiovascular function and reflect overall fetal well-being. In cases of suspected placental pathology, calculation of a pulsatility index enables a quantitative assessment of placental resistance. Doppler evaluation of the umbilical vein in the free-floating cord is most useful in cases of suspected fetal heart failure.¹⁰³ Normally, the umbilical venous waveform pulsates in response to fetal breathing, but it should not vary with the fetal cardiac cycle. Pulsatile flow in the free-floating umbilical cord, reflecting fetal cardiac contractions, suggests markedly elevated fetal right atrial pressure and represents a manifestation of significant CHF.¹²³

HYDROPS

Initial evaluation of the fetus itself should assess for the presence of fluid accumulation suggestive of CHF. Normally, no more than a trivial (loculated and <2 mm) pericardial effusion should be present.⁸⁴ A greater accumulation of pericardial fluid (circumferential or >2 mm) (Figs. 23-9 and 23-10) or the presence of any pleural fluid or ascites (see Fig. 23-1) should be considered abnormal, with a differential diagnosis that includes CHF, myopericarditis, viral infection, anemia, and aneuploidy.

VISCEROATRIAL SITUS

After the determination of fetal number, position, gestational age, umbilical waveforms, and presence or absence of hydrops, attention should be directed toward the structure and function of the fetal cardiovascular system itself. This assessment should begin with an abdominal assessment of visceral situs (Figs. 23-11 and 23-12; see Video 23-2). Transverse imaging of the abdomen should demonstrate the descending aorta, in cross section, just anterior and slightly leftward of the spine. The stomach should be anterior and leftward, and the inferior vena cava (IVC) and liver should both be anterior and rightward. A prominent vein (usually the azygos) should not be visualized

Figure 23-9 Fetal echocardiographic image of loculated pericardial effusion (anterior to tricuspid valve atrioventricular groove, and adjacent to the right ventricular free wall). This image demonstrates right heart disproportion, as well.

Figure 23-10 Fetal echocardiographic sagittal image of circumferential pericardial effusion. Note that the heart appears to swim in the pericardial sac.

posterior to the descending aorta (Fig. 23-13); on the other hand, a small azygos vein in this location can occasionally be seen in normal fetuses. Angulation of the probe from transverse to sagittal imaging should demonstrate the IVC draining into the right atrium. Finally, transverse imaging of the thorax should demonstrate the heart on the left, with the apex directed anteriorly and leftward. Abnormalities of any of these features should prompt further evaluation for situs abnormalities (asplenia or polysplenia) or associated CHD, or both.

BEATING FOUR-CHAMBER VIEW

Central to screening for CHD, the 4CV also represents a critically important aspect of the formal fetal echocardiogram.^{10,11,124}

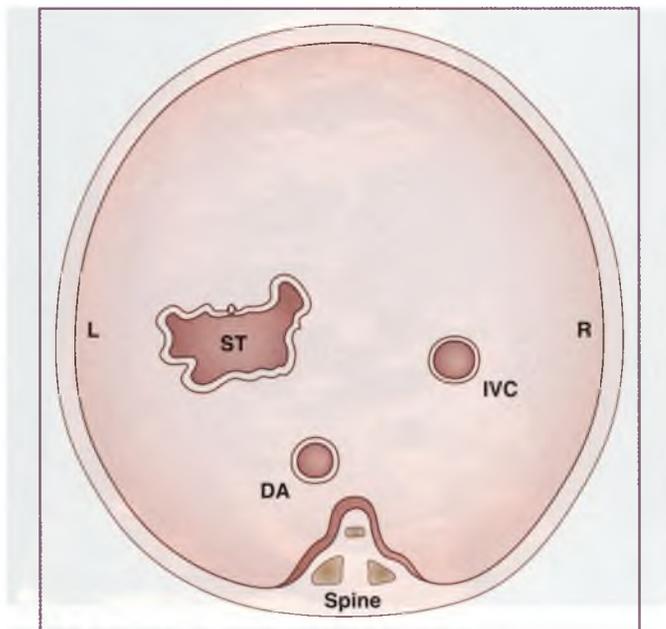

Figure 23-11 Schematic diagram of abdominal situs view. DA, descending aorta; IVC, inferior vena cava; L, fetal left; R, fetal right; ST, stomach. (Courtesy of Irving R. Tessler, MD.)

Figure 23-12 Fetal echocardiographic image of abdominal situs view. Compare with Figure 23-11. DA, descending aorta; IVC, inferior vena cava; L, fetal left; R, fetal right; St, stomach.

As with screening, detailed fetal echocardiography begins by demonstrating the fetal heart to be in the left thorax with the apex directed approximately 45 degrees to the left (see Fig. 23-2, Fig. 23-3, and Video 23-1). The heart should fill less than one third of the area of the thorax,⁸⁶ and the heart's circumference

Figure 23-13 Transverse cut through the fetal abdomen demonstrating right-sided descending aorta, left-sided stomach, and left-sided azygos vein posterior to and leftward of the descending aorta. This finding suggests an interrupted inferior vena cava with azygos continuation to the superior vena cava, commonly associated with polysplenia.

should be less than half the thoracic circumference. These quantitative measurements, like most such measurements in fetal echocardiography, should be considered optional unless an abnormality is suspected, normalcy is in doubt, or measurements are desired for incorporation into a database.

The fetal heart's right-sided structures should be equal to or, more commonly, slightly larger than their respective left-sided structures.⁸⁷ Mild right heart disproportion appears to occur in some cases of trisomy 21, even in the absence of structural disease.¹²⁵ With advancing gestation, the right side of the heart becomes progressively more dominant, making the diagnosis of right-sided heart disproportion much more common during the third trimester than during the second.⁸⁷ For this reason, false-positive diagnoses of coarctation of the aorta occur most frequently late in gestation.

Venous Drainage

Although evaluation of systemic and pulmonary venous drainage may be accomplished with 2D imaging alone, color flow imaging helps to confirm the anatomy and to demonstrate areas of obstruction,¹²⁶ and spectral Doppler may help to assess cardiovascular status still further.^{103,107,108,123} With slight inferior angulation or tilting of the transducer from the 4CV, the coronary sinus should be seen coursing from left to right just above the mitral groove (Fig. 23-14). At the level of the 4CV, the coronary sinus sometimes may be seen in cross section laterally, adjacent to the left atrial free wall just above the mitral annulus. However, enlargement of the coronary sinus (Fig. 23-15) should prompt evaluation for either a left-sided superior vena cava (LSVC)^{127,128} (Fig. 23-16) or drainage of some or all pulmonary veins directly into the coronary sinus. All four pulmonary veins may be seen, but such visualization can be time consuming and

Figure 23-14 Schematic diagrams of coronary sinus views. A, Longitudinal coronary sinus view obtained with slight inferior angulation from the four-chamber view. The coronary sinus (arrow) drains along the mitral annulus before opening into the right atrium and can be seen in normal fetuses. B, Four-chamber view demonstrating dilated coronary sinus in cross section (arrow) at the lateral aspect of the mitral annulus. A normal coronary sinus is usually small or not seen at all with this perspective. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (Courtesy of Irving R. Tessler, MD.)

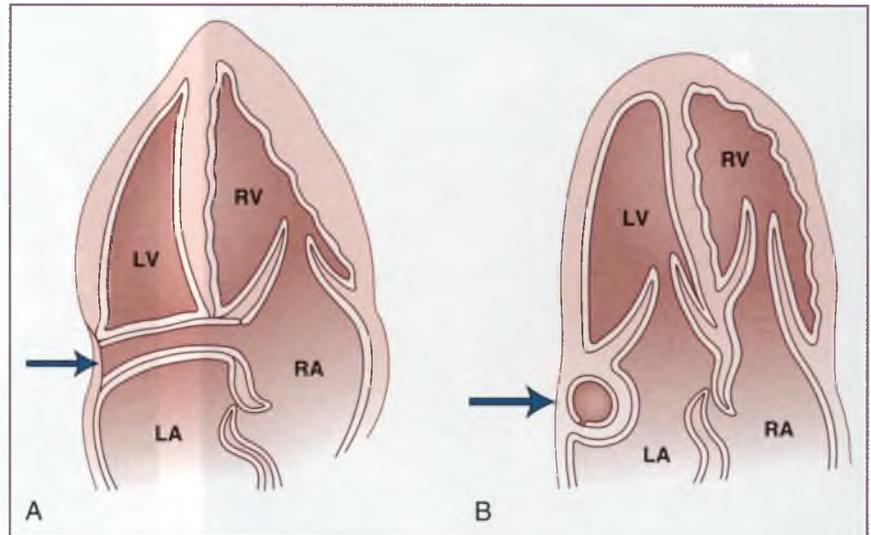

Figure 23-15 Fetal echocardiographic image of four-chamber view. Note the dilated coronary sinus in cross section immediately above the posterior aspect of the mitral valve. The left ventricular outflow tract appears narrowed, as commonly occurs in association with a persistent left-sided superior vena cava draining to the coronary sinus.

Figure 23-16 Sagittal image of the fetal thorax and heart demonstrating a left-sided superior vena cava draining posteriorly into the coronary sinus. Generally, a left-sided superior vena cava is found more posteriorly than a right-sided superior vena cava.

challenging; therefore, visualization by color flow Doppler of even one or two pulmonary veins (Figs. 23-17 and 23-18; see Fig. 23-3) draining normally to the left atrium is generally sufficient^{1,102} in the absence of suspected disease. The presence of a ridge of tissue (normal pericardial reflection, or infolding of tissue between the left atrial appendage and left pulmonary vein) extending a short distance medially from the posterior and lateral aspect of the left atrium helps to rule out total anomalous pulmonary venous return. Color flow imaging should be performed to confirm normal, unobstructed pulmonary venous return to the left atrium. Spectral Doppler analysis may be performed if color Doppler suggests pathology.¹⁰⁸

Structural abnormalities of venous return raise the possibility of heterotaxy.^{126,129,130}

Atrial Septum

Because the foramen ovale normally shunts oxygenated blood from the right atrium to the left atrium, the flap of the foramen ovale should be deviated toward the left atrium. Although this flap typically moves back and forth during the cardiac cycle, the dominant position should be leftward (see Fig. 23-2). The flap itself should occupy a central position in the atrial septum, and it should extend increasingly farther into the left atrium with advancing gestational age. Both the superior and inferior aspects

Figure 23-17 Fetal echocardiographic image of four-chamber view. Color flow imaging demonstrates a right-sided pulmonary vein (arrow) draining into the left atrium. LV, left ventricle; RV, right ventricle.

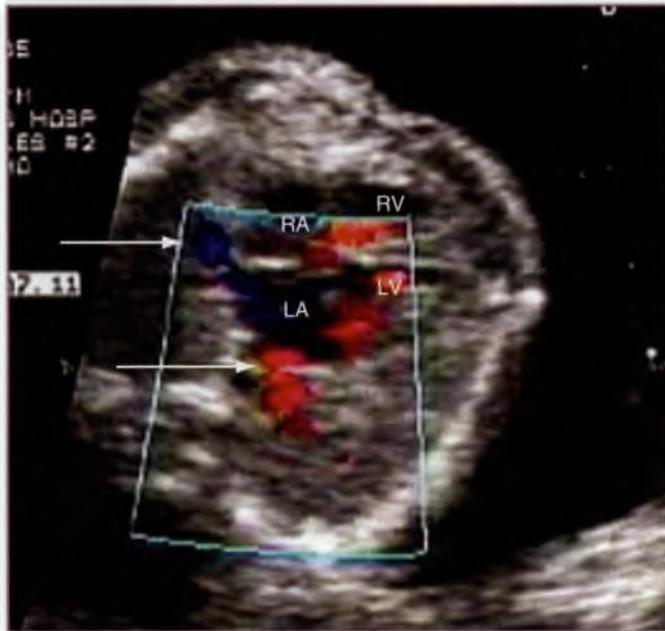

Figure 23-18 Fetal echocardiographic image of four-chamber view. Color flow imaging demonstrates right and left pulmonary veins (arrows) draining into the left atrium. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

of the atrial septum should appear intact, although the superior rim may not always be seen with routine screening. Occasionally, particularly when dilated, the coronary sinus (seen longitudinally) may generate the appearance of an absent inferior portion of the atrial septum (Fig. 23-19).¹²⁷ For this reason, if this portion of the atrial septum appears deficient, care must be taken to confirm that the image plane has not simply been directed too far posteriorly and inferiorly from the 4CV.

Figure 23-19 Fetal echocardiographic image of dilated coronary sinus, obtained with a slight inferior angulation from the four-chamber view. The dilated coronary sinus orifice (arrow) mimics ostium primum atrial septal defect.

Atrioventricular Valves

The atrioventricular valve morphology and function should be evaluated, along with the rest of the heart, during real-time motion. Both valves may be evaluated in their entirety from the 4CV (see Figs. 23-2 and 23-3), although visualization from other views may be useful, particularly if abnormalities are present or suspected. The tricuspid valve annulus should be the same size as or slightly larger than the mitral annulus. The leaflets should appear thin and delicate, with unrestricted diastolic excursion into their respective ventricles. A subtle abnormality of either valve early in the second trimester may progress to a severe abnormality, or even to hypoplastic right- or left heart syndrome, at term. The septal leaflet of the tricuspid valve should insert slightly more apically onto the ventricular septum than the septal leaflet of the mitral valve does. The papillary muscles of the tricuspid valve should have attachments to the ventricular septum and the right ventricular free wall. In contrast, the papillary muscles of the mitral valve should have no attachments to the ventricular septum. Evaluation of the atrioventricular valves should always include color flow imaging to assess for diastolic turbulence or valvar regurgitation. A trace amount of early systolic tricuspid regurgitation is probably normal,¹³¹ although previously many investigators considered any prenatal tricuspid regurgitation to be abnormal.¹³² Prenatal valvar regurgitation of any other valve is generally considered abnormal. Fetuses with trisomy appear to have an increased incidence of tricuspid regurgitation, even in the presence of a structurally normal heart.¹²⁵ Measurement of tricuspid and mitral valve annulus size,^{114-116,118,119} as well as spectral Doppler evaluation of inflow patterns,¹⁰⁹⁻¹¹¹ should be performed if an abnormality is suspected, if normalcy cannot be confirmed, or if additions to a database are desired.

Ventricles

The structure and function of both ventricles should be evaluated in detail. The 4CV provides the single best perspective to

evaluate ventricular structure (see Figs. 23-2 and 23-3). Both ventricles should extend to the cardiac apex, and both should squeeze symmetrically during systole. The left ventricle should be smooth walled, aligned with the mitral valve, and located leftward and posterior to the right ventricle. The right ventricle should be more heavily trabeculated and should have a moderator band that crosses it near the apex; it should be aligned with the tricuspid valve and located rightward and anterior to the left ventricle. The right ventricle should be equal in size to, or, more commonly, slightly larger than, the left ventricle, and the right heart predominance increases normally with advancing gestational age. Mild right heart disproportion (Fig. 23-20) has been associated with trisomy 21.¹²⁵ Quantitative assessment of ventricular systolic and diastolic function^{103-106,109-111,121,133} may be performed if an abnormality is suspected, if normalcy cannot be confirmed, or if additions to a database are desired. However, close attention to ventricular systolic function should always be made qualitatively and from multiple views, including the 4CV and the basal short-axis view (obtained from a sagittal fetal orientation) (Video 23-6). Ventricular dysfunction may be isolated and primary,¹³⁴ or it may be associated with structural heart disease.

The presence of small, circumscribed, echogenic densities, foci, or reflectors in the chordal apparatus of the mitral valve (or, less commonly, the tricuspid valve) should probably be considered, from a cardiovascular standpoint, as benign variants of normal (Fig. 23-21).¹³⁵⁻¹³⁷ If doubt exists regarding the diagnosis, further evaluation should be performed to rule out CHD. Although the data remain somewhat controversial, such echogenic foci do appear to be more prevalent among fetuses with aneuploidy than among those with normal

chromosomes.¹³⁶⁻¹³⁹ An important but sometimes subtle distinction should be made between echogenic reflectors, as described earlier, and a more diffuse echogenicity along the mitral and tricuspid valve annuli, throughout the supportive apparatus of the mitral and tricuspid valves, and occasionally more generally in other aspects of the endocardium (Fig. 23-22); this unusual manifestation of fibroelastosis can represent damage related to maternal anti-SSA/SSB antibodies.

Figure 23-21 Four-chamber view of the fetal heart demonstrating a single echogenic reflector (focus) in the chordal apparatus of the mitral valve.

Figure 23-20 Fetal echocardiographic image of apical short-axis view. Right ventricular disproportion is demonstrated. LV, left ventricle; RV, right ventricle.

Figure 23-22 Fetal four-chamber view demonstrating multiple echogenic densities in the mitral and tricuspid valve grooves, as well as diffusely along the chordal apparatus of the tricuspid valve. These densities reflect damage to the endocardium from maternal anti-SSA/SSB antibodies. The differential diagnosis includes echogenic reflectors/foci, which may represent a soft marker for aneuploidy, but which have not been related to anti-SSA/SSB antibodies.

Ventricular Septum

The ventricular septum should be evaluated for thickness, motion, and the presence of a VSD. The ventricular septum should be roughly the same thickness as the left ventricular posterior free wall, and it should contract symmetrically with the left ventricular free wall. Ventricular septal thickness may be evaluated from the 4CV and the basal short-axis view. In cases of suspected septal hypertrophy, the septal thickness should be measured, typically during both diastole and systole. The entirety of the ventricular septum then needs to be evaluated for VSDs. Using multiple views and multiple sweeps, 2D imaging should be performed to identify any defect in any portion of the ventricular septum. To avoid false-positive dropout in the inlet and membranous or outlet portions of the ventricular septum, the 2D imaging should be as perpendicular as possible to the ventricular septum and with the transducer angled slowly from the 4CV into the left ventricular long-axis view (see Fig. 23-4, Fig. 23-5, and Video 23-3). Color flow imaging should also always be performed in search of VSDs (Fig. 23-23), using the same perpendicular orientations and sweeps; some defects may not be visualized with 2D imaging alone. On the other hand, some defects, particularly before 18 to 20 weeks, may be evident with 2D imaging but have no visible shunting with color flow evaluation.

OUTFLOW TRACTS IN MOTION

Semilunar Valves

The semilunar (aortic and pulmonary) valves should be evaluated with at least as much attention to anatomy and function as is given to the evaluation of the atrioventricular valves. Consistent with the right-sided predominance seen at the levels of the atrium, atrioventricular valve, and ventricle, the pulmonary valve annulus should be equal in size or, more commonly, slightly larger than the aortic valve annulus. The aortic valve can be best visualized with a left ventricular long-axis view (see

Figure 23-23 Fetal echocardiographic image of apical short-axis view. Color flow imaging demonstrates intact muscular ventricular septum.

Fig. 23-5), which is obtained with slight anterior/superior angulation from the 4CV. In addition, ideally, the probe can be rotated slightly from a transverse cut toward a partially sagittal plane. The aortic valve may be evaluated further with a basal short-axis view, which is obtained from a sagittal orientation of the fetus. The pulmonary valve (RVOT crossing view; see Fig. 23-7) may be evaluated with slight anterior/superior angulation from the left ventricular long-axis view. In addition, the pulmonary valve may be evaluated further with a basal short-axis view (see Video 23-4). The aortic valve should arise from the anterior aspect of the left ventricle, and the pulmonary valve from the anterior aspect of the right ventricle. Both aortic and pulmonary valves should be thin and delicate, with unrestricted excursion during systole, resulting in the valve's practically disappearing from view when fully open (see Fig. 23-5). During diastole, the aortic and pulmonary valves should appear as central points or symmetric, thin plates. The aortic valve, during diastole, should appear on the left ventricular long-axis view as a thin, central plate, parallel to the axis of the aortic root. The pulmonary valve during diastole, in contrast, should appear on the basal short-axis view, also as a thin plate but perpendicular to the axis of the main pulmonary artery. A subtle abnormality of either valve (Fig. 23-24, Fig. 23-25, and Video 23-7; see Video 23-5) during the early second trimester may progress to a severe valve abnormality, or even to hypoplastic left or right heart syndrome, at term. Measurement of aortic or pulmonary valve annulus size, or evaluation of the systolic Doppler flow profile, or both, should be performed if an abnormality is suspected, if normalcy cannot be confirmed, or if additions to a database are desired. However, evaluation of aortic and pulmonary valves should always include color flow imaging to assess for aortic or pulmonary (Fig. 23-26) regurgitation (always abnormal) or systolic turbulence (Fig. 23-27) suggestive of increased flow volume or anatomic obstruction.

Great Arteries and Ductal and Aortic Arches

The ascending aorta (aortic root) and main pulmonary artery should arise from the left and right ventricles, respectively, and

Figure 23-24 Oblique fetal echocardiographic image of left ventricular long-axis view demonstrating thickened aortic valve. The normal-appearing aortic valve should disappear during systole and reappear as a symmetric, thin plate during diastole.

Figure 23-25 Fetal right ventricular outflow tract demonstrating thickened, asymmetric pulmonary valve. The main pulmonary artery appears well formed.

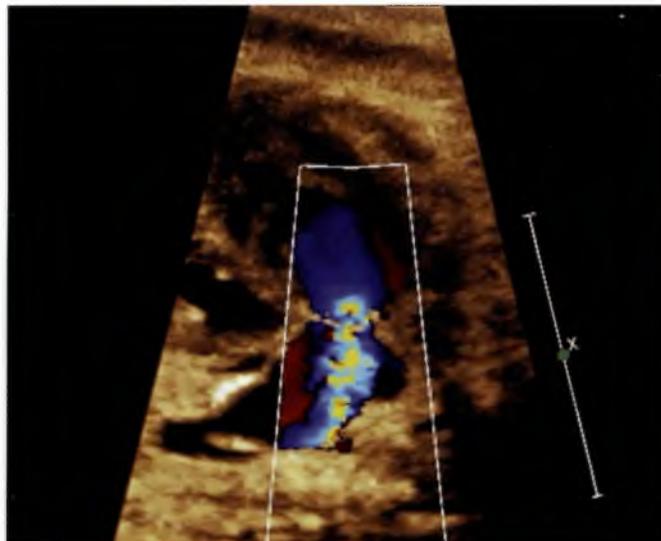

Figure 23-27 Fetal right ventricular outflow tract demonstrating turbulent flow across the pulmonary valve during systole. The jet appears eccentric and may contribute to dilation of the main pulmonary artery segment distal to the obstruction.

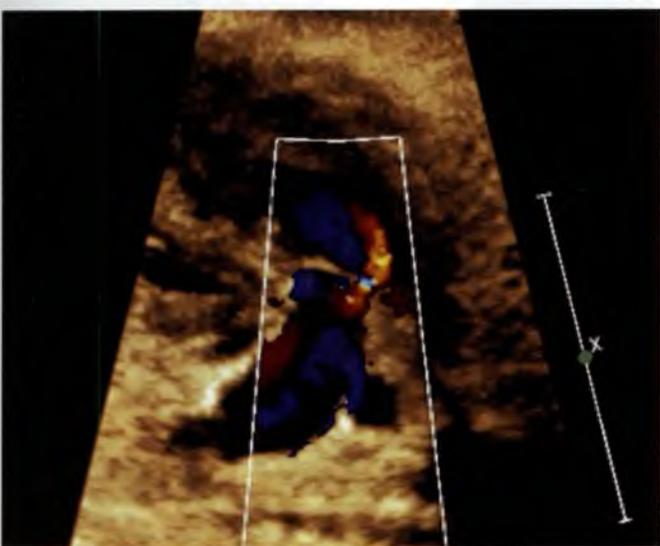

Figure 23-26 Fetal right ventricular outflow tract demonstrating pulmonary valve regurgitation during diastole (red jet).

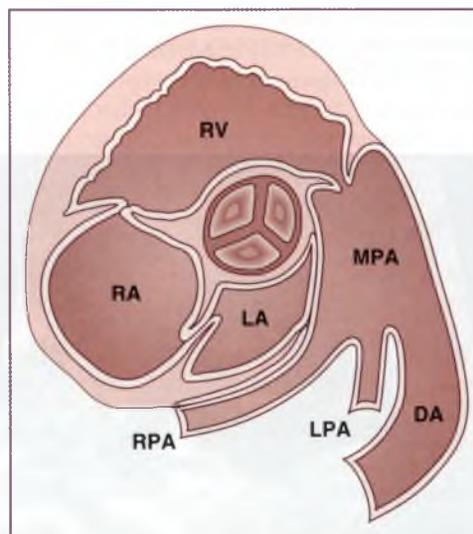

Figure 23-28 Schematic diagram of fetal basal short-axis and ductal arch view. The left pulmonary artery and ductus arteriosus (DA) commonly appear superimposed in this view. LA, left atrium; LPA, left pulmonary artery; MPA, main pulmonary artery; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle. (Courtesy of Irving R. Tessler, MD.)

then cross at an angle of roughly 45 to 90 degrees. Demonstration of great-artery crossing represents an important finding on the normal fetal echocardiogram. This crossing can be seen either with transverse imaging (slight anterior/superior angulation from the 4CV to left ventricular long-axis view to RVOT crossing view) (see Video 23-2) or, preferably, with sagittal imaging (slight leftward angulation from sagittal aortic arch view to ductal arch view) (Video 23-8). In general, the aortic root should point to the right of the spine (see Fig. 23-5), and the main pulmonary artery should point to the left of the spine (see Fig. 23-7). As with other right-left ratios in the fetal heart, the main pulmonary artery should be equal in size to, or more commonly, slightly larger than, the aortic root. The ductal arch and basal short-axis views (Figs. 23-28, 23-29, and 23-30) should demonstrate the trifurcation of the main pulmonary

artery into the right pulmonary artery (which wraps around the aorta in the basal short-axis view), the left pulmonary artery (which extends more posteriorly than the right pulmonary artery), and the ductus arteriosus (the largest of the three branches).

In cases of suspected pathology, the branch pulmonary arteries should be measured and their Doppler flow profiles obtained. For example, fetal pulmonary artery diameter may correlate with outcome in cases of congenital diaphragmatic hernia.¹⁴⁰ In cases of suspected ductal constriction (i.e., tricuspid and pulmonary regurgitation across normal-appearing valves, or simply fetal exposure to indomethacin¹⁴¹), the flow

Figure 23-29 Fetal echocardiographic image of basal short-axis view during systole. The pulmonary artery bifurcates into the right and left pulmonary arteries. The ductus arteriosus appears superimposed over the left pulmonary artery. The pulmonary valve is open and is closely opposed to the main pulmonary artery (PA). Ao, aorta; RA, right atrium; RV, right ventricle.

Figure 23-30 Fetal echocardiographic image of basal short-axis view during diastole. The aortic and pulmonary valves appear in their closed positions, and the tricuspid valve is open.

profile of the ductus arteriosus should be obtained parallel to flow on the sagittal ductal arch view. A pulsatility index of less than 1.9 suggests ductal constriction,¹⁴¹ whereas a pulsatility index greater than 3 suggests increased right ventricular output and left heart obstruction.¹⁴² The sagittal aortic arch view (Figs. 23-31 and 23-32), obtained with rightward angulation from the ductal arch view, demonstrates the aortic arch in its entirety,

including aortic root, transverse aortic arch, aortic isthmus, and descending aorta. Color flow imaging should always be performed of the entire aortic (Fig. 23-33) and ductal arches. Measurements of aortic dimensions^{114,115,117} should be obtained if an abnormality is suspected, if normalcy cannot be confirmed, or if additions to a database are desired.

EVALUATION FOR FETAL CONGESTIVE HEART FAILURE

Fetal CHF may be related to extracardiac disease (e.g., anemia, cerebral arteriovenous fistula, twin-twin transfusion syndrome) or to fetal heart disease (Box 23-4). Some of the most severe

Figure 23-33 Echocardiographic image of fetal aortic arch, sagittal view. Color flow imaging demonstrates prograde flow into aortic arch (Ao) and descending aorta (DA). IVC, inferior vena cava.

BOX 23-4 CAUSES OF FETAL CONGESTIVE HEART FAILURE

Anemia
Twin-twin transfusion syndrome
Arteriovenous malformation
Diaphragmatic hernia
Pericardial effusion
Cardiac causes
Hypertrophic cardiomyopathy
Dilated cardiomyopathy
Sustained bradycardia/tachycardia
Valvar regurgitation
Restrictive foramen ovale
Ductal constriction

forms of CHD (e.g., hypoplastic left heart syndrome [HLHS], TOF with pulmonary atresia and ductal-dependent pulmonary blood flow) do not typically generate fetal CHF. Rather, fetal heart disease that causes CHF almost invariably includes one or more of the following^{123,143,144}: sustained tachycardia or bradycardia (e.g., supraventricular tachycardia [SVT] or complete heart block), myocardial dysfunction (e.g., dilated cardiomyopathy), valvar regurgitation (e.g., Ebstein anomaly of the tricuspid valve or TOF with absent pulmonary valve), or restrictive flow across the foramen ovale or ductus arteriosus.¹⁴² The fetus with absence of a valve (e.g., tricuspid atresia) or absence of a ventricle (e.g., HLHS) generally does better prenatally than one with a poorly functioning valve or ventricle.

Unlike the postnatal diagnosis of CHF, which relies more on clinical signs (tachycardia, tachypnea, hepatomegaly, rales, and peripheral edema) than on radiographic or echocardiographic findings, the prenatal diagnosis of CHF relies exclusively on sonographic findings.^{103,123,143,144} The sonographic findings associated with fetal CHF from any cause include (1) dilated, poorly squeezing ventricle with systolic and diastolic dysfunction, (2)

BOX 23-5 SONOGRAPHIC FINDINGS IN FETAL CONGESTIVE HEART FAILURE

Cardiomegaly
Tricuspid regurgitation
Pericardial effusion
Diminished ventricular systolic function
Increased atrial flow reversal in systemic veins

cardiomegaly, (3) pericardial effusion, (4) tricuspid regurgitation, and (5) increased atrial flow reversal in the systemic veins (Box 23-5). More detailed cardiac and peripheral Doppler evaluation may also be performed.^{103,123,144-146} Severe forms of CHF lead to hydrops (see Fig. 23-1) and cardiac pulsations in the free-floating umbilical vein. The diagnosis of fetal CHF or hydrops should prompt further evaluation for clues to the etiology, as well as serial follow-up studies, because of the potential for progression of disease and even fetal demise.

THREE-DIMENSIONAL FETAL CARDIAC IMAGING

Despite great excitement and academic attention, 3D and 4D fetal cardiac imaging^{69-71,75,89,147-174} remain predominantly investigational tools for academic centers seeking to improve and enhance the prenatal detection and diagnosis of CHD. Because of persistent challenges related to image resolution, substantial learning curves, vulnerability to artifact, and expensive equipment, 3D fetal cardiac imaging has not yet become an acceptable alternative to conventional 2D imaging. The primary advantage of 3D or 4D over conventional 2D fetal cardiac imaging is its ability to help teach fetal cardiac anatomy and improve sonographer expertise with conventional 2D fetal cardiac imaging.

However, compared with 2D fetal cardiac imaging, 3D imaging carries important advantages that could ultimately revolutionize the clinical approach to fetal cardiac imaging.^{69,72,152,161,171-174} First, 3D imaging, by acquiring a comprehensive volume data set within a matter of a few seconds, makes fetal cardiac imaging less operator dependent and less time consuming to perform—at least in theory. Unfortunately, obtaining high-quality volumes, in fact, does require expertise and, frequently, extended periods of time. Second, 3D volume data sets may be evaluated interactively offline, enabling virtual examinations of the entire fetal heart, with reconstruction of any plane or sweep, after the initial, short acquisition. Such interactive evaluations may be performed at the bedside, remotely by centers with expertise,^{88,175} or even, potentially, automatically using evolving algorithms designed to automate the process of screening for CHD.^{72,73} Three- and four-dimensional fetal cardiac imaging dramatically enhances the opportunity for telemedicine.^{176,177} Third, volume-rendering algorithms display data with a “surgeon’s-eye” view, enabling visualization of the internal architecture and anatomy of the fetal heart (Figs. 23-34 and 23-35) or great arteries from any perspective. Such displays improve comprehension of complex forms of CHD, leading to improved patient counseling and patient selection for fetal interventions. Moreover, evolving technology allows the 3D visualization of color-flow jets in volume-rendered displays or as stand-alone “angiograms.”^{156,159} Finally, 3D volume data sets enable more accurate quantitative measurements of ventricular size and function,^{160,162,172,178} which

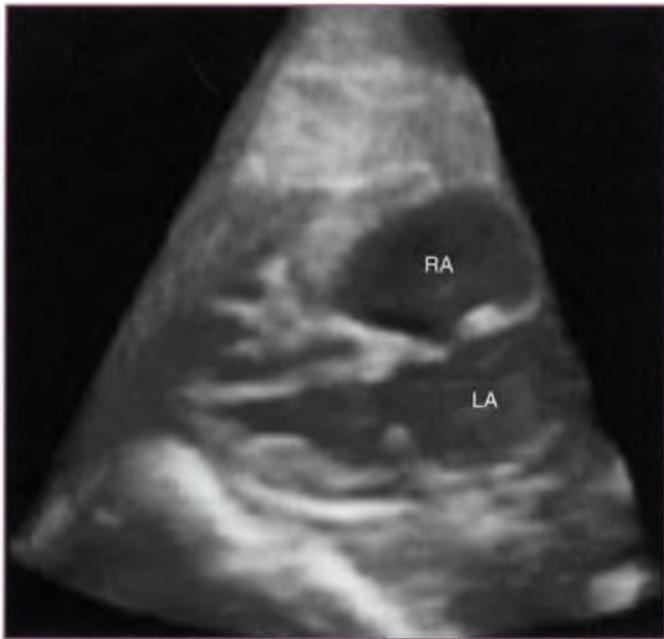

Figure 23-34 Fetal echocardiographic real-time three-dimensional rendered image of normal four-chamber view. LA, left atrium; RA, right atrium.

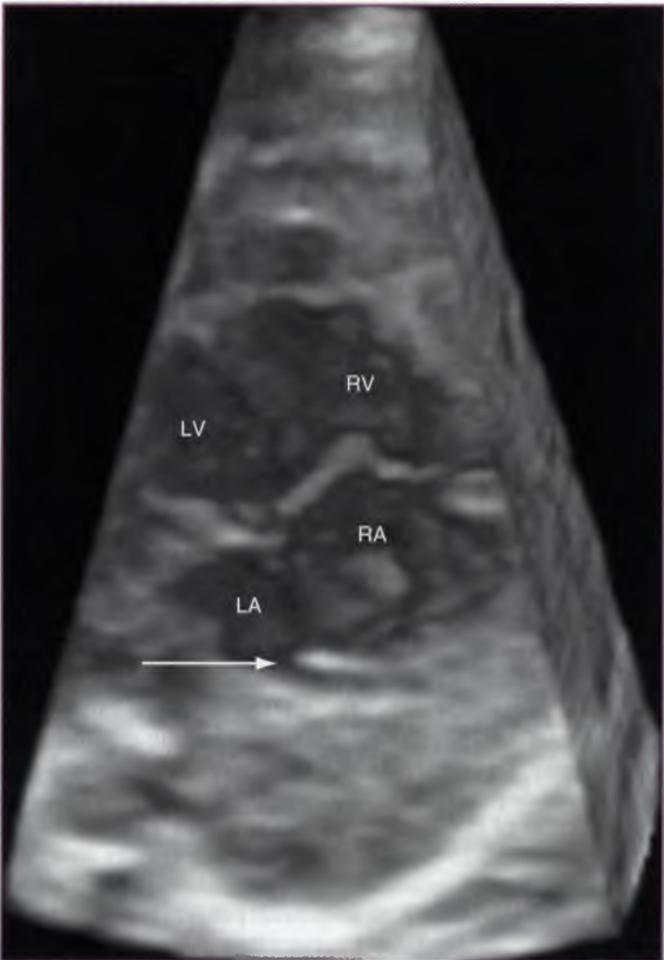

Figure 23-35 Fetal echocardiographic real-time three-dimensional rendered image of mitral atresia with hypoplastic left ventricle. Arrow points to right-sided pulmonary vein draining to left atrium. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

can translate into improved ability to predict the prenatal and postnatal courses of CHD from early in the second trimester (or even earlier).

Technique

Three-dimensional fetal cardiac imaging may be performed with either a reconstructive^{70,71,147-151,163-165,173,174} or a real-time^{69,153,154,157,158,160,166,167} approach. Reconstructive approaches use specialized probes to image the fetal heart as an automated sweep, acquiring a series of parallel planar images over 7 to 15 seconds. The images and their spatial coordinates are subsequently reconstructed into a volume data set or, using gating algorithms to view cardiac motion,^{147,150,163,168} into a series of volume data sets for subsequent display and review. This approach to gating, first described in 1996,^{147,148} has become widely commercialized as spatiotemporal image correlation.^{173,174} Reconstructive approaches have a disadvantage in that they require the fetus and mother to be relatively motionless throughout the acquisition; any fetal or maternal motion distorts the reconstructed volume data set.

In contrast, real-time approaches use specialized probes to image the fetal heart as a volume, acquiring the entire fetal heart (or a portion thereof) virtually instantaneously. The volume data do not require reconstruction, and they do not require gating algorithms (as do reconstructive techniques) to view cardiac motion. Real-time approaches make the most sense for imaging the fetal heart, given their quick acquisition time (2 seconds), relative resistance to artifact derived from random fetal motion, and lack of a need for cardiac gating.^{69,153,157,158,166,167}

However, real-time approaches are unable to acquire large volumes in real time, and they have relatively poor image resolution compared with reconstructive approaches.

After volume data have been acquired, via either reconstructive or real-time techniques, volume data sets may be reviewed interactively, displaying any plane,^{71,149} rendered volume,^{69,71,164,165} or sweep of interest and allowing precise quantitative measurements of ventricular size and function.¹⁶⁸⁻¹⁷⁰ Investigators continue to develop new ways to display volume data,^{89,159,165} in an effort to maximally exploit the potential clinical usefulness of 3D sonographic data (Figs. 23-36 and 23-37).

The Future

Within the next 10 years, 3D imaging of the fetal heart is likely to become far more common. However, without improvements in resolution, speed, and display algorithms, 3D/4D fetal cardiac imaging is unlikely to become the standard of care, either for prenatal screening for CHD or for detailed evaluation of complex CHD. Ultimately, 3D/4D technology may enable automated display of important planes and sweeps, representing a novel approach to computer-aided prenatal detection and diagnosis of CHD.^{72,73} In the meantime, the technique continues to improve the understanding of fetal cardiac anatomy, thereby helping to advance the field of fetal cardiac imaging by helping to educate and train those who participate in the evaluation of fetal cardiac anatomy and function.

Fetal Cardiac Malformations: Diagnosis, Management, and Prognosis

The aim of this section is to help the obstetrician, perinatologist, radiologist, cardiologist, and sonographer to recognize and

diagnose the most common and important forms of fetal cardiac malformations (Box 23-6) and to understand their management and prognosis. The embryology of certain defects is described briefly; more detailed descriptions may be found elsewhere.^{10,11,179-182} Likewise, more thorough descriptions of individual defects, as well as lesion-specific management and prognosis, may be found elsewhere in standard texts.^{10,11,181,182}

Readers should keep in mind that any single heart defect may occur in conjunction with other cardiac defects; often, the most difficult fetal cardiac defect to detect is the second one. Because of the complexity of various forms of fetal structural heart defects, as well as their common association with maternal or extracardiac fetal disease, a multidisciplinary team (e.g., obstetrician, perinatologist, radiologist, pediatric cardiologist, neonatologist, social worker, genetics counselor, nurse, and cardiothoracic surgeon) should jointly manage pregnancies complicated by complex fetal heart disease.

SYSTEMIC VENOUS ANOMALIES*Persistent Umbilical Vein*

Definition and Pathogenesis. Normally, during embryonic development, bilateral umbilical veins course along each side of the fetal liver, carrying oxygenated blood from the placenta to

Figure 23-38 Fetal echocardiographic image of persistent right umbilical vein. The persistent right umbilical vein (RUV) is shown draining to the right atrium (RA). RV, right ventricle.

the fetal heart. The right umbilical vein involutes, along with the left umbilical vein's connection to the heart. The persistent portion of the left umbilical vein becomes the fetal umbilical vein, which carries oxygenated blood to the IVC via the ductus venosus. Rarely, the right umbilical vein fails to involute and appears later in gestation as a persistent umbilical vein.

Key Diagnostic Feature. The fetus is typically found to have a large, unobstructed vein connecting from the cordal insertion site directly to the right atrium (Fig. 23-38).

Associated Abnormalities. A persistent right umbilical vein may be associated with structural cardiac defects, right heart disproportion, extracardiac defects, or aneuploidy, or it may simply be an isolated anomaly, usually well tolerated but occasionally associated with CHF.¹⁸³⁻¹⁸⁵ Commonly, a persistent right umbilical vein is associated with absence of the ductus venosus. The finding of a persistent right umbilical vein should prompt a detailed evaluation for other structural defects, cardiac and extracardiac, as well as an evaluation of cardiac function.¹⁸³⁻¹⁸⁵ Also, patients should be advised of the potential for aneuploidy.

Management and Prognosis. All cases deserve neonatal clinical and echocardiographic follow-up, although if the anomaly is isolated, the infant typically does well, as the persistent umbilical vein involutes after occlusion of the cord at delivery.

Persistent Left-Sided Superior Vena Cava

Definition and Pathogenesis. Normally, during embryogenesis, the right-sided superior vena cava forms from the right anterior cardinal vein and the right common cardinal vein. Abnormal persistence of the left anterior cardinal vein, which normally involutes during embryogenesis, leads to the presence of a persistent LSVC in the fetus and newborn. A persistent LSVC typically drains through the coronary sinus and into the right atrium (Fig. 23-39; see Figs. 23-14 and 23-19). In such cases, a right-sided superior vena cava (normal) may or may

Figure 23-39 Fetal echocardiographic sagittal image of left-sided superior vena cava. The persistent left-sided superior vena cava (arrow) is shown draining into the coronary sinus.

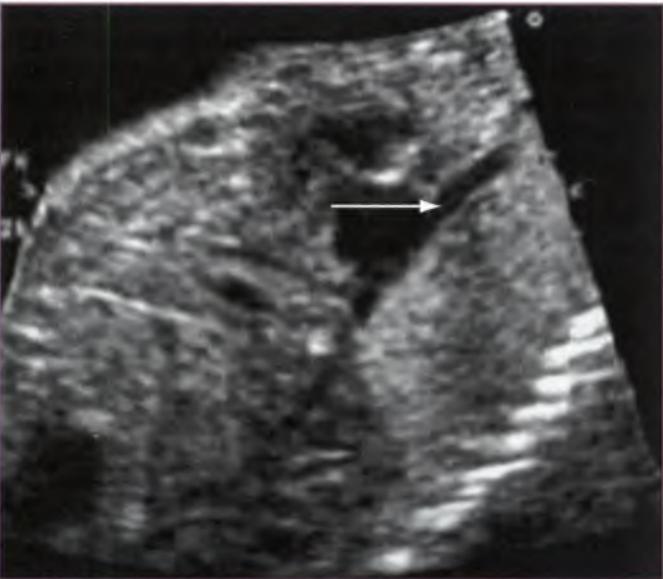

Figure 23-40 Fetal echocardiographic sagittal image of right-sided superior vena cava. The normal right-sided superior vena cava (arrow) is shown draining into the right atrium. Note inferior vena cava draining into right atrium from below.

not be present (Fig. 23-40). A persistent LSVC may be found as an incidental finding in approximately 0.5% of the adult population.

Key Diagnostic Features. Cases of persistent LSVC may be detected in the fetus by visualization of an enlarged coronary sinus (see Figs. 23-14 and 23-15) in the 4CV^{126,127} or by direct visualization of the LSVC (see Figs. 23-39 and 23-16). The finding of a persistent LSVC may be isolated, resulting in physiologic return of deoxygenated blood to the right atrium, albeit via an abnormal pathway. Such cases represent variations of normal and do not require any intervention, either prenatally or after birth.

Figure 23-41 Fetal echocardiographic sagittal image of azygos vein draining into the superior vena cava. In contrast to retrograde flow into either the aorta or the pulmonary artery (pulsatile), venous flow appears continuous during real-time imaging.

Associated Abnormalities. A persistent LSVC may be associated with left-sided obstructive lesions (e.g., coarctation of the aorta, valvar aortic stenosis, HLHS),¹²⁸ so the finding should prompt a detailed fetal echocardiographic evaluation and, probably, neonatal echocardiographic follow-up. In some cases, persistent LSVC is associated with extracardiac abnormalities or heterotaxy.^{129,130,186}

Management and Prognosis. The prognosis is excellent, with no need for medical or surgical intervention, unless the LSVC is associated with other cardiac or extracardiac abnormalities.

Interrupted Inferior Vena Cava

Definition and Pathogenesis. Normally during embryogenesis, the IVC forms from the right supracardinal vein, subcardinal-supracardinal anastomosis, right subcardinal vein, hepatic vein, and hepatic sinusoids. Occasionally, the hepatic portion of the IVC fails to form, resulting in an interruption of the IVC.¹⁸³ In such cases, venous return from the lower half of the fetus drains via a so-called azygos continuation of the IVC. The azygos vein returns deoxygenated blood to the right atrium via the superior vena cava.

Key Diagnostic Features. Interrupted IVC with azygos continuation may be diagnosed prenatally from a transverse view of the abdomen. The cross-sectional image will show, in place of the IVC (in the liver), a cross-sectional image of an azygos vein located posterior to the descending aorta (see Fig. 23-13). Sagittal imaging confirms the absence of a direct connection from the IVC to the right atrium; only the hepatic veins are seen to connect directly. Using both 2D and low-velocity color flow sagittal imaging, the azygos vein can be seen longitudinally, located posterior to the aorta and coursing superiorly and anteriorly (Fig. 23-41) to its termination in the superior vena cava.¹²⁶

Associated Abnormalities. The finding of an interrupted IVC should prompt detailed fetal and neonatal echocardiographic evaluations because of the association of interrupted IVC with polysplenia^{130,183,186} with or without structural heart disease. The diagnosis of polysplenia may be further suggested

by the presence of a midline liver or fetal bradycardia (absent sinus node).

Management and Prognosis. The presence of an IVC with azygos continuation does not, in itself, require any treatment, either prenatally or postnatally. However, given the strong association with polysplenia-related abnormalities, all cases deserve neonatal echocardiographic follow-up.

PULMONARY VENOUS ABNORMALITIES

Definition and Pathogenesis. Normally, during embryonic development, the common pulmonary vein evolves to form not only four separate pulmonary veins but also much of the left atrium itself. Cases of partial anomalous pulmonary venous return (PAPVR), involving one to three veins, or total anomalous pulmonary venous return (TAPVR), involving all four veins, result from abnormalities of this portion of embryogenesis.¹⁷⁹⁻¹⁸³

Key Diagnostic Features. As with abnormalities of systemic venous return, both 2D and color flow imaging play important roles in the diagnosis of anomalous pulmonary venous return. Color flow imaging can facilitate visualization of normal (see Figs. 23-17 and 23-18) or anomalous (Figs. 23-42 and 23-43) pulmonary venous return when the scale has been adjusted for low-velocity flows.

Associated Abnormalities. Anomalous pulmonary venous return frequently occurs in association with other structural cardiac defects, commonly in association with heterotaxy.^{126,130,186}

Partial Anomalous Pulmonary Venous Return

Because even detailed fetal echocardiography may not routinely demonstrate all four pulmonary veins, many cases of PAPVR are overlooked prenatally unless they are associated with other cardiac abnormalities. This section discusses two types of PAPVR that may be detectable before birth because of associated findings. In general, however, PAPVR does not usually

require neonatal intervention and carries an excellent long-term prognosis.

Scimitar Syndrome

Definition and Pathogenesis. Scimitar syndrome represents an unusual form of PAPVR in which the right-sided pulmonary vein (or veins) returns to a vein that descends through the diaphragm before joining the IVC just proximal to the right atrium. Postnatally, this vein may appear radiographically like a sword, or scimitar; hence, the name of the syndrome.

Key Diagnostic Features. Typically, a descending vein may be found draining a portion of the right lung to the IVC. Color flow imaging may demonstrate such anomalously draining right-sided pulmonary venous return. Commonly, a collateral vessel arising from the descending aorta supplies a separate part of the right lung. Further evaluation may demonstrate a collateral vessel arising from the descending aorta and supplying a portion of the right lung. The fetus with scimitar syndrome may have minimal or no right heart disproportion but frequently presents with dextrocardia or mesocardia.¹⁸⁷ Commonly, the syndrome occurs in association with a secundum ASD, which similarly presents a diagnostic challenge prenatally.

Management and Prognosis. Typically, surgery for scimitar syndrome can be postponed beyond the neonatal period or even beyond infancy. Other than having the potential for development of pulmonary hypoplasia, arrhythmias, and infection, most affected infants do well.

Sinus Venosus Atrial Septal Defect

Associated Abnormalities. Sinus venosus ASDs (discussed in more detail later) typically occur in association with anomalous pulmonary venous return of one or both right-sided pulmonary veins to the superior vena cava.

Key Diagnostic Features. Although affected fetuses may not present with right heart disproportion, the ASD high in the atrial septum may be detectable prenatally, with an absent

Figure 23-42 Fetal echocardiographic sagittal image of infradiaphragmatic total anomalous pulmonary venous return. Color flow imaging demonstrates the descending vein (Desc vein) as continuous flow directed inferiorly toward the liver.

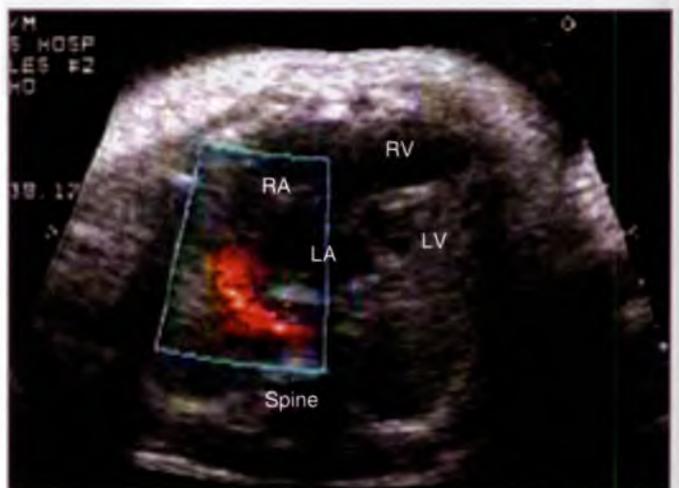

Figure 23-43 Fetal echocardiographic transverse image of supra-cardiac total anomalous pulmonary venous return. Color flow imaging demonstrates the pulmonary confluence draining continuously toward the right atrium (RA). LA, left atrium; LV, left ventricle; RV, right ventricle.

superior rim of the atrial septum. Color flow imaging may demonstrate anomalously draining right-sided pulmonary veins.

Management and Prognosis. Sinus venosus defects do not generally require intervention during infancy; ultimately, however, closure of the defect is required, with baffling of the right-sided pulmonary venous drainage to the left atrium. Prognosis is usually excellent, but some patients have residual pulmonary venous obstruction or atrial arrhythmias.

Total Anomalous Pulmonary Venous Return

Definition and Pathogenesis. TAPVR involves abnormal drainage (and usually abnormal connection) of all four pulmonary veins to anywhere in the heart other than the left atrium.

Key Diagnostic Features. TAPVR can usually be diagnosed prenatally.¹⁸⁸⁻¹⁹⁰ Although right heart disproportion is present in many cases, in others it is minimal or absent.¹⁹⁰ However, affected fetuses do not have the normal infolding of tissue between the left atrial appendage and the left pulmonary vein, and color flow imaging will demonstrate absence of pulmonary venous return to the left atrium. With intracardiac TAPVR, the pulmonary veins drain to the coronary sinus, causing the coronary sinus to be markedly dilated. Infradiaphragmatic TAPVR may manifest as a dilated IVC, because the pulmonary veins turn below the diaphragm and form a common vein before draining into the IVC. The descending vein, which is typically partially obstructed in the liver, should be evaluated with color flow imaging (see Fig. 23-42). Finally, in cases of supracardiac TAPVR, 2D and color flow imaging may demonstrate a large common vein draining cephalad toward a left-sided vertical vein or toward a right-sided superior vena cava (see Fig. 23-43).¹⁸⁹

Associated Abnormalities. Although commonly occurring as an isolated defect, many cases of TAPVR occur in association with other structural cardiac or extracardiac defects.^{130,186}

Management and Prognosis. Obstructed forms of TAPVR (infradiaphragmatic and some cases of supracardiac TAPVR) usually manifest in the immediate neonatal period with respiratory distress and cyanosis. In such instances, prostaglandin is contraindicated, despite the presence of cyanotic CHD, because the result would be exacerbation of pulmonary venous obstruction and edema. Infants with obstructed forms of TAPVR (usually infradiaphragmatic) are at risk for pulmonary hypertension and usually require surgical repair relatively emergently as newborns. For this reason, delivery should be performed at facilities prepared to manage such high-risk cases. Obstructed TAPVR carries a guarded prognosis, but infants who do well with the initial surgical intervention may have a good long-term prognosis in the absence of significant pulmonary hypertension. Nonobstructed forms of TAPVR usually require repair during infancy, although typically not emergently; occasionally, repair may be postponed for several months.

SEPTAL DEFECTS

This section discusses ASD and VSD, two of the most common forms of CHD. Prenatally, the aortic isthmus normally shunts flow between the right and left heart distributions. The foramen ovale allows oxygenated blood flow to stream from the right atrium to the left atrium, and the ductus arteriosus directs the majority of right ventricular output toward the fetal body, away from the high-resistance pulmonary circuit. Postnatally, the ductus arteriosus closes via constriction, and the foramen ovale

closes via pressure-related closure of a one-way valve or flap door. Thus, the normal fetus has a right-to-left atrial shunt, as well as a patent ductus arteriosus, but never a communication between right and left ventricles.

Atrial Septal Defect

Secundum Atrial Septal Defect

Definition and Pathogenesis. A secundum ASD represents a deficiency of the middle portion of the atrial septum, in the same general location as the normal foramen ovale. A secundum ASD results, embryologically, from either inadequate development of the septum secundum or excessive resorption of the septum primum. Unlike most forms of CHD, the secundum ASD occurs far more commonly in females than in males.

Key Diagnostic Features. Prenatally differentiating a normal foramen ovale from a secundum ASD can be challenging, if not impossible. Even postnatally, this distinction can be difficult to make. During the second and third trimesters, the flap of the foramen ovale (septum primum) becomes progressively more aneurysmal and more deviated into the left atrium. In some cases, the flap appears more aneurysmal than normal for gestational age, or the foramen itself appears to occupy a greater proportion of the atrial septum than normal. In such cases, a detailed evaluation for associated cardiac abnormalities, such as right heart obstruction in the case of excessive deviation, should be performed. However, no convincing association has yet been demonstrated between an abnormal prenatal appearance of the foramen ovale and the postnatal diagnosis of a true secundum ASD.

Management and Prognosis. Fortunately, isolated ASDs, which are probably more common than currently suspected, usually close spontaneously and rarely require intervention during infancy. If the foramen ovale does appear abnormal prenatally, particularly in association with other cardiac abnormalities or other risk factors for fetal heart disease, elective postnatal echocardiography would be prudent.

Sinus Venosus Atrial Septal Defect

Definition and Pathogenesis. Sinus venosus ASDs occur far less commonly than secundum ASDs, and they typically occur in conjunction with anomalous return of the right-sided pulmonary veins to the superior vena cava or right atrium.

Key Diagnostic Features. Unlike secundum ASDs, sinus venosus defects may be readily diagnosed prenatally by demonstrating absence of the superior rim of the atrial septum. Moreover, the right-sided pulmonary veins can occasionally be demonstrated to drain anomalously to the superior vena cava on 2D and color flow imaging.

Management and Prognosis. Like secundum ASDs, these defects rarely require any neonatal intervention. Unlike secundum ASDs, however, sinus venosus defects never close spontaneously, and they typically require surgical repair electively during the first 5 years of life. Long-term prognosis is excellent.

Ostium Primum Atrial Septal Defect

Definition and Pathogenesis. The most important ASDs to detect prenatally are the ostium primum ASDs, which are common, always require surgery, and are frequently associated with trisomy 21. Ostium primum defects result from failure of fusion of the septum primum with the endocardial cushions. These defects, also known as partial atrioventricular canal (AVC) defects, commonly occur in conjunction with a cleft mitral valve.

Key Diagnostic Features. Ostium primum ASDs can and should be readily detected, even on a standard fetal ultrasound study. The most reliable and consistent prenatal sonographic finding is absence of the lower, inferior portion of the atrial septum. Care should be taken to avoid false-positive diagnoses, because posterior/inferior angulation of the probe from the 4CV opens up a longitudinal view of the coronary sinus (see Figs. 23-14 and 23-19), which may appear similar to an ostium primum ASD. The distinction may be made simply with anterior/superior angulation of the probe: A true ostium primum ASD is evident on a true 4CV, whereas the coronary sinus should mimic this defect only with posterior/inferior angulation.

Associated Abnormalities. The diagnosis of an ostium primum ASD carries prenatal and postnatal implications. First, these defects carry an increased risk for trisomy 21,^{25,32} so karyotype analysis may be indicated. Second, ostium primum ASDs commonly occur in conjunction with other cardiac and extra-cardiac abnormalities, so detailed prenatal evaluation should be performed.

Management and Prognosis. Isolated defects generally do not require neonatal intervention, but they uniformly require surgical repair, usually during the first 5 years of life. Long-term prognosis is usually excellent, although abnormalities of the mitral valve can rarely persist and may require additional medical or surgical attention.

Ventricular Septal Defect

Ventricular septal defects are probably the most common form of CHD, excluding patent ductus arteriosus and bicommissural aortic valve. The size and type (location) of a VSD and its associated cardiac abnormalities, if any, as well as any extracardiac structural, or genetic or syndromic, abnormalities, dictate both the prenatal and postnatal clinical implications and the approach to, and feasibility of, prenatal detection.

Muscular Ventricular Septal Defect

Definition and Pathogenesis. Fortuitously, the most common forms of VSD (muscular and membranous) are known to close spontaneously, either prenatally or postnatally.¹⁶ Muscular VSDs may be visualized on the 4CV (Fig. 23-44) or short-axis view (Fig. 23-45). By definition, muscular VSDs do not reside immediately beneath the mitral and tricuspid valves; such inlet VSDs occur in conjunction with abnormalities of the mitral and tricuspid valves and represent an AVC type of VSD. Inlet defects, although detectable on the 4CV, do not close spontaneously and usually require surgery; they are discussed in the next section.

Key Diagnostic Features. Muscular VSDs may be demonstrated with 2D imaging if they are moderate or large, but small ones may be difficult to detect without color flow imaging. Color flow imaging helps confirm the diagnosis, but spectral Doppler evaluation should also be performed. Muscular VSDs, like membranous VSDs, usually shunt predominantly left to right prenatally (see Figs. 23-44 and 23-45); predominant right-to-left shunting should prompt further evaluation for right-sided obstructive lesions.

Associated Abnormalities. The finding of even a small muscular VSD appears to increase the risk for additional cardiac abnormalities. Whether the presence of a single, isolated small muscular VSD increases the risk for a genetic syndrome remains controversial.

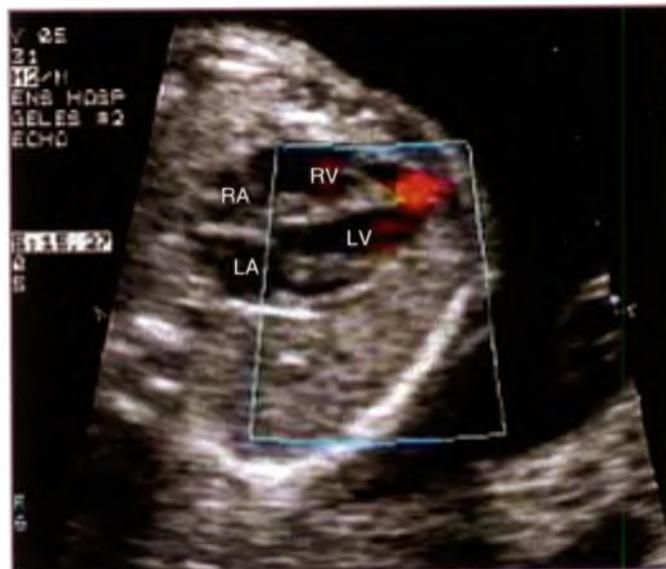

Figure 23-44 Fetal echocardiographic image of the four-chamber view. Color flow imaging demonstrates a small apical ventricular septal defect with left-to-right shunting. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Figure 23-45 Fetal echocardiographic image of apical short-axis view. Color flow imaging demonstrates a moderate-sized mid-muscular ventricular septal defect with left-to-right shunting. LV, left ventricle; RV, right ventricle.

Management and Prognosis. Small or moderate muscular defects may close prenatally or within a few years after delivery. Large muscular defects manifest in infancy with tachypnea and failure to thrive and may require surgical closure during the first year of life. Because muscular defects occur in a heavily trabeculated portion of the ventricular septum, effective surgical closure can be difficult to achieve. Alternative approaches include pulmonary artery banding, followed by removal of the band once the defect has decreased in size; rarely, such VSDs

may be closed percutaneously with a device. The long-term prognosis is usually excellent unless delayed surgery has allowed the development of pulmonary vascular disease.

Membranous Ventricular Septal Defect

Definition and Pathogenesis. Membranous VSDs occur in the membranous and perimembranous region of the ventricular septum.

Key Diagnostic Features. Unlike muscular VSDs, membranous VSDs cannot be visualized on the 4CV. The membranous septum resides anteriorly a small distance beneath the aortic valve. A left ventricular long-axis view of the LVOT is the ideal approach for visualizing a membranous VSD (Fig. 23-46). Moreover, because false-positive dropout through the thin (i.e., membranous) septum occurs commonly when the ultrasound beam is oriented parallel with the septum, the diagnosis can best be confirmed with the ultrasound beam perpendicular to the ventricular septum. Small defects may be missed, although color flow imaging and spectral Doppler evaluation are helpful for both prenatal detection and confirmation.

Associated Abnormalities. Membranous VSDs commonly occur in isolation but may be found in association with other structural cardiac or extracardiac defects.

Management and Prognosis. Because of the proximity of the membranous septum to the aortic valve, membranous VSDs may cause the gradual development of aortic regurgitation, with or without prolapse of one or more aortic cusps into the defect. Although most membranous VSDs close spontaneously, larger defects may require surgical closure within the first year in infants with failure to thrive or progressive aortic regurgitation. Long-term prognosis is usually excellent unless irreversible damage to the aortic valve has occurred. In such cases, aortic valve repair or even replacement may be necessary.

Subarterial Ventricular Septal Defect

Definition and Pathogenesis. Subarterial defects may reside predominantly under the aortic valve (subaortic) or under the pulmonary valve (subpulmonary). Unlike membranous VSDs, which occur close to but not immediately beneath the aortic

valve, subarterial defects occur immediately beneath one or both semilunar valves.

Key Diagnostic Features. Subarterial VSDs cannot be visualized on the 4CV; prenatal detection requires meticulous evaluation of the outflow tracts.

Associated Abnormalities. Subarterial VSDs commonly occur in conjunction with other cardiac abnormalities.

Management and Prognosis. Subarterial VSDs never close spontaneously. These defects almost invariably require surgical correction within the first year of life. The prognosis, although generally good, relates in part to associated cardiac abnormalities and to any residual aortic or pulmonary pathology.

Malalignment Ventricular Septal Defect

Definition and Pathogenesis. Malalignment VSDs occur when the upper (conal or infundibular) portion of the ventricular septum separates from the rest of the septum and deviates either anteriorly into the RVOT or posteriorly into the LVOT. Malalignment VSDs secondary to anterior deviation of the conal septum generate RVOT obstruction (subvalvar and valvar pulmonary stenosis and pulmonary artery hypoplasia); TOF is the most common manifestation of such a defect (Figs. 23-47 and 23-48). In contrast, posterior malalignment of the conal septum generates a malalignment VSD in association with LVOT obstruction (e.g., aortic stenosis, bicommissural aortic valve, aortic arch hypoplasia, coarctation of the aorta) (Figs. 23-49 and 23-50).

Key Diagnostic Features. Like subarterial VSDs, malalignment VSDs may appear normal on 4CV, but both the VSD and its associated outflow tract abnormalities should be seen with outflow tract imaging.

Management and Prognosis. Severe malalignment in either direction may generate severe enough outflow tract obstruction to require maintenance of ductal patency (with prostaglandin) after delivery. Management and prognosis depend on the type and severity of outflow tract obstruction.

Figure 23-46 Fetal echocardiographic image of membranous ventricular septal defect seen in left ventricular long-axis view. Ao, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.

Figure 23-47 Fetal echocardiographic image of tetralogy of Fallot seen in left ventricular long-axis view. The aorta (Ao) overrides the crest of the ventricular septum. LA, left atrium; LV, left ventricle; RV, right ventricle.

Figure 23-48 Fetal echocardiographic image of tetralogy of Fallot seen in apical short-axis view. The conal septum (asterisk) deviates anteriorly into the right ventricular outflow tract, causing subvalvar pulmonary stenosis, aortic override, and an anterior-malalignment ventricular septal defect. Note that the pulmonary valve appears smaller than the aortic valve. Ao, aorta; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Figure 23-49 Fetal echocardiographic image of transposition with subvalvar and valvar pulmonary stenosis seen in left ventricular long-axis view. The conal septum deviates posteriorly into the left ventricular outflow tract, causing subvalvar pulmonary stenosis and a posterior malalignment ventricular septal defect. With normally related great arteries, posterior malalignment of the conal septum would cause aortic rather than pulmonary obstruction. LV, left ventricle; MPA, main pulmonary artery; RV, right ventricle.

Figure 23-50 Fetal left ventricular long-axis view demonstrating posterior malalignment of the conal septum into the left ventricular outflow tract. Note the crowding beneath the aortic valve. This finding commonly occurs in association with arch obstruction, either coarctation of the aorta or interrupted aortic arch.

ATRIOVENTRICULAR CANAL DEFECT

Definition and Pathogenesis. Normally, during embryonic development, the septum primum and the endocardial cushions fuse together. Abnormal development of these structures results in several forms of AVC defect, all of which should be detected with standard fetal screening ultrasound evaluations as well as with detailed fetal echocardiography.

Associated Abnormalities. Most forms of atrioventricular canal have relatively high associations with trisomy 21^{25,32,191} or other cardiac abnormalities.¹⁹²

Management and Prognosis. All forms of AVC defects ultimately require surgical intervention. The prognosis is generally good but depends on the associated cardiac and extracardiac abnormalities,¹⁹³ as well as on postoperative mitral, tricuspid, and ventricular function.

Partial Atrioventricular Canal Defect

Definition and Pathogenesis. In partial AVC defects, the septum primum fails to fuse with the endocardial cushions. As a result, the fetal heart develops an ostium primum ASD and, typically, a cleft in the mitral valve (with some degree of mitral regurgitation).

Key Diagnostic Features. In part because of this defect's close association with trisomy 21 or heterotaxy,^{25,32,192} great care should be taken not to miss a partial AVC defect on routine screening ultrasonography. Partial AVC defects may be readily detected in the 4CV by the conspicuous absence of the septum primum (the lowest, most inferior portion of the atrial septum).¹⁹⁴ Moreover, the absence of an atrioventricular septum results in absence of the normal apical displacement of the septal leaflet of the tricuspid valve; instead, the septal leaflets of the mitral and tricuspid valves insert onto the ventricular septum at the same level. Care should be taken not to confuse this defect with a dilated coronary sinus (usually secondary to a persistent LSVC), which would be seen in a plane immediately posterior/inferior to the 4CV (see Figs. 23-14 and 23-19).¹²⁷

True AVC defects will be noted with anterior/superior angulation of the probe from the level of the coronary sinus into a true 4CV.

Associated Abnormalities. Many patients have trisomy 21³² or other cardiac disease (heterotaxy).¹⁹²

Management and Prognosis. Partial AVC defects look clinically similar to secundum ASDs, usually with a heart murmur in an asymptomatic child between 2 months and 2 years of age. The cleft in the mitral valve typically does not generate signs or symptoms unless it is associated with more severe degrees of mitral regurgitation. The long-term prognosis after surgical closure during the first several years of life is usually excellent, unless significant mitral valve pathology persists.

Complete Atrioventricular Canal Defect

Definition and Pathogenesis. In complete AVC defects, the endocardial cushions fail to fuse, and the septum primum fails to fuse with the endocardial cushions. As a result, the fetal heart has not only an ostium primum ASD and cleft mitral valve but also a large inlet VSD (contiguous with the ostium primum ASD) and a single, common atrioventricular valve.

Key Diagnostic Features. This type of AVC defect should be readily detected with a routine 4CV (Figs. 23-51 and 23-52). Beyond the diagnosis of complete AVC defect, detailed fetal echocardiographic evaluation should include assessment of atrioventricular valvar regurgitation using color flow imaging and close attention to the relative development of both ventricles and possible outflow tract obstruction.

Associated Abnormalities. Although isolated forms of complete AVC defects carry an exceptionally high association with trisomy 21,^{25,32} complete AVC defects in association with other cardiac abnormalities carry a high association with heterotaxy syndrome.^{192,193} Unbalanced forms of AVC, in which the right or left side of the heart is underdeveloped, tend to have a much weaker association with trisomy 21 than do balanced forms of AVC.

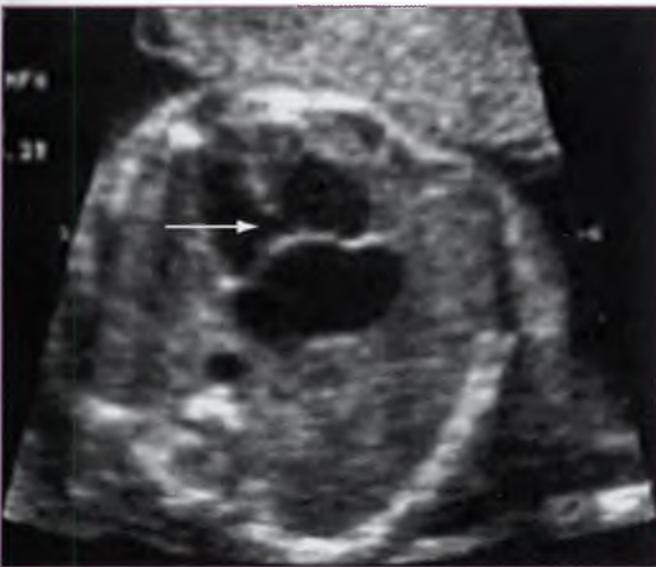

Figure 23-51 Fetal echocardiographic image (four-chamber view) demonstrating a balanced complete atrioventricular canal defect. During systole, the common atrioventricular valve is closed, and the large atrial and ventricular (arrow) defects are readily apparent. Note the absence of the septum primum.

Management and Prognosis. When complete AVC defects occur with well-balanced right and left ventricles (so-called balanced complete AVC), corrective surgery may be offered at 3 to 6 months of age. Such patients usually have an excellent long-term prognosis in the absence of severe residual atrioventricular valve regurgitation.¹⁹⁵ On the other hand, the fetus with a hypoplastic right ventricle (left ventricle–dominant AVC) (Fig. 23-53) or a hypoplastic left ventricle (right

Figure 23-52 Fetal echocardiographic image (four-chamber view) demonstrating a balanced complete atrioventricular canal defect. During diastole, the common atrioventricular valve is open, and the large atrial and ventricular defects (in continuity) are readily apparent. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Figure 23-53 Fetal echocardiographic image (four-chamber view) demonstrating an unbalanced, left ventricle–dominant atrioventricular canal. Note the large primum atrial septal defect and large inlet ventricular septal defect, as well as the hypoplastic right ventricle (RV). LA, left atrium; LV, left ventricle; RA, right atrium.

ventricle–dominant AVC) is likely to require single-ventricle palliation, meaning three palliative surgical procedures within the first 2 to 3 years of life. Some of these patients may undergo early pulmonary artery banding (during the first month after delivery) to provide a controlled source of pulmonary blood flow for the first 6 months and to avoid the development of pulmonary vascular disease. Because single-ventricle palliation involves rerouting of the systemic venous return through the lungs without the benefit of a subpulmonary ventricle, elevated pulmonary vascular resistance may be considered a relative contraindication (or at least a risk factor) for subsequent palliative procedures (i.e., Glenn and Fontan procedures, which redirect, respectively, the superior vena cava or the IVC directly to the right pulmonary artery). In the best of cases, the patient with an unbalanced complete AVC defect faces a much more guarded, palliated long-term prognosis than the patient with a balanced complete AVC defect. Therefore, making such a distinction in a fetus is of great importance.

Transitional Atrioventricular Canal Defect

Definition and Pathogenesis. Transitional AVC defects have embryologic origins similar to partial or complete forms of AVC. However, unlike the VSD in complete AVC, the VSD in transitional AVC defects is small and restrictive to pressure, thus helping to protect the pulmonary arteries postnatally from the development of pulmonary vascular disease.

Key Diagnostic Features. A transitional AVC defect should be recognized readily from the 4CV. Affected fetuses have an ostium primum defect and, with absence of the atrioventricular septum, the mitral and tricuspid valves insert onto the crest of the ventricular septum at the same level. The mitral valve is frequently cleft, and some degree of mitral regurgitation is visualized with color flow imaging. In contrast to a complete AVC defect, transitional AVC defects may have two relatively well formed mitral and tricuspid valves, and the inlet VSD is only small to moderate in size, largely occluded by mitral and tricuspid valve tissue (Fig. 23-54).

Figure 23-54 Fetal echocardiographic image of a transitional form of atrioventricular canal during diastole. Note the large primum atrial septal defect and asymmetry to the right- and left-sided atrioventricular valve apparatus.

Management and Prognosis. Transitional AVC defects, when balanced and not associated with other cardiac defects, typically require a single surgical procedure between 6 months and 5 years of age, and they generally carry a good long-term prognosis.

EBSTEIN ANOMALY OF THE TRICUSPID VALVE AND TRICUSPID VALVE DYSPLASIA

Both fetal Ebstein anomaly of the tricuspid valve and tricuspid valve dysplasia carry a wide spectrum of potential outcomes, depending on severity.¹⁹⁶⁻¹⁹⁸ Fortunately, the more severe cases are those that should be most readily detected on a standard 4CV. Although Ebstein anomaly and tricuspid valve dysplasia are occasionally associated with fetal exposure to maternal lithium, most cases occur in pregnancies not identified as high risk.

Definition and Pathogenesis. Tricuspid valve dysplasia refers to thickening and distortion of the tricuspid valve leaflets and supportive apparatus, with the primary pathophysiologic manifestation being tricuspid regurgitation. The more severe the tricuspid regurgitation, the more dilated the right atrium and right ventricle will be, which leads to the more likely development of pulmonary valve stenosis or atresia (related to diminished antegrade flow), and then the more likely development of hydrops or pulmonary hypoplasia or both (related to elevated right atrial pressure and right-sided heart enlargement). Sharing similar pathophysiology, Ebstein anomaly of the tricuspid valve may be considered a subset of tricuspid valve dysplasia. In Ebstein anomaly, the dysplastic tricuspid valve is partially fused against the ventricular septum, causing the coaptation point to be apically displaced in the right ventricle. Both disorders carry an association with episodic SVT and Wolff-Parkinson-White (WPW) syndrome.

Key Diagnostic Features. Both Ebstein anomaly and tricuspid valve dysplasia can be visualized on the 4CV, with enlargement of the right side of the heart (particularly the right atrium), dysplasia of the tricuspid valve (Fig. 23-55), and apical

Figure 23-55 Fetal echocardiographic image (four-chamber view) demonstrating tricuspid valve dysplasia. Note absence of apical displacement of the septal insertion site of the tricuspid valve. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

displacement of the tricuspid valve coaptation point in the case of Ebstein anomaly (Fig. 23-56). Color flow imaging is useful to demonstrate the degree of tricuspid regurgitation (Fig. 23-57), although such information should be suspected from the degree of right atrial enlargement. In cases of severe tricuspid regurgitation, Ebstein anomaly and tricuspid valve dysplasia commonly have some degree of pulmonary valve stenosis, or even atresia, along with hypoplasia of the main and branch pulmonary arteries; such findings should be evident on evaluation of the outflow tracts.

Figure 23-56 Fetal echocardiographic image (four-chamber view) demonstrating Ebstein anomaly of the tricuspid valve. Note apical displacement of the septal insertion site of the tricuspid valve (TV). Compare with Figure 23-55. LV, left ventricle; RA, right atrium; RV, right ventricle.

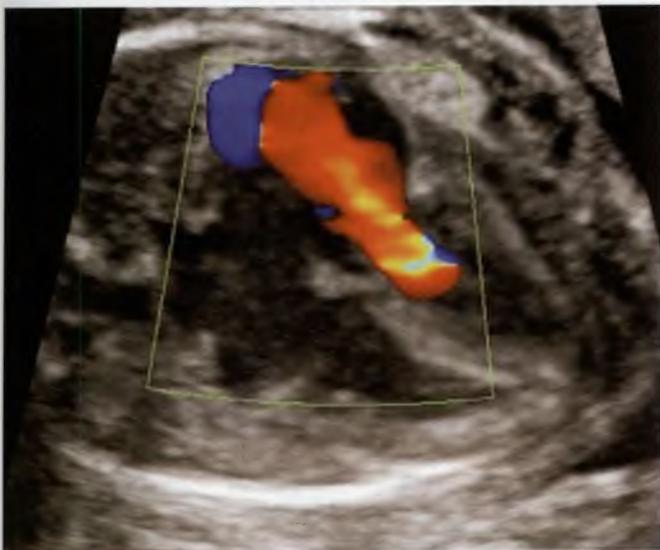

Figure 23-57 Four-chamber view demonstrating fetal Ebstein anomaly of the tricuspid valve. The color flow jet demonstrates extensive tricuspid regurgitation, arising at a coaptation point that appears mildly displaced apically. In this case, the septal leaflet of the tricuspid valve is only mildly adherent to the ventricular septum, raising the possibility of a diagnosis of tricuspid valve dysplasia rather than Ebstein anomaly. This distinction generally lacks therapeutic or prognostic relevance.

Associated Abnormalities. The risk for associated aneuploidy is probably mildly increased over that in the general fetal population. Ebstein anomaly represents a common finding in the rare setting of congenitally corrected transposition (discussed later).

Management and Prognosis. The overriding determinants of short- and long-term survival are the degree of fetal heart failure or hydrops, the degree of pulmonary hypoplasia, and the degree of left ventricular dysfunction. Progressive fetal CHF (related to tricuspid regurgitation, SVT, and ventricular dysfunction) puts the fetus at risk for hydrops and fetal demise. Newborns with a history of hydrops prenatally may present with diffuse edema or anasarca, and they face significant neonatal morbidity and mortality. Pulmonary hypoplasia, related to marked cardiomegaly, particularly early in gestation, represents the other primary determinant of neonatal survival and may not always be accurately predicted with prenatal assessments. Fetuses with moderate or severe forms of Ebstein anomaly or tricuspid valve dysplasia should be delivered at centers that can provide optimal medical and surgical care for high-risk neonates.

TRICUSPID ATRESIA

Definition and Pathogenesis. Tricuspid atresia represents the most basic form of single ventricle and generally carries the best long-term prognosis among single-ventricle disorders. In tricuspid atresia, the tricuspid valve either is not formed or simply does not open. As a result, all flow entering the right atrium must cross the foramen ovale into the left atrium and, from there, into the left ventricle. From the left ventricle, some portion of the blood exits via the aortic valve, and some passes through a VSD (usually present with tricuspid atresia) and into the pulmonary artery. Because flow into the right ventricle and pulmonary artery must come via the VSD, the right ventricle and pulmonary artery generally appear hypoplastic, and the pulmonary valve is usually stenotic, if not atretic. However, when tricuspid atresia occurs in conjunction with transposition of the great arteries (TGA), the pulmonary valve and pulmonary artery (in this case arising from the left ventricle) are usually well formed, whereas the aortic valve may be stenotic, with a hypoplastic aortic arch and possible coarctation.

Key Diagnostic Features. In the fetus, tricuspid atresia shows up in an abnormal 4CV (Fig. 23-58) with an abnormal (or absent) tricuspid valve and hypoplastic right ventricle.¹⁹⁹ Rarely, color flow imaging demonstrates the foramen ovale to be restrictive to flow. The outflow tracts also demand close attention, given the close association of tricuspid atresia with TGA or with underdevelopment of the great artery arising from the right ventricle, or both. The degree of pulmonary stenosis (in normally related great arteries) or aortic stenosis (in TGA) is critically important in the assessment of likelihood for ductal dependence after delivery.

Management and Prognosis. After delivery, most affected babies appear cyanotic, but ductal dependency is determined by the amount of pulmonary blood flow (in normally related great arteries) or by the presence of aortic stenosis, coarctation, or inadequate mixing (in TGA). Infants with tricuspid atresia ultimately require palliation with a Glenn procedure (anastomosis of the cephalic end of the superior vena cava to the right pulmonary artery, usually at about 6 months of age) followed by a Fontan procedure (anastomosis of the IVC directly to the

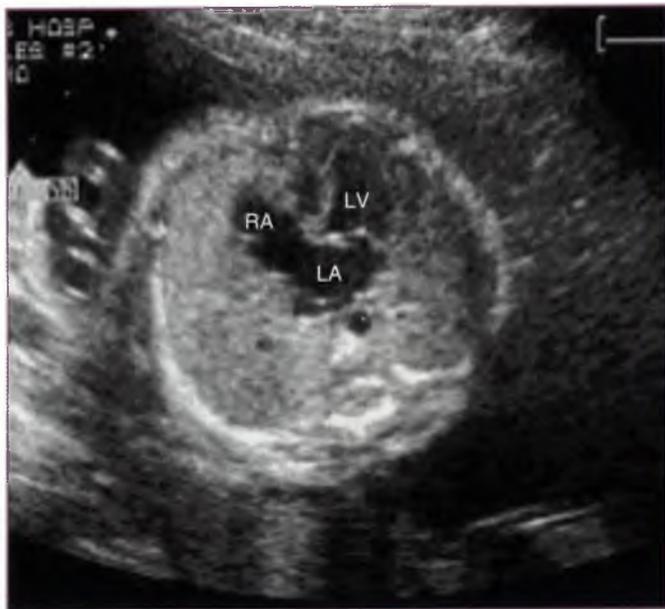

Figure 23-58 Fetal echocardiographic image (four-chamber view) demonstrating tricuspid atresia. Note the hypoplastic right ventricle, atretic and membranous tricuspid valve, and bowing of the atrial septum laterally into the left atrium. LA, left atrium; LV, left ventricle; RA, right atrium.

right pulmonary artery with interposition graft, usually at 2 to 3 years of age). Whether a neonatal shunt or arch repair is needed depends on the details of the anatomy and pathophysiology. Long-term prognosis for tricuspid atresia tends to be better than for other forms of single-ventricle disease, but the child will still have increasing risks for heart failure and arrhythmias and possible need for cardiac transplantation in later decades.

PULMONARY ATRESIA WITH INTACT VENTRICULAR SEPTUM

Definition and Pathogenesis. In pulmonary atresia with intact ventricular septum, the RVOT ends blindly (pulmonary atresia). As a result, during fetal life, the right side of the heart must direct its share of cardiac output entirely through the foramen ovale. In the presence of a competent tricuspid valve (which is typical), the right ventricle hypertrophies in response to the high pressure generated by the absence of egress. This lesion results, in some cases, from prenatal progression of pulmonary stenosis to pulmonary atresia.¹⁸ The right ventricle, along with its tricuspid valve, typically develops some degree of hypoplasia. Those fetuses with markedly elevated right ventricular pressure may develop sinusoidal connections between the right ventricular cavity and the coronary arteries. Such sinusoids may occur in association with significant coronary artery stenoses, placing these patients at risk for acute myocardial infarction.

Key Diagnostic Features. Pulmonary atresia with intact ventricular septum usually manifests in fetal life with an abnormal 4CV (Figs. 23-59 and 23-60), including an abnormal-appearing tricuspid valve and a hypoplastic, hypertrophied, poorly functioning right ventricle. Occasionally, the degree of

Figure 23-59 Fetal echocardiographic image (four-chamber view) demonstrating pulmonary atresia with intact ventricular septum. Note similarity to tricuspid atresia (see Fig. 23-61), but with a more normal appearance to the tricuspid valve. LA, left atrium; LV, left ventricle; RA, right atrium.

Figure 23-60 Fetal echocardiographic image (four-chamber view) of fetus with pulmonary atresia and an intact ventricular septum. Color flow imaging demonstrates absence of prograde flow across the tricuspid valve during diastole and right-to-left flow across the atrial septum. LA, left atrium; LV, left ventricle; RA, right atrium.

tricuspid valve and right ventricular hypoplasia is mild enough to be missed on a cursory 4CV; other cases may mimic tricuspid atresia (compare Figs. 23-58 and 23-59). Color flow imaging should be used to evaluate the tricuspid valve for evidence of tricuspid regurgitation. Color flow imaging may also detect significant sinusoids in the ventricular septum or the right ventricular free wall, or both. Careful evaluation of the 4CV in real time should almost always detect some abnormality in size, structure, or function of the tricuspid valve or right ventricle. Imaging of the outflow tracts should invariably demonstrate the pulmonary valve to be atretic, with no prograde flow from right ventricle to pulmonary artery. Detailed cardiac imaging should include evaluation of the continuity and size of the main and branch pulmonary arteries, supplied through the ductus arteriosus in a retrograde manner.

