The only nutrition-related laboratory testing needed by most pregnant women is a hematocrit or hemoglobin measurement to screen for anemia. Because of the physiologic anemia of pregnancy, the reference values for hemoglobin and hematocrit must be adjusted during pregnancy. The lower limit of the normal range for hemoglobin during pregnancy is 11 g/dl in the first and third trimesters and 10.5 g/dl in the second trimester (compared with 12 g/dl in the nonpregnant state). The lower limit of the normal range for hematocrit is 33% during the first and third trimesters and 32% in the second trimester (compared with 36% in the nonpregnant state) (CDC, 2011). Diagnostic values for anemia are higher in women who smoke or live at high altitudes because the decreased oxygen carrying capacity of their RBCs causes them to produce more RBCs than other women produce.

A woman's history or physical findings can indicate the need for additional testing. These tests might include a complete blood cell count with a differential to identify megaloblastic or macrocytic anemia and measurement of levels of specific vitamins or minerals believed to be lacking in the diet.

Nutritional Care and Teaching

For many women with uncomplicated pregnancies, the nurse serves as the primary source of nutrition education. The registered dietitian, who has specialized training in diet evaluation and planning, nutritional needs during illness, ethnic and cultural food patterns, as well as translating nutrient needs into food patterns, frequently serves as a consultant. Pregnant women with serious nutritional problems, those with intervening illnesses such as diabetes (either preexisting or gestational), and any others requiring in-depth dietary counseling should be referred to the dietitian. The nurse, dietitian, physician, and certified nurse-midwife collaborate in helping the woman achieve nutrition-related expected outcomes. Nutritional care and teaching generally involve:

TABLE 15-6 Physical Assessment of Nutritional Status

SIGNS OF GOOD NUTRITION	SIGNS OF POOR NUTRITION
General Appearance Alert, responsive, energetic, good endurance	Listless, apathetic, cachectic, easily fatigued, looks tired
Muscles Well developed, firm, good tone, some fat under skin	Flaccid, poor tone, tender, "wasted" appearance
Gastrointestinal Function Good appetite and digestion, normal regular elimination, no palpable organs or masses	Anorexia, indigestion, constipation or diarrhea, liver or spleen enlargement
Cardiovascular Function Normal heart rate and rhythm, no murmurs, normal blood pressure for age	Rapid heart rate, enlarged heart, abnormal rhythm, elevated blood pressure
Hair Shiny, lustrous, firm, not easily plucked, healthy scalp	Stringy, dull, brittle, dry, thin and sparse, depigmented, can be easily plucked
Skin (General) Smooth, slightly moist, good color	Rough, dry, scaly, pale, pigmented, irritated, easily bruised, petechiae
Face and Neck Skin color uniform, smooth, pink, healthy appearance; no enlargement of thyroid gland; lips not chapped or swollen	Scaly, swollen, skin dark over cheeks and under eyes, lumpiness or flakiness of skin around nose and mouth; thyroid enlarged; lips swollen, angular lesions or fissures at corners of mouth
Oral Cavity Reddish pink mucous membranes and gums; no swelling or bleeding of gums; tongue healthy pink or deep red in appearance, not swollen or smooth, surface papillae present; teeth bright and clean, no cavities, no pain, no discoloration	Gums spongy, bleed easily, inflamed or receding; tongue swollen, scarlet and raw, magenta color, beefy, hyperemic and hypertrophic papillae, atrophic papillae; teeth with unfilled caries, absent teeth, worn surfaces, mottled
Eyes Bright, clear, shiny, no sores at corners of eyelids, membranes moist and healthy pink color, no prominent blood vessels or mound of tissue (Bitot spots) on sclera, no fatigue circles beneath	Eye membranes pale, redness of membrane, dryness, signs of infection, redness and fissuring of eyelid corners, dryness of eye membrane, dull appearance of cornea, blue sclerae
Extremities No tenderness, weakness, or swelling; nails firm and pink	Edema, tender calves, tingling, weakness; nails spoon-shaped, brittle
Skeleton No malformations	Bowlegs, knock-knees, chest deformity at diaphragm, beaded ribs, prominent scapulae

- Educating the woman about nutritional needs during pregnancy and the components of an adequate diet, if necessary
- Helping her individualize her diet so that she achieves an adequate intake while conforming to her personal, cultural, financial, and health circumstances

- Discussing with her strategies for coping with the nutrition-related discomforts of pregnancy
- Helping her use nutrition supplements appropriately
- Consulting with and making referrals to other professionals or services as indicated

For women with limited financial resources, two programs in the United States provide nutrition services: the Supplemental Nutrition Assistance Program (SNAP or food stamps) and the Special Supplemental Nutrition Program for Women, Infants and Children (WIC), which provides vouchers for selected foods for pregnant and lactating women as well as for infants and children at nutritional risk. WIC foods include items such as eggs, milk (or cheese, soy milk, or tofu), juice, fortified cereals, legumes, and peanut butter. WIC participants receive nutrition counseling, and the program encourages breastfeeding.

Nutrition counseling can take place in a one-on-one interview or in a group setting. In either case, teaching should emphasize the importance of choosing a varied diet composed of readily available foods (rather than specialized diet supplements) (see the Nursing Care Plan). Good nutrition practices (and avoidance of poor practices such as smoking and alcohol or drug use) are essential content for prenatal classes designed for women in early pregnancy.

Daily Food Guide and Menu Planning. MyPlate (www.choosemyplate.gov) can be used as a guide to making daily food choices during pregnancy and lactation, just as it is during other stages of the life cycle. A woman can create a profile, and the MyPlate program will generate an individualized daily food plan. Additional individualized information and resources for professionals are available from the website. The importance of consuming adequate amounts from the milk, yogurt, and cheese group should be emphasized, especially for adolescents

NURSING CARE PLAN

Nutrition During Pregnancy

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Deficient Knowledge related to nutritional requirements during pregnancy</i>	Woman will describe nutritional requirements and exhibit evidence of incorporating requirements into her diet.	Review basic nutritional requirements for healthy diet by using recommended dietary guidelines and MyPlate.	To provide knowledge baseline for discussion
		Discuss increased nutrient needs (calories, protein, minerals, vitamins) that occur as the result of being pregnant.	To increase knowledge needed for altered dietary requirements
		Discuss relation between weight gain and fetal growth.	To reinforce interdependence of fetus and mother
		Calculate appropriate total weight gain range during pregnancy using woman's body mass index as a guide, and discuss recommended rates of weight gain during various trimesters of pregnancy.	To provide concrete measures of dietary success
		Review food preferences, cultural eating patterns or beliefs, and prepregnancy eating patterns.	To enhance integration of new dietary needs
		Discuss how to fit nutritional needs into usual dietary patterns and how to alter any identified nutritional deficits or excesses.	To increase chances of success with dietary alterations
		Discuss food aversions or cravings that can occur during pregnancy and strategies to deal with these if they are detrimental to the fetus (e.g., pica).	To ensure well-being of fetus
		Have woman keep a food diary delineating eating habits, dietary alterations, aversions, and cravings.	To track eating habits and potential problem areas

Nutrition During Pregnancy

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<p><i>Imbalanced Nutrition: Less Than Body Requirements related to inadequate intake of needed nutrients</i></p>	<p>Woman's weekly weight gain will be increased to appropriate rate using her body mass index (BMI) and recommended weight gain ranges as guidelines.</p>	<p>Review recent diet history (including food aversions) using food diary, 24-hour recall, or food frequency approach.</p> <p>Review normal activity and exercise routines and discuss eating patterns and reasons that lead to decreased food intake (e.g., morning sickness, pica, fear of becoming fat, stress, boredom).</p> <p>Review optimal weight gain guidelines and their rationale.</p> <p>Set target weight gains for remaining weeks of pregnancy.</p> <p>Review increased nutrient needs (calories, protein, minerals, vitamins) that occur as the result of being pregnant.</p> <p>Review relation between weight gain and fetal growth.</p> <p>Discuss with woman what changes can be made in diet, activity, and lifestyle.</p> <p>If woman has fear of being fat, if symptoms of eating disorder are evident, or if problems in adjusting to changing body image surface, refer her to appropriate mental health professional for evaluation.</p>	<p>To ascertain dietary inadequacies contributing to insufficient weight gain</p> <p>To determine level of energy expenditure and to identify habits that contribute to inadequate weight gain</p> <p>To ensure that woman is knowledgeable about healthful weight gain rates</p> <p>To establish set goals</p> <p>To ensure woman is knowledgeable about altered dietary requirements</p> <p>To reinforce that adequate weight gain is needed to promote fetal well-being</p> <p>To enhance chances of meeting set weight gain goals and nutrient needs of mother and fetus</p> <p>Because intensive treatment and follow-up may be required to ensure fetal health</p>
<p><i>Nausea related to physiologic alterations of first trimester of pregnancy</i></p>	<p>Nausea will not be so severe that it interferes with adequate nutrient intake or substantially reduces quality of life.</p>	<p>Assess state of hydration and assess pattern of weight gain during pregnancy.</p> <p>Review nausea history (i.e., frequency of episodes of nausea, likelihood of nausea progressing to vomiting, factors precipitating or associated with nausea, and any relief measures that woman has tried).</p> <p>Review measures for prevention or relief of nausea and vomiting (morning sickness).</p> <p>Discuss with woman what relief measures she will try.</p>	<p>To ensure that woman does not have deficient fluid volume; to ensure that nausea is not preventing adequate energy intake</p> <p>To determine severity of problem and to begin to identify effective and ineffective measures for coping with nausea</p> <p>To ensure that woman is knowledgeable about measures that are often effective in alleviating morning sickness</p> <p>To determine whether she understands how to implement measures</p>

and women younger than 25 years, who are still actively adding calcium to their skeletons; adolescents need at least three or four servings from the milk group daily.