Management and Prognosis. After delivery, babies with this lesion require prostaglandin to maintain patency of the ductus arteriosus for pulmonary blood flow. Neonatal surgery is always necessary; it usually includes placement of a shunt, and sometimes reconstruction of the RVOT. Long-term prognosis varies from an excellent two-ventricle repair to single-ventricle palliation, and those patients with coronary artery abnormalities face additional short- and long-term risks for myocardial infarction. Some fetal echocardiographic parameters, including tricuspid valve size and the presence of tricuspid regurgitation, can help predict outcome.^{200,201}

HYPOPLASTIC LEFT HEART SYNDROME

Definition and Pathogenesis. One of the most common and most feared cardiac diagnoses, HLHS (Video 23-9) represents a heterogeneous constellation of various forms of CHD, the result of which in the newborn infant is a left heart with a surgically resistant inability to sustain systemic cardiac output. Some forms of multiple left-sided obstructive lesions (e.g., Shone syndrome) may be corrected with surgical procedures addressing the left ventricular inflow tract, outflow tract, and aortic arch; these cases do not qualify as HLHS. Although this distinction is of tremendous clinical importance, it is sometimes subtle, even postnatally. An excellent review of the diagnosis of, management of, and prognosis for patients with HLHS was recently published.²⁰²

Key Diagnostic Features. This section discusses the most common and classic form of HLHS, mitral and aortic atresia, with the caution that other forms of HLHS may differ in their prenatal appearance and postnatal course. Mitral or aortic stenosis, for example, may manifest with a relatively well formed left ventricle at mid-gestation but with HLHS at term (Fig. 23-61).^{18,96,203} In fetuses with mitral and aortic atresia, there is a markedly abnormal 4CV at mid-gestation, with no inflow into the left ventricle (effectively no mitral valve) and a severely hypoplastic left ventricle (Fig. 23-62; see Fig. 23-35). The foramen ovale needs close prenatal evaluation with 2D and color flow imaging, because restriction to (left-to-right) flow (Fig. 23-63) may lead to pulmonary venous congestion (Fig. 23-64) and irreversible pulmonary vascular disease.²⁰⁴ Such restriction to flow occasionally does not develop until late in the third trimester. The aortic arch fills from the ductus arteriosus in a retrograde manner (Fig. 23-65) and may be visualized with both 2D and color flow imaging. Tricuspid valve and right ventricular structure and function also require close evaluation, using both 2D and color flow imaging

Figure 23-61 Four-chamber view of the fetal heart demonstrating mitral stenosis and hypoplastic left ventricle, strongly suggestive of hypoplastic left heart syndrome. The appearance of the mitral valve and the left ventricle suggest the presence of some forward flow across the mitral valve, but this cannot be determined from this isolated image.

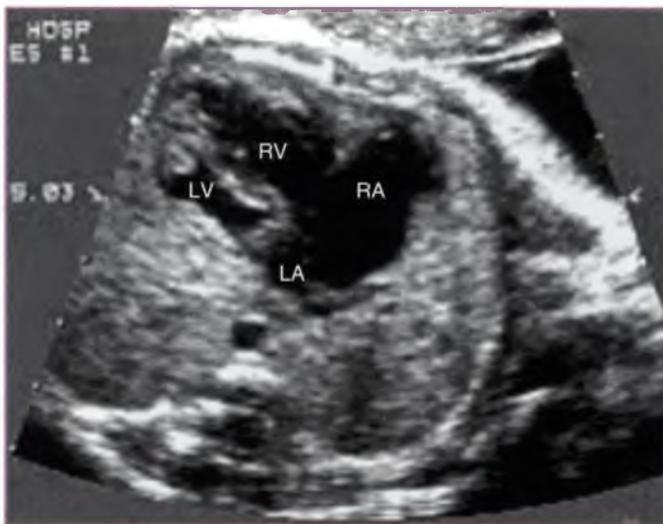

Figure 23-62 Fetal echocardiographic image (four-chamber view) demonstrating hypoplastic left heart syndrome with mitral atresia and ventricular septal defect. The ventricular septal defect, although not visualized, may be inferred from the presence of a moderately well formed left ventricle (LV) with mitral atresia. LA, left atrium; RA, right atrium; RV, right ventricle.

to assess for tricuspid regurgitation and right ventricular dysfunction.

Associated Abnormalities. Most cases of HLHS carry an increased risk for congenital or acquired central nervous system abnormalities,^{48,205} as well as an increased risk for aneuploidy.²⁰⁶

Management and Prognosis. The fetus with HLHS should be delivered at a tertiary care center experienced with complex CHD in newborns. Some fetuses with HLHS and a restrictive

Figure 23-63 Four-chamber view of the fetal heart demonstrating a restrictive foramen ovale in the presence of hypoplastic left heart syndrome (HLHS). The atrial septum appears mildly thickened and bows into the right atrium. Restriction at the level of the foramen ovale, a negative prognostic indicator for the fetus with HLHS, typically requires dynamic imaging with spectral and color flow Doppler of the atrial septum (with or without the pulmonary veins) to confirm.

Figure 23-64 Fetal echocardiographic image (four-chamber view) demonstrating hypoplastic left heart syndrome with restrictive foramen ovale. The left atrium and pulmonary veins appear dilated in response to left atrial hypertension (lack of egress of pulmonary venous return from left atrium). HLV, hypoplastic left ventricle; LA, left atrium; RA, right atrium; RV, right ventricle.

foramen ovale may be candidates for percutaneous enlargement of the foramen ovale during the second trimester, with the hope of avoiding the development of pulmonary vascular disease and improving long-term survival.²⁰⁴ All newborns with HLHS are, by definition, ductal dependent for systemic blood flow, so prostaglandin infusion should be initiated. Supplemental

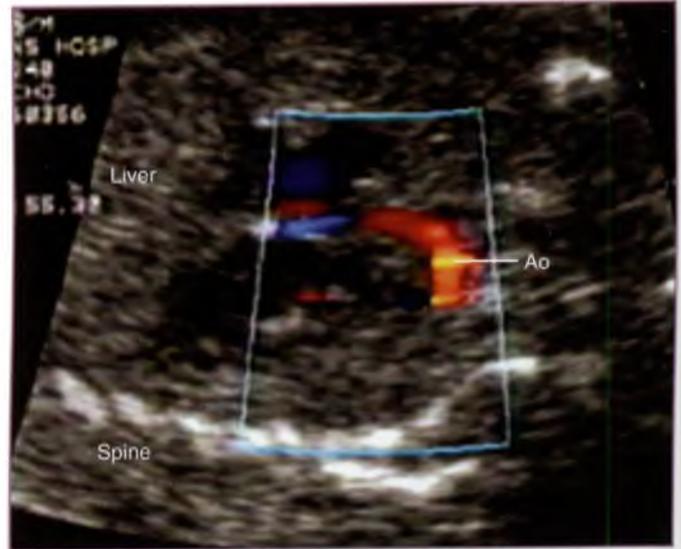

Figure 23-65 Fetal echocardiographic sagittal image of aortic arch in fetus with hypoplastic left heart syndrome. Color flow imaging demonstrates pulsatile, retrograde flow into the transverse aortic arch (Ao).

oxygen should generally be avoided, because in these patients it usually worsens pulmonary overcirculation and systemic hypoperfusion. The newborn with HLHS and a restrictive foramen ovale may require emergent atrial septostomy or septectomy within the first several hours after delivery. In general, infants with HLHS require the first of three palliative surgical procedures (the Norwood operation) within the first week after delivery, followed by a Glenn procedure at approximately 6 months and a Fontan procedure at 2 to 3 years. Some patients undergo cardiac transplantation,²⁰⁷ and others receive comfort care only.^{207,208} With surgery, the current long-term prognosis begins with a 5-year survival rate of up to 75% to 80% at the best and largest centers. Although many patients do extremely well early on, long-term data are lacking because the surgical approach is so new.²⁰⁷⁻²⁰⁹ Many survivors have some degree of neurodevelopmental delay.^{48,205} Long-term survivors with progressive right-sided heart failure may require cardiac transplantation during adulthood.

VALVAR AORTIC STENOSIS

Definition and Pathogenesis. Valvar aortic stenosis (see Video 23-7), usually secondary to a thickened, bicommissural aortic valve, is one of the most common lesions known to have the potential to evolve dramatically during the second and third trimesters.¹⁸ Severe cases of valvar aortic stenosis, particularly if present by 18 to 20 weeks' gestation, may adversely affect the prenatal development of the left ventricle, potentially generating a form of dilated cardiomyopathy that then evolves into HLHS.^{203,210} All degrees of valvar aortic stenosis may occur in conjunction with coarctation of the aorta. From a flow-related explanation of CHD, either lesion may cause the other.

Key Diagnostic Features. Mild to moderate valvar aortic stenosis may be detected prenatally by visualization of a thickened, usually small aortic valve on imaging of the LVOT (see Fig. 23-24). The 4CV view typically appears normal. Spectral

Figure 23-66 Fetal echocardiographic image (four-chamber view) demonstrating a dilated left ventricle with endocardial fibroelastosis in a fetus with severe aortic stenosis. Note the left-sided heart disproportion. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

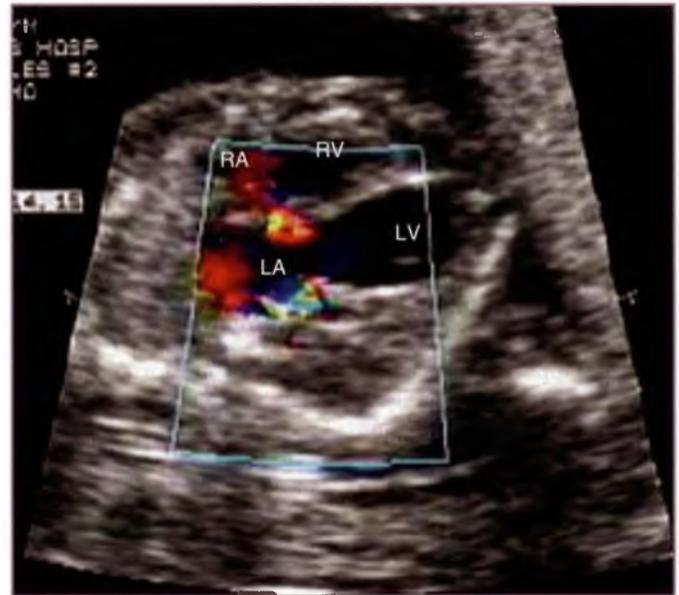

Figure 23-67 Fetal echocardiographic image (four-chamber view) demonstrating a dilated left ventricle with endocardial fibroelastosis in a fetus with severe aortic stenosis. Color flow imaging demonstrates mitral regurgitation and left-to-right flow across the foramen ovale. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

and color flow Doppler imaging may demonstrate flow acceleration with an increased velocity in the ascending aorta; rarely, this lesion may also have some degree of aortic regurgitation.

Severe forms of valvar aortic stenosis may manifest during the second trimester with abnormalities of both the 4CV and the outflow tracts. The 4CV may include a dilated, poorly functioning left ventricle (Fig. 23-66); in some cases, diminished diastolic excursion of the mitral valve, mitral valve regurgitation, and, often, endocardial fibroelastosis (brightened left ventricular endocardium) are present. The foramen ovale may shunt predominantly from left to right (Fig. 23-67). The outflow tract views may demonstrate a small, thickened aortic valve with diminished excursion, and color flow imaging of the aortic arch may demonstrate retrograde (see Fig. 23-65) or bidirectional flow in the transverse arch. Some cases of severe valvar aortic stenosis may evolve into HLHS by term, whereas others manifest in the newborn period with valvar aortic stenosis and a well-formed but poorly functioning left ventricle.^{203,210}

Associated Abnormalities. Valvar aortic stenosis, particularly when related to a bicommissural (“bicuspid”) aortic valve, commonly occurs in association with coarctation of the aorta. Frequently, valvar aortic stenosis may be associated with extracardiac structural or genetic disorders, or both.

Management and Prognosis. In a subset of those cases judged most likely to evolve into HLHS, the fetus may be a candidate for second-trimester dilation of the aortic valve.^{203,210} Such fetal intracardiac interventions may prevent the development of some cases of HLHS and allow a neonatal two-ventricle repair rather than single-ventricle palliation. Some fetuses may also benefit from the procedure’s ability to establish prograde, pulsatile flow to the brain. However, the procedure carries risks for both mother and fetus. Although the safety of the procedure and the ability to predict which cases will evolve

into HLHS both improve with advancing gestation, the likelihood of procedural efficacy decreases with advancing gestational age. The procedure, and the data to support it, both remain inadequately developed.

After delivery, mild to moderate valvar aortic stenosis usually requires observation over months to years; transcatheter or surgical intervention is postponed until the disease has significantly progressed. In contrast, severe valvar aortic stenosis typically manifests immediately after delivery with poor left ventricular systolic and diastolic function. These newborns require prostaglandin to maintain ductal patency for systemic blood flow. Affected infants undergo, soon after birth, either transcatheter balloon dilation of the aortic valve, surgical aortic valvuloplasty, or the Ross procedure (replacement of the patient’s own aortic valve with the patient’s own pulmonary valve and placement of a pulmonary homograft into the patient’s RVOT). Most cases of severe valvar aortic stenosis ultimately require valve replacement, but the prognosis remains quite good as long as left ventricular function recovers after the initial intervention.

COARCTATION OF THE AORTA

Definition and Pathogenesis. Coarctation of the aorta is not only one of the most common forms of ductal-dependent CHD but also one of the most difficult cardiac lesions to detect prenatally.²¹¹⁻²¹³ Normally, the fetal left ventricle supplies the coronary and cerebral circulations, with only a relatively small component of left ventricular cardiac output crossing the aortic isthmus to supply the lower body. The fetal right ventricle, in contrast, normally supplies most of the lower body of the fetus, with most of the right ventricular output passing from right to left through the ductus arteriosus and joining the descending

aorta just distal to the aortic isthmus. Coarctation of the aorta is a narrowing of the aortic isthmus, but it frequently also involves hypoplasia of the transverse and distal aortic arches.

Key Diagnostic Features. Prenatally, coarctation may be difficult to detect as long as the ductus arteriosus remains widely patent. With closure of the ductus arteriosus postnatally, ductal tissue extending circumferentially around the descending aorta and isthmus constricts, allowing a previously unrecognized coarctation to become visible.

As a result, the prenatal detection and diagnosis of coarctation remains challenging, particularly with relatively discrete forms of the disease.²¹¹⁻²¹⁴ Mild and moderate forms of coarctation may appear normal prenatally. More severe forms of coarctation, however, commonly result in abnormalities of the 4CV and outflow tracts (Fig. 23-68). The right atrium and ventricle commonly appear larger than expected (right heart disproportion), probably related to redistribution of flow to the right side of the heart, and color flow imaging may detect some degree of tricuspid regurgitation. A persistent LSVC draining to the coronary sinus is a commonly associated finding¹²⁸ and should increase the suspicion for coarctation of the aorta. Evaluation of the outflow tracts should again demonstrate right heart disproportion. Because a bicommissural aortic valve is another commonly associated finding, the aortic valve may appear mildly thickened or eccentric. The aortic valve annulus, aortic root, transverse aortic arch, and aortic isthmus may all appear small. Quantitative measurements of the aortic annulus and arch may be useful,^{96,117,214} as may Doppler evaluation of the aortic isthmus.²¹⁵ Finally, in the presence of coarctation, the

third main branch of the aortic arch, the left subclavian artery, may have its origin somewhat distally displaced closer to the isthmus than normal (Fig. 23-69).

Associated Abnormalities. Coarctation of the aorta appears commonly in association with a bicommissural or bicuspid aortic valve, persistent left-sided superior vena cava, and chromosomal abnormalities including Down, Turner, or Noonan syndrome.

Management and Prognosis. More severe forms of coarctation of the aorta manifest as ductal-dependent lesions requiring initiation of prostaglandin after delivery to maintain systemic cardiac output. These patients require neonatal repair, via either transcatheter dilation or surgical correction. Prenatal detection may prevent the inadvertent discharge to home of a newborn with severe coarctation whose ductus arteriosus has not yet closed.⁴⁶ Unless end-organ damage occurs at home before the diagnosis is made, the prognosis is generally excellent for isolated coarctation of the aorta. However, up to 50% of cases with neonatal repair require reintervention for recoarctation, and many patients, even with successful repair, have lifelong systemic hypertension.

TETRALOGY OF FALLOT

Definition and Pathogenesis. TOF is both the most common form of cyanotic CHD and the most common major CHD associated with a normal 4CV. It comprises a series of four cardiac findings, all believed to be related to anterior, superior, and rightward deviation of the conal septum into the RVOT. As a result of this deviation of the conal septum, TOF manifests with pulmonary stenosis, malalignment VSD, overriding aorta, and, postnatally, right ventricular hypertrophy secondary to persistent exposure of the right ventricle to systemic pressure.

Associated Abnormalities. Although most cases of TOF occur in isolation, it is also one of the most common forms of

Figure 23-68 Fetal echocardiographic image (left ventricular long-axis view) demonstrating right-sided heart disproportion suggestive of coarctation. The presence of a bicommissural aortic valve, possibly thickened, would help to support the diagnosis of coarctation. Ao, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.

Figure 23-69 Fetal echocardiographic image (sagittal view) demonstrating of aortic arch. The origin of the left subclavian is displaced distally, with severe hypoplasia of the aortic isthmus. The ductus arteriosus can be seen to enter the descending aorta immediately distal to the isthmus. The ascending aorta remains well formed.

CHD associated with maternal diabetes, trisomy 21, DiGeorge syndrome,²¹⁶ omphalocele, and pentalogy of Cantrell, among other conditions.²⁵ In addition, tetralogy of Fallot is commonly associated with right aortic arch, which can be detected prenatally using sagittal or three-vessel tracheal views.

Management and Prognosis. The detection, management, and prognosis of TOF depend on details of the anatomy and physiology.²¹⁷ Continuity and size of the branch pulmonary arteries vary considerably.²¹⁸ The following categories of TOF are discussed in this section: TOF with pulmonary stenosis, TOF with pulmonary atresia (TOF/PA), and TOF with absent pulmonary valve (TOF/APV).

Tetralogy of Fallot with Pulmonary Stenosis

Definition and Pathogenesis. In TOF with pulmonary stenosis, the degree of RVOT obstruction and the degree of hypoplasia of the main and branch pulmonary arteries determine the extent of cyanosis after delivery, the timing for initial surgical intervention, and, to some degree, the prognosis. The pulmonary stenosis in a fetus with TOF usually progresses prenatally, although at a variable rate.^{18,95}

Key Diagnostic Features. In a fetus with TOF with pulmonary stenosis, the 4CV is usually normal. Occasionally, the right ventricle appears slightly dilated or hypertrophied. Evaluation of the outflow tracts demonstrates a large malalignment VSD beneath the aortic valve and an overriding aorta (Fig. 23-70; see Figs. 23-47 and 23-48).^{219,220} The pulmonary valve appears small and thickened (see Fig. 23-48) in all but the mildest cases, and the main and branch pulmonary arteries typically appear somewhat hypoplastic.

Management and Prognosis. Patients with TOF with pulmonary stenosis may or may not require any neonatal intervention. After postnatal confirmation of the diagnosis, those with mild pulmonary stenosis may be discharged home without neonatal surgery or medical treatment, with definitive repair

planned for sometime during the first year of life. Those with more severe pulmonary stenosis will require earlier surgical intervention, either primary intracardiac repair (reconstruction of the RVOT and closure of the VSD) or early placement of an aortopulmonary shunt (to augment pulmonary blood flow) followed by intracardiac repair later during the first year. The outlook for these patients is generally excellent,²¹⁹ although those with more severely affected pulmonary valves may require multiple pulmonary valve replacements over a lifetime.

Tetralogy of Fallot with Pulmonary Atresia

Definition and Pathogenesis. In patients with TOF/PA, the lungs receive their blood supply either from retrograde flow through the ductus arteriosus or through multiple aortopulmonary collaterals arising from various points along the aortic arch. Patients with ductal-dependent pulmonary blood flow usually have well-formed pulmonary arteries; their long-term prognosis is excellent and is comparable to that of patients with TOF and severe pulmonary stenosis. In contrast, patients with pulmonary blood flow dependent on aortopulmonary collaterals usually have severely hypoplastic or absent true pulmonary arteries and face a much more guarded long-term prognosis.

Key Diagnostic Features. TOF/PA, like TOF with pulmonary stenosis, typically exhibits a normal 4CV prenatally. Evaluation of the outflow tracts demonstrates an atretic pulmonary valve and, often, absence of the main pulmonary artery.²²⁰ Patients with ductal-dependent pulmonary blood flow have a large, tortuous ductus arteriosus flowing into hypoplastic but relatively well-formed branch pulmonary arteries (Fig. 23-71). In contrast, patients with collateral-dependent pulmonary blood flow have severely hypoplastic or absent pulmonary arteries, an absent ductus arteriosus, and multiple aortopulmonary collaterals visible with color flow imaging of the aortic arch (Fig. 23-72).¹⁶⁵

Figure 23-70 Fetal echocardiographic image of tetralogy of Fallot (left ventricular long-axis view). Compare with Figure 23-47. Color flow demonstrates right-to-left shunting across the malalignment ventricular septal defect. Ao, aorta; LV, left ventricle; RV, right ventricle; St, fetal stomach.

Figure 23-71 Fetal echocardiographic image of tetralogy of Fallot with pulmonary atresia. Color flow imaging demonstrates retrograde flow into the pulmonary artery (PA), helping to distinguish this lesion from truncus arteriosus. Ao, aorta; LV, left ventricle; RV, right ventricle.

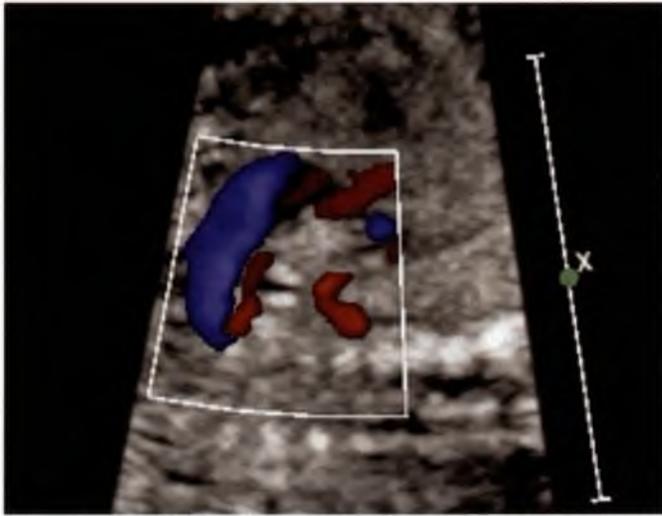

Figure 23-72 Sagittal image of the fetal aortic arch demonstrating, with color flow Doppler, the presence of tortuous aortopulmonary collaterals (red) arising from the descending aorta.

Management and Prognosis. After delivery, some patients with TOF/PA may require cardiac catheterization to visualize the source of pulmonary blood flow. Patients with ductal-dependent pulmonary blood flow may undergo neonatal placement of an aortopulmonary shunt. Those patients with collateral-dependent pulmonary blood flow face a far more complicated course, requiring case-specific medical and surgical management, and a much more guarded prognosis.

Tetralogy of Fallot with Absent Pulmonary Valve

Definition and Pathogenesis. TOF/APV is an unusual lesion with risks for both cardiac and pulmonary complications. In TOF/APV, primitive, donut-shaped pulmonary valve tissue causes both pulmonary stenosis and pulmonary regurgitation. As a result, the right ventricle and tricuspid valve annulus dilate, frequently causing tricuspid regurgitation and the potential for CHF, or even hydrops, prenatally. Typically, the ductus arteriosus is absent even during fetal life. The combination of an augmented right ventricular stroke volume and absent ductus arteriosus causes the branch pulmonary arteries to dilate aneurysmally. As a result, patients with TOF/APV may be born with pulmonary hypoplasia or severe airway disease, or both, related to chronic extrinsic compression by markedly dilated pulmonary arteries during fetal life.

Key Diagnostic Features. Unlike simple forms of TOF, TOF/APV manifests typically during fetal life with both an abnormal 4CV and abnormal outflow tracts.²²¹⁻²²³ Because of the pulmonary regurgitation, the right ventricle typically appears dilated. With significant stretch of the tricuspid valve annulus, tricuspid regurgitation may cause right atrial enlargement. In addition, elevated right ventricular diastolic pressure contributes to right atrial enlargement. Scanning into the LVOT demonstrates the malalignment VSD and overriding aorta. Angulation toward the RVOT demonstrates a small, donut-like pulmonary valve annulus, with pulmonary stenosis and regurgitation seen with color flow imaging. Probably the most recognizable features of TOF/APV are its aneurysmally dilated branch pulmonary arteries (Fig. 23-73), which may resemble Mickey Mouse ears and may appear to pulsate.

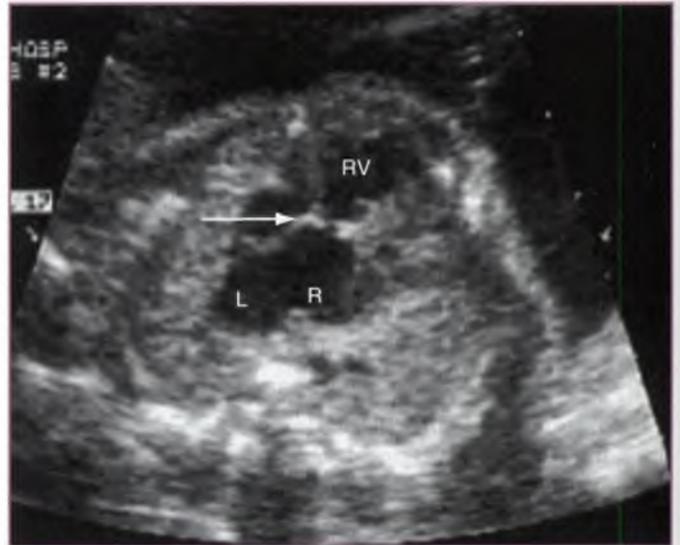

Figure 23-73 Fetal echocardiographic image demonstrating tetralogy of Fallot with absent pulmonary valve. Primitive tissue at the level of the pulmonary annulus (arrow) allows both pulmonary stenosis and pulmonary regurgitation, which in turn lead to aneurysmal dilation of the branch pulmonary arteries and dilation of the right ventricle (RV). L, left pulmonary artery; R, right pulmonary artery.

Management and Prognosis. After delivery, many newborns with TOF/APV suffer from pulmonary hypoplasia or severe airway disease. This type of presentation carries a poor prognosis. Many infants without respiratory compromise have a good long-term prognosis,²²¹⁻²²³ albeit with multiple pulmonary valve replacements during a lifetime. Because patients with TOF/APV typically do not have a ductus arteriosus, prostaglandin generally has little benefit during the neonatal period. Those infants without respiratory compromise need detailed echocardiographic and clinical evaluation to determine the appropriate timing for surgical intervention.

DOUBLE-OUTLET RIGHT VENTRICLE

Definition and Pathogenesis. DORV represents a heterogeneous group of congenital heart defects that have in common the origin of both great arteries from the right ventricle. Technically, DORV also implies mitral-aortic discontinuity, with conal tissue beneath both great arteries. Because of the varying size and location of the VSD, as well as variable degrees of pulmonary stenosis, infants with DORV may present with the pathophysiology of TOF, TGA, VSD, or single-ventricle disorder. Neonatal management and prognosis vary accordingly.

Key Diagnostic Features. Although some fetuses with DORV exhibit a large VSD or ventricular asymmetry on the 4CV, virtually all have abnormalities of the outflow tracts.²¹⁹ The left ventricular long-axis view does not demonstrate the aorta arising from the left ventricle. Instead, the aorta is seen to arise entirely or in part from the right ventricle. The pulmonary artery similarly arises entirely or in part from the right ventricle. If either great artery arises partially from the left and partially from the right ventricle, a VSD is seen immediately beneath the straddling great artery. In addition, in DORV, the relative spatial relationship between the aortic and pulmonary valves may vary considerably. The great arteries in DORV commonly, but not always,

lack the normal crossing seen in hearts with normally related great arteries. Finally, DORV typically manifests with pulmonary stenosis, and rarely with aortic stenosis. As with other cardiac lesions, pulmonary stenosis commonly coexists with pulmonary artery hypoplasia, and aortic stenosis commonly coexists with aortic arch hypoplasia and coarctation of the aorta.

Associated Abnormalities. DORV commonly occurs in conjunction with other structural defects.²²⁴

Management and Prognosis. The approach to management of DORV in the neonate requires detailed clinical and echocardiographic evaluation after delivery, because details of the anatomy and pathophysiology dictate the medical and surgical approach. Prognosis varies from that of mild TOF (excellent) to that of HLHS with hypoplastic pulmonary arteries (very poor).²¹⁹

TRANSPOSITION OF THE GREAT ARTERIES

In TGA, the aorta arises from the right ventricle, and the pulmonary artery arises from the left ventricle. Management and prognosis vary widely, depending on details of the anatomy and pathophysiology. Two major types of TGA have been described: dextro- or D-TGA (Video 23-10) and levo- or L-TGA. These are discussed separately.

D-TGA

Definition and Pathogenesis. Generally, D-TGA refers to TGA in which the visceral situs is normal (stomach on the left and liver on the right) and the ventricular looping is normal (D-looped). In D-TGA, the aortic valve is typically anterior and rightward of the pulmonary valve. As a result, systemic venous return passes from right atrium to right ventricle to aorta, and pulmonary venous return passes from left atrium to left ventricle to pulmonary artery.

Key Diagnostic Features. The fetus with isolated D-TGA usually has an entirely normal 4CV, but the views of the outflow tracts are markedly abnormal.²¹⁹ Any restriction to flow at the level of the foramen ovale should be noted with spectral and color flow Doppler evaluations,^{20,225} because newborns with restricted interatrial communications may require emergent balloon atrial septostomies, something not available at most hospitals. Unlike normally related great arteries, the great arteries in D-TGA do not cross each other (Figs. 23-74, 23-75, and 23-76; see Fig. 23-49). Instead, the pulmonary artery arises from the left ventricle and heads posteriorly, and the aorta arises from the right ventricle and heads superiorly to give off the head and neck vessels before joining the descending aorta at the isthmus. In addition, in D-TGA, the pulmonary valve and main pulmonary artery (both arising from the left ventricle) should appear slightly larger than the aortic valve and aortic root (both arising from the right ventricle). The ductus arteriosus should be evaluated with 2D imaging and color or spectral Doppler for evidence of ductal constriction.^{20,225}

Associated Abnormalities. Unlike TOF or HLHS, D-TGA typically occurs in isolation, without associated genetic syndromes or extracardiac abnormalities. On the other hand, D-TGA is commonly associated with a VSD or a coronary anomaly, or both, and occasionally with pulmonary stenosis or heterotaxy.^{130,186}

Management and Prognosis. The newborn with D-TGA is usually dependent on the ductus arteriosus for adequate oxygenation. In addition, unless a large VSD is present, oxygenation

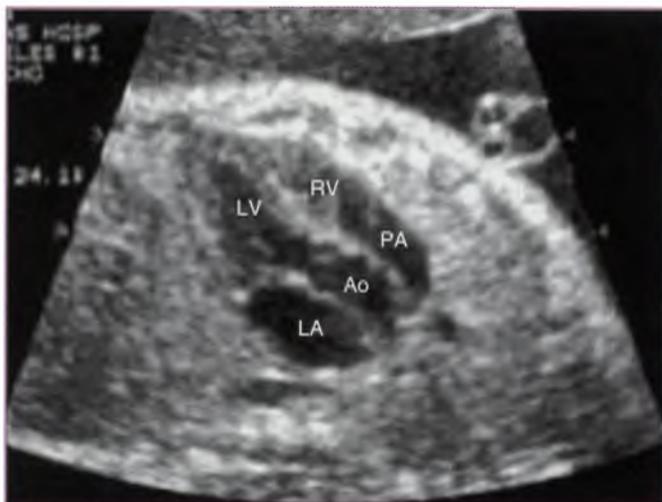

Figure 23-74 Fetal echocardiographic image demonstrating transposition of the great arteries. Note the absence of crossing of the great arteries. Ao, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RV, right ventricle.

Figure 23-75 Sagittal image of the fetal outflow tracts demonstrating transposition of the great arteries. Note the head and neck vessels arising from the more anterior and superior vessel (aorta), and the bifurcation of the main pulmonary artery into the ductal arch (overlying the left pulmonary artery) and the right pulmonary artery.

Figure 23-76 Split-screen (color-compare) fetal sagittal image demonstrating transposition of the great arteries. The reversal of flow from aorta to pulmonary artery (red) reflects the presence, in this fetus, of pulmonary stenosis.

relies on a large atrial communication. As a result, patients with D-TGA usually require prostaglandin infusion and may require balloon atrial septostomy relatively emergently after delivery. Subsequently, patients with straightforward D-TGA usually undergo the arterial switch operation within the first week after delivery. The prognosis can be excellent, but this depends largely on associated cardiac (see Fig. 23-49) and extracardiac abnormalities.²¹⁹

L-TGA

Definition and Pathogenesis. The term *L-TGA* describes the heart with normal visceral situs, L-looped ventricles, and TGA. Usually, in fetuses with L-TGA, the aortic valve sits anterior and leftward of the pulmonary valve. The systemic venous return passes from right atrium to left ventricle to pulmonary artery, and the pulmonary venous return passes from left atrium to right ventricle to aorta. For this reason, L-TGA has been described as a congenitally corrected transposition.

Key Diagnostic Features. Typically, L-TGA manifests in the fetus with both an abnormal 4CV and abnormal outflow tracts.^{226,227} L-looped ventricles are present on the 4CV, with a left ventricle anterior and rightward of a posterior and leftward right ventricle (Fig. 23-77). The right ventricle can be distinguished from the left ventricle by the presence of coarse trabeculations and a moderator band, and by a tricuspid valve that inserts onto the ventricular septum slightly more apically than the left ventricle's mitral valve. In addition, those fetuses with associated Ebstein anomaly of the tricuspid valve, which is always associated with the right ventricle, have that lesion's characteristic findings (but with left atrial rather than right atrial dilation). Imaging of the outflow tracts demonstrates absence of crossing of one outflow over the other. The aortic

Figure 23-77 Fetal echocardiographic image (four-chamber view) demonstrating congenitally corrected transposition of the great arteries. Note the presence of a smooth-walled left ventricle (LV) anteriorly and rightward and a more trabeculated right ventricle (RV) posteriorly and leftward. The tricuspid valve, associated with the right ventricle, inserts more apically onto the ventricular septum than does the right-sided mitral valve. LA, left atrium; RA, right atrium.

valve, arising anterior to and leftward of the pulmonary valve, gives rise to the aorta, which heads superiorly. In contrast, the pulmonary valve, arising posterior to and rightward of the aortic valve, gives rise to the pulmonary artery, which heads posteriorly. Pulmonary stenosis or atresia is detectable with 2D and color flow imaging and may affect the development of the main and branch pulmonary arteries. The presence of a VSD may be seen on either the 4CV or outflow tract views, depending on the size and location of the VSD: The more anterior the VSD, the more likely it is to be seen with imaging of the outflow tracts, and the less likely to be seen on the 4CV. Finally, heart block may develop at any time prenatally or after birth and may be documented with 2D imaging, spectral Doppler, or M-mode evaluation (see later discussion).

Associated Abnormalities. In many cases, L-TGA occurs in conjunction with a VSD, Ebstein anomaly of the left-sided tricuspid valve, heart block, pulmonary stenosis or atresia, or some combination of these. Such associated abnormalities affect the prenatal and postnatal presentation, management, and prognosis.

Management and Prognosis. After delivery, patients with straightforward L-TGA may not require any intervention, even for many years. However, the presence of any associated abnormalities may require neonatal or subsequent medical or surgical intervention. All patients require close clinical, echocardiographic, and electrocardiographic evaluation postnatally. Long-term prognosis varies widely, but, without surgery, all patients remain at risk for heart failure and arrhythmias because of their systemic right ventricle.^{226,227} Because of the long-term risks associated with systemic right ventricles, particularly those with incompetent tricuspid valves, some patients undergo an aggressive and controversial double-switch procedure, which combines the arterial switch procedure with an atrial switch procedure. The double-switch operation carries significant risk up front but enables the left ventricle to become the systemic ventricle.

TRUNCUS ARTERIOSUS

Definition and Pathogenesis. Truncus arteriosus represents a complex conotruncal malformation wherein a single arterial trunk arises from the heart and gives rise to the systemic, pulmonary, and coronary circulations. Truncus arteriosus arises from abnormal development of the truncal ridges and aortopulmonary septum and carries a strong association with DiGeorge syndrome.²⁵ Most cases have no ductus arteriosus during fetal life, except in the rare form associated with interrupted aortic arch.

Key Diagnostic Features. Prenatally, truncus arteriosus exhibits a normal 4CV but markedly abnormal outflow tract views.^{219,228,229} The truncal valve commonly appears mildly thickened, overrides a large VSD, and may have some degree of regurgitation on color flow imaging. The pulmonary arteries arise from the truncal root either as a common main pulmonary artery (Fig. 23-78) or as separate origins of right and left branch pulmonary arteries. It can be difficult to differentiate truncus arteriosus from TOF/PA prenatally. Both lesions show a single semilunar valve overriding a VSD. Both lesions have a normal 4CV, and both have strong associations with DiGeorge syndrome.²⁵ The distinction may be made, however, by assessing the direction of blood flow in the pulmonary arteries. In the case of TOF/PA, blood flow in the pulmonary arteries is

Figure 23-78 Fetal echocardiographic sagittal image of truncus arteriosus. The pulmonary artery (PA) arises from the proximal truncal root (T). Ao, aorta; St, stomach.

Figure 23-79 Fetal echocardiographic image (four-chamber view) demonstrating multiple ventricular rhabdomyomas. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

retrograde from the ductus arteriosus (see Fig. 23-71), or it may not be seen at all in the case of collateral-dependent pulmonary blood flow. In truncus arteriosus, blood from the pulmonary arteries is prograde from the truncal root. In addition, whereas the aortic valve in TOF/PA usually appears large but thin and delicate, the truncal valve in truncus arteriosus typically appears somewhat thickened, eccentric, and, occasionally, regurgitant.

Associated Abnormalities. The single most important association with truncus arteriosus is DiGeorge syndrome.²⁵ Occasionally, truncus arteriosus may be associated with other cardiac or extracardiac defects.

Management and Prognosis. After delivery, all patients require close clinical and echocardiographic evaluation, as well as evaluation for DiGeorge syndrome. Commonly, patients with truncus arteriosus undergo surgical repair within the first few weeks after delivery, with VSD closure and placement of a pulmonary homograft into the RVOT. As with TOF/PA, the pulmonary homograft will require multiple replacements during a lifetime. Long-term prognosis depends on the associated abnormalities and truncal valve function but can be quite good if all goes well.^{228,229}

CARDIAC TUMORS

Fetal cardiac tumors, although rarely malignant in the oncologic sense, may be life threatening in their own right or may be associated with systemic syndromes. This section reviews two of the most common cardiac tumors seen in the fetus: rhabdomyoma and intrapericardial teratoma. Both appear to have their greatest period of growth from mid-gestation to term. Readers may consult other sources for more detailed discussions of fetal cardiac tumors.^{10,11,181,182,230,231}

Cardiac Rhabdomyoma

Definition and Pathogenesis. By far the most common fetal cardiac tumor,^{230,231} cardiac rhabdomyoma may occur as an isolated, single cardiac mass or, more commonly, as a collection of

well-circumscribed tumors. In a substantial percentage of cases, cardiac rhabdomyomas occur as one manifestation of tuberous sclerosis.^{232,233} Although tuberous sclerosis may be associated with significant neurologic disease, including seizures, developmental delay, and cognitive impairment,²⁵ cardiac rhabdomyomas often do not cause cardiovascular pathology, either prenatally or after delivery. Occasionally, however, cardiac rhabdomyomas may become obstructive to flow in or out of one or both ventricles, may adversely affect myocardial function, may generate atrial or ventricular arrhythmias, and may be associated with WPW syndrome.

Key Diagnostic Features. The diagnosis of cardiac rhabdomyomas can generally be made from a 4CV. Most cardiac rhabdomyomas manifest as echogenic, homogeneous, well-circumscribed masses in or extending partially into the ventricular free wall or ventricular septum or both (Fig. 23-79). Rarely, cardiac rhabdomyomas reside predominantly in the walls of the right or left atrium. In contrast, benign echogenic reflectors or foci reside exclusively in the chordal apparatus of the mitral or tricuspid valves and do not extend into the ventricular myocardium.

Associated Abnormalities. The fetus with suspected cardiac rhabdomyomas should be evaluated thoroughly for tuberous sclerosis, possibly including sonography, magnetic resonance imaging, or genetic testing. After delivery, affected infants should again undergo comprehensive evaluation for tuberous sclerosis, a repeat echocardiographic evaluation, and an electrocardiogram to assess for WPW.

Management and Prognosis. In the absence of fetal arrhythmias, diminished ventricular function, obstruction to flow, or CHF, the fetus with cardiac rhabdomyomas will, rarely, develop cardiovascular pathology postnatally, short of SVT in the presence of WPW. As a result, long-term prognosis, from a cardiovascular standpoint, is excellent if no significant rhythm, ventricular dysfunction, or hemodynamic obstruction manifests during the late fetal or neonatal periods. Cardiac rhabdomyomas typically regress or remain stable in size postnatally,^{232,233} in contrast to other tumors, which may grow substantially after delivery.

Intrapericardial Teratoma

Definition and Pathogenesis. The intrapericardial teratoma is probably the second most common primary fetal cardiac tumor. Like the cardiac rhabdomyoma, it may be considered benign in the oncologic sense,^{10,181,230,231} but affected fetuses may develop CHF or hydrops secondary to progressive enlargement of the pericardial effusion. Histologically, the intrapericardial teratoma represents a combination of cystic areas, lined by various forms of epithelium, surrounded by solid areas composed of muscle, nerve, pancreas, cartilage, thyroid, or bone tissue. Intrapericardial teratomas typically arise from the ascending aorta and secrete fluid into the pericardial space.

Key Diagnostic Features. The diagnosis of intrapericardial teratoma may be suspected in the fetus with a pericardial effusion in conjunction with a heterogeneous, cystic mass with areas of calcification that arises from the ascending aorta (Fig. 23-80).

Management and Prognosis. Affected fetuses require close observation and may benefit from pericardiocentesis for progressive enlargement of the pericardial effusion and worsening tamponade.²³⁴ Over time, the expanding pericardial effusion can impede cardiac output, and the resultant tamponade physiology can result in fetal demise. After delivery, mass effect of the tumor may impede cardiac output or cause respiratory compromise by compressing the trachea or mainstem bronchi.²³⁴ Delivery should be arranged to allow for rapid intubation, if necessary, and subsequent early surgical resection of the tumor. Long-term prognosis after expeditious, early resection is excellent, with little chance for recurrence.

Ectopia Cordis

Definition and Pathogenesis. Ectopia cordis, strictly speaking, refers to an abnormally positioned (ectopic) heart (cordis). However, the term *ectopia cordis* has come to refer to the heart that extends, in part or entirely, outside the thorax, sometimes

residing in the neck or abdomen, but usually protruding through the chest wall into the amniotic cavity.

Key Diagnostic Features. The diagnosis of ectopia cordis relies on sonographic demonstration that the heart resides, in part or entirely, outside the thorax (Figs. 23-81 and 23-82). Once an ectopic heart (cordis) has been identified, detailed evaluation of cardiac and extracardiac anatomy should be performed, given the common association with complex CHD,

Figure 23-81 Fetal echocardiographic image of complete ectopia cordis, with the heart located entirely outside of the fetal thorax. Note the presence of venous and arterial flow between the thorax and the common atrium. This four-chamber view of the heart also demonstrates an abnormality of the atrioventricular canal and hypoplasia of the left ventricle.

Figure 23-80 Fetal echocardiographic image of intrapericardial teratoma (IPT) arising from the ascending aorta. Note the heterogeneous appearance of the tumor. LV, left ventricle; PCE, pericardial effusion; RV, right ventricle.

Figure 23-82 Transverse cut through the fetal thorax demonstrating partial ectopia cordis. Note the extrusion of the cardiac apex through a defect in the anterior chest wall.

defects in the diaphragm or chest wall, and the presence of omphalocele.

Associated Abnormalities. Ectopia cordis is commonly associated with complex forms of CHD, as well as omphalocele, diaphragmatic defects, and pentalogy of Cantrell.

Management and Prognosis. Most cases of ectopia cordis carry a poor prognosis, with neonatal death related to infection, heart failure, or hypoxemia. More mild cases may undergo repositioning of the heart into the thorax, closure of chest or diaphragmatic defects, and repair of associated CHD or omphalocele.²³⁵

Fetal Arrhythmias: Diagnosis, Management, and Prognosis

This section reviews the diagnosis, management, and prognosis of the most common and important fetal arrhythmias (Box 23-7), with a distinctively clinical approach. For more detailed discussions of fetal arrhythmias, readers may refer to other, more comprehensive reviews.^{10,11,181,236-238}

Beyond demonstrating a normal transverse abdominal view, 4CV, and standard views of the outflow tracts, the normal fetal screening ultrasound evaluation should demonstrate physiologic rate and variability of the fetal heartbeat. The fetal heart rate should be physiologic (120 to 160 beats/min) and should have physiologic variability (small but real changes in heart rate during scanning, with prolonged or severe bradycardia only during periods of deep transducer pressure). Abnormal variability (irregular beats or extrasystoles) and abnormalities in rate (sustained bradycardia or tachycardia) should be noted, evaluated, and, if appropriate, treated. Most fetal arrhythmias are benign, are self-resolving, and do not require treatment.²³⁶⁻²³⁸

Treatment of a fetus for arrhythmia should be undertaken only after careful weighing of desired benefits against potential maternal and fetal complications and after full disclosure to the mother. Table 23-1 lists some of the most common antiarrhythmic medications used to treat fetal arrhythmias.

PREMATURE ATRIAL CONTRACTIONS

Premature atrial contractions (PACs), the most common fetal arrhythmia,²³⁶⁻²³⁹ manifest as an irregularly irregular variability in fetal heart rate, usually beginning between 18 and 24 weeks'

gestation, but occasionally appearing initially during the third trimester. The diagnosis of PACs typically is made empirically by observing the rhythm with 2D imaging. However, to confirm the diagnosis, spectral Doppler inflow and outflow evaluation of the left ventricle or M-mode analysis should be performed.

Normally, by orienting the ultrasound beam in parallel with both left ventricular inflow and outflow (Fig. 23-83), spectral Doppler evaluation of sinus rhythm will demonstrate a biphasic

TABLE 23-1 Antiarrhythmic Medications for Fetal Arrhythmias

Fetal Arrhythmia	Potential Treatments*
Premature atrial/ventricular contractions	None
Atrial bigeminy (blocked or conducted)	None
Nonsustained supraventricular tachycardia	Usually none (see text)
Sustained supraventricular tachycardia	Digoxin Flecainide Amiodarone
Atrial flutter	Digoxin Sotalol Amiodarone Propranolol
Ventricular tachycardia	Propranolol Sotalol Mexiletine Amiodarone
First/second/third-degree heart block (positive antibodies)	Dexamethasone?

*Note that all antiarrhythmic medications have the potential for serious, possibly fatal maternal or fetal (or both) proarrhythmia. Treatment of a specific fetus for an arrhythmia should be done only after careful consideration of anticipated benefits and potential risks and after full disclosure has been made to the mother.

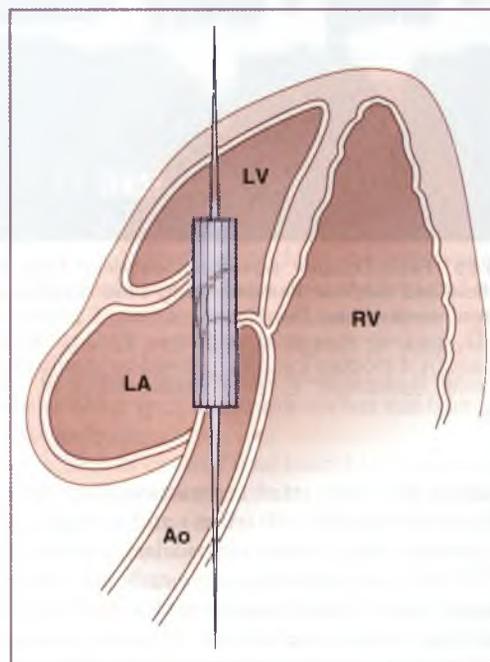

Figure 23-83 Schematic diagram of left ventricular inflow and outflow. The Doppler cursor is positioned in parallel with mitral and aortic flows to assist with the diagnosis of fetal arrhythmias. - Atrial bradycardia
- Blocked atrial bigeminy
- Atrial flutter with high-degree block
- Complete heart block

SUSTAINED TACHYCARDIA

- Sinus tachycardia
- Supraventricular tachycardia
- Atrial flutter
- Ventricular tachycardia

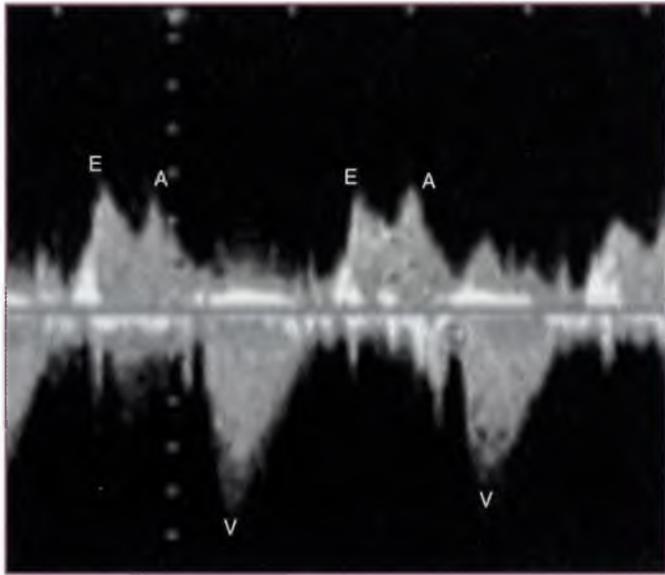

Figure 23-84 Fetal Doppler waveform, obtained from left ventricular inflow and outflow, demonstrating sinus rhythm. The Doppler cursor is positioned as in Figure 23-83. Note the biphasic mitral inflow, with passive early inflow (E wave) followed by atrial contraction (A wave). Each mitral inflow pattern is followed by single outflow. A, atrial contraction; E, early passive filling; V, ventricular contraction.

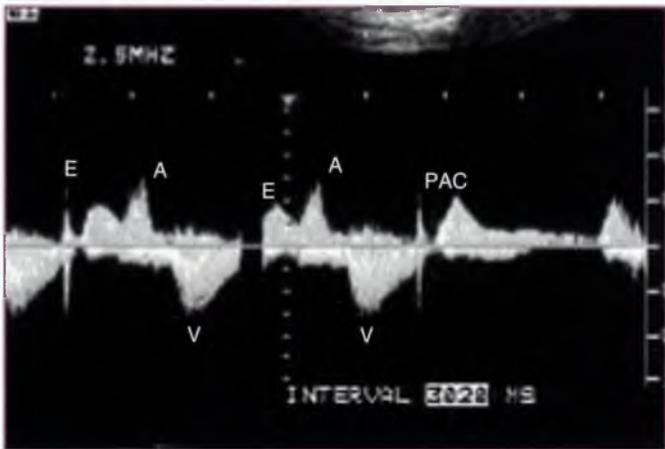

Figure 23-85 Fetal Doppler waveform, obtained from left ventricular inflow and outflow, demonstrating sinus rhythm with premature atrial contraction. The Doppler cursor is positioned as in Figure 23-83. The premature atrial contraction (PAC) comes early and is monophasic; it is blocked (i.e., not followed by ventricular contraction). A, atrial contraction; E, early passive filling; V, ventricular contraction.

inflow pattern for every atrial contraction (i.e., early passive filling followed by atrial contraction) and a single, uniphasic outflow pattern after each ventricular contraction (Fig. 23-84).^{240,241} PACs, by definition, come early, and they typically lack the early passive filling component (E wave) of the Doppler waveform (Fig. 23-85). Alternatively, M-mode echocardiography allows visualization of atrial and ventricular contractions simultaneously when, guided by a 2D image, the M-mode sampling line is directed through the fetal atrium and ventricle (Fig. 23-86).²⁴² The use of color Doppler superimposed onto conventional M-mode can be less angle-dependent than

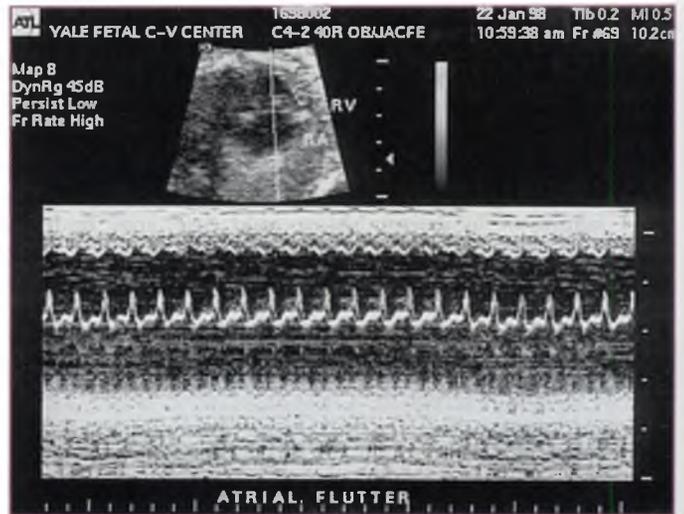

Figure 23-86 Fetal echocardiographic image of M-mode analysis of fetal arrhythmia. The M-mode cursor is placed across the right atrium and right ventricle (inset). This M-mode image demonstrates atrial flutter. (Courtesy of Charles Kleinman, MD, Joshua Copel, MD, and Rodrigo Nehgme, MD.)

traditional M-mode to acquire, and easier to interpret (Fig. 23-87). Other, more sophisticated approaches to evaluating fetal arrhythmias have also been developed.¹²⁰

Rarely, PACs are associated with intermittent SVT. PACs may be exacerbated by ingestion of caffeine, decongestant medications (stimulants), or tobacco. Typically, PACs resolve spontaneously within 2 to 3 weeks after diagnosis. PACs do not represent any real risk to the fetus, and they do not require treatment. However, a small percentage of fetuses with isolated PACs develop SVT. Referral for further evaluation should be considered if concerns persist regarding the diagnosis or the possibility of additional arrhythmias or structural CHD.

SUSTAINED BRADYCARDIA

A sustained fetal heart rate of less than 120 beats/min represents fetal bradycardia and merits further evaluation. In contrast, fetal bradycardia related to deep transducer pressure or a particular maternal lie might represent a normal fetal response to stress. In such cases, if the fetal heart rate normalizes after relief of transducer pressure or change in maternal or fetal position, no further cardiac evaluation may be necessary.

The differential diagnosis of fetal bradycardia includes sinus bradycardia, atrial bradycardia, blocked atrial bigeminy, atrial flutter with high-degree block, and complete heart block. Treatment approaches and prognosis depend on the precise diagnosis. Sinus bradycardia, manifesting with a slow rate but with physiologic variability and with 1:1 conduction between the atria and ventricles, may represent fetal distress and therefore should prompt a thorough evaluation of fetal well-being and placental function. Particularly if it is associated with some degree of heart block, fetal sinus bradycardia may, rarely, be the first sign of long QT syndrome.²⁴³ Affected fetuses and newborns are at risk for ventricular tachycardia. For this reason, fetuses in good health that demonstrate unexplained sinus bradycardia without fetal distress should undergo electrocardiographic evaluation after delivery. In addition, because long QT syndrome may run in families, a family history of long QT

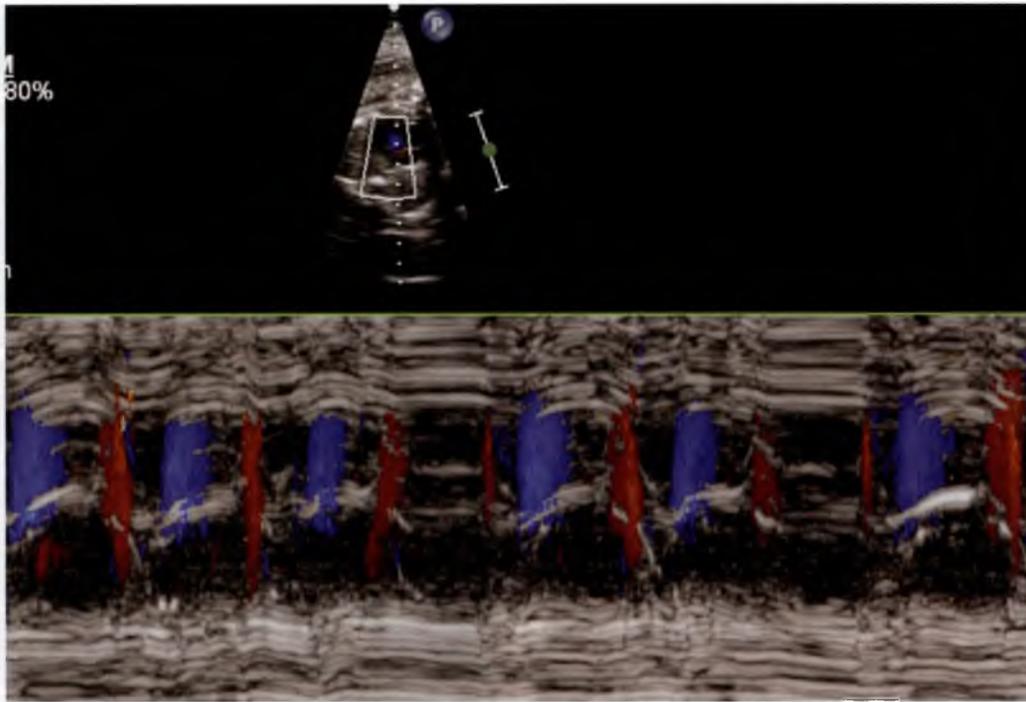

Figure 23-87 Fetal premature atrial contraction demonstrated with color M-mode. Note the inflow (red) alternating with outflow (blue). The premature atrial contraction can be seen as an early inflow (thin red) following a sinus inflow (red), without an intervening outflow. The color helps to clarify the M-mode demonstration of a premature atrial contraction.

syndrome, recurrent syncope, or sudden infant death syndrome should be sought. In contrast, atrial bradycardia may appear identical to sinus bradycardia, but it actually represents the normal rate of an accessory atrial pacemaker in the absence of an effective sinus node. Such an atrial bradycardia commonly occurs in conjunction with polysplenia, so the suspicion of this rhythm should prompt evaluation for the cardiac and abdominal abnormalities seen with polysplenia.^{126,130,186}

Occasionally, fetal sinus bradycardia represents blocked atrial bigeminy, in which normal sinus beats alternate with blocked PACs. In atrial bigeminy, the premature beats may be blocked if they occur very early, when the atrioventricular node is still refractory. In such cases, only sinus beats conduct, generating a uniform ventricular rate exactly half of the atrial rate. No specific therapy is warranted other than close observation and avoidance of caffeine, decongestant medications, and tobacco. Prognosis is excellent.

In some cases, atrial flutter may conduct consistently 3:1 or 4:1, and such fetuses may present with bradycardia. Close inspection of the heart with 2D imaging, M-mode, or spectral Doppler can diagnose the arrhythmia and assess the degree of conduction. Although atrial flutter usually has an atrial rate of 300 to 500 beats/min, high degrees of atrioventricular block may lead to fetal bradycardia; for example, atrial flutter with a flutter rate of 300 beats/min and a 3:1 conduction would present with a fetal ventricular rate of 100 beats/min. Unlike SVT, atrial flutter rarely manifests as intermittent tachycardia; flutter is typically incessant, although the ventricular response rate may vary. Like other fetal arrhythmias, fetal atrial flutter may be associated with structural heart disease. Treatment of atrial flutter, typically with pharmacologic therapy (e.g., digoxin,

sotalol, amiodarone) administered orally to the mother, can slow the ventricular response rate and decrease the likelihood of development of fetal CHF or hydrops. Some investigators believe that sotalol has emerged as a potential first-line agent for the treatment of atrial flutter.²⁴⁴

Complete heart block (CHB) in the fetus typically manifests with a sustained fetal heart rate in the range of 40 to 70 beats/min (Fig. 23-88). In the fetus with complete heart block, the atrial rate remains normal but atrial contractions do not conduct to the ventricles. As a result, the ventricles depolarize with their own intrinsic rate. Approximately 50% of cases of fetal complete heart block occur in the presence of structural heart disease (L-looped ventricles, atrioventricular septal defects, or complex forms of heart disease associated with polysplenia).^{186,236,245} These patients have a relatively poor prognosis, with a high rate of fetal demise related to progressive heart failure and hydrops. Therapy with maternal oral agents such as terbutaline or other sympathomimetics has not been shown to improve the outcome.

The other 50% of cases of fetal heart block occur secondary to damage to the fetal atrioventricular node by maternal anti-Ro or anti-La antibodies (or both),²⁴⁵⁻²⁴⁷ usually in the context of maternal systemic lupus erythematosus, Sjögren syndrome, or related connective tissue disorders. In some of these cases, maternal treatment with dexamethasone may improve fetal outcome, probably by improving myocardial function in the face of presumptive immune-mediated myocarditis.²⁴⁸⁻²⁵¹ Some investigators have used sympathomimetic agents to increase ventricular rates in this setting, particularly for rates that remain slower than 55 beats/min,²⁵² but sustained increases in fetal heart rate have rarely been achieved. Pregnancies complicated

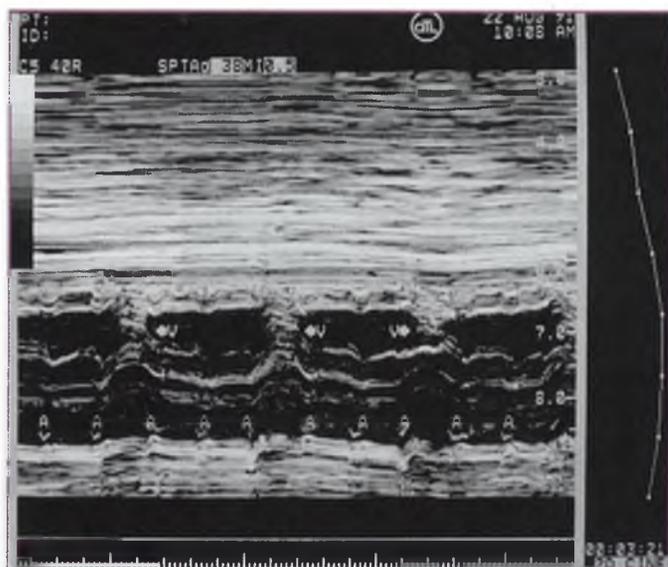

Figure 23-88 Fetal echocardiographic image of M-mode demonstration of complete heart block. A, atrial contraction; V, ventricular contraction. (Courtesy of Charles Kleinman, MD, Joshua Copel, MD, and Rodrigo Nehgme, MD.)

by anti-Ro or anti-La antibodies carry a risk of approximately 1% for the development of fetal heart block,²⁵³ and the recurrence rate for a second fetus with heart block in antibody-positive pregnancies may be as high as 15%.²⁴⁷ Spectral Doppler evaluation of the fetal PR interval has been shown to be a useful way to identify fetuses in anti-Ro or anti-La antibody-positive pregnancies with evidence of atrioventricular node disease.^{254,255} Treatment of fetuses at risk (first-, second-, or third-degree heart block in antibody-positive pregnancies) with dexamethasone or intravenous immunoglobulin may prevent the progression to CHB or otherwise improve outcome by protecting myocardial function, but such management remains highly controversial.^{248-250,256-258}

SUSTAINED TACHYCARDIA

Supraventricular tachycardia comprises the great majority of instances of sustained fetal tachycardia. Sinus tachycardia represents an unusual response to fetal heart failure or distress. Fetal ventricular tachycardia occurs still less commonly.

Supraventricular Tachycardia

Fetal SVT typically occurs via an accessory pathway, although autonomic forms of fetal SVT also occur relatively commonly. Fetal SVT, usually in the range of 240 to 280 beats/min, occurs most frequently in fetuses with structurally normal hearts and rarely occurs in the setting of structural CHD. However, fetal SVT may be associated with WPW syndrome. The diagnosis of SVT may be suggested by 2D imaging, by spectral Doppler assessment of the left ventricular inflow and outflow tracts (see Fig. 23-83), or by M-mode analysis (Fig. 23-89). Ventricular tachycardia, which is typically slower but less well tolerated than SVT, may be associated with ventricular structural abnormalities or tumors or may occur in the context of long QT interval. Ventricular tachycardia can be difficult to discriminate from fetal SVT, even with M-mode or spectral Doppler

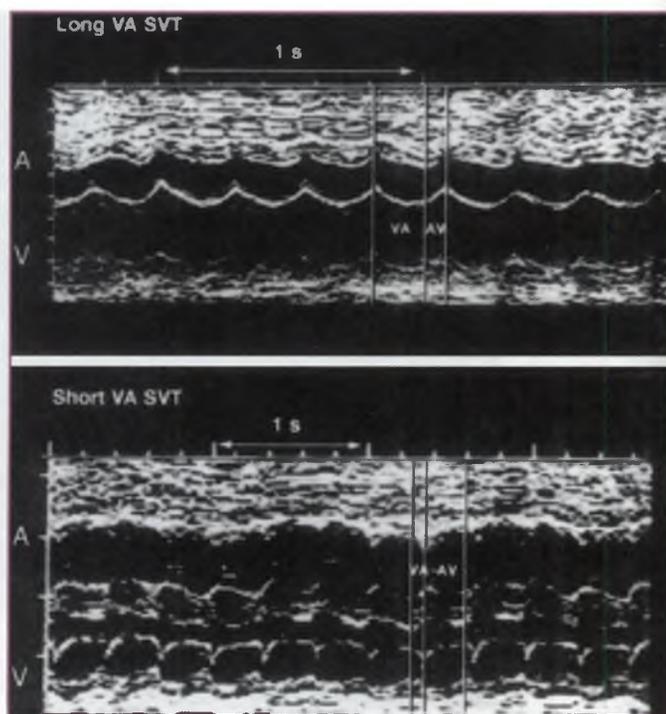

Figure 23-89 Fetal echocardiographic image of M-mode demonstration of two types of supraventricular tachycardia. In contrast to ventricular tachycardia, both long- and short-VA supraventricular tachycardia (SVT) have 1:1 atrioventricular association. A, atrial contraction; AV, interval between atrial and ventricular contraction; V, ventricular contraction; VA, interval between ventricular and atrial contraction. (Reproduced with permission from Jaeggi E, Fouron JC, Fournier A, et al: Ventriculo-atrial time interval measured on M-mode echocardiography: a determining element in diagnosis, treatment, and prognosis of fetal supraventricular tachycardia, *Heart* 79:582, 1998.)

analysis,^{236,237,259} although ventricular tachycardia is typically far less well tolerated. Because fetal SVT typically manifests as an intermittent, nonsustained arrhythmia, the presence of PACs or atrial couplets can help strengthen the certainty of the diagnosis. Moreover, unlike ventricular tachycardia, SVT usually conducts 1:1 from atria to ventricles.

Although few would dispute treatment of fetal SVT in the face of hydrops and in the absence of lung maturity, no consensus exists on the approach to the second-trimester (or early third-trimester) fetus with SVT in the absence of hydrops.^{236,237,259-261} As would be expected, SVT in a fetus with structural heart disease is far less well tolerated than SVT in one with a structurally normal heart. However, therapeutic strategies advocated for the nonhydropic, immature fetus with SVT remain largely divergent, ranging from treatment of any documented SVT to treatment only with the development of hydrops.²⁵⁹ No consensus has been reached on the exact relationship between heart rate, type of SVT, and development of hydrops in the context of fetal SVT. Antiarrhythmic agents, dosage schedules, and routes of administration are separate areas of controversy and disagreement, similarly without consensus.

Although different cases may be handled somewhat differently, depending on patient characteristics and physician biases, the following is our institution's approach. The presence of structural heart disease in the context of SVT lowers the tolerance for shortened diastolic filling times and elevated central

venous pressure, so such fetuses typically receive treatment earlier than do fetuses with structurally normal hearts. When fetal SVT becomes complicated by hydrops, the threshold for treatment falls much further. In the absence of fetal structural heart disease or hydrops, fetal SVT usually receives treatment if the tachycardia occurs more than 33% of the time. However, beyond 32 to 34 weeks' gestation, many cases of fetal tachycardia may be better approached with delivery than with maternally administered medications, all of which have variable efficacy and carry the potential for both maternal and fetal toxicity. Before treatment, all potential precipitating factors (tobacco, decongestant medications, and caffeine) are withdrawn, and the fetal rhythm is monitored in-house for 8 to 24 hours to assess the percentage of time during which the fetus is in tachycardia. The mother is informed of all possible fetal and maternal risks to therapy, as well as the anticipated benefit to treatment. All antiarrhythmic agents have the potential for maternal or fetal proarrhythmia. Because maternal serum factors may, rarely, react with assays for digoxin,²⁶² a maternal serum digoxin level is determined, along with a set of electrolytes and creatinine. A maternal electrocardiogram and, ideally, consultation with an adult cardiologist is performed before therapy is initiated. The presence of WPW or another abnormality on the maternal electrocardiogram may contraindicate the use of certain forms of antiarrhythmic therapy (e.g., digoxin).

When indicated, and only in the absence of any contraindication, treatment may begin with a digoxin load, using 0.25 to 0.5 mg orally (or intravenously, if response is considered more urgent) every 6 to 8 hours, with a maternal serum digoxin measurement and electrocardiogram performed before each dose. Loading continues until effect (reduced time in tachycardia or decreased hydrops, or both), therapeutic level (2.0 µg/mL), maternal toxicity (maternal symptoms or electrocardiographic abnormalities beyond first-degree heart block), or fetal toxicity (worsening of arrhythmia) is reached, whichever comes first. After a desired effect has been safely achieved, digoxin is administered orally two to four times daily, usually at 0.25 to 0.5 mg per dose. Often, consultation with the hospital pharmacologist is useful. Patients are discharged after a steady state has been achieved with acceptable control of the fetal arrhythmia, acceptable maternal serum digoxin levels, and absence of maternal or fetal toxicity. However, close outpatient follow-up is essential to confirm continued effect and lack of toxicity, and occasionally to increase the dosage as maternal volumes of distribution continue to increase during the second and third trimesters. If digoxin fails to achieve adequate control, second-line agents such as propranolol,^{236,237} flecainide,²⁶³ or amiodarone²⁶⁴ may be substituted or added, but the potential for toxicity increases and the likelihood for efficacy decreases.^{236,237}

Atrial Flutter

In contrast to fetal SVT, fetal atrial flutter ranges between 300 and 500 atrial contractions per minute, with a ventricular rate that may vary from less than 100 to more than 300 beats/min.^{236,237,265} In atrial flutter, the atrioventricular node refractory periods may vary, occasionally producing 1:1 conduction but more typically allowing only every second or third atrial contraction to conduct to the ventricles (2:1 or 3:1 conduction, respectively) (see Fig. 23-86). Flutter usually manifests in a much more sustained fashion than does SVT, which commonly produces intermittent runs of tachycardia interspersed with

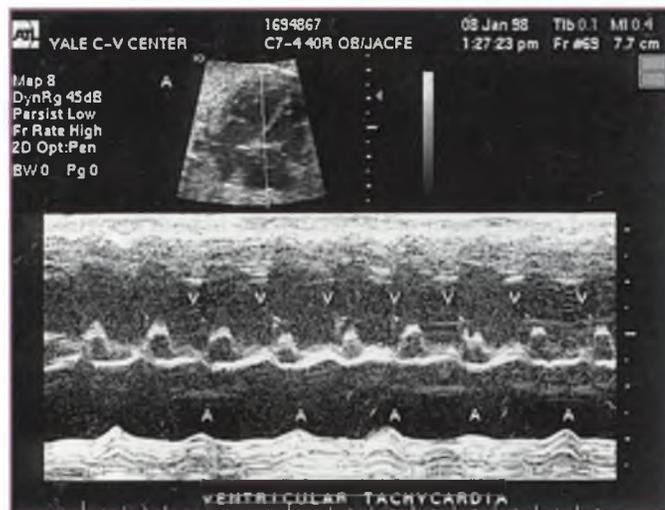

Figure 23-90 Fetal echocardiographic image of M-mode demonstration of ventricular tachycardia. Note atrioventricular dissociation, with ventricular rate faster than atrial rate. A, atrial contraction; V, ventricular contraction. (Courtesy of Charles Kleinman, MD, Joshua Copel, MD, and Rodrigo Nehgme, MD.)

periods of sinus rhythm. Compared with SVT, atrial flutter has a higher association with structural heart disease, although structural heart disease is still rare in the neonate with atrial flutter.²⁶⁶ Finally, although flutter may be successfully treated with maternally administered digoxin, recent reports suggest that sotalol is an excellent second-line agent, and some centers have chosen sotalol as their first-line therapy for fetal atrial flutter.^{244,267} Propranolol has also been used successfully to control the ventricular response rate in the fetus with atrial flutter.²³⁷

Ventricular Tachycardia

Ventricular tachycardia in the fetus, as in newborns and children, is a commonly fatal arrhythmia when sustained. In part for this reason, fetal ventricular tachycardia is diagnosed far less often than fetal SVT, although fetal ventricular tachycardia is also far less common than fetal SVT. Fetal ventricular tachycardia usually manifests with fetal rates between 180 and 300 beats/min and, often, poor ventricular function. Discrimination of ventricular tachycardia from SVT can be challenging, but it is important because digoxin is contraindicated for ventricular tachycardia. Unlike SVT, ventricular tachycardia has dissociation between atrial and ventricular contractions (Fig. 23-90). Ventricular tachycardia that is associated with structural heart disease carries a particularly poor prognosis. Fetal ventricular tachycardia has been associated with tumors (usually rhabdomyomas), structural heart disease (cardiomyopathy, severe right or left ventricular hypertrophy or coronary abnormalities), prolonged QT interval,²⁴³ and fetal distress or acidosis. Lower ventricular rates (180 to 220 beats/min) may be better tolerated, with better outcomes than higher ventricular rates. In some cases, treatment may be attempted with lidocaine (administered directly into the fetal umbilical vein) or with oral maternal administration of propranolol, mexiletine, sotalol, or amiodarone, but the prognosis remains guarded.^{236,237,264}

Conclusions

The detection, diagnosis, and management of fetal structural heart defects and arrhythmias remain important challenges for those involved in fetal screening ultrasonography or detailed evaluation of the fetal heart. The importance of early detection of major forms of CHD is increasingly recognized. The assessment and management of the fetal heart, in both low-risk and high-risk pregnancies, requires attention to detail, experience,

and a collaborative effort among multiple specialists caring for the fetal patient. Although emerging technologies and increasingly sophisticated equipment facilitate detection and evaluation of structural and functional fetal cardiac pathology, image quality appears likely to be the single most important factor in the evaluation of the fetal heart.

Abdominal Imaging

RICHARD B. WOLF, DO, MPH

24A ABDOMINAL ASCITES

Diagnosis

DEFINITION

Ascites is an abnormal fluid collection in the fetal peritoneal cavity, and it is often the first finding in *hydrops fetalis* (Video 24-1). Ascites is present in 85% of cases of nonimmune hydrops fetalis.

INCIDENCE AND PATHOGENESIS

- Hydrops fetalis occurs in approximately 1:2500 births; the incidence of *isolated* ascites is much lower.
- Free fluid in the abdomen could represent
 - A *transudate*, the result of increased fluid leaking from the fetal capillary beds without adequate lymphatic return
 - An *exudate*, as an inflammatory response to infection or malignancy
 - *Leaked urine*, from an overdistended or ruptured bladder (Video 24-2)
 - *Meconium*, from perforated bowel producing meconium peritonitis
 - *Chylous fluid*, resulting from peritoneal lymphangiectasia

DIFFERENTIAL DIAGNOSIS

- Markedly overdistended bladder (megacystis), as seen with posterior urethral valves
- Ovarian cyst (or cysts)
- Dilated fetal bowel, particularly the descending and sigmoid colon
- Pseudoascites
 - Abdominal wall muscles can produce a thin echolucent rim that can be confused with ascites.
 - Acoustic “shadowing” from echodense structures (e.g., bone) proximal in the ultrasound beam

KEY DIAGNOSTIC FEATURES

- Ascites appears as an echolucent fluid accumulation in the fetal abdomen, outlining the fetal liver, loops of bowel, stomach, and bladder.
- The falciform ligament or the extrahepatic portion of the umbilical vein (or both) may be outlined by fluid in extreme cases of ascites.
- Cases of meconium peritonitis exhibit echogenic calcifications on peritoneal surfaces.
- Systematic assessment of the fetal anatomy for other abnormalities and for evidence of hydrops fetalis:
 - Scalp and skin edema
 - Pleural effusion (Video 24-3)
 - Pericardial effusion
 - Polyhydramnios
 - Placentomegaly (>4 cm thick)

ASSOCIATED ANOMALIES

- Gastrointestinal defects, including cystic fibrosis, meconium peritonitis, biliary atresia
- Congenital heart defects and arrhythmias
- Genitourinary sources, including ruptured bladder or kidney
- Ruptured fetal ovarian cyst
- TORCH (*toxoplasmosis, other* [including parvovirus and syphilis], *rubella, cytomegalovirus, herpesvirus*) infection
- Primary lymphangiectasia
- Isoimmune fetal anemia resulting from Rh or other red cell antigen incompatibility
- Nonimmune hydrops fetalis
- Other miscellaneous conditions, including fetal-maternal hemorrhage, inborn errors of metabolism, aneuploidy, fetal neoplasia

Imaging

Figure 24-1 Ascites, sagittal view. Ultrasound image of the fetal abdomen shows ascites (arrowheads) outlining the fetal liver (L), loops of bowel (Bo), and bladder (Bl). H, heart.

Figure 24-4 Extreme ascites. Axial-view ultrasound image of a fetus with extreme ascites shows the readily identified falciform ligament (arrow) in the fetal abdomen. L, liver.

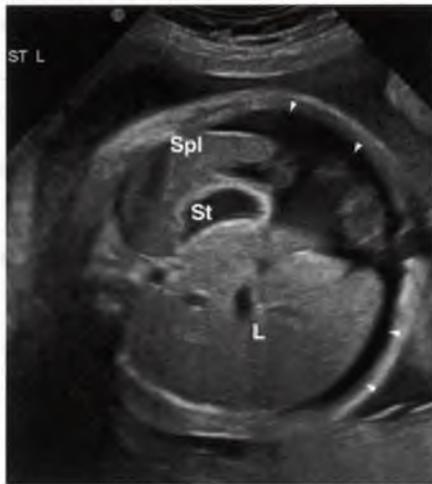

Figure 24-2 Ascites, axial view. Ultrasound image of the fetal abdomen shows ascites (arrowheads) outlining the liver (L), spleen (Spl), and fluid-filled stomach (St).

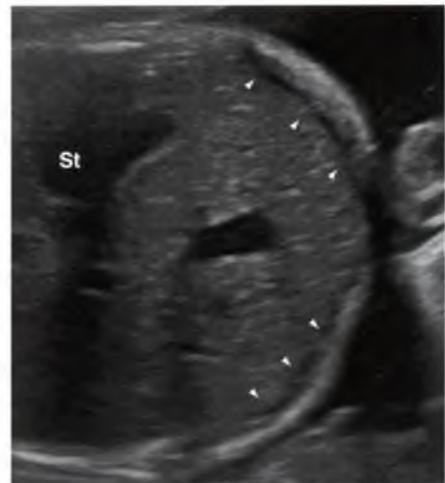

Figure 24-5 Pseudoascites. Axial-view ultrasound image of the fetal abdomen shows thin anechoic rim surrounding the abdominal contents, representing abdominal wall muscle (arrowheads). St, stomach.

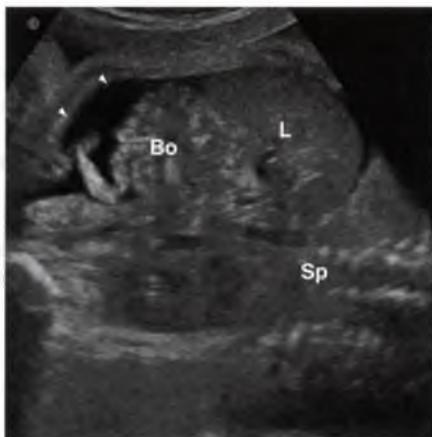

Figure 24-3 Ascites, coronal view. Ultrasound image shows fluid accumulation (arrowheads) in nondependent portions of the fetal abdomen. Bo, bowel; L, liver; Sp, spine.

Figure 24-6 Pseudoascites. Acoustic shadowing from overlying echodense structures (e.g., bone) produces what appears to be fluid along the abdominal walls (arrows) in this fetus. St, stomach.

Management

ANTENATAL MONITORING

- Maternal blood testing:
 - Blood type, antibody screen
 - Kleihauer-Betke
 - Rapid plasma reagin test
 - TORCH, including parvovirus titers
- Serial ultrasound examination to monitor fetal growth, amniotic fluid, worsening ascites, and progression to generalized hydrops fetalis
- Doppler assessment of umbilical and cerebral artery flow
- Amniocentesis to assess
 - Karyotype
 - Infection (polymerase chain reaction [PCR] for cytomegalovirus [CMV] and parvovirus)
 - Genetic or metabolic disease
- Cordocentesis to assess hemoglobin, Coombs test, infection
- Consider diagnostic paracentesis for protein concentration, cultures, and lymphocyte count to determine whether transudate or exudate.
- Begin fetal nonstress test or biophysical profile testing (or both) at viability.

OBSTETRIC MANAGEMENT

- Delivery in a tertiary care facility is recommended.
- Consider therapeutic fetal paracentesis:

- To prevent abdominal dystocia and to facilitate vaginal delivery
- To decrease mechanical compression of the lungs
- To facilitate neonatal resuscitative efforts
- Cesarean delivery is reserved for obstetric indications.

NEONATAL MANAGEMENT

- Neonatal paracentesis should be considered if ascites is causing respiratory compromise.
- Continue diagnostic evaluation to learn underlying etiology of ascites.

PROGNOSIS

- Overall prognosis depends on underlying condition.
 - Best prognosis with chylous ascites (0% mortality)
 - Poor prognosis if ascites is diagnosed before 24 weeks or with associated fetal hydrops (mortality, approximately 75%)
 - Worst prognosis with metabolic storage disease (100% mortality)
- 30%-75% of cases of *isolated* fetal ascites resolve spontaneously.

24B CYSTIC ABDOMINAL LESIONS

Diagnosis

DEFINITION

Cystic abdominal lesions are collections of fluid contained in a distinct membrane, independent from physiologic fluid-containing structures in the fetal abdomen.

INCIDENCE AND PATHOGENESIS

- Excluding renal obstruction or dilated bowel (discussed elsewhere), the most common cystic abdominal masses are functional ovarian cysts in female fetuses. Approximately 30% are born with small follicular cysts.
- Sonographically apparent functional ovarian cysts (>2 cm in diameter) have an incidence of approximately 4/10,000 pregnancies and are seen only in the second half of pregnancy in response to maternal and placental hormones.
- Other abnormal intraabdominal cystic masses are less common and occur because of faulty canalization of gut lumen or deformation of otherwise normal, fluid-containing structures.

DIFFERENTIAL DIAGNOSIS

- Physiologic fluid accumulation in the fetal abdomen, including stomach, bladder, kidney (renal pelvis), gallbladder
- *Abnormal* cystic abdominal masses include
 - **Renal:** pelvicaliceal dilation, renal duplication, megaureter, megacystis, solitary or multiple renal cysts
 - **Bowel:** obstruction, enteric duplication cysts, or meconium pseudocyst
 - **Hepatobiliary:** hepatic, biliary, or choledochal cysts
 - **Reproductive:** ovarian cysts, hydrometrocolpos, or cloaca

- **Other:** splenic, pancreatic, urachal, mesenteric, or omental cysts; adrenal hemorrhage; umbilical vein varix

KEY DIAGNOSTIC FEATURES

- Cysts appear as rounded sonolucent structures in the fetal abdomen.
- The size, number, and location of the cyst (or cysts), along with the fetal sex, help determine the presumptive etiology; however, final diagnosis may not be known in 25%-50% of cases, pending postnatal investigation.
- Cysts may have a mixed echogenic pattern, which represents internal septations, hemorrhage, or calcifications.
- Color flow Doppler imaging may be necessary to distinguish cysts from vascular structures (e.g., umbilical varix, portal vein), and to assess for torsion.
- Fetal MRI may be a useful adjunct to identify the source of the cyst.
- Accurate *prenatal* identification may be unnecessary, unless fetal intervention (e.g., termination, fetal surgery) is planned.

ASSOCIATED ANOMALIES

- All fetal organs need to be assessed to rule out other congenital malformations and genetic syndromes, although cystic abdominal lesions are often isolated.
- Polyhydramnios is common and results from small bowel obstruction caused by compression by a large cyst.
- Ascites may result from a ruptured cyst (or cysts) or transudation.
- Hydronephrosis or ureteromegaly (or both) can be seen with a massively enlarged uterus, with hydrometrocolpos compressing the ureters.
- Meconium pseudocyst can be associated with *cystic fibrosis*.

Imaging

Figure 24-7 Ovarian cyst, sagittal view. Ultrasound image at almost 32 weeks' gestation shows an ovarian cyst in the lower abdomen, inferior and anterior to the fetal kidney. RK, right kidney.

Figure 24-8 Ovarian cyst, axial view. Ultrasound image from the patient seen in Figure 24-7 shows ovarian cyst in the midline lower abdomen. The smaller cyst (arrow) is a "daughter cyst," often seen with ovarian cysts.

Figure 24-9 Choledochal cyst, axial view. Ultrasound image near 21 weeks' gestation shows a cystic mass anterior to the right kidney (RK) in the area of the fetal liver (Video 24-4). The gallbladder appears normal. Sp, spine.

Figure 24-10 Adrenal hemorrhage. Sagittal-view ultrasound image near term demonstrates a cystic mass (arrows) superior to the left kidney (LK). H, heart; St, stomach.

Figure 24-11 Adrenal hemorrhage. This axial image shows a 3-cm cystic mass in the retroperitoneal space of the fetal upper abdomen. The echogenic area in the cyst (arrow) is consistent with a resolving clot. Sp, spine; St, stomach.

Figure 24-12 Hydrometrocolpos. This axial image near term shows a 10-cm septated cystic mass in the lower abdomen. The bladder (BI) is compressed anteriorly. There was concomitant hydronephrosis.

Management

ANTENATAL MONITORING

- Serial ultrasound examinations to monitor fetal growth, amniotic fluid, and worsening fetal condition
- Large (>5 cm) ovarian cysts are at risk for torsion, rupture, and hemorrhage.
 - New fluid levels or mixed echogenicity in an ovarian cyst may represent torsion.
 - Echogenic areas in a cyst may represent hemorrhage or clot formation.
- Fetal nonstress or biophysical profile testing (or both), twice weekly, beginning at 32-34 weeks
- Prenatal neonatology and pediatric surgery consultations to discuss postnatal management and prognosis

OBSTETRIC MANAGEMENT

- Delivery in a tertiary care facility is recommended.
- Cesarean delivery should be considered for cystic abdominal lesions that are large (>5 cm), to prevent rupture and soft tissue dystocia.

- Cyst aspiration before delivery is controversial, as this may cause intracystic bleeding, seeding of malignancy, preterm labor, and infection.

NEONATAL MANAGEMENT

- Continued postnatal investigation, including ultrasound, MRI, and other imaging modalities as appropriate.
- Expectant management may be appropriate, particularly with ovarian cysts, but surgical exploration may be warranted, depending on final postnatal diagnosis and neonatal condition.

PROGNOSIS

- Prenatal or postnatal resolution occurs spontaneously in approximately 25% of isolated fetal abdominal cysts, and in 50% of simple anechoic ovarian cysts noted in utero.
- Approximately one third of liveborn newborns with an abdominal cyst require surgical intervention.
- Long-term prognosis of cystic abdominal lesions depends on the organ involved.
- Perinatal mortality related to a fetal cystic abdominal lesion is approximately 5%.

ECHOGENIC ABDOMINAL LESIONS

Diagnosis

DEFINITION

Echogenic abdominal lesions are areas of abnormal brightness in the fetal abdomen, with echogenicity similar to that of surrounding bone, and producing various amounts of acoustic shadowing.

INCIDENCE AND PATHOGENESIS

- The most common echogenic abdominal lesions are
 - **Echogenic bowel** (approximately 1% of second-trimester pregnancies) results from excessively thick meconium caused by an aperistaltic small bowel. Swallowed blood can also produce an echogenic appearance.
 - **Echogenic hepatic lesions** (5-6/10,000 pregnancies) include echogenic foci on the hepatic *peritoneal surface* caused by meconium peritonitis, and intrahepatic *parenchymal* lesions caused by infection, tumor, or thrombosis (Videos 24-5 and 24-6).
 - **Meconium peritonitis** (3-4/10,000 live births) is caused by in utero bowel perforation and resultant chemical peritonitis.

DIFFERENTIAL DIAGNOSIS

- **Bowel:** aneuploidy, TORCH (*toxoplasmosis, other* [e.g., syphilis, parvovirus B19, varicella], *rubella*, cytomegalovirus [CMV], *herpesvirus*) infection, meconium ileus, cystic fibrosis, placental hemorrhage, ischemia, or normal variant
- **Hepatobiliary:** TORCH infection, hemangioma, hamartoma, cholelithiasis
- **Renal:** infantile polycystic kidney disease, nephroma, Wilms tumor
- **Peritoneal:** meconium peritonitis, meconium pseudocyst

- **Other:** teratoma, adrenal neuroblastoma, adrenal hemorrhage, subdiaphragmatic extrapulmonary sequestration, normal variant

KEY DIAGNOSTIC FEATURES

- Echogenic lesions appear as bright echodense structures in the fetal abdomen (Video 24-7).
- For bowel to be considered echogenic, it should be “bright as bone” and persist with harmonic-enhanced imaging disabled.
- *Meconium peritonitis* appears as multiple echogenic foci in the visceral and parietal peritoneum.
- *Meconium pseudocyst* appears in the area of perforated bowel as a hypoechoic structure surrounded by an irregular hyperechoic wall.
- The size, number, and location of the echogenic lesion (or lesions), along with other associated abnormalities, helps determine the presumptive etiology.
- Fetal MRI may be a useful adjunct to identify echogenic abdominal lesions.
- Maternal α -fetoprotein (AFP) and human chorionic gonadotropin (hCG) may be helpful in determining etiology and prognosis.

ASSOCIATED ANOMALIES

- All fetal organs need to be assessed to rule out other congenital malformations and genetic syndromes.
 - Approximately 50% of patients with echogenic bowel have other structural abnormalities or fetal growth restriction (or both).
 - Aneuploidy (trisomy 13, 18, 21, triploidy) is present in up to 10%.
 - *Cystic fibrosis* is present in 13%-40% of patients with meconium ileus.
 - TORCH infections are present in 10%.

Imaging

Figure 24-13 Echogenic bowel, sagittal view. Ultrasound image at 22 weeks' gestation shows echogenic bowel in the lower abdomen (arrows), in a case associated with cystic fibrosis.

Figure 24-14 Echogenic bowel, axial view. Ultrasound image of the patient seen in Figure 24-13 again shows markedly echogenic bowel (arrows), without acoustic shadowing. Sp, spine.

Figure 24-15 Intrahepatic mass, axial view. Ultrasound image at 21 weeks shows typical echogenic mass in the fetal liver (arrow). Note the minimal shadowing beneath the lesion. St, stomach.

Figure 24-16 Intrahepatic mass, coronal view. Ultrasound image at 25 weeks demonstrates a solitary 4.6-mm intrahepatic echogenic lesion (arrow). Again there is minimal acoustic shadowing beneath the lesion.

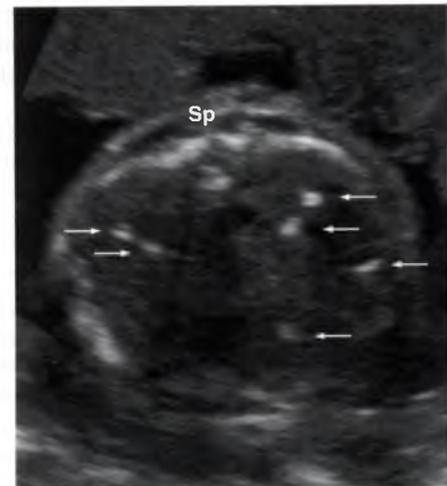

Figure 24-17 Meconium peritonitis. Ultrasound image shows multiple echogenic foci (arrows) in the fetal abdomen, representing meconium peritonitis. Sp, spine.

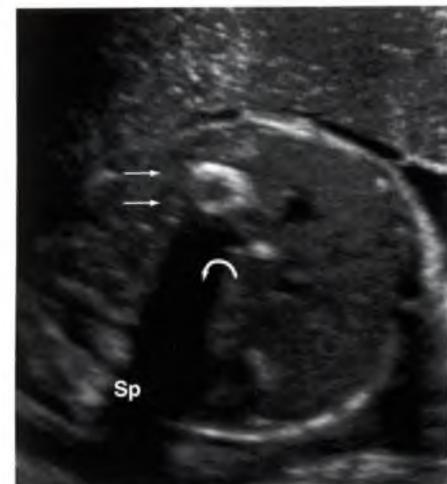

Figure 24-18 Meconium pseudocyst. Axial view at 29 weeks shows the echogenic, circular appearance of a meconium pseudocyst (arrows) in the left fetal abdomen. Note the acoustic shadowing under the lesion (curved arrow). Sp, spine.

Management

ANTENATAL MONITORING

- Amniocentesis should be considered for karyotype, cystic fibrosis gene mutation(s), and polymerase chain reaction (PCR) testing for intra-amniotic infection (e.g., CMV), depending on location and appearance of echogenic lesions seen on ultrasound.
- Maternal blood samples for cystic fibrosis carrier status and for TORCH titers (IgM and IgG)
- Serial ultrasound examinations to monitor fetal growth, amniotic fluid, and worsening fetal condition (e.g., hydrops fetalis)
- Fetal nonstress or biophysical profile testing (or both), twice weekly, beginning at 32-34 weeks

OBSTETRIC MANAGEMENT

- Delivery in a tertiary care facility is recommended.
- Cesarean delivery is reserved for obstetric indications.

NEONATAL MANAGEMENT

- Continue postnatal investigation, including ultrasound, plain radiography of the abdomen, upper and lower

gastrointestinal tract barium studies, MRI, and other imaging modalities as appropriate.

- Expectant management may be appropriate, depending on final postnatal diagnosis and neonatal condition; however, surgical treatment may be warranted (e.g., bowel obstruction with or without perforation).

PROGNOSIS

- Approximately 50% of cases of isolated echogenic bowel resolve spontaneously prenatally.
- Isolated singular intrahepatic echogenic lesions generally have a good outcome; multiple intrahepatic lesions are more often associated with infection and a poorer prognosis.
- Approximately 50% of liveborn newborns with meconium peritonitis require surgical intervention for bowel obstruction.
- Long-term prognosis of echogenic abdominal lesions depends most on other associated abnormalities or underlying disease (e.g., aneuploidy, infection).
- Assuming no chromosome defects, cystic fibrosis, infection, growth restriction, or other associated anatomic abnormalities, the prognosis is good for normal outcome.
- Perinatal mortality related to a fetal echogenic abdominal lesion is approximately 5%-10%.

24D GASTROSCHISIS

Diagnosis

DEFINITION

Gastroschisis is a full-thickness paraumbilical defect through which bowel herniates. In distinction to an omphalocele, the bowels are not enveloped by a membrane.

INCIDENCE AND PATHOGENESIS

- The incidence of gastroschisis is approximately 5/10,000 live births; global incidence is increasing.
- The embryogenesis of gastroschisis is unclear. Proposed theories include
 - Abnormal involution with vascular compromise of the right umbilical vein results in mesenchymal damage and weakened abdominal wall.
 - Vascular accident involving the right omphalomesenteric artery with ischemia of the body wall at the umbilical cord insertion site
- Risk factors for developing gastroschisis include young maternal age, smoking, vasoactive drug use, and low socioeconomic status.

DIFFERENTIAL DIAGNOSIS

- Normal physiologic gut herniation
 - Occurs between 6th and 10th weeks of embryonic development
 - Loops of intestine herniate, rotate about the superior mesenteric artery, and return to the abdominal cavity.
 - Gut herniation persisting beyond 12 weeks is probably gastroschisis.
- Ruptured omphalocele
- Limb-body wall complex
- Umbilical cord cysts
- Urachal cysts

- Loops of normal umbilical cord
- Bladder or cloacal exstrophy
- Pentalogy of Cantrell

KEY DIAGNOSTIC FEATURES

- Multiple loops of bowel are seen floating freely in the amniotic fluid, with a typical cauliflower appearance.
- Abdominal wall defect is typically located to the right of the abdominal cord insertion; left-sided defects are less common (Video 24-8).
- Intraabdominal and extraabdominal dilated loops of bowel may be seen late in pregnancy.
- Maternal serum α -fetoprotein is elevated.
- Excluding omphalocele is important because up to 40% of omphalocele cases are associated with aneuploidy; *isolated* gastroschisis is not typically associated with aneuploidy, making amniocentesis unwarranted.

ASSOCIATED ANOMALIES

- Approximately 85% of gastroschisis cases occur in isolation.
- Intrauterine growth restriction and oligohydramnios are common.
- Gastrointestinal malformations can include bowel atresia, malrotation, volvulus, and perforation.
 - Vessels are constricted at the level of the abdominal defect.
 - Torsion of the mesentery leads to bowel ischemia and necrosis.
 - Polyhydramnios is suggestive of bowel atresia.
- Nongastrointestinal abnormalities (e.g., arthrogryposis, cardiac defects, genitourinary anomalies) are infrequent (<5%).

Imaging

Figure 24-19 Gastrochisis, sagittal view. Ultrasound image at 20 weeks' gestation shows gastrochisis in the lower abdomen (arrows), with typical cauliflower appearance.

Figure 24-20 Gastrochisis, axial view. Ultrasound image at 20 weeks' gestation shows gastrochisis mass (arrows) extending to the right side of the umbilical cord insertion (Video 24-9). Bl, bladder.

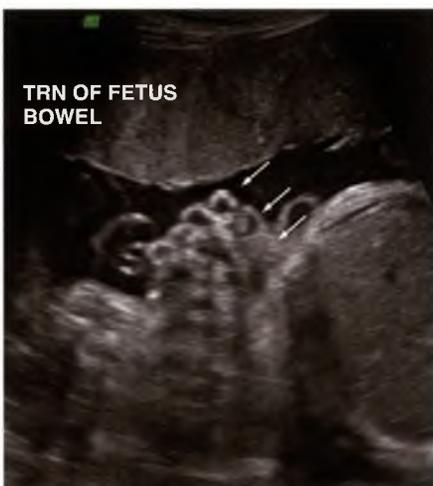

Figure 24-21 Mildly dilated bowel. Axial-view ultrasound image shows typical mild extraabdominal bowel dilation with gastrochisis (arrows) in a near-term fetus.

Figure 24-22 Markedly dilated bowel. Axial-view ultrasound image demonstrates gastrochisis near term with marked intraabdominal and extraabdominal bowel dilation (*); maximal dilation is 25 mm. St, stomach.

Figure 24-23 Physiologic gut herniation. This axial ultrasound image at 11 weeks shows significant herniation of abdominal contents (arrows), causing concern for gastrochisis.

Figure 24-24 Physiologic gut herniation. This axial view at 13 weeks in the fetus seen in Figure 24-23 shows complete resolution of physiologic gut herniation at the abdominal cord insertion (arrow).

Management

ANTENATAL MONITORING

- Serial ultrasound examinations to monitor fetal growth, amniotic fluid, and worsening bowel distention
 - Data about whether bowel dilation is a poor prognostic sign or an indication for immediate delivery are inconsistent.
- Doppler assessment of umbilical and cerebral artery flow
- Fetal echocardiogram to confirm normal anatomy
- Fetal nonstress or biophysical profile testing (or both), twice weekly, beginning at 32-34 weeks
- Prenatal neonatology and pediatric surgery consultation to discuss postnatal management and prognosis

OBSTETRIC MANAGEMENT

- Delivery in a tertiary care facility is recommended.
- Cesarean delivery is reserved for obstetric indications.
 - Systematic reviews and retrospective case series have shown no neonatal or long-term benefit with elective cesarean delivery.
 - In many cases, a nonreassuring fetal status necessitates cesarean delivery.

SUGGESTED READINGS

Adra AM, Landy HJ, Nahmias J, et al: The fetus with gastroschisis: impact of route of delivery and prenatal ultrasonography, *Am J Obstet Gynecol* 174: 540-546, 1996.

David AL, Tan A, Curry J: Gastroschisis: sonographic diagnosis, associations, management and outcome, *Prenat Diagn* 28:633-644, 2008.

Drewett M, Michailidis GD, Burge D: The perinatal management of gastroschisis, *Early Hum Dev* 82:305-312, 2006.

Durfee SM, Downard CD, Benson CB, et al: Postnatal outcome of fetuses with the prenatal diagnosis of gastroschisis, *J Ultrasound Med* 21:269-274, 2002.

NEONATAL MANAGEMENT

- Intravenous fluid hydration
- Orogastric or nasogastric decompression
- Protect herniated bowel from heat loss and dehydration by placing baby in a sterile plastic bag up to the trunk.
- Surgical repair
 - Primary closure with reduction of bowel into the peritoneal cavity
 - Staged silo closure to gradually replace bowel into abdomen

PROGNOSIS

- Survival in uncomplicated cases exceeds 90%.
- Long stays in the neonatal ICU are typical, taking 30 days on average to achieve enteral feeds.
- Short-term complications include necrotizing enterocolitis (4%-10%) and central line infection (up to 24%). Long-term complications include dysfunctional bowel (50%) and short bowel syndrome (5%).

24E INTESTINAL ATRESIAS

Diagnosis

DEFINITION

Intestinal *atresia* is complete obstruction of the bowel lumen; *stenosis* is a narrowing of the lumen of the fetal bowel. Both produce a distended proximal gastrointestinal tract.

INCIDENCE AND PATHOGENESIS

- Intestinal atresias occur in approximately 1-3/10,000 live births; *colonic* atresia accounts for less than 10% of all intestinal atresias.
- The causes of intestinal atresias vary by location of the obstruction:
 - *Duodenal atresia*: lack of revacuolization during the solid-core stage of embryonic intestinal development
 - *Jejunoileal* and *colonic atresias*: vascular accident, resulting from intestinal volvulus, intussusception, internal hernia, or strangulation in the case of tight abdominal wall defect with gastroschisis or omphalocele.

DIFFERENTIAL DIAGNOSIS

- Mildly dilated, normal colon
- Markedly distended, normal fetal stomach or gallbladder
- Meconium ileus, particularly associated with cystic fibrosis
- Hirschsprung disease
- Hydroureter
- Hydrocolpos
- Umbilical vein varix
- Other abdominal cystic masses can mimic distended bowel:
 - Choledochal cysts
 - Ovarian cysts
 - Duplication cysts
 - Mesenteric cysts
 - Renal cysts
 - Splenic cyst
 - Urachal cyst

KEY DIAGNOSTIC FEATURES

- Bowel loops greater than 7 mm suggest obstruction; normal colon diameter varies with gestational age (Fig. 24-25).
- Duodenal atresia produces the classic echolucent “double-bubble,” which represents the dilated stomach and proximal duodenum (Videos 24-10 and 24-11).
 - A thin echolucent connection between these two structures confirms this diagnosis.

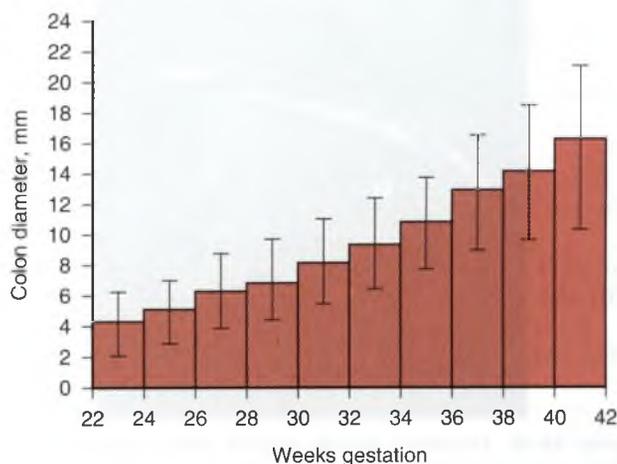

Figure 24-25 Normal colon diameters in the fetus. Bar graph shows normal progression of colon diameter with increasing gestational age. (Adapted and redrawn from Harris RD, Nyberg DA, Weinberger E: *Anorectal atresia: prenatal sonographic diagnosis*, AJR Am J Roentgenol 149:395-400, 1987.)

- Polyhydramnios is typical in cases of duodenal atresia and is particularly marked in the third trimester.
- Jejunoileal atresia produces multiple dilated loops of bowel with increased proximal peristalsis.
- Distal lesions are difficult to diagnose prenatally; many cases of jejunoileal and colonic atresia may remain undetected before delivery.
- Careful sonographic anatomic survey is needed to detect other anomalies.

ASSOCIATED ANOMALIES

- Nearly half of intestinal atresia cases have an associated abnormality.
- Trisomy 21 is present in up to 30% of duodenal atresia cases.
- Congenital heart defects (e.g., atrial and ventricular septal defects)
- Malrotation
- Meconium ileus and peritonitis
- Volvulus
- Annular pancreas
- Esophageal atresia
- Genitourinary malformations
- Anorectal atresia
- Ventral wall defects
- Skeletal defects

Imaging

Figure 24-26 Duodenal atresia, sagittal view. Ultrasound image shows distended, fluid-filled stomach (St) and duodenum (Du), connected at the pylorus (arrow).

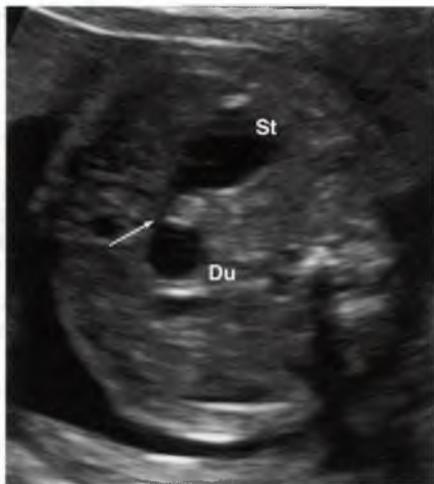

Figure 24-27 Duodenal atresia, axial view. Ultrasound image of the fetal abdomen shows distended stomach (St) and duodenum (Du), connected at the pylorus (arrow).

Figure 24-28 Extremely distended stomach. Axial-view ultrasound image of the fetal abdomen shows massively distended stomach (St) and duodenum (Du) in later pregnancy.

Figure 24-29 Colonic atresia, sagittal view. Ultrasound image shows a massively dilated transverse colon. The maximal dilation (solid calipers) is 33 mm. The stomach and amniotic fluid were normal. Bl, bladder.

Figure 24-30 Colonic atresia, axial view. Ultrasound image shows dilated colon, measuring 35 mm (calipers), and dilated loops of bowel (*). Haustra are visible (arrow). The stomach (St) appears to be of normal size.

Figure 24-31 Anorectal atresia. Ultrasound image shows markedly dilated colon with echogenic meconium resembling a bag of marbles.

Management

ANTENATAL MONITORING

- Monitor fetal growth, amniotic fluid, worsening bowel distention, and progression to bowel perforation with meconium peritonitis.
- Amniocentesis to assess karyotype, cystic fibrosis status
- Fetal echocardiogram
- Consider MRI to determine level of obstruction.
- Fetal nonstress or biophysical profile testing (or both) in the third trimester
- Pediatric surgery consultation

OBSTETRIC MANAGEMENT

- Delivery in a tertiary care facility is recommended.
- Therapeutic amnioreduction may reduce the risk of preterm labor and prolapsed umbilical cord or abruption with rupture of membranes.
- Cesarean delivery is reserved for obstetric indications.

NEONATAL MANAGEMENT

- Orogastric or nasogastric decompression to prevent aspiration
- IV fluid hydration
- Confirm diagnosis of intestinal atresia.
 - Plain abdominal radiograph
 - Upper gastrointestinal contrast-enhanced radiograph
 - Barium enema

- Surgical management depends on site of lesion and associated conditions. Most are treated with primary anastomosis.
 - Duodenal atresia is treated with direct duodenojejunostomy or duodenoduodenostomy.
 - Jejunioileal atresia is managed with tapering enteroplasty or intestinal plication.
 - Colonic atresia is repaired with primary anastomosis.

PROGNOSIS

- Overall prognosis depends on level of lesion and other associated anomalies, particularly aneuploidy.
- Survival data have shown improvement over time from approximately 60% in the 1960s and 1970s, to 90%-100% in the 1990s and 2000s.
- Jejunioileal atresia has consistently lower survival (60%-90%) as a result of short bowel syndrome.
- Chronic total parenteral nutrition may lead to cholestasis and subsequent liver damage.
- Small bowel transplantation may be necessary, with a 5-year patient survival rate of 55%; the survival rate after grafting is 45%.

24F OMPHALOCELE

Diagnosis

DEFINITION

Omphalocele is a midline ventral wall defect, with bowel or liver (or both) herniating through the base of the umbilicus and covered by a membrane consisting of peritoneum and amnion.

INCIDENCE AND PATHOGENESIS

- The incidence of omphalocele is approximately 0.5-1/10,000 live births.
- Omphalocele results from a defect in the lateral folding in the embryo, with failure of abdominal wall closure at the umbilical ring and persistence of intestinal loops or liver (or both) in the umbilical cord stalk after physiologic gut herniation.
- Risk factors for developing omphalocele include advanced maternal age (>35 years) and assisted reproductive technology (ART).

DIFFERENTIAL DIAGNOSIS

- Normal physiologic gut herniation (see Gastroschisis)—*never includes liver*
- Gastroschisis
- Limb-body wall complex
- Umbilical hernia
- Umbilical cord cysts and pseudocysts
- Allantoic cyst
- Bladder or cloacal exstrophy

KEY DIAGNOSTIC FEATURES

- Midline mass is seen at the base of the umbilical cord, with the liver and bowel herniating from the abdominal cavity, surrounded by a smooth, limiting membrane (Video 24-12).

- The umbilical cord passes *through the mass* and inserts on the membranes. This key feature distinguishes omphalocele from gastroschisis in cases of ruptured omphalocele sac (Video 24-13).
- Ascites may be seen in the omphalocele sac.
- The absence of liver in the omphalocele sac (intracorporeal liver) is strongly associated with aneuploidy.
- Maternal serum α -fetoprotein is not uniformly elevated with omphalocele.

ASSOCIATED ANOMALIES

- Meticulous assessment of all fetal organs is needed to rule out other congenital malformations and genetic syndromes.
- Approximately 70% of omphaloceles have other associated malformations:
 - Cardiac defects (up to 50%)
 - Gastrointestinal atresia (40%)
 - Renal anomalies
 - Central nervous system malformations (e.g., agenesis of the corpus callosum, hydrocephalus)
 - Duplication cysts
- Up to 40% have chromosome abnormalities (trisomy 13, 18, 21; Turner syndrome; triploidy).
- Polyhydramnios is common.
- Omphalocele can be a component of a syndrome:
 - Beckwith-Wiedemann syndrome
 - Pentalogy of Cantrell
 - OEIS complex (omphalocele, exstrophy, imperforate anus, and spinal anomalies)

Imaging

Figure 24-32 Omphalocele, sagittal view. Ultrasound image at 18 weeks' gestation shows omphalocele in the lower abdomen (arrows), surrounded by a smooth-appearing sac.

Figure 24-33 Omphalocele, axial view. Ultrasound image at 18 weeks' gestation shows omphalocele mass (arrows) extending from the midline abdominal wall, with the portal vein (Pv) coursing through the mass. The fetal stomach (ST L) is located within the left side of the fetal abdomen (single arrow).

Figure 24-34 Omphalocele with ascites. Axial-view ultrasound image shows typical echolucent ascites seen in the omphalocele sac (arrows). The portal vein (Pv) is passing through the mass. St, stomach.

Figure 24-35 Umbilical cord insertion. Axial-view ultrasound image shows the umbilical cord (arrows) inserting onto the omphalocele sac, which measures approximately 39 mm. St, stomach.

Figure 24-36 Omphalocele. Three-dimensional rendered image at 14 weeks' gestation. The large, smooth-walled sac in the anterior abdominal wall is an early omphalocele.

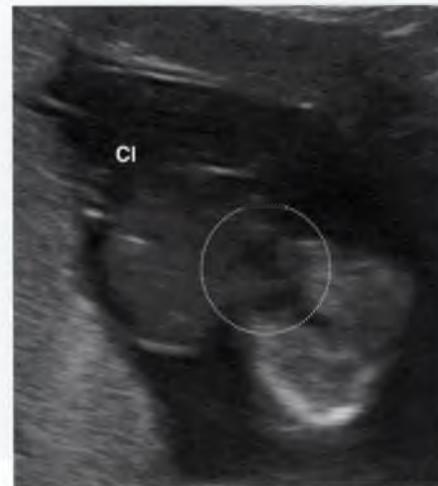

Figure 24-37 Pentology of Cantrell. This axial view at 13 weeks shows the fetal heart (circle) herniating through a large ventral wall defect in a case of pentology of Cantrell. CI, cord insertion.

Management

ANTENATAL MONITORING

- Amniocentesis is recommended because of the high risk of aneuploidy associated with omphalocele.
- Fetal echocardiogram to confirm normal anatomy
- Serial ultrasound examinations to monitor fetal growth, amniotic fluid, and worsening fetal condition
- Fetal nonstress or biophysical profile testing (or both), twice weekly, beginning at 32-34 weeks
- Prenatal neonatology and pediatric surgery consultation to discuss postnatal management and prognosis

OBSTETRIC MANAGEMENT

- Delivery in a tertiary care facility is recommended.
- Cesarean delivery is recommended for large (>5 cm) omphalocele mass, particularly when containing liver; fetuses with a smaller omphalocele can be delivered vaginally.
 - Nonreassuring fetal status will necessitate cesarean delivery in many cases.

NEONATAL MANAGEMENT

- Intravenous fluid hydration
- Orogastric or nasogastric decompression

- Protect omphalocele sac with moist, nonadherent dressings (e.g., Xeroform), followed by a mildly compressive gauze wrap around the abdomen, but not so tight as to restrict ventilation or distort the sac.
- Surgical repair
 - Primary closure with reduction of bowel is possible if omphalocele is small (<5 cm).
 - Staged closure for larger omphaloceles after mild compression, or silo closure to gradually reduce bowel before surgery
 - “Paint and wait”: coat sac with antimicrobial agent (e.g., Silvadene) and allow sac to epithelialize.

PROGNOSIS

- Increased risk of in utero and neonatal demise, regardless of defect size or liver position with omphalocele
- Survival in cases with *isolated* omphalocele is approximately 80%; survival with concomitant abnormalities is as low as 10%-20%.
- Short-term complications include infection, respiratory insufficiency, and abdominal compartment syndrome.
- Long stays in the neonatal ICU are typical, with a need for long-term ventilatory support.
- Long-term prognosis depends on whether omphalocele is part of a syndrome; psychomotor development is often delayed.

SUGGESTED READINGS

Urogenital Imaging

RICHARD B. WOLF, DO, MPH

25A BLADDER EXSTROPHY

Diagnosis

DEFINITION

Bladder exstrophy is a lower ventral wall defect that results in an open and everted bladder that drains directly into the amniotic cavity.

INCIDENCE AND PATHOGENESIS

- Bladder exstrophy occurs in 1/25,000 to 1/40,000 live births, with a male-to-female ratio of 2:1.
- Caused by the persistence of the cloacal membrane, which prevents mesoderm fusion and proper lower abdominal wall development. The cloacal membrane ruptures, exposing the urinary bladder and posterior urethra.

DIFFERENTIAL DIAGNOSIS

- Cloacal exstrophy
- Omphalocele
- Gastroschisis
- *Transient* nonvisualization of a normal bladder as a result of recent fetal urination (watch for >30 minutes)
- Other causes of persistent nonvisualized bladder:
 - Dysplastic kidneys
 - Renal agenesis
 - Placental insufficiency

KEY DIAGNOSTIC FEATURES

- *Persistent* (>30 minutes) absent bladder in the absence of other causes for nonvisualized bladder (Video 25-1)
- *Normal* amniotic fluid
- Isoechoic mass inferior to the abdominal cord insertion on axial or sagittal imaging
- Abdominal cord insertion is displaced inferiorly.
- Male genitalia are displaced superiorly and may appear ambiguous.

ASSOCIATED ANOMALIES

- Epispadias, short phallus, and undescended testicles in males
- Bifid clitoris, wide separation of the labia, and vaginal duplication in females
- Bilateral inguinal hernias (males 82%, females 11%)
- Pubic diastasis
- OEIS complex (*omphalocele, exstrophy of the bladder, imperforate anus, spinal deformities*)

Imaging

Figure 25-1 Absent bladder. Color Doppler imaging demonstrates the umbilical arteries without interspaced echolucent bladder visualized despite prolonged monitoring. Note normal amniotic fluid.

Figure 25-2 Bladder exstrophy, axial view. Ultrasound image shows area of “absent” bladder with an irregular suprapubic mass at the body surface (arrowheads).

Figure 25-4 Suprapubic exophytic mass. Irregular suprapubic exophytic mass (arrows) seen at 20 weeks' gestation in a patient with bladder exstrophy, representing the open bladder mucosa.

Figure 25-3 Bladder exstrophy, sagittal view. Ultrasound image shows a mixed echogenic mass along the anterior surface of the suprapubic area (arrowheads). No bladder is visualized.

Figure 25-5 Displaced phallus. Male fetus at 32 weeks with bladder exstrophy with ambiguous-appearing genitalia and superiorly displaced genitalia (arrows).

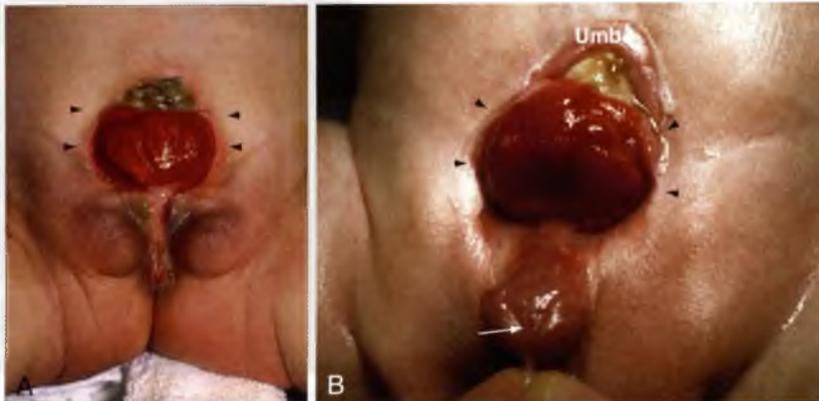

Figure 25-6. Postnatal appearance. A, Female infant with bladder exstrophy (arrowheads). The labia majora are widely separated with superiorly displaced vaginal introitus. B, Male infant with bladder exstrophy (arrowheads). The glans penis is being retracted inferiorly to demonstrate the epispadias (arrow). (Courtesy of George Kaplan, MD, Pediatric Urology, Rady Children's Hospital, San Diego, CA.)

Management

ANTENATAL MONITORING

- Consider amniocentesis to rule out aneuploidy and determine gender.
- Serial ultrasound examinations to monitor fetal growth and amniotic fluid
- Amniotic fluid assessment at least weekly, beginning at 32-34 weeks
- Prenatal neonatology and pediatric urology consultation to discuss postnatal management and prognosis

OBSTETRIC MANAGEMENT

- Delivery at a tertiary care facility is recommended to promote early postnatal surgical repair.
- Cesarean delivery is reserved for obstetric indications.

NEONATAL MANAGEMENT

- Protect herniated bladder against dehydration by placing baby in a sterile plastic bag up to the trunk.
- Antibiotic prophylaxis

- Postnatal renal assessment:
 - Renal ultrasound
 - Pelvic MRI
 - Nuclear medicine renography
- Pediatric urology consultation
- Staged surgical management:
 - Bladder and abdominal wall closure within first 72 hours
 - Genital reconstruction at 6-12 months
 - Bladder neck reconstruction and ureteral reimplantation at 4-5 years to improve continence and prevent vesicoureteral reflux

PROGNOSIS

- Overall survival prognosis is excellent but depends on surgical repair and other concomitant anomalies.
- Quality of life issues:
 - Urinary incontinence, 25%
 - Erectile dysfunction, 25%
 - Male infertility, 90%
 - Female infertility, 75%
- Malignancy (bladder or colon carcinoma), 17%
- Women are predisposed to vaginal uterine prolapse.

SUGGESTED READINGS

25B ECHOGENIC DYSPLASTIC KIDNEYS

Diagnosis

DEFINITION

Echogenic dysplastic kidneys appear abnormally bright on ultrasound, indicative of abnormal renal parenchyma and suggesting abnormal function.

INCIDENCE AND PATHOGENESIS

- Autosomal dominant polycystic kidney disease (ADPKD), also known as “adult” PKD
 - Frequency is 1/1000 live births.
 - Mutations in the *PKD-1* or *PKD-2* genes encode abnormal proteins, *polycystins*, leading to upregulation of cellular proliferation, and large cysts form throughout the nephron, with concurrent interstitial fibrosis.
 - May not be discovered until hypertension and renal failure appear in adulthood
- Autosomal recessive polycystic kidney disease (ARPKD), also known as “infantile” PKD
 - Frequency is 1/40,000 live births.
 - Mutations in the *PKHD-1* gene encode abnormal proteins, *fibrocystins*, causing numerous small cysts to form in the collecting tubules
- Obstructive cystic dysplasia
 - Frequency is 1/8000 live births.
 - Pressure from chronic first- or second-trimester urinary tract obstruction (e.g., posterior urethral valves) damages the nephron, with subsequent renal involution.

DIFFERENTIAL DIAGNOSIS

- Multicystic dysplastic kidney
- Glomerulosclerosis
- Tuberous sclerosis
- Infection (e.g., cytomegalovirus [CMV])
- Renal vein thrombosis
- Adrenal neuroblastoma or hematoma
- Normal variant

KEY DIAGNOSTIC FEATURES

- ADPKD
 - Enlarged echogenic kidneys
 - Normal bladder
 - Normal amniotic fluid
 - Parent (or both parents) with renal cysts
- ARPKD
 - Massive echogenic kidneys
 - Small or absent bladder
 - Oligohydramnios
 - Affected siblings possible
- Obstructive cystic dysplasia
 - *Small* echogenic kidneys
 - Oligohydramnios if bilateral
 - Early ultrasound may show dilated bladder, ureter, kidney
- To be considered echogenic, the kidneys appear *brighter than the liver* (Video 25-2).
- The fetal kidneys should be measured and compared with standard reference tables.
- Kidney size may be normal at <20 weeks' gestation.

ASSOCIATED ANOMALIES

- Meticulous assessment of all fetal organs is needed to rule out other congenital malformations and genetic syndromes.
- Syndromes associated with enlarged echogenic kidneys
 - Beckwith-Wiedemann
 - Meckel-Gruber
 - Finnish-type nephrotic syndrome (high level of α -fetoprotein [AFP])
 - Perlman syndrome
- VACTERL association (*vertebral abnormality, anal atresia, cardiac defect, tracheoesophageal fistula, renal and radial limb abnormality*)
- Aneuploidy (trisomy 13, 18, 21)
- Oligohydramnios

Imaging

Figure 25-7 Suspect kidneys. This coronal view at 27 weeks' gestation shows bilaterally prominent-appearing kidneys with multiple small cysts. This finding warrants repeat imaging.

Figure 25-10 Echogenic kidneys, coronal view. Ultrasound image of the fetus seen in Figure 25-8 with bilaterally echogenic kidneys but normal bladder (Bl).

Figure 25-8 Echogenic kidneys, axial view. Ultrasound image at 31 weeks' gestation shows bilaterally echogenic kidneys, but normal amniotic fluid, consistent with autosomal dominant polycystic kidney disease.

Figure 25-11 Massively enlarged kidneys. This coronal ultrasound image at 20 weeks' gestation shows massively enlarged echogenic kidneys (*calipers*). The fetus also had a posterior encephalocele, consistent with Meckel-Gruber syndrome.

Figure 25-9 Echogenic kidneys, sagittal view. Ultrasound image of the fetus seen in Figure 25-8 shows echogenic kidney consistent with autosomal dominant polycystic kidney disease.

Figure 25-12 Enlarged kidneys. This axial view of the fetus seen in Figure 25-11 shows the distended abdominal circumference caused by massively enlarged kidneys filling the abdomen in Meckel-Gruber syndrome.

Management

ANTENATAL MONITORING

- Amniocentesis should be considered, particularly if there are other associated anomalies or to test for genetic markers.
- TORCH (*toxoplasmosis, other agents, rubella, cytomegalovirus, and herpes simplex*) titers if other findings indicate possible intrauterine infection
- Fetal echocardiogram to rule out associated congenital heart defects
- Referral to genetic counselor or geneticist to obtain detailed family history of inherited renal disease
- Parental renal ultrasound to assess possible inherited renal disease
- Consider termination if ARPKD or anhydramnios is suspected.
- Serial ultrasound examinations to monitor fetal growth, amniotic fluid, and general fetal condition
- Fetal nonstress or biophysical profile testing (or both), twice weekly, beginning at 32–34 weeks
- Prenatal neonatology and pediatric nephrology consultation to discuss postnatal management and prognosis

OBSTETRIC MANAGEMENT

- Delivery at a tertiary care facility is recommended.
- Cesarean delivery may be necessary to prevent abdominal dystocia from massively enlarged kidneys.

SUGGESTED READINGS

Chaumoitre K, Brun M, Cassart M, et al: Differential diagnosis of fetal hyperechogenic cystic kidneys unrelated to renal tract anomalies: a multicenter study, *Ultrasound Obstet Gynecol* 28:911–917, 2006.

Estroff JA, Mandell J, Benacerraf BR: Increased renal parenchymal echogenicity in the fetus:

importance and clinical outcome, *Radiology* 181:135–139, 1991.

Tsatsaris V, Gagnadoux MF, Aubry MC, et al: Prenatal diagnosis of bilateral isolated fetal hyperechogenic kidneys: is it possible to predict long term outcome? *Br J Obstet Gynaecol* 109:1388–1393, 2002.

Winyard P, Chitty L: Dysplastic and polycystic kidneys: diagnosis, associations and management, *Prenat Diagn* 21:924–935, 2001.

NEONATAL MANAGEMENT

- Renal ultrasound, voiding cystourethrogram (VCUG), and nuclear renography
- Monitor serum creatinine and blood urea nitrogen.
- Pediatric nephrology consultation

PROGNOSIS

- Hyperechoic renal parenchyma is associated with abnormal renal function in 80% of cases.
- Short-term prognosis depends most on amniotic fluid.
 - Oligohydramnios or anhydramnios is associated with a poor prognosis, with neonatal mortality resulting from pulmonary hypoplasia or renal failure (or both).
 - Normal or increased amniotic fluid is associated with a good prognosis for neonatal survival.
- Long-term survivors will probably develop hypertension, frequent urinary tract infections, and end-stage renal failure requiring dialysis or transplant (or both).

25C MULTICYSTIC KIDNEY

Diagnosis

DEFINITION

Multicystic kidney, also known as multicystic dysplastic kidney (MCDK), is an abnormally functioning kidney in which normal renal tissue is replaced by various-sized cysts.

INCIDENCE AND PATHOGENESIS

- Multicystic dysplastic kidney is seen in 1/4000 live births.
- Male-to-female ratio is approximately 2:1, but female fetuses are more likely to have bilateral MCDK and other nonrenal anomalies.
- Pathogenesis of MCDK disease is probably the result of obstruction in the metanephric stage of embryogenesis, causing atresia of the ureteral bud, with subsequent enlarged and noncommunicating collecting tubules forming cysts.

DIFFERENTIAL DIAGNOSIS

- Autosomal dominant (“adult”) or autosomal recessive (“infantile”) polycystic kidney disease
- Obstructive cystic dysplasia
- Tuberous sclerosis
- Simple isolated renal cyst (or cysts)
- Pyelectasis or hydronephrosis
- Ureteromegaly
- Adrenal hemorrhage

KEY DIAGNOSTIC FEATURES

- Multiple irregular *noncommunicating* echolucent cysts are seen in the kidney, with the intervening parenchyma mildly echogenic because of compression by the cysts (Videos 25-3 and 25-4).
- Normal reniform outline is lost.
- Sonographic appearance can change over time.

ASSOCIATED ANOMALIES

- Approximately 25% of contralateral kidneys have urologic defects:
 - Vesicoureteral reflux
 - Ureteropelvic junction (UPJ) obstruction
 - Ureterovesical junction (UVJ) obstruction
 - Ectopic ureter
 - Renal agenesis
- Compensatory hypertrophy of the normal contralateral kidney is typical.
- Oligohydramnios or anhydramnios may be present if bilateral disease.
- Approximately 35% of cases have associated nonrenal abnormalities, including cardiac, gastrointestinal, spine, extremity, central nervous system, and facial anomalies; single umbilical artery (two-vessel cord) is common.
- MCDK can be seen in over 80 syndromes (e.g., VATER [vertebral defects, imperforate anus, tracheoesophageal fistula, renal defects], VACTERL [vertebral abnormality, anal atresia, cardiac defect, tracheoesophageal fistula, renal and radial limb abnormality])
- Aneuploidy is possible, but typically there are other nonrenal congenital anomalies.

Imaging

Figure 25-13 Multicystic kidney. Sagittal image of multicystic dysplastic kidney, showing numerous noncommunicating echolucent cysts in the renal parenchyma.

Figure 25-14 Multicystic kidney. Coronal view of multicystic dysplastic kidney, with enlarged-appearing renal length resulting from the multiple cystic masses.

Figure 25-15 Normal contralateral kidney. In this coronal view, the right kidney (between arrows) appears to have multiple cysts, but the contralateral kidney (arrowheads) appears normal.

Figure 25-16 Possible duplication. In this sagittal image, there is a large dominant cyst (calipers) suggestive of renal duplication with an obstructed ectopic ureter. There are also multiple noncommunicating cysts.

Figure 25-17 Contralateral agenesis. Coronal image shows multicystic dysplastic kidney with an absent contralateral kidney and anhydramnios. The neonate expired of pulmonary hypoplasia.

Figure 25-18 Pelvic kidney. This coronal image shows a multicystic kidney (arrowheads) just above the fetal bladder (BI), consistent with a pelvic kidney. The contralateral kidney was in the normal position.

Management

ANTENATAL MONITORING

- Amniocentesis should be considered if there are other associated anomalies.
- Consider fetal echocardiogram to rule out heart defect.
- Consider termination if bilateral MCDK or anhydramnios is suspected.
- Serial ultrasound examinations to monitor fetal growth, amniotic fluid, and renal appearance
- Fetal nonstress or biophysical profile testing (or both), twice weekly, beginning at 32-34 weeks
- Prenatal neonatology and pediatric urology consultation to discuss postnatal management and prognosis

OBSTETRIC MANAGEMENT

- Delivery in a tertiary care facility if bilateral disease, oligohydramnios, other nonrenal anomaly, or uncertain diagnosis
- Cesarean delivery is reserved for obstetric indications.

SUGGESTED READINGS

Aslam M, Watson AR: Unilateral multicystic dysplastic kidney: long term outcomes, *Arch Dis Child* 91:820-823, 2006.

Eckoldt F, Woderich R, Smith RD, et al: Antenatal diagnostic aspects of unilateral multicystic kidney dysplasia: sensitivity, specificity, predictive values, differential diagnoses, associated malformations

and consequences, *Fetal Diagn Ther* 19:163-169, 2004.

Lazebnik N, Bellinger MF, Ferguson JE 2nd, et al: Insights into the pathogenesis and natural history of fetuses with multicystic dysplastic kidney disease, *Prenat Diagn* 19:418-423, 1999.

van Eijk L, Cohen-Overbeek TE, den Hollander NS, et al: Unilateral multicystic dysplastic kidney: a combined pre- and postnatal assessment, *Ultrasound Obstet Gynecol* 19:180-183, 2002.

NEONATAL MANAGEMENT

- Assess kidneys for function and reflux
 - Voiding cystourethrogram (VCUG)
 - Nuclear medicine renography
- Antibiotic prophylaxis if vesicoureteral reflux is present
- Follow-up renal ultrasound at 3- to 6-month intervals
- Pediatric urology consultation
- Consider surgical excision of nonfunctional kidney.

PROGNOSIS

- Isolated unilateral MCDK has good prognosis, although the cystic kidney is likely to be nonfunctional.
- Involved kidney involutes during childhood:
 - 33% by 2 years old
 - 50% at 5 years old
 - 60% at 10 years old
- Bilateral MCDK or unilateral MCDK with contralateral renal agenesis has a poor prognosis and is probably lethal.
- Long-term complications include vesicoureteric reflux, recurrent infection, and hypertension.
- Malignant degeneration (e.g., Wilms tumor) is unlikely.

25D POSTERIOR URETHRAL VALVES

Diagnosis

DEFINITION

Posterior urethral valves are membranes in the posterior urethra that cause bladder outlet obstruction with subsequent hydronephrosis and pressure-induced renal dysplasia.

INCIDENCE AND PATHOGENESIS

- Posterior urethral valves (PUV) are seen in 1/8000 to 1/25,000 live births.
- PUV occurs almost exclusively in males; in females, a similar syndrome is *urethral atresia* with complete obstruction.
- The embryogenesis of PUV is not fully understood, but it is believed to follow faulty canalization of the posterior urethra at the vesicourethral interface, resulting in a membrane that acts like a valve, preventing normal fetal micturition, and causing the bladder and subsequently ureters and kidneys to distend.
- Pressure on the developing nephron causes renal dysplasia and poor function, and eventual long-standing anhydramnios produces potentially lethal pulmonary hypoplasia.

DIFFERENTIAL DIAGNOSIS

- Urethral atresia
- Megacystis-microcolon syndrome
- Megacystis-megaureter syndrome
- Prune-belly syndrome
- Ureteral duplication
- Vesicoureteral reflux
- Multicystic dysplastic kidney
- Persistent cloaca

KEY DIAGNOSTIC FEATURES

- Sonographic appearance varies, but classic PUV presents with
 - Megacystis (markedly enlarged bladder)
 - Thickened bladder wall (>3 mm)
 - Dilated posterior urethra ("*keyhole*" sign) (Videos 25-5)
 - Bilateral hydronephrosis or cortical cysts indicating renal dysplasia
 - Oligohydramnios
- Can be seen in late first trimester, with worse prognosis
- A minimum of three sequential vesicocenteses, 48-72 hours apart, should be performed to assess fetal renal function.
- Normal values for fetal urine:
 - Sodium, <100 mg/dL
 - Chloride, <90 mg/dL
 - Osmolarity, <200 mOsm/L
 - Calcium, <8 mg/dL
 - Total protein, <20 mg/dL
 - β_2 -microglobulin, <4 mg/dL

ASSOCIATED ANOMALIES

- Oligohydramnios
- Urinary ascites with ruptured bladder; perinephric urinoma with ruptured kidney
- Echogenic atrophied kidney(s)
- Pulmonary hypoplasia (small, bell-shaped chest)
- Other genitourinary anomalies, present in approximately 40%
- Aneuploidy
- Potter sequence malformations with long-standing oligohydramnios
- Careful ultrasound examination should be performed to detect other nonurologic anomalies.

Imaging

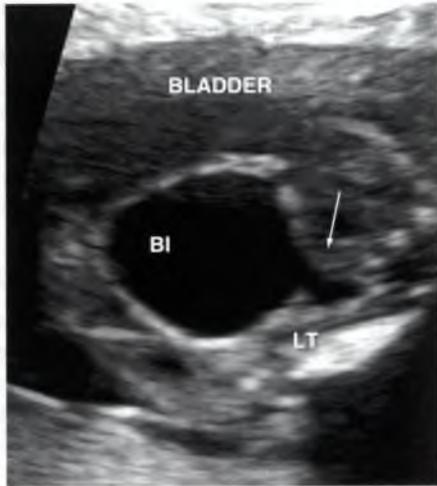

Figure 25-19 Keyhole bladder. Posterior urethral valves with characteristic “keyhole” appearance of the posterior urethra (arrow). BL, bladder.

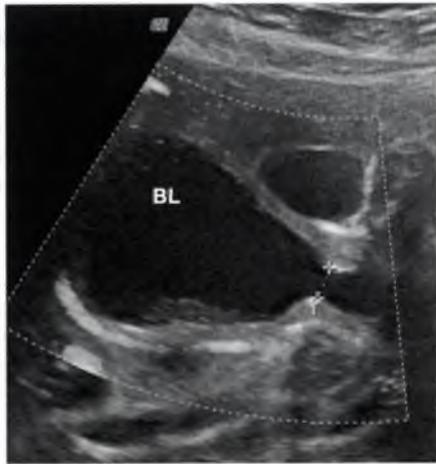

Figure 25-20 Keyhole bladder. Massively distended bladder (BL) with an enlarged posterior urethra, measuring 7 mm wide (calipers), consistent with keyhole bladder.

Figure 25-21 Keyhole bladder. Enlarged fetal bladder outlined by urinary ascites (arrowheads) with enlarged posterior urethra (arrow).

Figure 25-22 Hydronephrosis, hydroureter. Markedly dilated kidneys (arrows) and bilaterally enlarged ureters (*).

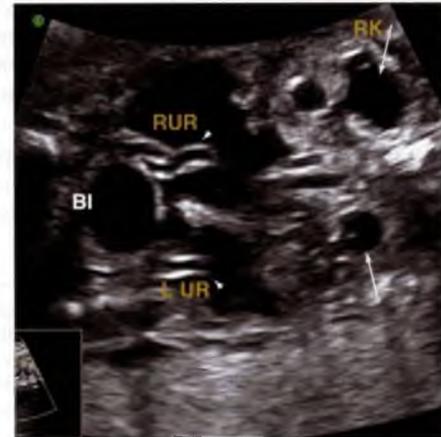

Figure 25-23 Urinary ascites. Coronal image showing bladder (BL) and ureters (arrowheads) outlined by urinary ascites, and bilateral hydronephrosis (arrows).

Figure 25-24 Hydronephrosis. Axial view showing bilateral hydronephrosis with the kidneys and bowel loops outlined by urinary ascites (*). Bo, bowel.

Management

ANTENATAL MONITORING

- Consider in utero therapy to prevent pulmonary hypoplasia and preserve renal function (the therapies have various degrees of success and complications):
 - Vesicoamniotic shunting
 - Open fetal surgery
 - Fetal cystoscopy
- Fetuses with normal amniotic fluid or bilateral echogenic dysplastic kidneys are unlikely to benefit from in utero therapy.
- Serial ultrasound examinations to monitor fetal growth, amniotic fluid, and worsening fetal condition
- Fetal echocardiogram to confirm normal anatomy
- Fetal nonstress or biophysical profile testing (or both), twice weekly, beginning at 32-34 weeks
- Prenatal neonatology and pediatric urology consultation to discuss postnatal management and prognosis

OBSTETRIC MANAGEMENT

- Delivery at a tertiary care facility is recommended.
- Vesicocentesis may be warranted to decompress the fetal bladder to prevent abdominal dystocia with vaginal delivery and improve respiratory compliance in the neonate.
- Cesarean delivery is reserved for obstetric indications.

NEONATAL MANAGEMENT

- Respiratory distress is a common result of pulmonary hypoplasia and distended bladder.
- Transurethral bladder catheterization pending surgical correction of PUV
- Monitor renal function and electrolytes closely.
- Consultation with pediatric urology or nephrology (or both)

PROGNOSIS

- Fetal mortality is approximately 30%-40%.
- Short-term prognosis is based on sonographic appearance of kidneys, fetal urine concentration, and amniotic fluid volume
 - Good prognosis (10% mortality) with nondysplastic kidneys and normal (hypotonic) fetal urine
 - Poor prognosis (70% mortality) if kidneys appear abnormal or if there is *any* abnormal fetal urine parameter
 - Worst prognosis (95% mortality) with severe oligohydramnios or anhydramnios
- Long-term prognosis in survivors can include more than 50% with chronic renal insufficiency, necessitating dialysis or transplantation.

25E PYELECTASIS

Diagnosis

DEFINITION

Pyelectasis is a fluid collection causing dilation of the fetal renal pelvis and indicating a risk for persistent postnatal renal impairment or the need for surgical intervention.

INCIDENCE AND PATHOGENESIS

- Renal pyelectasis is seen in 2%-5% of all pregnancies.
- Isolated renal pelviectasis results from
 - Ureteropelvic junction (UPJ) obstruction, secondary to incomplete canalization or maturation of the ureter(s)
 - Vesicoureteral reflux, particularly in male fetuses

DIFFERENTIAL DIAGNOSIS

- Ureterovesical junction (UVJ) obstruction: ureter(s) dilated
- Bladder outlet obstruction (posterior urethral valves): bladder dilated
- Duplicated renal collecting system with dilated upper or lower pole moiety with reflux or ureterocele (or both)
- Multicystic dysplastic kidney
- Isolated renal cyst
- Normal variant

KEY DIAGNOSTIC FEATURES

- The measurement of the renal pelvis is its anteroposterior (AP) diameter (Video 25-6).
- Criteria used to define pyelectasis that is clinically significant (i.e., likely to need postpartum treatment):
 - Ouzounin and coworkers (1996)
 - ≥ 5 mm at any gestational age
 - Corteveille and coworkers (1991)
 - ≥ 4 mm at 16-33 weeks
 - ≥ 7 mm at 33-40 weeks
 - Anderson and coworkers (1995)
 - >4 mm at 16-23 weeks
 - >6 mm at 23-30 weeks
 - >8 mm at 30-40 weeks
- Maternal hydration status may affect renal dilation.

ASSOCIATED ANOMALIES

- *Caliectasis* (distended renal calyces) implies a greater degree of hydronephrosis, increasing the likelihood of postnatal surgery or renal compromise (Video 25-7).
- Ureteromegaly or distended bladder (or both)
- Oligohydramnios if severe bilateral ureteral or bladder outlet obstruction (e.g., posterior urethral valves)
- Aneuploidy (trisomy 13, 18, 21, triploidy)
- As an *isolated* finding, pelviectasis does not increase the risk of aneuploidy.

Imaging

Figure 25-25 Bilateral pyelectasis. Axial-view ultrasound image at 35 weeks shows markedly dilated renal pelvises (*calipers*), each measuring over 10 mm.

Figure 25-28 Pyelectasis with caliectasis. Sagittal image demonstrates dilated renal pelvis (*arrow*) and calyces (*arrowheads*).

Figure 25-26 Pyelectasis. Sagittal-view ultrasound image shows mildly dilated renal pelvis (*arrowheads*), consistent with pyelectasis. The renal calyces appear normal. St, stomach.

Figure 25-29 Severe hydronephrosis. This sagittal image shows hydronephrosis with the renal pelvis massively dilated and the calyces obliterated.

Figure 25-27 Pyelectasis. In this coronal view, both renal pelvises are seen to be mildly dilated, with a normal-appearing bladder (Bl).

Figure 25-30 Neonatal ureteral reflux. Voiding cystourethrogram shows unilateral reflux with mildly dilated ureter (*black arrowheads*) and renal pelvis (*white arrowheads*). Bl, bladder.

Management

ANTENATAL MONITORING

- Consider amniocentesis for karyotyping if additional ultrasound abnormalities seen.
- Repeat ultrasound assessment of the fetal kidneys in the third trimester to monitor progression or resolution.
- Consider referral to a pediatric urologist for prenatal consultation if
 - Renal pelvis > 10 mm
 - Associated caliectasis
 - Additional renal findings
- Fetal nonstress or biophysical profile testing (or both), twice weekly, beginning at 32-34 weeks if associated oligohydramnios

OBSTETRIC MANAGEMENT

- Delivery in a tertiary care facility with pediatric urology availability is required only if there is severe obstruction.
- Cesarean delivery is reserved for obstetric indications.
- Notify the pediatricians of the suspected renal dilation to ensure adequate postnatal evaluation and treatment as appropriate.

NEONATAL MANAGEMENT

- Renal ultrasound. If renal pelvic dilation is ≥ 7 mm, or there are other renal anomalies, further investigation is recommended.

- Voiding cystourethrogram (VCUG)
- Intravenous pyelography (IVP)
- MRI
- Nuclear medicine renography
- Antibiotic prophylaxis
- Follow-up renal ultrasound at 3-month intervals
- Pediatric urology consultation

PROGNOSIS

- Long-term prognosis depends on the presence of coexisting anomalies or aneuploidy, and whether unilateral or bilateral kidneys are affected.
- Approximately 90% of pelviectasis seen in mid-trimester ultrasound resolves during the antenatal or early neonatal period.
- Approximately one third of the fetuses with *persistent* moderate to severe hydronephrosis (≥ 7 mm or with associated caliectasis) require postnatal urologic surgery.
- Untreated vesicoureteral reflux can lead to recurrent renal infections, parenchymal scarring, and ultimate renal failure.

25F URETEROCELE

Diagnosis

DEFINITION

Ureterocele is a cystic dilation of the ureter within the fetal bladder with obstruction of the ureter at the ureterovesical junction, causing a dilated ureter and hydronephrosis.

INCIDENCE AND PATHOGENESIS

- Ureterocele occurs in 1/5000 live births, with a male-to-female ratio of 1:5.
- Ureterocele develops because of incomplete canalization of the ureteral membrane between the ureteral bud and the mesonephric duct, causing a stenotic ureteral orifice at the ureterovesical junction.

DIFFERENTIAL DIAGNOSIS

- Posterior urethral valves
- Ureteropelvic junction obstruction
- Ureterovesical junction obstruction
- Vesicoureteral reflux
- Congenital megaureter
- Megacystis-megaureter syndrome

KEY DIAGNOSTIC FEATURES

- Thin-walled cystic mass seen in the fetal bladder (Videos 25-8 and 25-9)

- Dilated ureter and kidney with obstructed ureterocele (Video 25-10)
- Approximately 80% of ureterocele is associated with a *duplicated* renal collecting system with dilated *upper pole moiety*.
- 10% of ureterocele is bilateral, producing a complex multiseptated-appearing bladder.
- American Academy of Pediatrics classification of ureterocele:
 - *Intravesical* (25%): ureterocele inserts entirely in the bladder
 - *Ectopic* (75%): ureterocele located distal to the trigone, inserting into the bladder neck, urethra (cecoureterocele), or elsewhere in the pelvis

ASSOCIATED ANOMALIES

- The contralateral kidney and ureter need to be assessed to rule out bilateral disease, and nonurologic congenital malformations should be ruled out; however, ureterocele is usually an isolated anomaly.
- Vesicoureteral reflux in the *lower pole moiety* in duplicated kidneys
- Megacystis can develop if ureterocele prolapses through urethra, causing obstruction.
- Oligohydramnios with obstructing or bilateral ureterocele
- Cystic renal dysplasia (of upper pole moiety) if long-standing obstruction

Imaging

Figure 25-31 Ureterocele. Axial view demonstrating typical ureterocele appearance of a "cyst" in the bladder (arrow).

Figure 25-34 Bilateral ureteroceles. Axial view demonstrating bilateral ureteroceles, giving the appearance of a septated bladder mass.

Figure 25-32 Subtle ureterocele. Axial view shows how easily the ureterocele (arrow) can be missed, particularly with acoustic shadowing from overlying echodense structures.

Figure 25-35 Bilateral ureteroceles. Coronal view demonstrating bilateral ureteroceles with what appears to be a septated bladder mass.

Figure 25-33 Ureterocele with dilated ureter. Axial view shows a ureterocele in the bladder (arrow) with a cross section of a dilated ureter immediately posterior (arrowheads).

Figure 25-36 Hydroureter. This oblique coronal view shows a tortuous dilated ureter (*) leading to a normal-size bladder with ureterocele (arrow), as seen with renal duplication.

Management

ANTENATAL MONITORING

- Consider in utero therapy to preserve renal function if there is bladder outlet obstruction with severe oligohydramnios.
 - Vesicoamniotic shunting
 - Fetal cystoscopy with laser ureterocele incision
- Serial ultrasound examinations to monitor fetal growth, amniotic fluid, and worsening fetal condition
- Amniotic fluid assessment at least weekly, beginning at 32-34 weeks
- Prenatal neonatology and pediatric urology consultation to discuss postnatal management and prognosis

OBSTETRIC MANAGEMENT

- Delivery at a tertiary care facility is recommended if there is bilateral disease or severe oligohydramnios.
- Cesarean delivery is reserved for obstetric indications.

NEONATAL MANAGEMENT

- Postnatal assessment:
 - Renal and bladder ultrasound
 - Voiding cystourethrogram (VCUG)
 - Nuclear medicine renography

- Antibiotic prophylaxis
- Pediatric urology consultation
- Surgical treatment depends on whether there is vesicoureteral reflux or renal duplication (or both).
 - Endoscopic ureterocele decompression
 - Heminephrectomy
 - Bladder reconstruction
 - Ureteral reimplantation

PROGNOSIS

- Overall prognosis depends on whether ureteroceles are unilateral or bilateral, the presence of renal dysplasia, and the surgical approach used.
- New-onset vesicoureteral reflux after surgical repair is common.
- Prenatal diagnosis improves surgical outcomes:
 - 85% less preoperative and 50% less postoperative urinary tract infections
 - 50% lower secondary procedure rate, irrespective of initial surgical treatment modality

Skeletal Imaging

RICHARD B. WOLF, DO, MPH

26A ARTHROGRYPOSIS AND POLYDACTYLY

Diagnosis

DEFINITION

Arthrogryposis describes a clinical finding of two or more fixed joint contractures in multiple areas of the body. *Polydactyly* indicates that one or more supernumerary digits are present in the hand or foot.

INCIDENCE AND PATHOGENESIS

- *Arthrogryposis* occurs in approximately 1/3000 live births and is caused by lack of fetal movement (akinesia) resulting from
 - *Intrinsic factors* (e.g., anomalies of fetal development)
 - *Extrinsic factors* (e.g., teratogen exposure, oligohydramnios)
- *Polydactyly* is present in 1/3000 live births and results from defective embryologic differentiation of the digits with mesodermal rays that persist beyond programmed cell death, producing an extra digit.
- Polydactyly is classified as
 - *Preaxial*—extra digit located on the radial or tibial side of the distal extremity
 - *Postaxial*—extra digit on ulnar or fibular side of distal extremity; 10 times more common in African Americans, occurring in 1/300 live births (probably an autosomal dominant trait)
 - *Central*—a rare finding, with one or more extraneous middle digits

DIFFERENTIAL DIAGNOSIS

- Temporary unusual posture of the hand
- Amniotic band sequence
- Vascular disruption
- Skeletal dysplasia

KEY DIAGNOSTIC FEATURES

- Arthrogryposis is seen as abnormal limb posturing that is fixed in position with persistent lack of movement, and typically affects more than one joint (Video 26-1).

- Polydactyly appears as an extra digit, and the hand or foot should be examined in the outstretched open position and the digits enumerated.
- Consider 3D imaging or MRI (or both) to aid in diagnosis.

ASSOCIATED ANOMALIES

- Arthrogryposis may be a component of
 - Fetal neuromuscular disorders (spinal muscular atrophy, Pena-Shokeir, cerebro-oculofacial syndrome)
 - Primary myopathies (amyoplasia, myotonic dystrophy)
 - Connective tissue disease (diastrophic dysplasia)
 - Infection (rubella, coxsackievirus, enterovirus)
 - Maternal myasthenia gravis (transplacental passage of acetylcholine receptor antibodies)
 - Other syndromes (e.g., VACTERL association [vertebral abnormality, anal atresia, cardiac defect, tracheoesophageal fistula, renal and radial limb abnormality])
- Polydactyly is an isolated finding in 85% of cases; associated anomalies are more commonly seen in preaxial (20%) than in postaxial (12%) polydactyly.
 - Most common associated anomaly is another limb defect (e.g., syndactyly).
 - Can be an inherited trait, the result of teratogen exposure (e.g., diabetic embryopathy, valproic acid), or can be a component of a recognizable syndrome:
 1. Aneuploidy (trisomy 13, 21)
 2. Meckel-Gruber syndrome
 3. Orofacialdigital (OFD) syndrome
 4. Skeletal dysplasias
 - Ellis-van Creveld
 - Short-rib polydactyly
 5. VACTERL association
 6. Smith-Lemli-Opitz syndrome
 7. Esophageal atresia

Imaging

Figure 26-1 **Clenched hand.** Ultrasound image at 29 weeks' gestation shows an unchanging closed hand with what appears to be overlapping digits (*arrows*) (Video 26-2).

Figure 26-2 **Clenched hands, 3D view.** 3D ultrasound view of the patient seen in Figure 26-1 clearly exhibits clenched hands with overlapping digits, consistent with arthrogryposis.

Figure 26-3 **Abnormal wrist posturing.** Ultrasound image of wrist is flexed at 90 degrees, with hooking fingers (*arrow*). This posturing (the "waiter's tip" position) is associated with amyoplasia.

Figure 26-4 **Arthrogryposis, gross pathology.** This cross-legged "tailor's position" is typical with arthrogryposis. Note the left clubfoot (*arrowheads*). There is also webbing in the flexor surface of the knee joint (*arrow*) (Video 26-3).

Figure 26-5 **Polydactyly, hand.** Ultrasound image of the fetal hand shows fingers 2 through 6 with polydactyly. The thumb is not visible in this image. Postaxial polydactyly was a family trait in this case.

Figure 26-6 **Polydactyly, foot.** Ultrasound image of a clubfoot demonstrates polydactyly with six toes readily apparent. Amniocentesis revealed trisomy 13.

Management

ANTENATAL MONITORING

- Amniocentesis should be considered for karyotyping, particularly if there are other associated CNS, cardiac, or renal anomalies present.
- Consider fetal echocardiogram when arthrogryposis is present, to assess cardiac structure and function.
- Serial ultrasound examinations when arthrogryposis is present, to monitor fetal growth, thoracic development, and amniotic fluid
- Prenatal genetics consultation to determine if a syndrome is likely
- Prenatal orthopedic surgery consultation to discuss post-natal management and prognosis

OBSTETRIC MANAGEMENT

- Delivery in a tertiary care facility is recommended only if other anomalies or syndromes are suspected.
- Cesarean delivery should be reserved for usual obstetric indications.

SUGGESTED READINGS

Castilla EE, Lugarinho R, da Graca Dutra M, et al: Associated anomalies in individuals with polydactyly, *Am J Med Genet* 80:459–465, 1998.

Graham TJ, Rens AM: Finger polydactyly, *Hand Clin* 14:49–64, 1998.

Hall JG: Arthrogryposis multiplex congenita: etiology, genetics, classification, diagnostic approach, and general aspects, *J Pediatr Orthop B* 6:159–166, 1997.

Rink BD: Arthrogryposis: a review and approach to prenatal diagnosis, *Obstet Gynecol Surv* 66:369–377, 2011.

NEONATAL MANAGEMENT

- Pulmonary hypoplasia or difficulty with airway access (or both) should be anticipated if there is global akinesia, significant kyphoscoliosis, or suspected jaw involvement.
- Careful physical examination should be performed to assess for other anomalies, syndromes, or aneuploidy.
- Consultation with geneticist and pediatric orthopedics department to establish diagnosis and plan treatment.
- Physical therapy should be initiated as soon as possible to improve range of motion in arthrogryposis cases.
- Surgical ablation of rudimentary supernumerary digits can be accomplished by suture ligation, but well-formed extra digits may require orthopedic reconstructive surgery.

PROGNOSIS

- Prognosis of arthrogryposis and polydactyly depends on associated abnormalities and whether this finding is part of a syndrome.
- Perinatal morbidity and mortality related to an *isolated* limb defect is low.

26B CLUBFOOT

Diagnosis

DEFINITION

Congenital clubfoot, also known as *talipes equinovarus*, is a malformation of the fetal ankle producing various abnormal posturings of the foot.

INCIDENCE AND PATHOGENESIS

- The incidence of clubfoot is approximately 1-3/1000 live births; the male-to-female ratio is 2:1.
- Approximately two thirds of cases of clubfoot are bilateral; one third are unilateral.
- Clubfoot etiology is multifactorial, with disruption of the neuromuscular unit (brain, spinal cord, nerve, muscle) and unopposed muscle activity restricting the ankle in a distorted position.
- Genetic factors have been implicated (25% of cases are familial), but the genetic mechanism is unclear.

DIFFERENTIAL DIAGNOSIS

- Transient positional finding in *normal* fetus, particularly in the third trimester
- Rocker-bottom feet
- Arthrogryposis
- Skeletal dysplasia
- Amniotic band sequence
- Ectrodactyly

KEY DIAGNOSTIC FEATURES

- Clubfoot deformity is diagnosed when both the tibia and the fibula are seen in coronal plane, with the sole of the foot visible in the same plane, and this persists during the course of the ultrasound examination.

- The foot is most often seen as being plantar flexed (equinus) and inverted medially (varus) = *talipes equinovarus*; however, other abnormal ankle posturing is possible.
- The severity of clubfoot and the potential need for corrective surgery is difficult to predict prenatally.
- A false-positive rate for prenatal diagnosis of clubfoot is up to 30%.

ASSOCIATED ANOMALIES

- In approximately two thirds of cases, clubfoot is an *isolated* finding (idiopathic).
- Once clubfoot is diagnosed, a detailed anatomic survey of the fetus should be performed to rule out other congenital malformations.
- Other associated anomalies (*complex* clubfoot) include
 - Open neural tube defects (e.g., myelomeningocele, caudal regression)
 - Neuromuscular disorders (e.g., akinesia sequence, myotonic dystrophy)
 - Aneuploidy (up to 30% with other structural anomalies present)
 - Genetic syndromes and other malformation sequences
 - Other anomalies may include cardiovascular, genitourinary, gastrointestinal, and facial anomalies

Imaging

Figure 26-7 Clubfoot, sole of foot. Ultrasound image shows the tibia and fibula of the lower extremity with the sole of the foot in the same plane, consistent with clubfoot (Video 26-4).

Figure 26-10 Bilateral clubfoot. Ultrasound image demonstrates bilateral clubfoot with the toes from each foot pointing medially.

Figure 26-8 Clubfoot, metatarsal view. Ultrasound image of tibia and fibula, seen parallel, with the metatarsals of the foot visible in the same image (arrows).

Figure 26-11 Bilateral clubfoot, crossed legs. Ultrasound image showing crossed legs with clubfoot in an unnatural posture that did not change during the examination. Persistently crossed legs can indicate arthrogyposis.

Figure 26-9 Clubfoot, toe view. Ultrasound image of clubfoot: the toes of the foot can be seen at right angles to the parallel tibia and fibula.

Figure 26-12 Clubfoot, 3D view. 3D ultrasound image clearly shows the sole of the right foot inverted medially, with the lower leg visible above it (arrows). Th, thigh.

Management

ANTENATAL MONITORING

- Consider repeat ultrasound examinations to reassess for other associated anomalies and to confirm the finding of clubfoot.
- Amniocentesis should be considered for karyotyping if additional anomalies are present.
- Prenatal pediatric orthopedic consultation may be helpful to discuss postnatal management and prognosis.

OBSTETRIC MANAGEMENT

- No change in routine obstetric management is necessary for isolated clubfoot.

NEONATAL MANAGEMENT

- No changes in usual neonatal management are necessary.
- Arrange for pediatric orthopedic follow-up.

SUGGESTED READINGS

Bakalis S, Sairam S, Homfray T, et al: Outcome of antenatally diagnosed talipes equinovarus in an unselected obstetric population, *Ultrasound Obstet Gynecol* 20:226–229, 2002.

Canto MJ, Cano S, Palau J, et al: Prenatal diagnosis of clubfoot in low-risk population: associated

anomalies and long-term outcome, *Prenat Diagn* 28:343–346, 2008.

Dobbs MB, Gurnett CA: Update on clubfoot: etiology and treatment, *Clin Orthop Relat Res* 467:1146–1153, 2009.

Mammen L, Benson CB: Outcome of fetuses with clubfeet diagnosed by prenatal sonography, *J Ultrasound Med* 23:497–500, 2004.

PROGNOSIS

- Approximately 90% of clubfeet are found postnatally to have *structural* defects requiring orthopedic treatment; 10% are *positional* defects requiring no postnatal treatment.
- Postnatal classification systems (Dimeglio or Pirani) are used to assess clubfoot severity with a point score based on physical findings.
- Treatment generally consists of serial splinting or casting (Ponseti method); approximately 40% will require tendon-release surgery.
- Long-term prognosis of clubfoot depends on associated abnormalities; however, the prognosis for normal function with isolated clubfoot is excellent.

26C NEURAL TUBE DEFECT

Diagnosis

DEFINITION

Open neural tube defect is an embryologic defect of the formation of the posterior vertebral arches of the spine, exposing the neural elements.

INCIDENCE AND PATHOGENESIS

- Open neural tube defect (ONTD), also known as *spina bifida* or *spinal dysraphism*, occurs in approximately 1/1000 live births.
- The embryonic neural tube is formed via neurulation, which involves shaping, folding, and midline fusion of the neural plate, and it is typically complete by the 25th day after conception. ONTD results from a defect in primary neurulation, with failed caudal fusion of the neural tube.
- ONTD is associated with increased maternal serum α -fetoprotein (AFP).
- Risk factors for developing ONTD include a prior affected pregnancy, folic acid deficiency, pregestational diabetes, and teratogen exposures (e.g., valproic acid, carbamazepine).

DIFFERENTIAL DIAGNOSIS

- Sacrococcygeal teratoma
- Lumbosacral lipoma
- Sirenomelia
- Limb–body stalk anomaly
- Amniotic band syndrome

KEY DIAGNOSTIC FEATURES

- ONTD appears on sagittal-view ultrasound as a defect in the dorsal aspect of the spine, typically with an overlying cystic mass, and with splaying of the posterior vertebral elements seen on coronal and axial views.

- ONTD is classified by the appearance of tissues overlying the bony defect:
 - *Myelomeningocele*—sac containing spinal cord or other neural elements
 - *Meningocele*—sac containing only protruding meninges and cerebrospinal fluid
 - *Myeloschisis*—wide splaying of the vertebral arch with no visible covering (neural tube completely exposed) (Video 26-5)
- Lesion level is defined as the highest vertebral level at which dysraphism is visualized.
- 3D and MRI imaging may be helpful in determining lesion level.

ASSOCIATED ANOMALIES

- Intracranial findings with ONTD:
 - Chiari II malformation with effacement of the cisterna magna and caudal retraction of the cerebellum (“banana sign”) (Video 26-6)
 - Scalloping of the frontal bone (“lemon sign”)
 - Ventriculomegaly (atrial width, ≥ 10 mm), probably in second and third trimesters
- Clubfeet typical
- Aneuploidy is present in 10% (primarily trisomy 18 or 13, triploidy)
- Other anomalies (cardiac, urogenital, skeletal, craniofacial, neurologic) present in 15%-30% of *euploid* fetuses; higher incidence in aneuploid fetuses
- ONTD can be part of a syndrome (e.g., VATER [vertebral defects, imperforate anus, tracheoesophageal fistula, renal defects] or VACTERL [vertebral abnormality, anal atresia, cardiac defect, tracheoesophageal fistula, renal and radial limb abnormality] syndrome).

Imaging

Figure 26-13 Spinal dysraphism, axial view. Ultrasound image shows widely spaced posterior elements of the sacrum (*large arrows*) with an overlying cystic mass (*small arrows*), consistent with an open neural tube defect.

Figure 26-16 Spinal dysraphism. 3D imaging demonstrates splaying of the posterior elements of the sacrum (*arrowheads*), consistent with open neural tube defect.

Figure 26-14 Spinal dysraphism, sagittal view. Ultrasound image shows a disruption in the continuity of the posterior spinal elements, with an overlying mixed cystic mass (*arrows*), consistent with myelomeningocele.

Figure 26-17 Cranial findings. Axial view of the fetal cranium with open neural tube defect shows frontal scalloping ("lemon sign," *arrows*) and effacement of the cisterna magna ("banana sign," *arrowheads*).

Figure 26-15 Spinal dysraphism. Coronal ultrasound image shows splaying of the posterior elements in the sacral region (*arrow*). The vertebrae are numbered, based on T12 (ribs attached).

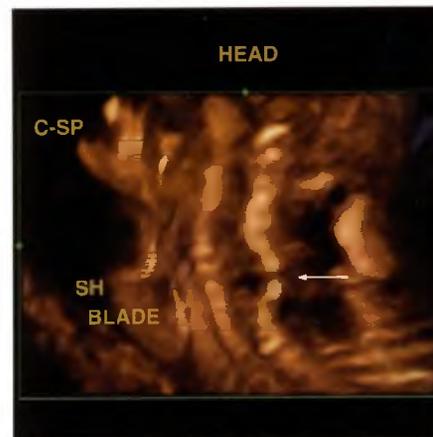

Figure 26-18 Cervicothoracic dysraphism. 3D image shows the head (oriented toward the top of the picture), and the cervicothoracic spine is seen widely splayed (*arrow*).

Management

ANTENATAL MONITORING

- Amniocentesis should be considered for karyotyping; will show increased amniotic fluid AFP and acetylcholinesterase.
- Fetal echocardiogram is recommended to assess cardiac structure and function.
- Serial ultrasound examinations to monitor fetal growth, amniotic fluid, and worsening fetal condition
- Fetal nonstress or biophysical profile testing (or both), twice weekly, beginning at 32-34 weeks
- Fetoscopic in utero treatment reduces need for cerebral ventricular shunt placement by 50% and improves motor function, but it increases preterm delivery compared with conventional postnatal treatment (80% versus 15%).
- Prenatal neonatology and pediatric neurosurgery consultation to discuss postnatal management and prognosis

OBSTETRIC MANAGEMENT

- Delivery in a tertiary care facility is recommended.
- Cesarean delivery should be performed before the onset of labor to improve functional neurologic outcome.

NEONATAL MANAGEMENT

- Protect open spinal lesion or cyst from infection and drying by wrapping with moist sterile bandages, and keep the neonate in *sterile* isolette pending surgery.

- Prophylactic antibiotics pending surgery
- Postnatal surgical repair should be performed after delivery as soon as feasible (<48 hours).

PROGNOSIS

- Prognosis of ONTD depends on
 - Level and size of lesion
 - Associated anomalies
 - Aneuploidy
 - Ventriculomegaly
 - Type of surgical closure
- In general, the larger and higher the lesion is, the worse the prognosis for survival, motor function, and continence.
- Perinatal mortality related to *isolated* ONTD is approximately 10%-15%.
- Long-term morbidity includes paraparesis or paraplegia (or both), bowel and bladder dysfunction, orthopedic abnormalities, hydrocephalus requiring repeat ventriculo-peritoneal shunting, developmental delay, and learning disabilities.
- Periconception folic acid supplementation can reduce the risk of recurrence by 70%.

26D SACROCOCYGEAL TERATOMA AND SACRAL AGENESIS

Diagnosis

DEFINITION

Sacrococcygeal teratoma is a germ cell tumor extending from the presacral area. Sacral agenesis (caudal regression) is a lack of embryonic development of the sacrum and lower spine.

INCIDENCE AND PATHOGENESIS

- Sacrococcygeal teratoma (SCT)
 - Occurs in 1/40,000 live births with a male-to-female ratio of 1:3
 - Caused by continued growth of pluripotential cells in Hensen node, producing a tumor composed of embryonic ectoderm, mesoderm, and endoderm tissue
- Sacral agenesis
 - Occurs in 1-5/100,000 live births; classically reported in approximately 1% of diabetic pregnancies
 - Etiology not well understood but results from faulty embryogenesis with disruption of distal neural tube formation

DIFFERENTIAL DIAGNOSIS

- Meningocele/meningomyelocele
- Lipoma
- Sirenomelia
- Vestigial tail (Video 26-7)
- Arthrogyriposis
- Imperforate anus
- Amniotic band syndrome
- Bladder outlet obstruction

KEY DIAGNOSTIC FEATURES

- SCT appears as a solid or cystic mass extending from the coccyx to beyond the perineum (Videos 26-8 and 26-9).
 - Color Doppler imaging may show high-volume, high-velocity flow.

- MRI imaging is useful to determine extent of intrapelvic extension.
- American Academy of Pediatrics—Surgical Section (AAPSS) SCT classification
 - Type I—external tumor with minimal presacral involvement
 - Type II—external tumor with intrapelvic extension
 - Type III—external tumor with pelvic mass extending into abdomen
 - Type IV—presacral mass with no external component
- Sacral agenesis appears as an abruptly ending lower spine on sagittal imaging, confirmed on axial view (Video 26-10).

ASSOCIATED ANOMALIES

- Cardiac, gastrointestinal, and genitourinary anomalies may be present.
- Anomalies associated with *SCT*
 - Hydrops fetalis may develop as a result of high-output cardiac failure.
 - Polyhydramnios or oligohydramnios.
 - Placentomegaly with hydrops
 - Genitourinary obstruction may produce hydronephrosis or hydroureter.
- Anomalies associated with *sacral agenesis*
 - Lower extremities are hypoplastic, appearing “cross-legged” and clubbed, with little movement.
 - May be part of a syndrome:
 1. VATER syndrome (vertebral defects, imperforate anus, tracheoesophageal fistula, renal defects)
 2. VACTERL association (vertebral abnormality, anal atresia, cardiac defect, tracheoesophageal fistula, renal and radial limb abnormality)
 3. Cloacal exstrophy
 4. Fraser syndrome

Imaging

Figure 26-19 Sacrococcygeal teratoma. Sagittal-view ultrasound image at 24 weeks illustrates a mixed echogenic mass (arrows) emanating inferior to the intact sacrum (arrowheads), consistent with sacrococcygeal teratoma.