The daily food plan in Table 15-4 is consistent with MyPlate and can be used for educating women about nutritional needs during pregnancy and lactation. This food plan is general enough to be used by women from a wide variety of cultures, including those who follow a vegetarian diet. The nurse or dietitian can help the woman plan daily menus that follow the food plan and are affordable, have realistic preparation times, and are compatible with personal preferences and cultural practices. Women who follow a healthy eating pattern before and during pregnancy reduce their risk of developing complications such as gestational diabetes (Asemi, Tabassi, Samimi, et al., 2013; Tobias, Zhang, Chavarro, et al., 2012). A healthy pattern emphasizes intake of whole grains; fruits and vegetables; low-fat dairy products; nuts, seeds, and legumes; and lean meats, poultry, and fish while limiting intake of solid fats, fatty or processed meats, and sweets.

Food Safety. Food-borne illnesses can cause adverse maternal and fetal effects. The woman's understanding of safe food-handling practices should be assessed. The nurse can provide simple instructions that are essential to preventing food-borne illnesses. According to the FDA (2013d), there are four simple steps:

- **Clean:** Cleanse hands, food preparation surfaces, and utensils frequently.
- **Separate:** Avoid contact between raw meat, fish, or poultry and other foods that will not be cooked before consumption.
- **Cook:** Cook foods to a proper temperature.
- **Chill:** Store foods properly and refrigerate promptly.

Pregnant women have altered immune function that places them at increased risk for developing food-borne illnesses such as listeriosis and toxoplasmosis that can cause maternal illness, miscarriage, and severe fetal effects such as cognitive impairment, hearing loss, blindness, or death. To prevent listeriosis, foods that should be avoided altogether during pregnancy include soft cheeses made from unpasteurized milk, including Brie, feta, Camembert, Roquefort, queso blanco, and queso fresco; raw cookie dough and cake batter; sushi, raw oysters, and other raw or undercooked fish and seafood; unpasteurized juice and cider, including fresh squeezed; unpasteurized milk; raw or undercooked sprouts; and ham, chicken, or seafood salads and similar products that are made in a store. Even if they are labeled as ready to serve, these foods should be thoroughly cooked if they are to be consumed during pregnancy: hot dogs, luncheon meats, cold cuts, fermented or dry sausage, and other deli-style meat and poultry; eggs; fresh meat, poultry, and fish; poultry stuffing (preferably bake in a separate dish, rather than inside the bird); and refrigerated smoked seafood, meat paste, or pâté (canned versions can be consumed). To prevent infection from *Salmonella* and *Campylobacter*, pregnant women should not consume raw eggs, raw milk, and raw or undercooked meats; commercial products with pasteurized eggs and milk may be used. Women can develop toxoplasmosis from eating raw or undercooked meat or from using utensils or cutting boards that were in contact with raw meat; toxoplasmosis can result from contact with contaminated cat feces or garden soil (FDA, 2013a, b, and c; Hark & Catalano, 2012).

Medical Nutrition Therapy. During pregnancy and lactation the food plan for women with special medical nutrition therapy may have to be modified. The registered dietitian can instruct these women about their diets and assist them in meal planning. However, the nurse should understand the basic principles of the diet and be able to reinforce the teaching.

The nurse should be especially aware of the dietary modifications necessary for women with diabetes mellitus (either gestational or preexisting). This disease is relatively common, and fetal morbidity and mortality occur more often in pregnancies complicated by hyperglycemia or hypoglycemia (see discussion of diabetes in Chapter 29). Every effort should be made to maintain blood glucose levels in the normal range throughout pregnancy. The food plan of the woman with diabetes usually includes four to six meals and snacks daily, with the daily carbohydrate intake distributed fairly evenly among the meals and snacks. The complex carbohydrates—fibers and starches—should be well represented in the diet. To maintain strict control of the blood glucose level, the pregnant woman with diabetes usually must monitor her own blood glucose daily.

Nutrition-Related Concerns During Pregnancy. It is important for the pregnant woman to understand the need for adequate weight gain during pregnancy and to be able to evaluate her own gain in terms of the desirable pattern. Many women, particularly those who have worked hard to control their weight before pregnancy, find it difficult to understand why the weight gain goal is so high when a newborn infant is so small. The nurse can explain that maternal weight gain consists of increases in the weight of many tissues, not just the growing fetus (see Table 15-3).

Dietary overindulgence, which can result in excessive fat stores that persist after giving birth, should be discouraged. Nevertheless, it is best not to focus solely on weight gain

TEACHING FOR SELF-MANAGEMENT

Iron Supplementation

- A diet rich in vitamin C (in citrus fruits, tomatoes, melons, and strawberries) and heme iron (in meats) increases the absorption of iron supplements; therefore, include these in the diet often.
- Bran, tea, coffee, milk, oxalates (in spinach and Swiss chard), and egg yolk decrease iron absorption. Avoid consuming them at the same time as the iron supplement.
- Iron is absorbed best if it is taken when the stomach is empty, so it is best to take it between meals with a beverage other than tea, coffee, or milk.
- Iron may be taken at bedtime if abdominal discomfort occurs when it is taken between meals.
- If an iron dose is missed, take it as soon as it is remembered if that is within 12 hours of the scheduled dose. Do not double up on the dose.
- Keep the supplement in a childproof container and out of the reach of any children in the household.
- The iron can cause stools to be black or dark green. This is normal.
- Constipation is common with iron supplementation. A diet high in fiber with adequate fluid intake (about 8 to 10 glasses [2 L] of fluids daily) will help to avoid constipation.

because this can result in feelings of stress and guilt in the woman who does not follow the preferred pattern of gain; instead, the nurse emphasizes a healthy diet plan. Teaching regarding weight gain during pregnancy is summarized in Table 15-2.

Iron Supplementation. The nutrition supplement most commonly needed during pregnancy is iron. However, a variety of dietary factors can affect the completeness of absorption of an iron supplement, and some women experience discomfort when taking the supplement. The Teaching for Self-Management box: Iron Supplementation summarizes important points regarding iron supplementation.

Nutrition-Related Discomforts of Pregnancy

Nausea and Vomiting. Nausea and vomiting of pregnancy (NVP) is most common during the first trimester. Usually NVP causes only mild to moderate problems nutritionally, although it can be a source of substantial discomfort. The pregnant woman may find the suggestions in Box 15-6 helpful in alleviating NVP. Antiemetic medications, vitamin B₆, ginger, and P6 acupressure may be effective in reducing the severity of nausea.

SAFETY ALERT

Ginger has anticoagulant properties and should be avoided by women receiving anticoagulant therapy or other drugs or herbal agents that can prolong clotting time (Tiran, 2012).

Hyperemesis gravidarum, or severe and persistent vomiting causing weight loss, dehydration, and electrolyte abnormalities, occurs in up to 1% of pregnant women (see Chapter 29). Intravenous fluid and electrolyte replacement, enteral tube feeding, and in some instances total parenteral nutrition have been used to nourish women with hyperemesis gravidarum. There is very limited evidence that acupressure and ginger might provide some relief.

Constipation. Improved bowel function generally results from increasing the intake of fiber (e.g., whole grains, fresh fruit, and raw or lightly steamed vegetables). Fiber helps create a bulky stool that stimulates intestinal peristalsis. The recommendation for pregnant women for fiber is 28 g daily. An adequate fluid intake (at least 50 ml/kg/day) helps hydrate the fiber and increase the bulk of the stool. Making a habit of regular physical activity that uses large muscle groups (walking, swimming, water aerobics) also helps stimulate bowel motility. Pregnant women may take psyllium fiber supplements (Hark & Catalano, 2012).

Heartburn. Heartburn, or *pyrosis*, is usually caused by reflux of gastric contents into the esophagus. This condition can be minimized by eating small, frequent meals rather than two or three larger meals daily. Fluids increase the distention of the stomach, so it can help if they are not consumed with foods. The woman needs to drink adequate amounts between meals. Avoiding spicy foods can possibly help alleviate the problem. Reflux can be exacerbated by lying down immediately after eating and wearing clothing that is tight across the abdomen. Walking after eating can aid in reducing heartburn. Use of antacids may be recommended by the health care provider.

Vegetarian Diets. Foods basic to almost all vegetarian diets are vegetables, fruits, legumes, nuts, seeds, and grains, but with many variations. *Lacto-vegetarians* include milk products. *Lacto-ovovegetarians* consume eggs and dairy products in addition to plant products. Strict vegetarians, or *vegans*, consume only plant products. All of these types of vegetarian diets, if well planned, can be nutritionally adequate for pregnant and lactating women. Pregnant women who adhere to vegan diets need to be attentive to their intake of protein, iron, calcium, and vitamin B₁₂.

Plant proteins tend to be “incomplete,” in that they lack one or more amino acids required for growth and the maintenance of body tissues. However, consuming a variety of different plant proteins—grains, dried beans and peas, nuts, and seeds—on a daily basis can provide all of the essential amino acids. Because vitamin B₁₂ is found naturally only in foods of animal origin, the vegan diet is deficient in vitamin B₁₂. As a result, strict vegetarians should take a supplement or regularly consume vitamin B₁₂-fortified foods such as fortified plant milks two or three times a day. Vitamin B₁₂ deficiency can result in megaloblastic anemia, glossitis (inflamed red tongue), and neurologic deficits in the mother. Infants born to affected mothers are likely to have megaloblastic anemia and exhibit neurodevelopmental delays. The diet should be carefully planned to include adequate

BOX 15-6 Suggestions for Managing Nausea and Vomiting During Pregnancy

- Eat dry, starchy foods such as dry toast, melba toast, or crackers on awakening in the morning and at other times when nausea occurs.
- Avoid consuming excessive amounts of fluids early in the day or when nauseated (but compensate by drinking fluids at other times).
- Eat small amounts frequently (every 2 to 3 hours), and avoid large meals that distend the stomach.
- Avoid skipping meals and thus becoming extremely hungry, which can worsen nausea. Have a snack such as cereal with milk, a small sandwich, or yogurt before bedtime.
- Avoid sudden movements. Get out of bed slowly.
- Decrease intake of fried and other fatty foods. Try high-carbohydrate foods such as toast, rice, or potatoes. Some women find high-protein meals or snacks helpful.
- Breathe fresh air to help relieve nausea. Keep the environment well ventilated (e.g., open a window), go for a walk outside, or decrease cooking odors by using an exhaust fan.
- Eat foods served at cool temperatures and foods that give off little aroma. Avoid spicy foods.
- Avoid brushing your teeth immediately after eating.
- Try salty and tart foods (e.g., potato chips or lemonade) during periods of nausea. Sucking a lemon slice may help.
- Try herbal teas such as those made with raspberry leaf or peppermint to decrease nausea.
- Try ginger (ginger-ale soda, ginger tea, ginger snaps, ginger jam on toast).
- Try sucking on flavored lollipops (e.g., Peggie Pops®).
- Wear acupressure bands (seabands) used for motion sickness around the wrist.
- If nausea and vomiting are severe and/or if weight loss occurs, notify your health care provider. Some providers recommend a combination of vitamin B₆ and doxylamine. For more severe problems, other medications may be prescribed. Do not take any medication without consulting your health care provider.

minerals. Iron and zinc may not be as well absorbed from plant foods as they are from meats, and calcium intake can be low if milk products are avoided.

Cultural Influences. Consideration of a woman's cultural food preferences enhances communication and provides a greater opportunity for following the agreed-on pattern of intake. The nurse needs to be aware of what constitutes a typical diet for each cultural or ethnic group present in his or her client population, although variations can occur within a group. Thus a careful exploration of individual preferences is needed. Although ethnic and cultural food beliefs can seem at first glance to conflict with the dietary instruction provided by physicians, nurses, and dietitians, it is often possible for the empathic health care provider to identify cultural beliefs that are congruent with the modern understanding of pregnancy and fetal development. Many cultural food practices have some merit or the culture would not have survived. Food cravings during pregnancy are considered normal by many cultures, but the kinds of cravings often are culturally specific. Cultural influences on food intake usually lessen if the woman and her family become more integrated into the dominant culture.

Nutritional beliefs and the practices of selected cultural groups are summarized in Table 15-7.

Postpartum Nutrition. A nutritionally sound, balanced diet is important in the postpartum period as the woman's body is recovering from birth and going through the normal physiologic changes of the postpartum period (see Chapter 20).

An important goal of postpartum nutrition is for the woman to lose the weight gained during pregnancy and attain a healthy weight. Retaining the weight gained during pregnancy can contribute to overweight and obesity and the development of later health problems including metabolic syndrome, cardiovascular disease, and diabetes. Obese women and normal-weight women who gain more than the recommended amount of weight during pregnancy are less likely to breastfeed than normal-weight women with appropriate weight gain. Obesity is associated with lower breastfeeding initiation rates, decreased duration of breastfeeding, lower milk supply, and delayed onset of lactogenesis II ("milk coming in") (Turcksin, Bel, Galjaard, & Devlieger, 2012).

The woman who does not breastfeed can lose weight gradually if she consumes a balanced diet that provides slightly less

TABLE 15-7 Popular Foods of Various Cultural and Ethnic Groups and Their Place in MyPlate

CULTURAL OR ETHNIC GROUP OR EATING PATTERN	FOOD GROUPS

†Varies widely depending on tribal grouping and locale.

than her daily energy expenditure, although overweight and obese women with excessive weight gain during pregnancy have an increased likelihood of failing to return to their prepregnancy weights (ACOG Committee on Obstetric Practice, 2013). Women should have realistic expectations for weight loss after pregnancy. For some it can take months or years to return to their prepregnancy weight. Postpartum complications such as thyroiditis can interfere with weight loss. A reasonable weight loss goal for nonlactating women is 0.5 to 0.9 kg (1.1 to 2 lb) per week; a loss of 1 kg (2.2 lb) per month is recommended for most lactating women. Those at risk for obesity and overweight need follow-up to ensure that they know how to make wise food choices, primarily from fruits, vegetables, whole grains, lean meats, and low-fat dairy products. An hour of moderately vigorous physical activity (e.g., walking, jogging, swimming, cycling, aerobic dance) most days of the week will improve the woman's ability to lose weight gradually and maintain the weight loss.

Nutrient Needs During Lactation. Nutritional needs during lactation are similar in many ways to those during pregnancy. Needs for energy (calories), protein, calcium, iodine, zinc, the B vitamins (thiamine, riboflavin, niacin, pyridoxine, and vitamin B₁₂), and vitamin C remain greater than nonpregnant needs. The recommendations for some of these (e.g., vitamin C, zinc, and protein) are slightly to moderately higher than during pregnancy (see Table 15-1). This allowance covers the amount of the nutrients released in the milk, as well as the needs of the mother for tissue maintenance. In the case of iron and folic acid, the recommendation during lactation is lower than that during pregnancy. Both of these nutrients are essential for RBC formation and thus for maintaining the increase in the blood volume that occurs during pregnancy. With the decrease in maternal blood volume to nonpregnant levels after birth, maternal iron and folic acid needs also decrease. Many lactating women have a delay in the return of menses, which

also conserves blood cells and reduces iron and folic acid needs. It is especially important that the calcium intake is adequate; if it is not, a supplement of 600 mg of calcium per day may be needed.

According to the IOM, the recommended energy intake for the first 6 months is an increase of 330 kcal more than the woman's nonpregnant intake; this means an average daily intake of approximately 2700 calories (Panel on Dietary Reference Intakes for Macronutrients, IOM, 2005). The AAP recommends that breastfeeding women who are well nourished should add 450 to 500 kcal/day to a balanced diet (AAP Section on Breastfeeding, 2012). Because of the deposition of energy stores, the woman who has gained the optimal amount of weight during pregnancy is heavier after birth than at the beginning of pregnancy. As a result of the caloric demands of lactation, the lactating mother usually experiences a gradual but steady weight loss. Most women rapidly lose several kilograms during the first month after birth, whether or not they breastfeed. After the first month, the average loss during lactation is 0.5 to 1 kg (1.1 to 2.2 lb) a month, and a

woman who is overweight may be able to lose up to 2 kg without decreasing her milk supply.

Fluid intake must be adequate to maintain milk production, but the mother's level of thirst is the best guide to the right amount. There is no need to consume more fluids than those needed to satisfy thirst (Scott, 2013).

Smoking, alcohol intake, and excessive caffeine intake should be avoided during lactation. Smoking not only can impair milk production but also exposes the infant to the risk of passive smoking. It is speculated that the infant's psychomotor development may be affected by maternal alcohol use, and alcohol use may impair the milk-ejection reflex. Caffeine intake can lead to a reduced iron concentration in milk and consequently contribute to the development of anemia in the infant. The caffeine concentration in milk is only approximately 1% of the mother's plasma level, but caffeine levels build up in the infant. Breastfed infants of mothers who drink large amounts of coffee or caffeine-containing soft drinks can be unusually active and wakeful (Scott, 2013).