Figure 26-20 Sacrococcygeal teratoma. A, Axial view. Ultrasound image of fetus seen in Figure 26-19 at 29 weeks, with a sacrococcygeal teratoma of approximately 10 cm in diameter. Note the mixed echotexture in the mass. B, Postnatal appearance. Neonate seen in Figure 26-19 and in A following delivery. The mass measured approximately 15 cm in diameter and weighed 1 kg following excision.

Figure 26-21 Cystic sacrococcygeal teratoma. Sagittal-view ultrasound image of a male fetus shows a predominantly cystic sacrococcygeal teratoma at the fetal perineum (arrows). The fetal spine was intact. BI, bladder.

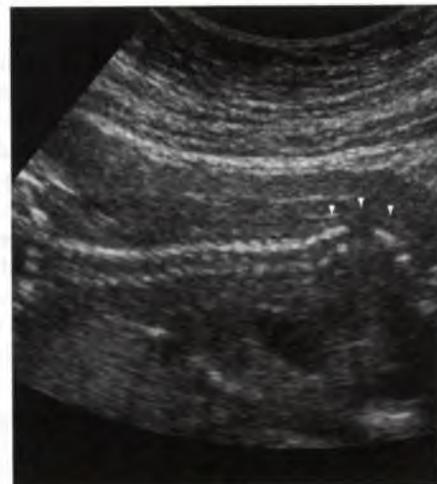

Figure 26-22 Sacral agenesis, sagittal view. Ultrasound imaging shows what at first glance appears to be a normal sacrum, but when counting vertebrae, sacral agenesis was diagnosed (arrowheads).

Figure 26-23 Sacral agenesis, axial view. Ultrasound imaging of the abdomen shows the cord insertion anteriorly (arrows), but the spine is not visible posteriorly (arrowheads), consistent with sacral agenesis.

Figure 26-24 Sacral agenesis. Postmortem radiograph shows the spine terminating at the L2 level (arrowheads), consistent with sacral agenesis.

Management

ANTENATAL MONITORING

- Amniocentesis should be considered for karyotyping.
- Fetal echocardiogram is recommended to assess cardiac structure and function.
- For SCT, frequent ultrasound and color Doppler imaging to monitor fetal growth, amniotic fluid, and worsening fetal condition (e.g., hydrops fetalis)
- Monitor maternal health in cases of SCT, for development of preeclampsia or mirror syndrome.
- Fetal in utero surgery for SCT has been proposed.
- Twice-weekly fetal nonstress or biophysical profile testing (or both), beginning at 32-34 weeks
- Prenatal neonatology, pediatric surgery, and pediatric orthopedics consultation to discuss postnatal management and prognosis

OBSTETRIC MANAGEMENT

- Deliver when there is confirmation of lung maturity or evidence of hydrops, or if maternal compromise (preeclampsia or mirror syndrome) is seen.
- Delivery in a tertiary care facility is recommended.
- Drainage of predominantly cystic SCT may facilitate vaginal delivery.
- Cesarean delivery should be performed to improve perinatal outcome, particularly if SCT mass is solid or >5 cm in diameter.

- Caution: risk for rupture and hemorrhage of SCT mass during delivery

NEONATAL MANAGEMENT

- SCT tumor mass should be protected from trauma, torsion, and desiccation.
- Surgical repair should be arranged as soon as possible, particularly if the neonate is in a high cardiac output state.
- Pediatric surgery and pediatric orthopedics consultation

PROGNOSIS

- Perinatal mortality related to the status of the SCT:
 - Solid, highly vascularized tumors have worst prognosis (intratumor hemorrhage, malignancy)
 - Associated hydrops fetalis almost always fatal
 - Preterm delivery reduces survival to 25%.
 - Tumor size > 10 cm has 50% perinatal mortality.
 - In the absence of hydrops or polyhydramnios with SCT, >70% survival is expected.
- Sacral agenesis results in significant orthopedic disability (similar to paraplegia).
- Long-term morbidity includes stool and urinary incontinence.

26E SKELETAL DYSPLASIA

Diagnosis

DEFINITION

Skeletal dysplasia comprises a genetically diverse group of more than 350 disorders of the skeleton causing abnormal bone length, shape, and density, with varying degrees of disability.

INCIDENCE AND PATHOGENESIS

- The incidence of skeletal dysplasia is approximately 2.4/10,000 live births.
- Skeletal dysplasia results from heterogeneous genetic defects that affect embryonic limb development through abnormalities at the molecular level:
 - Extracellular structural proteins
 - Metabolic pathways
 - Folding and degradation of macromolecules
 - Hormone and signal transduction mechanisms
 - Nuclear proteins and transcription factors
 - Oncogenes and tumor suppressor genes
 - RNA and DNA processing and metabolism

DIFFERENTIAL DIAGNOSIS

- Intrauterine growth restriction
- Aneuploidy
- Constitutionally small fetus (e.g., hereditary, familial short stature)
- Nongenetic limb reduction conditions:
 - *Malformation*—disordered tissue development resulting from early embryonic teratogen exposure (e.g., viral infection, radiation, medications, diabetes)
 - *Disruption*—breakdown of normal tissue (e.g., amniotic band sequence, vascular accident)
 - *Deformation*—distorted shape of normal tissue (e.g., clubbed feet with prolonged premature rupture of membranes)

KEY DIAGNOSTIC FEATURES

- Assess for skeletal dysplasia if measured femur length is short (<2 SD below mean) for gestational age.
- A *systematic approach* (Box 26-1) should be used to assess the fetus, with all long bone lengths compared with standard biometric tables (Table 26-1).
- Skeletal dysplasias are classified by site of shortened bones (Fig. 26-25):
 - *Rhizomelia*—proximal limb shortened (humerus, femur)
 - *Mesomelia*—intermediate limb shortened (radius, ulna, tibia, fibula)
 - *Acromelia*—distal limb shortened (hands, feet)
 - *Micromelia*—entire limb shortened. Micromelia is further subdivided by measured bone length:
 - Mild (<2 SD)
 - Severe (<3 SD)
- Mineralization is assessed through sonographic echogenicity of bones:

BOX 26-1 SUGGESTED ULTRASOUND ASSESSMENT OF FETUS WITH SUSPECTED SKELETAL DYSPLASIA

Confirm gestational age on basis of last menstrual period or first-trimester ultrasound

Measurements:

- Record lengths of *all* long bones bilaterally: femur, humerus, radius, ulna, tibia, fibula, clavicle. Measure foot length. Assess size and shape of scapula.
- Measure circumference of head, abdomen, chest, and cardiac area.
- Measure thorax in sagittal plane; note contour for bell-shape in coronal plane.
- Calculate ratios:
 - Thoracic circumference-to-abdominal circumference: normal, ≥ 0.8
 - Cardiac circumference-to-thoracic circumference: normal, < 0.6
 - Femur length-to-abdominal circumference: normal, > 0.16
 - Femur-to-foot length: normal, ≥ 1.0

Note morphology of bones:

- Shape: straight, curved, fractures, absent; unilateral versus bilateral
- Echodensity: normal versus poorly mineralized
- Appearance of metaphyseal segment: premature ossification, spikes, epiphyseal calcifications
- Abnormal posturing: clubbing, arthrogryposis

Assess hands for number of digits and shape of phalanges: polydactyly, syndactyly

Note shape and mineralization of cranium and vertebral bodies: macrocrania, cloverleaf skull; scoliosis, platyspondyly, sacral agenesis

Obtain fetal profile: frontal bossing, hypoplastic/absent nasal bone, micrognathia; assess biorbital diameter in coronal plane: hypertelorism or hypotelorism

Evaluate fetus for other congenital anomalies: hydrocephalus, heart defects, hydrops fetalis

Amniotic fluid assessment

Doppler imaging to rule out growth restriction

Additional 3D or MRI imaging may be helpful for assessing face and spine

Modified from Krakow D, Lachman RS, Rimoin DL: *Guidelines for the prenatal diagnosis of fetal skeletal dysplasias*, Genet Med 11:127, 2009.

- Normal bone is *hyperechoic* (brighter white), and produces *acoustic shadowing*.
- Poorly mineralized bone is less echogenic (lighter gray) with less shadowing.
- Prominent ultrasound findings and their associated conditions are listed in Box 26-2.
- Achondroplasia, the most common form of dwarfism, may not become apparent until measured in the third trimester.
- Brief descriptions of common skeletal dysplasias are listed in Table 26-2.

ASSOCIATED ANOMALIES

- Polyhydramnios
- Hydrops fetalis
- Nonskeletal anomalies (cardiac, CNS, urogenital, and facial anomalies)

TABLE 26-2 Common Skeletal Dysplasias and Gene Defects

Skeletal Dysplasia	OMIM #	Gene Defect	Inheritance	Features
Achondrogenesis I	IA, 200600 IB, 600972	TRIP11 SLC26A2	AR	Severe micromelia, poorly mineralized skull and spine, bowing and numerous fractures present, polyhydramnios, hydrops; lethal
Achondrogenesis II	200610	COL2A1	De novo AD	Severe micromelia, poorly mineralized distal spine, normally mineralized calvarium, macrocephaly, short ribs, polyhydramnios, hydrops; lethal
Achondroplasia, heterozygous	100800	FGFR3	AD, new mutation	Rhizomelic shortening, frontal bossing with midface hypoplasia, bowed femur, brachydactyly with trident hand; most frequent form of dwarfism
Achondroplasia, homozygous	100800	FGFR3	AD	Appears similar to thanatophoric dysplasia, type 1 (see below); lethal
Asphyxiating thoracic dysplasia (Jeune syndrome)	208500	Unknown	AR	Mild micromelia, narrow thorax with short horizontal ribs, pulmonary insufficiency, renal abnormalities; variably lethal
Camptomelic dysplasia	114290	SOX9	AR, de novo AD	Mild micromelia with bowed femur and tibia, macrocephaly with micrognathia, absent scapulae, clubfeet, polyhydramnios; lethal
Chondrodysplasia punctata	215100	PEX7	AR	Rhizomelic shortening, microcephaly with frontal bossing, micrognathia, epiphyseal calcifications, mental retardation, seizures; lethal in <2 yr
Diastrophic dysplasia	222600	SLC26A2	AR	Mild micromelia with thick short bones, kyphoscoliosis, "hitchhiker thumb," clubfeet
Ellis-van Creveld syndrome	225500	LBN, EVC	AR	Also known as chondroectodermal dysplasia. Mild micromelia, narrow chest with underdeveloped ribs, heart defects, polydactyly; variably lethal
Hypophosphatasia	241500	ALPL	AR	Severe micromelia, small thorax with rib fractures, poorly mineralized skull and bones with numerous fractures, bowed femurs; lethal
Mesomelic dysplasia	Various	Various	AR, AD	Represents group of syndromes exhibiting nonlethal mesomelic shortening but otherwise generally normal phenotype
Osteogenesis imperfecta II	166210	COL1A1, COL1A2	AR, AD	Severe micromelia with poorly mineralized skull, numerous fractures and bowing, "beaded" ribs, soft calvaria, platyspondyly, hydrops fetalis; lethal
Osteogenesis imperfecta III	259420	COL1A1, COL1A2	AR, AD	Mild micromelia with poorly mineralized skull and bones, numerous fractures and bowing, normal-size chest, kyphoscoliosis; not lethal
Short-rib polydactyly syndrome	263520, 253530	NEK1, DYNC2H1	AR	Severe micromelia, underdeveloped ribs and small chest with pulmonary hypoplasia, polydactyly; lethal
Thanatophoric dysplasia I	187600	FGFR3	De novo AD	Severe micromelia with "telephone receiver" femurs, macrocephaly with frontal bossing, hydrocephalus, platyspondyly, polyhydramnios; lethal
Thanatophoric dysplasia II	187601	FGFR3	De novo AD	Severe micromelia with "cloverleaf" (Kleeblattschädel) skull, short ribs with narrow thorax, platyspondyly, polyhydramnios; lethal

AD, autosomal dominant; AR, autosomal recessive; OMIM, Online Mendelian Inheritance in Man (www.ncbi.nlm.nih.gov/omim).

Imaging

Figure 26-26 Short bowed femur. Ultrasound image at 18 weeks gestation shows markedly short femur (*calipers*), resembling a telephone receiver, in thanatophoric dysplasia type I.

Figure 26-27 Small chest, coronal view. Ultrasound image illustrates the small, bell-shaped chest, suggestive of pulmonary hypoplasia, as is often seen in severe (lethal) micromelia.

Figure 26-28 Poorly mineralized bone. Ultrasound image, axial view, shows decreased echogenicity of the skull in hypophosphatasia. The intracranial anatomy is "seen too well," and the skull deforms with pressure from the ultrasound probe.

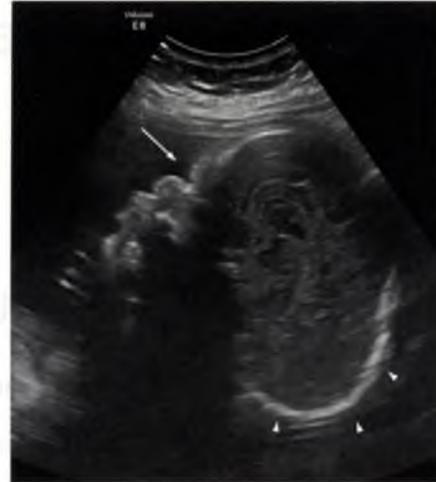

Figure 26-29 Cloverleaf skull, sagittal image. Ultrasound image shows an abnormal cloverleaf skull with midface hypoplasia (*arrow*) and prominent occiput (*arrowheads*) seen in thanatophoric dysplasia type II.

Figure 26-30 Frontal bossing. 3D rendered image shows a prominent forehead, consistent with frontal bossing, seen in heterozygous achondroplasia.

Figure 26-31 Trident hand. Ultrasound image shows the short stubby fingers seen in heterozygous achondroplasia. Note the size of the fingers compared with the head.

BOX 26-3 LETHAL SKELETAL DYSPLASIAS

Achondrogenesis
 Achondroplasia (homozygous)
 Camptomelic dysplasia (variable)
 Chondrodysplasia punctata (variable)
 Hypophosphatasia
 Osteogenesis imperfecta II
 Short-rib polydactyly syndrome
 Thanatophoric dysplasia

Management**ANTENATAL MONITORING**

- Amniocentesis should be considered for karyotyping, molecular testing (see Table 26-2).
- Consider termination for suspected lethal skeletal dysplasias (Box 26-3) (Videos 26-11 and 26-12).
- Fetal echocardiogram is recommended to assess cardiac structure and function.
- Serial ultrasound examinations to monitor fetal growth, amniotic fluid, and worsening fetal condition (e.g., hydrops fetalis)
- Prenatal neonatology and genetics consultations to discuss postnatal management and prognosis
- If the patient herself has a skeletal dysplasia (e.g., achondroplasia), prenatal consultation should include obstetric, neonatal, and anesthesia management plans.

OBSTETRIC MANAGEMENT

- Delivery in a tertiary care facility is recommended.
- Cesarean delivery should be considered for skeletal dysplasias associated with bone fractures and/or poor mineralization

SUGGESTED READINGS

Krakow D, Lachman RS, Rimoin DL: Guidelines for the prenatal diagnosis of fetal skeletal dysplasias, *Genet Med* 11:127–133, 2009.

Spirt BA, Oliphant M, Gottlieb RH, et al: Prenatal sonographic evaluation of short-limbed dwarfism: an algorithmic approach, *Radiographics* 10:217–236, 1990.

Teele RL: A guide to the recognition of skeletal disorders in the fetus, *Pediatr Radiol* 36:473–484, 2006.

(see Box 26-2), or if the patient herself has a skeletal dysplasia.

NEONATAL MANAGEMENT

- With lethal skeletal dysplasias, neonatal resuscitative efforts are not generally recommended.
- Comfort care and supportive measures may be appropriate to allow parents time to accept the lethal nature of the anomaly.
- Continuing diagnostic assessment:
 - Skeletal, spinal, and cranial radiographs
 - Molecular testing
- Consultation with geneticist to help with formulating diagnosis and providing prognosis

PROGNOSIS

- Prognosis depends on which skeletal dysplasia is suspected or diagnosed, and on associated anomalies.
- Conditions associated with *lethal* outcome (see Box 26-3) include
 - Early *severe* micromelia (<3 SD below mean)
 - Femur length-to-abdominal circumference ratio, <0.16
 - Thoracic circumference, <5th percentile
 - Thoracic circumference-to-abdominal circumference ratio, <0.79
 - Cardiac circumference-to-thoracic circumference ratio, >0.60
 - Poor bone mineralization
- Long-term morbidity includes short stature with varying degrees of orthopedic complications, developmental delay, and learning disabilities. Long-term survivors of skeletal dysplasia may have a shortened life span.

Placenta and Umbilical Cord Imaging

THOMAS R. MOORE, MD

27A

MARGINAL AND VELAMENTOUS UMBILICAL CORD INSERTION

Diagnosis

DEFINITION

The placental insertion of the umbilical cord (PCI) may occur centrally into the placental disk, eccentrically at the margin, or into the membranes beyond the margin of the placenta (so-called velamentous insertion, or VCI).

INCIDENCE AND PATHOGENESIS

- The developmental dynamics that determine the directions of growth of the placental disk and the relative point of insertion of the umbilical vessels as the placental disk expands are poorly documented and understood.
- Based on first-trimester ultrasound observations, VCI appears to be a very early occurrence.
- VCI occurs in approximately 1%-4% of singletons.¹
- In twin gestation, VCI is more common, occurring in 10% or more. Marginal insertion occurs in approximately 20% of multifetal gestations.²
- VCI is more frequent with placenta previa³ (incidence, 7.5%).

KEY DIAGNOSTIC FEATURES

- The PCI is determined using color Doppler and gray-scale imaging to identify the location on the placental surface where the umbilical cord and its vessels insert.

- The location of the PCI should be confirmed in two right-angle planes.
- The sensitivity of second-trimester ultrasound in diagnosing VCI is 60%-70%, and specificity is >99%.⁴ However, the sensitivity is only 50% if VCI is on the posterior uterine wall and 40% if it is on the lateral fundus.
- With lower uterine placental implantations, transvaginal imaging may be necessary to accurately characterize the location of PCI.

DIFFERENTIAL DIAGNOSIS

- To differentiate marginal PCI from VCI, at least 1 cm of umbilical vessels should be seen traveling in the membranes beyond the placental edge.
- If VCI is suspected, care should be taken to exclude *vasa previa* (velamentous umbilical vessels coursing within 1 cm of the endocervical os).

ASSOCIATED ANOMALIES

- VCI is associated with multifetal gestation and placenta previa.
- VCI is not associated with fetal structural anomalies.
- In multifetal gestations with VCI, serial assessment of growth is indicated.

Imaging

Figure 27-1 Eccentric umbilical cord insertion. Color Doppler image shows that the cord insertion is more than 2 cm from the placental margin.

Figure 27-4 Marginal umbilical cord insertion. Color Doppler image demonstrates umbilical cord insertion at the placental margin.

Figure 27-2 Central umbilical cord insertion. Color Doppler image localizes the umbilical cord insertion to the center of the placental mass.

Figure 27-5 Velamentous umbilical cord insertion. Color Doppler image shows a cord insertion into the membranes 5 cm from the placental margin.

Figure 27-3 Marginal umbilical cord insertion. Sagittal view of the posterior placenta in the uterine fundus with a vascular structure near the upper placental margin.

Figure 27-6 Pathology specimen with velamentous umbilical cord insertion. The umbilical arteries insert into the margin of the placenta, and the umbilical vein traverses through the membranes.

Management

OBSTETRIC MANAGEMENT

- VCI increases risk of umbilical cord avulsion during placental delivery.
- See “Vasa Previa” for management of velamentous umbilical vessels over the endocervical os.

NEONATAL MANAGEMENT

- Management is dictated by the degree of birth weight abnormality.
- See “Vasa Previa” for management of newborn after intrapartum rupture of velamentous umbilical vessels.

PROGNOSIS

- Central and marginal PCI have no associations with abnormal fetal outcome.
- VCI has been associated with low birth weight, prematurity, and abnormal fetal heart patterns in labor.⁵
- However, if twin gestations and vasa previa are excluded, there is no current evidence that VCI has a significant adverse effect on perinatal or subsequent outcome of the offspring.
- VCI in the lower uterine segment has been associated with nonreassuring fetal heart rate patterns and emergency cesarean sections.

27B MOLAR GESTATION

Diagnosis

DEFINITION

A molar gestation arises when only the spermatid, but not the ovarian, chromosomes replicate in a fertilized ovum. The result is a hydatidiform intrauterine mass.

INCIDENCE AND PATHOGENESIS

- Molar gestation occurs in 1 of every 1000 pregnancies in the United States. In Asia, the frequency is as high as 1 in 100 pregnancies.
- A complete mole is caused when a single (90%) or two (10%) sperm combine with an egg that lacks nuclear DNA.
- Molar pregnancy genotype is typically 46,XX (diploid), with both X chromosomes of paternal origin, but can also be 46,XY.
- A partial mole occurs when an egg is fertilized by multiple sperm, yielding genotypes of triploidy (69,XXY) or quadruploidy (92,XXXXY).
- In complete moles, all chorionic villi are avascular and vesicular, with no embryonic tissue present.
- In partial moles, some villi are vesicular and others are vascularized. Fetal development may occur, but the fetus

is almost always affected by severe aneuploidy and nonviable.

KEY DIAGNOSTIC FEATURES

- The classic appearance presents a “snowstorm” pattern marked by numerous diffuse echolucent and echodense structures smaller than 5 mm.
- Bilateral multicystic ovaries

DIFFERENTIAL DIAGNOSIS

- Missed abortion
- Endometrial carcinoma
- Ovarian neoplasm

ASSOCIATED ANOMALIES

- Vaginal bleeding
- Uterine size greater than indicated by dates
- Bilateral ovarian masses (theca lutein cysts)
- Extremely elevated levels of human chorionic gonadotropin (hCG)
- Hyperthyroidism, thyroid storm
- Partial mole: severe fetal growth restriction

Imaging

Figure 27-7 Hydatidiform mole. The uterine fundus is filled with relatively uniform cystic and solid material at 12 weeks of gestation. No fetal parts were identified.

Figure 27-9 Partial mole. Upper uterine fundus in a gestation with coexisting fetus demonstrates uniform solid and cystic components, consistent with hydatidiform gestation.

Figure 27-8 Molar gestation with multicystic adnexal mass. Hydatidiform uterine contents with adjacent cystic mass (*left*), consistent with theca lutein cysts. The contralateral ovary was also enlarged and multicystic.

Figure 27-10 Partial mole with coexisting fetus. The lower uterine fundus demonstrates a small but relatively normal area of placenta (*upper right*) and a large area of cystic and solid components, consistent with hydatidiform gestation. Between the two placentas is an amniotic cavity with fetus (fetal pelvis and femurs shown). The karyotype of the gestation was triploid (69,XXY) (Video 27-1).

Management

ANTENATAL MONITORING

- Obtain hCG level and thyroid function test results

OBSTETRIC MANAGEMENT

- Uterine evacuation
- For uterine size 20 weeks or more, transfusion capabilities needed to manage potential hemorrhage
- Follow hCG levels until undetectable

NEONATAL MANAGEMENT

- Complete mole: none indicated
- Partial mole: comfort care for aneuploid fetus

PROGNOSIS

- Recurrence risk, 1%
- Invasive mole risk, 10%
- Choriocarcinoma risk, 2%-5%

SUGGESTED READINGS

27C PLACENTA ACCRETA-INCRETA-PERCRETA

Diagnosis

DEFINITION

Placenta accreta is the abnormal invasion of trophoblast into or through the myometrium and into adjacent extrauterine tissues.

INCIDENCE AND PATHOGENESIS

- The incidence of placenta accreta is rising. Recent estimates indicate 1 of every 300 to 500 pregnancies have placenta accreta.
- Risk factors for placenta accreta include prior uterine curettage or fundal surgery, prior cesarean section, and placenta previa (Table 27-1).
- Types of invasive placentation
 - Accreta (82%): invasion into the uterine muscle but not full thickness
 - Increta (12%): invasion into the full thickness of the uterine muscle but not beyond the serosa
 - Percreta (6%): invasion beyond the uterine serosa

KEY DIAGNOSTIC FEATURES

- Loss of hypoechoic space between placenta and myometrium on ultrasound examination
- Multiple vascular lacunae within the placental mass, giving a “Swiss cheese” appearance
- Blood vessels bridging the uterine-placental or myometrial-bladder interface
- Retroplacental myometrial thickness of less than 1 mm

TABLE 27-1 Percent Risk of Placenta Accreta

Pregnancy No.	Placenta Previa	No Placenta Previa
First (primary)	3.3	0.03
Second	11	0.2
Third	40	0.1
Fourth	61	0.8
Fifth	67	0.8
≥Sixth	67	4.7

From Publications Committee, Society for Maternal-Fetal Medicine: Quality of evidence: placenta accreta, Am J Obstet Gynecol 203:430–439, 2010.

- “Bulging” of the placental-myometrial tissues into adjacent spaces (e.g., into the urinary bladder) seen on ultrasound or laterally/posteriorly on MRI imaging.

DIFFERENTIAL DIAGNOSIS

- Normal placenta
- Chorangioma
- Uterine myoma
- Uterine sarcoma

ASSOCIATED ANOMALIES

- Placenta previa

Imaging

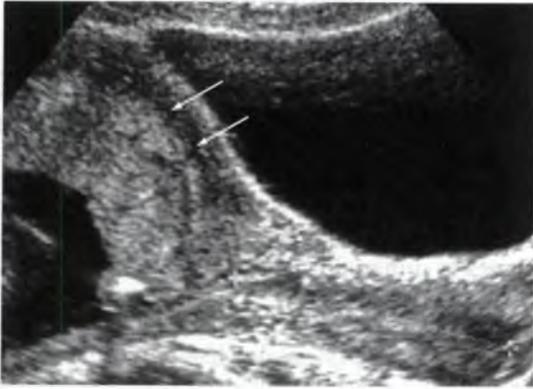

Figure 27-11 Placenta previa. A sagittal abdominal scan of the lower uterine segment shows a complete placenta previa with a relatively homogeneous placental mass and a consistent echolucent line demarcating the placental boundary from the myometrium (arrows).

Figure 27-14 Posterior placenta accreta. Color Doppler vaginal scan shows bulging of placenta into the cervix (upper center) with crossing vessels from placenta to cervical and bladder tissues (Video 27-2).

Figure 27-12 Marginal placenta previa. A vaginal gray-scale scan shows the cervix with posterior placenta extending close to the internal os. The placental mass appearance is homogeneous, and an echolucent line is seen at the boundary with the myometrium (arrow).

Figure 27-15 Placenta accreta invading the bladder. Sagittal abdominal scan shows heterogeneous placental mass bulging into the urinary bladder with multiple echolucencies and absence of echolucent line between placenta and bladder muscularis.

Figure 27-13 Placenta previa invading cervix. A vaginal scan demonstrates cervical tissues (upper right) indistinguishable from the central placenta previa overlying. Multiple echolucencies ("Swiss cheese") and blood vessels are seen.

Figure 27-16 Anterior placenta previa and accreta. Color Doppler image demonstrates "crossing vessels" from placenta into urinary bladder tissues.

Management

ANTENATAL MONITORING

- All women with a prior cesarean delivery should be evaluated for placenta accreta.
- The diagnosis cannot be confidently made until after 20 weeks' gestation.
- MRI imaging can be confirmatory and provides visualization of lateral and posterior tissues.
- Use of gadolinium (pregnancy category C) in MRI imaging should be avoided or minimized.
- Admission to a facility capable of complex care (rapid transfusion, ICU, NICU) for observation if patient has vaginal bleeding to ensure ability to respond to torrential hemorrhage.
- Planning consultations with anesthesia, general surgeon, or gynecologic oncology surgeon and neonatology are recommended.

OBSTETRIC MANAGEMENT

- Current evidence favors scheduled cesarean delivery followed by hysterectomy at 34 weeks after antenatal steroids unless significant bleeding occurs before that time.
- Placement of intraarterial balloon catheters preoperatively is controversial.

- Rapid transfusion and severe hemorrhage management capabilities are essential.
- Attempted removal of the placenta is not recommended unless the suspicion for placenta accreta is extremely low.

NEONATAL MANAGEMENT

- Level of care depends on gestational age at delivery.

PROGNOSIS

- Potential complications of delivery for women with placenta accreta are severe and include maternal death, shock, injuries to urinary tract and gastrointestinal systems, and recurrent laparotomy.
- Women managed by a multidisciplinary team are less likely to require large-volume blood transfusion, reoperation within 7 days, or prolonged maternal admission to ICU.

SUGGESTED READINGS

Publications Committee, Society for Maternal-Fetal Medicine: Quality of evidence: placenta accreta, *Am J Obstet Gynecol* 203:430–439, 2010.

27D PLACENTAL ECHOLUCENCIES: LAKES, CYSTS, CHORANGIOMA

Diagnosis

DEFINITION

- Placental lakes are enlarged intervillous vascular spaces containing maternal blood.
- Placental cysts are fluid-filled blebs near the fetal surface of the placenta, often near the umbilical cord insertion.
- Chorangioma is a nonmalignant vascular placental tumor.

INCIDENCE AND PATHOGENESIS

- Placental lakes are identified in 20% of second-trimester ultrasound examinations.
- Placental cysts occur in fewer than 1 of 2000 pregnancies.
- Chorangiomas (chorioangiomas) occur in 1 of every 3500 to 9000 pregnancies.

KEY DIAGNOSTIC FEATURES

Placental lakes

- Variable size and location over serial examinations
- May completely resolve
- Color Doppler shows no arterial flow in lakes, but swirling, venous flow is seen on real-time scanning

- Numerous lakes have been associated with placental insufficiency and fetal growth restriction, but recent data do not support this.

Placental cysts

- Originate from cord or placental surface
- Increased morbidity with large cysts (>5 cm), including fetal growth restriction and hemorrhage

Chorangioma

- Appears as a well-defined mass contained within the placenta or on its fetal surface.
- Appears hypoechoic but may be heterogeneous if hemorrhage, infarction, or degeneration is present/
- Variable amount of blood flow on color Doppler scanning

DIFFERENTIAL DIAGNOSIS

- Placenta accreta
- Placental lakes, cysts
- Chorangioma
- Uterine fibroid

ASSOCIATED ANOMALIES

- None

Imaging

Figure 27-17 Placental cyst. A 2.1- x 1.1-cm cystic area underlies the umbilical cord insertion, a typical location for a placental cyst. No arterial flow within the cystic area was documented on color Doppler imaging.

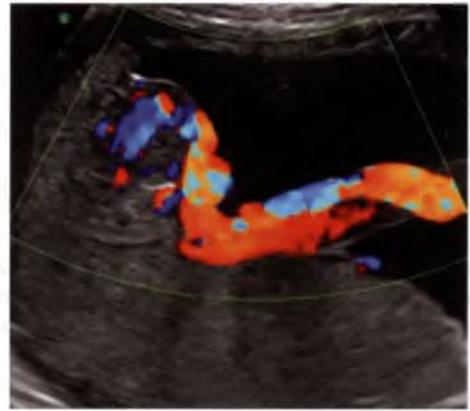

Figure 27-20 Vascular placental mass. Color Doppler image of the heteroechoic mass shown in Figure 27-19 demonstrates extensive internal vascular flow, consistent with a chorangioma.

Figure 27-18 Placental cyst. A cyst measuring 2.8 x 1.7 cm is present near the placental surface. There are no internal echoes. This cyst was resolved when imaged at 20 weeks.

Figure 27-21 Placental echolucencies. Extensive areas of echolucency are scattered throughout this placenta at 12 weeks' gestation. No arterial flow was noted with color Doppler scanning, and the echolucencies resolved by 18 weeks.

Figure 27-19 Heteroechoic placental mass. A 4.5- x 3.7-cm lesion on the surface of the placenta is shown at 32 weeks' gestation with complex and echogenic internal echoes suggestive of a chorangioma. The remaining placental mass is unremarkable.

Figure 27-22 Placental echolucencies. This image at 19 weeks' gestation shows multiple clear spaces within the placenta in an otherwise normal pregnancy. No arterial flow was documented with color Doppler imaging.

Management

ANTENATAL MONITORING

- Placental lakes require no follow-up.
- For placental cysts >3 cm in diameter, serial assessment of fetal growth and cardiac function may be considered.
- For chorangiomas >2 cm in diameter with evidence of intralesional arterial flow, frequent biophysical testing and serial evaluation of fetal growth, cardiac function, and amniotic fluid will help identify a fetus requiring early delivery to avoid hydrops.

OBSTETRIC MANAGEMENT

- Routine obstetric management for placental lakes and cysts.
- Obstetric management with chorangioma is dictated by fetal status.

SUGGESTED READINGS

Brown DL, DiSalvo DN, Frates MC, et al: Placental surface cysts detected on sonography: histologic and clinical correlation, *J Ultrasound Med* 21:641–646; quiz 647–648, 2002.

Reis NS, Brizot ML, Schultz R, et al: Placental lakes on sonographic examination: correlation with obstetric outcome and pathologic findings, *J Clin Ultrasound* 33:67–71, 2005.

Wou K, Chen MF, Mallozzi A, et al: Pregnancy outcomes and ultrasonographic diagnosis in patients with histologically-proven placental chorioangioma, *Placenta* 32:671–674, 2011.

NEONATAL MANAGEMENT

- Routine neonatal management with a normally grown fetus and without hydrops.

PROGNOSIS

- Prognosis with placental lakes is excellent
- Prognosis with placental cysts <3–4 cm is excellent.
- Placental cysts >4 cm may burst, hemorrhage internally, or be associated with fetal growth restriction (33%).
- Chorangiomas >2 cm diameter with arteriovenous shunting may result in fetal anemia, hydrops, polyhydramnios, antepartum hemorrhage, and preterm labor. Preterm birth and fetal growth restriction lead to increased perinatal morbidity or mortality.

27E PLACENTA PREVIA

Diagnosis

DEFINITION

Placenta previa occurs when implantation is near or covers the internal os of the cervix. It is a leading cause of antepartum hemorrhage.

INCIDENCE AND PATHOGENESIS

- Placenta previa affects approximately 0.5% of all third-trimester pregnancies.
- Placenta previa is diagnosed in 5% of mid-trimester sonograms.
- The pathogenesis of placenta previa is unknown, but risk factors include parity, prior cesarean, prior placenta previa, and prior uterine curettage.

KEY DIAGNOSTIC FEATURES

- A complete previa is defined when the bulk of the placental mass overlies the internal cervical os.
- In a partial previa, the placental edge covers the internal cervical os and extends beyond it by up to 20 mm.¹

- In a marginal previa, the placental edge approaches the internal cervical os within 20 mm.¹
- In a low-lying previa, the placental edge approaches the internal cervical os within 21-40 mm.¹
- Vaginal sonography is necessary to accurately diagnose placenta previa with the exception of complete previa.
- Detailed evaluation of the myometrium underlying the placenta is necessary if placenta accreta is suspected.

DIFFERENTIAL DIAGNOSIS

- Low-lying placenta
- Localized uterine contraction near the lower margin of a low-lying placenta
- Placenta accreta
- Succenturiate lobe

ASSOCIATED ANOMALIES

- Placenta accreta
- Vasa previa

Imaging

Figure 27-23 Suspected placenta previa at 17 weeks. Abdominal image of the lower uterus and bladder demonstrates the bulk of placenta centrally located over the probable location of the cervix. However, details of the relationship between internal cervical os and placenta are not visualized.

Figure 27-26 Marginal placenta previa. Endovaginal scan demonstrates a posterior placenta approaching the endocervical os within 1.77 cm. Encroachment of the endocervical os by placental margin within 2 cm is termed “marginal placenta previa.”

Figure 27-24 Central placenta previa. Endovaginal scanning of the same patient as in Figure 27-23 clearly shows the bulk of placenta overlying the endocervical os.

Figure 27-27 Marginal placenta previa. Endovaginal scan demonstrates a posterior placenta within 1 cm of the internal cervical os.

Figure 27-25 Partial placenta previa at 22 weeks. Endovaginal scanning demonstrates a posterior placenta previa extending past the endocervical os by 1.5 cm.

Figure 27-28 Anterior marginal placenta previa at 38 weeks' gestation. Endovaginal scanning demonstrates an anterior placenta approaching the internal cervical os within 1.65 cm.

Management

ANTENATAL MONITORING

- Placenta previa is not associated with altered fetal growth, and serial growth sonography is not indicated.
- In cases with vaginal bleeding, imaging can help localize the source and extent of hemorrhage.
- Follow-up of marginal and partial previa:
 - Of all types of previa diagnosed at 15-19 weeks, 20-23 weeks, 24-27 weeks, 28-31 weeks, and 32-35 weeks, previa resolved by delivery in 88%, 64%, 51%, 38%, and 27%, respectively.²
 - Follow-up scanning for persistence of previa should be performed at 33-35 weeks or with vaginal bleeding.³

OBSTETRIC MANAGEMENT

- Confirm placenta previa within 1-2 weeks before delivery.
- Deliver uncomplicated placenta previa at 36-37 weeks.⁴
- Amniocentesis for lung maturity may impose an unwise delay in delivery and should be avoided unless dates are uncertain.⁴

- If placenta accreta is suspected, deliver at 34-35 weeks.⁴
- Administration of antenatal corticosteroids reduces neonatal respiratory morbidity.⁵
- Because of the increased risk of hemorrhage, blood for transfusion should be available.

NEONATAL MANAGEMENT

- Neonatal morbidity and mortality are more than doubled with placenta previa, largely because of premature delivery for bleeding.
- Anticipatory management and delivery should be conducted in a maternity center with NICU capabilities appropriate to the gestational age of the fetus.

PROGNOSIS

- Maternal prognosis is guarded because of the risk of torrential hemorrhage before and after delivery.
- Newborn prognosis depends on the gestational age at delivery and whether antenatal corticosteroids were administered.

27F SINGLE UMBILICAL ARTERY

Diagnosis

DEFINITION

The normal human umbilical cord contains two arteries but only a single vein due to early atrophy of the left umbilical vein. In single umbilical artery (SUA), also called a two-vessel cord, there is only one artery and one vein.

INCIDENCE AND PATHOGENESIS

- SUA occurs in approximately 1 of every 200 singletons and up to 5% of twins.¹
- Absent left artery is slightly more frequent than absent right artery (60%-70%).²

KEY DIAGNOSTIC FEATURES

- Two umbilical arteries are most accurately visualized with color Doppler imaging of the fetal bladder. Umbilical arteries are seen on both sides of the fetal urinary bladder.
- Imaging of a cross section of the umbilical cord is less reliable.

- Coexistent structural anomalies may be found in up to 30% of fetuses with SUA and can include cardiac, gastrointestinal, and renal defects.

DIFFERENTIAL DIAGNOSIS

- Properly imaged with color Doppler at the fetal bladder, absence of one umbilical artery has no alternative diagnosis.

ASSOCIATED ANOMALIES

- Approximately one third of infants with SUA have additional structural anomalies including cardiovascular, gastrointestinal (esophageal and anal atresias), and renal malformations.
- Chromosomal anomalies, which are frequent in SUA, are uncommon in *isolated* SUA. Among cases of SUA with coexisting anomalies, 5%-50% are aneuploid.
- Fetal growth restriction (FGR), preterm birth, and perinatal mortality are increased in cases of SUA, especially with coexisting structural lesions.³

Imaging

Figure 27-29 Cross-sectional view of the umbilical cord. Three vessels are apparent. However, this method is less sensitive than visualizing umbilical vessels over the fetal bladder, because twisting of loops of umbilical cord in the amniotic fluid may falsely give the appearance of three vessels.

Figure 27-32 Axial view of the fetal pelvis at 22 weeks. Color Doppler image demonstrates a single umbilical artery.

Figure 27-30 Axial view of fetal pelvis. Color Doppler image demonstrates two umbilical arteries coursing over the fetal bladder (BLD).

Figure 27-33 Axial view of the fetal pelvis. This gray-scale view is suspicious for single umbilical artery. The adjacent echolucent area is the top of the fetal bladder.

Figure 27-31 Single umbilical artery. Cross-sectional view of the umbilical cord suggests a vein and a single artery.

Figure 27-34 Axial view of the fetal pelvis. Color Doppler image confirms presence of a single umbilical artery.

Management

ANTENATAL MONITORING

- Detailed search for coexisting structural anomalies
- Consider amniocentesis for karyotype particularly if other anomalies are present
- Serial growth assessment in the third trimester
- Antenatal biophysical testing if anomalies are present or FGR is present

OBSTETRIC MANAGEMENT

- Determined by presence of anomalies or FGR
- If structural anomalies are present, consider delivery in a level III center

REFERENCES

2. Geipel A, Germer U, Welp T, et al: Prenatal diagnosis of single umbilical artery: determination of the absent side, associated anomalies, Doppler findings and perinatal outcome, *Ultrasound Obstet Gynecol* 15:114–117, 2000.
3. Horton AL, Barroilhet L, Wolfe HM: Perinatal outcomes in isolated single umbilical artery, *Am J Perinatol* 27:321–324, 2010.

NEONATAL MANAGEMENT

- Assess newborn for undiagnosed structural anomalies.

PROGNOSIS

- Isolated SUA has not been directly linked to postnatal neurologic abnormalities, but one study documented a 60% excess of children who did not complete compulsory schooling.

Uterus and Adnexae Imaging

THOMAS R. MOORE, MD

28A ADNEXAL MASS, COMPLEX AND SIMPLE

Diagnosis

DEFINITION

An adnexal mass is a lump in the tissue of the adnexa of the uterus, usually in the ovary or fallopian tube. Adnexal masses can be benign or cancerous.

INCIDENCE AND PATHOGENESIS

- Adnexal masses are detected in 1%-4% of pregnant women.
- 1%-3% of adnexal masses detected in pregnancy are malignant.

KEY DIAGNOSTIC FEATURES

- Cystic:
 - Follicular cysts are <3 cm, with no internal echoes.
 - Corpus luteum cysts are 3-6 cm, with a color Doppler circumferential “ring of fire.”
 - Theca lutein cysts are multiloculated.

- Cystadenomas are predominantly cystic but may have internal excrescences.
- Solid:
 - A fibroma may appear as a uterine myoma.
- Solid with cystic components:
 - Hemorrhagic cysts have internal echoes with “sludge”
 - Endometriomas have blood in the cystic components.
 - Teratomas have multiple echogenicities and cystic components and may have shadowing of calcifications.

DIFFERENTIAL DIAGNOSIS

- Paraovarian cyst
- Hydrosalpinx
- Leiomyoma

ASSOCIATED ANOMALIES

- Bilaterality
- Metastasis if malignant

Imaging

Figure 28-1 Normal ovary. Multiple follicles are present. Overall dimensions are 2.4 x 2.1 cm.

Figure 28-2 Simple ovarian cyst. Clear echolucent cyst measuring 1.8 x 1.7 cm, with adjacent follicles distributed in the ovarian stroma.

Figure 28-3 Ectopic pregnancy in fallopian tube. No uterine outline is visible here, and normal-appearing uterus was seen adjacent. The crown-rump length of 8 mm is consistent with 6 weeks and 5 days with fetal heart activity present. The tubal structures appear intact without evidence of hematoma.

Figure 28-4 Serous cystadenoma. A multicystic left ovarian mass at 28 weeks of gestation measures 4.6 x 3.0 cm. Color Doppler demonstrates lack of arterial flow in the lesion.

Figure 28-5 Endometrioma in left adnexa. This adnexal mass, 4.5 x 5.5 cm at 18 weeks, has flocculent internal echoes consistent with hemorrhage. The patient had a history of a "chocolate cyst" at prior laparoscopy.

Figure 28-6 Right adnexal mass with complex internal echoes. MRI scanning demonstrated fat and bone in this 6.6- x 4.7-cm mass, consistent with a benign cystic teratoma (dermoid). The contralateral adnexa was normal (Video 28-1).

Management

ANTENATAL MONITORING AND MANAGEMENT

- Serial measurements of the size of an adnexal mass may influence expectant versus surgical management.
- Documentation of size and internal characteristics near term may influence management at delivery.
- MRI may help differentiate dermoid tumors from other neoplasms.
- Surgery, if performed, has least fetal morbidity at 17-22 weeks.

OBSTETRIC MANAGEMENT

- Routine obstetric management for stable cystic lesions <6 cm when vaginal delivery is planned
- If cesarean delivery is performed, appropriate surgical management, including staging if indicated, should be performed on all adnexal masses.

- Planned cesarean delivery should be reserved for complex lesions that are strongly suspected to be malignant, or that are likely to obstruct labor.

NEONATAL MANAGEMENT

- As indicated by gestational age and newborn condition at delivery

PROGNOSIS

- Resolution occurs in 80%-90% of cases.
- Lesions more likely to resolve include simple cysts <5-6 cm in diameter and diagnosed before 16 weeks.
- Persistent masses are more likely to result in torsion (1%-22%), rupture (0%-9%), or obstruction of labor (2%-17%).
- Malignancy occurs in 1%-2% of lesions overall.

28B AMNIOTIC FLUID VOLUME

Diagnosis

DEFINITIONS

- Oligohydramnios: abnormally low amniotic fluid volume, typically lower than the 5th percentile.
- Polyhydramnios: abnormally high amniotic fluid volume, typically higher than the 95th percentile.

NORMAL VALUES FOR ESTIMATION OF AMNIOTIC FLUID VOLUME USING ULTRASOUND

- Amniotic fluid volume can be estimated by the maximum vertical pocket (MVP) method or by the amniotic fluid index (AFI), a four-quadrant sum of pocket depths.
 - See Table 28-1 for AFI normal values.
 - See Table 28-2 for MVP normal values.

KEY DIAGNOSTIC FEATURES

- Technical aspects:
 - Pockets should be measured in the maternal sagittal plane without angling.
 - Gain should be set to allow visualization of umbilical cord if present in amniotic fluid pockets.
 - Amniotic fluid pockets measured should be clear of intervening fetal parts or umbilical cord.
 - Do not measure into narrow pockets or within 1 cm of fetal body parts.
- Oligohydramnios: AFI < 5 cm; MVP < 2 cm, or less than the 5th percentile

- Polyhydramnios: AFI > 24 cm; MVP > 8 cm, or more than the 95th percentile

DIFFERENTIAL DIAGNOSIS

- Oligohydramnios may be caused by maternal dehydration.
- Maternal ingestion of 2 L of water can increase AFI by 2-4 cm.

ASSOCIATED ANOMALIES

- Oligohydramnios:
 - Fetal growth restriction
 - Maternal dehydration
 - Fetal urinary tract anomalies
 - Ruptured membranes
- Polyhydramnios:
 - Maternal diabetes
 - Obstruction to fetal swallowing (esophageal atresia, thoracic mass or effusion, duodenal atresia, facial malformation, or tumor)
 - Fetal hydrops (resulting from fetal anemia, cardiac failure, or arrhythmia)

Management

ANTENATAL MONITORING

- Oligohydramnios at term should be evaluated for delivery or submitted to further testing, which may consist of

repeat AFI measurement after maternal hydration, biophysical profile, nonstress testing, or contraction stress testing. Because of the increased risk of fetal demise and emergent delivery with oligohydramnios, pregnancies with borderline-low amniotic fluid may benefit by weekly or semi-weekly biophysical testing.

- Polyhydramnios near term should prompt frequent biophysical testing because of the increased risk of fetal demise.

OBSTETRIC MANAGEMENT

- Oligohydramnios should not be the sole indication for obstetric intervention, which is called for if coexisting factors (e.g., term gestation, fetal growth restriction, low biophysical score) are present.
- Polyhydramnios at term should be evaluated for delivery. Consider hospitalization near term if fetus is in an unstable lie.

NEONATAL MANAGEMENT

- Deliver in a center with advanced care capabilities if the fetus has a significant structural anomaly.

PROGNOSIS

- Oligohydramnios is associated with increased fetal demise, operative delivery, and meconium staining. With the exception of severe urinary tract anomalies (e.g., renal agenesis, posterior urethral valves), outcome of cases with oligohydramnios is excellent with proper management.
- Polyhydramnios is associated with increased fetal demise, fetal malpositioning, umbilical cord prolapse, and operative delivery.

28C UTERINE ANOMALIES

Diagnosis

DEFINITION

Defects in uterine unification occur during embryonic development and may be complete, yielding two uteri and two cervixes, or with varying degrees of incompleteness, including bicornuate, unicornuate, septate, and arcuate uteri.

INCIDENCE AND PATHOGENESIS

- Uterine anomalies occur in 1%-10% of women and are associated with increased miscarriage, fetal growth restriction, premature birth, and malpresentation.
- Uterine anomalies arise from abnormal fusion or canalization of müllerian ducts during embryonic development.
- Uterine anomalies are present in 1%-10% of women, in 2%-8% of women seeking fertility treatment, and in 5%-30% of women with a history of miscarriage.

KEY DIAGNOSTIC FEATURES

- Types of anomalies (with percentage of uterine anomalies):
 - *Bicornuate* (51%) has two uterine horns with a cleft between them, and a single cervix.
 - *Didelphys* (25%) has two complete uterine horns and two cervixes.
 - *Septate* (13%) has a single uterine horn without a cleft but with two cavities divided by a septum of varying length, and a single cervix.

- *Unicornuate* (3%) has a single uterine horn and cervix, and usually only one tube and ovary. The contralateral horn and usually tube and ovary are absent.
- *Arcuate* has a single but shallowly indented uterine horn and a single (heart-shaped) cervix. The uterine cavity is deformed with a variably sized central thickening at the fundus.
- A second horn adjacent to the gravid horn may appear to be a uterine or adnexal mass but will have an echogenic endometrial "stripe."

DIFFERENTIAL DIAGNOSIS

- Adnexal mass
- Uterine fibroid
- Gastrointestinal tumor

ASSOCIATED ANOMALIES

- Absent kidney (30% of anomalies)
- Septate vagina (5%)
- Fetal growth restriction (odds ratio [OR] = 2.0)
- Placental abruption (OR = 3.1)
- Preterm birth < 34 weeks (OR = 7.4)
- Malpresentation (OR = 8.6)
- Cervical incompetence and second-trimester loss

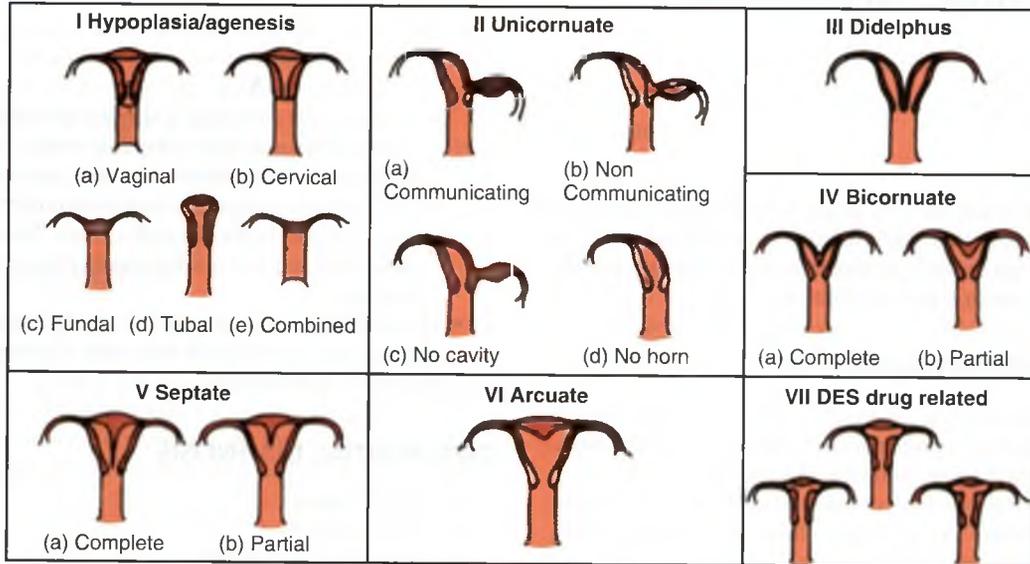

Figure 28-7 Illustrations of the different types of uterine anomalies. (From American Fertility Society classifications of adnexal adhesions, distal tubal occlusion, tubal occlusion secondary to tubal ligation, tubal pregnancies, müllerian anomalies and intrauterine adhesions, *Fertil Steril* 49:944-955, 1988.)

Figure 28-8 Septate uterus. A septate uterus has minimal fundal indentation and an internal septum of variable length. The septum shown extends inferiorly to just above the cervix. A 5-week pregnancy is in the right uterine horn.

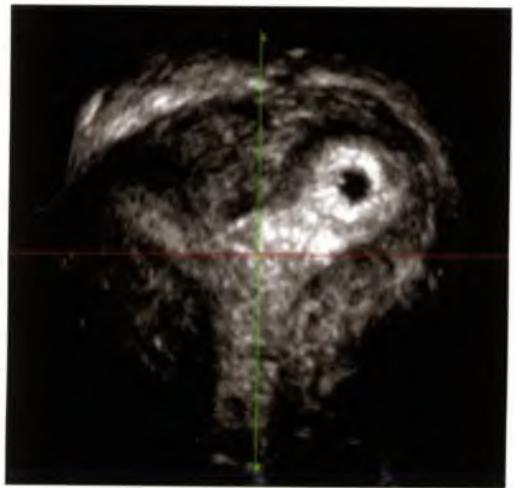

Figure 28-10 Arcuate uterus. This arcuate uterus has minimal external indentation with a rounded protuberance into the uterine cavity. A pregnancy is in the left horn.

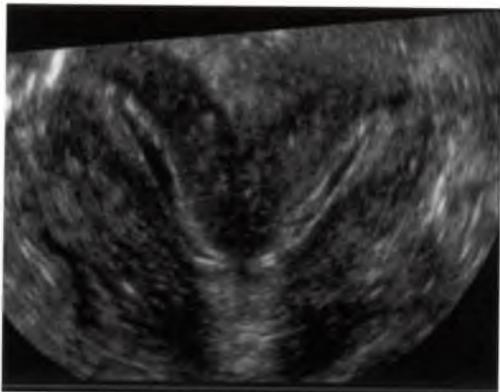

Figure 28-9 Bicornuate uterus. Two distinct uterine horns and uterine cavities are noted with a single cervix (Video 28-2).

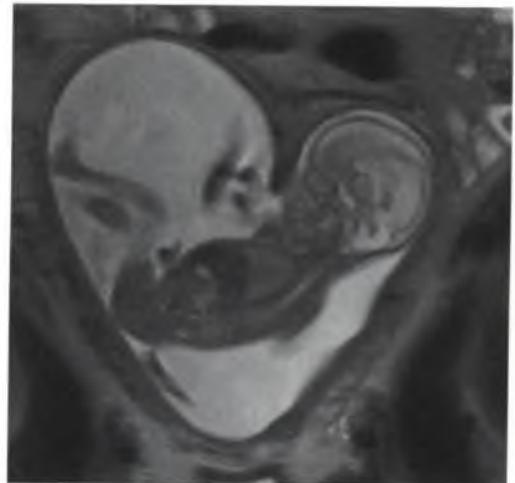

Figure 28-11 Arcuate uterus. MRI image shows an arcuate uterus distinguished by the heart-shaped external appearance and a moderate-size internal septum. The fetus is in a transverse lie.

Management

ANTENATAL MONITORING

- Assess coexisting maternal renal anomalies.
- Serial growth assessments in the third trimester
- Antenatal corticosteroids if preterm birth is imminent
- Assessment of fetal position near term for delivery planning

OBSTETRIC MANAGEMENT

- Dictated by presence or absence of fetal growth restriction, malpresentation

NEONATAL MANAGEMENT

- Dictated by gestational age at delivery

PROGNOSIS

- Incidence of preterm birth is not increased in women with arcuate uteri.
- Fetal growth restriction is most frequent in septate and bicornuate uteri with medial placental implantations.

SUGGESTED READINGS

American Fertility Society classifications of adnexal adhesions, distal tubal occlusion, tubal occlusion secondary to tubal ligation, tubal pregnancies, müllerian anomalies and intrauterine adhesions, *Fertil Steril* 49(6):944–955, 1988.

28D UTERINE FIBROIDS

Diagnosis

DEFINITION

A uterine fibroid (also myoma, leiomyoma) is a benign tumor that originates from the myometrial layer of the uterus.

INCIDENCE AND PATHOGENESIS

- The incidence of uterine fibroids at the mid-trimester ultrasound evaluation is 3%-4%.
- Fibroids are monoclonal smooth-muscle tumors.
- Risk factors include African-American descent, nulliparity, obesity, polycystic ovary syndrome, diabetes, and hypertension.
- Fibroid growth is stimulated by estrogen and progesterone. Paradoxically, most fibroids typically do not grow during pregnancy.

KEY DIAGNOSTIC FEATURES

- Types: submucosal, intramural, subserosal, pedunculated
- Appearance: generally a spherical, well-defined, largely hypoechoic mass

- Location: may be anywhere on the uterine fundus, extending into the uterine cavity, bulging into the adnexae
- Degenerated fibroids more heterogeneous and variable in echogenicity
- With color Doppler, usually no blood flow is evident in the fibroid.

DIFFERENTIAL DIAGNOSIS

- Localized contraction
- Ovarian mass
- Placental abruption
- Duplicate uterine horn
- Chorangioma
- Uterine sarcoma

ASSOCIATED ANOMALIES

- Breech fetal presentation
- Placenta previa

Figure 28-12 Intrauterine pregnancy with anterior uterine myoma. The 3- x 3-cm myoma is located on the anterior uterine surface and beneath the maternal bladder (at center top). A portion of the placenta is implanted on the myoma and covers the cervix. Scanning later in pregnancy will help determine whether the anterior myoma limits fetal growth or obstructs labor.

Figure 28-15 Retroplacental uterine myoma at 17 weeks of gestation. Color Doppler shows lack of vascularity in the myoma, which increases the risk of infarction or "red degeneration."

Figure 28-13 Right fundal fibroid. A 12-week intrauterine gestation (on the right) with a 6.7- x 4.9-cm mass in the fundal area connected to the myometrium by a narrow base, possibly pedunculated, consistent with a myoma.

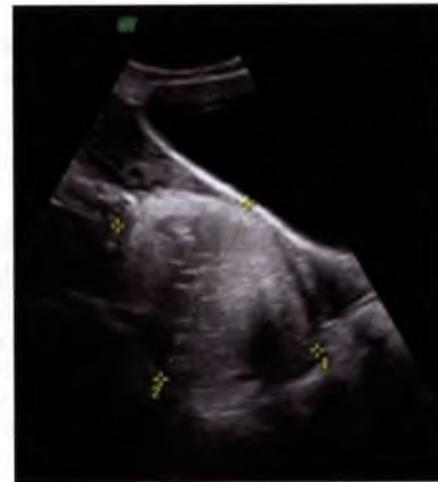

Figure 28-16 Submucosal uterine fibroid in the lower uterine segment. The large 9- x 7-cm fibroid distends the lower segment of the uterus just above the cervix and behind the maternal bladder. The fetus (not seen in this image) is above the fibroid to the left (Video 28-3).

Figure 28-14 Retroplacental uterine myoma at 17 weeks of gestation in the lower uterine segment. A major portion of the placenta (at the left) is implanted on the lateral uterine myoma measuring 4.7 x 3.7 cm. Retroplacental location can be associated with fetal growth restriction. Characteristic heterogenic echoes in the myoma indicate possible early degeneration.

Figure 28-17 Lower uterine segment fibroid with central degeneration. Sagittal view of the uterus shows a 9-week gestation on the left and a contiguous 9- x 6-cm mass in the lower segment, with a clear cystic center, consistent with degenerating fibroid.

Management

ANTENATAL MONITORING

- Fibroids should be enumerated and individually measured at each examination.
- However, change of fibroid dimension or appearance is of little prognostic value.
- If the placental implantation is over one or more fibroids, profiling fetal growth in the third trimester may identify cases of reduced placental function.
- If fibroids are noted in the lower uterine segment, ultrasound assessment of their size and location near term can aid in delivery planning.
- Acute infarction of a fibroid during pregnancy, accompanied by severe abdominal pain, labor, and possibly preterm birth, may appear as internal liquefaction and decreased echogenicity of the fibroid.

OBSTETRIC MANAGEMENT

- Because risk for uterine rupture during labor in a pregnancy after myomectomy is 1% or less, a trial of labor is not contraindicated.
- Caution in delivery is recommended because of increased risk for fetal malpresentation, retained placenta, and postpartum hemorrhage.

- Cervical or lower uterine segment fibroids may obstruct delivery.

NEONATAL MANAGEMENT

- Neonatal care is based on gestational age at delivery.

PROGNOSIS

- Fibroids may grow, infarct, or degenerate during pregnancy, but this is rare.
- Fetal growth restriction is possible if placental implantation is on one or more fibroids.
- Pregnancy complications with fibroids:
 - Malpresentation
 - Preterm rupture of membranes
 - Preterm birth
 - Fetal demise at <32 weeks
 - Placenta previa
 - Abruption
 - Postpartum hemorrhage

First-Trimester Imaging

BRYANN BROMLEY, MD | THOMAS D. SHIPP, MD

29A ANOMALIES

Diagnosis

DEFINITION

Fetal structural anomalies can often be identified between 11 and 13 ½ gestational weeks. Knowledge of normal embryologic development is vital to making the diagnosis.

INCIDENCE AND PATHOGENESIS

- Many different types of structural anomalies can be diagnosed at the time of nuchal translucency (NT) evaluation.
- At least one third and as many as two thirds of structural anomalies can be detected in the first trimester among low-risk women.^{1,2}

KEY DIAGNOSTIC FEATURES

- Physiologic midgut herniation of bowel into the base of the umbilical cord begins in the embryonic period and is usually complete by the time the crown-rump length reaches 45 to 54 mm. Midgut herniation is abnormal after the crown-rump length reaches 61 mm.³⁻⁵
- The fetal stomach is normally visible by 10 weeks' gestation.⁵
- The falx cerebri and choroid plexus are visible by 10 weeks' gestation. Lack of lateralization is abnormal and suggests holoprosencephaly.⁶
- Primary ossification of the cranium begins at 11 weeks' gestation and should be complete by the end of 14 weeks' gestation.^{4,6}
- Abnormalities in cephalic contour suggest cranial defects such as anencephaly or acrania. Encephaloceles may be seen as a protrusion of brain tissue outside the cranium.

- Myelomeningocele can be identified by the presence of an acorn-shaped cranium with an irregular appearance of the spine.⁶
- The fetal bladder is seen by 12 weeks' gestation.⁴ Megacystitis is diagnosed with a bladder length of ≥ 7 mm and may be associated with aneuploidy or obstructive genitourinary anomalies.²
- Fetal genitalia have male or female characteristics but are not fully developed until the end of the 14th week.⁴
- The atria, ventricles, atrioventricular valves, veins, and outflow tracts are fully formed before 11 weeks' gestation⁵ and may be identifiable during NT testing.
- The amniotic fluid is primarily a transudate and not dependent on fetal renal function in this gestational age window.

DIFFERENTIAL DIAGNOSIS

- Differentiating a bowel-containing omphalocele from physiologic herniation of the bowel is difficult before a crown-rump length of 61 mm, because of variability in embryologic development.³⁻⁵
- Liver identified in the base of the umbilical cord is abnormal and consistent with an abdominal wall defect.³
- Acrania or anencephaly is diagnosed when the cranium is absent. An abnormally shaped cephalic contour may suggest this diagnosis earlier in gestation.^{4,6}
- Enlarged fourth ventricles can be a physiologically normal variant seen during NT testing.⁶
- Normal appearance of fetal kidneys in the first trimester does not exclude polycystic kidneys, as these can develop later in pregnancy.⁷
- Normal amniotic fluid volume in the first trimester does not exclude a significant renal anomaly.

Imaging

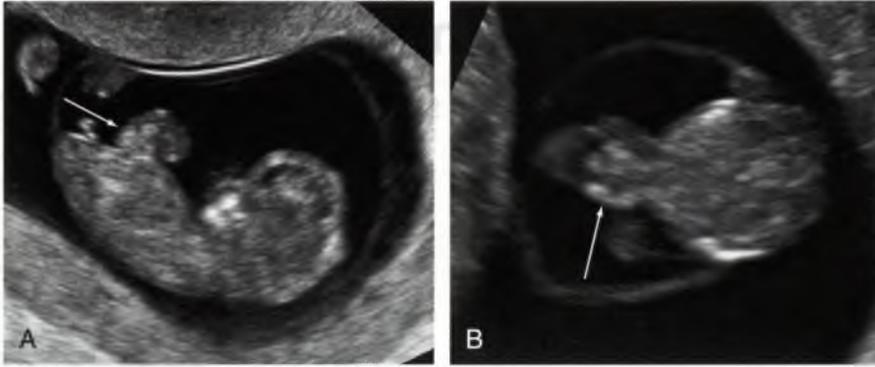

Figure 29-1 Bowel herniation. Sagittal (A) and transverse (B) views of an 11-week fetus showing a physiologic herniation of bowel (arrow). Note the echogenic characteristics of the bowel.

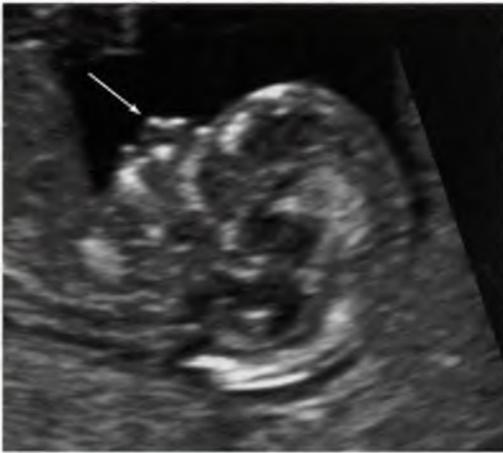

Figure 29-2 Facial cleft. Midsagittal view of the profile in a 12-week fetus showing a maxillary protruberance (arrow) characteristic of a large facial cleft.

Figure 29-3 Acrania. Sagittal image of a 12-week fetus with acrania (arrow). Arrowheads show amniotic bands.

Figure 29-4 Acrania. 3D-rendered image of a 12-week fetus with acrania and a small amount of irregular brain tissue (arrow).

Figure 29-5 Alobar holoprosencephaly. Transverse image of a fetal head at 12 weeks demonstrating the monoventricle of alobar holoprosencephaly (arrow).

Figure 29-7 Megacystis. Oblique image of an 11-week fetus with megacystis (arrow).

Figure 29-6 Congenital diaphragmatic hernia. Transverse image of the fetal chest at 12 weeks demonstrating a congenital diaphragmatic hernia. Arrow, stomach; arrowhead, heart.

Figure 29-8 Postaxial polydactyly. Sagittal image of a 13-week fetus with upper extremity postaxial polydactyly. The arrow shows the extra digit. The thumb is not in the imaging plane.

IMAGING REQUIREMENTS

- No clear protocol exists for first-trimester fetal evaluation to optimize detection of structural defects.
- A high rate of detection of acrania or anencephaly, alobar holoprosencephaly, omphalocele, gastroschisis, megacystis, and gross limb abnormalities should be expected in the first trimester.² These anomalies should be specifically excluded.
- Many first-trimester imaging studies incorporate transvaginal sonography to increase the detection of structural defects.²

- A standardized protocol can lead to complete anatomy scans in 95% of fetuses at 12 to 13 weeks' gestation.⁷
- A reasonable approach to first-trimester anatomic imaging includes the following:
 - View of the head to demonstrate the cranium
 - Transverse view of brain to demonstrate the midline falx
 - Transverse view of thorax, including the fetal heart
 - Views of abdomen to demonstrate stomach, bladder, and abdominal umbilical cord insertion
 - Views of extremities demonstrating long bones, hands, and feet

Management

ANTENATAL MONITORING

- Some abnormalities may not be identified in the first trimester, including agenesis of the corpus callosum and cerebellar vermian abnormalities. The time line for their normal development extends beyond the first trimester.
- Certain cardiac abnormalities, such as some cases of coarctation of the aorta or ventricular hypoplasia, may not be identified in the first trimester, as the pathologic process may occur later.²

- Standardization of approach and further understanding of embryonic and fetal development will improve first-trimester detection rates.
- If one defect is identified, a diligent search for other defects is mandatory.
- Some suspected abnormalities require second-trimester evaluation for definitive diagnosis.

PROGNOSIS

- The prognosis depends on the specific structural anomaly, the severity of the lesion, and associated defects and syndromes.

29B NUCHAL TRANSLUCENCY

Diagnosis

DEFINITION

Nuchal translucency (NT) is the sonographic measurement of the subcutaneous fluid collection between the soft tissue of the cervical spine and the skin in a fetus. The measurement is generally taken between 11 and 13 $\frac{1}{2}$ gestational weeks and is used, along with serum analytes, to assess the risk of aneuploidy.

INCIDENCE AND PATHOGENESIS

- Lucency behind the neck is a normal physiologic space and is measured in a standardized manner to determine NT.
- Fetal NT increases with increasing crown-rump length.¹
- NT thickness can be used to screen for aneuploidy.¹
- NT thickening may be caused by abnormal or delayed lymphangiogenesis, cardiac anomalies with abnormal ductus venosus flow, or extracellular matrix abnormalities.

ASSOCIATED ANOMALIES

- Risk of associated anomalies increases with wider NT.²
- Increased NT is associated with many structural anomalies, including cardiac defects, diaphragmatic hernia, omphalocele, and skeletal anomalies.
- Risk for cardiac anomalies increases with wider NT.³
- Numerous genetic syndromes are associated with thickened NT.²
- Discordant NT measurements may predict twin-to-twin transfusion syndrome in monochorionic twins.⁴

IMAGING REQUIREMENTS

- Gestational age requirement^{5,6} for performing NT varies slightly between laboratories, but generally it is a crown-rump length of 45-84 mm, corresponding to 11-13 $\frac{1}{2}$ gestational weeks.

- A midsagittal view of the head, neck, and upper thorax reveals the tip of the nose, the third and fourth ventricles of the brain, and the palate. The orbit or zygoma should not be visible.
- The image must be magnified so that the head, neck, and upper thorax occupy most of the available space. Movement of the caliper should be in 0.1-mm increments.
- The fetal head should be in line with the spine. The neck must be in a neutral position (not flexed or extended).
- The whole NT line should be visible, and it must be crisp (not fuzzy).
- The amnion must be seen as a separate line from the NT.
- Measurements must be made with a crossbar caliper (+).
- The calipers must be placed at the widest part of the NT.
- The calipers must be placed perpendicular to the long axis of the fetus.
- The calipers must be placed *on* the inner border of the nuchal line, immediately adjacent to the nuchal space. The crossbar of the caliper must not be in the nuchal space.
- The *largest* of several technically good measurements should be reported.
- In the event of a nuchal cord, the NT should be measured above and below the nuchal cord and the values averaged. This is the *ONLY* time the NT is averaged.
- Measurement should be reported to one digit after the decimal (e.g., 1.2, not 1.21)
- Semi-automated measurement is acceptable if image quality requirements are met and practitioner verifies caliper placement.
- The average of three good crown-rump length measurements should be reported with the NT measurement.

Imaging

Figure 29-9 Measurement of crown-rump length. The crown-rump length is measured using a midsagittal view, with the fetus in a neutral position. An average of three good measurements is needed, in conjunction with the nuchal translucency measurement and serum analytes, to assess the risk of aneuploidy.

Figure 29-10 Subcutaneous fluid collection. First trimester fetus with extensive subcutaneous fluid (arrow) extending from behind the neck, down the body, and around to the anterior abdominal wall.

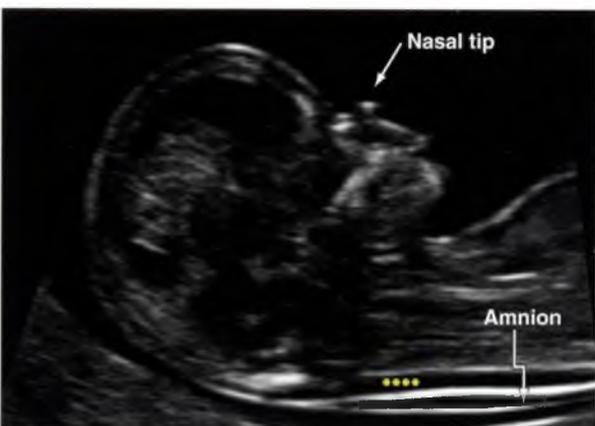

Figure 29-11 Nuchal translucency (NT). Midsagittal view of a 12-week fetus demonstrating the NT (yellow dots in the lucency) and the amnion. The head, neck, and upper thorax fill most of the available space, and the neck is in a neutral position.

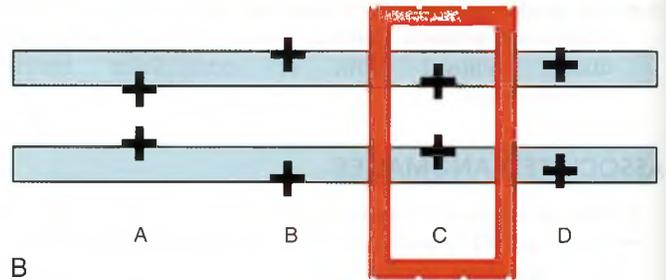

Figure 29-12 Nuchal line. A, Ultrasound image of a 12-week fetus demonstrating the whole nuchal line. B, Schematic shows the correct caliper placement (at C). The crossbar of the + caliper is on the line, at the edge of the lucency, with none of the caliper in the lucency. The gain is turned down to make the nuchal line crisp. (Used by permission of the Perinatal Quality Foundation Nuchal Translucency Quality Review [NTQR] Program.)

Figure 29-13 Nuchal translucency (NT) evaluation. NT evaluation of fetus with a nuchal cord demonstrated by color Doppler. In this situation only, the NT measurement above and below the cord should be averaged.

Management

ANTENATAL MONITORING

- A wide NT may be a transient finding.
- Combined with serum biochemistry, the NT can detect 79%-90% of trisomy 21 cases, with a screen-positive rate of 5%.⁷ The detection rate for trisomy 18 is 90%, with a screen-positive rate of 2%.⁷
- When NT > 3 mm, there is minimal added benefit from serum screening, and there is no benefit when NT > 4 mm.⁸
- Genetic consultation and karyotyping/microarray should be available for those choosing to undergo diagnostic testing. Additional genetic evaluation may be useful for detecting Noonan syndrome.
- When NT ≥ 3.5 mm, patients should be offered detailed sonography and fetal echocardiography even if karyotype and microarray are normal.⁷
- Fetal echocardiography is recommended when NT ≥ 95% or 99%, depending on the performance characteristics desired.^{3,9}

OTHER CONSIDERATIONS

- Accurate and reproducible NT results are achieved only with standardization in measurement, training, and ongoing monitoring.^{5,6}
- NT measurement may not be technically feasible due to high maternal BMI, fibroids, or fetal position.
- Inaccurate measurements lead to inaccurate risk assessment and decrease in sensitivity for the detection of DS.¹⁰
- NT alone (without biochemistry) has a 60% detection rate for DS at a 5% screen-positive rate.⁷

PROGNOSIS

- Prognosis depends on karyotype and associated structural anomalies.
- Risk for adverse outcome depends on degree of NT thickening.
- The majority of fetuses with an increased NT, normal karyotype, and normal detailed sonogram have a normal outcome and no increase in developmental delay.¹¹

Fetal Disorders: Diagnosis and Therapy

Prenatal Diagnosis of Congenital Disorders

RONALD J. WAPNER, MD

Prenatal diagnosis, a term once considered synonymous with invasive fetal testing and karyotype evaluation, now encompasses pedigree analysis, population screening, fetal genetic risk assessment, genetic counseling, and fetal diagnostic testing. Although prenatal evaluation of the fetus for genetic disorders can have a huge impact on individual families, most screening and testing is done for events that occur in less than 1% of pregnancies. In this chapter, we describe different modalities available for in utero fetal diagnosis of congenital disorders, the approach to screening ongoing pregnancies for genetic disease, and the counseling requirement for each.

Screening for Fetal Genetic Disorders

Detecting or defining risk for disease in an asymptomatic low-risk population is the goal of screening. As opposed to diagnostic testing, intended to identify or confirm an affected individual, screening is intended to identify populations who have an increased risk for a specific disorder, and for whom diagnostic testing may be warranted. An ideal perinatal genetic screening test should fulfill the following criteria:

- Identify common or important fetal disorders
- Be cost-effective and easy to perform
- Have a high detection rate and a low false-positive rate
- Be reliable and reproducible
- Screen for disorders for which a diagnostic test exists
- Be positive early enough in gestation to permit safe and legal options for pregnancy termination if desired

Sensitivity and specificity are two key concepts in screening test performance (see Chapter 16). Sensitivity is the percentage of affected pregnancies that are screen positive. Specificity is the percentage of individuals with unaffected pregnancies who screen negative. The reciprocal of specificity is the false-positive rate. Sensitivity and specificity are independent of disease frequency, and they describe the anticipated performance of a screening test in the population. Alternatively, positive and negative predictive values depend on disease prevalence and are vital in the interpretation of the test result for an individual patient. These latter two values represent, respectively, the likelihood that a person with a positive or negative test does or does not have an affected pregnancy. The impact of the prevalence of the disease on the positive and negative predictive values is described in Chapter 16 and is shown in Tables 16-6 and 16-7.

Use of screening tests requires that cutoff values for “positive” tests be set. Performance of the test depends on this cutoff; for example, an increased detection rate can be obtained by lowering the cutoff threshold, but the concomitant lowered specificity would result in more false-positive results. Table 30-1

shows the performance of second-trimester maternal serum screening for Down syndrome based on various cutoffs.¹ A receiver operating characteristic curve can be used as a statistical method to find the best balance between sensitivity and specificity. A line diagram is plotted with sensitivity on the vertical axis and the false-positive rate plotted horizontally (Fig. 30-1). The greater the area under the curve (toward the upper left corner), the better the test’s performance is, with increasing sensitivity and a reduced false-positive rate.

When screening for Down syndrome, cutoff values are important for laboratories that provide the testing and for clinicians who interpret the results. When viewed from the patient’s perspective, reporting tests as positive or negative can be confusing. Receipt of a “positive” result of 1 in 250 may lead to a choice of a diagnostic test that carries a risk for complications, whereas a “negative” result of 1 in 290 may provide greater reassurance than intended, when in fact the actual risk for Down syndrome is similar for both patients. Often, explaining the significance of a positive or negative result before the screening test is performed helps patients understand the results. Many centers report the absolute risk to the patient to further help in interpretation. Regardless of the counseling approach, understanding the concept of screening is difficult for many patients. From the perspective of the laboratory or clinician, selection of a cutoff that is too high or too low will lead to overuse or underuse of diagnostic tests, and the consequent risk for procedure-related pregnancy loss or false reassurance, respectively.

LIKELIHOOD RATIOS

The impact of a positive screening test depends on the pretest (a priori) risk of an affected pregnancy. Likelihood ratios are statistical means to modify an individual’s risk based on known data for a population. For binary risk factors that are either present or absent, likelihood ratios are determined by comparing the frequency of positive tests in affected pregnancies to the frequency in normal pregnancies. This is calculated as the sensitivity of the test divided by its false-positive rate (likelihood ratio = sensitivity ÷ false-positive rate). For tests that use continuous variables (such as serum marker measurements), likelihood ratios are calculated from the log of the gaussian distributions of normal and affected pregnancies. Once a likelihood ratio is determined, it can be used to modify the a priori risk (Table 30-2). If more than one likelihood ratio is available, and if these are independent of other parameters, they can also be used to modify risk. In this way, multiple factors (such as maternal age, serum analytes, and ultrasound findings) can be simultaneously used to modify risk.

TABLE 30-1 Down Syndrome Detection: False-Positive Rates (FPR) at Different Cutoff Values

Triple-Screen Cutoff	Detection Rate (%)	FPR (%)	Quadruple-Screen Cutoff	Detection Rate (%)	FPR (%)
1:200	57	4.3	1:200	60	3.5
1:250	61	5.6	1:250	64	4.5
1:300	64	6.8	1:300	67	5.5
1:350	67	8.1	1:350	69	6.5
1:400	69	9.3	1:400	72	7.6

Data from Huang T, Watt H, Wald N: The effect of differences in the distribution of maternal age in England and Wales on the performance of prenatal screening for Down's syndrome, *Prenat Diagn* 17:615, 1997.

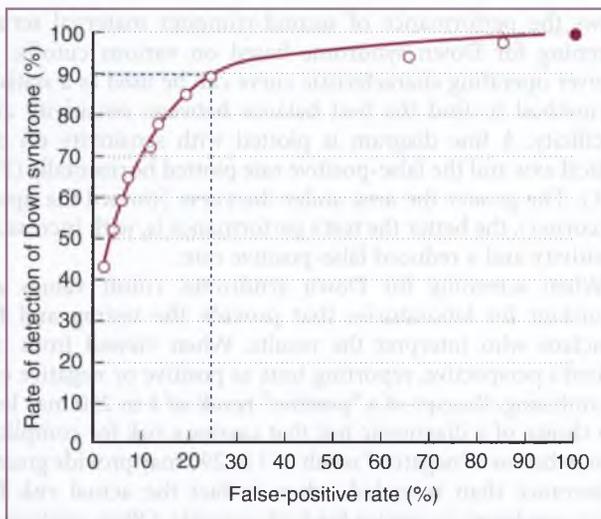

Figure 30-1 Receiver operating characteristic curve for Down syndrome detection. Cutoff points for sensitivity versus false-positive rate are determined by these curves. (From Haddow JE, Palomaki GE, Knight GJ, et al: Reducing the need for amniocentesis in women 35 years of age or older with serum markers for screening, *N Engl J Med* 330:1114, 1994.)

TABLE 30-2 Adjusting the Risk for Down Syndrome Using Likelihood Ratios for Binary Ultrasound Markers

A priori risk for Down syndrome (age or serum screen)	1:1000
Positive ultrasound marker for Down syndrome	
Rate in Down syndrome population (sensitivity of marker)	10%
Rate in general population (FPR of marker)	1.0%
Likelihood ratio (sensitivity/FPR)	10.0
Adjusted risk for Down syndrome	
(A priori risk \times likelihood ratio) \times $\frac{1}{1000} \times 10$	1:100

FPR, false-positive rate.

Antenatal Screening for Down Syndrome

There has been a general consensus in the United States that invasive testing for Down syndrome should be offered to women with a second-trimester risk of 1/270 or higher (liveborn risk of 1/380). The cutoff level and subsequent public policy was determined more than 25 years ago and was based on a maternal age risk of 35 years at delivery. The factors considered in

determining this value included the prevalence of disease, a perceived significant increase in the trisomy 21 risk after this age, the risk of invasive testing, the availability of resources, and a cost-to-benefit analysis.

MATERNAL AGE AS A SCREENING TEST

The association of Down syndrome with advancing maternal age was first reported in 1909.² Fifty years later, karyotype analysis was developed and correlated the Down syndrome phenotype with an extra G chromosome.³ This led to the development of genetic amniocentesis, through which the prenatal diagnosis of Down syndrome became feasible. To standardize the use of this emerging technology, a consensus report from the National Institutes of Health (NIH) in 1979 suggested that amniocentesis be routinely offered to women 35 years or older at delivery. At that time, maternal age risks of Down syndrome were available only in 5-year groupings. Using these data, the age of 35 seemed a natural cutoff, because women in the 30- to 34-year grouping had a risk of 1/880, and the risk for women aged 35 to 40 was almost fourfold higher. This cutoff was based on a number of factors, including the availability of experienced operators and cytogenetics laboratories, the cost-to-benefit ratio, and the balance between procedure-related losses and the possibility of a positive finding.

The risk for Down syndrome is now recognized to be continuous, which emphasizes the arbitrary nature of an absolute age threshold of 35. In addition to maternal age, the risk for trisomy 21 depends on the gestational age at which testing is performed, because only 69% of first-trimester and 76% of second-trimester Down syndrome pregnancies are viable (Table 30-3).⁴ In addition, although the risk for Down syndrome increases with age, 70% of affected pregnancies are born to women younger than 35. For these reasons, and because more refined risk analysis has been developed, maternal age alone is no longer used as an independent indication for invasive testing.

FIRST-TRIMESTER ULTRASOUND SCREENING FOR ANEUPLOIDY

In his initial description of the syndrome that bears his name, Langdon Down described skin so deficient in elasticity that it appeared to be too large for the body. This was particularly noticeable in the neck area. The skin and underlying lymphatic fluid in the fetal neck can now be seen with ultrasound at as early as 10 to 12 weeks of gestation. This nuchal translucency (NT) is defined as the collection of fluid under the skin behind the neck in fetuses between 11 and 14 weeks' gestation. It can be successfully measured by transabdominal ultrasound

examination in approximately 95% of cases, and quantification of the NT is used for first-trimester Down syndrome screening.⁵

An association between increased NT and fetal chromosomal defects is now well known,⁶⁻²³ with an NT thickness above the 95th percentile present in approximately 80% of trisomy 21 fetuses.²² This association between fetal aneuploidy and NT thickness allows the NT measurement to be converted into a likelihood ratio. Because the median NT increases with gestational age or crown-rump length, the actual measurement must first be converted into gestational age-specific multiples of the median (MoM) or a measurement of the deviation from the expected mean (delta NT) before conversion into a likelihood ratio. Figure 30-2 illustrates the NT measurement between 11 and 14 weeks' gestation.