KEY POINTS

- A woman's nutritional status before, during, and after pregnancy contributes, to a significant degree, to her well-being and that of her developing fetus and newborn.
- Many physiologic changes occurring during pregnancy influence the need for additional nutrients and the efficiency with which the body uses them.
- Both the total maternal weight gain and the pattern of weight gain are important determinants of the outcome of pregnancy.
- The appropriateness of the woman's prepregnancy weight for height (BMI) is a major determinant of her recommended weight gain during pregnancy.
- Nutritional risk factors include adolescent pregnancy; abuse of nicotine, alcohol, or drugs; bizarre or faddish food habits; a low or high weight for height; and frequent pregnancies.
- Iron supplementation is usually routinely recommended during pregnancy. Other supplements may be warranted when nutritional risk factors are present.
- Food safety is important for pregnant women to prevent adverse maternal and fetal effects.
- Women who are pregnant should consume seafood that is low in methylmercury.
- The nurse and the woman are influenced by cultural and personal values and beliefs during nutrition counseling.
- Pregnancy complications that can be nutrition-related include anemia, gestational hypertension, gestational diabetes, and IUGR.
- Dietary modifications can be effective interventions for some of the common discomforts of pregnancy, including nausea and vomiting, constipation, and heartburn.

Labor and Birth Processes

Kitty Cashion

<http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Explain the five major factors that affect the labor process.
- Describe the anatomic structure of the bony pelvis.
- Recognize the normal measurements of the diameters of the pelvic inlet, cavity, and outlet.
- Explain the significance of the size and position of the fetal head during labor and birth.
- Summarize the cardinal movements of the mechanism of labor for a vertex presentation.
- Examine the maternal anatomic and physiologic adaptations to labor.
- Describe factors thought to contribute to the onset of labor.
- Describe fetal adaptations to labor.

During late pregnancy a woman and fetus prepare for the labor process. The fetus has grown and developed in preparation for extrauterine life. The woman has undergone various physiologic adaptations during pregnancy that prepare her for giving birth and for motherhood. Labor and birth represent the end of pregnancy, the beginning of extrauterine life for the newborn, and a change in the lives of the family. This chapter discusses the factors affecting labor, the process involved, the normal progression of events, and the adaptations made by both the woman and fetus.

FACTORS AFFECTING LABOR

At least five factors affect the process of labor and birth. These are easily remembered as the five P's: *passenger* (fetus and placenta), *passageway* (birth canal), *powers* (contractions), *position* of the mother, and *psychologic* response. The first four factors are presented here as the basis for understanding the physiologic process of labor. The fifth factor is discussed in Chapter 19. The following factors may also affect the process of labor and birth. VandeVusse (1999) identified external forces including place of birth, preparation, type of provider (especially nurses), and procedures. Physiology (sensations) was identified as an internal force. These factors are discussed generally in Chapter 19 as they relate to nursing care during labor. Further research investigating essential forces of labor is recommended.

Passenger

The way the passenger, or fetus, moves through the birth canal is determined by the following interacting factors: the size of the fetal head, fetal presentation, fetal lie, fetal attitude, and fetal position. Because the placenta also must pass through the

birth canal, it can also be considered a passenger; however, the placenta rarely interferes with the process of labor in a normal vaginal birth. An exception is the case of placenta previa (see Chapter 28).

Size of the Fetal Head

Because of its size and relative rigidity, the fetal head has a major effect on the birth process. The fetal skull is composed of two parietal bones, two temporal bones, the frontal bone, and the occipital bone (Fig. 16-1, A). These bones are united by membranous sutures: sagittal, lambdoidal, coronal, and frontal (see Fig. 16-1, B). Membrane-filled spaces called fontanels are located where the sutures intersect. During labor, after rupture of membranes, palpation of fontanels and sutures during vaginal examination reveals fetal presentation, position, and attitude.

The two most important fontanels are the anterior and posterior (see Fig. 16-1, B). The larger of these, the anterior fontanel, is diamond shaped, is about 3 cm by 2 cm, and lies at the junction of the sagittal, coronal, and frontal sutures. It closes by 18 months after birth. The posterior fontanel lies at the junction of the sutures of the two parietal bones and the occipital bone, is triangular, and is about 1 cm by 2 cm. It closes 6 to 8 weeks after birth.

Sutures and fontanels make the skull flexible to accommodate the infant brain, which continues to grow for some time after birth. However, because the bones are not firmly united, slight overlapping of the bones, or molding of the shape of the head, occurs during labor. This capacity of the bones to slide over one another also permits adaptation to the various diameters of the maternal pelvis. Molding can be extensive, but the heads of most newborns assume their normal shape within 3 days after birth.

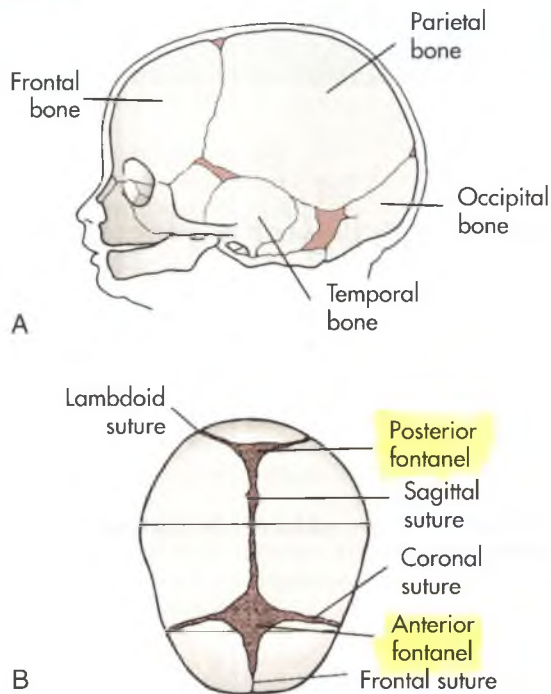

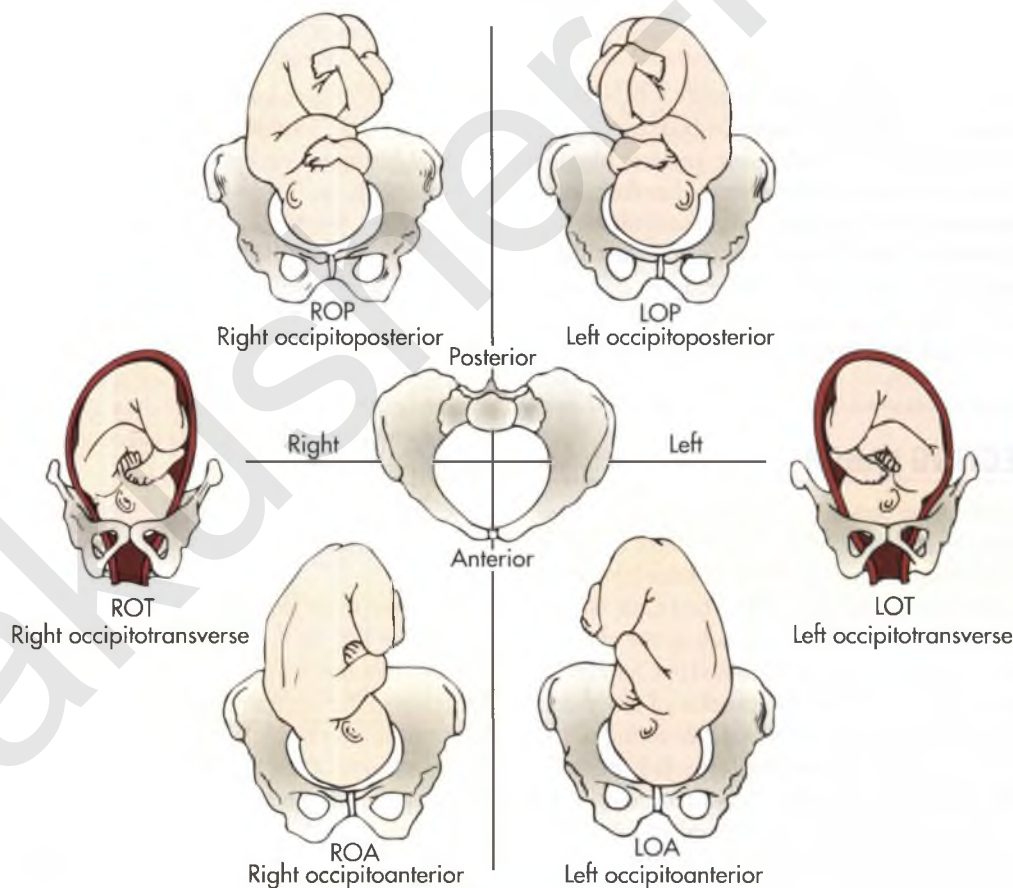

FIG 16-1 Fetal head at term. A, Bones. B, Sutures and fontanels.

Although the size of the fetal shoulders may affect passage, their position can be altered relatively easily during labor, so one shoulder may occupy a lower level than the other. This creates a shoulder diameter that is smaller than the skull, facilitating passage through the birth canal. After the birth of the head and shoulders, the rest of the body usually emerges quickly (Cunningham, Leveno, Bloom, et al., 2014).