The performance of the NT test combined with the maternal age and gestational age to assess the risk for Down syndrome was studied in a series of more than 100,000 pregnancies.²⁴ The risk for Down syndrome was calculated by the maternal age and gestational age prevalence multiplied by the NT likelihood ratio,

with a cutoff of greater than 1:300 used as screen positive. The sample included 326 fetuses with trisomy 21. Eighty-two percent of trisomy 21 fetuses were identified, for a screen-positive rate of 8.3%.²⁴ When a screen-positive rate of 5% was selected, the sensitivity was 77% (95% confidence interval [CI], 72 to 82). Subsequent studies have demonstrated similar Down syndrome detection rates, between 70% and 75% (Table 30-4).

A screening paradigm using an ultrasound measurement to determine a likelihood ratio is reliable only if NT is measured in a standard fashion. Standards for NT measurements include the following:

1. The minimal crown-rump length should be 45 mm and the maximal 84 mm. The success rate for accomplishing a measurement for these gestational ages is between 98% and 100%. The success rate falls to 90% at 14 weeks and onward.²⁵
2. Either transabdominal or transvaginal scanning can be used; about 95% of cases can be imaged by the transabdominal route.²⁶
3. A true midline sagittal section of the fetus length must be obtained.

TABLE 30-3 Risk for Down Syndrome Based on Maternal and Gestational Ages

Maternal Age (yr)	Gestational Age			
	12 Wk	16 Wk	20 Wk	Liveborn
20	1/1068	1/1200	1/1295	1/1527
25	1/946	1/1062	1/1147	1/1352

4. The magnification must be such that the fetus occupies at least three fourths of the image, and each increment in the distance between the calipers should be only 0.1 mm. Studies have demonstrated that ultrasound measurements can be accurate to the nearest 0.1 to 0.2 mm.²⁷
5. Care must be taken to clearly distinguish between the fetal skin and the amnion. At this gestational age, both structures appear as thin membranes. Distinction can be accomplished by either waiting for spontaneous fetal movement away from the amniotic membrane or by bouncing the fetus off the amnion by asking the mother to cough or by tapping on her abdomen (Fig. 30-3).
6. The maximal thickness of the subcutaneous translucency between the skin and the soft tissue overlying the cervical spine should be measured by placing the calipers on the lines as illustrated in Figure 30-4.
7. The maximum measurement is recorded and used for Down syndrome risk calculation.
8. The NT should be measured with the fetal head in the neutral position. When the fetal neck is hyperextended, the measurement can be increased by 0.6 mm, and when

the neck is flexed, the measurement can be decreased by 0.4 mm.²⁸

9. The umbilical cord is found around the fetal neck in approximately 5% to 10% of cases, which may produce a falsely increased NT, adding about 0.8 mm to the measurement.²⁹ In such cases, the measurements of NT above and below the cord differ, and the smaller measurement is the more appropriate.

Even with these criteria, standardization of NT measurements remains difficult. The ability to achieve a reliable measurement has been linked to the motivation of the sonographer. One study compared results obtained from hospitals where NT was used for clinical purposes, with results from hospitals where they were merely measured but not acted on; in the interventional groups, successful measurement was achieved in 100% of cases, whereas the noninterventional centers were successful in only 85%.³⁰ In a prospective study,³¹ the NT was measured by two to four operators in 200 pregnant women; after an initial measurement, a second one made by the same operator or another operator varied from the initial measurement by less than 0.5 or 0.6 mm, respectively, in 95% of cases. It is suggested that placement of the calipers rather than generation of the appropriate image accounts for a large part of the variation between operators. Subsequent studies³²⁻³⁴ continue to report small interoperator differences.

Because NT values are incorporated into a standardized algorithm along with biochemical analyte values, it is critical that these ultrasound measurements be performed and monitored appropriately. To accomplish this, certification and quality review programs have been developed to ensure that accurate and precise NT measurements are obtained. The Fetal Medicine Foundation of London was the first to offer formalized NT training and quality review. In the United States, the Nuchal Translucency Quality Review (NTQR) program was initiated in 2005. Both programs teach the mechanics of obtaining an NT measurement, have an image review process to ensure that the standard technique is used correctly, and perform ongoing epidemiologic monitoring of sonographer and sonologist performance. Two studies have evaluated the techniques used to ensure consistent NT results. Both confirmed that ongoing expert review of images is an inefficient and impractical approach. Epidemiologic monitoring in which an individual operator's performance is compared with expected standards is preferable.^{34,35}

Figure 30-3 First-trimester nuchal translucency (NT) measurement. Clear distinction between the amnion and the skin edge is made by waiting for fetal movement. Measurement before the fetus moves (A) is less accurate than after fetal movement (B).

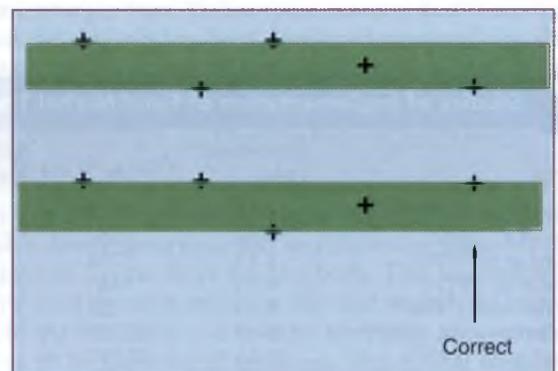

Figure 30-4 Proper placement of the calipers for measuring nuchal translucency. (From Nicolaidis KH, Sebire NJ, Snijders RJM: The 11-14 week scan, New York, 1999, Parthenon.)

FIRST-TRIMESTER BIOCHEMICAL SCREENING

Two maternal serum analytes are useful for first-trimester screening. Pregnancy-associated plasma protein A has been demonstrated to have a mean value of 0.4 MoM in trisomy 21 pregnancies. The free β subunit of human chorionic gonadotropin (hCG) is elevated in Down syndrome pregnancies, with a mean value of 1.8 MoM. Screening using pregnancy-associated plasma protein A (PAPP-A) alone identifies about 40% to 45% of trisomy 21 pregnancies, and free β -hCG identifies about 23%, both with a screen-positive rate of 5%.³⁶⁻³⁸ Combining both free β -hCG and PAPP-A can identify 60% to 65% of trisomy 21 pregnancies, for a similar 5% screen-positive rate.³⁹

The total hCG molecule can also be used for first-trimester screening but has slightly less discrimination power than does the free β subunit,⁴⁰ especially at less than 11 weeks' gestation. Free β -hCG begins to increase in performance as a Down syndrome marker at as early as 9 weeks' gestation, reaching values almost twice those in unaffected pregnancies by 13 weeks. Levels of total hCG begin to increase above those in unaffected gestations at 11 weeks.^{41,42} The impact of substituting total hCG for the free β subunit on overall Down syndrome screening remains uncertain. A meta-analysis showed that in younger patients (<35 years), detection of Down syndrome increased by 4, 5, 6, and 7 percentage points at 9, 10, 11, and 12 weeks, respectively, when free β was added to PAPP-A and NT, compared with 0, 0, 2, and 4 percentage points when intact hCG was added.⁴³ In patients with advanced maternal age (>35), inclusion of free β -hCG reduced the false-positive rate by 2.5, 3.1, 3.8, and 4.4 percentage points, compared with 0.1, 0.3, 1.0, and 2.2 percentage points for intact hCG at 9, 10, 11, and 12 weeks, respectively. Other authors have found less impact. Using samples from the FASTER study, Canick and coworkers⁴⁴ showed that at 12 weeks' gestation, the addition of free β -hCG to NT and PAPP-A added only 0.9% (-3.3 to 6.3) detection. However, at earlier gestational ages, the impact of free β -hCG would be greater.

COMBINED FIRST-TRIMESTER NUCHAL TRANSLUCENCY AND BIOCHEMISTRY SCREENING

Combining NT with serum analytes improves first-trimester Down syndrome detection rates. Table 30-5 summarizes the large international experience with first-trimester Down syndrome screening using free β -hCG, PAPP-A, and NT measurements. Overall, for a 5% screen-positive rate, combined first-trimester risk assessment provides a Down syndrome detection rate of approximately 88% (95% CI, 84.0 to 89.4). In women older than 35, 90% to 92% of trisomy 21 pregnancies

can be identified with a 16% to 22% false-positive rate.^{45,46} First-trimester screening can also identify trisomy 18 pregnancies. Over 90% of such pregnancies are screen positive when combined biochemical and NT screening is used.⁴⁶

Gestational age-specific variation in the performance of individual analytes can affect screening performance.⁴⁷⁻⁴⁹ At all gestational ages between 9 and 12 weeks, NT and PAPP-A are the most efficient markers. In combination, they are most efficient at 11 weeks—a gestational age when free and total hCG are least efficient. In practice, screening is performed between 11 and 13 weeks of gestation.

ADDITIONAL FIRST-TRIMESTER MARKERS OF DOWN SYNDROME

Biochemical Markers

ADAM 12 is the secreted form of a disintegrin and metalloproteinase 12, a glycoprotein of the meltrin family synthesized by the placenta and secreted throughout pregnancy. ADAM 12 has proteolytic function against insulin-like growth factor (IGF) binding proteins (BP) IGFBP-3 and IGFBP-5 and regulates the bioavailability and action of IGF-1 and -2.⁵⁰ Studies have shown that first-trimester ADAM 12 levels are reduced in women carrying a Down syndrome pregnancy, and that the reduction is more pronounced earlier in the gestation.⁵¹⁻⁵³ Discrimination appears to be best at around 8 to 10 weeks, with an overall MoM of 0.79 in Down syndrome pregnancies.⁵³ Population modeling shows that a combination of ADAM 12 and PAPP-A measured at 8 to 9 weeks, combined with NT and free β -hCG measured at 12 weeks, could achieve a detection rate of 97% with a 5% false-positive rate, or 89% with a 1% false-positive rate.⁵³

Ultrasound Markers

Nasal Bone. Assessment of the fetal nasal bone (NB) can be used in the first trimester to predict trisomy 21. This ultrasound marker is based on the flat nasal bridge area, which is a well-described component of the Down syndrome phenotype, and is supported by histopathologic and radiographic studies demonstrating differences in the NBs of Down syndrome fetuses. Stempfle and colleagues⁵⁴ found that NB ossification was absent in one quarter of Down syndrome fetuses investigated between 15 and 40 weeks' gestation, compared with none of the controls. Similarly, Tuxen and colleagues⁵⁵ evaluated Down syndrome fetuses between 14 and 25 weeks' gestational age by radiograph and pathologic study and found that the NB was absent in one third.

Sonek and colleagues⁵⁶ published the first large prospective trial of aneuploid risk evaluation using first-trimester ultrasound assessment of the fetal nasal bone. They determined that

TABLE 30-5 Studies of Down Syndrome Detection Rates in First-Trimester Screening

Source	Pregnancies Screened	Down Syndrome Cases (Screen-Positive/Total)	Detection Rate (%)
Wapner et al, 2003 ⁴⁶ (BUN study)	8216	48/61	79
Malone et al, 2005 ⁴⁵ (FASTER Consortium)	38,033	100/117	86
Wald et al, 2003 ¹⁴⁷ (SURUSS study)	47,053	84/101	83
Nicolaides et al, 2005 ¹⁵²	75,821	321/325	93
TOTAL	167,210	533/604	88.2

Screening tests were for free β -subunit of human chorionic gonadotropin, pregnancy-associated plasma protein A, and nuchal translucency (with a 5% false-positive rate).

Figure 30-5 Ultrasound images of the fetal nasal bone (NB) in the first trimester. First-trimester ultrasound images of euploid (left) and trisomy 21 (right) fetuses demonstrate the presence of the NB in the normal gestation and its absence in trisomy 21. Scanning techniques suggested by the Fetal Medicine Foundation for assessing NB include the following: (1) The image is magnified so that each movement of the calipers causes a 0.1-mm incremental change. (2) A midsagittal view of the fetal profile is obtained. (3) The angle between the ultrasound transducer and a line passing from the fetal forehead to the chin is 45 degrees. (4) When the NB is present, three echogenic lines should be visible. The NB and overlying skin look like an equal sign. In the same view, the skin over the nasal tip should be visible. If both the nasal tip and skin are present, and the NB echo cannot be visualized or is less echogenic than the skin, the NB is considered absent. (From the Fetal Medicine Foundation: Nasal bone [website]. <http://www.fetalmedicineusa.com/nasalbone.php>. Accessed May 30, 2013.)

the fetal NB could be imaged routinely and that its absence was associated with trisomy 21 (Fig. 30-5). The NB was absent in 73% of trisomy 21 fetuses compared with only 0.5% of euploid fetuses. They estimated that if NB assessment were combined with maternal age and NT measurement, 93% of Down syndrome pregnancies would be detected with a false-positive rate of 5%, and 85% with a false-positive rate of 1%.

A recent review of the literature by Rosen and D'Alton⁵⁷ evaluated 35,312 women having first-trimester ultrasound assessment for NB. In 33,314 cases (94.3%), the NB was successfully imaged. The sensitivity of NB alone for detecting trisomy 21 was 65%, with a false-positive rate of 0.8%. The positive predictive value of the screen was 54%, meaning that approximately one in two fetuses with an absent NB had trisomy 21. If the NB was absent, the likelihood that a fetus had trisomy 21 was increased 87-fold. The negative likelihood ratio with a normal NB was 0.35 (95% CI, 0.32 to 0.39).

As experience with NB has increased, relationships between absent NB, fetal crown-rump length (i.e., gestational age), NT, and ethnicity have been established. The current data demonstrate that in euploid pregnancies, NB absence occurs more frequently with increasing NT. In a series of 5851 high-risk patients containing 333 trisomy-21 fetuses, absence of the NB had a likelihood ratio of 37.1 when the NT was less than the 95th percentile, and this was reduced to 13.4 when the NT was 4 or greater.⁵⁸ The same study showed that the NB was more likely to be absent at earlier gestational ages. For example, in euploid fetuses with a crown-rump length between 45 and 54 mm, the NB was absent in 4.7% of cases. At a crown-rump length between 75 and 84 mm, the NB was absent in only 1.0% of cases. Prefumo and colleagues⁵⁹ found that NB hypoplasia was more common in the euploid fetuses of women of African descent than in either Asian or white populations (odds ratio,

2.3). Cicero and colleagues⁶⁰ also found an increased incidence of absent fetal NB in the first trimester in women of Afro-Caribbean and southern Asian descent. The NB was absent in 2.5%, 9.0%, and 5.0% of white, Afro-Caribbean, and southern Asian populations, respectively. Likelihood ratios for trisomy 21 with absent NB were 31.3, 8.8, and 14.2, respectively, in these three populations.

NB status is independent of serum biochemistry, allowing NB assessment to be combined with measurements of NT and maternal serum markers to increase first-trimester screening performance.⁶¹ In a retrospective case-control study of a high-risk population with a median maternal age of more than 38 years, assessed by NT, NB, and biochemistry, it was estimated that 97% of Down syndrome cases would be detected, with a false-positive rate of 5%.⁶² For a false-positive rate of 0.5%, the detection rate would be 90.5%. Although these data are promising, detection rates using this combined screen would be expected to be significantly lower in an unselected population using a similar 5% false-positive rate. In addition, appropriate imaging of the NB appears to be technologically more difficult than measurement of the NT, making its use in a primary screening program less attractive.⁶³

Tricuspid Regurgitation. Another potential ultrasound marker is tricuspid regurgitation determined by pulsed wave Doppler ultrasonography.^{64,65} This finding is present in around 8% of normal fetuses and 65% of those with trisomy 21. Combining tricuspid regurgitation with NT and PAPP-A would be expected to achieve a detection rate of 95% with a 5% false-positive rate, or 90% with a 2% false-positive rate.⁶⁶

Ductus Venosus Waveform. A third potential marker is abnormal blood flow through the ductus venosus. Studies have shown

that pulsation of the ductus venosus gives detection rates of 65% to 75% with a 4% to 5% false-positive rate,⁶⁷ and the rate increased to 75% to 80% when NT was added. When serum biochemical markers measured at 10 weeks were also added, the modeled detection rate increased to 92% with a 5% false-positive rate, or 84% with a 1% false-positive rate.⁶⁸

IMPACT OF SPONTANEOUS MISCARRIAGES ON FIRST-TRIMESTER SCREENING

A potential disadvantage of earlier screening is that chromosomally abnormal pregnancies that are destined to miscarry will be identified. Sixty-nine percent of trisomy 21 fetuses living in the first trimester and 76% of those alive in the second trimester will be born alive.⁴ Using this information, Dunstan and Nix⁶⁹ calculated that a detection rate of 80% in the first trimester is approximately equivalent to a second-trimester sensitivity of 75%, suggesting that even when early spontaneous losses of trisomy 21 pregnancies are considered, first-trimester screening is superior to that presently available in the second trimester.

First-trimester screening would be less desirable if screen-positive pregnancies or those with enlarged NTs were preferentially lost. In a study of 108 fetuses with trisomy 21 diagnosed in the first trimester because of increased NT, Hyett and colleagues found that six patients elected to continue the pregnancy.⁷⁰ In five of the six fetuses, the translucency resolved, and at the second-trimester scan the nuchal fold thickness was normal. All six of these trisomy 21 fetuses were born alive. Wapner and colleagues⁴⁶ calculated that greater than 80% of screen-positive trisomy 21 pregnancies would be born alive.

SECOND-TRIMESTER MATERNAL SERUM SCREENING

Until recently, serum screening performed in the second trimester (approximately 16 to 18 weeks' gestation) was the primary tool in Down syndrome risk assessment. This approach is derived from a 1984 report of lower maternal serum α -fetoprotein (MSAFP) levels in women carrying a Down syndrome fetus. Women with Down syndrome pregnancies had a median MSAFP value of 0.75 multiples of the unaffected median.^{71,72} Using this deviation to calculate a likelihood ratio, the age-related risk for Down syndrome could be modified. When the standard 1:270 cutoff was used, approximately 25% of Down syndrome pregnancies among women less than 35 years of age were screen positive.⁷³⁻⁷⁵

Elevated hCG (mean, 2.3 MoM) and reduced levels of unconjugated estriol (mean, 0.7 MoM) were subsequently linked to an increased risk for trisomy 21.^{72,76,77} The use of hCG alone or reduced levels of unconjugated estriol alone to modify the maternal age risk has a Down syndrome detection rate of only 20% to 30%. However, because they are independent variables, they can be analyzed simultaneously with maternal age and α -fetoprotein (AFP) to form a composite risk calculation (i.e., a triple screen).

The sensitivity of the triple screen for Down syndrome detection in women younger than 35 years ranges between 57% and 67% if the false-positive rate is held constant at 5%.⁷⁸⁻⁸¹ Overall, the odds of having an affected pregnancy with a positive screen are approximately 1 in 33 to 1 in 62, depending on the age range of the population studied,^{82,83} an improvement over the 1:100 odds when maternal age is the sole screening

parameter. Because of the impact of maternal age on the risk analysis, screening women who will be 35 years of age or more increases the sensitivity, using the same cutoffs, to approximately 87%, but with a false-positive rate of nearly 25%.^{79,84}

Inhibin A, a protein produced initially by the corpus luteum and later by the placenta, is now routinely included in second-trimester Down syndrome screening, resulting in a quad screen. Inhibin A levels are elevated in Down syndrome pregnancies (1.3 to 2.5 MoM) and do not vary with gestational age in the second trimester. There is, however, a small correlation with hCG levels, making the added sensitivity for Down syndrome detection less robust.⁸⁵ Detection rates when a quad screen of AFP, hCG, unconjugated estriol, and inhibin A are used are about 75% (screen-positive rate, 5%) in the population younger than 35 years.⁴⁵ For women older than 35, the detection rate is approximately 92%, with a screen-positive rate of 13%.

Other analytes or combinations of analytes have been tested to further increase sensitivity. Hyperglycosylated hCG excreted in maternal urine has been tested as a marker for Down syndrome. One study of nearly 1500 women (1448 control subjects and 39 Down syndrome pregnancies) reported a sensitivity of 96% of affected pregnancies with a 5% false-positive rate, and 71% detection with a 1% false-positive rate, when a combination of hyperglycosylated hCG, urine β -core hCG fragment, MSAFP, and maternal age was used.⁸⁶ This detection rate, however, has not been duplicated by others.

With the addition of extra markers, the potential benefit must be balanced against the cost. With each additional marker, costs to society can balloon into the millions because of the number of pregnancies tested each year with only a minimal improvement in detection. The relative cost value of raising the sensitivity or lowering the false-positive rate a few percentage points is an ongoing debate.

ABNORMAL SECOND-TRIMESTER MATERNAL SERUM MARKERS IN PREGNANCIES WITH A NORMAL KARYOTYPE

Unexplained Elevated Maternal Serum α -Fetoprotein

When an elevated MSAFP is reported in a structurally normal pregnancy in which the gestational age is correctly assigned, and the amniotic fluid AFP (AFAFP) is normal, the biologic explanation is almost always a breach in the maternal-fetal interface. This leads to higher AFP levels in the maternal circulation. Not surprisingly, women with unexplained elevation in AFP levels have an increased risk for obstetric complications, including fetal growth restriction, fetal death, prematurity, oligohydramnios, abruptio placentae, and preeclampsia. Table 30-6 summarizes the numerous reports; the higher the MSAFP level, the greater is the risk. Crandall and colleagues⁸⁷ studied 1002 women with MSAFP values greater than 2.5 MoM and stratified them by the degree of elevation. In those with a normal ultrasound and amniocentesis, the risk for adverse outcome was 27% overall but varied with the degree of elevation. Adverse outcome occurred in 16% when the MSAFP was 2.5 to 2.9 MoM, 29% when it was 3.0 to 5.0 MoM, and 70% when it was greater than 5.0 MoM. Waller and coworkers⁸⁸⁻⁹⁰ investigated 51,008 women screened for MSAFP in California to evaluate the predictive value of high MSAFP compared with low levels. The risk for delivery before 28 weeks was 0.4% with low values (<0.81 MoM) and 3.2% for those with high values (>2.5 MoM), an eightfold

+, risk increased but not quantified; IUFD, intrauterine fetal demise; IUGR, intrauterine growth retardation; LBW, low birth weight; MoM, multiples of the median; MSAFP, maternal serum α -fetoprotein.

Data from Milunsky A, editor: Genetic disorders and the fetus: diagnosis, prevention, and treatment, ed 3, Baltimore, 1992, Johns Hopkins University Press.

difference. The rates for delivery before 37 weeks were 2.6% for the low MSAFP group and 24.3% for the high MSAFP group. Notably, women with MSAFP values greater than 2.5 MoM had a 10.5-fold increase in preeclampsia and a 10-fold increased risk for placental complications. To date, no management protocol has been demonstrated to improve outcome in these cases.

Unexplained Elevated Human Chorionic Gonadotropin Levels

The risk for adverse pregnancy outcome with elevated hCG levels appears to be independent of the risks associated with elevated AFP. Studies have shown that unexplained elevated hCG (>2.0 MoM) is associated with an increased risk for preeclampsia, preterm birth, low birth weight, fetal demise, and possibly hypertension.⁹¹ It appears that the higher the hCG is, the greater the risk.

Elevated Human Chorionic Gonadotropin and Maternal Serum α -Fetoprotein

The combination of elevated MSAFP and hCG levels occurs rarely but may have an overall pregnancy complication rate exceeding 50%. A study of 66 singleton and 33 multiple pregnancies with an MSAFP of greater than 2 MoM and an hCG of greater than 3.0 MoM found that 60% of singletons and 81% of twins had at least one of several obstetric complications, including preeclampsia, preterm birth, growth restriction, placental abnormalities, and fetal death.⁹² Confined placental mosaicism for chromosome 16 has been reported to be associated with extremely high levels of both analytes, as well as with similarly poor outcomes.^{93,94}

Low Second-Trimester Maternal Serum Estriol

Low maternal serum unconjugated estriol levels have been linked to adverse pregnancy outcomes.^{95,96} Very low or absent estriol levels of 0.0 to 0.15 MoM suggest biochemical abnormalities of the fetus or placenta, including placental steroid sulfatase deficiency,^{97,98} Smith-Lemli-Opitz syndrome, congenital adrenal hypoplasia, adrenocorticotropin deficiency,⁹⁹ hypothalamic corticotropin deficiency, and anencephaly.

Smith-Lemli-Opitz syndrome occurs in approximately 1/60,000 pregnancies and is an autosomal recessive disorder resulting from a defect in 3β -hydroxysteroid- Δ 7-reductase, altering cholesterol synthesis and resulting in low cholesterol levels and the accumulation of the cholesterol precursor 7-dehydrocholesterol in blood and amniotic fluid. Because cholesterol is a precursor of estriol, the defect results in reduced or undetectable levels of estriol in maternal serum and amniotic fluid. Smith-Lemli-Opitz syndrome is characterized by low birth weight, failure to thrive, and moderate to severe mental retardation. It is associated with multiple structural anomalies, including syndactyly of the second and third toes, microcephaly, ptosis, and a typical-appearing facies.¹⁰⁰⁻¹⁰² Undermasculinization of the genitalia, including complete sex reversal, can be seen in male fetuses.

Bradley and colleagues¹⁰³ summarized findings in 33 women who delivered infants with Smith-Lemli-Opitz syndrome. Twenty-four of 26 women whose second-trimester estriol values were obtained had levels in less than the 5th percentile (<0.5 MoM). The median level in this group was 0.23 MoM (below the 1st percentile). A risk assessment based on low maternal-serum unconjugated estriol levels, usually less than

0.2 MoM, has been suggested but is not routinely used.¹⁰⁴ Reliable and inexpensive prenatal testing for Smith-Lemli-Opitz syndrome based on amniotic fluid cholesterol or 7-dehydrocholesterol levels is available.¹⁰⁵

Placental steroid sulfatase deficiency is an X-linked recessive disorder that occurs in 1/1500 male fetuses, and it most frequently results from a deletion of Xp22.3, although some cases may result from a point mutation. This enzyme deficiency prevents removal of the sulfate molecule from fetal estrogen precursors, preventing conversion to estradiol. The fetal phenotype depends on the extent of the deletion, with greater than 90% of cases presenting as X-linked ichthyosis. However, in about 5% of cases, there can be a deletion of contiguous genes causing mental retardation. The deletion can, on occasion, extend to cause Kallmann syndrome or chondrodysplasia punctata. The lack of estrogen biosynthesis may result in delayed onset of labor, prolonged labor, or stillbirth.

Prenatal diagnosis for the deletion leading to placental sulfatase deficiency and congenital ichthyosis can be performed by identifying the gene deletion by chromosomal microarray or fluorescence in situ hybridization.¹⁰⁶⁻¹⁰⁸ Although very low estradiol levels, usually below the level of detection, can identify males at risk for this disorder, testing in these cases is not routinely offered because the phenotype is usually mild. However, the rarer, more serious cases of extensive deletions will be missed.¹⁰⁹

SECOND-TRIMESTER ULTRASOUND MARKERS OF DOWN SYNDROME

The postnatal diagnosis of Down syndrome is suspected by the presence of characteristic physical findings that occur frequently in infants with Down syndrome but also in normal individuals. These include a simian crease, a short femur or humerus, clinodactyly, and excessive nuchal skin. Similarly, the in utero diagnosis of Down syndrome can be suspected when certain associated anomalies or physical features are noted on an ultrasound examination. Certain of these anomalies, such as atrioventricular canal defect or duodenal atresia, strongly suggest the possibility of Down syndrome and are independent indications for invasive testing. Although these anomalies are highly specific for trisomy 21, they have low sensitivity and are not useful for population screening. For example, 40% of pregnancies with duodenal atresia have trisomy 21, but it is seen in only 8% of affected fetuses.

Physical characteristics that are not themselves anomalies but that occur more commonly in fetuses with Down syndrome are called *soft markers*. The ratio of the prevalence of these markers in Down syndrome fetuses to their prevalence in the normal population will result in a likelihood ratio that can be used to modify the a priori age or serum screening risk. This is the basis for ultrasound screening for Down syndrome.

For a marker to be useful for Down syndrome screening, it should be sensitive (i.e., present in a high proportion of Down syndrome pregnancies), specific (i.e., rarely seen in normal fetuses), easily imaged in standard sonographic examination, and present early enough in the second trimester that subsequent diagnostic testing by amniocentesis can be performed and its results available in time for pregnancy termination to be an option. A list of available markers and their likelihood ratios are seen in Box 30-1 and Table 30-7, respectively.

No soft marker is independently an indication for invasive testing; it should be part of a total risk analysis including the a

BOX 30-1 SECOND-TRIMESTER ULTRASOUND MARKERS ASSOCIATED WITH DOWN SYNDROME

Brachycephaly
Increased nuchal thickness
Congenital heart defects
Hyperechoic bowel
Shortened femur
Shortened humerus
Renal pyelectasis
Duodenal atresia
Hypoplasia of the midphalanx of the fifth digit
Echogenic intracardiac focus
"Sandal gap" of the foot
Widened ischial spine angle
Short foot length
Short or absent nasal bone

TABLE 30-7 Likelihood Ratios (LR) for Isolated Markers in Three Studies

Sonographic Marker	AAURA LR* (N = 1042)	Nyberg et al. LR (95% CI)† (N = 8830)	Smith-Bindman et al. LR (95% CI)‡ (N = meta-analysis of >131,000)

CI, confidence interval.

priori risk determined by maternal age, the results of serum markers (either first or second trimester or both), and the presence or absence of other sonographic findings. It is wise, therefore, to defer discussion of the impact of specific markers until the ultrasound examination has been completed, the results of serum screening are available, and a final adjusted risk is calculated.

Markers commonly sought to assess the risk for Down syndrome include the following:

1. An increased nuchal fold (>6 mm) in the second trimester is the most distinctive marker. The fetal head is imaged in a transverse plane, the plane used to measure the biparietal diameter. The thalami and the upper portion of the cerebellum should be in the plane of the image. The distance between the external surface of the occipital bone

and the external surface of the skin is then measured. About 35% of Down syndrome fetuses but only 0.7% of normal fetuses have a nuchal skin fold measurement greater than 5 mm. This ratio yields a likelihood ratio of 50 but includes fetuses with more than one marker. When an increased nuchal fold is an isolated finding, the likelihood ratio is still strong at 20-fold. This high likelihood ratio is obtained because of the rarity of an increased nuchal fold in an unaffected population (i.e., high specificity). For women with an a priori risk of less than 1/1600 (age-related risk for a 20-year-old), a 20-fold increase results in a risk estimate of at least 1/270. Thus, the presence of an increased nuchal fold alone is an indication to offer invasive testing.¹¹⁰⁻¹¹⁵

2. The fetal nasal bone has been demonstrated to be hypoplastic or absent in up to 60% of Down syndrome pregnancies imaged in the second trimester and only about 1% to 2% of unaffected pregnancies. Complete absence occurs in about 37% of affected cases, with hypoplasia occurring in about half. In normal pregnancies, absence is seen in 0.9% of cases and hypoplasia in 2.4%. NB length can be converted to a likelihood ratio and used for Down syndrome risk assessment. When performed by experienced operators, NB evaluation may be the best single ultrasound marker for second-trimester risk assessment.⁵⁶
3. Down syndrome fetuses in the second trimester may have short proximal extremities (humerus and femur) relative to the expected length for their biparietal diameter. This can be used to identify at-risk pregnancies by calculating a ratio of observed-to-expected femur length based on the fetus's biparietal diameter. An observed-to-expected ratio of less than 0.91 or a biparietal diameter-to-femur ratio of more than 1.5 has a reported likelihood ratio of 1.5 to 2.7 when present as an isolated finding. A short humerus is more strongly related to Down syndrome, with reported likelihood ratios ranging from 2.5 to 7.5. Bahado-Singh and coworkers¹¹⁶ combined humerus length with nuchal skin fold to estimate Down syndrome risk and calculated the likelihood ratios for various measurements to adjust estimated Down syndrome risk for each patient.
4. Echogenic intracardiac foci occur in up to 5% of normal pregnancies and in approximately 13% to 18% of Down syndrome gestations.¹¹⁷ The likelihood ratio for Down syndrome when an echogenic focus is present as an isolated marker has ranged from 1.8 to 2.8 but may be lower in an Asian population, where their frequency in unaffected pregnancies may be higher.^{118,119} The risk does not seem to vary if the focus is in the right or left ventricle or if it is unilateral or bilateral.
5. Increased echogenicity of the fetal bowel, when brighter than the surrounding bone, has a Down syndrome likelihood ratio of 5.5 to 6.7.¹²⁰⁻¹²² This finding can also be seen with fetal cystic fibrosis, congenital cytomegalovirus infection, swallowed bloody amniotic fluid, and severe intrauterine growth restriction. Therefore, if amniocentesis is performed for this finding, testing for the other potential etiologies should be considered.
6. Mild fetal pyelectasis (a renal pelvis anterior-posterior diameter greater than 4 mm) has been suggested as a potential marker for Down syndrome. As an isolated marker, the likelihood ratio ranges from 1.5 to 1.9 (see

Table 30-7). This has been found by Snijders and coworkers¹²³ to be not significantly more frequent in Down syndrome pregnancies than in normal pregnancies (i.e., low specificity).

7. Other markers described include a hypoplastic fifth middle phalanx of the hand,¹²⁴ short ears, a sandal gap between the first and second toes,^{125,126} an abnormal iliac wing angle,¹²⁷ an altered foot-to-femur ratio,¹²⁸ an altered frontomaxillary angle,^{129,130} and an increased prenasal thickness.^{131,132} These markers are inconsistently used because of the time and expertise required to obtain them.

USE OF SECOND-TRIMESTER ULTRASOUND TO ESTIMATE THE RISK FOR DOWN SYNDROME

As with other screening modalities, second-trimester ultrasound can be used to alter the a priori risk in either direction. A second-trimester scan having none of the known soft markers and no anomalies has a likelihood ratio of 0.4, assuming the image quality is satisfactory. Nyberg and coworkers¹³³ used this approach to calculate an age-adjusted ultrasound risk assessment for Down syndrome in 8914 pregnancies (186 fetuses with Down syndrome, 8728 control subjects). Some type of sonographic finding (major abnormality, soft marker, or both) was observed in 68.8% of fetuses with trisomy 21 compared with 13.6% of control fetuses ($P < .001$). Since a third of fetuses with Down syndrome have neither a marker nor an anomaly, a patient with a normal scan still has a residual risk. When the "genetic ultrasound" is normal, the estimated risk for Down syndrome can be adjusted downward by approximately 60% to 65% (likelihood ratio, 0.4). This sensitivity was observed in a single experienced center. A similar risk reduction may not be achieved in all centers.¹³⁴

Similarly, the presence of soft markers can increase risk. The magnitude of the increase depends on the markers or anomalies seen. Nyberg and colleagues reviewed their own data^{133,135} and the data of others¹³⁶ to estimate a likelihood ratio for each marker as an isolated finding (see Table 30-7). An isolated minor (or soft) marker was the only sonographic finding in 42 (22.6%) of 186 fetuses with trisomy 21, compared with 987 (11.3%) of 8728 control fetuses ($P < .001$). Nuchal thickening, NB hypoplasia, and hyperechoic bowel showed the strongest association with trisomy 21 as isolated markers, followed by shortened humerus, echogenic intracardiac focus, shortened femur, and pyelectasis. Echogenic intracardiac focus was the single most common isolated marker in both affected fetuses (7.1%) and control fetuses (3.9%), but it carried a low risk.

Because soft markers may be present even though the adjusted risk for trisomy 21 remains low, centers should develop policies on when to notify patients and offer invasive testing. Many centers do not inform patients of a single soft marker unless the risk for trisomy 21 exceeds that at which they routinely offer invasive testing with other screening approaches such as first-trimester serum and NT. This cutoff is frequently between 1:200 and 1:300.

COMBINED ULTRASOUND AND SECOND-TRIMESTER MATERNAL SERUM MARKER RISK ASSESSMENT

Ultrasound markers can be combined with serum markers because they are independent. Souter and coworkers¹³⁷

demonstrated a relatively small correlation that needs to be taken into consideration if a quantitative approach is used. Bahado-Singh and colleagues¹³⁸ combined ultrasound markers with maternal analytes, including urinary hyperglycosylated hCG and urinary α -core fragment of hCG. In a sample of 585 pregnancies, the sensitivity for trisomy 21 was 93.7%, with a false-positive rate of 5%.

SECOND-TRIMESTER ULTRASOUND SCREENING FOR OTHER CHROMOSOMAL ABNORMALITIES

Fetal aneuploidy other than Down syndrome can be suspected on the basis of ultrasound findings (Table 30-8). Choroid plexus cysts occur in 1% of fetuses between 16 and 24 weeks' gestation and have been associated with trisomy 18. Among fetuses with trisomy 18, 30% to 35% have choroid plexus cysts. Among fetuses with a choroid plexus cyst, about 3% have trisomy 18, and most (65% to 90%) of these have other ultrasound findings (Table 30-9). Although an isolated choroid plexus cyst was estimated to yield a probability of trisomy 18 of 1 in 150, many series contain a high proportion of older women, which would overstate the risk. Snijders and coworkers¹³⁹ calculated that an isolated choroid plexus cyst has a likelihood ratio of 1.5 for trisomy 18, and thus it can be used to calculate an individual's risk for trisomy 18. The size, location, or persistence of the cyst does not alter this risk.¹⁴⁰⁻¹⁴⁴

Table 30-8 displays the magnitude of the associations between various ultrasound findings and aneuploid conditions

as estimated from a referral population. The rates noted may overestimate the strength of the association when such findings are noted on a screening examination.

OTHER APPROACHES TO DOWN SYNDROME SCREENING: COMBINING FIRST- AND SECOND-TRIMESTER SCREENING TESTS

Screening performance may be improved by combining analytes performed at different gestational ages.^{145,146} These approaches include the following.

TABLE 30-9 Ultrasound Findings Associated with Trisomy 18

Finding	Frequency (%)
Growth restriction	46
Hand or foot abnormalities*	39
Cardiac abnormality	31
CNS abnormality	29
Diaphragmatic hernia	13

Integrated Aneuploidy Screening (Noninformative Sequential). Wald and colleagues¹⁴⁶ described a protocol for screening based on tests performed during both the first (NT and PAPP-A) and second trimesters (quad screen). A single risk estimate is calculated in the second trimester using all six of the measured analytes. Integrated screening has a detection rate of approximately 95%, with a 5% false-positive rate.^{45,146} Approximately 85% of affected pregnancies would be detected with a false-positive rate of only 0.9%.^{146,147} Although this screening approach is quite sensitive and specific, withholding the risk estimate until the second trimester precludes earlier prenatal diagnosis by chorionic villus sampling (CVS) and is not an acceptable approach for many women.¹⁴⁸

If NT scanning is not available, an integrated serum-only screen may be performed (PAPP-A in the first trimester and a quad screen in the second trimester). This approach has a detection rate of 86% to 90%, with a 5% false-positive rate.^{45,146}

Sequential Testing. In an attempt to maximize screening performance by combining first- and second-trimester analytes and yet retain the benefit of first-trimester diagnosis, various methods of sequential screening have been proposed. In these approaches, first-trimester risk results are calculated and used for clinical management, with second-trimester testing performed in selected cases.

Three approaches to sequential risk assessment are presently available. In independent sequential testing, a first-trimester combined risk is calculated with a 1/270 screen-positive cutoff. Decisions on invasive testing are made on the basis of these results. In the second trimester, a quad screen is performed and calculated independently of the first-trimester results. This approach provides detection rates greater than 95%,^{45,145} but it has an unacceptably high false-positive rate—greater than 10%—because independent calculation of the quad screen risk does not take into consideration the reduced second-trimester prevalence of Down syndrome pregnancies after first-trimester prenatal diagnosis.

Stepwise sequential testing reduces the high false-positive rate of independent sequential testing and offers the highest-risk patients the option of first-trimester invasive testing by using a high first-trimester risk cutoff and calculating the second-trimester risk by integrating information from both trimesters.¹⁴⁹ For example, using a 1:65 cutoff in the first trimester identifies 70% of affected pregnancies with only a 1% false-positive rate. If all screen-negative patients proceed to second-trimester screening, an overall detection rate of 95% can be obtained with a 5% false-positive rate. Although this approach has excellent performance, with a high proportion of affected pregnancies identified in the first trimester, it is logistically demanding.

Contingent sequential screening is similar to stepwise sequential screening, but patients with a very low first-trimester combined risk do not have second-trimester analysis performed. Using an approach in which patients with a first-trimester risk of 1/1300 or less complete screening in the first trimester, only 15% to 20% of patients have to return for second-trimester analysis.^{150,151} Contingent sequential screening has a detection rate of 92% to 94%, with a 5% screen-positive rate.¹⁴⁹

Nasal Bone Contingency Screening. NB assessment is technically more difficult to perform than NT, which may limit its

usefulness as a component of first-tier screening. To address this, Nicolaides and colleagues¹⁵² proposed a two-stage screen, reserving NB assessment for patients at intermediate risk after the combined first-trimester screen is complete. In this model, patients evaluated by NT and serum markers with a risk of 1 in 100 or greater would be offered CVS, and those with a risk of less than 1/1000 would be deemed to have such a low risk that no further testing is offered. Those with a risk between 1/101 and 1/1000 would have NB evaluation. In initial studies, performance of this two-stage approach was similar to using NB assessment as part of the initial screen. The two-stage approach would have a significant advantage, because only about 15% of pregnancies would require NB evaluation, which could be performed in centers that have developed special expertise in this technique.

ANEUPLOIDY SCREENING USING CELL-FREE FETAL DNA IN THE MATERNAL CIRCULATION

Characteristics of Cell-Free DNA in the Maternal Circulation

Approximately 5% to 20% of the cell-free DNA circulating in maternal plasma comes from the fetus and provides 25 times more fetal DNA present in a pregnant woman's serum than could be extracted from circulating fetal cells.¹⁵³ Analysis of this has led to the development of techniques for noninvasive prenatal screening.

Circulating fetal DNA is predominantly a product of placental apoptosis as opposed to degradation of fetal erythroblasts.¹⁵⁴⁻¹⁵⁶ This cell-free DNA consists of small fragments (fewer than 450 base pairs), undergoes a rapid turnover, and may appear in apoptotic bodies or nucleosomes.¹⁵⁷ Fetal *SRY* gene sequences are present in the circulation as early as 18 days after embryo transfer, before the definitive fetoplacental circulation, which is not established until 28 days after conception. Fetal DNA is continuously liberated into the maternal circulation with a mean half-life estimated to be 16 minutes at term. Levels increase until around 10 weeks' gestation, remain level between 10 and 21 weeks, and then continue to increase until the third trimester.¹⁵⁸ Fetal DNA levels are undetectable about 2 hours after birth.¹⁵⁹

ANEUPLOIDY DETECTION USING CELL-FREE FETAL DNA IN THE MATERNAL PLASMA

In 2008 two groups identified Down syndrome pregnancies^{160,161} by analyzing the cell-free fetal DNA (cffDNA) in the maternal plasma. Using massively parallel shotgun sequencing, the first 36 bases of all circulating DNA fragments (both maternal and fetal) were sequenced and identified to determine their specific chromosomal origin (Fig. 30-6A). If the fetus has a third chromosome 21, the percentage of chromosome 21 fragments compared to disomic chromosomes will be slightly higher than expected. In a pregnancy in which 10% of the cell-free DNA is fetal, a woman carrying a trisomy 21 fetus should have about 1.05 times more DNA from chromosome 21 fragments than a woman carrying a disomy 21 fetus. Trisomy 21 prediction is based on the ability to distinguish this difference by sequencing millions of fragments, identifying their chromosome origin, and then quantifying their relative proportion (see Fig. 30-6B).

A more recently described approach uses targeted sequencing, which selectively amplifies the genomic regions of interest

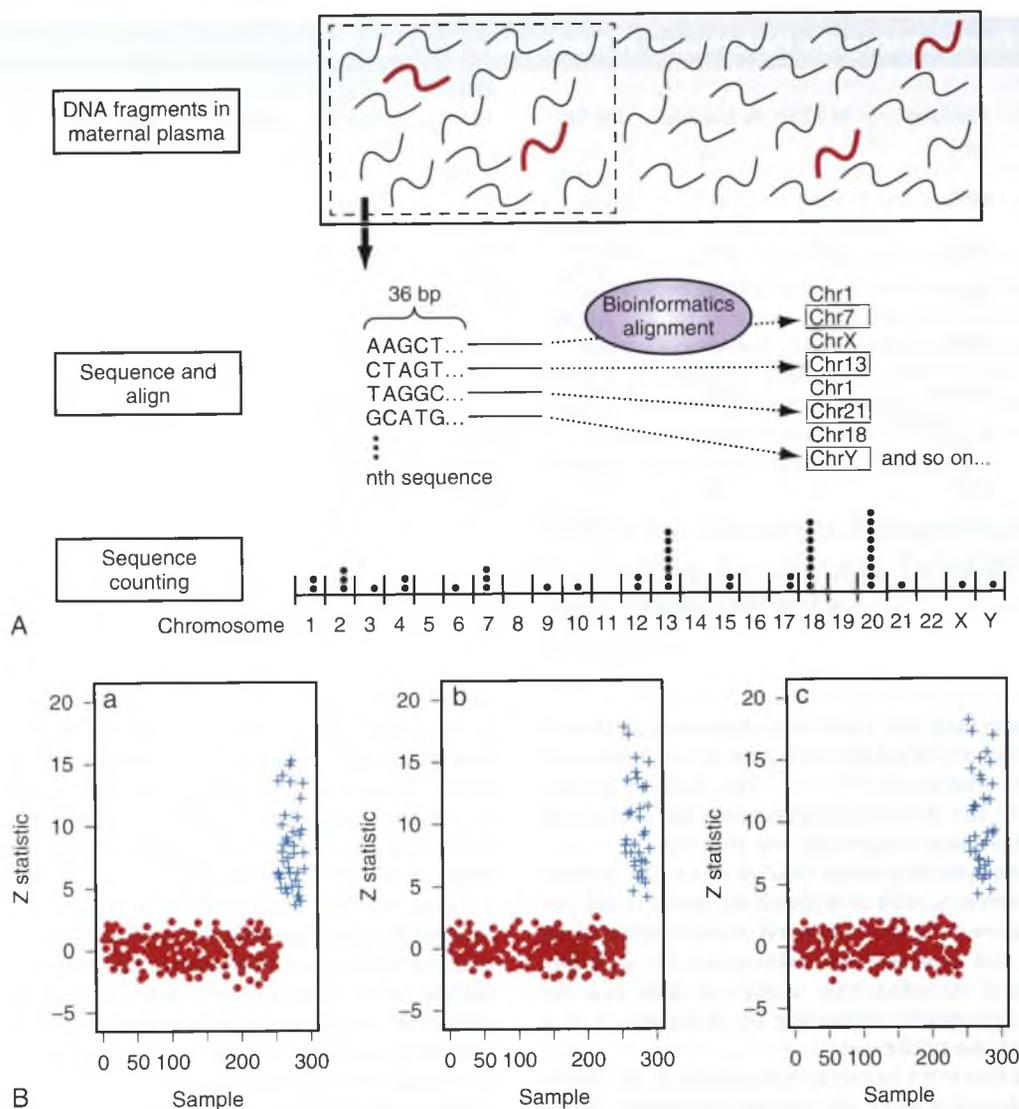

Figure 30-6 A, Fragments of maternal (black) and fetal (red) DNA in the maternal plasma. The fragments are sequenced and, using bioinformatics, aligned to the originating chromosomes. The sequences are then counted to evaluate the relative contribution from chromosome 21. B, Separation of normal pregnancies from Down syndrome pregnancies using a Z score as a cutoff. (From Zhang Z, Wells MC, Boswell MG, et al: Identification of robust hypoxia biomarker candidates from fin of medaka (*Oryzias latipes*), *Comp Biochem Physiol C Toxicol Pharmacol* 155:11–17, 2012.)

(such as nonpolymorphic loci on chromosomes 21 and 18), and then reads and counts only those. The ability to sequence specific regions of the genome in cell-free DNA allows for a focused analysis of clinically important chromosomes such as 13, 18, 21, X, and Y. This strategy significantly reduces the total number of reads analyzed with a concomitant improvement in efficiency and a 10-fold reduction in overall costs.¹⁶² Also, the reduced read requirement enables the use of small bench-top sequencers that affords both financial and practical benefits to the laboratory. This approach results in a higher sensitivity and specificity for the detection of fetal trisomy 21 and 18,^{158,163} but the detection rate for other aneuploidies varies from chromosome to chromosome, partially because of the varying guanine-cytosine content making sequencing of some chromosomes less efficient.

A third approach focuses on evaluating single nucleotide polymorphisms (SNPs). By measuring these polymorphic loci, the number and identity of each allele from each sequence read

is determined. The allelic information from the mother (and from the father, if available) is used to model a set of hypotheses corresponding to different genetic inheritance patterns and crossover locations for every possible copy number count. Bayesian statistics then assign a probability to each hypothesis (whether the findings are most consistent with monosomy, disomy, or trisomy) and a maximum likelihood analysis is performed to calculate that the probability of that hypothesis is correct.¹⁶⁴

Presently, no approach has proven to be significantly better. When evaluated in populations with a high incidence of trisomy 21, all laboratories report detection rates greater than 98% with a false-positive rate as low as 0.2%^{158,164–170} (Table 30-10). About 5% of samples may initially be unacceptable for analysis for a number of reasons, including a low percentage of fetal DNA. This rate is higher in patients with a body mass index greater than 30, probably due to the increased apoptosis of maternal cells reducing the percent of fetal DNA.^{160,165,171}

Noninvasive screening for some sex chromosome abnormalities has also been reported but with a lower sensitivity and specificity than for trisomy 21.^{164-166,172,173} This reduced performance is related to the differing guanine-cytosine content of the chromosomes, making sequencing less efficient.

Down syndrome screening using cfDNA has better performance than biochemistry, with or without NT, but it is still not diagnostic. All screen-positive cases need to be confirmed by invasive testing, and false-negatives do occur. In addition, studies to date have included only women at high risk for trisomy 21, although studies evaluating its performance in a low-risk population are underway.

The role of cell-free DNA in prenatal screening is still evolving. Whether it should replace the current approach, which includes NT measurement is uncertain, because the incremental value of an elevated NT in identifying fetal structural, mendelian, and nontrisomic karyotype abnormalities would be lost. Women electing this approach must be aware that the major trisomies make up only about 50% of the cytogenetic abnormalities that would be found by karyotype following CVS and amniocentesis. If microdeletions or duplications are included (see Chromosomal Microarray for Prenatal Testing later), even a smaller percentage of cytogenetic abnormalities will be detected. Because the major trisomies are much less common in younger women, the percent of abnormalities identified by cell-free DNA testing will be even smaller in this population. For example, in women 35 years old, 43% of abnormalities will be missed by noninvasive prenatal testing (NIPT) and in those younger than age 35, 75% of karyotype abnormalities will be missed by NIPT.¹⁷⁴ Recent studies have demonstrated the potential of cell-free DNA to diagnose additional abnormalities, including sex chromosome abnormalities¹⁶⁶ and microdeletions.¹⁷⁵ At present, this work is still ongoing and there is insufficient data to evaluate its performance in clinical practice.

In December 2012 the American College of Obstetricians and Gynecologists (ACOG) and the Society for Maternal-Fetal Medicine jointly published guidelines for the use of NIPT for fetal aneuploidy.¹⁷⁶ These guidelines recommend that “patients

at increased risk of aneuploidy can be offered testing with cell-free fetal DNA.” This includes women of advanced maternal age, those with ultrasound markers for Down syndrome, a trisomy in a prior pregnancy, a positive screening test for Down syndrome, and a parent with a balanced rearrangement putting them at risk for trisomy 21.

They further suggest that “this technology can be expected to identify approximately 98% of cases of Down syndrome with a false-positive rate of less than 0.5%. Cell-free fetal DNA testing should not be part of routine laboratory prenatal testing, but it should be an informed patient choice after pretest counseling. Cell-free fetal DNA should not be offered to low-risk women or women with multiple gestations because it has not been sufficiently evaluated in these groups. Pretest counseling should include a review that although cell-free DNA is not a diagnostic test, it has high sensitivity and specificity. The test will only screen for the common trisomies and, at the present time, will give no other genetic information about the pregnancy. A negative cell-free DNA test does not ensure an unaffected pregnancy. A patient with a positive test should be referred for genetic counseling and offered invasive prenatal diagnosis for confirmation of test results. Cell-free DNA does not replace the accuracy and diagnostic precision of CVS or amniocentesis which remain an option for all women.” Similar statements have been developed by the American College of Medical Genetics (ACMG), the International Society of Prenatal Diagnosis, and the National Society of Genetic Counselors.^{174,177,178}

IS MATERNAL AGE ALONE AN INDICATION FOR INVASIVE TESTING?

Maternal age of 35 or older has been a standard indication for invasive testing for more than 35 years. When it was initially suggested, approximately 5% of births were to women older than 35 years, as were 30% of trisomy 21 gestations. Now, almost three times as many women giving birth are older than 35, and this group contains about 50% of trisomy 21 conceptions. For every invasive procedure done with maternal age as

TABLE 30-11 Comparison* of Screening Approaches for Women† 35 Years Old and Older

	Invasive Procedures	First-Trimester Screening	Second-Trimester Screening
Down syndrome pregnancies	100	100.0	100
Down syndrome detected	100	90.0	87
Down syndrome missed	0	10.0	13
Invasive procedures performed	10,000	1500.0	2500
Pregnancies lost due to procedure	50	7.5	13
Pregnancies lost to diagnose one trisomy 21 pregnancy in screen-negative women	N/A	4.3	3

*Assumes one procedure-related loss for every 200 invasive procedures performed. First-trimester screening: sensitivity, 90%; false-positive rate, 16%. Second-trimester screening: sensitivity, 87%; false-positive rate, 25%.

†Based on a population of 10,000 pregnant women ≥ 35 years old.

the only indication, the odds of being affected are approximately 1:100.⁴⁵ As screening has improved, the importance of maternal age as a single indication for testing has been reevaluated.

In women 35 years and older, 87% of Down syndrome pregnancies and 25% of unaffected pregnancies will be triple-screen positive at a cutoff of 1/250.⁸⁴ The incidence of Down syndrome in this age group is approximately 1/100. Table 30-11 demonstrates that performing an amniocentesis on screen-negative women (risk, $<1/270$) 35 years or older would lead to the loss of three normal pregnancies from procedure-induced complications for every Down syndrome pregnancy identified. First-trimester screening has a greater than 90% sensitivity, with a 15% false-positive rate, in women 35 years or older.⁴⁶ Using the approach illustrated in Table 30-1, it can be calculated that almost four normal pregnancies will be lost for each Down syndrome pregnancy identified.

Screening the entire population of pregnant women regardless of age provides the most effective use of resources. At present, 14.2% of women older than 35 are offered invasive testing, as are about 5% of women under age 35 who are screen positive, making greater than 18% of pregnant women eligible for testing. If second-trimester screening were used for all patients regardless of age and only screen-positive patients were offered invasive testing, the number of procedures would be reduced to only 6.4% of the pregnant population. If first-trimester screening is used, the number of eligible patients is only 3.8%.

Age-related autosomal and sex chromosome trisomies other than trisomy 21 would potentially be missed if invasive testing for age were abandoned. At present, both second- and first-trimester screenings for trisomy 18 are available and efficient. Wapner and colleagues⁴⁶ showed a 100% detection rate using first-trimester combined screening in women 35 years and older. About 50% of the sex chromosome abnormalities will be screen positive in the second trimester in women 35 years and older.¹⁷⁹

ACOG has recommended that maternal age of 35 years should no longer be used as an independent screen to determine who is offered screening and who is offered invasive testing.¹⁸⁰ Instead, all women should have biochemical and/or ultrasound screening, and the decision to proceed with invasive testing should be based on these results. This approach has to be preceded by explicit patient counseling to explain the risks and advantages of both options.

The decision to have invasive testing is based on many factors, including the risk that the fetus will have an abnormality, the risk for pregnancy loss from an invasive procedure, and the patient's perceived consequences of having an affected child. Studies of women's preferences have shown that they weigh these potential outcomes differently.¹⁸¹⁻¹⁸³ Thus, ACOG recommends that all women should be offered the option of invasive testing regardless of their risk.¹⁸⁴

Maternal Serum α -Fetoprotein Screening for Neural Tube and Other Structural Defects

PHYSIOLOGY

Because 95% of neural tube defects occur in families without a history of a previously affected offspring, their prenatal detection was largely fortuitous before 1980 when MSAFP screening was introduced. Based on the finding that elevated levels of AFP occur in both the maternal serum (MSAFP) and the amniotic fluid (AFAFP) in cases involving anencephaly and spina bifida, these levels could be used to identify affected pregnancies.

AFP is a fetal-specific globin similar to albumin in molecular weight and charge but with a different primary structure and distinct antigenic properties. The gene for AFP is located on chromosome 4q. AFP is synthesized early in gestation by the yolk sac and subsequently by the fetal gastrointestinal tract and liver. The level of fetal plasma AFP peaks between 10 and 13 weeks of gestation and declines exponentially from 14 to 32 weeks and then more sharply until term. The exponential fall in fetal plasma AFP is most likely the result of the dilution effect of increasing fetal blood volume, as well as of a decline in the amounts synthesized by the fetus, as fetal albumin is increasingly produced as the primary oncotic protein in fetal blood.

AFP enters the fetal urine and is excreted into the amniotic fluid. Peak levels of AFAFP are reached between 12 and 14 weeks' gestation, declining between 10% and 15% per week during the second trimester, and levels are almost undetectable at term.

Maternal serum AFP rises above nonpregnant levels as early as the 7th week of gestation. MSAFP levels are significantly lower than AFAFP levels but progressively increase during gestation until 28 and 32 weeks, when they peak. This paradoxical rise in MSAFP when amniotic fluid and fetal serum levels are decreasing is believed to be accounted for by increasing placental mass and progressive permeability to fetal plasma proteins. Thus, the amount of AFP detected in maternal serum is increased in the presence of multiple placentas (i.e., in a multi-fetal gestation).

The AFP concentration gradient between fetal plasma and amniotic fluid is about 150 to 200:1 and differential between fetal and maternal serum is about 50,000:1. Thus, the presence of a small volume of fetal blood or serum in the amniotic fluid can raise the AFP level significantly, which serves as the basis

TABLE 30-12 Odds of Having a Fetus with Open Spina Bifida, Based on Serum α -Fetoprotein (AFP) Level at 16 to 18 Weeks' Gestation

Serum AFP (MoM)	A Priori Birth Incidence*	
	1 per 1000	2 per 1000
2.0	1:800	1:400
2.5	1:290	1:140
3.0	1:120	1:59
3.5	1:53	1:27
4.0	1:26	1:13
4.5	1:14	1:7
5.0	1:7	1:4

*In the absence of antenatal diagnosis. Multiple pregnancies excluded by ultrasonography.

MoM, multiples of the median.

for using this fetal protein to screen for fetal lesions such as neural tube defects, which leak high amounts of fetal serum into the amniotic fluid and, hence, the maternal serum.

Screening

MSAFP screening for neural tube defects is ideally performed between 16 and 18 weeks of pregnancy. Cutoffs between 2.0 and 2.5 MoM yield detection rates of almost 100% for anencephaly and 85% to 92% for open spina bifida, with a false-positive rate between 2% and 5%. As with all screening modalities, the positive predictive value for an individual patient depends on the population risk. Table 30-12 demonstrates the odds of an individual woman having a child with a neural tube defect, based on the degree of elevation of her serum AFP and on her a priori risk for having a child with a neural tube defect. Because MSAFP values rise between 16% and 18% per week during the second trimester, use of gestational age–corrected MSAFP MoM for comparison between laboratories is recommended. The median is preferred to the mean because it is less influenced by occasional outliers.

MSAFP is performed using an enzyme immunoassay. All laboratories performing this test should have their own normal ranges and a mechanism for continuous quality control assessment. The College of American Pathologists operates a nationwide external proficiency test that is an essential element in population-based screening programs. Most laboratories presently use an upper-limit cutoff of 2.0 MoM. Some laboratories use a somewhat higher cutoff, up to 2.5 MoM. The choice of a specific cutoff is a balance between the anticipated detection rate and the false-positive rate.

A number of factors influence the interpretation of an MSAFP value. The most important factor for efficient MSAFP screening is the accuracy of the gestational age determination. Because there is an exponential rise in MSAFP over the recommended screening period of 15 to 20 weeks, a variation of 2 weeks between the actual gestational age and that used for MSAFP interpretation can be misleading. A potential confounding factor is that fetuses with spina bifida may have biparietal diameters that are reduced by approximately 2 weeks. Because of this, a first-trimester ultrasound is the preferred

means of documenting gestational age, and this result can be submitted to the laboratory in place of the last menstrual period.

Maternal weight affects the MSAFP concentration. The heavier the woman, the lower is the MSAFP value as a result of dilution in the larger blood volume. Adjusting MSAFP values for maternal weight increases the detection rate for open spina bifida. Dividing the observed MoM by the expected MoM for a given weight enables adjustment for differences in weight. Correction for weights greater than 250 lb significantly increases the rate of elevated MSAFP results, suggesting overcorrection. Therefore, some laboratories recommend linear correction of MSAFP only up to a weight of 200 lb. At present, weight correction of MSAFP reports is routinely performed.

Maternal ethnicity may also alter the interpretation of an MSAFP level, because black women have a 10% to 15% higher MSAFP than nonblacks.¹⁸⁵ This is important because the incidence of neural tube defects in blacks is lower. Other ethnic groups also have slightly different MSAFP levels, but they do not vary sufficiently to warrant corrections.

Pregnant women with insulin-dependent diabetes mellitus have MSAFP values that are significantly lower than nondiabetic women in the second trimester,^{186,187} which requires adjustments in the interpretation. This is critical because there is up to a 10-fold-higher frequency of neural tube defects in the offspring of these patients. MSAFP also must be altered in multiple gestations, and this adjustment is discussed later.

There may be a genetic component to raised MSAFP. Women with an elevated MSAFP in one pregnancy appear to have an increased risk for elevated values in subsequent gestations. A false-positive AFP has been seen in multiple members of some families.^{188,189}

Evaluation of an Elevated Maternal Serum AFP

Once an elevated MSAFP has been detected, the next step is ultrasound evaluation to confirm the gestational age, rule out twin gestation, identify other causes of elevated MSAFP such as fetal demise and oligohydramnios, and identify other structural defects that can cause elevated MSAFP, such as omphalocele, gastroschisis, and duodenal atresia (Table 30-13). The most important aspect of this ultrasound evaluation is confirmation of gestational age. In up to 50% of cases, incorrect dating is identified, and adjustment of the initial value resolves the issue. If the elevated MSAFP remains unexplained, further testing by either amniocentesis or targeted ultrasound is required.

Until recently, the standard diagnostic test for an elevated MSAFP was amniocentesis with evaluation of AFAFP and acetylcholinesterase (AChE) levels. AFAFP determination has nearly a 100% detection rate for anencephaly and a 96% to 99% detection rate for open spina bifida, with a false-positive rate of 0.7% to 1.0%.¹⁸⁸ The accuracy of amniotic fluid determination is enhanced by the addition of AChE. As opposed to AFP, which is a fetal serum protein, AChE is predominantly neuronally derived, giving it additional specificity for nervous system lesions. The most common assay for AChE is a polyacrylamide gel electrophoresis, by which AChE can be distinguished from nonspecific cholinesterases on the basis of mobility. A combined use of AFP and AChE together appears to be the most sensitive and specific in determining neural tube defects.

As with AFP, there are a number of potential confounders with AChE. When fetal blood is present in the amniotic fluid, interpretation of the AChE level might be complicated and

TABLE 30-13 Fetal Anomalies Identified by an Elevated Amniotic Fluid α -Fetoprotein, Enhanced by Acetylcholinesterase (AChE)

Positive AChE	Negative AChE

Epidermolysis bullosa	
Aplasia cutis congenita	
Normal gestation	

inaccurate. In addition, false-positive AChE results have been clearly documented in normal pregnancies before 15 weeks' gestation and may be seen in up to one third of cases at less than 12 weeks' gestation.

In experienced hands, targeted ultrasound for elevated MSAFP has been found to be as sensitive and specific as AFAP and AChE levels.^{190,191} Although ultrasound as a primary screening tool for spina bifida may identify only 60% to 80% of neural tube defects, targeted sonographic evaluation in high-risk cases is remarkably accurate. Sensitivities have been reported between 97% and 100%, with 100% specificity.

Ultrasound diagnosis of meningomyelocele is frequently based on the finding of a cystic mass protruding from the dorsal vertebral bodies without skin covering. This is ideally seen in the transverse plane as a wide separation of the lateral processes of the lamina. In the coronal plane, widening of the parallel lines of the normal spine can be seen. It should be cautioned that occasionally coronal and sagittal views can be misleading, and the present standard for spina bifida screening by ultrasound is an image of transverse planes of individual vertebrae. Some cases of meningomyelocele do not have a cystic structure and are identified only by a subtle widening of the posterior processes.

Indirect sonographic signs of meningomyelocele have been found to be as important as visualization of the spinal lesion and are somewhat easier to image. These include ventriculomegaly, microcephaly, frontal bone scalloping (lemon sign), and obliteration of the cisterna magna with either an "absent" cerebellum or an abnormal anterior curvature of the cerebellar hemispheres (banana sign) (Fig. 30-7).¹⁹² These findings are seen in more than 95% of cases of neural tube defects imaged in the middle of the second trimester. The banana sign and lemon sign may not be present after 22 to 24 weeks' gestation. Anencephaly should be routinely identified by ultrasound at as early as 11 or 12 weeks' gestation but should be reconfirmed by a scan at around 13 weeks because ossification of the skull in some cases may not be completed until that time.

At present, the best approach to evaluate an elevated MSAFP is a combination of ultrasound imaging and amniocentesis. When ultrasound expertise is available and optimal images can be obtained of both the spine and the central nervous system,

amniocentesis can be avoided. If ultrasound expertise or high-resolution equipment is not available, or fetal position or maternal body habitus prevents optimal fetal visualization, further evaluation by amniocentesis should be offered.

OTHER FETAL CAUSES OF ELEVATED MATERNAL SERUM AFP AND AMNIOTIC FLUID AFP

The greater the elevation in both MSAFP and AFAP, the greater is the risk for fetal abnormalities. Crandall and Chua¹⁹³ analyzed 1086 amniotic fluid samples with elevated AFP levels and found abnormalities associated with AFAP elevations of 2.0 to 4.9, 5.0 to 9.9, and more than 10.0 MoM in 25%, 88.1%, and 97.7% of pregnancies, respectively.

In addition to neural tube defects, other lesions leaking fetal serum into the amniotic fluid can cause elevations of both MSAFP and AFAP. These include fetal abdominal wall defects such as omphalocele, gastroschisis, or exstrophy of the bladder; weeping skin lesions such as epidermolysis bullosa or aplasia cutis; and some cases of sacrococcygeal teratoma and fetal urinary tract obstruction. Table 30-13 lists other fetal conditions associated with elevated MSAFP, with and without elevations of AChE.

Because AFP is produced in the fetal gastrointestinal tract and liver, reduced intestinal AFP clearance with regurgitation of intestinal contents has been associated with elevated MSAFP and AFAP. Reflux of lung fluid can also cause elevated levels. This occurs with duodenal atresia, annular pancreas, intestinal atresia, pharyngeal teratoma, and congenital cystic adenomatoid malformation of the lung.

Exceedingly high MSAFP and AFAP levels are associated with the rare condition of congenital fetal nephrosis.¹⁹⁴⁻¹⁹⁶ The elevated AFP is a result of altered filtering capabilities of the fetal glomeruli. Congenital nephrosis is an autosomal recessive disorder, with the most common mutations mapping to chromosome 19q, the nephrin gene (*NPHS1*). In the Finnish population, 36 mutations have been located in the gene, with two, Finmajor and Finminor, accounting for 94% of cases.¹⁹⁷ Lenkkeri and colleagues¹⁹⁸ reported that 20% (7 of 35) of non-Finnish cases have no detectable mutation along the nephrin gene sequence. Therefore, non-Finnish cases may have mutations in other sequences or on other chromosomes.^{197,198}

The condition is lethal in infancy if untreated, with an average life span of 7 months.¹⁹⁹ More aggressive treatments have been attempted, including dialysis and bilateral nephrectomy with subsequent renal transplant, resulting in some survivors. Unfortunately, a transplant cannot be performed until 2 years of age, on average.²⁰⁰

In Finland, where the disorder occurs in 1 of 2600 to 8000 pregnancies, screening programs using mid-trimester MSAFP have been used successfully to identify this condition.¹⁸⁹⁻²⁰¹ In other areas of the world, when markedly elevated AFP levels are found without ultrasound-detected anomalies, congenital nephrosis must be considered.

The diagnosis is strongly suggested with the finding of an elevated MSAFP (usually greater than 5 to 6 MoM) followed by an extremely elevated (frequently more than 10 MoM) level in the amniotic fluid. Although one case of congenital nephrosis with a low AFP level (<2.5) has been described,¹⁸⁹ this is extremely unusual and probably was related to too early testing, because the degree of elevation of AFAP increases with gestational age, proportionate to the contribution that fetal urine

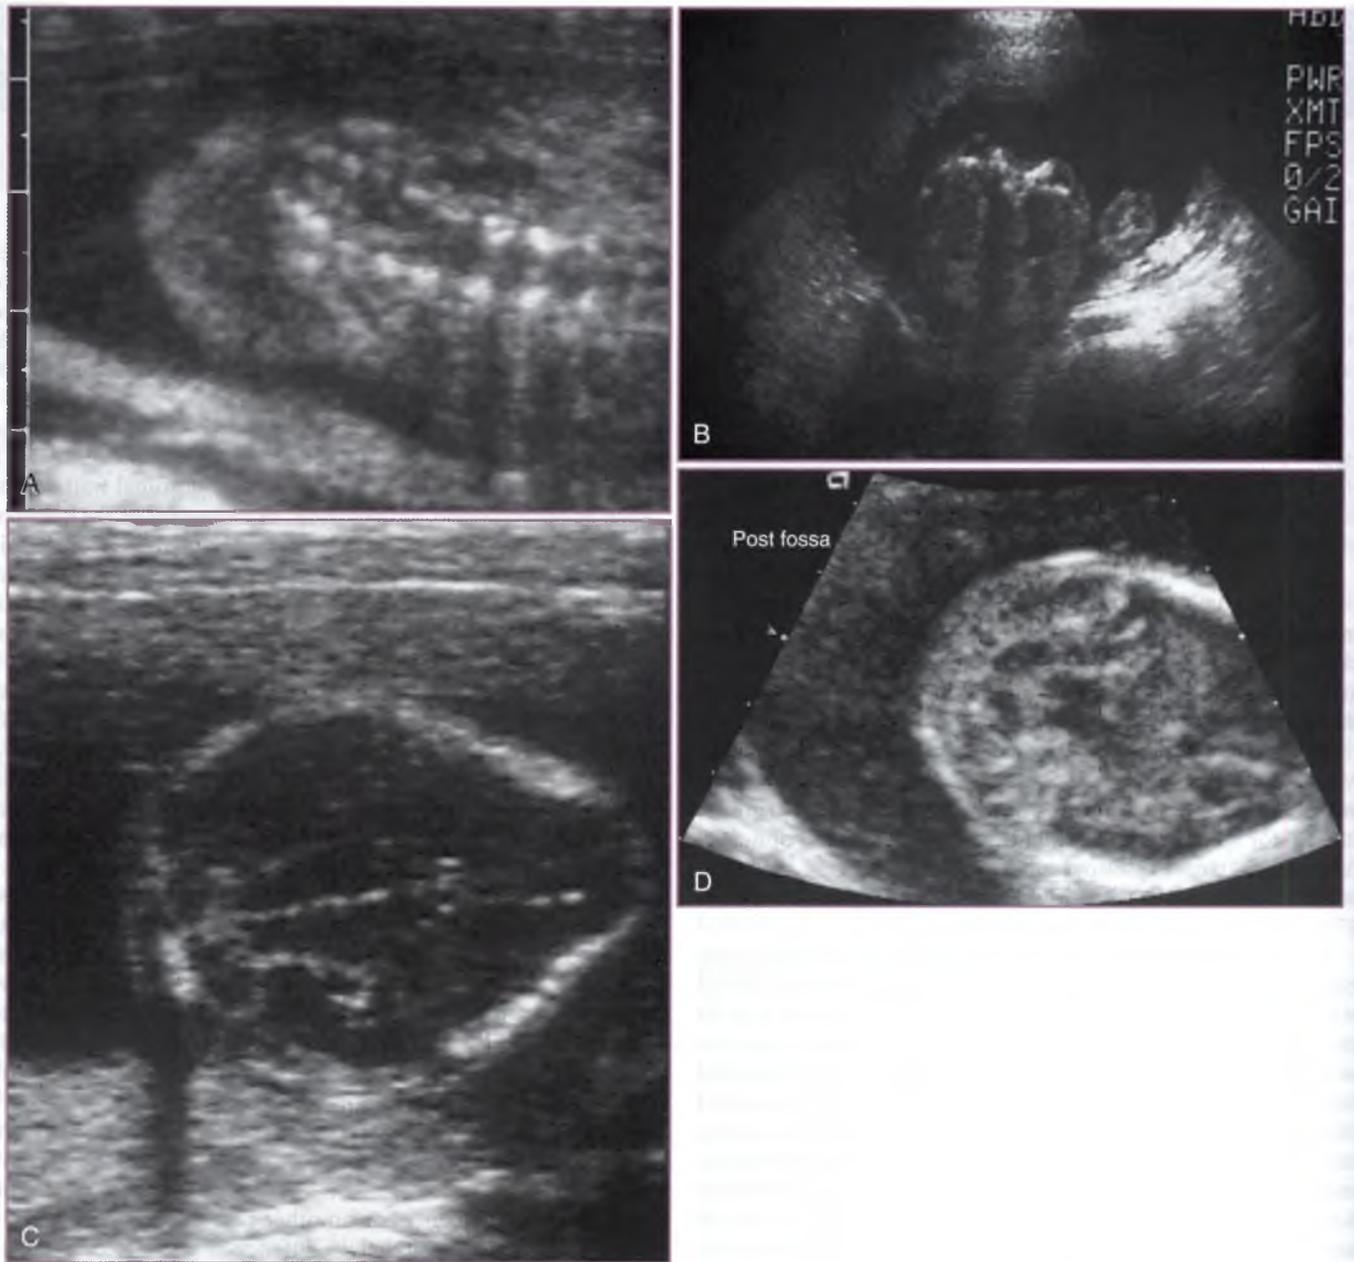

Figure 30-7 Ultrasound of a fetus with a neural tube defect. Sagittal (A) and transverse (B) views of the spine. Transverse view of the skull, with scalloping of the frontal bones, the lemon sign (C), and herniation of the cerebellum, the banana sign (D).

makes to the amniotic fluid. Consistent with this is a case report in which serial amniocenteses showed a rapid increase in AFP levels between 14 and 18 weeks.²⁰² Other amniotic fluid markers of congenital proteinuria such as transferrin and albumin have been examined to help make a more definitive diagnosis, but the sensitivity of these substances is not sufficient.^{203,204}

Confirming congenital nephrosis in utero is confounded by the lack of ultrasound findings. Although echogenic and slightly enlarged kidneys have been described, in most cases the kidneys appear normal, the amount of amniotic fluid is normal, and placentomegaly, which may occur, does not appear until late in gestation. If no ultrasound anomalies are seen, the karyotype is normal, and elevated AFAFP is confirmed, congenital nephrosis must be suspected, but a normal gestation (false-positive) is

possible.¹⁸⁹ In these cases, in utero fetal kidney biopsy provides a means to examine the renal cortex, glomerular basement membrane structure, and podocyte morphology,²⁰⁵ because the pathologic characteristics are present in the second trimester.²⁰⁶ Electron microscopic evaluation of the biopsy sample is required to visualize the altered podocyte morphology diagnostic of this condition.

Ultrasound Screening for Fetal Congenital Anomalies

The value of routine second-trimester ultrasound as a screening test is unknown. The Routine Antenatal Diagnostic Imaging Ultrasound Study¹³⁴ was a randomized controlled trial to test

whether routine ultrasound during pregnancy would reduce perinatal morbidity and mortality. This study concluded that routine ultrasound did not alter perinatal outcomes and therefore should not be routinely performed on all women. Limitations to this study are numerous; for example, nearly 70% of the control group received an ultrasound examination at some point in their pregnancy, and more congenital anomalies were detected in the screened group, but the overall rate of detected anomalies was only 35%, and experienced referral centers demonstrated a 23% higher detection rate (35% versus 13%) than nontertiary centers.

At present, ACOG does not recommend ultrasound as a routine part of prenatal care,²⁰⁷ but other authors argue that denial of access to universal ultrasound with its current abilities may be unethical.²⁰⁸ Whether routine or targeted, anatomic screening should be done by experienced centers to increase detection of anomalies and limit false-positive results.²⁰⁹

INCREASED NUCHAL TRANSLUCENCY AND NORMAL KARYOTYPE

An increased NT has been described with certain nonchromosomal fetal disorders.^{12,13,15-17,19,210-222} In some cases, this may be coincidental. However, in others, such as cardiac defects, diaphragmatic hernias, and fetal skeletal and neurologic abnormalities, a true relationship appears likely. Additionally, an association between increased NT and poor perinatal outcomes, including miscarriage and perinatal death, exists.²²³ This information is important in counseling patients who have an elevated NT and a normal karyotype.

In approximately 90% of explored cases in which the NT is greater than the 99th percentile but below 4.5 mm, a healthy infant can be expected. With NTs between 4.5 and 6.4 mm, about 80% of births will result in a healthy newborn. Measurements greater than 6.5 mm have only a 45% incidence of normal results.²²³

The association of increased NT with fetal cardiac and great vessel defects is significant (Table 30-14).²²⁴⁻²³³ A large series from the Fetal Medicine Foundation Project showed that the prevalence of major cardiovascular abnormalities increases with increasing NT.²²³ With an NT measurement between the 95th percentile and 3.4 mm, the frequency of heart and great vessel anomalies was 4 per 1000. When the NT was between 3.5 and 4.5 mm, the incidence increased to 27 per 1000, and when

the NT was greater than 6.5 mm, the frequency was 170 per 1000. In a similar but retrospective study of approximately 30,000 chromosomally normal singleton pregnancies, the prevalence of cardiac defects increased from 0.8 per 1000 in individuals with an NT below the 95th percentile, to almost 64 per 1000 when the NT was above the 99th percentile.²³⁴ Alternatively, approximately 40% of all fetuses with cardiac defects will have an NT above the 99th percentile, and 66% will be above the 95th percentile.²³⁴

This information strongly suggests that the presence of an NT above the 99th percentile, and perhaps above the 95th, should be followed with a fetal echocardiogram. In this group of individuals, the frequency of major cardiac defects would be anticipated to be about 2%, which is higher than the threshold risk for pregnancies presently receiving echocardiograms, such as those with a mother affected with diabetes mellitus or with a family history of an affected offspring. If a cutoff at the 95th percentile is used and 5% of all pregnancies would be offered testing, resources to accomplish this may be insufficient. However, if a 99th percentile NT measurement is used, only about 1% of patients would require echocardiograms, with an incidence of positive findings of approximately 6%. Recent improvements in the resolution of ultrasound and increasing experience with first-trimester cardiac scanning suggest that major cardiac defects could be identified by the end of the first trimester.^{225,235-238} This means that patients identified with an enlarged NT who presently have their echocardiograms performed at 20 weeks may not need to delay testing.

Fetal anomalies occur frequently enough after an elevated NT that follow-up scans in the second trimester are recommended. These anomalies include diaphragmatic hernias, severe skeletal defects, and omphaloceles.²²³ Box 30-2 lists the anomalies that have a possible relationship with an increased NT.

The most difficult counseling issue involves patients with an elevated NT, a normal karyotype, and a normal second-trimester ultrasound. In a certain percentage of these cases, genetic syndromes not identifiable by ultrasound may be present, including Noonan syndrome, as well as others listed in Box 30-2. There has also been some speculation of an increased frequency of unexplained developmental delay in some of these infants (E. Pergament, personal communication, 2002). At present, there is insufficient information to counsel patients specifically; however, in most cases, patients can be reassured that this frequency appears to be less than 10%.²³⁹

Screening for Gene Mutations That Lead to Fetal Disease

Certain populations have an increased frequency of specific, identifiable, disease-causing gene mutations. This may occur because the population has remained relatively isolated, because many individuals in the population are descended from a few common relatives having a specific mutation (founder effect), or because the carrier state has a beneficial effect on survival in a particular environment (sickle cell carrier state granting protection from malaria). It has become a part of routine obstetric care to identify these at-risk individuals. At present, candidates for screening are identified because of their race or heritage, but techniques for universal carrier detection in which ethnic-specific testing is not required have recently become available.

Table 30-15 lists the standard screening tests that should be offered to pregnant patients on the basis of their ethnicity.

The goal of testing is to provide individuals with information that will permit them to make informed reproductive decisions. Such testing is of maximal benefit when it is part of a

comprehensive screening program including patient education, counseling, and the availability of invasive diagnostic testing when needed. Counseling should include information on basic inheritance patterns, the variable nature of disease expression, the risk of occurrence, and the diagnostic and therapeutic options available. Educating a couple can be accomplished by using direct counseling, printed materials, or interactive online systems.

Before carrier testing is performed, informed consent should be obtained. This should demonstrate that the individual has fully understood the multiple options that ensue from testing. It is equally important to ensure that those who decline testing do so knowledgeably, and this should be documented. Any testing performed must be voluntary, and patients must be assured that every effort will be made to ensure confidentiality. As molecular diagnostics has become more available, the complexity of gene-based diagnosis and screening has become clear. The vast number of mutations with their varying phenotypic consequences frequently require sophisticated laboratory capabilities and subsequent counseling by individuals explicitly trained in this area.

CYSTIC FIBROSIS SCREENING

Cystic fibrosis (CF) is a multisystem genetic disorder in which defective chloride transport across membranes causes dehydrated secretions, leading to tenacious mucus in the lungs, mucous plugs in the pancreas, and high sweat chloride levels. CF is an autosomal recessive disorder with the responsible gene on chromosome 7 coding for the CF transmembrane conductance regulator (CFTR). CF can have a highly variable presentation and course, which ranges from severe pulmonary and gastrointestinal disease in infancy to relatively mild disease such as congenital absence of the vas deferens or chronic sinusitis or bronchitis.

CF is one of the most common genetic diseases in the white population, with an incidence of about 1 in 3300 individuals. The disease is relatively common in Ashkenazi Jews, and it has a fairly high incidence among Hispanics (1 in 8000 to 9550). CF

TABLE 30-15 Common Autosomal Recessive Disorders in Ethnic Groups: Carrier Screening Recommended

Ethnic Group	Genetic Disorder	Carrier Frequency in Ethnic Group	Frequency of Carrier Couples	Screening Test Available?	Detection Rate (%)

is rare in native Africans and Asians (<1 in 50,000) but somewhat higher in American populations of these ethnic groups (1 in 15,300 and 1 in 32,100, respectively). Table 30-16 demonstrates the incidence of CF and the carrier frequency in various ethnic groups.

The gene causing CF was first cloned in 1989 and provided the initial ability to screen individuals with no family history. More than 600 mutations and DNA sequence variations have since been identified. The $\Delta F508$ mutation, the most common, is a frame-shift mutation caused by a three-base-pair deletion in exon 10 of the CF transmembrane conductance regulator that codes for phenylalanine at the 508th amino acid. Although present in almost all populations, its relative frequency varies among different geographies and ethnic groups. The highest frequency is observed in the white population, where it accounts for approximately 70% of CF mutations. Some 15 to 20 other "common" mutations account for 2% to 15% of CF alleles, depending on the ethnic composition of the patient group.

The sensitivity of CF screening using DNA mutation analysis depends on the frequency of common identifiable mutations in the screened population. Although greater than 90% carrier detection is presently possible in a number of ethnic groups, a standard panel of mutations has been developed to maximize overall screening efficiency that provides the greatest and can be practically performed (Table 30-17). This panel was initially composed of pan-ethnic detection of 25 mutations, but in 2004 the number was reduced to 23.²⁴⁰ The panel contains all CF-causing mutations with an allele frequency of at least 0.1% in the general U.S. population. An understanding of the distribution of mutations in the CF transmembrane conductance regulator is continually advancing, and it is likely that this panel will continue to evolve. Panels with more mutations are available, as is complete gene sequencing, and may be useful in certain specific clinical situations.

There has been much discussion and debate over which ethnic and racial groups should be offered CF carrier testing. Some maintain that screening should be limited to the highest-risk populations, such as non-Jewish whites of European ancestry and Ashkenazi Jews, in which both the carrier frequency (1/25 to 1/30) and the mutation detection rate (25 mutations detect more than 80% of CF alleles) are sufficiently high to make screening cost-effective. This would exclude African Americans, with a detection rate of only about 75%. Hispanics would also be excluded, despite their relatively high incidence of the disease, because detectable alleles account for only 57% of their CF mutations. Screening would be even less effective in

Asian Americans, who would have only 30% sensitivity. Others argue that the admixture of populations in the United States makes it difficult to exclude patients on the basis of specific ethnic group, and that even attempting to make such a determination in a busy clinical setting may place an undue burden on primary care physicians.

To resolve this debate, the NIH issued a consensus statement in 1997 indicating that CF testing should be offered to adults with a positive family history of CF, to partners of people with CF, to all couples planning a pregnancy, and to couples seeking prenatal testing, particularly those in high-risk populations. It was believed that genetic testing should be offered in the prenatal setting to enhance the ability to make reproductive choices and to engage individuals when their interest and use of the information was maximal.

A second NIH-sponsored conference focusing on implementation of the consensus recommendations was held in 1998. Shortly thereafter, the American Colleges of Medical Genetics and Obstetrics and Gynecology, in conjunction with the National Human Genome Research Institute, issued a joint

opinion entitled "Preconception and Prenatal Carrier Screening for Cystic Fibrosis." This document recommended narrowing the population screened to non-Jewish whites and Ashkenazi Jews. Information about screening should be made available to other ethnic and racial groups through educational brochures or other efficient methods. These lower-risk groups should be informed of the availability of testing but should also be advised of the limitations encountered for their particular situation. For example, Asian Americans, African Americans, and Native Americans without a significant white genetic component should be informed of the rarity of the disease and the low yield of the test in their respective populations.^{241,242} Pre-conception testing should be encouraged, but for practical purposes, most testing should continue to occur in the prenatal setting.

In appropriate populations, there are two possible approaches to screening. In sequential screening, one member of the couple (usually the woman) is tested first, and only if a positive result is obtained is the partner tested. Alternatively, couple-based screening analyzes specimens from both partners, with each informed of his or her specific results. Present recommendations are that either is appropriate, with the method depending on the target population, the nature of the clinical setting, and the judgment of the practitioner. Couple-based testing is recommended for white couples of northern European and Ashkenazi Jewish descent, particularly when concurrently testing for other common genetic disorders. Sequential screening is believed to be more useful for groups in which the carrier frequency is lower and when obtaining a simultaneous sample from the partner is impractical. In general, the individual provider or center should choose the method they believe is most practical in their setting.

All patients with negative screen results should be reminded that carrier screening is not 100% sensitive. This is particularly pertinent in couples when one partner is found to carry a mutation. The residual risk after a negative CF carrier test depends on the ethnic and racial group of the patient (Table 30-18). In northern and eastern European populations, in which CF mutation screening detects up to 90% of mutant alleles and in

which the carrier frequency is 1 in 25, a negative screen reduces the risk of being a carrier to 1 in 241. Screen-negative couples will then reduce their risk of having an affected child from 1 in 2500 ($\frac{1}{4} \times \frac{1}{25} \times \frac{1}{25}$) to 1 in 232,324 ($\frac{1}{4} \times \frac{1}{241} \times \frac{1}{241}$). If one parent has a mutation and the other is negative, the risk of an affected child is 1 in 964 ($\frac{1}{4} \times 1 \times \frac{1}{241}$). When both parents are found to have identifiable mutations, the risk of an affected child is 1 in 4. Prenatal diagnosis by either CVS or amniocentesis, along with genetic counseling, would be recommended.

For individuals with a family history of CF, medical records identifying the mutation should be obtained. If the mutation has not been identified, screening with an expanded panel of mutations, or in some cases complete sequencing, may be necessary. Individuals with a reproductive partner with either CF or congenital bilateral absence of the vas deferens may also benefit from either an expanded panel or gene sequencing.

In most cases, interpretation of the screening results is straightforward, but complicated situations may occur and frequently involve the 5T variant polymorphism. This is one of three poly(T) (thymidine) alleles (5T, 7T, and 9T) in intron 8 of the CF transmembrane conductance regulator gene. It occurs in about 5% of the population and decreases production of the CFTR protein. The 5T mutation can cause congenital bilateral absence of the vas deferens or atypical CF when present in a male in *trans* with a common CF allele. This arrangement has no clinical significance in females. Accordingly, identification of the 5T variant will produce complicated counseling issues, because it expands the risk ascertainment beyond classic CF. Because of this, most laboratories do not offer 5T analysis as part of routine screening. Testing for this variant is appropriate only as a reflex test when the R117H mutation is detected on the primary screen. This is required because classic CF occurs when 5T is in *cis* with R117H on one chromosome, and a CFTR mutation is present on the other chromosome. Accordingly, patients positive for both R117H and 5T require further analysis to determine if the 5T is in *cis* or *trans* with the R117H allele. To accomplish this, the laboratory requests specimens from appropriate family members. Using this approach, the initial screening is for classic CF rather than fertility of the fetus.

TABLE 30-18 Impact of a Negative Cystic Fibrosis (CF) Screening Panel (25 Mutations) on the Carrier Risk*

Ethnic Group	Detection Rate (%)	Estimated Carrier Risk	
		Before Test	After Negative Test
Ashkenazi Jews	97	1/29	Approx. 1 in 930
European white	80	1/29	Approx. 1 in 140
African American	69	1/65	Approx. 1 in 207

*Residual carrier risk after a negative test is modified by the presence of a positive family history.

†This is a pooled set of data and requires additional information to accurately predict risk for specific Hispanic populations.

JEWISH GENETIC DISEASE TESTING

Diseases commonly grouped together as Jewish genetic disorders range in incidence from 1/900 to 1/40,000 in the Jewish community, specifically those individuals of Ashkenazi (Eastern European) heritage. Although some of these disorders in isolation would be considered rare, the overall carrier rate in this population is significant, with between 1 in 4 and 1 in 5 Ashkenazi Jews carrying a mutation for any one of these disorders. Both ACOG²⁴³ and ACMG²⁴⁴ recommend carrier testing for three of these (Tay-Sachs disease, Canavan disease, and familial dysautonomia) along with CF testing in this population. ACMG also recommends screening for Fanconi anemia group C, Niemann-Pick type A, Bloom syndrome, mucopolysaccharidosis type IV, and Gaucher disease to all Ashkenazi Jewish couples.²⁴⁵ Although the frequency of some of these latter disorders is relatively low, each is caused by a relatively few mutations in the Ashkenazi population, so greater than 95% of carriers can be detected.

Tay-Sachs Disease

Tay-Sachs disease is an autosomal recessive lysosomal storage disorder caused by deficiency of the enzyme hexosaminidase A.

This results in a group of neurodegenerative disorders caused by intralysosomal storage of the specific glycosphingolipid GM₂ ganglioside. Classic Tay-Sachs disease is characterized by loss of motor skills beginning between 3 and 6 months of age, with progressive neurodegeneration, including seizures, blindness, and eventual total incapacitation and death usually before the age of 4. The juvenile (subacute), chronic, and adult-onset variants of the hexosaminidase A deficiencies have later onsets, slower progression, and more variable neurologic findings, including progressive dystonia, spinocerebellar degeneration, motor neuron disease, and, in some individuals with adult-onset disease, a bipolar form of psychosis.

The incidence of the Tay-Sachs carrier state is between 1/27 and 1/30 in the Ashkenazi Jewish population (i.e., from Central and Eastern Europe), resulting in a birth prevalence of 1 in 3600 infants. Among Sephardic Jews and all non-Jews, the disease frequency is approximately 100 times less, corresponding to a 10-fold lower carrier frequency (1 in 250 to 1 in 300). As the result of extensive genetic counseling of carriers and prenatal diagnosis, the incidence of Tay-Sachs disease in Ashkenazi Jews in North America has already been reduced by greater than 90%.^{246,247}

In addition to occurring in Ashkenazi Jews, Tay-Sachs disease can occur in children of any ethnic, racial, or religious group, but certain populations that are relatively isolated genetically, such as French Canadians of the eastern St. Lawrence River valley area of Quebec, Cajuns from Louisiana, and the Amish in Pennsylvania, have been found to carry hexosaminidase A mutations with frequencies comparable with, or even greater than, those observed in Ashkenazi Jews.

Population screening for the carrier state of Tay-Sachs disease uses serum or leukocyte determination of hexosaminidase A enzyme activity using synthetic substrate. Carriers have significantly reduced levels compared with noncarriers. Serum samples are used for testing all males and for nonpregnant women not on oral contraceptives. Pregnant women, those on oral contraceptives, and women who have a tissue destructive disorder such as diabetes mellitus, hepatitis, or rheumatoid arthritis should have a white blood cell determination of enzyme activity, because these conditions artificially lower the serum hexosaminidase A level, leading to a false diagnosis of the carrier state. When the enzymatic testing is abnormal or inconclusive,

DNA analysis of the hexosaminidase A gene is performed to confirm the diagnosis, identify the specific mutation, and rule out the presence of a pseudodeficiency allele that is present in approximately 2% of the Ashkenazi Jewish population and approximately 35% of the non-Jewish population.²⁴⁸

Two pseudodeficiency alleles exist and can be tested for. Individuals heterozygous for the pseudodeficiency allele have an apparent deficiency of hexosaminidase A enzymatic activity with the synthetic substrate but not with the natural substrate, GM₂ ganglioside. Their levels are similar to those of Tay-Sachs carriers, leading to a potentially incorrect determination of a carrier. Homozygous pseudodeficient individuals, like individuals affected with Tay-Sachs disease, have extremely low or absent hexosaminidase A levels. Neither compound heterozygotes having one Tay-Sachs allele and one pseudodeficient allele, nor homozygotes for the pseudodeficient allele, have any neurologic abnormality.

There are more than 90 disease-causing mutations in the hexosaminidase A gene, but routine mutation analysis tests for only the six most common mutations.²⁴⁹ Molecular analysis of the six-mutation hexosaminidase panel will identify between 92% and 98% of Jewish carriers but only between 23% and 46% of non-Jewish carriers (Table 30-19). Some laboratories use mutation analysis as their primary screening approach in the Ashkenazi population. However, this will identify only 92% to 94% of carriers, so some will be missed. Laboratories seeing a high proportion of French-Canadian patients may offer extended panels or test for selected mutations that are specific to that population. In Quebec, a 7.6-kb deletion is the most common allele associated with Tay-Sachs disease. Accordingly, when testing individuals from the French-Canadian population or other populations with founder mutations, care should be taken to identify a laboratory performing analysis for the appropriate mutations. It is not uncommon for a couple in which one partner is Jewish and the other is not to inquire about testing. It is presently recommended that such couples be offered carrier analysis by enzymatic testing, because DNA analysis with the routine six-mutation panel would fail to detect a significant proportion of the non-Jewish carriers. Also, individuals who have French-Canadian, Cajun, and Amish ancestry should be offered carrier testing. Individuals who are pursuing reproductive technologies that involve gamete donation and who are at

*Obligate heterozygotes (i.e., parents of a child with hexosaminidase A deficiency).

†Individuals identified in screening programs as having levels of hexosaminidase A enzymatic activity in the heterozygous range.

‡Primarily persons of Celtic, French, Cajun, or Pennsylvania Dutch background.

From Kaback M, Lim-Steele J, Dabholkar D, et al: Tay-Sachs disease-carrier screening, prenatal diagnosis, and the molecular era: an international perspective, 1970 to 1993. *The International TSD Data Collection Network, JAMA* 270:2307, 1993.

increased risk of being heterozygous for hexosaminidase A because of their ethnic background should also be screened.

Prenatal diagnosis of Tay-Sachs disease is possible by enzymatic analysis of either amniocytes or chorionic villi. Hexosaminidase A deficiency can be identified by CVS within 30 minutes of retrieval, or from uncultured amniotic fluid.²⁵⁰⁻²⁵² However, very few laboratories use this approach, preferring to use mutation analysis if the disease-causing mutation has been identified in both parents. Prenatal testing may also be recommended when one parent is a known heterozygote and the other has inconclusive enzymatic activity without a disease-causing mutation found on DNA analysis. It also may be recommended when the mother is a known heterozygote and the father is either unknown or unavailable for testing. Both of these latter scenarios require intensive genetic counseling.

Canavan Disease

Screening of Ashkenazi Jewish patients or couples for Canavan disease is now part of routine obstetric care.²⁵³ This disorder is caused by a deficiency in aspartoacylase and is characterized by developmental delay by the age of 3 to 5 months, with severe hypotonia and failure to achieve independent sitting, ambulation, or speech.²⁵⁴ Hypotonia eventually changes to spasticity, requiring assistance with feeding. Life expectancy is usually into the teens.²⁵⁵ Because about 99% of disease-causing mutations in persons of Ashkenazi Jewish heritage are identified by only three alleles, carrier testing is done by DNA mutation analysis.^{256,257} Testing by biochemical analysis is not routinely available because it relies on a complex enzyme assay and cultured skin fibroblasts.²⁵⁸ Of the disease-causing alleles in non-Jewish individuals, 55% are identified by analysis of these three alleles as well.²⁵⁹ Prenatal testing for pregnancies that are at 25% risk can be performed by either amniocentesis or CVS using mutation analysis. For the unusual couple in which one partner is known to be a carrier, but a mutation or the carrier status of the other is uncertain or unknown, prenatal testing can be performed by measuring the level of *N*-acetyl aspartic acid in amniotic fluid at 16 to 18 weeks.^{260,261}

Familial Dysautonomia

Familial dysautonomia is a severe neuropathy resulting in inadequate development of the sensory and autonomic systems, with onset in infancy and recurrence of life-threatening autonomic crises. Familial dysautonomia occurs almost exclusively in the Ashkenazi Jewish population, with an incidence of 1/3600 and a carrier frequency of 1/31. A single mutation of the *IKBKAP* gene on chromosome 9 accounts for greater than 99% of the mutations in the Ashkenazi Jewish people. Addition of a second mutation accounts for the remainder of the Ashkenazi Jewish mutations. Greater than 99% of carriers can be identified, as well as greater than 99% of affected fetuses.²⁴⁴

Other Diseases Increased in the Jewish Population

A number of other disorders have been found more frequently among the Ashkenazi Jewish population (Table 30-20) or have been found to be caused by a relatively few mutations and are screened for in some centers.²⁶² The gene frequency for some of these disorders may be relatively low compared with those for Tay-Sachs or Canavan disease,²⁶³ and in some of these disorders the phenotype is relatively benign or treatable.

Gaucher disease type 1 is an autosomal recessive lysosomal storage disease with a carrier frequency of 1 in 18 in Ashkenazi

Jewish individuals. Its clinical course is heterogeneous, ranging from early onset of severe disease, with major disability or death in childhood, to a mild disease compatible with a normal productive life. The phenotype in this disorder is well correlated with the genotype. Of the more than 200 mutations in the affected acid α -glucosidase gene, four mutations (N370S, 84GG, L444P, and IVS2) account for 95% of those in Ashkenazi Jews. Although an affected individual who carries two copies of any combination of the 84GG, L444P, and IVS2 mutations will have severe neurodegenerative disease, individuals homozygous for the most common N370S mutation have a non-neurologic disorder with an average age at onset of 30. Some individuals may never come to medical attention. Those having the N370S mutation with one of the other three common mutations will also have non-neurologic disease but of a somewhat more severe phenotype than seen in N370S homozygotes. This predominance of relatively mild non-neurologic disease in the Ashkenazi Jewish population has led some to question whether screening in this population is appropriate. In addition, effective treatment of type 1 Gaucher disease with enzyme replacement exists.

At present, in some centers, the availability of these carrier tests is discussed with Jewish couples so they can make individualized decisions about whether to have them performed. Overall, if these diseases are screened for, greater than one in six Ashkenazi Jews will be determined to be a carrier for at least one disorder. To avoid the anxiety that such a high carrier rate may engender, it is recommended that both members of a couple be screened simultaneously, so that genetic counseling need be provided only to carrier couples.²⁶⁴

Having one Jewish grandparent is sufficient to offer testing. However, if someone is unsure as to their precise lineage, it is recommended to offer testing. If only one member of a couple is of Ashkenazi Jewish background, testing should still be offered, with the Jewish member of the couple tested first. If the Jewish partner has a positive test result, the other partner, regardless of background, should be screened for that particular disorder. The mutation detection rate and carrier frequency among different ethnic or racial groups for some of these disorders may not be well established, requiring a discussion about the lack of a precise residual risk in the case where the non-Jewish partner is negative on mutation analysis.

HEMOGLOBINOPATHIES

Sickle Cell Syndromes

Sickle cell diseases are a common group of inherited hemoglobin disorders characterized by chronic hemolytic anemia, heightened susceptibility to infection, end-organ damage, and intermittent attacks of vascular occlusion causing both acute and chronic pain. Approximately 70,000 Americans of different ethnic backgrounds have sickle cell disease. In the United States, sickle cell syndromes are most frequently present in African Americans and occur at a frequency of 1/400. The disease is also found in high frequency in individuals from certain areas of the Mediterranean basin, the Middle East, and India.²⁶⁵

Sickle cell syndromes include sickle cell anemia, variant hemoglobin sickle cell disease, and hemoglobin S- β -thalassemia. Normal hemoglobin consists of hemoglobin A (α , β), hemoglobin F (α , γ), and hemoglobin A₂ (α , δ). The protein sequences are coded on chromosome 11 for the β , δ , and γ chains, and the

TABLE 30-20 Potential Screening Available for Autosomal Recessive Disorders in the Ashkenazi Jewish Population

Disease	Status	Genetic Defect	Carrier Frequency in Ashkenazi Jews	Comments
Cystic fibrosis	S	Transmembrane conductance regulator (CFTR) mutation	1:26	97% detection rate with 97 mutation panel
Tay-Sachs	S	Hexosaminidase A deficiency	1:30	Screening done by enzyme analysis. Carrier screening during pregnancy, while on oral contraceptives, or with debilitating illness requires leukocyte analysis. Pseudodeficient allele exists. 97% to 98% detection with enzyme analysis, and 92% to 94% with mutation analysis.
Canavan	S	Aspartoacylase (ASPA) deficiency	1:40	Three common mutations account for 99% of disease-causing alleles.
Niemann-Pick type A	A	Acid sphingomyelinase deficiency	1:90	Three mutations with 95% detection.
Gaucher disease type 1	A	Glucocerebrosidase deficiency	1:14	The type 1 Gaucher disease seen in this population is the mild variant with no CNS involvement. Some affected individuals with mild disease may be identified through screening. Five mutations with 95% detection.
Fanconi anemia	A	Chromosome breakage	1:89	One mutation with 99% detection
Bloom syndrome	A	Chromosome breakage	1:100	One mutation with 97% detection
Congenital deafness	A	Connexin 26 mutation	1:21	Wide variability in severity of disease
Glycogen storage disease type IA	A	Glucose-6-phosphatase	1:71	Two mutations with 99% detection
Maple syrup urine disease	A	Branched-chain alpha-ketoacid dehydrogenase (BCKAD) complex	1:81	Four mutations with 99% detection
Mucopolipidosis type IV	A	MCOLN1	1:122	Two mutations with 96% detection
Familial dysautonomia	A	IKBKAP gene mutation	1:30	Two mutations with 99% detection
Walker-Warburg syndrome	A	—	1:149	One mutation with 99% detection
Joubert syndrome	A	TMEM216	1:92	One mutation with 95% detection

A, available for screening at-risk families (could be used for population screening); CNS, central nervous system; S, standard of care.

β variants such as hemoglobin S, hemoglobin C, and hemoglobin D all occur from a mutation of this gene. Sickle cell anemia is the most common variant and results when an individual inherits a substitution of valine for the normal glutamic acid in the sixth amino acid position of the β globin chain. This substitution alters the hemoglobin molecule so that it crystallizes and alters the red cell into a sickle shape when the hemoglobin loses oxygen. Hemoglobin C is caused by a substitution of lysine in the same location.

Screening for sickle cell disease should be offered to individuals of African and African-American descent and to those from the Mediterranean basin, the Middle East, and India. Approximately 1 in 12 African Americans has sickle cell trait. The definitive test to determine the carrier state of sickle cell disease is hemoglobin electrophoresis, which is based on the altered electrical charge of abnormal hemoglobins caused by the amino acid substitutions. A simple sickle cell preparation fails to identify individuals carrying β -thalassemia or certain sickle cell variants (hemoglobins C, D, and E) and is no longer acceptable for screening. In addition, routine cellulose acetate gel hemoglobin electrophoresis cannot delineate all hemoglobin variants. If routine electrophoresis is abnormal, further

testing by high-performance liquid chromatography may be necessary.

Hemoglobin Variants. Hemoglobin C occurs in higher frequency in individuals with heritage from West Africa, Italy, Greece, Turkey, and the Middle East. Individuals who are hemoglobin C homozygotes have a mild hemolytic anemia, microcytosis, and target cell formation. They may very occasionally have episodes of joint and abdominal pain. Splenomegaly is common, and aplastic crisis and gallstones may occur. Compound-heterozygous patients with hemoglobin S and C have a sickle syndrome that is very similar to sickle cell anemia. Hemoglobin C carriers have no anemia but usually have target cells on blood smear and may have a slightly low mean corpuscular volume (MCV) with no other clinical problems. Individuals who are compound heterozygotes for hemoglobin C and β -thalassemia who inherit a β^0 mutation have a moderately severe anemia, have splenomegaly, and may have bone changes. Individuals who inherit a β^+ mutation with hemoglobin C have only a mild anemia, a low MCV, and target cells on blood smear.

On occasion, hemoglobin E is seen by electrophoresis. This is a structurally abnormal hemoglobin caused by a substitution

of lysine for glutamic acid at the 26th position of the β globin chain, which causes abnormal processing of pre-messenger RNA to functional messenger RNA, resulting in decreased synthesis of hemoglobin E. The hemoglobin E gene is very common in areas of Southeast Asia, India, and China. Heterozygotes for hemoglobin E and hemoglobin A have no anemia, a low MCV, and target cells on blood smear. Hemoglobin electrophoresis shows approximately 75% hemoglobin A and 25% hemoglobin E. Homozygotes for hemoglobin E may have normal hemoglobin levels or only a slight anemia. The MCV is low, and many target cells are present. There is a single band in the hemoglobin C or A position on cellulose acetate electrophoresis and increased hemoglobin F (10% to 15%). There are no clinically significant problems. Individuals who are compound heterozygotes for hemoglobin E and β^0 -thalassemia can have a severe disease with profound anemia, microcytosis, splenomegaly, jaundice, and expansion of marrow space. Hemoglobin electrophoresis in these individuals shows hemoglobin E and a significant increase in hemoglobin F (30% to 60%). Individuals who are compound heterozygote for hemoglobin E and β^+ -thalassemia have a moderate disease with anemia, microcytosis, splenomegaly, and jaundice. Hemoglobin electrophoresis shows hemoglobin E at approximately 40%, hemoglobin A at 1% to 30%, and a significant increase in hemoglobin F (at approximately 30% to 50%).

Sickle Thalassemias. Beta-thalassemias are caused by mutations that reduce or abolish the production of the β globin subunits of hemoglobin. Compound heterozygotes of β -thalassemia and hemoglobin S have very significant clinical problems. In hemoglobin S- β^0 -thalassemia, no normal hemoglobin A is made, so electrophoresis of hemoglobin shows only hemoglobin S, increased hemoglobin A₂, and increased hemoglobin F. In hemoglobin S- β^+ -thalassemia, hemoglobin A is reduced, so hemoglobin electrophoresis shows hemoglobin A (5% to 25%), hemoglobin F, hemoglobin S, and increased hemoglobin A₂. The severity of the clinical manifestations of sickle cell thalassemia can vary greatly between patients. Most individuals with the hemoglobin S- β^+ -thalassemia have preservation of spleen function and fewer problems with infections, fewer pain episodes, and less organ damage than those with sickle cell disease. Individuals with hemoglobin S- β^0 -thalassemia may have very severe disease, identical to that in those homozygous for sickle cell anemia.

Sickle cell anemias are inherited as autosomal recessive disorders. Therefore, when both parents carry the hemoglobin S gene, the couple has a 1 in 4 risk of having an affected child. Prenatal diagnosis using molecular DNA detection of the

mutation is routine. When one parent has a hemoglobin S mutation and the other is a carrier of β -thalassemia, the couple has a 25% risk of having a child with sickle thalassemia. If the specific parental mutation responsible for thalassemia is known, the gene can be detected by molecular analysis of villi or amniocytes and an affected child identified. If the thalassemia mutation is not identifiable, fetal blood sampling for globin chain synthesis may be required.

β -Thalassemia

β -Thalassemia is characterized by reduced hemoglobin β chain production and results in microcytic, hypochromic anemia, and an abnormal peripheral blood smear with nucleated red cells. There are reduced (β^+) to absent (β^0) amounts of hemoglobin A on hemoglobin electrophoresis.²⁶⁶ Patients homozygous for a β -thalassemia mutation have thalassemia major with severe anemia and hepatosplenomegaly. They usually come to medical attention within the first 2 years of life, and without treatment, affected children have severe failure to thrive and a shortened life expectancy. Treatment requires a program of regular transfusions and chelation therapy, which can result in normal growth and development.

β -Thalassemia is inherited in an autosomal recessive manner, with two carrier parents having a 25% chance of having an affected child. Heterozygotes are clinically asymptomatic and may have only slight anemia. Carriers are referred to as having thalassemia minor.²⁶⁷ The β -thalassemias result from more than 200 different hemoglobin β chain mutations.²⁶⁸ Despite this marked molecular heterogeneity, the prevalent molecular defects are limited in each at-risk population—that is, each racial or ethnic population has only four to 10 mutations that account for the large majority of the disease-causing alleles in that population (Table 30-21). For example, in individuals of Mediterranean, Middle Eastern, Indian, Thai, or Chinese extraction, a limited number of population-specific mutations account for between 90% and 95% of the disease genes. In Africans and African-Americans, common mutations account for approximately 75% to 80%. This phenomenon has significantly facilitated molecular genetic testing.

Screening for thalassemia should be offered to all individuals of Mediterranean, Middle Eastern, Transcaucasian, Central Asian, Indian, and Far Eastern groups. Because thalassemia is also common in individuals of African heritage, carrier testing should be offered to all African Americans. As with sickle cell disease, the distribution is probably related to selective pressure from malaria, because the disease distribution is similar to that of endemic *Plasmodium falciparum* malaria.²⁶⁷ However, because of population migration and, in limited part, the slave

TABLE 30-22 Red Blood Cell Indices in β -Thalassemia

Red Blood Cell Index	Normal		Affected β -Thalassemia Major	Carrier β -Thalassemia Minor
	Male	Female		
Mean	80.0-	80.0-	50-70	<80
corpuscular volume (fL)	100.0	100.0		
Mean	27.5-	27.5-	12-20	18-22
corpuscular hemoglobin (pg)	33.2	33.2		
Hemoglobin (g/dL)	14-18	12-16	<7	11-14

From Hann IM, Gibson BES, Letsky EA: Fetal and neonatal haematology, Philadelphia, 1991, Saunders.

trade, β -thalassemia is now also commonly seen in northern Europe, North and South America, the Caribbean, and Australia.

Carriers are identified by evaluation of the red blood cell indices, quantitative hemoglobin analysis, and hemoglobin β chain mutation studies. Carriers are initially identified by their red blood cell indices that show microcytosis (low MCV, <80) and a reduced content of hemoglobin per cell (low mean corpuscular hemoglobin). Next, hemoglobin electrophoresis displays a hemoglobin A_2 level of greater than 3.5% (Table 30-22). On rare occasions, carrier identification using MCV can be misleading. For example, coinheritance of an α -thalassemia gene may normalize red blood cell indices. Also, coinheritance of the δ -thalassemia gene can reduce the normal increased hemoglobin A_2 levels typical of β -thalassemia. Likewise, screening using only a routine hemoglobin electrophoresis as the primary test is insufficient, because thalassemia carriers can easily be missed when hemoglobin levels are normal, and the subtle increases in hemoglobin A_2 and F on electrophoresis may be overlooked. Therefore, a complete blood count with MCV and red cell count should be obtained, and a quantitative hemoglobin electrophoresis should be performed, because the MCV is almost always low in β -thalassemia and the red cell count is elevated. Quantitative hemoglobin electrophoresis for hemoglobin A_2 and F is diagnostic.²⁶⁶

When the initial hematologic analysis is abnormal and the couple is at risk for having a child with either homozygous β -thalassemia or thalassemia-sickle cell disease syndrome, DNA analysis of the hemoglobin β chain is indicated to identify the disease-causing mutation. This helps identify carriers of mild and silent mutations of β -thalassemia that result in attenuated forms of the disease. Knowledge of the specific mutations will also be required if subsequent prenatal diagnosis is performed. However, the sensitivity of molecular testing remains less than 100%, so for some individuals a specific mutation cannot be identified.

Prenatal diagnosis is offered to couples when both members are carriers of β -thalassemia and their gene mutations have been identified. In these cases, mutation analysis can be performed by DNA extracted from either CVS or amniocentesis. Prenatal testing is occasionally offered to families in which one parent is a definitive heterozygote and the other parent has a β -thalassemia-like hematologic picture but no mutation can be identified by sequence analysis. If the father of a pregnancy with

a known heterozygote mother is unavailable for testing and belongs to a population at risk, prenatal diagnosis can be offered. In either of the latter two situations, if the known mutation is identified by CVS or amniocentesis, globin chain synthesis analysis is available for definitive diagnosis.

α -Thalassemia

α -Thalassemia is a hemoglobinopathy caused by the deficiency or absence of α globin chain synthesis. The α globin gene cluster is located on chromosome 16 and includes two adult genes ($\alpha 1$ and $\alpha 2$), so that normal individuals have four α globin genes ($\alpha 1\alpha 2/\alpha 1\alpha 2$). α^0 -Thalassemia can be divided into two forms based on the number of functioning genes. A severe form called α^0 -thalassemia results in a typical thalassaemic blood picture in heterozygotes and a severe, perinatally lethal form in homozygotes. α^0 -Thalassemia results from 1 of 17 gene deletions, all of which delete both α globin genes on each chromosome. On the other hand, α^+ -thalassemia is milder and is almost completely silent in heterozygotes. This form is commonly caused by one of six deletions that remove one of the two α globin genes on chromosome 16.

The homozygous state of α^0 -thalassemia resulting from deletions of all four α globin genes ($---$) causes severe hydrops fetalis and the predominance of hemoglobin Barts ($\gamma 4$) and a small amount of hemoglobin Portland ($\zeta 2\gamma 2$) in the fetus. This is routinely lethal in utero or in the early neonatal period if untreated. Although cases of fetal survival after in utero transfusion have been described, this must be followed by repeated transfusions of the infant and subsequent bone marrow transplant. This approach is not routinely recommended. Maternal risks of hemoglobin Barts hydrops fetalis syndrome include preeclampsia and postpartum hemorrhage.

Hemoglobin H disease results from the compound heterozygous state for α^0 and α^+ ($---/\alpha$)-thalassemia, leading to the deletion of three of the four α chain genes. These individuals have a moderately severe hypochromic microcytic anemia and produce large amounts of hemoglobin H (β^4) because of the excessive quantities of β chains in their reticulocytes. In the most common form, these individuals lead a relatively normal life but may have fatigue, general discomfort, and splenomegaly. They rarely require hospitalization. There is a rare, more severe form of hemoglobin H disease arising from a compound heterozygous state of α^0 -thalassemia and nondeletion α^+ -thalassemia involving the more dominant $\alpha 2$ gene.

α^0 -Thalassemia gene deletions are found in high frequency in individuals from Southeast Asia, South China, the Philippine Islands, Thailand, and a few Mediterranean countries, such as Greece and Cyprus. Because these populations are at risk for the homozygous state leading to hemoglobin Barts disease, they should be screened for the presence of the gene. The α^+ -thalassemia genes are frequent in Africa, the Mediterranean area, the Middle East, the Indian subcontinent, Melanesia, Southeast Asia, and the Pacific area. Because this leads to a mild form of thalassemia, routine screening for α -thalassemia in these populations is not recommended.

The carrier state for α^0 -thalassemia is identified by performing a complete blood count with indices. Carriers ($---/\alpha\alpha$) have a decreased MCV (<80 fL) and a mean corpuscular hemoglobin level (<27 pg), as seen with α -thalassemia, but the carriers are differentiated by having a normal hemoglobin A_2 level (<3.5%). The diagnosis is confirmed by DNA testing, which can identify the specific deletion. Prenatal diagnosis is available by CVS or

amniocentesis and is based on the molecular determination of the gene status.

FRAGILE X SYNDROME

Fragile X syndrome is characterized by relatively typical phenotypic characteristics and moderate mental retardation in affected males. Affected females have somewhat milder mental retardation.²⁶⁹ Classic features become more prevalent with age, including long face, large ears, prominent jaw, and macrotestes. There is delayed attainment of motor milestones and speech. Abnormal temperament is frequently associated with hyperactivity, hand flapping, hand biting, and autism spectrum disorder. Behaviors in postpubertal males include tactile defensiveness, poor eye contact, and perseverative speech. Physical and behavioral features can be seen in female heterozygotes, but with a lower frequency and milder involvement.

Adult manifestations of the fragile X premutation carrier state occur. The fragile X–associated tremor/ataxia syndrome (FXTAS) is characterized by late-onset, progressive cerebellar ataxia and intention tremor in males and some females who have a premutation.²⁷⁰ Other neurologic findings include short-term memory loss, executive function deficits, cognitive decline, parkinsonism, peripheral neuropathy, lower-limb proximal muscle weakness, and autonomic dysfunction. Penetrance is age related; symptoms in men are seen in 17% aged 50 to 59 years, in 38% aged 60 to 69 years, in 47% aged 70 to 79 years, and in 75% aged 80 years and older. Some female premutation carriers may also develop tremor and ataxia. In girls and women, premature ovarian insufficiency (POI), defined as cessation of menses before age 40 years, has been observed in carriers of premutation alleles.²⁷¹ A review by Sherman²⁷² concluded that the risk for POI was 21% (estimates ranged from 15% to 27% in various studies) in premutation carriers compared with a 1% background risk. In this review, an odds ratio of 2.5 was estimated for intermediate repeat sizes of 41 to 58. Ovarian failure occurred at as early as 11 years of age. In contrast, carriers of full mutation alleles are not at increased risk for POI.

Prevalence estimates of the fragile X syndrome have been revised downward since the isolation of the gene in 1991. Despite this, the original estimates are still occasionally quoted in the fragile X literature. Most recent studies using molecular genetic testing have estimated a prevalence of 1 in 4000 males. The prevalence of affected females is presumed to be approximately one half that of the male prevalence.

Fragile X syndrome is inherited in X-linked dominant fashion. The molecular mutations leading to this syndrome result from expansion of a trinucleotide repeat (CGG) causing aberrant methylation of the gene. This results in decreased or complete absence of the protein gene product termed *fragile X mental retardation 1 protein* (FMR-1 protein). This protein is found in the cytoplasm of many cells but is most abundant in neurons.²⁷³ The function of the protein remains unknown, but its absence leads to developmental abnormalities.

FMR-1 alleles are categorized according to the repeat number, which is correlated with the likelihood of expansion during maternal meiosis and the clinical manifestations. However, the distinction between allele categories is not absolute and must be modified by considering both family history and repeat instability. Normal alleles are approximately 5 to 40 repeats. Alleles of this size are stably transmitted without any increase or decrease in repeat number. In these stable normal alleles, the

CGG region is interrupted by an AGG triplet after every nine or 10 CGG repeats. These AGG triplets are believed to maintain repeat integrity by preventing DNA strand slippage during replication. Mutable normal alleles or intermediate alleles (also termed gray zone) may be broadly defined as 41 to 58 repeats. The risk for instability of alleles with 41 to 49 repeats when transmitted from mother to child is minimal. Any changes in repeat number are typically very small (plus or minus one or two repeats). Historically, the largest repeat included in the intermediate range has been 54. In fact, the intermediate range may extend slightly higher, as no transmission of alleles with 56 or fewer repeats is known to have resulted in an affected individual.²⁷⁴ Because most clinical testing laboratories state that repeat measurements are plus or minus two to three repeats, it may be wise to consider reported test results with 55 to 58 repeats as potential premutations.

Premutation alleles of approximately 59 to 200 repeats have an increased risk of expansion to a full mutation and of causing the clinical phenotype. Alleles of this size are not associated with mental retardation but do convey increased risk for FXTAS and premature ovarian failure. Because of potential repeat instability with transmission of premutation alleles through maternal meiosis, women with alleles in this range are considered to be at risk for having children affected with fragile X syndrome and should consider prenatal diagnosis. Full mutation alleles are those with more than 200 repeats, with several hundred to several thousand repeats being typical. Aberrant hypermethylation of the deoxycytidylate residues contained in the CGG repeats usually occurs once repeat expansion exceeds approximately 200, leading to complete absence of FMR-1 protein and resulting in the complete fragile X phenotype in males. The phenotype of full mutation females, although also dependent on the size of the mutation, can be modified by random inactivation of either the normal or the mutated X chromosome in the brain.²⁷⁵ Approximately 50% of females who have a full fragile X mutation are intellectually disabled but are usually less severely affected than males with the full mutation.²⁷⁶ Importantly, about 50% of females who are heterozygotes for the full mutation are intellectually normal.²⁷⁷

The probability of a carrier of a premutation having a child with a full mutation depends on the size of the premutation, the sex of the carrier, and the number and position of AGG repeats.²⁷⁴ When premutations are transmitted by the father, only small increases in the trinucleotide repeat number may occur, and they do not result in full mutations. All daughters of transmitting males are unaffected premutation carriers, with the potential of subsequent expansion in their offspring. Women who are premutation carriers have a 50% risk of transmitting the abnormal chromosome in each pregnancy.²⁷⁸ Their risk of having an offspring with a full mutation if the affected X chromosome is transmitted is on the basis of their premutation size. Table 30-23 demonstrates the likelihood of expansion to a full mutation based on the maternal premutation size. In some categories, risks may be significantly different if the premutation is carried by a woman with a family history of fragile X syndrome. For example, maternal premutation alleles with 70 to 79 CGG repeats have a 54% risk for expansion if there is a family history of fragile X, versus an 18% risk in its absence. Recent results have also linked the uninterrupted length of the 3' CGG repeat length (i.e., uninterrupted by an AGG repeat) with the likelihood of expansion and suggest a minimum threshold for expansion risk.²⁷⁹ This test may be valuable for

TABLE 30-23
Risks for Expansion from a Maternal Premutation to a Full Mutation When Transmitted to Offspring

Number of Maternal Premutation CGG Repeats	Total Maternal Transmissions	Expansions to Full Mutations* (%)
55-59	27	1 (3.7%)
60-69	113	6 (5.3%)
70-79	90	28 (31.1%)
80-89	140	81 (57.8%)
90-99	111	89 (80.1%)
100-109	70	70 (100%)
110-119	54	53 (98.1%)
120-129	36	35 (97.2%)
130-139	18	17 (94.4%)
140-200	19	19 (100%)

*Unlike in classic X-linked dominant disorders, in which all females with a mutation are affected, only about 50% of females with a full mutation are mentally retarded. This variability in phenotype is likely to be related to X-chromosome inactivation, a phenomenon independent of *FMR1* mutations.

Adapted from Nolin SL, Brown WT, Glucksman A, et al: Expansion of the fragile X CGG repeat in females with premutation or intermediate alleles, *Am J Hum Genet* 72:454-464, 2003.

female carriers of intermediate and small premutation alleles to better estimate their risk of expansion to a full mutation, but the clinical usefulness of such testing awaits further confirmation. At present, all premutation carrier females should be offered invasive prenatal analysis.

The presence of normal transmitting males and the variable likelihood of full expansion by females carrying a premutation will lead to pedigrees with skipped generations or the seemingly spontaneous occurrence of the fragile X syndrome.²⁸⁰ Therefore, carrier testing should be offered to all individuals seeking reproductive counseling who have either a family history of fragile X syndrome or undiagnosed mental retardation in individuals of either sex.²⁶⁸

Some centers offer all women seeking prenatal diagnosis the opportunity to have fragile X testing performed as part of routine screening. This approach is based on evidence that the frequency of the premutation is relatively high in the general population. One study of a French-Canadian population found that 1 in 259 women had a premutation in the *FMR-1* gene.²⁸¹ A more recent study of 14,334 Israeli women of childbearing age identified 127 carriers with greater than 54 repeats, including three asymptomatic women with full mutations, representing a prevalence of 1 in 113 (885 in 100,000).²⁸⁰ The benefits of such a screening strategy have not been demonstrated.

Methodologies for molecular testing vary from laboratory to laboratory. Most laboratories screen patient DNA samples by the polymerase chain reaction (PCR) specific for the trinucleotide repeat region of the *FMR-1* gene.²⁸² This technique has high sensitivity for *FMR-1* repeats in the normal and lower premutation range but may, rarely, fail to detect *FMR-1* alleles in the upper premutation range. It also can fail to detect full mutations with a high repeat number (especially when used for prenatal testing). Because of these limitations, many laboratories also perform Southern blot analysis, which detects the presence of full mutations and large premutations. When PCR reveals a normal or premutation allele size in male patients or two alleles

in the normal or premutation range in female patients, further testing by Southern blot is not necessary.^{283,284}

Prenatal testing for fetuses at increased risk for *FMR-1* full mutations is performed using DNA extracted from either amniocytes or chorionic villi. The Southern blot patterns for DNA expansions derived from amniocytes are identical to those found in adult tissues. Because the methylation pattern is predictive of gene function, it is occasionally used to make the distinction between a large premutation and a small full mutation. However, unreliable methylation patterns can occur in DNA from cells obtained by CVS, because methylation of villus tissue may occur at varying gestational ages.²⁸⁵ As a result, on occasion, follow-up amniocentesis may be requested. Because of the complexity of *FMR-1* trinucleotide repeat expansion detection and the accompanying methylation issues, a laboratory with known competence for *FMR-1* prenatal molecular testing is strongly suggested.^{282,284,286}

SPINAL MUSCULAR ATROPHY

Spinal muscular atrophy (SMA) is a severe neuromuscular disease characterized by degeneration of the anterior motor neurons, leading to progressive muscle weakness and paralysis. SMA is the leading inherited cause of infant death with an incidence of 1/10,000.^{287,288} Childhood SMA is subdivided based on age of onset and clinical severity.²⁸⁹ Approximately 60% of SMA patients have type I (Werdnig-Hoffmann) disease,²⁹⁰ with severe generalized muscle weakness and hypotonia at birth or within the first few months of life, and respiratory failure leading to death or permanent ventilator support by 2 years of age. Type II accounts for 27% of SMA,²⁹⁰ and is variable, with some children having severe respiratory insufficiency and transient ability to sit, whereas others have milder respiratory involvement and are mobile with mechanical support. Individuals with type III SMA (Kugelberg-Welander) experience delayed motor milestones, mild muscle weakness, and fatigue.

SMA is inherited as an autosomal recessive disorder caused by mutations in the survival motor neuron 1 (*SMN1*) gene²⁹⁰ located in a complex region of 5q13. The homozygous absence of *SMN1* is responsible for 95% of SMA. This region also contains at least one copy of *SMN2*, a pseudogene that differs from *SMN1* by five nucleotides, which affects splicing and results in only about 10% expression of the full-length functional protein gene.²⁹¹ An inverse relationship between disease severity and *SMN2* copy number in affected individuals has been observed but is not absolute.²⁹² Other modifying factors, including *SMN2* sequence variants, may also influence phenotypic variability.²⁹³

Most individuals have two copies of *SMN1*, one on each homologous chromosome. However, a smaller number (4% to 7%) have two copies of *SMN1* on the same chromosome (Fig. 30-8).²⁹⁴ Carriers usually have one copy of *SMN1*, with the other copy deleted. However, some carriers can have two copies on one chromosome and an absent gene on the other. Determination of a single *SMN1* copy number permits identification of approximately 90% to 94% of SMA carriers in all ethnic groups except African Americans, in whom the carrier detection rate is just over 70% because of a higher frequency of carriers with a two-copy allele, making detection unsuccessful. This also will result in an increased residual risk for screen-negative African Americans (Table 30-24). For example, a white individual with a two-copy result after carrier screening would have a 1 in 800

TABLE 30-24 Carrier Frequency and Risk Reduction for Spinal Muscular Atrophy by Ethnicity

Ethnicity	Detection Rate (%)	A Priori Risk* (95% CI)	Reduced Risk for 2-Copy Result	Reduced Risk for 3-Copy Result
Mixed ethnicity†				
White	94.8	1:47 (1:43-1:51)	1:834	1:5600
Ashkenazi Jewish	90.5	1:67 (1:54-1:83)	1:611	1:5400
Asian	93.3	1:59 (1:47-1:74)	1:806	1:5600
Hispanic	90.0	1:68 (1:57-1:83)	1:579	1:5400
Asian Indian	90.2	1:52 (1:33-1:82)	1:443	1:5400
African American	70.5	1:72 (1:54-1:94)	1:130	1:4200

*A priori risk includes the [1+0], [1+1^o], [2+0], and [2+1^o] allele pairings for individuals with no family history of spinal muscular atrophy.

†For mixed ethnicity, consider using the ethnic background with the most conservative visits.

Adapted from Sugarman EA, Nagan N, Zhu H, et al: Pan-ethnic carrier screening and prenatal diagnosis for spinal muscular atrophy: clinical laboratory analysis of >72,400 specimens, *Eur J Hum Genet* 20:27-32, 2012.

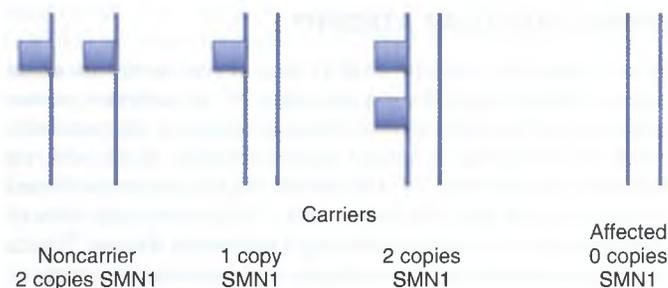

Figure 30-8 Copies of the survival motor neuron 1 (SMN1) gene among noncarriers, carriers, and those affected by spinal muscular atrophy.

residual risk to be a carrier, whereas an African American with the same result would have a 1 in 130 risk to be a carrier.

Fetal testing is appropriate when a parent with one SMN1 copy is identified during screening. Even if the other parent has two copies of SMN1, it is uncertain whether they are on one chromosome or two. The risk for a fetus to be affected with SMA, when one parent is identified as a one-copy carrier and the other parent has an SMN1 copy number of two, can vary by ethnic background. In a white couple, the risk of having an affected fetus is 1 in 2528. In contrast, the risk for an African-American couple with the same parental results is 1 in 264. Furthermore, a one-copy fetal result in this situation would be associated with a 1 in 4000 risk for the fetus to be affected with SMA, as a result of compound heterozygosity for an allele containing a mutation rather than a deletion of the gene.²⁹⁴

In 2008, the ACMG issued practice guidelines recommending that all couples be offered SMA carrier screening, regardless of race or ethnicity.²⁹⁵ The guidelines identified SMA as meeting generally accepted criteria for a successful screening program, including clinical severity, a high frequency of carriers in the screened population, reliable testing with high sensitivity and specificity, available prenatal diagnosis, and access to genetic counseling. In 2009, ACOG recommended restricting carrier screening to individuals with a family history of SMA. ACOG asserted that assessment of pilot programs, educational materials, cost-effectiveness of screening, and absence of laboratory standards and guidelines should be considered before widespread implementation of a carrier screening program for SMA.²⁹⁶

UNIVERSAL CARRIER SCREENING

Although ethnicity-specific carrier screening has worked well, there are limitations to its ability to maximize identification of couples at increased risk for having a pregnancy with a mendelian disorder. First, identification of the ethnicity of patients and couples has become increasingly complex. Second, although the carrier frequency of specific disorders presently screened for is individually high, these disorders account for only a small percentage of the recessive disease load. For example, the worldwide carrier frequency of a relatively common disorder, such as CF, is 1.7%, but the disease itself is relatively infrequent compared with the overall frequency of all recessive disorders.²⁹⁷ This has led to the development of universal carrier screening, in which a large number of both common and rare disorders are screened for simultaneously in the general population.

Universal carrier screening has only recently become viable, as the ability to screen simultaneously for a large number of mutations has become technically possible and cost-effective. Universal carrier testing uses a highly customized, multiple molecular inversion probe assay²⁹⁸⁻³⁰⁰ to convert the information content of a genetic variant into fluorescently labeled tag sequences.²⁹⁸ This approach identifies both the mutant and the wild-type alleles of each variant. More than 100 diseases can now be screened for, costing significantly less than the price of targeted screening currently available for many disorders.²⁹⁷

As with all screening tests, universal carrier testing is risk reducing rather than risk eliminating, as not all mutations for any disorder can be identified because many rare variants remain uncharacterized. Srinivasan and colleagues have reported a test for more than 100 mendelian disorders, with multiple mutations tested per allele, in which 35% of individuals were found to be a carrier for at least one mutation, and the rate of carrier couples was approximately 0.6% to 0.8%.²⁹⁷ Although this carrier rate appears high, it should be considered that every individual is suspected to carry between four and six deleterious mutations.

The role of universal carrier screening in routine care is not yet clear. Unanswered questions include the criteria for including diseases and specific mutations on the array, appropriate pretest counseling, individual versus couple testing, and the need for sequencing screen-negative partners of a documented carrier.

Diagnostic Tests

INDICATIONS FOR INVASIVE TESTING

Indications for diagnostic testing are dominated by advanced maternal age (>35 years) and positive screening tests and have been discussed. A prior history of a fetus with a chromosomal abnormality is the next most frequent indication for cytogenetic testing. The recurrence risk after the birth of one child with trisomy 21 varies in the literature, with most studies quoting an empiric risk of approximately 1% to 1.5% for any trisomy.³⁰¹ Closer scrutiny suggests that the risk depends on the age of the mother at the birth of the initial trisomic child. Warburton and colleagues³⁰² demonstrated that if the initial trisomic child is born when a mother is less than 30 years old, a future pregnancy born while the mother is still less than 30 years old has an eightfold increased risk over maternal age-related risk. This usually results in a risk of just less than 1%. If the initial trisomy 21 birth occurred when the mother was older than 30, the risk for another trisomic child is not statistically greater than her age-related risk at the time of the next pregnancy.

The risk for a liveborn trisomic child after a trisomy 21 conception that was either spontaneously or electively terminated is uncertain. The work of Warburton and colleagues³⁰³ suggests that the karyotype of a miscarried pregnancy may predict the karyotype of subsequent miscarriages, but the relevance of this to live births is uncertain. At present, most authorities recommend the conservative approach of offering the same risks as for a liveborn conception, so prenatal diagnosis in subsequent pregnancies is recommended.

After the birth of two or more trisomy 21 pregnancies, the possibility that one of the parents is either a somatic or germ cell mosaic for Down syndrome must be considered, and peripheral blood chromosome studies of the parents should be offered. Uchida and Freeman³⁰⁴ reported parental mosaicism in 2.7% to 4.3% of peripheral karyotypes in such parents. Mothers appeared to have a higher risk than fathers. The risk of recurrence in these families may be as high as 10% to 20%, and prenatal testing is indicated.

About 3% to 5% of Down syndrome cases result from either a *de novo* or an inherited robertsonian translocation. If the translocation is *de novo*, risk of another affected child is minimal, although gonadal mosaicism leading to a recurrence has been suspected in some families. Prenatal diagnosis may be offered in these cases. If the balanced translocation is present in the mother, the overall risk for an unbalanced liveborn child with Down syndrome is 10% to 15%, but this varies according to the specific translocation (Table 30-25). If the translocation is paternal, the risk for an unbalanced offspring is approximately 0.5%, but this also depends on the nature of the translocation. In all cases of parental translocation, prenatal diagnosis is indicated.

Some offspring with inherited balanced robertsonian translocations have been found to have uniparental disomy (UPD). This can have phenotypic consequences if chromosome 14 or 15 is involved. When a balanced robertsonian translocation involving one of these acrocentric chromosomes is present in a pregnancy, additional testing for UPD is indicated.³⁰⁵

The recurrence risk after the birth of a child with a trisomy other than 21 is poorly quantified. In a recent collaborative study of 1076 Japanese women with a history of a previous

TABLE 30-25 Parental Carrier of Robertsonian Translocation: Empiric Risk for Down Syndrome Live Birth

Carrier	Risk for Down Syndrome Live Births (%)
Mother: 13/21, 14/21, 15/21 translocation	10.0-15
Mother: 21/22 translocation	4.0-15
Father: 13/21, 14/21, 15/21 translocation	0.5-5
Father: 21/22 translocation	0.5-2
Either parent: 21/21	100

trisomy, in whom second-trimester amniocentesis was performed, none of the 170 women with previous trisomy 18 offspring and none of the 46 women with a previous trisomy 13 offspring had another such fetus.³⁰⁶ In general, an empiric risk of about 1% is appropriate, and prenatal diagnosis should be offered.

A previous 45,X pregnancy does not significantly increase the risk of a recurrence, but cases of maternal 45,X/46,XX mosaicism leading to a second affected child have been described.³⁰⁷ The recurrence after a triploid pregnancy is exceedingly low but has been reported to occur.²³⁹

Other cytogenetic indications for invasive testing include a parental reciprocal translocation or inversion, a parent or previous child with a mosaic karyotype or marker chromosome, or a sex chromosome or autosome translocation. The risk for an unbalanced offspring in these cases depends on the mode of ascertainment and the specific rearrangement, and genetic counseling is recommended.

Prenatal invasive testing is also indicated to obtain material for biochemical or DNA studies. The molecular abnormalities responsible for many disorders are being identified at a rapid rate, and any listing of these is soon outdated. A list of the more common genetic conditions for which DNA-based prenatal diagnosis is available is given in Table 30-26. A more detailed list, and a list of the centers performing each test, can be found at www.ncbi.nlm.nih.gov/sites/GeneTests. Many of these conditions are rare, and their diagnosis is complex, so consultation with a genetics unit is encouraged before performing an invasive test.

Ultrasound identification of fetal structural anomalies is increasing in frequency as an indication for invasive testing. In addition to major structural defects that have long been known to be associated with fetal aneuploidy, more subtle markers have been demonstrated to increase the risk.^{308,309} In addition, ultrasound markers for fetal infection, anemia, or other disorders frequently require evaluation by amniocentesis.

AMNIOCENTESIS

Historical Perspective

Amniocentesis was first performed in the 1880s for decompression of polyhydramnios.^{310,311} It was during the 1950s that it became a significant diagnostic tool, when measurement of amniotic fluid bilirubin concentration began to be used in the monitoring of Rh isoimmunization.^{312,313} In that same decade, amniotic fluid investigation for fetal chromosome analysis was initiated, as laboratory techniques for cell culture and

TABLE 30-26 Common Conditions for Which Molecular Prenatal Diagnosis Is Available

Disorder	Mode of Inheritance	Prenatal Diagnosis
α_1 -Antitrypsin deficiency	AR	Determine PiZZ allele. Not all homozygotes have liver involvement; pre-procedure genetic counseling critical.
α -Thalassemia	AR	α -Hemoglobin gene mutation (see text)
Adult polycystic kidney	AD	PKD1 and PKD2 gene mutations. In large families, linkage is possible in >90%. Gene mutation identifiable in ~50% of PKD1 and 75% of PKD2.
β -Thalassemia	AR	β -Hemoglobin gene mutation (see text)
Congenital adrenal hyperplasia	AR	CYP21A2 gene mutations/deletions. Nine common mutations/deletions detect 90% to 95% of carriers. Sequencing available.
Cystic fibrosis	AR	CFTR gene mutation (see text)
Duchenne/Becker muscular dystrophy	XLR	Dystrophin gene mutation
Fragile X syndrome	XLR	CGG repeat number (see text)
Hemoglobinopathy (SS, SC)	AR	β -Chain gene mutation (see text)
Hemophilia A	XLR	Factor VIII gene inversion 45%, other gene mutations 45% (not available in all labs), linkage analysis in appropriate families.
Huntington disease	AD	CAG repeat length (PGD and non-informing PND possible to avoid disclosing presymptomatic parents' disease status)
Marfan syndrome	AD	Fibrillin (<i>FBN-1</i>) gene mutation. Linkage in large families. Approximately 70% have mutation identified (not always clinically available).
Myotonic dystrophy	AD	CTG expansion in the <i>DMPK</i> gene
Neurofibromatosis type 1	AD	<i>NF1</i> gene mutation identifiable in >95% of cases but requires sequencing. Linkage in appropriate families.
Phenylketonuria	AR	4 to 15 common mutations, 40% to 50% detection. Further mutation analysis, >99%
Spinal muscular atrophy	AR/AD	
Tay-Sachs disease	AR	Enzyme absence; gene mutation (see text)

AD, autosomal dominant; AR, autosomal recessive; PGD, preimplantation genetic diagnosis; PND, prenatal diagnosis; XLR, X-linked recessive.

karyotyping were developed. The first reported applications were limited to fetal sex determination by Barr body analysis.³¹⁴ The feasibility of culturing and karyotyping amniotic fluid cells was demonstrated in 1966,³¹⁵ and the first prenatal diagnosis of an abnormal karyotype, a balanced translocation, was reported in 1967.³¹⁶

Technique of Amniocentesis

Mid-trimester amniocentesis for genetic evaluation is most commonly performed between 15 and 18 weeks' gestation. At this age, the amount of fluid is adequate (approximately 150 mL), and the ratio of viable to nonviable cells is greatest. Before the procedure, an ultrasound scan is obtained to determine the number of fetuses, confirm gestational age, ensure fetal viability, document anatomy, and locate the placenta and cord insertion. After an appropriate sampling path has been chosen, the maternal abdomen is washed with antiseptic solution. Continuously guided by ultrasound, a 20- to 22-gauge needle is introduced into a pocket of amniotic fluid free of fetal parts and umbilical cord (Fig. 30-9). The pocket should be large enough to allow advancement of the needle tip through the free-floating amniotic membrane that may occasionally obstruct the flow of fluid. The first 1 to 2 mL of aspirated amniotic fluid is discarded to prevent maternal cell contamination of the tissue culture, and then 20 to 30 mL of amniotic fluid is withdrawn. Fetal heart rate and activity are documented immediately after the procedure.

Transplacental passage of the needle should be avoided when possible, but if it is unavoidable, attempts should be made to traverse the thinnest portion, away from the placental edge and the umbilical cord insertion.³¹⁷ If the placenta must be traversed, color Doppler is helpful to avoid any large fetal vessels

at the sampling site. The area close to the placental cord insertion should be avoided, because it contains the largest vessels. Using this approach, transplacental amniocentesis does not increase fetal loss rates in the hands of experienced operators.^{318,319}

Amniocentesis should be performed using continuous ultrasound guidance. Guidance should be maintained throughout the procedure to avoid inadvertent puncture of the fetus and to identify uterine contractions that occasionally retract the needle tip back into the myometrium. Romero and colleagues³²⁰ showed that continuous guidance decreases the number of insertions as well as the number of dry and bloody taps.

The procedure may be performed either freehand or with a needle guide.^{317,321} The freehand technique allows easier manipulation of the needle if the position of the target is abruptly altered by a uterine contraction or fetal movement. On the other hand, a needle guide allows more certain ascertainment of the needle entry point and a more precise pre-entry determination of the sampling path. The guide may allow easier sampling in certain situations, such as when oligohydramnios is present or for patients who are morbidly obese. A needle guide is especially helpful for relatively inexperienced operators or sonographers. Most guides now allow easy intraoperative removal of the needle from the guide and quick adaptation to freehand guidance once the uterus has been entered.³²²

If the initial attempt to obtain fluid is unsuccessful, a second attempt in another location should be performed after reevaluation of the fetal and placental positions. Amniotic membrane tenting and the development of needle-induced uterine wall contractions are most frequently the cause of initial failure. No more than two attempts should be made at any single session. If two attempts have been unsuccessful, the patient may be

Figure 30-9 Ultrasound for amniocentesis procedure. Amniocentesis can be performed with a needle guide (A) or by freehand technique (B). The technique used usually depends on practitioner preference. Needle guides can be helpful when one member of the team (operator or sonographer) is less experienced, or when dealing with oligohydramnios or morbid obesity.

rescheduled in several days. Studies have demonstrated that fetal loss rate increases with the number of insertions. Marthin and coworkers³¹⁹ reported a postamniocentesis loss rate of 3.8% after three insertions, compared with 1.2% after a single pass. Loss rates do not increase with the number of separate procedures. In experienced centers, return visits are rarely required, occurring in less than 1% of cases.³²³

Complications of Amniocentesis

A common finding after amniocentesis is cramping that lasts for 1 to 2 hours. Lower abdominal discomfort may occur for up to 48 hours after the procedure but is usually not severe. Fortunately, serious maternal complications such as septic shock are rare. Amnionitis occurs in 0.1% of cases³²⁴ and can occur from contamination of the amniotic fluid with skin flora or from inadvertent puncture of the maternal bowel. It may also follow procedure-induced amnion rupture. Postamniocentesis chorioamnionitis can have an insidious onset and frequently appears with flulike symptoms and with few early localizing signs. This can evolve into a systemic infection with marked maternal morbidity unless early aggressive treatment is undertaken. Therefore, a high index of suspicion is necessary.

The development of rhesus isoimmunization occurs in approximately 1% of Rh-negative women undergoing amniocentesis,³²⁵⁻³²⁷ but it can be avoided by prophylactic administration of anti-D immunoglobulin after the procedure.

Amniotic fluid leakage or vaginal bleeding is noted by 2% to 3% of patients after amniocentesis. Unlike spontaneous second-trimester amnion rupture, which has a dismal prognosis, fluid leakage after amniocentesis usually resolves after a few days of bed rest. Successful pregnancy outcome after such an event is common.³²⁸ Occasionally, leakage of amniotic fluid persists throughout pregnancy,^{329,330} but if the amniotic fluid volume remains adequate, a good outcome can be anticipated.

Pregnancy Loss after Mid-Trimester Amniocentesis

The safety of mid-trimester amniocentesis was documented in the mid 1970s by three collaborative studies performed in the United Kingdom, the United States, and Canada.^{329,331,332} These studies, performed prior to the clinical use of ultrasound, were not randomized but rather included unsampled matched control groups. The U.S. and Canadian studies showed similar loss rates (spontaneous abortions, stillbirths, and neonatal

deaths) between the two groups. A greater risk for loss occurred with needles of 19 gauge or larger and with more than two needle insertions per procedure. Both studies reported total postprocedure loss rates of 3% to 4%.

In contrast to these studies, the British Collaborative Study found an excess of fetal loss (1% to 1.5%) in the amniocentesis group compared with control subjects. This study has been criticized for a number of concerns, including a significant proportion of sampled patients with elevated MSAFP levels, an unusually low complication rate in the control group, and a change in the matching criteria during the study.

Seeds³³³ performed a contemporary review of more than 68,000 amniocenteses from centers reporting 1000 or more procedures and analyzed results from both controlled and noncontrolled studies (Table 30-27). From this analysis he concluded the following:

1. Amniocentesis with concurrent ultrasound guidance is associated with a procedure-related rate of excess pregnancy loss of 0.33% (95% CI, 0.09 to 0.56) in a comparison of all studies. Among only controlled studies, the procedure-related rate of loss is 0.6% (95% CI, 0.31 to 0.90). When calculating the total postprocedure rate of loss (to 28 weeks' gestation), the procedure-induced losses should be added to the 1.08% rate of natural losses occurring in women not undergoing amniocentesis.
2. The use of concurrent ultrasound guidance appears to reduce the number of punctures and the incidence of bloody fluid. In a comparison of all studies, pregnancy loss is diminished with the use of concurrent ultrasound guidance; however, when only controlled studies are compared, this trend remains, but the advantage is not significant.
3. The reported experience does not support an increased rate of pregnancy loss after placental puncture. Transplacental amniocentesis is associated with an aggregate rate of reported loss of 1.4%, which is identical to the overall rate of loss among all amniocentesis patients and lower than that reported from controlled studies.

Certain clinical factors influence the risk for pregnancy loss, independent of the amniocentesis procedure. For example, spontaneous abortion is more common in older patients and may be more common among patients of any age with an abnormal serum screen result. A prior pregnancy loss is reported

TABLE 30-27 Studies* Describing Ultrasound Guidance to Visualize Needle Placement

Study	Amniocentesis Cases (N)	Losses at ≤ 28 Weeks' Gestation (n)	Control Type, No. of Losses (No. of Control Subjects)	Comment
Farahani et al, 1984 ⁵⁵⁹	2100	19 (0.9%)	Unmatched, 11 (2200)	No fetal trauma detected
Leschot et al, 1985 ⁵⁶⁰	2920	64 (2.19%)		First 1500 cases were in Verjaal and Leschot
Dacus et al, 1985 ³³⁷	1981	32 (1.6%)		Risk increased with the number of passes, bloody fluid, or no ultrasound scan
Tabor et al, 1986 ³³⁸	2242	29 (1.3%)	Randomized, 8 (2270)	18-gauge needle; more risk with transplacental; losses through 24 wk of gestation
Andreasen and Kristoffersen, 1989 ³³⁴	1289	28 (2.2%)	Unmatched, 2 (258)	More risk with transplacental
Bombard et al, 1995 ³¹⁸	1000	12 (1.3%)		More risk, but not significant, with transplacental
Marthin et al, 1997 ³¹⁹	2083	28 (1.3%)		No increase with transplacental
Canadian Early versus Mid-trimester Amniocentesis Trial, 1999 ³²³	2090	40 (1.9%)		
Eiben et al, 1997 ⁵⁶¹	1802	12 (0.8%)		
Tongsong et al, 1998 ⁵⁶²	2045	36 (1.8%)	Matched, 29 (2045)	
Roper et al, 1999 ⁵⁶³	2924	35 (1.2%)		
Reid et al, 1999 ⁵⁶⁴	3774	29 (0.8%)		More risk, but not significant, with transplacental
Antsaklis et al, 2000 ³³⁵	3696	79 (2.1%)	Unmatched, 80 (5324)	
Horger et al, 2001 ⁵⁶⁵	4198	35 (0.83%)		Losses only to 60 days after procedure
TOTALS	34,144	478 (1.4%)	130/12,097 (1.08%)	

*Studies include those with at least 1000 cases, with or without control subjects. From Seeds JW: Diagnostic mid trimester amniocentesis: how safe? *Am J Obstet Gynecol* 191:607-615, 2004.

to increase the risk, as is previous vaginal bleeding. The number of needle placements, the observation of bloody fluid, and especially the observation of green or murky fluid are seen to be associated with a significantly increased risk for pregnancy loss after amniocentesis.³³⁴⁻³³⁹

The only prospective randomized controlled trial evaluating the safety of second-trimester amniocentesis is a Danish study, which reported on 4606 low-risk healthy women, 25 to 34 years old, who were randomly allocated to either amniocentesis or ultrasound examination.³³⁸ The total fetal loss rate in the amniocentesis group was 1.7% and in the control subjects, 0.7% ($P < .01$). The observed difference of 1% (95% CI, 0.3 to 1.5) gave a relative risk of 2.3. The conclusions of this study were initially criticized because the original report stated that a 17-gauge needle (which is associated with higher risks than smaller needles) was used. Tabor and colleagues³³⁹ subsequently reported that they had in fact used a 20-gauge needle for most of the procedures.

Both the U.K. and Danish studies^{334,338} found an increase in respiratory distress syndrome and pneumonia in neonates from the amniocentesis groups. Other studies have not found this association. The U.K. study also showed an increased incidence of talipes and dislocation of the hip in the amniocentesis group.³³² This finding has not been confirmed.

In early experience with amniocentesis, needle puncture of the fetus was reported in 0.1% to 3.0% of cases^{329,340} and was associated with fetal exsanguination,³⁴¹ intestinal atresia,^{342,343} ileocutaneous fistula,³⁴⁴ gangrene of a fetal limb,³⁴⁵ unioocular

blindness,³⁴⁶ porencephalic cysts,³⁴⁷ patellar tendon disruption,³⁴⁸ skin dimples,³⁴⁹ and peripheral nerve damage.³⁴⁰ Continuous use of ultrasound to guide the needle minimizes needle puncture of the fetus, which, in experienced centers, is an exceedingly rare but still seen complication.³³³

No long-term adverse effects have been demonstrated in children undergoing amniocentesis. Baird and colleagues³⁵⁰ compared 1296 liveborn children whose mothers had a mid-trimester amniocentesis to unsampled control subjects. With the exception of hemolytic disease resulting from isoimmunization, the offspring of women who had amniocentesis were no more likely than control subjects to have a disability during childhood and adolescence. Finegan and colleagues³⁵¹ reported an increased incidence of middle-ear abnormalities in children whose mothers had amniocentesis.

Early Amniocentesis (Performed before 15 Weeks' Gestation)

The desire for a first-trimester diagnosis stimulated interest in the feasibility of performing amniocentesis at less than 15 weeks' gestation. The technique at this gestational age varies from conventional amniocentesis in that less fluid is available, and incomplete fusion of the amnion and chorion frequently causes tenting of the membranes, resulting in failed procedures in 2% to 3% of cases.^{323,352}

Although initial experience with early amniocentesis was reassuring,³⁵³⁻³⁵⁶ subsequent studies have raised serious concerns about its safety. In 1994, Nicolaidis and coworkers³⁵⁷

reported on more than 1300 women undergoing first-trimester diagnoses. In this study, significantly higher rates of fetal loss (5.3% versus 2.3%) were seen in the early amniocentesis group. This finding was echoed by Vandenbussche and coworkers,³⁵⁸ who reported a 6.7% higher occurrence of pregnancy loss for early amniocentesis compared with CVS. Sundberg and colleagues,³⁵⁹ in a prospective randomized comparison of CVS to early amniocentesis, also found a higher loss rate with early amniocentesis but had to terminate the study early because of an unanticipated increase in talipes equinovarus (clubfoot) in the early amniocentesis group. Higher loss rates have also been found when comparing early amniocentesis to second-trimester amniocentesis. The Canadian Early and Mid-Trimester Amniocentesis trial reported a 1.7% higher incidence of fetal loss in the early amniocentesis group compared with second-trimester sampling when taking all fetal losses into account (7.6% versus 5.9%).³⁵² There is also an increased frequency of culture failure and ruptured membranes compared with later procedures.^{352,357,359}

Of most concern is that fetal talipes equinovarus occurs in 1% to 2% of cases sampled by early amniocentesis.^{352,357,359,360} This rate is 10-fold higher than the 1 per 1000 births seen in the U.S. population. The clubfoot deformities are believed to occur as a result of procedure-induced fluid leakage, because they occurred in 1% of cases in which no leakage occurred and in 15% of cases when leakage occurred.³⁵² For these reasons, amniocentesis should rarely, if ever, be performed before the 13th week of gestation. The safety of amniocentesis in weeks 13 and 14 is uncertain. Until its safety can be ensured, it is best to delay routine sampling until week 15 or 16 of pregnancy.

CHORIONIC VILLUS SAMPLING

The major drawbacks of conventional second-trimester genetic amniocentesis are the delayed availability of the karyotype and the increased medical risks of a pregnancy termination late in pregnancy. Furthermore, delaying the procedure until after fetal movement is appreciated by the mother is believed to inflict a severe emotional burden on the patient. As a result of these concerns, attempts have been made to move prenatal diagnosis into the first trimester. CVS, which samples the developing placenta rather than penetrating the amniotic membrane, has been the most successful means to date of accomplishing this.

History of Chorionic Villus Sampling

The ability to sample and analyze villus tissue was demonstrated more than 25 years ago by the Chinese, who, in an attempt to develop a technique for fetal sex determination, inserted a thin catheter into the uterus guided only by tactile sensation.³⁶¹ When resistance from the gestational sac was felt, suction was applied and small pieces of villi were aspirated. Although this approach seems crude by today's standards of ultrasonically guided invasive procedures, their diagnostic accuracy and low miscarriage rate demonstrated the feasibility of first-trimester sampling.

Initial experiences in other parts of the world were not as promising. In 1968, Hahnemann and Mohr³⁶² attempted blind transcervical trophoblast biopsy in 12 patients using a 6-mm diameter instrument. Although successful tissue culture was possible, half of these subjects subsequently aborted. In 1973, Kullander and Sandahl³⁶³ used a 5-mm-diameter fiberoptic endocervicoscope with biopsy forceps to perform transcervical

CVS in patients requesting pregnancy termination. Although tissue culture was successful in approximately half of the cases, two subjects subsequently became septic.

In 1974, Hahnemann³⁶⁴ described further experience with first-trimester prenatal diagnosis using a 2.5-mm hysteroscope and a cylindrical biopsy knife. Once again, significant complications, including inadvertent rupture of the amniotic sac, were encountered. By this time, the safety of mid-trimester genetic amniocentesis had become well established, and further attempts at first-trimester prenatal diagnosis were temporarily abandoned in the Western Hemisphere.

Two technologic advances in the early 1980s allowed reintroduction of CVS. The first of these was real-time sonography, which made continuous guidance possible. At the same time, sampling instruments were miniaturized and refined. In 1982, Kazy and associates³⁶⁵ reported the first transcervical CVS performed with real-time sonographic guidance. That same year, Old and colleagues³⁶⁶ reported the first-trimester diagnosis of β -thalassemia major using DNA from chorionic villi obtained by sonographically guided transcervical aspiration with a 1.5-mm-diameter polyethylene catheter. Using a similar sampling technique, Brambati and Simoni³⁶⁷ diagnosed trisomy 21 at 11 weeks' gestation.

After these preliminary reports, several CVS programs were established in both Europe and the United States, and the outcomes were informally reported to a World Health Organization (WHO)-sponsored registry maintained at Jefferson Medical College in Philadelphia. This registry, along with single-center reports, was used to estimate the safety of CVS until 1989, when two prospective multicenter studies, one from Canada³⁶⁸ and one from the United States,³⁶⁹ were published and confirmed the safety of the procedure.

Technique of Transcervical Chorionic Villus Sampling

Ultrasound examination immediately before the procedure confirms fetal heart activity, appropriate size, and placental location. The positions of the uterus and cervix are determined, and a catheter path is mapped. If the uterus is anteverted, additional filling of the bladder can be used to straighten the uterine position. Although most procedures require a moderately filled bladder, an overfilled bladder is discouraged, because it lifts the uterus out of the pelvis, lengthening the sampling path, which can diminish the flexibility required for catheter manipulation. Occasionally, a uterine contraction interferes with passage of the catheter. Delaying the procedure until the contraction dissipates is suggested (Fig. 30-10).

When the uterine condition and location are favorable, the patient is placed in the lithotomy position, and the vulva and vagina are aseptically prepared with povidone-iodine solution. A speculum is inserted, and the cervix is similarly prepared. The distal 3 to 5 cm of the sampling catheter is molded into a slightly curved shape and the catheter gently passed under ultrasound guidance through the cervix until a loss of resistance is felt at the endocervix. The operator then waits until the sonographer visualizes the catheter tip. The catheter is then advanced parallel to the chorionic membranes to the distal edge of the placenta. The stylet is then removed and a 20-mL syringe containing nutrient medium is attached. Negative pressure is applied by means of the syringe, and the catheter is removed slowly.

The syringe is then visually inspected for villi. These can frequently be seen with the naked eye as white branching

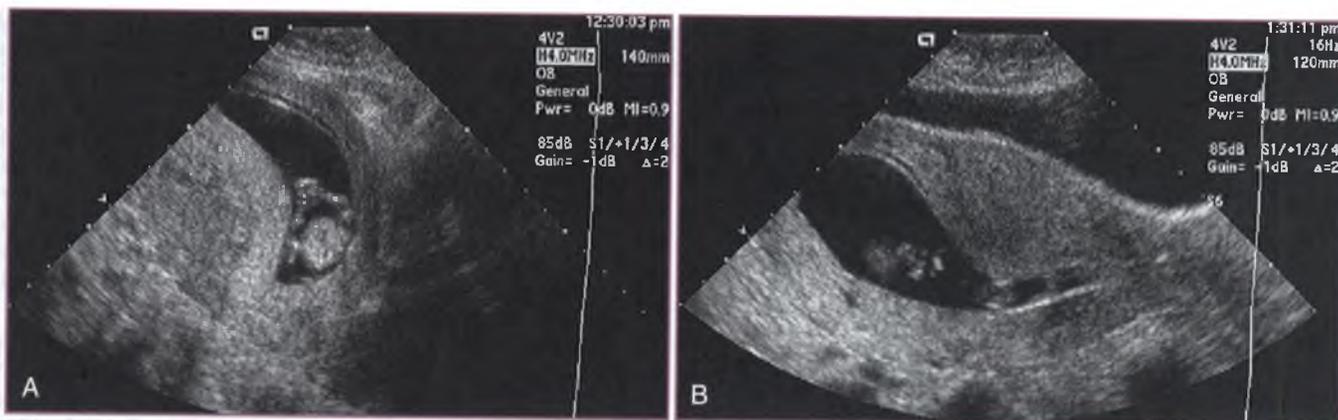

Figure 30-10 Ultrasound images of a transcervical chorionic villus sampling. A, Typical uterine focal contraction characteristic of this gestational age involves the posterior wall of the uterus. B, The same patient 60 minutes later. The contraction has dissipated, the bladder has filled, and the operator is now able to pass the catheter into the posterior chorionic frondosum.

structures floating in the medium. On occasion, however, viewing the samples under a low-power dissecting microscope is necessary to confirm the presence of sufficient villi. Maternal decidua is frequently retrieved with the sample but is usually easily recognized by its amorphous appearance. If sufficient villi are not retrieved with the initial pass, a second insertion can be made with minimal impact on pregnancy loss rate.

Technique of Transabdominal Chorionic Villus Sampling

Continuous ultrasound is used to direct a 19- or 20-gauge spinal needle into the long axis of the placenta (Fig. 30-11). After removal of the stylet, villi are aspirated into a 20-mL syringe containing tissue culture media. Because the needle is somewhat smaller than the cervical sampling catheter, three or four to-and-fro passes of the needle tip through the body of the placenta are required to retrieve the villi. Unlike transcervical CVS, which is best performed before 14 weeks' gestation, the transabdominal procedure can be performed throughout pregnancy and therefore constitutes an alternative to amniocentesis or percutaneous umbilical blood sampling (PUBS) when a karyotype is needed. If oligohydramnios is present, transabdominal CVS may be the only approach available.

Comparison of Transcervical and Transabdominal Chorionic Villus Sampling

The transabdominal and transcervical approaches to CVS have been shown to be equally safe.^{370,371} In most cases, operator or patient choice determines the sampling route; however, in about 3% to 5% of cases, one approach is clearly preferred, so operators must be skilled in both. For example, a posterior placenta is sampled most easily by the transcervical route, whereas a fundal placenta is more simply approached transabdominally. Bowel in the sampling path may preclude transabdominal CVS in some cases, whereas necrotic cervical polyps or an active herpetic lesion should lead to transabdominal sampling.

More chorionic tissue is obtained by the transcervical method, but the proportion of cases in which less than 10 mg is obtained is similar in both groups. There are no differences in birth weight, gestational age at delivery, or congenital malformations with either method.

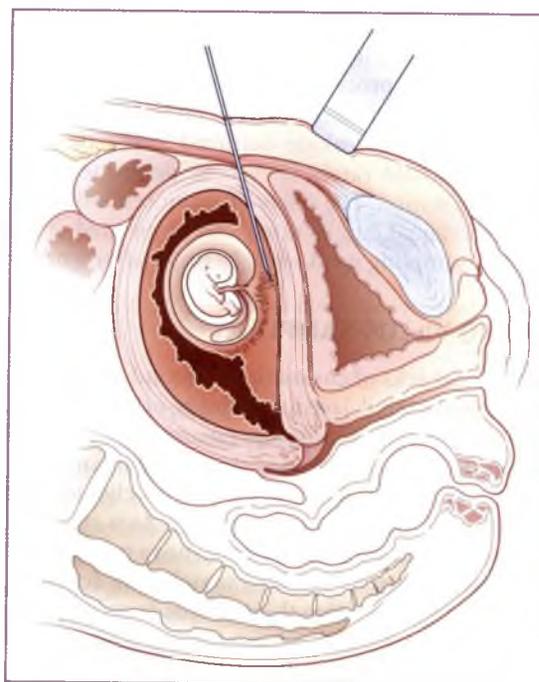

Figure 30-11 Transabdominal chorionic villus sampling. Continuous ultrasound guidance is used to help guide the needle into the chorionic frondosum, remaining parallel to the plate. The sample is then obtained by back-and-forth movement of the needle while maintaining negative pressure. The needle tip is continuously kept in sight via the ultrasound image. Pregnancy Loss after Chorionic Villus Sampling

Although loss rates after CVS (calculated from the time of the procedure until 28 weeks' gestation) are approximately 1% greater than those after amniocentesis (2.5% versus 1.5%), this comparison fails to take into consideration that the background miscarriage rate at 11 to 13 weeks is about 1% greater than at 15 to 16 weeks. To appropriately compare the two procedures,

studies must enroll all patients in the first trimester, assign them to either approach, and then calculate the frequency of all subsequent losses, including spontaneous and induced abortions. In 1989, the Canadian Collaborative CVS/Amniocentesis Clinical Trial Group³⁶⁸ reported such a prospective randomized trial and demonstrated equivalent safeties of CVS and second-trimester amniocentesis. In more than 2650 patients assigned to either procedure, there was a 7.6% loss rate in the CVS group and a 7.0% loss rate in the amniocentesis group (relative risk [RR] = 1.10; 95% CI, 0.92 to 1.30). No significant differences were noted in the incidence of preterm birth, low birth weight, or rate of maternal complication.

A U.S. multicenter prospective nonrandomized study enrolled 2235 women in the first trimester who chose either transcervical CVS or second-trimester amniocentesis.³⁶⁹ An excess pregnancy loss rate of 0.8% in the CVS group over the amniocentesis group was calculated, which was not statistically significant. Repeated catheter insertions were significantly associated with pregnancy loss, with cases that required three or more passes having a 10.8% spontaneous abortion rate, compared with 2.9% in cases that required only one pass.

Further information comes from a Danish randomized trial, which assigned 1068 patients to transcervical CVS, 1078 to transabdominal CVS, and 1158 to second-trimester amniocentesis. There was no difference in loss rates between transabdominal CVS and amniocentesis (RR = 0.9; 95% CI, 0.66 to 1.23). Overall, there was a slightly increased risk for pregnancy loss after CVS (RR = 1.30; 95% CI, 1.01 to 1.67) compared with amniocentesis, which was completely accounted for by an excess of losses in the group sampled transcervically (RR = 1.70; 95% CI, 1.30 to 2.22)—the technique with which this group of investigators had the least experience. Excess loss after transcervical CVS has not been replicated in four other direct comparisons.³⁷⁰⁻³⁷³

A prospective, randomized, collaborative comparison of more than 3200 pregnancies, sponsored by the European Medical Research Council,³⁷⁴ reported that CVS had a 4.6% greater pregnancy loss rate than amniocentesis (RR = 1.51; 95% CI, 1.24 to 1.84). The present consensus is that operator inexperience with CVS accounts for the discrepancy between this trial and the other major studies. The U.S. trial consisted of seven experienced centers and the Canadian trial 11, whereas the Medical Research Council trial used 31. There were, on average, 325 cases per center in the U.S. study, 106 in the Canadian study, and 52 in the European trial.

In conclusion, when appropriately compared, CVS and amniocentesis are equally safe, but the impact of operator experience should not be underestimated. CVS, particularly the transcervical approach, has a relatively prolonged learning curve. Saura and colleagues³⁷⁵ suggested that more than 400 cases may be required before safety is maximized. The role of experience is further demonstrated by three sequential trials sponsored by the National Institute of Child Health and Human Development in which the majority of operators remained relatively constant. The postprocedure loss rate after CVS fell from 3.2% in the initial trial performed from 1985 to 1987,³⁶⁹ to 2.4% for the trial performed from 1987 to 1989,³⁷¹ to only 1.3% in their most recent experience of 1997 to 2001.³⁶⁰ Most recently, Caughey and coworkers³⁷⁶ confirmed the continuing improvement seen with experience. When outcomes from their center were analyzed in 5-year intervals, the overall postprocedure loss rate decreased from 4.4% in the interval from 1983 to 1987, to 1.9% from 1998 to 2003. When compared with their

amniocentesis loss rates, no statistical or clinical difference between the two procedures was seen in the most recent interval.

Other Complications of Chorionic Villus Sampling

Postprocedure bleeding is the most common complaint after CVS. Most centers report postprocedure bleeding in 7% to 10% of patients sampled transcervically, whereas bleeding or spotting is relatively uncommon after transabdominal sampling, occurring in 1% or less of cases.³⁶⁹ Minimal spotting may occur in up to one third of women sampled by the transcervical route.³⁶⁹ On occasion, a small subchorionic hematoma may be seen after sampling.³⁷⁷ This usually resolves spontaneously within a few weeks and is rarely associated with adverse outcome. Hematomas occur when the catheter is passed too deeply into the underlying vascular decidua basalis. Because passage into the decidua gives a “gritty” sensation, careful attention to the feel of the catheter can minimize this complication. Operators should also avoid sampling near or in large placental “lakes,” which also leads to bleeding.³⁷⁸

Since the initial development of transcervical CVS, there has been concern that transvaginal passage of an instrument would introduce vaginal flora into the uterus. Although cultures of catheter tips have isolated bacteria in 30% of transcervical CVS cases,³⁷⁹⁻³⁸² the incidence of chorioamnionitis is extremely low and occurs equally infrequently after either the transcervical or transabdominal procedure. In the U.S. collaborative trial, infection was suspected as a possible etiology of pregnancy loss in only 0.3% of cases.³⁶⁹

Early in the development of transcervical CVS, two life-threatening pelvic infections were reported.^{383,384} The practice of using a new sterile catheter for each insertion was subsequently universally adopted, and there have been no additional reports of serious infections. Infection after transabdominal CVS has been demonstrated and may result from inadvertent bowel puncture by the sampling needle.³⁷⁰

Acute rupture of membranes is exceedingly rare in experienced centers.³⁶⁹ Fluid leakage with oligohydramnios has been reported days to weeks after the procedure.^{385,386} In most cases, this is unrelated to the procedure but occasionally may be secondary to a procedure-induced hematoma.