Fetal Presentation

Presentation refers to the part of the fetus that enters the pelvic inlet first and leads through the birth canal during labor. The three main presentations are *cephalic presentation* (head first), occurring in 96% of births (Fig. 16-2); *breech presentation* (buttocks, feet, or both first), occurring in 3% of births (Fig. 16-3, A-C); and *shoulder presentation*, seen in 1% of births (see Fig. 16-3, D). The **presenting part** is that part of the fetus that lies closest to the internal os of the cervix. It is the part of the fetal body first felt by the examining finger during a vaginal examination. In a cephalic presentation the presenting part is usually the occiput; in a breech presentation it is the sacrum; in the shoulder presentation it is the scapula. When the presenting part is the occiput, the presentation is noted as **vertex** (see Fig. 16-2). Factors that determine the presenting

Lie: Longitudinal or vertical
Presentation: Vertex
Reference point: Occiput
Attitude: General flexion

FIG 16-2 Examples of fetal vertex (occiput) presentations in relation to front, back, or side of maternal pelvis.

Frank breech

Lie: Longitudinal or vertical
Presentation: Breech (incomplete)
Presenting part: Sacrum
Attitude: Flexion, except for legs at knees

Single footling breech

Lie: Longitudinal or vertical
Presentation: Breech (incomplete)
Presenting part: Sacrum
Attitude: Flexion, except for one leg extended at hip and knee

Complete breech

Lie: Longitudinal or vertical
Presentation: Breech (sacrum and feet presenting)
Presenting part: Sacrum (with feet)
Attitude: General flexion

Shoulder presentation

Lie: Transverse or horizontal
Presentation: Shoulder
Presenting part: Scapula
Attitude: Flexion

FIG 16-3 Fetal presentations. A through C, Breech (sacral) presentations. D, Shoulder presentation.

part include fetal lie, fetal attitude, and extension or flexion of the fetal head.

Fetal Lie

Lie is the relation of the long axis (spine) of the fetus to the long axis (spine) of the mother. The two primary lies are longitudinal, or vertical, in which the long axis of the fetus is parallel with the long axis of the mother (see Fig. 16-2); and transverse, horizontal, or oblique, in which the long axis of the fetus is at a right angle diagonal to the long axis of the mother (see Fig. 16-3, D). Longitudinal lies, which are present in more than 99% of term labors, are either cephalic or breech presentations, depending on the fetal structure that first enters the mother's pelvis. Vaginal birth cannot occur when the fetus stays in a transverse lie. An oblique lie, one in which the long axis of the fetus is lying at an angle to the long axis of the mother, is less common and usually converts to a longitudinal or transverse lie during labor (Cunningham et al., 2014).

Fetal Attitude

Attitude is the relation of the fetal body parts to one another. The fetus assumes a characteristic posture (attitude) in utero

partly because of the mode of fetal growth and partly because of the way the fetus conforms to the shape of the uterine cavity. Normally the back of the fetus is rounded so that the chin is flexed on the chest, the thighs are flexed on the abdomen, and the legs are flexed at the knees. The arms are crossed over the thorax, and the umbilical cord lies between the arms and the legs. This attitude is termed *general flexion* (see Fig. 16-2).

Deviations from the normal attitude may cause difficulties in childbirth. For example, in a cephalic presentation the fetal head may be extended or flexed in a manner that presents a head diameter that exceeds the limits of the maternal pelvis, leading to prolonged labor, forceps- or vacuum-assisted birth, or cesarean birth.

Certain critical diameters of the fetal head are usually measured. The **biparietal diameter**, which is about 9.25 cm at term, is the largest transverse diameter and an important indicator of fetal head size (Fig. 16-4, B). In a well-flexed cephalic presentation, the biparietal diameter is the widest part of the head entering the pelvic inlet. Of the several anteroposterior diameters, the smallest and the most critical one is the suboccipitobregmatic diameter (about 9.5 cm at term). When the head is in complete flexion, this diameter allows the fetal head to pass through the

FIG 16-4 Diameters of the fetal head at term. A, Cephalic presentations: occiput, vertex, and sinciput; and cephalic diameters: suboccipitobregmatic, occipitofrontal, and occipitomenal. B, Biparietal diameter.

true pelvis easily (see Fig. 16-4, A; Fig. 16-5, A). As the head is more extended, the anteroposterior diameter widens, and the head may not be able to enter the true pelvis (see Fig. 16-5).

Fetal Position

The presentation, or presenting part, indicates that portion of the fetus that overlies the pelvic inlet. **Position** is the relationship of a reference point on the presenting part (occiput, sacrum, mentum [chin], or sinciput [deflexed vertex]) to the four quadrants of the mother's pelvis (see Fig. 16-2). Position is denoted by a three-part abbreviation. The first letter of the abbreviation denotes the location of the presenting part in the right (R) or left (L) side of the mother's pelvis. The middle letter stands for the specific presenting part of the fetus (O for occiput, S for sacrum, M for mentum [chin], and Sc for scapula [shoulder]). The final letter stands for the location of the presenting part in relation to the anterior (A), posterior (P), or transverse (T) portion of the maternal pelvis. For example, ROA means that the occiput is the presenting part and is located in the right anterior quadrant of the maternal pelvis (see Fig. 16-2). LSP means that the sacrum is the presenting part and is located in the left posterior quadrant of the maternal pelvis (see Fig. 16-3).

Station is the relationship of the presenting fetal part to an imaginary line drawn between the maternal ischial spines and is a measure of the degree of descent of the presenting part of the fetus through the birth canal. The placement of the presenting part is measured in centimeters above or below the ischial spines (Fig. 16-6). For example, when the lowermost portion of the presenting part is 1 cm above the spines, it is noted as being minus (−) 1. At the level of the spines the station is said to be 0 (zero). When the presenting part is 1 cm below the spines, the station is said to be plus (+) 1. Birth is imminent when the presenting part is at +4 to +5 cm. The station of the presenting part should be determined when labor begins so that the rate of descent of the fetus during labor can be determined accurately.

Engagement is the term used to indicate that the largest transverse diameter of the presenting part (usually the biparietal diameter) has passed through the maternal pelvic brim or inlet into the true pelvis and usually corresponds to station 0. It often occurs in the weeks just before labor begins in nulliparas and may occur before labor or during labor in multiparas. Engagement can be determined by abdominal or vaginal examination.

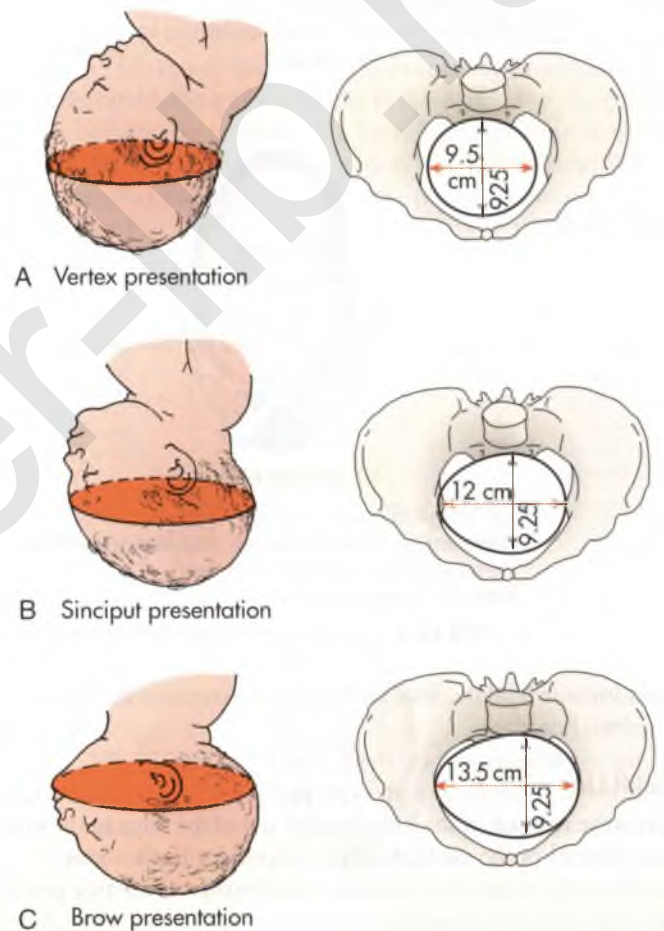

FIG 16-5 Head entering pelvis. Biparietal diameter is indicated with shading (9.25 cm). A, Suboccipitobregmatic diameter: complete flexion of head on chest so that smallest diameter enters. B, Occipitofrontal diameter: moderate extension (military attitude) so that large diameter enters. C, Occipitomenal diameter: marked extension (deflection), so that the largest diameter, which is too large to permit head to enter pelvis, is presenting.

Passageway

The passageway, or birth canal, is composed of the mother's rigid bony pelvis and the soft tissues of the cervix, the pelvic floor, the vagina, and the introitus (the external opening to the vagina). Although the soft tissues, particularly the muscular layers of the pelvic floor, contribute to vaginal birth of the fetus, the maternal

FIG 16-6 Stations of presenting part, or degree of descent. The lowermost portion of the presenting part is at the level of the ischial spines, station 0.

pelvis plays a far greater role in the labor process because the fetus must successfully accommodate itself to this relatively rigid passageway. The determination of the size and shape of the pelvis can be done at the initial prenatal visit or on admission in labor. This information can then be used in the assessment of labor progress (Thorpe & Laughon, 2014).