An acute rise in MSAFP after CVS has consistently been reported, implying a detectable degree of fetomaternal bleeding.³⁸⁶⁻³⁸⁹ The MSAFP elevation is not related to the technique used to retrieve villi but seems to depend on the quantity of tissue aspirated.³⁸⁹ Levels return to normal ranges by 16 to 18 weeks of gestation, thus allowing MSAFP serum screening to proceed according to usual prenatal protocols. All Rh-negative nonsensitized women undergoing CVS should receive Rh-D immune globulin after the procedure. Exacerbation of preexisting Rh immunization after CVS has been described. Existing Rh sensitization, therefore, represents a contraindication to the procedure.³⁹⁰

Risk for Fetal Abnormality after Chorionic Villus Sampling

Firth and colleagues³⁹¹ reported five occurrences of severe limb abnormalities out of 289 pregnancies sampled by CVS between 56 and 66 days. Four of these cases had the unusual but severe oromandibular-limb hypogenesis syndrome, which occurs in the general population at a rate of 1 per 175,000 births.³⁹¹ Burton and coworkers³⁹² then reported on 14 more post-CVS cases of limb reduction defects (LRD), ranging from mild to

severe, only two of which occurred when sampling was performed beyond 9.5 weeks. After these two early reports, the WHO gathered additional data from its CVS registry, published reports,^{391,392} and case-controlled studies^{393,394} and concluded that "far greater data supporting CVS not being associated with LRD were available in various collaborative studies, in individual centers having the greatest experience, and in the WHO-initiated registry comprising 138,996 procedures."³⁹⁵ They further concluded that CVS was not associated with LRD when performed after 8 completed weeks of pregnancy.³⁹⁶ This infrequent occurrence of LRD after CVS was echoed by ACOG, who stated that a risk for LRD of 1 in 3000 would be a prudent upper limit for counseling patients. Data on 216,381 procedures are now in the WHO CVS registry and have been reported.³⁹⁵ This report analyzed the frequency of limb anomalies, their pattern, and their associated gestational age at sampling and found no overall increased risk for LRD or any difference in the pattern of defects compared with the general population. To analyze a possible temporal relationship between CVS and LRD, a subset of 106,383 cases was stratified by the week at which the procedure was performed. The incidences of LRD were 11.7, 4.9, 3.8, 3.4, and 2.3 per 10,000 CVS procedures in weeks 8, 9, 10, 11, and more than 12, respectively. Only the rate at week 8 exceeded the background risk of 6.0 per 10,000 births. If cases from the cluster seen in the original report of Firth and coworkers³⁹¹ are removed, the rate for week 8 procedures also falls below baseline. Brambati and colleagues,³⁹⁷ in a small series of early CVS cases, had an LRD incidence of 1.6% for procedures performed in weeks 6 and 7, 0.1% in week 8, and (population frequency) 0.059% in week 9.

Present data confirm that performing CVS in the standard gestational window of 10 to 13 weeks does not increase the risk for LRD. Sampling before 10 weeks is not recommended, except in very unusual circumstances, such as when a patient's religious beliefs may preclude a pregnancy termination beyond a specific gestational age.⁴⁶ These patients, however, must be informed that the incidence of severe LRD could be as high as 1% to 2%.

LABORATORY ANALYSIS OF PRENATAL DIAGNOSTIC SAMPLES

Laboratory Considerations for Amniocentesis

The cells in the amniotic fluid arise from the fetal skin, respiratory tract, urinary tract, gastrointestinal tract, and placenta. After retrieval, the cells are put into tissue culture, some in flasks but more often on coverslips. After 3 to 7 days of growth, sufficient mitoses are present for staining and karyotype analysis. Cells grown in flasks are harvested and analyzed together, whereas those grown on coverslips are analyzed *in situ* as individual colonies. Amniocyte culture is quite reliable, with failure occurring in less than 1% of cases.

Mosaic Results. Chromosomal mosaicism—the presence of two or more cell lines with different karyotypes in a single sample—occurs in approximately 0.1% to 0.3% of amniocentesis cases. This most frequently results from postzygotic non-disjunction,³⁹⁸ but it can also occur from meiotic errors with trisomic rescue (see Laboratory Aspects of Chorionic Villus Sampling, later). The most common etiology is pseudomosaicism,³⁹⁸ where the abnormality is evident in only one of several

flasks or confined to a single colony on a coverslip. In this case, the abnormal cells have arisen *in vitro*, are not present in the fetus, and are not clinically important. Even the observation of multiple cell lines on more than one coverslip or in more than one flask in a sample does not necessarily mean that the fetus is mosaic, because the results are confirmed in only 70% of cases.³⁹⁹ Some mosaic results (e.g., trisomy 20) occur in the amniotic fluid relatively frequently, but these are rarely confirmed in the fetus.⁴⁰⁰

True fetal mosaicism is rare, occurring in 0.25% of amniocenteses, but it can be clinically important, leading to phenotypic or developmental abnormalities.³⁹⁸ In many cases, the question of whether amniotic fluid mosaicism involves the fetus can be resolved by karyotyping fetal lymphocytes obtained by PUBS.⁴⁰¹ However, this approach may not be valid in all cases, because the mosaic cell line may involve fetal tissues but be excluded from the fetal hematopoietic compartment, and therefore not present in a fetal blood sample.⁴⁰⁰ Certain chromosomes, such as 22, are notorious for exclusion from fetal blood and may require testing of additional fetal tissues, such as the skin.⁴⁰²

Evaluation of mosaic results should include detailed ultrasound assessment to assess fetal growth and exclude structural anomalies. If both ultrasound and fetal sampling are normal, the parents can be reassured that, in most cases, the fetus is unaffected.⁴⁰¹ However, a small chance of fetal involvement still exists, because the presence of an undetectable but clinically significant abnormal cell line can never be absolutely excluded. Because of the complexity of interpreting mosaic amniotic fluid results, consultation with a cytogenetics laboratory and a clinical geneticist is recommended.

Use of Fluorescence *In Situ* Hybridization. Fluorescence *in situ* hybridization (FISH) probes are relatively short, fluorescence-labeled DNA sequences that are hybridized to a known location on a specific chromosome, allowing the number and location of specific DNA sequences to be determined. Interphase cells are evaluated by counting the number of discrete fluorescent signals from each probe. A normal diploid cell queried with a probe for the centromere of chromosome 18 would have two signals, whereas a trisomy 18 cell would have three.

Prenatal interphase evaluation of uncultured amniotic fluid can detect aneuploidies caused by monosomies, free trisomies, trisomies associated with robertsonian translocations, triploidy, and other numerical chromosomal abnormalities. In standard practice, probes involving chromosomes 13, 18, 21, X, and Y are used. This technology does not routinely detect cytogenetic abnormalities such as mosaics, translocations, and rare aneuploidies.^{403,404}

Since 1993, the position of the ACMG has been that prenatal FISH is investigational. In 1997, the U.S. Food and Drug Administration cleared the specific FISH probes to enumerate chromosomes 13, 18, 21, X, and Y for prenatal diagnosis. Subsequent studies demonstrate an extremely high concordance rate between FISH and standard cytogenetics (99.8%) for the specific abnormalities that the assay is designed to detect.⁴⁰⁵⁻⁴⁰⁸ These performance characteristics support the use of FISH for prenatal testing when a diagnosis of aneuploidy of chromosome 13, 18, 21, X, or Y is highly suspected by virtue of maternal age, positive maternal serum biochemical screening, or abnormal ultrasound findings.⁴⁰⁹

At present, it is suggested that FISH analysis not be used as a primary screening test on all genetic amniocenteses because of its inability to detect structural rearrangements, mosaicism, marker chromosomes, and uncommon trisomies. Evans and coworkers⁴¹⁰ surveyed the results of almost 73,000 prenatal cases from seven centers and reported that only 67% of abnormalities would have been detected by routine FISH. This interpretation may be misleading, in that some of the missed abnormalities would not have had an impact on fetal development. Because all abnormalities would be detectable by tissue culture, FISH analysis is not cost-effective. Most laboratories use FISH to offer quick reassurance to patients with an unusually high degree of anxiety, or to test fetuses at the highest risk, such as those with ultrasound anomalies. It is also beneficial when rapid results are crucial to subsequent management, such as with advanced gestational age. FISH on metaphase chromosomes using probes for unique sequences has greatly expanded the resolution of conventional chromosome analysis. This has been demonstrated in countless case reports by the diagnosis of structural changes at the submicroscopic level (e.g., microdeletion syndromes), or by the determination of the origin of marker chromosomes and complex structural changes.²³⁹

Laboratory Aspects of Chorionic Villus Sampling

Chorionic villi have three major components: an outer layer of hormonally active and invasive syncytiotrophoblast, a middle layer of cytotrophoblast from which syncytiotrophoblast cells are derived, and an inner mesodermal core containing blood capillaries.

The average sample from a transcervical aspiration contains 15 to 30 mg of villous material. The villi identified in the syringe are carefully and aseptically transferred for inspection and dissection under a microscope. They are cleaned of adherent decidua and then exposed to trypsin to digest and separate the cytotrophoblast from the underlying mesodermal core. The cytotrophoblast has a high mitotic index, with many spontaneous mitoses available for immediate chromosome analysis. Either the liquid suspension containing the cytotrophoblast is dropped immediately onto a slide for analysis, or it may undergo a short incubation.^{411,412} This direct chromosome preparation can give preliminary results within 2 to 3 hours. However, most laboratories now use an overnight incubation to improve karyotype quality and thus report results within 2 to 4 days. The remaining villus core is placed in tissue culture and is typically ready for harvest and chromosome analysis within 1 week.⁴¹³

The direct method has the advantage of providing a rapid result and minimizing the decidual contamination, whereas tissue culture is better for interpreting discrepancies between the cytotrophoblast and the actual fetal state. Ideally, both the direct and culture methods should be used, because each evaluates slightly different tissue sources. Although the direct preparation is less likely to be representative of the fetus, its use minimizes the likelihood of maternal cell contamination, and, if culture fails, a nonmosaic normal direct preparation result can be considered conclusive, although rare cases of false-negative rates for trisomy 21 and 18 have been reported.^{414,415} Abnormalities in either may have clinical implications.

Most biochemical diagnoses that can be made from amniotic fluid or cultured amniocytes can usually be made from chorionic villi.⁴¹⁶ In many cases, the results are available more rapidly and efficiently when villi are used, because sufficient enzyme is present to allow direct analysis, rather than the products of

tissue culture being required. However, for certain rare biochemical diagnoses, villi are not an appropriate or reliable diagnostic source.⁴¹⁷ To ensure that appropriate testing is possible, the laboratory should be consulted before sampling.

Accuracy of Chorionic Villus Sampling

Cytogenetic Results. CVS is now considered a reliable method of prenatal diagnosis, but early in its development, incorrect results were reported.^{412,418,419} The major sources of these errors included maternal cell contamination and misinterpretation of mosaicism confined to the placenta. Today, genetic evaluation of chorionic villi provides a high degree of success and accuracy, particularly in regard to the diagnosis of common trisomies.^{420,421} The U.S. Collaborative Study revealed a 99.7% rate of successful cytogenetic diagnosis, with only 1.1% of the patients requiring a second diagnostic test such as amniocentesis or fetal blood analysis to further interpret the results.⁴²¹ In most cases, the additional testing was required to delineate the clinical significance of mosaic or other ambiguous results (76%), whereas laboratory failure (21%) and maternal cell contamination (3%) also required follow-up testing.

Maternal Cell Contamination. Chorionic villus samples typically contain a mixture of placental villi and maternally derived decidua. Although specimens are thoroughly washed and inspected under a microscope after collection, some maternal cells may remain and grow in the culture. As a result, two cell lines, one fetal and the other maternal, may be identified. In other cases, the maternal cell line may completely overgrow the culture, thereby leading to diagnostic errors, including incorrect sex determination,⁴²²⁻⁴²⁴ and potentially to false-negative diagnoses, although there are no published reports of the latter. Direct preparations of chorionic villi are generally thought to prevent maternal cell contamination,^{411,422} whereas long-term culture has a rate varying from 1.8% to 4%.⁴²³ Because, in contrast to cytotrophoblast, maternal decidua has a low mitotic index, it is highly desirable for laboratories to offer a direct chromosome preparation as well as a long-term culture on all samples of chorionic villus. Even in culture, the contaminating cells are easily identified as maternal and should not lead to clinical errors. Interestingly, for reasons still uncertain, maternal cell contamination occurs more frequently in specimens retrieved by the transcervical route.⁴²³

Contamination of samples with significant amounts of maternal decidual tissue is almost always the result of small sample size, making selection of appropriate tissue difficult. In experienced centers in which adequate quantities of villi are available, this problem has disappeared. Choosing only whole, clearly typical villus material and discarding any atypical fragments, small pieces, or fragments with adherent decidua avoids confusion.⁴²⁵ Therefore, if the initial aspiration is small, a second pass should be performed, rather than risk inaccurate results. When proper care is taken and good cooperation and communication exist between the sampler and the laboratory, absence of even small amounts of contaminating maternal tissue can be accomplished.

Confined Placental Mosaicism. The second major source of potential diagnostic error associated with CVS is mosaicism confined to the placenta. Although the fetus and placenta have a common ancestry, chorionic villus tissue does not always reflect fetal genotype.^{421,426} Although initially there was concern that this might invalidate CVS as a prenatal diagnostic tool, subsequent investigations have led to a clearer understanding

of villus biology, so that accurate clinical interpretation is now possible. This understanding has also revealed new information about the etiology of pregnancy loss, discovered a new cause of intrauterine growth retardation, and clarified the basic mechanism of UPD.

Discrepancies between the cytogenetics of the placenta and the fetus occur because the cells contributing to the chorionic villi become separate and distinct from those forming the embryo in early development. Specifically, at approximately the 32- to 64-cell stage, only three to four cells become compartmentalized into the inner cell mass to form the embryo, whereas the remainder become precursors of the extraembryonic tissues.⁴²⁷ Mosaicism can then occur through two possible mechanisms.⁴²⁷ An initial meiotic error in one of the gametes can lead to a trisomic conceptus that would normally spontaneously abort. However, if during subsequent mitotic divisions, one or more of the early aneuploid cells loses one of the trisomic chromosomes through anaphase lag, the embryo can be "rescued" by reduction of a portion of its cells to disomy. This results in a mosaic morula with the percentage of normal cells dependent on the cell division at which rescue occurred. More abnormal cells are present when correction is delayed to the second or a subsequent cell division. Because most cells in the morula proceed to the trophoblast cell lineage (processed by the direct preparation), it is highly probable that that lineage will continue to contain a significant number of trisomic cells. On the other hand, because only a small proportion of cells are incorporated into the inner cell mass, involvement of the fetus depends on the random distribution of the aneuploid progenitor cells. Involvement of the mesenchymal core of the villus, which also evolves from the inner cell mass, is similarly dependent on this random cell distribution. Noninvolvement of the fetal cell lineage produces *confined placental mosaicism*, in which the trophoblast and perhaps the extraembryonic mesoderm will have aneuploid cells but the fetus will be euploid.

In the second mechanism, mitotic postzygotic errors produce mosaicism with the distribution and percentage of aneuploid cells in the morula or blastocyst dependent on the timing of nondisjunction. If mitotic errors occur early in the development of the morula, they may segregate to the inner cell mass and have the same potential to produce an affected fetus as do meiotic errors. Mitotic errors occurring after primary cell differentiation and compartmentalization have been completed lead to cytogenetic abnormalities in only one lineage.

Meiotic rescue can lead to UPD. This occurs because the original trisomic cell contained two chromosomes from one parent and one from the other. After rescue, there is a theoretical one-in-three chance that the resulting pair of chromosomes came from the same parent, which is called UPD. UPD may have clinical consequences if the chromosomes involved carry imprinted genes in which expression is based on the parent of origin. For example, Prader-Willi syndrome may result from uniparental maternal disomy for chromosome 15. Therefore, a CVS diagnosis of confined placental mosaicism for trisomy 15 may be the initial clue that UPD could be present and lead to an affected child.^{428,429} Therefore, all cases in which trisomy 15 (either complete or mosaic) is confined to the placenta should be evaluated for UPD by amniotic fluid analysis. In addition to chromosome 15, chromosomes 7, 11, 14, and 22 are believed to be imprinted and require similar follow-up.⁴³⁰

Confined placental mosaicism (unassociated with UPD) can alter placental function and lead to fetal growth failure

or perinatal death.^{427,431-436} The exact mechanism by which abnormal cells in the placenta alter function is unknown, but the effect is limited to specific chromosomes. For example, confined placental mosaicism for chromosome 16 leads to severe intrauterine growth restriction, prematurity, or perinatal death, with less than 30% of pregnancies resulting in normal, appropriate-for-gestational-age, full-term infants.^{81,94,432,437,438}

Mosaicism occurs in about 1% of all CVS samples^{81,94,432,437,438} but is confirmed in the fetus in only 10% to 40% of these cases.^{420,423,437,439} In most cases, if the mosaic results are confined to the placenta, fetal development will be normal. If the mosaic cell line involves the fetus, significant phenotypic consequences are possible. The probability of fetal involvement appears to be related to the tissue source in which the aneuploid cells were detected, with culture results more likely than direct preparation to reflect a true fetal mosaicism.

The specific chromosome involved also predicts the likelihood of fetal involvement.⁴³⁰ Phillips and coworkers⁸¹ demonstrated that autosomal mosaicism involving common trisomies (i.e., 21, 18, and 13) was confirmed in the fetus in 19% of cases, whereas uncommon trisomies involved the fetus in only 3%. When sex chromosome mosaicism was found in the placenta, the abnormal cell line was confirmed in the fetus in 16% of cases.

When placental mosaicism is discovered, amniocentesis can be performed to elucidate the extent of fetal involvement. When mosaicism is limited to the direct preparation, amniocentesis correlates perfectly with fetal genotype.⁸¹ When a mosaicism is observed in tissue culture, amniocentesis predicts the true fetal karyotype in approximately 94% of cases, with both false-positive and false-negative results seen.⁸¹ Three cases were reported of mosaic trisomy 21 on villus culture, and despite a normal amniotic fluid analysis, a fetus or newborn was seen with mosaic aneuploidy.⁴²¹

If mosaicism is found, follow-up amniocentesis should be offered in most cases. Under no circumstances should a decision to terminate a pregnancy be based entirely on a CVS mosaic result. For CVS mosaicism involving sex chromosome abnormalities, polyploidy, marker chromosomes, structural rearrangements, and most uncommon trisomies, the patient can be reassured if amniocentesis results are euploid and detailed ultrasonographic examination is normal. However, no guarantees should be made. As described previously, in certain cases, testing for UPD is indicated. If common trisomies (21, 18, 13) are involved, amniocentesis should be offered, but the patient must be advised of the possibilities of a false-negative result. Follow-up may include detailed ultrasonography, fetal blood sampling, or fetal skin biopsy. At present, the predictive accuracy of these additional tests is uncertain.

Chromosomal Microarray for Prenatal Testing

The resolution of standard G-banded karyotypes in clinical practice is approximately 5 to 10 million base pairs (Mb)—that is, deletions or duplications of the genome smaller than this will not routinely be identified. With the development of molecular cytogenetic techniques, genomic alterations too small to be identified by karyotyping, but with significant impact on the fetal phenotype, have been discovered. Some of these microdeletions or duplications are associated with well-described syndromes, and others may have significant clinical implications (such as neurocognitive disability) but are nonsyndromal. To date, those associated with a discrete syndrome have been

diagnosed using FISH probes chosen on the basis of specific ultrasound findings, such as probes for 22q11.2 deletions when a conotruncal cardiac defect is identified. This approach does not identify nonsyndromal findings and is limited by the ability to select an appropriate probe.

Chromosomal microarray analysis (CMA), developed and integrated into clinical care over the past 5 years, has the ability to survey the entire genome and identify deletions and duplications 100 times smaller than those identified by karyotype, without the need to preselect the target. Microarray techniques are based on comparative genomic hybridization, which directly compares an unknown DNA sample to a normal control sample to identify those areas of the test genome that are either under- or over-represented (Fig. 30-12). Specifically, DNA from a test sample and a normal reference sample are labeled with different fluorophores, mixed together, and hybridized to a glass or silicon slide printed with several thousand probes containing short sequences (30 to 60 bp) from both known genes and select noncoding regions of the genome. The fluorescence intensity is measured for each probe to determine the relative ratio of test to control DNA. For any one probe, there should be equal amounts of DNA from both the patient sample and the reference sample. A deviation from the expected ratio is termed a *copy number variant*, and it represents either a duplication or a

deletion for a particular location in the genome. Only deletions or duplications causing an imbalance can be detected; point mutations, balanced translocations, and inversions cannot be.

Current Indications for Microarray Analysis in Prenatal Diagnosis

Evaluation of Ultrasound Structural Anomalies. Recent studies^{440,441} demonstrate that approximately 5% to 6% of structurally abnormal pregnancies identified by ultrasound and having a normal karyotype will have a clinically relevant copy number variant as identified by CMA, which will improve the ability to counsel patients. Unlike the common autosomal trisomies, whose ultrasound indications for invasive testing are well known, the anomalies likely to result from microdeletions or duplications are less well described. To date, the most common anomalies investigated have been cardiac, central nervous system, skeletal, urogenital, and renal. Increased NT measurements and intrauterine growth restriction have also been evaluated.⁴⁴²⁻⁴⁴⁴ These evaluations confirm the incremental value of microarray analysis compared with conventional cytogenetics or FISH.⁴⁴⁵

Interpretation of Uncertain Karyotype Findings. Because CMA identifies relatively small genomic imbalances and provides increased precision for determining the boundaries of deletions and duplications, it has clinical value in the interpretation of the following karyotype findings.

Marker Chromosomes. Counseling after the prenatal discovery of a supernumerary marker chromosome is based on the structure of the marker (satellited or nonsatellited), the chromosomal origin, and whether it is sufficiently large to suggest regions of euchromatin containing expressed genes. Empirically, nonsatellited markers have approximately a 5% risk for an abnormal phenotype, and a satellite marker has a risk of approximately 11%. The characteristics, origin, and content of marker chromosomes are not always fully determined by conventional cytogenetics or FISH.⁴⁴⁶ If sufficient unique sequence DNA (euchromatin) is present, CMA can precisely identify the chromosomal origin and marker content. Although evaluation of markers by CMA has theoretical value and should be more efficacious than FISH, additional experience is required to quantify its clinical usefulness for patient counseling.

Apparently Balanced de Novo Reciprocal Translocation. Standard counseling when a de novo, apparently balanced reciprocal translocation is identified by karyotype is that there may be up to a 6% risk for an abnormal phenotype.¹⁸¹ This residual risk exists because the breakpoints may be intragenic, disrupting gene function, or alternatively there may be submicroscopic gains or losses at the breakpoints. Recent reports¹⁸² have suggested that in up to 40% of individuals with apparently balanced rearrangements and phenotypic abnormalities, an imbalance involving one of the breakpoints will be identified by microarray analysis. At present, it is uncertain whether array evaluation of these rearrangements will be clinically valuable. De Gregori and colleagues⁴⁴⁷ reported 14 balanced rearrangements (two with ultrasound abnormalities) identified from prenatal samples in which no imbalances had been detected by CMA. Further study is required to quantify the risk reduction after a normal array.

Evaluation of a Stillborn Fetus. About 5% of structurally normal stillborn fetuses will have an abnormal karyotype, as will 35% to 40% of stillbirths that are structurally abnormal or macerated.⁴⁴⁸⁻⁴⁵⁰ Karyotyping after a fetal demise may be

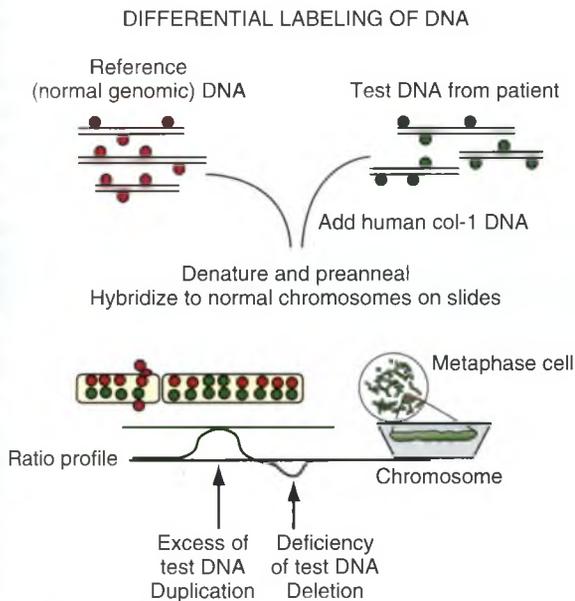

Figure 30-12 The potential use of comparative genomic hybridization to diagnose structural genomic changes in stillbirth. Illustration of the general principle underlying comparative genomic hybridization, used to identify DNA deletions or duplications. In this technique, fluorescence-labeled DNA from a normal control sample is mixed with a test sample that is labeled with a different-colored dye. The mixture then is hybridized to normal metaphase chromosomes. Regional differences in the fluorescence ratio represent gains and losses in the sample DNA compared with the control DNA. Arrays containing hundreds of thousands of small, well-defined DNA probes have replaced normal metaphase chromosomes, allowing more precise and detailed analysis of small, under- or over-represented areas. (From Reddy UM, Goldenberg R, Silver R, et al: Stillbirth classification—developing an international consensus for research: executive summary of a National Institute of Child Health and Human Development workshop, *Obstet Gynecol* 114:901–914, 2009.)

unsuccessful in up to 50% of cases because of the lack of viable tissue capable of growing in tissue culture, with failure most common in cases with anomalies or maceration. DNA-based tests can be especially helpful in this situation. A recent series performed by the Stillbirth Collaborative Research Network evaluated 532 stillborn infants and demonstrated that, compared with karyotyping, CMA provided results in an additional 21.3% of cases. CMA also increased the detection of pathologic microdeletions or duplications by 45.2%.⁴⁵¹

As First-Tier Test for Advanced Maternal Age and Positive Down Syndrome Screening. Because of the superior ability of CMA to identify small, clinically relevant chromosome abnormalities, some have suggested that it be considered for all pregnancies undergoing an invasive procedure. A recently completed NIH-sponsored study⁴⁴¹ and a large series from Italy⁴⁵² give some guidance as to the efficacy of CMA as a routine first-tier test. These series suggest that array is equally efficacious in the identification of the common autosomal and sex chromosomal anomalies; in karyotypically normal pregnancies sampled for advanced maternal age or positive aneuploid screening, CMA demonstrates clinically significant microdeletions and duplications in over 1.5% of cases.⁴⁴¹

At present, ACOG suggests that the usefulness of microarray as the first-line test for prenatal evaluation of chromosome abnormalities remains unknown, and conventional karyotyping remains the primary cytogenetic tool.⁴⁵³ However, targeted arrays in combination with genetic counseling can be offered in the setting of an abnormal ultrasound finding and a normal karyotype result. ACOG stresses that couples who choose to undergo microarray analysis should receive both pretest and post-test genetic counseling. ACOG acknowledges that further studies are necessary to fully determine the clinical use of microarrays in prenatal diagnostics.⁴⁵⁴

Interpretation of Copy Number Variation. All practitioners offering prenatal CMA should be aware of the reporting criteria of the laboratory analyzing the sample. Guidelines recently provided by the ACMG for postnatal CMA interpretation are available and have been adapted for prenatal use.⁴⁵⁵ These guidelines recommend that the interpreting laboratory geneticist assign a copy number variation (CNV) to one of four main categories of significance to facilitate unambiguous communication of clinical significance:

Normal: No copy number changes of clinical significance were identified. Normal results may or may not include mention of copy number changes that were identified and believed to be benign.

Benign: A CNV should be considered benign if it has been reported in multiple peer-reviewed publications or curated databases as a benign variant, particularly if the nature of the CNV has been well characterized, or if the CNV represents a common polymorphism documented in greater than 1% of the population.

Pathogenic: The CNV is documented as clinically significant in multiple peer-reviewed publications, even if penetrance and expressivity of the CNV are known to be variable. Although the full clinical effect of the patient's CNV is not known, the pathogenic nature of the CNV is not in question. The laboratory should provide an explanation of why the alteration is considered pathogenic, including a list of genes known to be dosage-sensitive that occur in the altered region.

Uncertain clinical significance: This designation represents a fairly broad category, including CNV findings that are later demonstrated to be either clearly pathogenic or clearly benign. However, if, at the time of reporting, insufficient evidence is available for unequivocal determination of clinical significance and the CNV meets the reporting criteria established by the laboratory, the CNV should be reported as a CNV of *uncertain clinical significance*. This uncertainty should be clear in the report. Laboratories are encouraged to include available evidence for the likelihood that the CNV is pathogenic or benign. Clinicians are encouraged to discuss uncertain variants with the reporting laboratory, and to share clinical information that might affect the interpretation.

These categories do not cover all scenarios, as each CNV has unique considerations requiring clinical judgment and corroboration with phenotypic findings.

Limitations of CMA. Balanced rearrangements, such as inversions and reciprocal or insertional translocations, are not detected by CMA. Overall, these occur in approximately 0.6% of individuals.⁴⁵⁶ One in 2000 prenatal cases has an apparently balanced translocation (0.05%).¹⁸¹ In most cases, this does not lead to an altered fetal phenotype, but the information will not be available for reproductive counseling.

CMA fails to detect pathogenic copy number changes in areas not represented on the specific array platform. Targeted arrays, whole-genome arrays, or a combination of the two are used. Targeted arrays contain probes designed to detect known microdeletion or microduplication syndromes and may not have coverage outside these regions. This approach can minimize the chance of a variant of uncertain significance, but it also may fail to detect a rare or novel genomic imbalance. Whole-genome arrays include dense, equally spaced probe coverage throughout the genome and are more prone to variants of uncertain significance. At present, targeted arrays with backbone coverage are most frequently used for prenatal testing and provide closely spaced probes in areas of certain clinical significance along with additional probes spaced throughout the genome to detect novel, clinically relevant CNVs.

CMA using an array based on comparative genomic hybridization does not routinely detect polyploidy, because there are no relative imbalances, but in many cases of trisomic loci, maternal cell contamination studies suggest this diagnosis. More recently developed arrays using probes with SNP arrays do routinely diagnose triploidy,⁴⁵⁶ but at present they are not routinely used. Because triploidy is an important cause of fetal loss and ultrasound-identified anomalies, all laboratories performing prenatal testing should have a reliable mechanism in place to make this diagnosis.

PRENATAL DIAGNOSIS AND MULTIFETAL GESTATIONS

Risk for Fetal Aneuploidy in Multifetal Gestations

The overall probability that a given twin gestation contains an aneuploid fetus depends on its zygosity. Because monozygotic twins originate from the same gamete, both fetuses possess the same karyotype, and the overall risk for aneuploidy is that of a singleton. Although this construct ignores the very small possibility of mitotic nondisjunction, this possibility is such a rare occurrence that it should not change the overall risk calculation.

In dizygotic twins, on the other hand, one or both fetuses may be affected, with the chances for aneuploidy in either fetus being independent.

The risk of both dizygotic twin fetuses being affected is low (the singleton risk squared), whereas the risk of at least one affected fetus is approximately twice the singleton risk.⁴⁵⁷ These risks can be used to counsel patients if the zygosity is known.

If zygosity is unknown, the ratio of the risk of at least one fetus (in a twin pregnancy) being aneuploid, to the risk of a singleton gestation being aneuploid, can be approximated as 5:3. This approximation is based on the assumption that one third of all twin gestations are monozygotic twins. Despite the slight inaccuracy of this approach caused by the varying rates of monozygotic twins and dizygotic twins (e.g., varying with maternal age and ethnicity), this approximation is quite satisfactory for patient counseling. A more accurate determination that takes these variations into account has been published by Meyers and colleagues.⁴⁵⁸ Based on their calculations, a 32-year-old woman with twins has nearly the same risk of having at least one aneuploid fetus as a 35-year-old woman with a singleton. Present recommendations are that invasive prenatal diagnosis be offered at this cutoff. Table 30-28 demonstrates the risk for fetal aneuploidy at different maternal ages in twin gestations using these calculations.

Higher-order multifetal gestations resulting from assisted reproductive technology (ART) have a greater predilection for polyzygosity than naturally occurring multiples. The risk for at least one aneuploid fetus can be approximated as the singleton risk multiplied by the number of fetuses. Although recent studies have shown that monozygotic twin pregnancies occur more frequently than anticipated after the use of ART,^{459,460} their frequency still remains low enough that this estimate is appropriate.

An even steeper increase in the risk of gene transmission for pregnancies at risk for mendelian disorders occurs with multifetal gestations. For example, for a twin gestation at risk for an autosomal recessive disorder, there is a three-in-eight chance of at least one fetus being affected, and a one-in-eight chance that both will inherit the affected genes.

Screening Tests in Twins

Second Trimester. For singleton pregnancies, second-trimester biochemical screening is a routine practice. For twins, however, the value and accuracy of serum screening is much less certain because the contribution of an abnormal fetus will, on average, be brought closer to the normal mean by an unaffected co-twin. This tends to decrease the overall screening sensitivity. Screening, however, can be useful nonetheless.

The mean and median values of MSAFP, unconjugated estriol, and hCG in twins have been studied and are presented in Table 30-29. Dividing the measured result by the twin median can be used to estimate a twin MoM for each analyte. These MoM values can then be used in singleton algorithms to estimate a risk for aneuploidy. Neveux and coworkers⁴⁶¹ evaluated this approach and, on the basis of a calculated model, predicted that 73% of monozygotic twin and 43% of dizygotic twin cases with a Down syndrome fetus would be detected, with a 5% false-positive rate. In their clinical sample of 274 twin pregnancies, 5.5% screened positive. They had no cases of Down syndrome, making evaluation of the sensitivity difficult. At present, the use of biochemical markers for aneuploidy screening in higher-order multifetal gestations is extremely limited and is not recommended for general practice.

For the detection of neural tube defects, the levels of maternal AFP are again affected by the presence of a co-fetus. The mean MSAFP level in twin pregnancies ranges from 2.0 to 2.5 MoM. This is not surprising, considering double production. In singleton gestations, an MSAFP upper cutoff of 2.5 MoM will identify 75% of fetuses with a neural tube defect, with a false-positive rate between 2% and 3.3%. A similar cutoff in twin gestations would identify 99% of anencephalic fetuses and 89% of open neural tube defects,⁴⁶² but this would be associated with an unacceptably high false-positive rate of 30%. A twin false-positive rate similar to that for singletons can be calculated by doubling the singleton cutoff level; for example, choosing an MSAFP cutoff value of 5.0 MoM for twins would have the same false-positive rate as a 2.5 MoM cutoff in singletons. The detection rate will be lower, however, because, when only one fetus has a neural tube defect, the normal coexisting fetus will contribute an AFP level near the singleton median. Maintaining the 75% sensitivity accomplished with singleton

TABLE 30-28 Calculated Risk, at Term, of Down Syndrome in at Least One Fetus in Twin Gestations

Maternal Age (yr)	Singleton Risk	Equivalent Twin Risk	Equivalent Maternal Age Risk
25	1/1250	1/679	32.5
30	1/952	1/508	33.8
32	1/769	1/409	34.7

screening would require an MSAFP elevation of approximately 3.5 MoM, which would have a false-positive rate of 15%.

At present, there is no standard agreement on the MSAFP elevation that warrants further evaluation in twins. Some centers use a cutoff of 4.0 MoM, which would identify approximately 60% of fetuses with open spina bifida, but this has approximately an 8% incidence of false-positive results. Other centers use a cutoff of 4.5 MoM, which has a sensitivity of approximately 50%.

First Trimester. First-trimester combined screening (NT, PAPP-A, hCG) for Down syndrome can be performed in twin gestations and may be preferable to second-trimester screening, as a fetus-specific risk rather than a pregnancy-specific risk can be obtained.^{49,463} The analyte levels are adjusted for twins as is done for second-trimester screening (see Table 30-29). In dichorionic gestations, the NT of individual fetuses is measured, and then a fetus-specific risk is obtained using maternal age and analyte levels. In monochorionic gestations in which the fetal karyotypes are identical, the NT measurements are averaged and a single likelihood ratio is calculated. This is combined with maternal age and serum analyte levels, resulting in a pregnancy-specific risk.

Overall, first-trimester combined Down syndrome screening in twins has a 72% detection rate, with a 5% false-positive rate.⁴⁶³ Using NT alone is less efficient, with a 69% detection rate. The performance of this approach is better for monochorionic gestations, as both fetuses will be affected and the analyte values from each will trend in the same direction. In dichorionic pregnancies, which are more likely to be dizygotic and have discordant karyotypes, the abnormal biochemical analytes from an affected gestation may be diluted by those from the normal fetus. Theoretical modeling suggests that combined screening has an 84% detection rate with a 5% false-positive rate in monochorionic gestations, compared with 70% in dichorionic twins. Performance in these subgroups is better when biochemical analytes are added to NT measurements.

Amniocentesis in Multifetal Gestations

Amniocentesis in multifetal pregnancies involves puncture of the first sac, withdrawal of amniotic fluid, injection of dye to mark the sampled sac, and then a new needle insertion to puncture the second sac.⁴⁶⁴ If the fluid aspirated after the second puncture is clear, this is confirmation that the first sac was not resampled. If color-tinged fluid is retrieved, the needle should be removed and another attempt at sampling the second sac should be made.

History has shown the possible toxic effects of dye instillation. Methylene blue is associated with small bowel atresia^{465,466} and an increased risk for fetal death.⁴⁶⁷ Its use is now contraindicated. Use of indigo carmine (the dye of choice) has been reviewed in large series by both Cragan and coworkers⁴⁶⁸ and Pruggmayer and coworkers,⁴⁶⁹ and no increased risk for small bowel atresia or any other congenital anomaly has been found. However, because of the theoretical risk of intra-amniotic dye, instillation-free techniques have evolved.^{321,470}

A single-puncture method has been described in which the site of needle insertion is determined by the position of the dividing membrane.³²¹ After entry into the first sac and aspiration of amniotic fluid, the same needle is advanced through the dividing membrane into the second sac. To avoid contamination of the second sample with fluid from the first, the first 1 mL

of fluid from the second sample is discarded. This method may cause iatrogenic rupture of the dividing membrane, with creation of a monoamniotic sac and its attendant risk for cord entanglement.⁴⁷¹ This appears to occur almost exclusively in monochorionic gestations.

Bahado-Singh and colleagues⁴⁷² described a technique of twin amniocentesis that entails identifying the separating membranes with a curvilinear or linear transducer. The first needle is inserted, fluid retrieved, and the needle left in place while a second needle is inserted into the coexisting sac. Visualization of the two needle tips on alternate sides of the membrane confirms sampling of both fetuses. Patient tolerance of this technique may be a problem, as well as the potential requirement of two operators when sampling.

Complications of Amniocentesis in Multifetal Gestations. A comparison of the relative safety of any invasive procedure in multifetal gestations must take into consideration that, at any gestational age, loss rates for multiples are significantly higher than for singletons. Evaluation of the safety of invasive procedures, therefore, needs to be kept in context. Pregnancy loss rates before 28 weeks of 4.5%,⁴⁷³ 5.8%,⁴⁷⁴ and 7.2% in unsampled twins with a normal second-trimester ultrasound have been reported.⁴⁷⁵ Most series reporting postprocedure loss rates of twins have been between 2% and 5% (Table 30-30). However, the ideal way to evaluate procedure-induced loss rates is to compare similar cohorts of sampled and unsampled twins. Ghidini and colleagues⁴⁷⁶ evaluated the risk of amniocentesis in twins by comparing 101 sampled pregnancies with an unsampled control group scanned at a matching gestational age. No significant difference in total loss rate was detected. A report attributed a 2% higher loss rate with amniocentesis (2.7% versus 0.6%) as compared with singletons or nonsampled twin gestations, with 13 losses in 476 pregnancies (95% CI, 1.5 to 4.6).⁴⁷⁷ The makeup of the sampled group (47% with maternal age of at least 35 years, 21% with abnormal MSAFP, and 11% with abnormal ultrasound) could have affected loss rates. No study in the current literature has the power to definitively quantify the procedure-induced loss rate in twins. Empirically, the procedure-related loss rate is 1% to 1.5%.

Patients with twins must also be counseled about the risk of finding a karyotypically abnormal child, which, because of the presence of two fetuses, is approximately twice that after a singleton procedure.⁴⁵⁷ Amniocentesis in twins does raise some very painful questions. Families need to consider the possibility of a test showing that one of the twins is normal and the other has an abnormality. Selective termination of the affected fetus is now a routine procedure and can be accomplished in 100% of cases, with a postprocedure loss rate of 5% to 10% in experienced centers.⁴¹⁰ However, this approach is also associated with an increased risk for preterm birth, especially when performed after 20 weeks' gestation or if the presenting fetus is terminated.⁴⁷⁸

Chorionic Villus Sampling in Multifetal Gestations

Twin and higher-order multifetal gestations have been sampled successfully using CVS.⁴⁷⁹⁻⁴⁸² Each distinct placental site must be identified and sampled individually. Because no dye marker is available to ensure retrieval from a gestation, a backup amniocentesis should be offered if there is any suspicion that two separate samples have not been obtained and if the fetal sexes are concordant.⁴⁷⁹ However, this is rarely required if meticulous

intraoperative ultrasound placement of the needle or catheter is performed. Another difficulty is the possible cross-contamination of samples when both placentas are on the same uterine wall (i.e., both anterior or both posterior). In these cases, sampling the lower sac transcervically and the upper transabdominally minimizes the chance of contamination. When a biochemical diagnosis is required, the potential for misinterpretation is even greater because a small amount of normal tissue could significantly alter the test result. These cases should be sampled only in experienced centers.

Complications of Chorionic Villus Sampling in Multifetal Gestations. Studies assessing procedure-related loss rates after CVS sampling of twins are shown in Table 30-31. In experienced centers, no increased risk of procedure-related loss is seen compared with second-trimester amniocentesis.

Which Procedure to Perform?

Whether to perform a first- or second-trimester procedure depends on a number of factors, including local availability of the procedures described. If both CVS and amniocentesis are available, the relative risks and the advantages of an earlier diagnosis need to be considered. Second-trimester amniocentesis is more readily available and technically easier to perform, but CVS provides the information more than 1 month sooner, thus giving earlier reassurance. When discordant results are encountered, if selective termination is chosen, its complications and loss rates are markedly decreased if it is performed at less than 16 weeks' gestation.⁴¹⁰

Only one study to date has analyzed outcomes for twins after CVS compared with after second-trimester amniocentesis.⁴⁸¹ In this work, 81 women had amniocentesis and 161 had CVS. Loss of the entire pregnancy before the 28th week followed

amniocentesis in 2.9% of the cases and CVS in 3.2%. The fetal loss rate, which included loss of one fetus, was 9.3% for amniocentesis and 4.9% for CVS.

PERCUTANEOUS UMBILICAL BLOOD SAMPLING

In 1983, Daffos and coworkers⁴⁸³ described a method of obtaining fetal blood using ultrasound guidance of a 20- to 22-gauge spinal needle through the maternal abdomen into the umbilical cord. This technique (variously called PUBS, fetal blood sampling, cordocentesis, or funipuncture) offered considerable advantage in both efficacy and safety over the fetoscopic methods previously used to obtain fetal blood.

Until recently, a common reason for PUBS was the need for a rapid karyotype. With the advent of rapid and safer cytogenetic diagnosis by either FISH of amniocytes or the rapid analysis of chorionic villi obtained by placental biopsy, the diagnostic indications for PUBS have changed. Currently, the primary genetic indication is evaluation of mosaic results found on amniocentesis or CVS. Most mendelian disorders that previously required fetal blood for diagnosis are now made using molecular DNA analysis of amniocytes or chorionic villi. PUBS is necessary only for the rare cases in which the specific mutation is not known. The most frequent nongenetic indications are assessment for fetal anemia, infection, and thrombocytopenia. These indications are described in detail in Chapters 35, 36, 37, and 51.

The main complication of PUBS is fetal loss, which is estimated to be approximately 2% higher than background risk.^{389,484} This exact risk is difficult to quantify because many of the fetuses studied had severe congenital malformations.

Best estimates for procedure-related risk are from the North American PUBS registry, which collected data from 16 centers in the United States and Canada. Information on 7462 diagnostic procedures performed on 6023 patients is available.⁴⁸⁵ Fetal loss is defined as intrauterine fetal death within 14 days of the procedure. The fetal loss rate in these cases is calculated to be 1.1% per procedure and 1.3% per patient.

The major causes of fetal loss were chorioamnionitis, rupture of membranes, puncture site bleeding, severe bradycardia, and thrombosis. The range of losses for participating centers varied from 1% to 6.7%, which reflects operator experience and differences in patient selection. These figures are subjective, relying on the operator's impression that a pregnancy loss was directly related to the procedure and not to the underlying fetal condition.

Technique of Percutaneous Umbilical Blood Sampling

Fetal vessels can be accessed in either the cord or the fetus itself. The cord is most reliably entered at the placental insertion site where it is anchored. Color Doppler imaging enhances visualization of the insertion site and is especially useful when oligohydramnios is present. Entering the cord near the umbilical insertion site or into a free loop is possible but can be more difficult. The hepatic vein is the most accessible and safe intrafetal location.⁴⁸⁶

It is essential to verify that the blood sample is fetal in origin. The most definitive way to establish this is to compare the MCV of the retrieved red cells with a sample of maternal blood. This comparison is easily performed on small aliquots of blood by a standard channeling instrument. Fetal red blood cells are considerably larger than those of an adult, but the value is gestational-age dependent. The mean MCV decreases from 145 fL at 16 weeks to 113 fL at 36 weeks of gestation.⁴⁸⁷ Alternatively, the appropriate location of the needle can be confirmed visually by injecting a small amount of sterile saline. If the needle is in the umbilical vein, microbubbles can be seen moving toward the fetus.

Forestier and colleagues⁴⁸⁸ recommended performing biochemical studies on the aspirated blood, including a complete blood count with differential analysis and determination of anti-I and anti-i cold agglutinin, β -hCG, factors IX and VIIIc, and AFP levels. It is not general practice to perform all of these studies.

OTHER INVASIVE DIAGNOSTIC PROCEDURES

On infrequent occasions, analysis of other fetal tissues may be required. Fetal skin biopsy is performed to diagnose fetal genetic skin disorders when molecular testing is not available, and it can also be helpful in the workup of fetal mosaicism for chromosomes (such as 22) known not to be manifested in fetal blood.⁴⁰² Fetal muscle biopsy for dystrophin analysis is used to diagnose muscular dystrophy in a male fetus if DNA testing is not informative.⁴⁸⁹ Fetal kidney biopsy has diagnosed congenital nephrosis in utero,²⁰³ and aspiration and analysis of fetal urine is imperative in the pre-shunt evaluation of fetal renal function.⁴⁹⁰ Each of these procedures is performed under ultrasound guidance. Because they are only rarely required, their use is usually confined to only a few regional referral centers in hopes of limiting procedural risk.

Preimplantation Genetic Screening

Over the past 2 decades, methods of in vitro fertilization and embryo culture and transfer have become routine clinical practice. Simultaneously, the introduction of increasingly sophisticated genetic diagnostic procedures now allows prenatal diagnoses to be performed by testing one or two cells of a developing preimplantation embryo. This technique was developed initially to benefit patients at high risk for a fetal genetic disorder and for whom termination of an affected fetus was not an option. Most of these diagnoses were for relatively rare mendelian disorders. However, as the technology has progressed and the ability to perform cytogenetic analysis on single cells has improved, preimplantation genetic screening (PGS) has been used to improve outcomes for in vitro fertilization (IVF), patients with repetitive miscarriages, and women of advanced

maternal age. As characterized by the European Society of Human Reproduction and Embryology (ESHRE), PGS is now divided into two general categories. High-risk PGS refers to analysis carried out for patients at risk of transmitting a genetic or chromosomal abnormality to their offspring. This includes single-gene defects as well as translocations and structural aberrations. Low-risk PGS (also referred to as PGS aneuploidy screening) is reserved for infertility patients undergoing IVF, with the goal of increasing pregnancy rates by screening for aneuploidy.⁴⁹¹

The techniques available to retrieve preimplantation cells include polar body biopsy of prefertilized oocytes, biopsy of one or two cells (called blastomeres) from the six- to eight-cell early-cleavage-stage embryo on day 3, or removal of five to 12 cells from the trophectoderm of the 5- to 7-day blastocyst.⁴⁹² In all cases, removal of the cells is well tolerated, with continued development of the embryo and no increased risk for congenital anomalies.⁴⁹³

PREIMPLANTATION GENETIC SCREENING FOR KARYOTYPE ANALYSIS

In 2003, more than 100,000 IVF cycles with PGS were reported in the United States, resulting in the birth of 48,000 babies.⁴⁹⁴ Centers continue to report their experience to an international clearing house (under the aegis of ESHRE), and detailed analyses of the accumulated experience of the participating clinics are documented in the annual reports of the ESHRE PGD consortium, which appear in the journal *Human Reproduction*. The most common indication was chromosomal evaluation for aneuploidy, including evaluation for both structural rearrangements and numerical abnormalities.

As techniques have improved, cytogenetic results can be obtained in almost 90% of cases.^{495,496} However, clinical interpretive errors have occurred, probably because early-stage embryos are frequently mosaic, with mosaicism rates of 42% to 50%.^{495,497} Abnormal-appearing zygotes have the highest rates of mosaicism,^{495,498} but those appearing normal still carry a risk of approximately 20%.⁴⁹⁵ Rates of mosaicism in the inner cell mass are similar to those in trophoblast precursors,⁴⁹⁹ showing that there is not a selection bias against aneuploid cells from integrating into the fetal precursor cells. Accordingly, the rate of misdiagnosis with one biopsied blastomere is at least 5.4%. Because of this potential for error, invasive prenatal diagnosis by CVS or amniocentesis is recommended for appropriate indications even when PGS has been performed. In contrast to blastomere biopsy, no misdiagnosis of aneuploidy has been reported with polar body biopsy to date.

INDICATIONS FOR PREIMPLANTATION GENETIC SCREENING

Carriers of Balanced Rearrangements

A parent who is the carrier of a balanced rearrangement typically has a high risk of producing unbalanced embryos, leading to recurrent miscarriages or a child with an unbalanced rearrangement. Preimplantation genetic diagnosis (PGD) permits the transfer of only those embryos with a normal or balanced chromosomal constitution, and it has been demonstrated to significantly improve outcomes.^{500,501} An impressive report comes from Otani and colleagues (2006),⁵⁰² who assessed PGD

in 33 couples having repetitive miscarriages, no liveborn children, and one of the couple being a translocation heterozygote. After PGD (an average of 1.24 cycles per patient), only 18% of the total embryos were either balanced or normal: 20/88 embryos from robertsonian translocation carriers and 86/491 from reciprocal translocation carriers. Of the 19 subsequent pregnancies, just one (5%) miscarried; the other 18 pregnancies proceeded into the second trimester or culminated in a live birth.

Aneuploid Screening

Aneuploid screening by FISH and preselection of normal embryos, particularly in women of advanced maternal age, has been suggested to improve IVF implantation and pregnancy rates even if no genetic indication for testing is present. However, early enthusiasm for this approach has been tempered.^{503,504} One large and stringent trial (multicenter, randomized, double-blind, controlled), conducted between 2003 and 2007 and comparing PGS with standard IVF in 408 women (age range, 35 to 41 years), showed a clear *lessening* in success (a 25% versus 37% pregnancy rate) in those receiving PGS.⁵⁰³ This paradoxical failure of aneuploidy screening to improve outcomes may have occurred because many potentially successful and ultimately normal embryos were suspected to be aneuploid by PGD FISH and rejected (perhaps indicating that biopsy of a single blastomere is not representative of the karyotype of the conceptus).^{505,506} During the two-, four-, and eight-cell stages of early embryo development, mosaicism in abnormal cells may be common, but only the small minority of normal cells will endure and give rise to the embryo.

Treff and coworkers provided data supporting a technical rather than a biologic reason for the high levels of mosaicism observed after FISH-based aneuploidy screening.⁵⁰⁷ In a prospective, randomized and paired comparison between FISH and SNP microarray-based aneuploidy screening, preimplantation embryos showed dramatically higher levels of mosaicism when analyzed by FISH than when the same embryos were analyzed using an SNP microarray.⁵⁰⁷ The authors concluded that SNP microarray-based PGD aneuploidy screening provides more complete and consistent results. In a separate study, day 3 FISH aneuploid screening was demonstrated to be poorly predictive of aneuploidy in morphologically normal blastocysts.⁵⁰⁸ Indeed, recent studies using microarray technology indicate that FISH-based PGS is inadequate for the diagnosis of aneuploidy in human embryos.^{507,508} Given the disappointing results in practice from FISH-based PGD aneuploid screening, an expert panel under the aegis of ESHRE⁵⁰⁹ concluded that the most effective way to resolve the debate about the usefulness of PGD aneuploid screening is to perform well-designed and well-executed randomized clinical trials.

The use of microarrays in the context of IVF is now slowly filtering into the PGD aneuploid screening arena and is most likely to become the more widely applied approach. Treff and colleagues⁵¹⁰ demonstrated the first validated comprehensive SNP microarray-based aneuploidy screening method. They reported an accuracy of 98.6%. This technique may lead to improved outcomes, but further evaluation is required.

PREIMPLANTATION GENETIC SCREENING FOR MONOGENETIC DISORDERS

PGS for monogenetic disorders requires the ability to evaluate the DNA of a single cell. To accomplish this, the DNA content

of a single blastomere is amplified by PCR and then analyzed. The most common monogenetic disorders evaluated by PGS are CF, thalassemia, and spinal muscular atrophy among the autosomal recessive disorders; myotonic dystrophy, Huntington disease, and Charcot-Marie-Tooth disease among the dominant disorders; and fragile X, Duchenne or Becker muscular dystrophy, and hemophilia among the X-linked disorders. PGS is especially valuable for adult-onset autosomal disorders such as Huntington disease, when the parents want to avoid the birth of an affected child but do not wish to have their own diagnosis confirmed. Using PGS, only unaffected zygotes can be implanted without informing the parents of whether the gene was present. However, to maintain parental nondisclosure, this approach must be performed on all subsequent pregnancies, even if no evidence of the gene is seen in prior cycles.

Although the molecular diagnosis is considered to be quite accurate, errors have occurred. For example, an error may occur as a result of the failure of a primer to anneal to a relevant sequence, a phenomenon called allele dropout. This may lead to an incorrect diagnosis, especially when there is a compound heterozygote. Real-time PCR has become the optimal choice for high-risk PGS because of the limited quantity of DNA in a sample, and because of the need to provide a genotype result within a specified and limited amount of time. The sensitivity of real-time PCR maximizes the detection of amplified DNA copies even when present in low amounts, which in turn reduces rates of amplification failure and allele dropout.⁵¹¹ Recent improvements in this technology have made errors exceedingly uncommon, with some centers now reporting 100% accuracy. Despite this, invasive prenatal diagnosis should still be performed to confirm the PGS result.

PERINATAL RISKS OF IN VITRO FERTILIZATION AND PREIMPLANTATION GENETIC SCREENING

ARTs, including IVF, are a significant contributor to preterm delivery, predominantly through an increased rate of multiple gestations. Over 30% of ART pregnancies are twins or higher-order multifetal gestations (triplets or greater), and more than half of all ART neonates are the products of multifetal gestations.^{512,513} Furthermore, the frequency of monozygotic gestations and their additional perinatal risks is increased, especially with blastocyst transfers.⁵¹³⁻⁵¹⁷

Only recently have appropriately performed studies and meta-analyses of sufficient size been available to explore the perinatal effects of IVF in singleton gestations.^{512,518-523} Although the majority of pregnancies are uncomplicated, there are higher rates of adverse pregnancy outcomes. These include an increased frequency of preterm and term low birth weight, preterm deliveries, and perinatal mortality. Two well-performed meta-analyses have been reported. One meta-analysis of 15 studies comprising 12,283 IVF singleton offspring and 1.9 million spontaneously conceived infants demonstrated approximately a 1.6- to 2.7-fold increased risk for these outcomes.⁵²³ The second meta-analysis of 25 studies showed similar results, with a 1.7- to 3.0-fold increased risk in these same outcomes.⁵¹⁹ Although evidence of the effect is convincing, questions remain about whether this is the result of treatment or of the underlying infertility.

Women with IVF-conceived singletons are at increased risk for preeclampsia, gestational diabetes, placenta previa, and stillbirth.⁵²⁴ They are also at a significantly higher risk of having

induction of labor and both emergent and elective cesarean deliveries. Thus, some of the adverse outcomes, including low birth weight, very low birth weight, and preterm delivery, may be attributable, in part, to iatrogenic intervention. An increased incidence of abnormal placentation, including a 2.4-fold increased risk for placental abruption and a 6.0-fold increased risk for placenta previa, have been noted in IVF pregnancies compared with controls.

One of the most frequently evaluated effects of IVF is the occurrence of birth defects.⁵²¹⁻⁵³¹ Despite numerous studies, the results remain uncertain because of concerns such as small sample size for specific anomalies, incomplete ascertainment of birth defects, confounding effects such as the cause of the infertility, and the potential of a parental genetic contribution. Two population-based studies with sufficient data to evaluate potential confounders demonstrated an increased risk for birth defects among ART infants.^{525,526} One registry-based study⁵²⁷ stands out because of its large sample size, including 4555 IVF children, 4467 other ART children, and 27,078 controls from the Finnish Registry of Congenital Malformations. The adjusted odds ratio for major malformations was 1.3 (95% CI, 1.1 to 1.6). The major malformation increased was hypospadias (rate of 76/10,000 births compared with 29/10,000 in controls). Other strongly associated malformations include other genitourinary anomalies, neural tube defects, gastrointestinal

defects, musculoskeletal defects, and cardiovascular defects. A meta-analysis of the prevalence of birth defects in infants after IVF or intracytoplasmic sperm injection (ICSI) compared with spontaneously conceived infants revealed a pooled odds ratio of 1.29 for 19 studies (95% CI, 1.01 to 1.67). Thus, the effect of IVF and other ART modifications on birth defects appears real but small.

Chromosomal abnormalities also appear to be slightly increased, especially after ICSI for male factor disorders.⁵³² In one study of 8319 liveborn ICSI children, there was a slight but significant increase in sex chromosomal aneuploidy (0.6% versus 0.2%) and de novo chromosomal abnormalities (0.4% versus 0.07%). For all of these anomalies, it is not presently possible to distinguish the treatment effect from the effect of the etiology of the infertility, because infertile men have a higher frequency of chromosomal abnormalities including microdeletions and translocations. Similarly, female partners of couples undergoing ART have an increased risk for chromosomal abnormalities.⁵³³ Although this risk is not high enough to routinely offer invasive testing to all women undergoing IVF, those having invasive testing to confirm PGS results should have a full karyotype analysis.

Teratogenesis and Environmental Exposure

CHRISTINA CHAMBERS, PhD, MPH | ANTHONY R. SCIALLI, MD

A *teratogenic exposure* is defined as one that has the potential to interfere with the normal functional or structural development of an embryo or fetus. An exposure includes an agent (e.g., chemical) and an exposure level (e.g., dose). Although teratogenic exposures typically increase the risk of major congenital anomalies, they also increase the risk of a spectrum of adverse pregnancy outcomes, including spontaneous abortion, stillbirth, minor structural anomalies, shortened gestational age, growth restriction, and behavioral or cognitive deficits. Excess risks for the latter events may be much more difficult to recognize.

Known teratogenic exposures comprise a wide range of doses and agents, including some prescription and over-the-counter medications, recreational drugs and alcohol, chemicals, physical agents, and maternal diseases. Although studies specifically evaluating human teratogenicity are lacking for most environmental agents, including prescription medications, it is estimated that about 10% of major birth defects are attributable to environmental exposures and are therefore preventable to some extent.

Historical Perspective

Before the 1940s, it was somewhat naively thought by clinicians that the placenta provided a protective barrier for the developing embryo and fetus and that agents to which the mother was exposed could not interfere with normal prenatal development. The revolutionary concept that a maternal exposure could pose a risk to the developing embryo or fetus was first raised in the clinical literature by an Australian ophthalmologist, Norman Gregg, who observed in his clinical practice an unusual number of children diagnosed with congenital cataracts shortly after a rubella epidemic. Gregg's work led to investigations that identified additional features of a variable but characteristic pattern of developmental abnormalities associated with fetal rubella infection, including congenital heart defects, hearing deficits, poor growth, and thrombocytopenia, which came to be known as the congenital rubella syndrome.¹

In the early 1960s, an Australian obstetrician and a German geneticist independently recognized that first-trimester maternal use of thalidomide, a sedative-hypnotic drug, was associated with the appearance of a characteristic pattern of limb reduction anomalies and other defects.^{2,3} Although the drug had undergone premarket testing in rodents, it had not shown the characteristic limb defects in these species. In the United States, subsequent recognition that therapeutic agents could induce malformations was a major stimulus for the implementation of the Kefauver-Harris Amendment to the Food, Drug, and Cosmetic Act, which expanded the role of the U.S. Food and Drug

Administration (FDA) as a regulatory agency charged with ensuring the efficacy and safety of products.⁴

Although the thalidomide experience raised public awareness of the potential risks of prenatal exposures, the thalidomide episode was accompanied by misunderstandings about how to differentiate exposures that cause birth defects from coincidental exposures occurring in women whose pregnancy outcome is abnormal for other, unrelated reasons. A classic example is doxylamine succinate and pyridoxine hydrochloride with or without dicyclomine hydrochloride (Bendectin), a once-popular antiemetic medication used by as many as 30% of American women for the treatment of nausea and vomiting of pregnancy. In 1983, this agent was voluntarily withdrawn from the market after an onslaught of litigation claiming teratogenicity despite voluminous scientific evidence to the contrary.⁵

Within the past 40 years, research in the field of teratology has advanced, and several new human teratogenic exposures have been identified, including several anticonvulsants, selected antineoplastic agents, inhibitors of enzymes in the renin-angiotensin system, methylmercury, ethanol, hyperthermia, tetracycline, warfarin, and isotretinoin. Work continues to better define the range of adverse outcomes associated with these exposures, the magnitude of the risk for a given dose at a specific gestational age, and the subpopulations of mothers and infants who may be at particularly increased risk because of their genotype. However, major knowledge gaps exist for most agents, few of which have been adequately evaluated in human pregnancy.

Drug exposure during pregnancy is extremely common. In one U.S. health care system sample of 98,182 deliveries, 64% of women were prescribed at least one medication during their pregnancy other than a vitamin or mineral supplement.⁶ In another U.S. population-based sample of women, more than 65% reported the use of one or more over-the-counter medications during pregnancy.⁷ In many cases, these medications are necessary for the health of the mother or fetus, but in other cases, the exposures could have been avoided. A theoretical and practical framework is necessary to aid clinicians in advising patients, who are likely to have experienced several exposures by the time their pregnancy is recognized, and to support clinical decision making in the common situations in which treatment during pregnancy is recommended.

Principles of Teratology

James G. Wilson⁸ outlined the basic principles of teratology in the early 1970s. These six principles, given in Wilson's own words, were based on experience with experimental animal studies, but they can be applied equally well to human pregnancy.

1. *Susceptibility to teratogenesis depends on the genotype of the conceptus and the manner in which this interacts with environmental factors.*

Exposures do not occur in a vacuum; women and their fetuses bring different genetic makeups to the exposure scenario. Different genetic characteristics may alter the way a drug or chemical is metabolized or may alter the susceptibility of a developmental process to disturbance by an exposure. For example, women with infants who have cleft lip with or without cleft palate or isolated cleft palate are approximately twice as likely to report heavy first-trimester tobacco use than are mothers of normal newborns. However, women who have a certain transforming growth factor- α (TGF- α) polymorphism and who smoke heavily have a 3 to 11 times higher risk of having a child with an oral cleft, suggesting an interaction of the genetic characteristics of the mother with the tobacco smoke exposure. This risk appears to be lessened by maternal multivitamin use.^{9,10} Similarly, a low level of epoxide hydrolase enzyme activity influenced by epoxide hydrolase polymorphisms has been implicated as a risk factor for fetal hydantoin syndrome in children whose mothers have taken phenytoin for the treatment of a seizure disorder during pregnancy.¹¹

2. *Susceptibility to teratogenic agents varies with the developmental stage at the time of exposure.*

The principle of *gestational timing*, or critical developmental windows of exposure, requires that the exposure occur during the stage in development when the targeted developmental process is most susceptible. For example, the critical window for an agent that interferes with closure of the neural tube in the human embryo is approximately 21 to 28 days after conception. Carbamazepine, an anticonvulsant linked to a 10-fold increased risk of neural tube defects, does not produce the defect if maternal exposure occurs after the second month of pregnancy.^{12,13}

Depending on the gestational timing of exposure, different outcomes may be induced. For example, warfarin therapy is associated with a pattern of nasal hypoplasia and skeletal abnormalities when prenatal exposure occurs during the latter portion of the first trimester, whereas later gestational exposure is associated with central nervous system (CNS) abnormalities.¹⁴ The first-trimester effects likely reflect vitamin K deficiency, and later effects are a complication of fetal bleeding.

Consistent with this concept, very early gestational exposure, usually limited to the first 2 weeks after conception, poses little potential for teratogenicity, because pluripotent cells of the early embryo are able to replace one another if there is exposure-induced damage, or if the magnitude of cell loss is too great, the conceptus is lost, resulting in spontaneous abortion.⁸

3. *Teratogenic agents act in specific ways (mechanisms) on developing cells and tissues to initiate abnormal embryogenesis (pathogenesis).*

There is no teratogenic exposure that increases the risk of all adverse outcomes; rather, teratogenic exposures act on specific developmental processes to produce a characteristic pattern of effects. This principle underlies the methods by which many human teratogens have been suspected. The pattern of abnormalities associated with a particular teratogenic exposure helps to identify the exposure as the cause of an outcome. For example, the characteristic pattern of abnormalities comprising the fetal alcohol syndrome includes minor craniofacial features (i.e.,

short palpebral fissures, smooth philtrum, and thin vermilion of the upper lip) accompanied by microcephaly, growth deficiency, and cognitive and behavioral deficits. The prenatal effects of ethanol, although pervasive, nevertheless represent a constellation of features that is unlikely to randomly occur without exposure to alcohol in substantial doses and during certain gestational weeks.

There are a few general mechanisms that lead to abnormal development. For example, a teratogenic agent can interact with a receptor, bind to DNA or protein, degrade cell membranes or proteins, inhibit an enzyme, or modify proteins. These mechanisms manifest as excessive or reduced cell death, failed cell interactions, reduced biosynthesis, impeded morphogenetic movement, or mechanical disruption of tissues. For this reason, some teratogenic exposures have the same end result because they act through a common pathway. For example, some anti-convulsants may increase the risk for neural tube defects through folate antagonism.¹⁵ Angiotensin I-converting enzyme inhibitors (ACEIs) such as enalapril and lisinopril may induce ACEI fetopathy, which consists of renal tubular dysplasia and hypocalvarium, possibly through drug-induced fetal hypotension that leads to hypoperfusion and oligohydramnios.¹⁶

4. *The final manifestations of abnormal development are death, malformation, growth retardation, and functional disorder.*

Depending on the nature of the exposure and timing during gestation, adverse outcomes may encompass effects ranging from spontaneous abortion or stillbirth to major and minor structural defects, prenatal or postnatal growth deficiency, preterm delivery, and functional deficits or learning disabilities. For example, moderate to heavy maternal ethanol intake, particularly if consumed in a binge pattern, increases the risks for spontaneous abortion; stillbirth; a characteristic pattern of minor craniofacial abnormalities; selected major structural defects, including atrial and ventricular septal defects and oral clefts; prenatal and postnatal growth deficiency; deficits in global IQ; and specific behavioral and learning abnormalities.¹⁷ Experimental animal and human studies support the notion that the entire spectrum of outcomes associated with ethanol may not manifest in any single affected pregnancy; rather, the results vary by dose and pattern of drinking, may correlate with gestational timing of exposure, and may be influenced by genetic susceptibility and other modifying factors such as maternal nutrition.

5. *The access of adverse environmental influences to developing tissues depends on the nature of the influences (agents).*

The effective dose of an agent is that dose biologically available to the embryo or fetus. This principle can be applied to human exposures by oral dosing compared with topical application. For example, therapy with oral retinoids increases the risk of malformations in human pregnancy. Isotretinoin (13-*cis*-retinoic acid) taken as an oral medication for only a few days in early pregnancy is associated with an approximately 20% risk of a pattern of brain, conotruncal heart, ear, and thymus abnormalities and mental deficiency in liveborn children.¹⁸ In contrast, topical tretinoin (all-*trans*-retinoic acid) used for acne or to reduce signs of skin aging has not been associated with an increased risk of the same pattern of adverse effects.^{19,20} These findings are attributed to the much lower blood concentration of retinoic acids from topical than from oral therapy.

6. *Manifestations of deviant development increase in degree as dosage increases from the no-effect level to the totally lethal level.*

The principle of *dose response* suggests that for all exposures, there is a threshold dose below which no effect is detected, higher doses produce stronger effects compared with lower doses, and the highest dose often is lethal. When the anticonvulsant and mood stabilizer valproic acid is taken by a pregnant woman during the critical window for neural tube closure, the risk for that defect increases by approximately 10- to 20-fold, from a baseline risk of 0.1% to a risk of 1% to 2%. However, there is evidence that the risk is dose related, because valproate-treated mothers who deliver infants with spina bifida on average have taken significantly higher doses than valproate-treated mothers of normal newborns.²¹

Sources of Safety Data on Exposures in Pregnancy

For most medications, information on pregnancy effects comes exclusively from experimental animal studies. These studies are useful in indicating the exposure level at which adverse effects are seen, the nature of those effects, and associated effects on the mother. Interpretation of this information for counseling women requires an understanding of similarities and differences in the pharmacokinetics of the drug in the experimental model and in humans, information that may not be readily available. Although precautions may appear in the product labeling solely on the basis of experimental animal data, it is desirable that experimental animal data be supplemented by data obtained in humans.

CASE REPORTS OF ADVERSE EVENTS

Reports of pregnancy exposures with adverse outcomes may appear as case reports in the literature, through safety data provided to the FDA by manufacturers, or in voluntary reports by clinicians or patients. Individual adverse outcome reports have the potential to generate hypotheses regarding teratogenicity, but case reports lack critical information about the number of exposed pregnancies with normal outcomes and cannot be used to determine whether the adverse event reports represent an excess risk over the baseline for that event or simply coincidence.

PREGNANCY REGISTRIES

Pregnancy registries retrospectively and prospectively collect data regarding exposures to a specific drug or group of drugs. The outcome of primary interest in traditional pregnancy registries is major birth defects. Registry data are periodically summarized and reviewed for signals that may lead to recommendations for initiation of a hypothesis-testing study. Strengths of registries include their potential for gathering early information about a new drug and the possibility of identifying a unique pattern of malformation that is associated with exposure to the drug of interest. However, traditional registries lack formal comparison groups and typically have outcome data on small numbers of pregnancies. These registries usually have insufficient sample sizes to detect an important increase in the frequency of specific birth defects.²² Nevertheless, collaborative registry designs such as the Antiepileptic Drugs in Pregnancy Registry have demonstrated success in identifying signals or

establishing higher than expected rates for major birth defects after selected exposures.²³

OBSERVATIONAL COHORT STUDIES

Observational studies include prospectively designed exposure cohort studies in which women with or without the exposure of interest are enrolled during pregnancy (preferably before recognition of the outcome to eliminate bias) and followed to outcome. These studies can evaluate a spectrum of outcomes, including major and minor malformations. They also have the advantage of including a comparison group or groups, allowing for the control of key factors that may be confounders or effect modifiers such as maternal age, socioeconomic status, and ethanol or tobacco use. This type of study design was successful in identifying carbamazepine therapy as a human teratogenic exposure.²⁴ One disadvantage of this approach is that the sample sizes are typically too small to rule out anything but the most dramatically increased birth prevalence of specific major birth defects.

DATABASE COHORTS

A variation of the observational cohort involves construction of a historical cohort using archived information in existing databases. For example, health maintenance organization claims data and records from government-supported health care agencies can be analyzed for information on pregnancies with or without specific medication exposures. The strengths of this approach include the potential cost savings for collecting data for a given number of pregnancies, but the limitations include sample sizes that are too small to detect increased risks for many or even most specific birth defects. Because database studies rely on information not collected primarily for research purposes, validation of exposure and outcome and data on some key potential confounders may be difficult or impossible to obtain. Nevertheless, database cohorts have been used, for example, to raise the question of a possible link between paroxetine and congenital heart defects.²⁵

CASE-CONTROL STUDIES

In case-control study designs, pregnancies are retrospectively selected for having a specific outcome, such as a particular birth defect. The frequency of exposure to an agent of interest among mothers of affected infants is compared with the frequency of exposure among mothers whose pregnancies did not result in that birth defect. A major strength of case-control studies is that with proper numbers of cases and controls, they can provide sufficient power to detect increased risks for rare outcomes. Because these studies include a comparison group, they can collect information on important potential confounding variables such as age, socioeconomic status, and ethanol and tobacco use. The case-control approach was used successfully to identify the association of misoprostol (used to induce abortion) with a very high risk of a rare congenital facial nerve paralysis, Möbius syndrome.²⁶ A limitation of case-control studies is the lag time inherent in collecting information on a new drug, especially if it is infrequently used by pregnant women. Another limitation is the inability to evaluate an agent for a spectrum of outcomes that have not been identified as part of the anomaly pattern. It is possible that women who are already aware of a negative outcome of their pregnancy may

recall exposures more carefully (or incorrectly) than those who had a normal outcome.

SUMMARY OF DATA SOURCES

The strengths and weaknesses of the methodologies that are available to evaluate potential teratogenicity reveal that no single approach is sufficient. From the clinical perspective, this means that conclusions drawn from one type of study must be interpreted with caution until they are confirmed or refuted by other types of studies. From a public health perspective, a combination of complementary study designs is desirable, one that ideally is initiated in a coordinated, systematic fashion to provide clinicians and patients with the best and earliest possible information.²⁷

Risk Assessments and Resources

The FDA established a widely used pregnancy safety category system that is incorporated into the product label with the intent of informing clinicians and pregnant women of the teratogenic risks associated with prescription drugs. This category system is frequently misunderstood by health care providers and patients, and it is being replaced by a system that relies on plain text to give information about medications.

In practice, the current FDA category assigned to a medication often misrepresents or oversimplifies the evidence. For example, the category assignments usually do not take into consideration factors such as exposure timing in gestation or dose and route of administration. Although some drugs assigned to category X (i.e., contraindicated in pregnancy) are known to harm the embryo or fetus at therapeutic dose levels, others (e.g., ribavirin, statins) were assigned to that category based on theoretical concerns or animal data without human data to establish a teratogenic risk.^{28,29} Incorporation of new data into the label and classification updates is often slow.

Communication of potential risk to a woman regarding an exposure that has already taken place varies substantially from that for an exposure that is anticipated. Such nuances are not reflected in the category statements.

Other information readily available to the clinician includes several print resources, each with different approaches to providing summary information.^{30,31} Some of these references are available in hard copy, compact disk (CD), and smartphone versions. Online databases that provide summary statements prepared by experts in the field of teratology and updated on a regular basis include TERIS, REPROTOX, Briggs, and Shepard. The Organization of Teratology Information Specialists (OTIS) provides individualized information to clinicians and the public by toll-free telephone access and Internet (<http://otispregnancy.org>). Clinicians or patients who are interested in pregnancy registries that are open for enrollment can locate a current list provided by the FDA's Office of Women's Health (<http://www.fda.gov/ScienceResearch/SpecialTopics/WomensHealthResearch/ucm251314.htm>).

Selected Human Teratogenic Exposures

For information about specific exposures, an updated information source such as those discussed previously should be consulted. Selected examples of teratogenic exposures are discussed in this section.

VITAMIN K ANTAGONISTS

A specific pattern of congenital anomalies referred to as the *fetal warfarin syndrome* has been identified in some children born to mothers who use medications such as phenprocoumon, acenocoumarol, fluindione, warfarin, and phenindione, which are vitamin K antagonists. The features include nasal hypoplasia, stippled epiphyses visible on radiographs, and growth restriction. CNS and eye abnormalities, including microcephaly, hydrocephalus, Dandy-Walker malformation, agenesis of the corpus callosum, optic atrophy, cataracts, and mental retardation, occur occasionally.^{32,33} The critical period for the nasal and bony effects of warfarin embryopathy appears to be between 6 and 9 weeks' gestation. A systematic review of 17 studies involving a total of 979 exposed pregnancies estimated a 6% incidence of warfarin embryopathy. In addition, 22% of exposed pregnancies ended in spontaneous abortion, 4% in stillbirth, and 13% in preterm delivery.³⁴ A large, multicenter study of 666 pregnancies with exposure to vitamin K antagonists reported a significant increase in the rate of major birth defects overall, relative to unexposed healthy comparison women (odds ratio [OR] = 3.86; 95% confidence interval [CI], 1.76 to 8.00). In that study, only 2 infants (0.6%) were thought to have warfarin embryopathy. The rate of preterm delivery was increased (16.0% versus 7.6%; OR = 2.61; CI, 1.76 to 3.86); the mean birth weight of term infants was significantly lower (3166 versus 3411 g); and the rate of spontaneous abortion was significantly higher (42% versus 14%; OR = 3.36; CI, 2.28 to 4.93) with exposure.¹⁴

In one study of 71 pregnancies occurring in 52 women with prosthetic heart valves who were being treated with warfarin, the risk for adverse outcome was significantly greater with doses greater than 5 mg/day.³⁵ A review of 85 pregnancies involving exposure to a coumarin drug only after the first trimester reported that 1 pregnancy ended in stillbirth, 3 in spontaneous abortion, and 19 in preterm births; 1 infant had a CNS anomaly, and none had the warfarin embryopathy.³⁴ In a large study that evaluated the cognitive performance of 307 children prenatally exposed to warfarin compared with that of unexposed children, the mean IQ scores did not differ significantly, but low scores (IQ < 80) occurred more frequently in children whose exposure was limited to the second and third trimester.³⁶

ANTIEPILEPTIC DRUGS

Most older drugs used to treat seizure disorders are associated with an increased risk of congenital malformations,^{37,38} perhaps indicating that the underlying disease is the teratogenic cause. Newer studies have challenged this concept.³⁸⁻⁴⁰ The use of multiple anticonvulsant medications (i.e., polytherapy) instead of a single drug (i.e., monotherapy) is associated with a greater risk of structural defects.^{39,41,42} It is unclear whether the disadvantage of polytherapy is a result of drug-drug interactions, more severe disease in women requiring treatment with polytherapy, or a combination of the two.

Phenytoin

Phenytoin as a treatment for seizure disorders has been associated with an increased risk for oral clefts and for a pattern of anomalies known as the *fetal hydantoin syndrome*. This pattern is estimated to occur in 10% of infants with prenatal exposure and includes prenatal or postnatal growth restriction,

microcephaly, hypoplasia of the digits and nails, and craniofacial abnormalities (i.e., short nose with low nasal bridge, ocular hypertelorism, abnormal ears, and a wide mouth with a prominent upper lip).⁴³⁻⁴⁵ Initial reports suggested that mental deficiency was also a common feature of fetal hydantoin syndrome.⁴⁶ However, the limited data published subsequently suggest that neurobehavioral effects may be milder.⁴⁷ For example, Scolnik and colleagues⁴⁸ reported that average IQ scores were 10 points lower in children exposed to phenytoin monotherapy compared with unexposed children born to mothers who were matched by age and socioeconomic status.

Valproic Acid

Studies during the past 2 decades have associated early-first-trimester exposure to valproic acid with an increased risk of neural tube defects, specifically spina bifida. The estimated risk is about 1% to 2%, with higher doses thought to be associated with higher risk.^{21,49} It has been estimated that the overall risk for major birth defects is increased by fourfold to sevenfold after valproate monotherapy, with increased risks for specific cardiovascular, limb, and genital anomalies described in some reports.²³ As with other anticonvulsants, a pattern of minor malformations and growth deficiency has been identified for valproic acid; it includes midface hypoplasia, epicanthal folds, short nose, broad nasal bridge, thin upper lip, thick lower lip, micrognathia, and subtle limb defects (primarily hyperconvex fingernails).⁵⁰ Valproic acid monotherapy is associated with reduced cognitive ability and additional educational needs in children prenatally exposed.⁵⁰⁻⁵²

Carbamazepine

Carbamazepine exposure in the early first trimester has been associated with an increased risk (approximately 1%) of spina bifida.¹² Carbamazepine has also been linked to a pattern of minor craniofacial abnormalities, including upslanting palpebral fissures, a long philtrum, and nail hypoplasia, as well as growth deficiency and microcephaly.²⁴ Although some small studies have suggested developmental delay after prenatal exposure to carbamazepine,⁵³ others have not.^{52,54,55}

Other Antiepileptic Drugs

Newer antiepileptic medications have been introduced into practice over the past several years. Increases in malformations, particularly cleft lip, and low birth weight have been associated with topiramate therapy by two registries, including the North American Antiepileptic Drugs in Pregnancy Registry conducted at Massachusetts General Hospital.^{56,57}

The Massachusetts General Hospital registry monitors the outcome of pregnancies in which anticonvulsant medications have been used. More information is available and subjects can be enrolled by phone (1-888-233-2334) or online (<http://www.massgeneral.org/aed>). Outside North America, information can be obtained through the International Registry of Antiepileptic Drugs and Pregnancy (<http://www.eurapinternational.org>).

CHEMOTHERAPEUTIC AND IMMUNOSUPPRESSIVE AGENTS

Cyclophosphamide

Eight case reports documenting a unique pattern of malformation in infants prenatally exposed to cyclophosphamide have

been published.⁵⁸ Features include growth deficiency, craniofacial anomalies, and absent fingers and toes. In three of these cases, the infant survived, and developmental information was available; significant delays were seen in all three. The magnitude of the risk is unknown, and the lack of denominator-based information prevents conclusions about possible fetal harm from this agent.