Bony Pelvis

The anatomy of the bony pelvis is described in Chapter 4. The following discussion focuses on the importance of pelvic configurations as they relate to the labor process. (It may be helpful to refer to Fig. 4-4.)

The bony pelvis is formed by the fusion of the ilium, the ischium, the pubis, and the sacral bones. The four pelvic joints are the symphysis pubis, the right and left sacroiliac joints (Fig. 16-7, A), and the sacrococcygeal joint (see Fig. 16-7, B). The bony pelvis is separated by the brim, or inlet, into two parts: the false pelvis and the true pelvis. The false pelvis is the part above the brim and plays no part in childbearing. The true pelvis, the part involved in birth, is divided into three planes: the inlet, or brim; the midpelvis, or cavity; and the outlet.

The pelvic inlet, which is the upper border of the true pelvis, is formed anteriorly by the upper margins of the pubic bone, laterally by the iliopectineal lines along the innominate bones, and posteriorly by the anterior, upper margin of the sacrum and the sacral promontory.

The pelvic cavity, or midpelvis, is a curved passage with a short anterior wall and a much longer concave posterior wall. It is bounded by the posterior aspect of the symphysis pubis, the ischium, a portion of the ilium, the sacrum, and the coccyx.

The pelvic outlet is the lower border of the true pelvis. Viewed from below it is ovoid, somewhat diamond shaped, and bounded by the pubic arch anteriorly, the ischial tuberosities laterally, and the tip of the coccyx posteriorly (see Fig. 16-7, B). In the latter part of pregnancy the coccyx is movable (unless it has been broken in a fall during skiing or skating, for example, and has fused to the sacrum during healing).

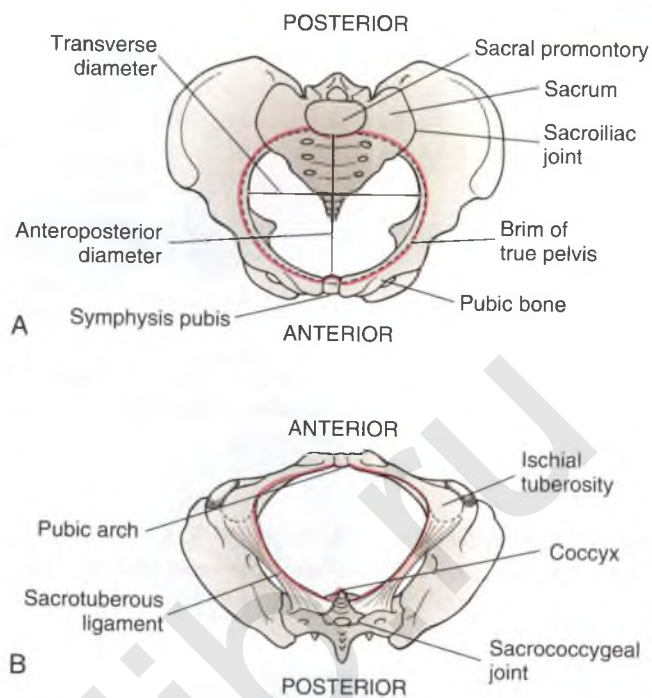

FIG 16-7 Female pelvis. A, Pelvic brim from above. B, Pelvic outlet from below, as seen by health care provider when the woman is lying supine.

The pelvic canal varies in size and shape at various levels. The diameters at the plane of the pelvic inlet, midpelvis, and outlet, plus the axis of the birth canal (Fig. 16-8), determine whether vaginal birth is possible and the manner by which the fetus may pass down the birth canal.

The subpubic angle, which determines the type of pubic arch, together with the length of the pubic rami and the intertuberous diameter, is of great importance. Because the fetus must first pass beneath the pubic arch, a narrow subpubic angle will be less accommodating than a rounded, wide arch. The method of measurement of the subpubic arch is shown in Fig. 16-9. A summary of obstetric measurements is given in Table 16-1.

The four basic types of pelvis are classified as follows:

1. *Gynecoid* (the classic female type)
2. *Android* (resembling the male pelvis)
3. *Anthropoid* (oval shaped, with a wider anteroposterior diameter)
4. *Platypelloid* (the flat pelvis)

The gynecoid pelvis is the most common, with major gynecoid pelvic features present in 50% of all women. Anthropoid and android features are less common, and platypelloid pelvic features are the least common. Mixed types of pelvis are more common than are pure types (Cunningham et al., 2014). Examples of pelvic variations and their effects on mode of birth are given in Table 16-2.

Assessment of the bony pelvis can be performed during the first prenatal evaluation and need not be repeated if the pelvis is of adequate size and suitable shape. In the third trimester of pregnancy the examination of the bony pelvis may be more thorough and the results more accurate because there is relaxation and increased mobility of the pelvic joints and ligaments owing to hormonal influences. Widening of the joint of the symphysis pubis and the resulting instability may cause pain in any or all of the pelvic joints.

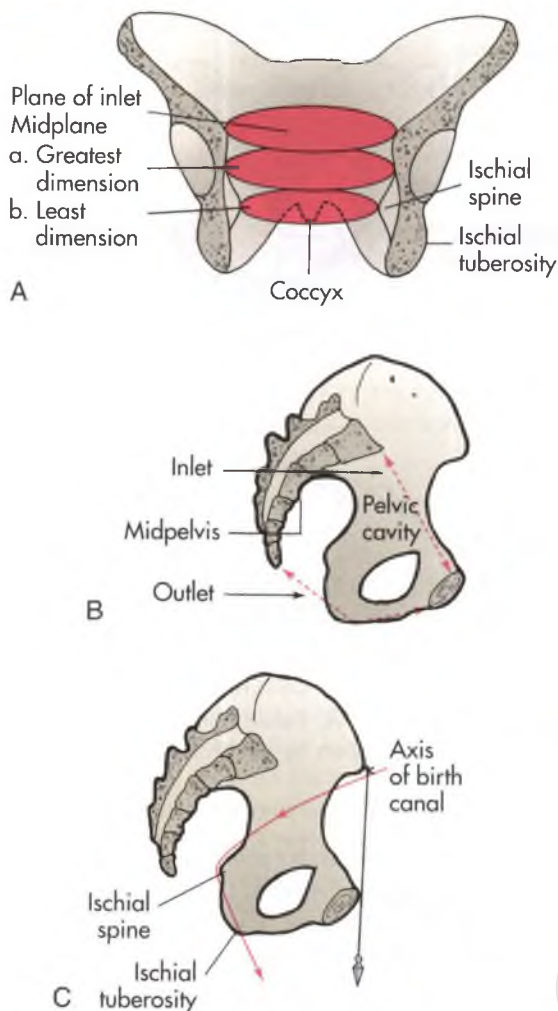

FIG 16-8 Pelvic cavity. A, Inlet and midplane. Outlet not shown. B, Cavity of true pelvis. C, Note curve of sacrum and axis of birth canal.

FIG 16-9 Estimation of angle of subpubic arch. With both thumbs, examiner externally traces descending rami down to tuberosities. (From Barkauskas, V., Baumann, L., & Darling-Fisher, C. [2002]. *Health and physical assessment* [3rd ed.]. St. Louis: Mosby.)

Because the examiner does not have direct access to the bony structures and because the bones are covered with varying amounts of soft tissue, size and shape are estimated. Precise bony pelvis measurements can be determined by use of computed tomography, ultrasound, or x-ray films. However, radiographic examination is rarely done during pregnancy because the x-rays may damage the developing fetus. Even precise measurements do not always predict a woman's ability to give birth vaginally because of the many ways the fetus can negotiate the pelvis and the accommodation of maternal soft tissues. Therefore, pelvimetry results would rarely contraindicate a trial of labor.

Soft Tissues

The soft tissues of the passageway include the stretchy lower uterine segment, the cervix, the pelvic floor muscles, the vagina, and the introitus. Before labor begins, the uterus is composed of the uterine body (corpus) and the cervix (neck). After labor has begun, uterine contractions cause the uterine body to have a thick and muscular upper segment and a thin-walled, passive, muscular lower segment. A *physiologic retraction ring* separates the two segments (Fig. 16-10). The lower uterine segment gradually stretches to accommodate the intrauterine contents as the wall of the upper segment thickens and its accommodating capacity is reduced. The contractions of the uterine body thus exert downward pressure on the fetus, pushing it against the cervix.

The cervix effaces (thins) and dilates (opens) sufficiently to allow the first fetal portion to descend into the vagina. As the fetus descends, the cervix is actually drawn upward and over this first portion.

The pelvic floor is a muscular layer that separates the pelvic cavity above from the perineal space below. This structure helps the fetus rotate anteriorly as it passes through the birth canal. As noted, the soft tissues of the vagina develop throughout pregnancy until at term the vagina can dilate to accommodate the fetus and permit its passage to the external world.

Powers

Involuntary and voluntary powers combine to expel the fetus and the placenta from the uterus. Involuntary uterine contractions, called the *primary powers*, signal the beginning of labor. Once the cervix has dilated, voluntary bearing-down efforts by the woman, called the *secondary powers*, augment the force of the involuntary contractions.