Methotrexate

Both aminopterin and its methyl derivative, methotrexate, have been associated with a specific pattern of malformation that includes prenatal-onset growth deficiency, severe lack of calvarial ossification, hypoplastic supraorbital ridges, small and low-set ears, micrognathia, limb abnormalities, and in some cases, developmental delay.^{59,60} Most affected infants have been born to women treated with high-dose methotrexate for psoriasis or neoplastic disease or as an abortifacient. Although the magnitude of the risk is unknown, it has been suggested that the dose necessary to produce the aminopterin/methotrexate syndrome is greater than 10 mg/week.^{61,62}

ADRENAL CORTICOSTEROIDS

Among four case-control studies, three concluded that systemic corticosteroid use in the first trimester was associated with a threefold to sixfold increased risk for cleft lip with or without cleft palate and possibly cleft palate alone.⁶³⁻⁶⁶ It is unclear to what extent this association was related to the various underlying maternal diseases involved in these studies. If only the positive studies are considered, this relative risk translates to a risk of approximately 3 to 6 cases per 1000 pregnancies exposed around the time of lip and palate closure toward the end of the first trimester. An association has long been recognized between prenatal exposure to corticosteroids and intrauterine growth restriction in humans. The risk appears to be dose related, suggesting that this concern can be minimized with lower doses.^{67,68}

MYCOPHENOLATE

Mycophenolate is available as mycophenolate mofetil or sodium, and it is used as an immunosuppressant in transplantation regimens and for lupus nephritis. The U.S. National Transplant Pregnancy Registry reported in 2006 that among 15 liveborn mycophenolate-exposed children, 4 had malformations.⁶⁹ Three of the children had microtia, and 2 of these children also had cleft lip and palate. There followed several case reports of infants exposed to mycophenolate with a variety of birth defects, the most characteristic of which were microtia or anotia, oral clefts, and conotruncal heart disease.⁷⁰

Denominator-based reports do not give a clear picture of the prevalence of a mycophenolate embryopathy. Adverse event reports summarized in the product labeling indicates that of 77 pregnancies exposed to mycophenolate, 25 spontaneously aborted, and 14 resulted in a malformed infant or fetus. Six of the 14 malformed offspring had ear abnormalities. As the labeling points out, spontaneous adverse event reporting does not give reliable prevalence rates, because adverse outcomes may be more likely to be reported compared with normal outcomes. However, the European Network of Teratology Information Services reported that malformations occurred in 8 of 57 prospectively ascertained pregnancies after mycophenolate

exposure (4 of whom had a clinical phenotype consistent with the case reports) and that the miscarriage rate (excluding voluntary abortions) was 28%.⁷¹

ACE INHIBITORS AND ANGIOTENSIN II RECEPTOR ANTAGONISTS

Based on case reports and case series, prenatal exposures to an ACEI (e.g., benazepril, captopril, enalapril, enalaprilat, fosinopril, lisinopril, moexipril, quinapril, ramipril) or to an angiotensin II receptor antagonist (e.g., losartan, candesartan, valsartan, tasosartan, telmisartan) during the second or third trimester of pregnancy have been associated with an increased risk of fetal hypotension, renal failure, and oligohydramnios leading to fetal growth restriction, joint contractures, pulmonary hypoplasia, and stillbirth or neonatal death. Calvarial hypoplasia has also been reported as part of the fetopathy. In children who survive the neonatal period, renal insufficiency may occur. The magnitude of the risk after second- or third-trimester exposure is not known.^{16,72}

First-trimester exposure to ACEIs or angiotensin receptor blockers (ARBs) was suggested by one database linkage study to be associated with an increased risk of cardiovascular defects (risk ratio [RR] = 3.72; CI, 1.89 to 7.30) and CNS defects (RR = 4.39; CI, 1.37 to 14.02) in infants born to mothers who had received a prescription for an ACEI in the first trimester of pregnancy compared with infants born to women with no exposure to antihypertensive medications during pregnancy. However, these findings have not been replicated, and it is possible that they were confounded by an inability to completely control for maternal diabetes.⁷³ The Swedish Medical Birth Registry described an association between antihypertensive medication use during early pregnancy and cardiovascular defects in the offspring; however, there was no difference in the risk estimates for ACEIs and β -blockers, and the association for ACEIs was not statistically significant.⁷⁴ A teratology information service study from Israel and Italy found no increase in malformations in the offspring of 252 women exposed to ACEIs or ARBs in the first trimester.⁷⁵

LITHIUM

Early reports from a lithium exposure registry⁷⁶ included information on 143 infants exposed to lithium in utero; 13 of them were reported to have malformations, 4 of which were Ebstein anomaly (i.e., downward displacement of the tricuspid valve within the right ventricle with atrialization of the right ventricle above the valve). This finding represented an excess over expected numbers, because the baseline incidence of Ebstein anomaly is approximately 1 in 20,000 births. The registry data are questionable because some women were reported to the registry after the pregnancy outcome was known, likely representing biased ascertainment. A subsequent prospective cohort study involving follow-up of 148 women with first-trimester exposure to lithium identified one case of Ebstein anomaly and no other cardiac malformations identified in the sample.⁷⁷ In contrast, a case-control study published by Zalstein and associates⁷⁸ found no prenatal exposure to lithium among 59 patients with Ebstein anomaly. The available data suggest that the use of lithium in the first trimester of pregnancy is associated with only a very small increased risk for Ebstein anomaly if there is any increased risk at all.

RETINOIDS

Vitamin A

The teratogenic potential of excessive doses of preformed vitamin A (retinol) is well described in animal models^{79,80}; however, the threshold dose at which naturally occurring vitamin A may be teratogenic in humans remains controversial. Two studies suggested that preformed vitamin A supplementation at amounts greater than 10,000 IU per day in the first trimester of pregnancy is associated with a small increased risk of selected defects that are consistent with those known to be induced by synthetic retinoids.^{81,82} However, other studies did not confirm these findings or suggested that the elevated risk occurs only at doses greater than 40,000 IU per day.⁸³⁻⁸⁵ The current recommended daily allowance (RDA) for pregnant women carrying a single fetus is 2560 IU of vitamin A. To avoid any of these potential concerns, many prenatal vitamin formulations have replaced retinol with β -carotene, which has no teratogenic potential. β -Carotene is cleaved in the liver to vitamin A, but the extent of conversion is controlled to meet and not exceed the body's needs.

Isotretinoin and Other Oral Synthetic Retinoids

Consistent with experimental animal data, an increased risk of pregnancy loss and a characteristic pattern of malformations and mental deficiency have been identified after prenatal exposure to isotretinoin. This pattern includes CNS malformations, microtia or anotia, micrognathia, cleft palate, conotruncal cardiac and great vessel defects, thymic abnormalities, eye anomalies, and some limb reduction defects.^{18,86} The estimated risks are at least as high as 22% for spontaneous abortion, 28% for structural defects, and 47% for mild to moderate mental deficiency, even if no structural abnormalities are present.^{18,87,88} Affected children have been reported with exposures to usual therapeutic doses and with treatment for durations shorter than 1 week in the first trimester. There does not appear to be a risk of malformations when the drug is discontinued before conception, which is consistent with the half-life of isotretinoin.^{88,89}

Pregnancy prevention among women who are prescribed isotretinoin continues to be a challenge. A third-generation restricted distribution program, iPledge, was implemented in March 2006; it mandates close monitoring of birth control practices and negative pregnancy testing before dispensing of prescriptions for isotretinoin.⁹⁰

Retinoid embryopathy is a risk with the use of other oral synthetic retinoids, including etretinate and its metabolite acitretin, which have been used for the treatment of psoriasis.⁹¹ The extremely long half-life of etretinate led to its removal from the U.S. market in 1998. The half-life of acitretin is considerably longer than that of isotretinoin (50 to 60 hours), and acitretin can be converted to etretinate with maternal ingestion of ethanol. The drug should be discontinued before pregnancy and ethanol avoided during the entire period of treatment and for at least 2 months after discontinuation of therapy.^{92,93}

IONIZING RADIATION

Prenatal exposure to high-dose radiation is associated with an increased risk of microcephaly, mental deficiency, and growth deficiency based on data derived from a small number of pregnant survivors of the atomic bombs in Nagasaki and Hiroshima.⁹⁴ It is estimated that doses of 50 rad (50 cGy) or greater

to the uterus are required to produce these effects. The highest risk appears to be associated with exposures between 8 and 15 weeks' gestation, with a higher threshold dose at more advanced gestational ages.⁹⁵ The available data do not support an increase in the risk of mental retardation associated with high-dose radiation exposure beyond 25 weeks' or before 8 weeks' gestation.⁹³ Based on dose-response calculations, diagnostic procedures involving radiation do not pose a risk to the fetus unless the cumulative dose to the uterus is greater than 10 cGy; conservative guidelines suggest that doses should be kept below 5 cGy to the uterus during pregnancy.⁹⁶

ENVIRONMENTAL AGENTS

Methylmercury

Prenatal exposure to methylmercury was recognized as a cause of neurodevelopmental disability after instances of contamination in Japan (Minamata Bay) and Iraq in the mid-20th century.^{97,98} The reported effects, called *Minamata disease*, include a cerebral palsy-like disorder and mental deficiency.⁹⁹ Although the lower limit of exposure that may pose a risk in prenatal development remains unclear, an independent U.S. National Research Council expert committee concluded that limiting maternal intake to no more than 0.1 mg/kg body weight/day was sufficient to protect the fetus.¹⁰⁰ Currently, consumption of contaminated fish or marine mammals is the major source of methylmercury exposure in most populations. In 2004, the U.S. Environmental Protection Agency and FDA advised pregnant women and women of childbearing age who may become pregnant to avoid eating predator fish (i.e., shark, swordfish, king mackerel, and tilefish) in which organic mercury may be bioconcentrated and to limit their average consumption of other cooked fish to 12 ounces (340 g) per week to prevent fetal exposure to excessive amounts of methylmercury.¹⁰¹ There are, however, substantial benefits from fish in the diet during pregnancy.¹⁰² In a large, longitudinal study conducted in the United Kingdom, maternal seafood consumption during pregnancy correlated with developmental outcomes on a variety of measures up to 8 years of age. Beneficial effects on child development in this study were shown only in children born to women with maternal seafood intakes of more than 340 g per week, suggesting that advice to limit seafood consumption may be detrimental.¹⁰³

Lead

In utero exposure to high levels of lead (maternal blood concentrations >30 mg/dL) has been associated with an increase in spontaneous abortion, preterm birth, and mental deficiency in the offspring.¹⁰⁴⁻¹⁰⁶ Prenatal exposure to lower levels (>10 mg/dL) may be associated with subtle neurobehavioral effects, but these effects may not persist into older childhood.¹⁰⁶⁻¹⁰⁸ Adverse effects of lower levels of lead exposure during pregnancy have been suggested but not confirmed. Occupational and environmental exposures to lead that precede pregnancy may result in fetal exposure due to mobilization of lead stored in maternal bone. These effects may be modified by maternal intake of calcium.¹⁰⁹

SOCIAL AND ILLICIT DRUGS

Ethanol

A pattern of anomalies, known as the *fetal alcohol syndrome* (FAS), was first described more than 35 years ago in a case series

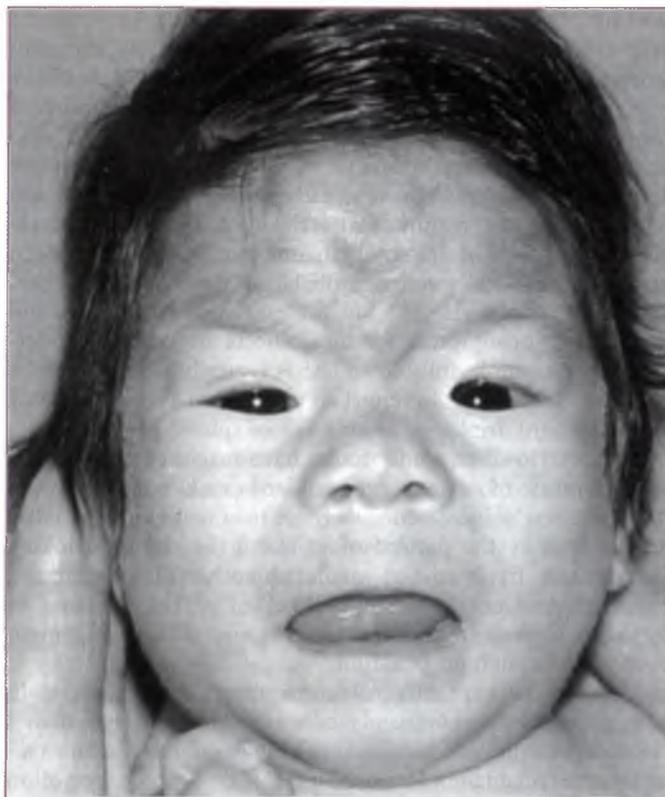

Figure 31-1 Nine-month-old infant with fetal alcohol syndrome. (From Streissguth AP, Aase JM, Clarren SK, et al: *Fetal alcohol syndrome in adolescents and adults*, JAMA 265:1961, 1991. Copyright 1991, American Medical Association.)

of infants born to alcoholic women.¹¹⁰ The characteristic features of this disorder are prenatal and postnatal growth retardation; microcephaly or other CNS dysfunction including neurobehavioral deficits, neurologic impairment; and characteristic facial anomalies consisting of short palpebral fissures and a smooth philtrum with a smooth, thin vermilion border of the upper lip (Fig. 31-1).^{111,112} Although FAS is difficult to diagnose, particularly in the newborn period, estimates of its incidence in selected U.S. and Western European populations are approximately 1 to 4 cases per 1000 live births.¹¹³

Many more children are thought to have alcohol-related neurobehavioral or neurologic impairment with or without some structural features of FAS. Congenital heart defects, oral clefts, and abnormalities of the eyes, brain, and kidneys are more common than expected among the children of women who drink moderately to heavily during pregnancy.¹¹⁴⁻¹¹⁷ These children, described as having partial FAS, alcohol-related neurodevelopmental abnormalities (ARNDs), or alcohol-related birth defects (ARBDs), are now considered to represent a continuum of fetal alcohol spectrum disorders (FASDs). Accurate estimates of the prevalence of FASDs are lacking; however, one population-based study in the Seattle, Washington, area suggested that the rates may be as high as 1 case per 100 children.¹¹³ Increased risks for spontaneous abortion, stillbirth, and sudden infant death syndrome have been linked to prenatal ethanol exposure, particularly exposure from ethanol consumed in a heavy episodic or binge pattern.¹¹⁸⁻¹²¹

Experimental animal and human data support a dose-response relationship in terms of risk for FAS/FASD. However,

because of variability in diagnosis and difficulties in obtaining and validating exposure information reported by pregnant women, estimates vary widely regarding the magnitude of the risk. For example, estimates for the fully expressed syndrome range from about 4% to 44% of children born to women who drink heavily during pregnancy.^{122,123} The women at highest risk appear to be those who have already had an affected child and who continue to consume ethanol during subsequent pregnancies. Lower levels of maternal ethanol consumption have been associated with less severe neurobehavioral outcomes and persistent growth effects,¹²⁴⁻¹²⁶ but the exact threshold doses and patterns of consumption for these effects are not well understood. For example, full-blown FAS is typically seen among the children of women who report consuming an average of six or more standard drinks (i.e., beer, wine, or spirits) per day during pregnancy. However, some studies have suggested that women who consume more than two standard drinks per day during pregnancy are at increased risk. These risks may be mediated or ameliorated by the pattern of drinking (i.e., binge drinking versus more frequent and smaller quantities), maternal age, nutrition, and genetic susceptibility.^{117,126-129} The duration of exposure is likely to be important because CNS development continues throughout gestation.¹³⁰

Current data are insufficient to assign a risk to certain common patterns of prenatal ethanol exposure, such as ethanol consumption limited to occasional binge episodes before recognition of pregnancy. However, the data do support the notion that reduction or discontinuation of ethanol consumption at any point in pregnancy may be beneficial. A lower threshold of exposure, below which no effects will be seen, has not been defined. For women who are planning pregnancy or who have the potential to become pregnant, the U.S. Surgeon General has recommended that the safest course is to avoid ethanol entirely during pregnancy.¹³¹

Tobacco

Maternal cigarette smoking is associated with a variety of harmful effects on the embryo and fetus, including increased risks for specific congenital malformations, spontaneous abortion, placental complications, preterm delivery, reduced birth weight, and sudden infant death syndrome. The structural malformations that have been significantly associated with first-trimester smoking include oral clefts and gastroschisis. A meta-analysis of 24 studies estimated the risk of oral clefts to be low; the relative risk for cleft lip with or without cleft palate was 1.34 (CI, 1.25 to 1.44), and that for cleft palate alone was 1.22 (CI, 1.10 to 1.35).¹³² Some studies have suggested gene-environment interactions in susceptibility for oral clefts when mothers smoke during early pregnancy. Infants who have a null deletion of the detoxifying gene *GSTT1* or certain polymorphisms at the *Taq1*-identified site for transforming growth factor- α (a gene known to be involved in facial development) and whose mothers smoke are at higher risk for certain oral

clefts than infants with either risk factor alone.^{133,134} Elevated risks for gastroschisis after maternal smoking are estimated to be low.¹³⁵ However, as with oral clefts, there is some evidence for gene-environment interactions between maternal smoking and polymorphisms of fetal genes involved in vascular responses.¹³⁶ Other defects that occur with increased frequency after pregnancy exposure to tobacco smoke include craniosynostosis and clubfoot.¹³⁷⁻¹³⁹ Most studies with dose information available have suggested a dose-response relationship for each of these defects, with the heaviest smokers being at highest risk.

The deleterious effects of cigarette smoking on other pregnancy outcomes are well documented. Intrauterine growth restriction is the most consistently reported adverse outcome. On average, babies born to women who smoke during pregnancy are 200 g lighter than those born to comparable women who do not smoke, with a clear dose-response gradient,¹⁴⁰ in part because of the reduction in uterine blood flow associated with plasma nicotine in women who smoke.¹⁴¹ Smaller reductions in birth weight have occurred when exposure is limited to environmental or passive smoke.¹⁴² Strong gene-environment and gene-gene-environment interactions have been demonstrated between the cytochrome P450 isozyme *CYP1A1* and *GSTT1* maternal metabolic genes and infant birth weight in mothers who smoke.¹⁴³

Perinatal mortality is increased with maternal smoking, in part because of the increased risks of placental complications and preterm delivery. In one large study, the combined risk for fetal or infant death for primiparous women who smoked less than one pack per day was estimated to be 25% higher than that for nonsmoking women, and the risk was 56% higher for those who smoked one pack per day or more.¹⁴⁴ However, if smoking is discontinued in the first half of gestation, evidence indicates that the effects on birth weight can be eliminated.¹⁴⁵⁻¹⁴⁷ Based on dose-response data, any reduction in the number of cigarettes smoked may reduce the risks of low birth weight, preterm birth, and placental complications.¹⁴⁷⁻¹⁵¹

Cocaine

The most consistently reported effects of prenatal cocaine exposure are a small but statistically significant increase in intrauterine growth restriction¹⁵² and abnormalities in neonatal state regulation and motor performance.¹⁵³ However, based on a synthesis of 36 published studies of children 6 years of age or younger, Frank and colleagues¹⁵⁴ concluded that no consistent negative association existed between prenatal cocaine exposure and postnatal physical growth, developmental test scores, receptive language, or standardized parent and teacher reports of child behavior. An association between prenatal cocaine exposure and decreased emotional expressiveness has been suggested.¹⁵⁵

Assessment of Fetal Health

ANJALI J. KAIMAL, MD, MAS

Assessment of fetal health is an important part of the management of any pregnancy, but it becomes more critical when maternal and fetal complications arise. Understanding the range of normal fetal behavior and considering the clinical context in which testing is performed are important parts of interpreting the results of fetal assessment. Given the wide variability in normal findings, even in the setting of abnormal test results, the likelihood of an adverse outcome may be relatively low in a low-risk population. Because the primary intervention available to the obstetrician wishing to facilitate treatment of the mother or the fetus is delivery, indications of potential fetal compromise must be carefully balanced against the complications of prematurity if the decision is made to proceed with delivery.

This chapter explores the physiology, pathophysiology, and components of various fetal testing strategies. The strengths and limitations of information about fetal health that can be gained from these modalities are considered.

Principles of Ideal Fetal Monitoring

Any fetal monitoring technology should be thought of as a screening test for fetal hypoxemia and acidosis. It must have measurable test performance characteristics, including sensitivity, specificity, and positive and negative predictive values. The ideal fetal monitoring system should have the following characteristics:

1. It should gather a wide range of information, with versatility for all maternal and fetal conditions and flexibility for all gestational ages.
2. It should detect fetal peril with specificity, sensitivity, and timeliness to allow preventive intervention. Measuring these performance characteristics requires correlation with measurable standards of fetal compromise, ultimately affecting long-term neonatal outcome. Proximal surrogate outcomes include antepartum pH and umbilical cord blood gas and pH determinations.
3. It should have a low false-positive rate, especially at earlier gestational ages, when the consequences of prematurity from intervention by delivery are most significant.
4. It should have high sensitivity for modest degrees of compromise to permit intervention early enough to prevent permanent fetal injury.
5. It should have a high and durable negative predictive value to reliably exclude stillbirth or permanent injury over a predictable period of time, allowing a reasonable testing interval to be defined. Allowing for the possibility of acute change such as placental abruption, a normal test

should exclude abnormal outcomes for a clinically important length of time, most commonly 7 days.

6. It should incorporate multiple variables to address both the complexity of normal fetal behavior and the individual nature of fetal compensation.
7. It should detect fetal compromise from a variety of sources, including asphyxia, poisoning, metabolic abnormalities, and anemia, to address the many origins of adverse outcomes.
8. It should be applicable in inpatient and outpatient settings, have readily available technology at a modest cost, and have a high likelihood of reproducibility.
9. It should have measurable benefits for high-risk populations in the reduction of perinatal mortality and perinatal morbidity, in part by safely extending intrauterine time.

In the context of the great variability in normal behavior and the complex cascades of responses to abnormal conditions, no single test can satisfy all of these objectives. In balancing the risks of stillbirth from intrauterine decompensation against the likelihood of neonatal death from prematurity, the use of multiple modalities is more likely to yield reliable results.

Assessment of Normal Fetal Physiology

Fetal assessment assumes that a change in fetal behavior implies a change in fetal status. Maternal evaluation of fetal activity, nonstress testing, and the use of ultrasound to assess the fetal biophysical profile (BPP) rely on this tenet. Doppler arterial flow velocimetry and ultrasound assessment of fetal growth provide information about the short- and long-term well-being of the fetus that places the findings of other testing modalities in context. All of these antepartum monitoring techniques aim to detect fetal compromise with adequate sensitivity and specificity to avoid underzealous or overzealous intervention, with a timeliness that allows improvement in outcome through in utero intervention or delivery. Understanding normal fetal physiology and development is an important part of interpreting the results of fetal assessment.

FETAL HEART RATE CHANGES DURING DEVELOPMENT

As gestation advances, the fetal heart rate (FHR) is increasingly dominated by the parasympathetic system, resulting in a gradual decrease in heart rate, increase in variability, and increasing responsiveness to acute changes in fetal status, including accelerations and decelerations.¹ The ability of the fetus to accelerate its heart rate in response to movement is related to

fetal oxygenation and metabolic state; this provides the basis for nonstress testing.

FETAL BEHAVIOR

Fetal movements appear and change in complexity over time, with tone and movement observable in the first trimester and breathing becoming evident at 21 weeks and beyond. By the end of pregnancy, defined kicking, hand movements, fetal breathing, and virtually all the individual behaviors of the term fetus can be demonstrated.² The presence of normal fetal muscle tone, gross body movements, and breathing have been reliably tied to the absence of fetal hypoxemia and acidemia, which is the basis for the BPP.

By the beginning of the third trimester, behavioral states 1F to 4F can be defined.^{3,4} They are analogous to the neonatal behavioral states originally described by Prechtl.⁵ Two patterns dominate: quiet sleep and active sleep. In quiet sleep (state 1F), rapid eye movements and repetitive mouthing movements are present, but almost all other movements are absent. As term approaches, this level of inactivity extends from a mean of about 220 seconds in mid-trimester to as long as 110 minutes by 40 weeks.² During state 2F (active sleep), movements are grouped, providing efficient monitoring, because multiple activities overlap. In state 4F (active awake), the “jogging fetus” illustrates a high level of voluntary activity and a sustained high heart rate, for which return to baseline may be interpreted as decelerations. As with its neonatal equivalent, state 3F (quiet awake) is unusual and short and is seldom observed before term. Understanding these behavioral states and particularly the patterns of time spent in particular states is useful for defining normal behavior, but these descriptions are rarely used clinically.

Near term, periods of inactivity that correspond to episodes spent in fetal behavioral state 1F (illustrated by the nonreactive NST [Fig. 32-1]) can be confused with fetal compromise. Although state 1F and the nonreactive NST result usually resolve by 40 minutes, intervals of up to 2 hours are likely normal.⁶ The definition of these abnormal periods depends on the modality of testing. Real-time ultrasound observation of fetal activity often reveals frequent, small movements of hands, mouth, and trunk when nonstress testing may elicit concern about complete inactivity. This illustrates the importance of using multiple modalities of fetal assessment to decrease the false-positive rate of any one test.

Methods of Monitoring Fetal Health

FETAL HEART RATE MONITORING

A valuable component of virtually all multivariable fetal assessment schemes, interpretation of FHR monitoring recognizes the unique coupling of fetal neurologic status to cardiovascular reflex responses.⁷ Because many studies have shown it to be the most sensitive, shorter-term predictor of worsening hypoxemia or acidosis,^{8,9} it has become part of fetal monitoring of labor and delivery. The range of FHR tracings that can be obtained for different fetuses and even for a single fetus over time is significant, which makes adjunctive testing with ultrasound useful in many situations.

The combination of fetal movements and FHR acceleration provides the basis of the nonstress test (NST). The classic criteria for a reactive NST result are at least two FHR accelerations lasting at least 15 seconds and rising at least 15 beats/min above the established baseline heart rate.¹⁰ Most term fetuses have many of these accelerations in each 20- to 30-minute period of active sleep, and the term fetus seldom goes more than 60 minutes and certainly not more than 100 minutes without meeting these criteria.⁶ However, preterm fetuses, fetuses with intrauterine growth restriction (IUGR) at similar gestations, or fetuses exposed to maternal medication such as narcotics or magnesium sulfate frequently have paired acceleration-movements that do not meet these criteria.¹¹ Modification of these criteria based on gestational age (e.g., including accelerations of 10 beats/min lasting 10 seconds in a background of normal FHR variability for fetuses less than 32 weeks) accepts the principle that earlier fetuses have smaller accelerations but that they should always demonstrate some degree of FHR acceleration with palpated fetal movements.

Falsely reassuring NST results (i.e., false-negative screening test result), as judged by fetal death within 1 week, occurred at a rate of 1.9 per 1000 fetuses in the largest study.¹² Although fetal nonstress testing in isolation has frequently been the first-line test for post-term pregnancies, additional fetal assessment may be helpful. Programs incorporating maternal counting of fetal movements and other published protocols for fetal assessment (in most cases, integrating an assessment of amniotic fluid volume) may help to identify additional pregnancies at risk.¹³

The nonreactive NST result is defined by an FHR monitoring interval that does not meet the criteria previously described. However, there is a large variation in the total duration allowed,

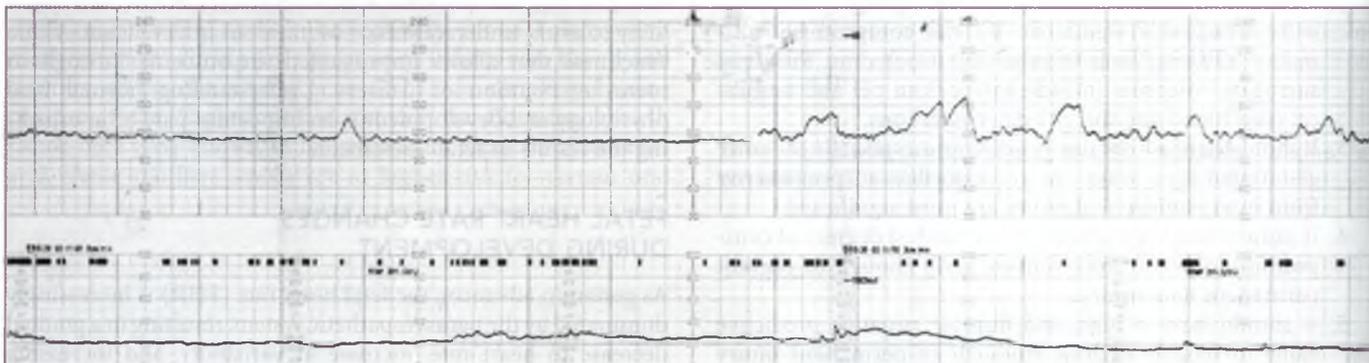

Figure 32-1 Eighteen-minute sleep-wake cycle in the term fetus. Virtually no activity (i.e., one kick, one acceleration) is seen in the first 9 minutes, with a low-variability fetal heart rate and behavioral state 1F. In the next 9 minutes, 60 discrete fetal movements are identified on real-time ultrasound, with multiple accelerations and increased variation between accelerations (2F).

and it ranges from a minimum of 10 minutes of monitoring to 40 or 60 minutes according to some investigators.¹⁴ In the context of the BPP, 30 minutes is allowed for the NST to demonstrate reactivity. About 10% to 12% of fetuses in the third trimester do not meet these criteria at 30 minutes. This number falls below 6% by 40 minutes.⁶ The choice of maximum duration for the NST is critical in determining the rate of false-positive screening test results, which is the major clinical drawback of using the NST. The most common explanation for a nonreactive NST result is a sleep cycle in a normal fetus that is longer than average.¹ A nonreactive result, especially if FHR variability continues and there are no decelerations, should not be assumed to indicate fetal compromise. Ultrasound evaluation with a formal BPP should be available as the backup test.

Beyond the BPP, ultrasound provides additional fetal evaluation that may help to diagnose the reason for an apparently abnormal NST result. For example, a repeatedly nonreactive finding for a fetus with normal serial ultrasound assessments may lead to a diagnosis of central nervous system abnormalities, drug ingestion, or prior fetal central nervous system injury. Late decelerations or variable decelerations may occur in the context of NST monitoring, with no clear deflection on the uterine pressure monitor. Either pattern should call for evaluation by ultrasound to exclude IUGR and oligohydramnios.

BIOPHYSICAL PROFILE

The BPP relies on the premise that multiple parameters of well-being are better predictors of outcome than any single parameter.¹⁵ Figure 32-2 shows a detailed evaluation of outcome variables performed during development.^{16,17} The traditional BPP study includes five variables (Table 32-1), with a total possible score of 10, but several variations have been proposed. Vintzileos and colleagues¹⁸ added placental grading, for a total possible score of 12. Several investigators proposed a modified BPP that usually includes heart rate monitoring and amniotic fluid evaluation.^{19,20} There are modest differences in these approaches, but all emphasize the principle of multivariable fetal assessment.

Biophysical Profile Score Variables

Amniotic Fluid Measurement. The underlying principle connecting decreased amniotic fluid volume to fetal compromise is the understanding that fetal oliguria in an anatomically normal fetus is a consequence of redistribution of fetal blood flow away from the kidneys and is frequently a reflection of uteroplacental insufficiency.²¹

Many methods of assessing amniotic fluid volume have been suggested. The technique for determining the BPP requires

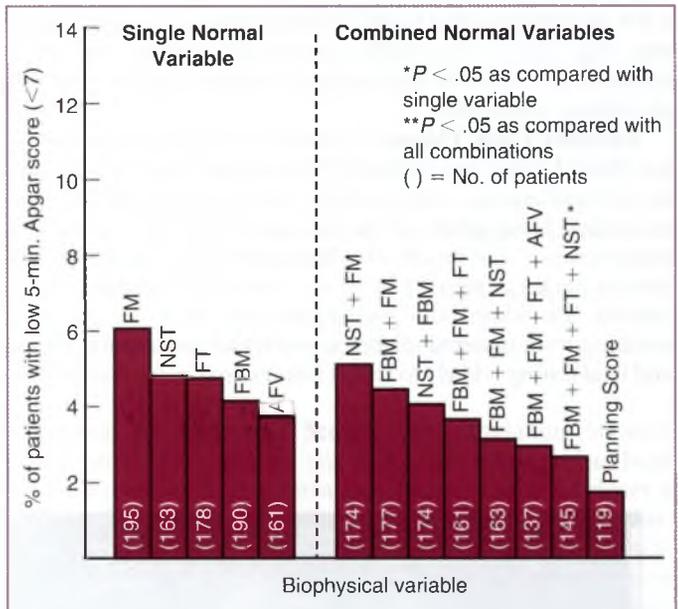

Figure 32-2 Prediction of outcome by individual biophysical profile score variables (left) or combinations of variables (right). In this example, a 5-minute Apgar score of less than 7 was best predicted by a combination of all five variables. The Planning Score, named for Platt and Manning, was the first full biophysical profile score. AFV, amniotic fluid volume; FBM, fetal breathing movement; FM, fetal movement; FT, fetal tone; NST, nonstress test.

TABLE 32-1 Interpretation of Biophysical Profile Score Variables

Fetal Variable	Normal Behavior (score = 2)	Abnormal Behavior (score = 0)
Fetal breathing movements (FBMs)	Intermittent, multiple episodes of more than 30 sec within a 30-min biophysical profile (BPP) time frame Hiccups count If continuous FBMs for 30 min, rule out fetal acidosis	Continuous breathing without cessation Completely absent breathing or no sustained episodes
Body or limb movements	At least three discrete body movements in 30 min Continuous, active movement episodes equal a single movement Includes fine motor movements, rolling movements, and so on, but not rapid eye movements or mouthing movements	Three or fewer body or limb movements in a 30-min observation period
Fetal tone or posture	Demonstration of active extension with rapid return to flexion of fetal limbs and brisk repositioning or trunk rotation Opening and closing of hand or mouth, kicking, and so on	Low-velocity movement only Incomplete flexion, flaccid extremity positions, abnormal fetal posture Must score 0 when fetal movement (FM) is completely absent
Nonstress test (NST)	Moderate variability Accelerations associated with maternal palpation FBMs (accelerations graded for gestation) on 20-minute NST	FM and accelerations not coupled Insufficient accelerations, absent accelerations, or decelerative trace Minimal or absent variability
Amniotic fluid evaluation	At least one pocket larger than 2 cm with no umbilical cord (text discusses subjectively decreased fluid)	No cord-free pocket greater than 2 cm or multiple definite elements of subjectively reduced amniotic fluid volume

assessment of a single adequate pocket of fluid. With the transducer vertical to the maternal abdomen, the maximum vertical depth of a clear amniotic fluid pocket is recorded. The transducer is then rotated 90 degrees in the same vertical axis, confirming that the measured pocket has true biplanar dimensions. The phrase 2×2 pocket does not mean that the pocket is 2 cm deep and 2 cm wide; it refers to the documentation that the pocket is 2 cm deep in at least two intersecting ultrasound planes, avoiding the possibility that a sliver of amniotic fluid is misconstrued as a true three-dimensional pocket. Amniotic fluid is measured in real time, and when there is doubt about a true pocket, it is confirmed by pulsed Doppler. Continuous color imaging may lead to the false impression of oligohydramnios (Fig. 32-3).²² This method reflects the relative amount of amniotic fluid and was not meant for determining an absolute physiologic parameter.²³

Amniotic Fluid Volume. A deepest vertical pocket that is less than 2 cm or more than 8 cm suggests oligohydramnios or polyhydramnios, respectively; in this setting, a detailed fetal evaluation is suggested to exclude anatomic and anomalous explanations.²⁴ For moderately increased fluid (i.e., maximum vertical pocket depth of 8 to 12 cm), the most common explanations are idiopathic polyhydramnios, fetal macrosomia resulting from maternal diabetes, and structural abnormalities, and fetal testing is likely to reflect fetal neurologic and acid-base

status accurately. For pockets deeper than 12 cm in singleton pregnancies, neurologic issues and structural defects associated with aneuploidy are more likely (especially if associated with fetal growth restriction), and the BPP may not predict the neonatal outcome.²⁵ Through the normal range (i.e., maximum vertical pocket depth of 3 to 8 cm), the maximum vertical depth method assigns normal status accurately, although it may not correlate precisely with absolute volumes.

Diagnosis of Oligohydramnios. The original criterion for the diagnosis of oligohydramnios was a maximum vertical pocket of only 1 cm. Although this finding highly correlated with IUGR, it was so uncommon as to be clinically meaningless. A meta-analysis identified four high-quality, randomized, controlled trials (RCTs) that compared the amniotic fluid index (AFI) with the single deepest vertical pocket (DVP) with respect to preventing adverse pregnancy outcome. The limits used were an AFI less than 5 cm and a DVP less than 2×1 cm. The trials included 3125 women, with the primary outcome measure defined as admission to the neonatal intensive care unit. No difference was observed for the primary outcome (risk ratio [RR] = 1.04; confidence interval [CI], 0.85 to 1.26).²⁶ When the AFI was used for fetal surveillance, however, the diagnosis of oligohydramnios was made more frequently (RR = 2.33; CI, 1.67 to 3.24); labor induction was used more frequently (RR = 2.1; CI, 1.6 to 2.76), and there was a higher rate of cesarean deliveries for lack of assurance of fetal well-being (RR = 1.45; CI, 1.07 to 1.97).²⁶ There were no differences in Apgar scores, umbilical artery pH (<7.1), or non-reassuring FHR tracings. The study authors concluded that the DVP seemed to be superior to the AFI for fetal surveillance because it required less intervention and resulted in a similar perinatal outcome. However, a systematic review of both methods with regard to diagnostic accuracy of decreased amniotic fluid volume has not been completed.

Fetal Breathing Movements. Rhythmic fetal diaphragm contractions or hiccups lasting more than 30 seconds meet normal criteria for fetal breathing movements. This fetal behavior is the one most easily suppressed by hypoxemia, but it is also the most episodic in normal fetuses. Because the amplitude of fetal breathing depends on gestational age, maternal glucose levels, exposure to increased oxygen concentrations, and many medications (e.g., xanthenes), careful evaluation of all parameters is necessary before intervention is undertaken.¹⁷ The unusual presence of continuous, monotonous fetal breathing or fetal gasping, with complete absence of all other behavior for an extended period, may indicate acidosis, especially in the fetus of a diabetic mother.²⁷⁻²⁹

Fetal Movement and Tone. One of the interpretive pitfalls for the BPP is that some movement must be present to evaluate tone. Tone is not simply the flexed posture of a normal fetus. The evaluation of tone is subjective, but absent tone strongly correlates with fetal acidosis.

Fine motor movement of the face and hands and purposeful movement such as swallowing, facial expressions, sucking, yawning, large kicks, small kicks, and rolling motions may be included as movements. When a fetus does not move for a period of 30 minutes, extended testing is required,³⁰ and completion of heart rate testing can help to extend the time of continuous observation. Further intervention is dictated by the clinical situation and gestational age.

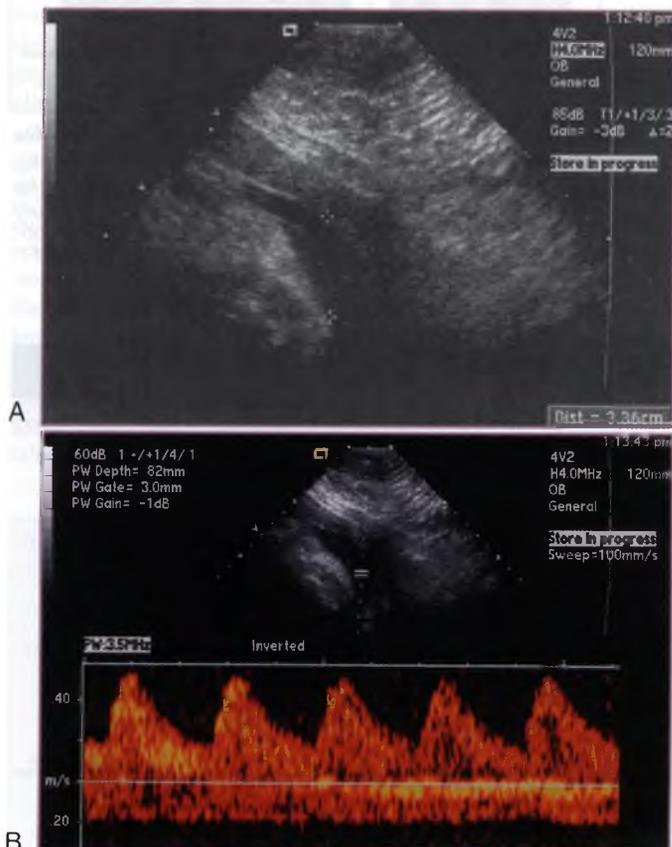

Figure 32-3 Fluid pocket verification. A, Amniotic fluid meets the vertical pocket criteria of the biophysical profile score. B, Pulsed Doppler demonstrates that this is a vertical pocket of the umbilical cord that contains no measurable amniotic fluid.

TABLE 32-2 Systematic Application of Biophysical Profile Scoring

BPP	Interpretation	Predicted PNM/1000*	Recommended Management
10/10, 8/8, 8/10 (AFV normal)	No evidence of fetal asphyxia	Less than 1/1000	No acute intervention on fetal basis; serial testing indicated by disorder-specific protocols
8/10-oligo	Chronic fetal compromise likely (unless ROM is proved)	89/1000	For absolute oligohydramnios, prove normal urinary tract, disprove undiagnosed ROM, consider antenatal steroids, and then deliver
6/10 (AFV normal)	Equivocal test; fetal asphyxia is not excluded	Depends on progression (61/1000 on average)	Repeat testing immediately, before assigning final value If score is 6/10, then 10/10, in two continuous 30-minute periods, manage as 10/10 For persistent 6/10, deliver the mature fetus, repeat within 24 hr in the immature fetus, then deliver if less than 6/10
4/10	Acute fetal asphyxia likely If AFV-oligo, acute on chronic asphyxia very likely	91/1000	Deliver by obstetrically appropriate method, with continuous monitoring
2/10	Acute fetal asphyxia likely with chronic decompensation	125/1000	Deliver for fetal indications (frequently requires cesarean section)
0/10	Severe, acute asphyxia virtually certain	600/1000	If fetal status is viable, deliver immediately by cesarean section

*Per test, within 1 week of the result shown, if no intervention. For scores of 0, 2, or 4, intervention should begin immediately if the fetus is viable. For all interventions, lethal anomaly should be excluded as a potential cause of the abnormal behavior.

AFV, amniotic fluid volume; BPP, biophysical profile; oligo, oligohydramnios; PNM, perinatal mortality; ROM, rupture of membranes.

Biophysical Profile Technique

Table 32-2 shows how the BPP is systematically interpreted and applied to management.

Score of 10/10, 8/8, or 8/10 with Normal Fluid Volume. A score of 6/8 does not constitute a full BPP. When the four ultrasound variables are measured first, but at least one of them is absent, the NST must be performed before the BPP is complete, and the score is then reported as 6/10 or 8/10. The only score that is allowed to stand alone after only the ultrasound variables have been evaluated is 8/8. In that case, an NST is not required, because the outcomes for a BPP of 8/10 and 10/10 are equivalent.³¹ Based on RCT data, the NST is used selectively after ultrasound variables have been assessed. When this protocol is followed, the NST is required in only about 10% of cases.³² For high-risk fetuses or fetuses at risk for conditions that may lead to specific changes in the fetal heart tracing (e.g., sinusoidal pattern of fetal anemia in an isoimmunized fetus, periodic decelerations in monoamniotic twins at risk for cord entanglement), the fetal heart tracing may provide useful information even in the setting of a BPP of 8/8.

Oligohydramnios with a Score of 8/10. The recommendation to proceed with delivery in a term pregnancy when there is no amniotic fluid pocket of 2 cm or greater is based on the association with adverse outcomes.³³ At term, the recommendation is to proceed with a trial of labor, despite the increased risk of FHR abnormalities in this setting. For preterm gestations, if the remainder of fetal behavior is within normal limits, additional time may be taken to administer antenatal steroids and transfer to a tertiary center if needed, provided close monitoring continues. No RCT data are available to demonstrate a decrease in neonatal morbidity with a policy of induction of labor for oligohydramnios at any gestational age. Mild oligohydramnios, which is more frequently seen in clinical practice, is likely not associated with significant fetal risk.

Equivocal or Abnormal Scores. The correlation between abnormal scores and high risk of a poor outcome has been demonstrated in large-population studies, and it produces a characteristically shaped outcome curve (Fig. 32-4).³⁴ Statistically, the most likely correlate of an equivocal score is coincidental absence of expected behavior in a normal fetus. Even an abnormal score should prompt consideration of a differential diagnosis, including many obstetric factors (Table 32-3). Extending the testing period, retesting after a brief interval, or adding ancillary tests can be done before moving to delivery because of equivocal scores. When a score of 0/10 to 4/10 without a correctable cause is found for a fetus whose screening results in the first and second trimesters were normal and especially when biophysical parameters and anatomic review findings were normal in the recent past, expeditious delivery is usually warranted.

VIBROACOUSTIC STIMULATION

If the NST or BPP is the primary means of evaluating fetal health, a nonreactive test finding resulting from fetal quiet sleep (state 1F) is a major source of falsely alarming tests and consumes an inordinate amount of time (usually nursing time) waiting for a state change. Vibroacoustic stimulation (VAS) (i.e., stimulating the fetus with a noxious vibration and noise) is effective in producing a state change, fetal startle movements, and increased FHR variability, thereby shortening the time it takes to demonstrate fetal well-being.^{35,36} It is not clear whether these responses require the combination of vibration and audible noise or can be provoked by vibration alone.

Vibration sense is fully developed throughout the body by 22 to 24 weeks and auditory response about a month later.³⁷ From this time on, the fetal sound environment is significant. The normal fetus is exposed to low-frequency sound energy from a variety of sources. Direct human data are scarce, but detailed evaluation of hearing in fetal sheep appears to be

TABLE 32-3 Factors That Influence Biophysical Profile Scoring Performance

Agent	Fetal Effect
Drugs	
Sedatives or sedative side effects (e.g., Aldomet)	Diminished activity of all varieties; abolition of none
Excitatory (e.g., theophylline)	Continuous, picket fence FBMs
Street drugs (e.g., crack cocaine)	Rachitic, rigid, furious, bizarre FMs
Indomethacin	Oligohydramnios
Maternal cigarette smoking	Various observations; FBM abolished or attenuated but some report no change; FM reduced
Maternal hyperglycemia (iatrogenic or unregulated)	Sustained FBMs or acidosis, diminution or abolition of FMs or FT or NST reactivity
Maternal hypoglycemia (e.g., poor nutrition, insulin excess)	Abnormal paucity of all behaviors, normal AFV
Single parameter removed by perinatal condition	
Persistent fetal arrhythmia	Uninterpretable NST
Spontaneous premature rupture of membranes	Obligatory oligohydramnios
Acute disasters (e.g., eclampsia, abruptio placentae, ketoacidosis)	May invalidate predictive accuracy
Corticosteroids	Transient decrease in fetal breathing movements

AFV, amniotic fluid volume; FBMs, fetal breathing movements; FMs, fetal movement; FT, fetal tone; NST, nonstress test.

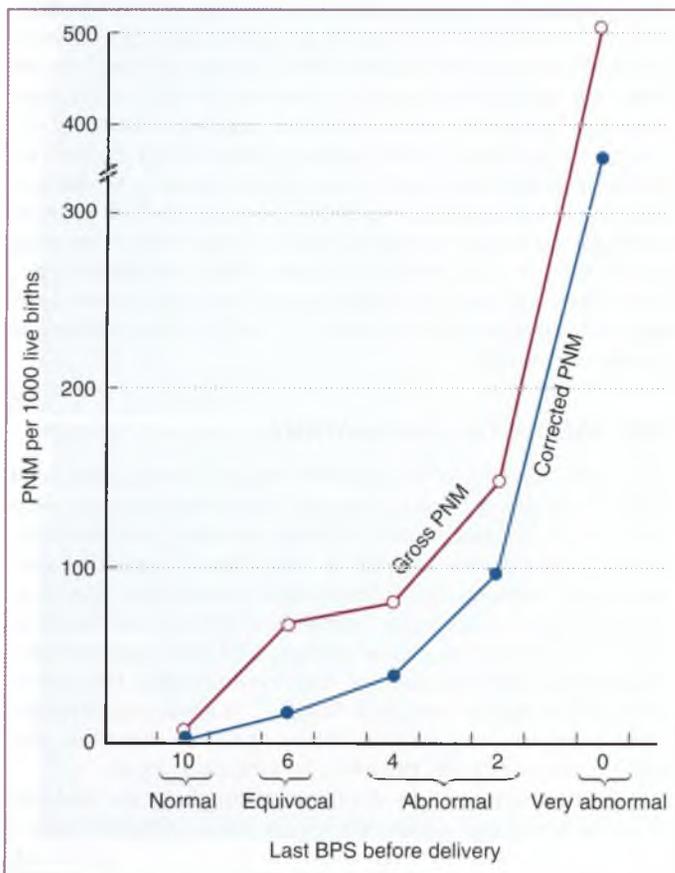

Figure 32-4 Perinatal mortality and biophysical profile score (BPP). Perinatal mortality (PNM) varies exponentially with declining BPP. The important contribution of lethal fetal anomalies accounts for the difference between the two curves.

analogous.³⁸ High-frequency sound is attenuated significantly, whereas low-frequency sound, such as thunder, airport noise, or the rhythm section of music, produces measurable evoked potentials in the cerebrum and appropriate deformation within the fetal ear.³⁹ High-decibel impact may even produce damage in low-frequency areas.⁴⁰ This discrimination probably extends to differentiation of vowels (i.e., low frequency and easily heard) from consonants (i.e., higher frequency and probably heard poorly) and produces apparent learning behavior. The latter includes recognition of or favoring the maternal voice over other voices, apparent recognition of music played during fetal life, and perceived responsiveness to intrauterine music.⁴¹ It is unclear whether it is the music and its multiple tones or merely its rhythmic or vibratory pattern that the fetus favors. Low-amplitude music with a slow rhythm appears to be soothing, whereas high-amplitude, high-frequency, high-rate rhythmic music produces significant FHR accelerations.⁴²

Considering the observations about fetal hearing and the exquisite sense of vibration that is developed even earlier, it is not surprising the fetus can be stimulated by electromechanical devices that induce a very broad band of atonal white noise from 0.1 to 10 kHz.⁴³ When the fetus is in quiet sleep (state 1F), even short bursts of VAS provoke the movement patterns, type of movement, fetal posture, FHR, and FHR variability typical of state 2F. If the fetus is already in state 2F (moving actively), the VAS may generate conversion to 4F (hyperactive “jogging” fetus) and almost always results in increased frequency of movements, amplitude of movements, rise in heart rate, and exaggerated FHR variability.⁴⁴ On occasion, fetal bradycardia has been incited.⁴⁵ The high frequency of state change in the human fetus, especially close to term, means that VAS achieves its purpose of shortening the monitoring time, converting a nonreactive NST result to a reactive one, and avoiding prolonged testing times; however, there is limited information on the long-term impact of VAS on fetal development and maternal well-being.⁴⁶

CONTRACTION STRESS TEST AND OXYTOCIN CHALLENGE TEST

The contraction stress test (CST) and the oxytocin challenge test (OCT) are provocative tests using FHR responses to uterine activity to evaluate fetal health. They were first introduced in the 1970s based on the observation that recurrent late decelerations were associated with fetal hypoxemia⁴⁷; they have been used less frequently since the NST, BPP, and other testing modalities were introduced. The CST uses spontaneously occurring contractions or contractions induced by maternal nipple stimulation.⁴⁸ The OCT uses intravenous oxytocin to cause repetitive uterine activity (Fig. 32-5).⁴⁷ Interpretation includes standard NST criteria (i.e., FHR accelerations, FHR baseline, and variability) and the FHR response after a contraction pattern has been established.

The technique is similar to that of the NST. After a contraction pattern is established with at least three contractions in 10 minutes, evaluation is possible. A negative OCT result has no decelerations or other unclassifiable changes from baseline with contractions.⁴⁷ Interpretation of a positive (abnormal) CST or OCT result is disputed. The classic standard is that FHR decelerations must accompany at least three consecutive contractions.⁴⁹ Another interpretation categorizes the CST result as positive if at least 50% of the contractions cause late

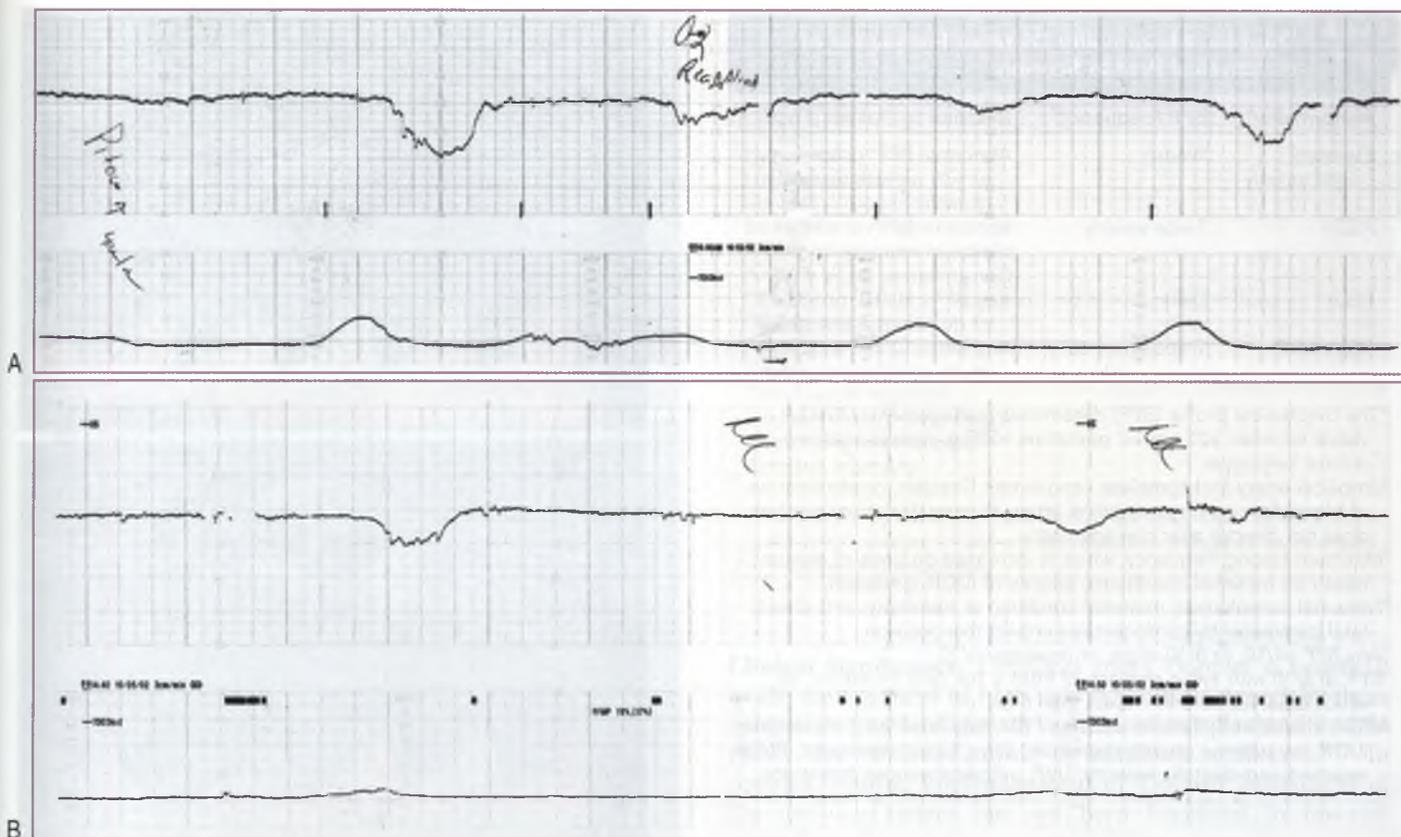

Figure 32-5 Oxytocin challenge test and contraction stress test. A, After contractions were established, repetitive late decelerations occurred with each contraction (a positive oxytocin challenge test result). Delivery was achieved by cesarean section because of fetal distress as induction of labor was attempted. Different strengths of contractions produced different depths of deceleration, all late in timing. B, Even trivial uterine activity caused late decelerations (a positive contraction stress test result) in this fetus with severe intrauterine growth restriction and with abnormal Doppler parameters. The biophysical profile score was 4/10 at 25 weeks.

decelerations (when there are at least three contractions in 10 minutes) or if all the contractions are associated with late decelerations but fewer than three occur in 10 minutes.⁵⁰ An equivocal CST or OCT result demonstrates repetitive decelerations not late in timing and pattern, usually classified as variable decelerations. Because this is a marker for oligohydramnios or cord entrapment, further assessment is required.⁵¹

For the OCT, intravenous oxytocin by continuous infusion pump is started per the labor and delivery protocol and titrated upward until three contractions occur in each 10-minute window. This is done in a hospital setting to enable an emergency response to hyperstimulation, continued contractions despite discontinuing the oxytocin, tetanic contractions, and fetal bradycardia.

Clinical application of these tests in the antepartum setting has become less common for several reasons. First, the method may have significant complications, and inducing contractions may not be prudent in all clinical situations, such as preterm labor, placenta previa, prior or classic cesarean delivery. Second, even for normal testing, the method is time consuming and expensive, usually taking up to 40 minutes to provoke contractions and ensure normality and much longer if the test result is equivocal or abnormal. Third, although these test results are good indicators of fetal well-being when negative (negative predictive values exceeding 99.8%), a positive test result alone is not sufficiently predictive to form the basis for clinical action. Positive predictive values for perinatal mortality and morbidity,

including low 5-minute Apgar scores, fetal distress, and cesarean delivery for an abnormal FHR in labor, show correlations but do not justify emergency delivery. When BPP is the backup test for a positive CST or OCT result, at least 50% of pregnancies may be safely allowed to continue 1 week or more.¹⁹ Few centers use either of these tests as a first-line method to assess fetal well-being in high-risk pregnancies. The primary residual role for OCT may be in facilitating a trial of labor in patients with third-trimester growth restriction.

DOPPLER ULTRASOUND

In the overall context of fetal evaluation, Doppler velocimetry allows assessment of placental status and, therefore, helps to place other testing results in context as well as helping to determine the relative risk of sudden fetal deterioration.⁵² For example, Doppler categories of risk can help to determine the frequency of BPP testing (Table 32-4). Extreme Doppler abnormalities may indicate intervention, but Doppler is not used in isolation or in all clinical contexts, and evaluation of fetal status using all available tools is important to avoid unnecessary iatrogenic prematurity, in utero deterioration, or stillbirth.

Umbilical artery Doppler in particular provides insight into the fetal aspects of placentation, reflecting placental vascular resistance. These findings strongly correlate with fetal growth restriction and multiple critical fetal and neonatal outcome characteristics, progressively worsening as reduction, loss, and

TABLE 32.4 Doppler Abnormality Dictates Frequency of Biophysical Profile Scoring*

Abnormality [†]	BPP Frequency [‡]	Decision to Deliver (Fetal) [§]
Elevated indices only	Weekly	Abnormal BPP or term or >36 wk with no fetal growth
AEDV	Twice weekly	Abnormal BPP or >34 wk of proven maturity
REDV	Daily	Conversion to REDV
REDV-UVP	Three times daily	Any BPP <10/10 [¶] or >32 wk of dexamethasone given
		Any BPP <10/10 [¶] or >28 wk of dexamethasone given

*The biophysical profile (BPP) determines management. Must be viable to enter: >25 weeks' gestation, >500 g, normal anatomy, normal karyotype.

[†]Umbilical artery and complete venous-tree Doppler; cerebralization of blood flow confirms umbilical artery abnormality as serious but does not directly alter management.

[‡]Minimum testing frequency, which is increased on basis of severity, based on maternal conditions, degree of IUGR, gestation.

[§]Neonatal consultation, maternal condition or instability, and direct fetal parameter by cordocentesis impact this decision.

^{||}Any BPP ≤4/10, or 8/10-oligo, or repeated 6/10.

[¶]BPP of 8/10 with cyclic absence of FBM is the only exception, in which case, repeat BPP in less than 6 hr.

AEDV, absent end-diastolic velocity; FBM, fetal breathing movement; IUGR, intrauterine growth restriction; oligo, oligohydramnios; REDV, reversed end-diastolic velocity; UVP, umbilical venous pulsations.

reversal of diastolic flow in a deteriorating sequence. As umbilical artery abnormalities advance, direct assessment of the fetal circulation using a combination of systemic arterial and venous Doppler waveforms (middle cerebral artery [MCA] and precordial veins, respectively), can be helpful in accurately depicting fetal status. These Doppler techniques can be combined efficiently in the context of a regular fetal assessment examination. Doppler information from all of these sources (i.e., placental, systemic arterial, and systemic venous), coupled with biophysical variables, provides a multifaceted assessment of fetal status. The use of multiple variables is particularly useful in the assessment of the preterm fetus.

Fetal Doppler Velocimetry

Although most literature and evidence is focused on umbilical artery velocimetry, placental and fetal systemic Doppler studies may be helpful to assess the compromised fetus.⁵³

Umbilical Artery

Hemodynamics. The umbilical arteries arise from the common iliac arteries and represent the dominant outflow of the distal aortic circulation. Because there are no somatic branches after their origin, the umbilical arteries purely mirror the downstream resistance of the placental circulation. Normal umbilical artery resistance falls progressively through pregnancy, reflecting the increased numbers of tertiary stem villous vessels (Fig. 32-6).⁵⁴ In several pathologic conditions, including preeclampsia and chronic hypertension, increased resistance in the umbilical arteries represents pruning of the placental arterial tree.⁵⁵ In the sheep model, infarction of multiple small vessels by infusing microspheres can be titrated to induce precise rises in umbilical artery resistance.^{56,57} As umbilical artery resistance

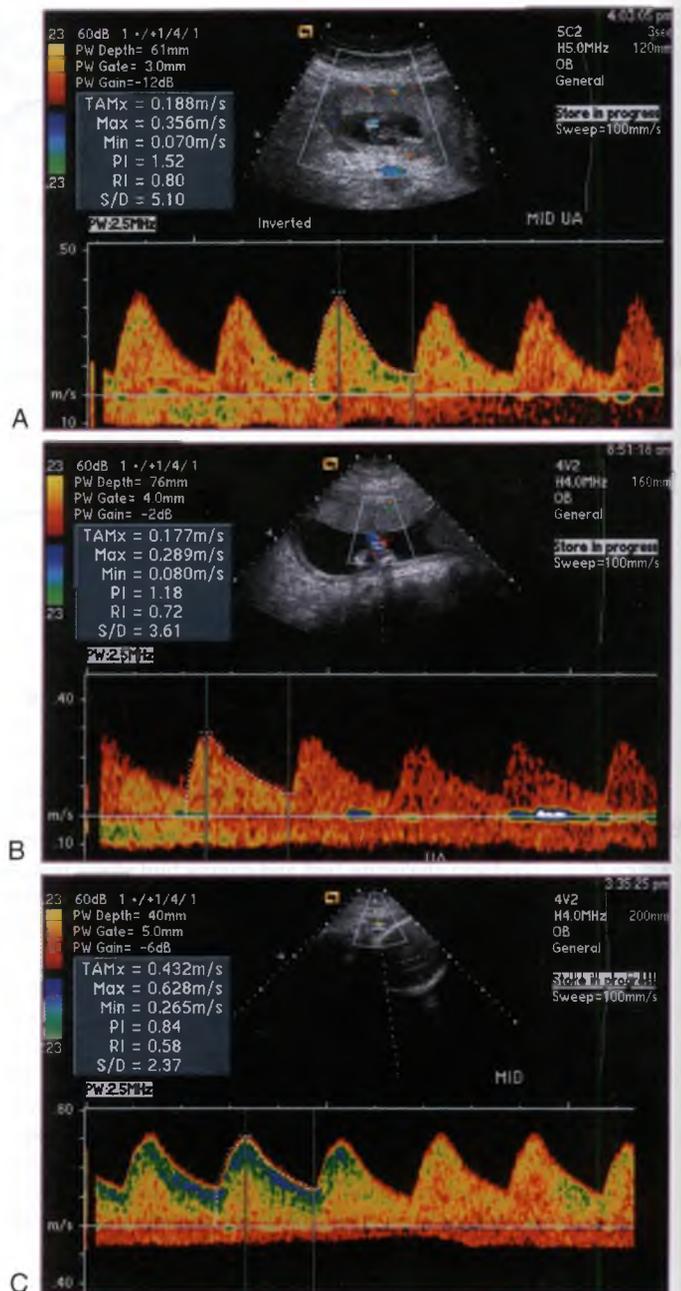

Figure 32-6 Evolution of normal umbilical artery resistance measured in the middle of the cord. Although there is an increase in diastolic velocities and a corresponding gradual decline in the systolic-to-diastolic ratio from the first to third trimester (A to C), diastolic flow in the earlier waveform is already well developed.

rises (Fig. 32-7), diastolic velocities fall and ultimately become absent (i.e., absent end-diastolic velocity [AEDV]).⁵⁶ As resistance rises even further, an elastic component is added, which induces reversed end-diastolic velocity (REDV) as the insufficient, rigid placental circulation recoils after being distended by pulse pressure.⁵⁸ Similar progression can be observed in the fetus with progressive placental dysfunction.

Measurement. The ultrasound beam sample gate is enlarged to encompass the entire vessel and to sample a single umbilical artery.⁵⁹ Because the Doppler index is calculated as a ratio of

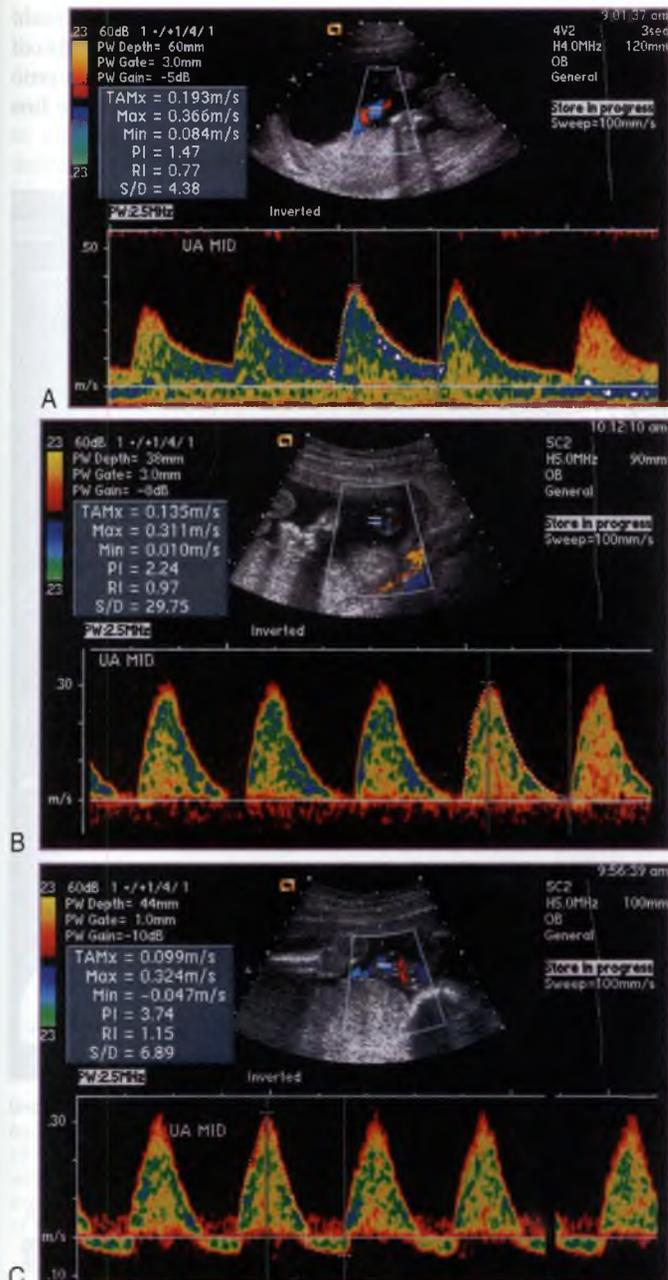

Figure 32-7 Progressive abnormality of umbilical artery resistance. Although initially almost normal at 18 weeks (pulsatility index = 1.47) (A), by 24 weeks (B), the umbilical artery shows absent end-diastolic velocities, which progressed to reversal of flow for 25% of the cardiac cycle (C). The infant had an umbilical venous pH of 7.18 after nonlabored cesarean section. All measurements were made in the middle of the cord.

the systolic and diastolic measurements, they are independent of the angle of insonation; however, minimizing the angle of insonation optimizes the waveform and maximizes accuracy. There is no established standard for where along the course of the umbilical artery the definitive evaluation should be made, although a free loop of cord in the midsection usually is chosen. Accurate measurement of the umbilical artery Doppler is complicated by fetal breathing or fetal movement and is optimally done when the fetus is at rest.

BOX 32-1 ABNORMAL UMBILICAL ARTERY DOPPLER PREDICTS ADVERSE OUTCOMES*

- Cesarean section for fetal distress
- Acidosis
- Hypoxemia
- Low Apgar score
- Ventilator required
- Long-term oxygen
- Bronchopulmonary dysplasia
- Anemia
- Increased number of nucleated red blood cells (NRBCs)
- Thrombocytopenia
- Prolonged NRBC release
- Neutropenia
- Transfusions required
- Intraventricular hemorrhage
- Necrotizing enterocolitis
- Perinatal mortality

*The frequency of all of these outcomes rises exponentially from abnormal indices to absent end-diastolic velocities to reversed end-diastolic velocities.

Clinical Significance. Umbilical artery Doppler is beneficial in the management of high-risk pregnancies, especially those complicated by fetal growth restriction and placental insufficiency due to preeclampsia or maternal conditions.^{60,61} In contrast, routine implementation of Doppler assessment of the umbilical artery has not been beneficial in low-risk pregnancies.⁶²

The most important prognostic feature of the umbilical artery waveform is the end-diastolic flow. Absent flow and reversed flow represent progressively ominous findings necessitating close monitoring or consideration of delivery based on the gestational age.⁶³ AEDV may exist in equilibrium over a long period, particularly in the very preterm fetus, but in many fetuses, AEDV is not stable and will progress to REDV over time.

Absent or reversed end-diastolic flow is associated with adverse perinatal outcomes, including increased perinatal mortality and a higher prevalence of aneuploidy and congenital anomalies. Even corrected for congenital anomalies and aneuploidy, the perinatal mortality rate may be as high as 340 per 1000 births.⁶⁴ The finding of absent or reversed diastolic flow at any gestational age is an indication to make preparations for delivery, including appropriate referral to a tertiary care center if needed, administration of antenatal steroids, and detailed maternal evaluation. Because up to 20% of such fetuses have malformations or aneuploidy, a diligent review of fetal anatomy and, in some cases, invasive testing for fetal karyotype are indicated. Although amniocentesis may seem invasive, knowledge of an abnormal fetal karyotype may help to avoid maternal morbidity due to cesarean section.

Beyond 34 weeks, the finding of persistent absent diastolic flow, most likely due to uteroplacental insufficiency, is an indication for delivery. Before 34 weeks, management may be individualized to incorporate multivariable fetal assessment and estimates of the ultimate perinatal prognosis. Infants who had AEDV due to placental insufficiency as fetuses are at risk for many neonatal complications from asphyxial events before and after delivery and the consequences of prematurity (Box 32-1).⁶⁵⁻⁶⁷ REDV is frequently an unstable clinical state that may precede fetal death by only hours to days. If REDV is discovered

on the first evaluation (e.g., on referral for evaluation of clinical IUGR), the progression for an individual fetus is difficult to determine. If the BPP is normal and amniotic fluid is adequate, there are no decelerations identified on the NST, and venous Doppler measurements are normal, there may be time to administer antenatal steroids before delivery. Because REDV is often associated with very significant abnormality of cerebral and venous circulations, it is associated with the highest frequency of fetal compromise, neonatal complications, perinatal mortality, and perinatal morbidity. Reducing the superimposed effects of prematurity on these infants optimizes the rate of intact survival.⁶⁸

Middle Cerebral Artery

Hemodynamics. The MCA is short, straight, and uniformly positioned relative to the fetal skull and other intracranial landmarks. Doppler measurements taken from this vessel are more reproducible than those taken from other vascular beds and have few collateral circulatory influences while representing a critical component of the fetal circulation. Because the Doppler angle can be minimized, direct interpretation of the peak systolic velocity can be used to evaluate the absolute speed of blood flow, which has direct application in fetal anemia.⁶⁹ As the fetal hematocrit falls and oxygen-carrying capacity of the blood falls, cardiac output increases, and transaortic velocities increase. The MCA offers an ideal location for direct interpretation of this increase in velocity as a decline in the fetal hematocrit (Fig. 32-8).

Placental insufficiency may alter peak systolic velocity in some fetuses by anemia or transmitted hypertension, or both, but the key MCA abnormality expressed by the compromised fetus is centralization.^{70,71} This increase in diastolic velocities represents increased brain blood flow (Fig. 32-9). A significant question is whether such changes are compensatory (i.e., parenchymal vasodilation by active mechanisms) or involuntary (i.e., increased shunting of blood away from somatic circulations under the force of hypertension dictated by accelerating placental vascular resistance). As fetal compromise progresses, both mechanisms may be at work. Cerebral blood flow as depicted by the MCA may be responsive to a number of stimuli, including maternal administration of oxygen (i.e., increased resistance),⁷² carbon dioxide (i.e., decreased resistance),⁷³ or nicotine (i.e., increased resistance and lack of responsiveness).⁷⁴ These

changes may occur gradually, indicated by subtle alterations in the cerebroplacental ratio, which reflects the calculated ratio of resistance indices in the MCA and umbilical artery. This ratio changes in response to redistribution of blood flow, the first stage of brain sparing.⁷⁵

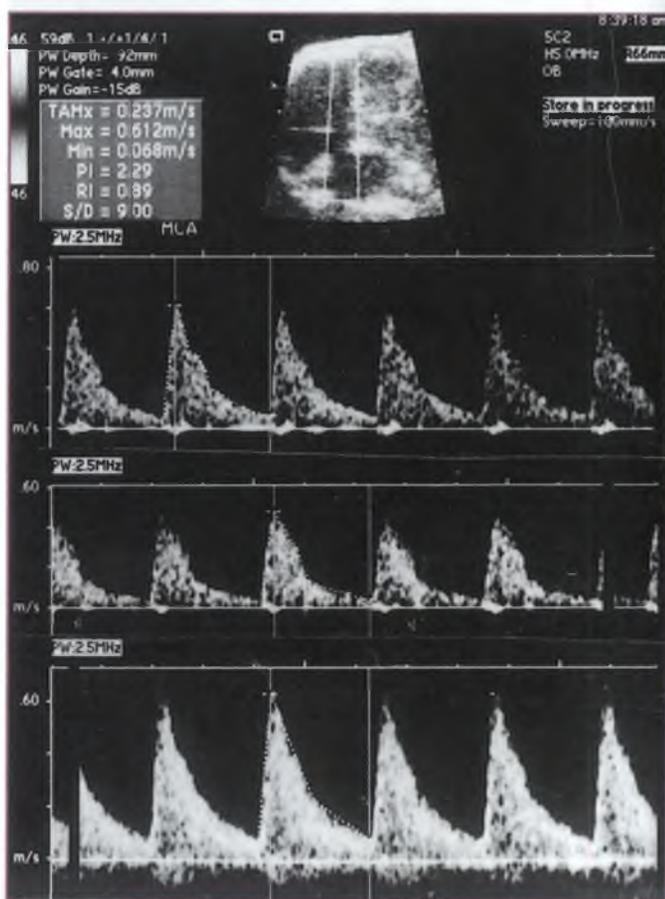

Figure 32-8 The peak systolic velocity (PSV) in the middle cerebral artery (MCA) reflects fetal hematocrit accurately. This fetus had serious anti-D isoimmune anemia. Before transfusion (top), an MCA PSV of 60 cm/sec accurately predicted anemia (hematocrit of 19.0). After intrauterine transfusion, the MCA peak fell to 41 cm/s as the hematocrit rose to 44.0. Before the next transfusion (bottom), the MCA rose to 62 cm/s, and the hematocrit fell to 20.0.

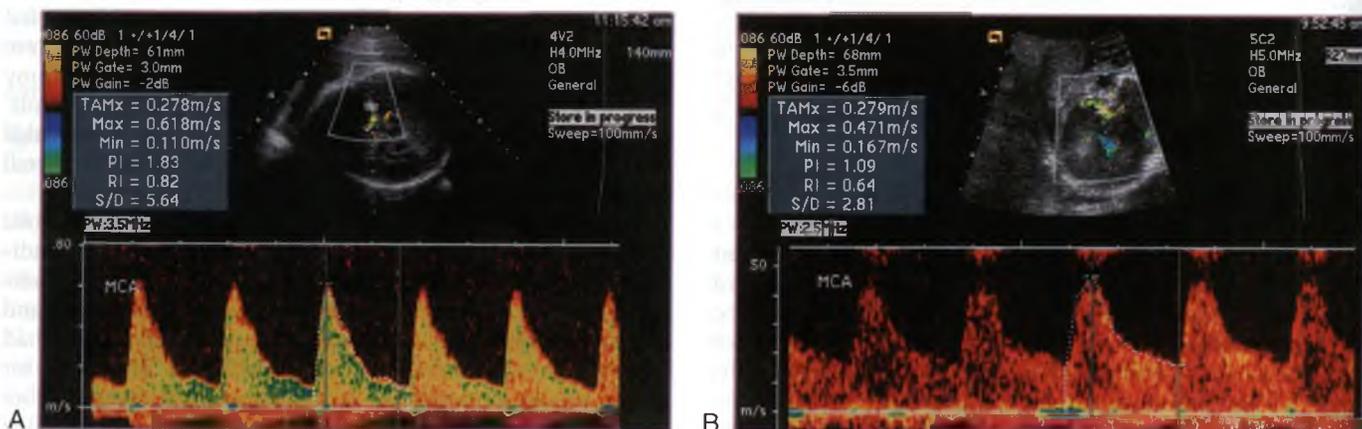

Figure 32-9 Centralization of blood flow. A, Normal middle cerebral artery (MCA) shows high resistance and low diastolic velocities. B, As placental resistance rises, brain blood flow increases, with falling resistance and increased diastolic velocities in the MCA.

Measurement. The ideal location for Doppler assessment of the MCA is 2 mm after its origin from the internal carotid.⁷⁶ As demonstrated in Figures 32-8 and 32-9, the gate is opened to encompass the vessel, and short periods of insonation are used to minimize the amount of direct multifocal ultrasound delivered to the fetal brain. Most authorities recommend that fetal MCA velocimetry should not be performed in the first trimester.

Clinical Significance. As IUGR worsens and compensatory mechanisms take place, MCA diastolic velocities rise. This centralization continues to increase in most fetuses with AEDV and in many with REDV.⁶³ At the point when REDV and fetal hypoxemia result in cardiac decompensation, MCA diastolic velocities may fall, returning to an apparently high-resistance pattern because cardiac output is no longer sufficient to force blood into the fetal circulation; fetal cerebrovascular tone and fetal brain edema are thought to contribute to this pattern. The reversion resulting from heart failure has been called *normalization*, and it is an ominous sign.⁷⁷ However, the MCA diastolic velocity is not independently predictive of fetal outcome. Doppler measurement of the vessel provides additional information to add to the clinical picture rather than dictating clinical management by itself.⁷⁸

Fetal Venous Doppler Studies

Ductus Venosus. The ductus venosus is a sharply tapered conduit that shunts blood from the proximal umbilical vein directly into the inferior vena cava (IVC) at its connection to the right atrium. Its hourglass shape regulates inflow to the central circulation through a narrow aperture that is constricted in the healthy near-term fetus, allowing only 20% of umbilical venous return into the right atrium. Because of fluid dynamics (i.e., Venturi effect), this narrow jet delivers highly oxygenated blood at high velocity directly to the foramen ovale, keeping it open and promoting right-to-left shunting of this nutrient-rich stream. In healthy fetuses, the ductus venosus regulates the distribution of oxygen and placental nutrients by restricting the centralization of flow.

The high-velocity flow through the ductus venosus makes it easy to identify with color flow Doppler imaging. When this short vessel is identified, Doppler insonation and depiction of the characteristic waveform (Fig. 32-10A) can be performed. The reflected wave seen in the ductus venosus waveform represents the impact of cardiac actions (analogous to the adult jugular venous waveform). The phases of the ductus venosus correspond to cardiac events (see Fig. 32-10B). During atrial systole, reduction in forward flow always occurs, producing the

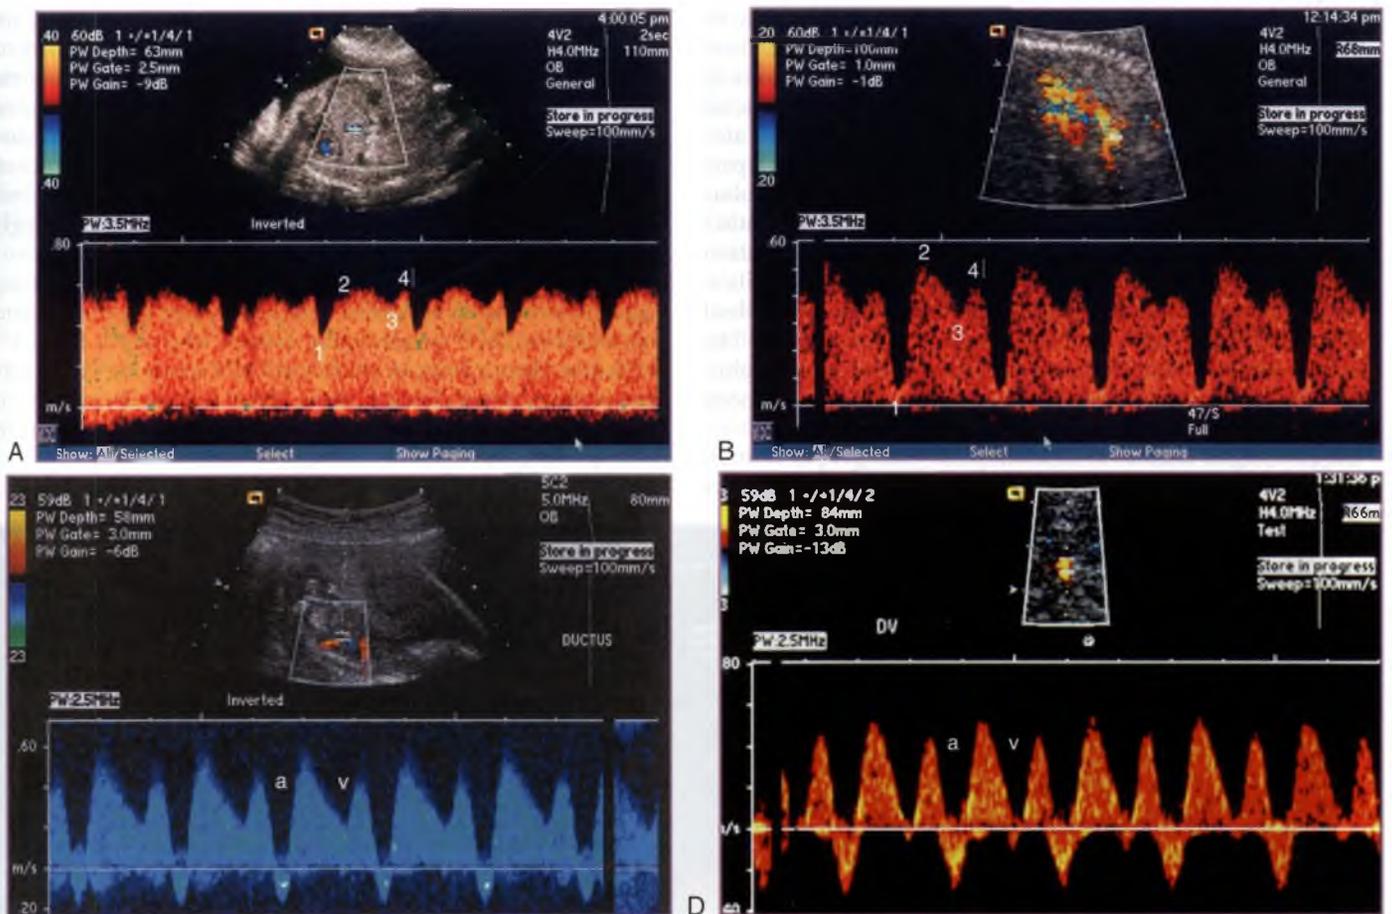

Figure 32-10 Ductus venosus waveforms. A, Normal four-phase waveform (1, atrial contraction, called an a-wave; 2, ventricular systole; 3, ascent of annulus; 4, diastole) with the a-wave showing only modest normal reduction in forward flow. B, In fetuses with growth restriction, increased afterload (from placental resistance) is reflected in the heart as markedly abnormal cardiac function, with an almost retrograde a-wave. C, Cardiac effects are reflected distally. Notice the retrograde a-wave and cardiac function producing distortion of v-descent (compare with 3 in a normal waveform). D, Severe cardiac decompensation results in both phases being negative.

most notable characteristic of this waveform, the a-wave. The a-wave becomes progressively deeper as high afterload develops as a result of adverse placental. It is further magnified as poor cardiac function superimposes (i.e., with hydrops, viral infection, or severe anemia) or as severe placental resistance results in respiratory dysfunction and direct hypoxemia. A retrograde a-wave (see Fig. 32-10C) signifies the onset of significant cardiac impairment. When cardiac function deteriorates toward preterminal pump failure, dramatic changes occur in the atrial and ventricular phases of the ductus venosus (see Fig. 32-10D).

The ductus venosus offers dual insights into oxygen-regulated flow and cardiovascular function. Multiple venous systems have been studied, and there is no statistical basis for choosing the IVC, umbilical vein within the free abdomen, or other venous index over the ductus venosus for accuracy in predicting fetal compromise. Only the ductus venosus can actively dilate with hypoxemia, an added benefit that supports its use. These factors and the ease of identification throughout gestation make the ductus venosus the precordial vein of choice.

Umbilical Vein. Pulsations in the umbilical vein occur for several reasons.⁷⁹ During FHR accelerations, temporary pulsation may reflect increased cardiac dynamic action. If the cord is tightly coiled around the body or limb or temporarily constricted by fetal position, umbilical venous pulsations may be documented. It is important to retain the context of these observations, because a series of umbilical vein pulsations in isolation or umbilical venous pulsations with a normal ductus venosus waveform are of uncertain significance. There is also the possibility of specific vascular anomalies, including a partially occluded or absent ductus venosus. Although the pulsation pattern has been suggested as a discriminator,⁸⁰ other investigators have not been able to duplicate this correlation (Fig. 32-11). Many groups have demonstrated that umbilical venous pulsations are an ominous finding and frequently lead to intrauterine demise or serious neonatal compromise. The lack of standard definitions means that there are many false-positive results, and action based solely on umbilical venous pulsations is unwarranted.

Other Veins. The IVC shares some characteristics with the ductus venosus but is not easily interpreted. Because it is normal to have a retrograde a-wave in the IVC, meticulous measurement of the venous resistance index is required. The IVC does not vary with hypoxemia, and reflection distally cannot be inferred as a marker for sequential fetal compromise. Similar observations can be obtained from cerebral veins, hepatic veins, or regional veins. All the precordial veins are involved in the fetal responses to hypoxemia.⁸¹ The apparent ease of measurement of the ductus venosus, its physiologic characteristics, and its association with outcome make it the most clinically useful vein.