Primary Powers

The involuntary contractions originate at certain pacemaker points in the thickened muscle layers of the upper uterine segment. From the pacemaker points, contractions move downward over the uterus in waves, separated by short rest periods. Terms used to describe these involuntary contractions include *frequency* (the time from the beginning of one contraction to the beginning of the next), *duration* (length of contraction), and *intensity* (strength of contraction at its peak).

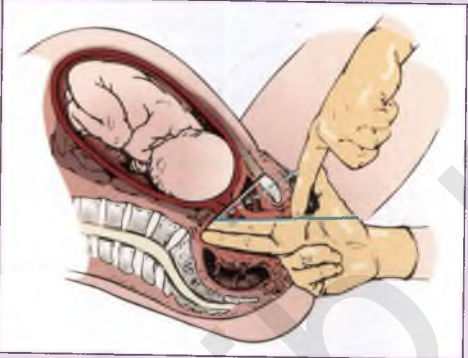

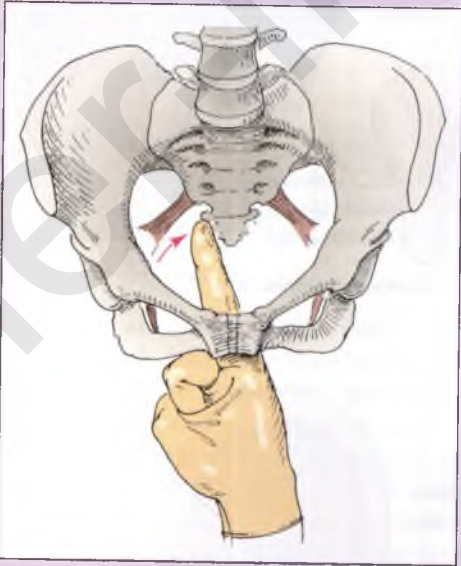

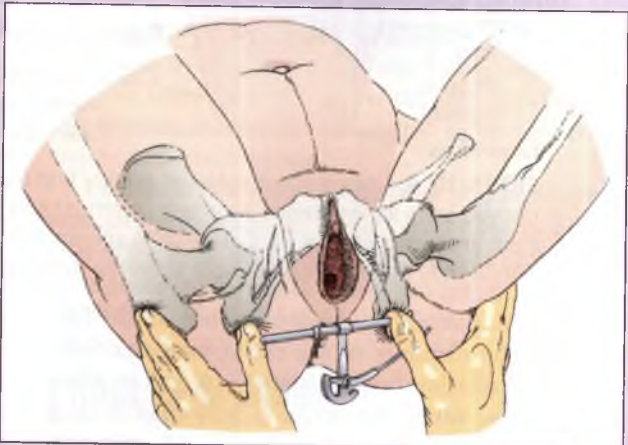

The primary powers are responsible for the effacement and dilation of the cervix and descent of the fetus. **Effacement** of the cervix means the shortening and thinning of the cervix during the first stage of labor. The cervix, normally 2 to 3 cm long and about 1 cm thick, is obliterated, or "taken up," by a shortening

of the uterine muscle bundles during the thinning of the lower uterine segment that occurs in advancing labor. Only a thin edge of the cervix can be palpated when effacement is complete. Effacement generally progresses significantly in first-time term pregnancy before more than slight dilation occurs. In subsequent

pregnancies effacement and dilation of the cervix tend to progress together. Degree of effacement is expressed in percentages from 0% to 100% (e.g., a cervix is 50% effaced) (Fig. 16-11, A-C).

Dilation of the cervix is the enlargement or widening of the cervical opening and the cervical canal that occurs once

TABLE 16-1 Obstetric Measurements

PLANE	DIAMETER	MEASUREMENTS
Inlet (superior strait) Conjugates Diagonal Obstetric: measurement that determines whether presenting part can engage or enter superior strait True (vera) (anteroposterior)	12.5-13 cm 1.5-2 cm less than diagonal (radiographic) ≥ 11 cm (12.5) (radiographic)	 <p>Length of diagonal conjugate (solid colored line), obstetric conjugate (broken colored line), and true conjugate (blue line)*</p>

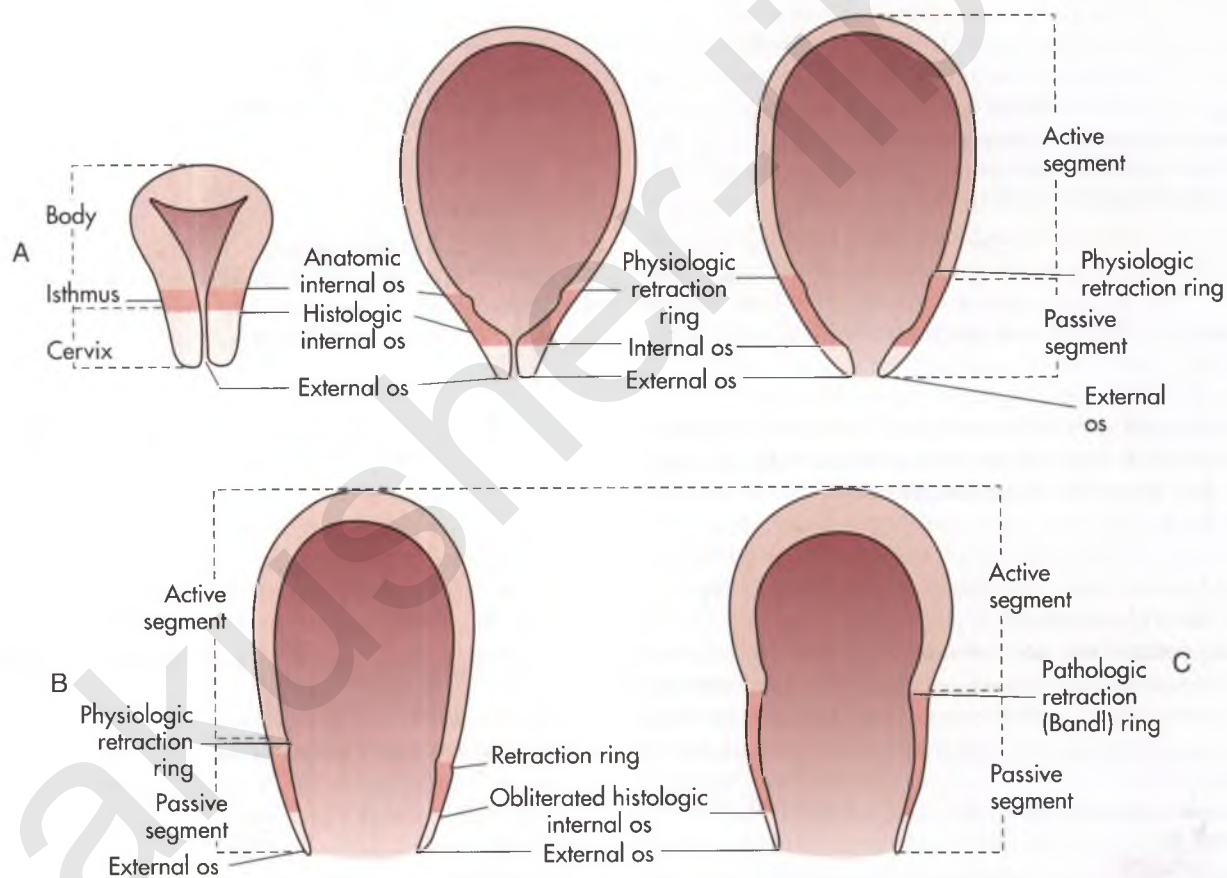

FIG 16-10 A, Uterus in normal labor in early first stage and, B, in second stage. Passive segment is derived from lower uterine segment (isthmus) and cervix, and physiologic retraction ring is derived from anatomic internal os. C, Uterus in abnormal labor in second-stage dystocia. Pathologic retraction (Bandl) ring that forms under abnormal conditions develops from the physiologic ring.

labor has begun. The diameter of the cervix increases from being closed to full dilation (approximately 10 cm) to allow birth of a term fetus. When the cervix is fully dilated (and completely retracted), it can no longer be palpated (see Fig. 16-11, D). Full cervical dilation marks the end of the first stage of labor.

Dilation of the cervix occurs by the drawing upward of the musculofibrous components of the cervix, caused by strong uterine contractions. Pressure exerted by the amniotic fluid while the membranes are intact or by the force applied by the presenting part also can promote cervical dilation. Scarring of the cervix as a result of prior infection or surgery may slow cervical dilation.

FIG 16-11 Cervical effacement and dilation. Note how cervix is drawn up around presenting part (internal os). Membranes are intact, and head is not well applied to cervix. **A**, Before labor. **B**, Early effacement. **C**, Complete effacement (100%). Head is well applied to cervix. **D**, Complete dilation (10 cm). Cranial bones overlap somewhat, and membranes are still intact.

In the first and second stages of labor, increased intrauterine pressure caused by contractions exerts pressure on the descending fetus and the cervix. When the presenting part of the fetus reaches the perineal floor, mechanical stretching of the cervix occurs. Stretch receptors in the posterior vagina cause release of endogenous oxytocin that triggers the maternal urge to bear down, or the *Ferguson reflex*.

Uterine contractions are usually independent of external forces. For example, laboring women who are paralyzed because of spinal cord lesions above the twelfth thoracic vertebra have normal but painless uterine contractions. In addition, use of epidural analgesia during labor does not decrease the frequency or intensity of contractions (Cunningham et al., 2014).

Secondary Powers

As soon as the presenting part reaches the pelvic floor, the contractions change in character and become expulsive. The laboring woman experiences an involuntary urge to push. She uses secondary powers (bearing-down efforts) to aid in expulsion of the fetus as she contracts her diaphragm and abdominal muscles and pushes. These bearing-down efforts result in increased intraabdominal pressure that compresses the uterus on all sides and adds to the power of the expulsive forces.

The secondary powers have no effect on cervical dilation, but they are of considerable importance in the expulsion of the infant from the uterus and vagina after the cervix is fully dilated.

When and how a woman pushes in the second stage of labor are much-debated topics. Continued study is needed to determine the effectiveness and appropriateness of strategies used by nurses to teach pushing techniques, the suitability and effectiveness of various pushing techniques related to abnormal fetal heart patterns, and the standards for length of pushing in terms of maternal and fetal outcomes. See Chapter 19 for further discussion regarding pushing during the second stage of labor.

Position of the Laboring Woman

Position affects the woman's anatomic and physiologic adaptations to labor. Frequent changes in position relieve fatigue, increase comfort, and improve circulation. Therefore, a laboring woman should be encouraged to find positions that are most comfortable to her.

Positioning for second-stage labor may be determined by the woman's preference, but choices are limited by her condition or that of the fetus, the environment, and the health care provider's confidence in assisting in a birth in a specific position. See Chapter 19 for further discussion of positioning during labor and birth.

PROCESS OF LABOR

The term *labor* refers to the process of moving the fetus, placenta, and membranes out of the uterus and through the birth canal. Various changes take place in the woman's reproductive

system in the days and weeks before labor begins. Labor itself can be discussed in terms of the mechanisms involved in the process and the stages through which the woman moves.

Signs Preceding Labor

In first-time pregnancies the uterus sinks downward and forward about 2 weeks before term, when the fetus's presenting part (usually the fetal head) descends into the true pelvis. This settling is called *lightening*, or dropping, and usually happens gradually. After lightening, women feel less pressure below the ribcage and breathe more easily, but usually more bladder pressure results from this shift. Consequently, a return of urinary frequency occurs. In a multiparous woman, lightening may not take place until after uterine contractions are established and true labor is in progress.

The woman may complain of persistent low backache and sacroiliac distress as a result of relaxation of the pelvic joints. She may identify strong and frequent but irregular uterine (Braxton Hicks) contractions.

The vaginal mucus becomes more profuse in response to the extreme congestion of the vaginal mucous membranes. Brownish or blood-tinged cervical mucus (*bloody show*) may be passed. The cervix becomes soft (ripens) and partially effaced and may begin to dilate. The membranes may rupture spontaneously.

Other phenomena are common in the days preceding labor: (1) loss of 0.5 to 1.5 kg (approximately 1 to 3½ pounds) in weight, caused by water loss resulting from electrolyte shifts that in turn are produced by changes in estrogen and progesterone levels; and (2) a surge of energy. Women speak of having a burst of energy that they often use to clean the house and put everything in order. Less commonly, some women have diarrhea, nausea, vomiting, and indigestion. Box 16-1 lists signs that may precede labor (see Clinical Reasoning Case Study).

CLINICAL REASONING CASE STUDY

"I Think I'm in Labor"

Erica is a 15-year-old G 1 P 0 at 39 weeks of gestation. She presents by ambulance to the triage area in your labor and birth unit and announces, "I'm here to have my baby. I think I'm in labor." Erica reports that she saw a thick brownish red vaginal discharge several days ago and noticed bright red vaginal spotting when wiping after peeing earlier today. She states that she has lower abdominal cramping ("It feels like the cramps I have with my periods") but denies leakage of vaginal fluid. Erica also reports active fetal movement. In answer to your question she replies that her current pain level is 8 on a scale of 1 to 10, while alternating between texting on her phone and chatting with her mother, who accompanied her to the hospital.

- Evidence—Is there sufficient evidence at this time to draw a conclusion about whether Erica is in labor?
- Assumptions—Describe an underlying assumption about each of the following issues:
 - Characteristics of false labor
 - Indications of true labor
 - Basic teaching for Erica and her mother at this time
 - Criteria necessary for discharging Erica from the labor and birth unit
- What implications and priorities for nursing care can be drawn at this time?
- Does the evidence objectively support your conclusion?

BOX 16-1 Signs Preceding Labor

- Lightening
- Return of urinary frequency
- Backache
- Stronger Braxton Hicks contractions
- Weight loss of 0.5 to 1.5 kg (approximately 1 to 3½ pounds)
- Surge of energy
- Increased vaginal discharge; bloody show
- Cervical ripening
- Possible rupture of membranes

Onset of Labor

The onset of true labor cannot be ascribed to a single cause. Many factors, including changes in the maternal uterus, cervix, and pituitary gland, are involved. Hormones produced by the normal fetal hypothalamus, pituitary, and adrenal cortex probably contribute to the onset of labor. Progressive uterine distention, increasing intrauterine pressure, and aging of the placenta seem to be associated with increasing myometrial irritability. This is a result of increased concentrations of estrogen and prostaglandins, as well as decreasing progesterone levels. The mutually coordinated effects of these factors result in the occurrence of strong, regular, rhythmic uterine contractions (Blackburn, 2013; Kilpatrick & Garrison, 2012). The outcome of these factors working together is normally the birth of the fetus and the expulsion of the placenta; however, how certain alterations trigger others and how proper checks and balances are maintained are not known.

Stages of Labor

The course of labor at or near term gestation in a woman without complications and a fetus in vertex presentation consists of (1) regular progression of uterine contractions, (2) effacement and progressive dilation of the cervix, and (3) progress in descent of the presenting part. Four stages of labor are recognized; an overview is discussed here. These stages are discussed in greater detail, along with nursing care for the laboring woman and family, in Chapter 19.

The *first stage of labor* is considered to last from the onset of regular uterine contractions to full effacement and dilation of the cervix. Commonly the onset of labor is difficult to establish because the woman may be admitted to the labor unit just before birth, and the beginning of labor may be only an estimate. The first stage is much longer than the second and third stages combined. Great variability is the rule, however, depending on the factors discussed previously in this chapter. The first stage of labor has traditionally been divided into three phases: a latent phase, an active phase, and a transition phase. In women who labor with epidural anesthesia, however, a separate transition phase may not always be identified based on maternal physical sensations and behavior (Simpson & O'Brien-Abel, 2014). During the latent phase there is more progress in effacement of the cervix and little increase in descent. During the active and transition phases there is more rapid dilation of the cervix and increased rate of descent of the presenting part.

The *second stage of labor* lasts from the time the cervix is fully dilated to the birth of the fetus. It is composed of two phases: the latent (passive fetal descent) phase and the active pushing

FIG 16-12 Cardinal movements of the mechanism of labor. Left occipitoanterior (LOA) position. Pelvic figures show the position of the fetal head as seen by the birth attendant. **A**, Engagement and descent. **B**, Flexion. **C**, Internal rotation to occipitoanterior position (OA). **D**, Extension. **E**, External rotation beginning (restitution). **F**, External rotation.

phase. During the latent phase the fetus continues to descend passively through the birth canal and rotate to an anterior position as a result of ongoing uterine contractions. The urge to bear down during this phase is not strong, and some women do not experience it at all. During the active pushing phase the woman has strong urges to bear down as the presenting part of the fetus descends and presses on the stretch receptors of the pelvic floor.

The *third stage of labor* lasts from the birth of the fetus until the placenta is delivered. The placenta normally separates with the third or fourth strong uterine contraction after the infant has been born. After it has separated, the placenta can be delivered with the next uterine contraction.

The *fourth stage of labor* begins with the delivery of the placenta and includes at least the first 2 hours after birth. During this stage the woman begins to recover physically from birth, so it is an important time to observe for complications, such as abnormal bleeding (see Chapter 33).

Mechanism of Labor

As already discussed, the female pelvis has varied contours and diameters at different levels, and the presenting part of

the passenger is large in proportion to the passage. Therefore, for vaginal birth to occur, the fetus must adapt to the birth canal during the descent. The turns and other adjustments necessary in the human birth process are termed the *mechanism of labor* (Fig. 16-12). The seven cardinal movements of the mechanism of labor that occur in a vertex presentation are engagement, descent, flexion, internal rotation, extension, external rotation (restitution), and finally birth by expulsion. Although these movements are discussed separately, in actuality a combination of movements occurs simultaneously. For example, engagement involves both descent and flexion.

Engagement

When the biparietal diameter of the head passes the pelvic inlet, the head is said to be engaged in the pelvic inlet (see Fig. 16-12, A). In most nulliparous women, this occurs before the onset of active labor because the firmer abdominal muscles direct the presenting part into the pelvis. In multiparous women, because the abdominal musculature is more relaxed, the head often remains freely movable above the pelvic brim until labor is established.

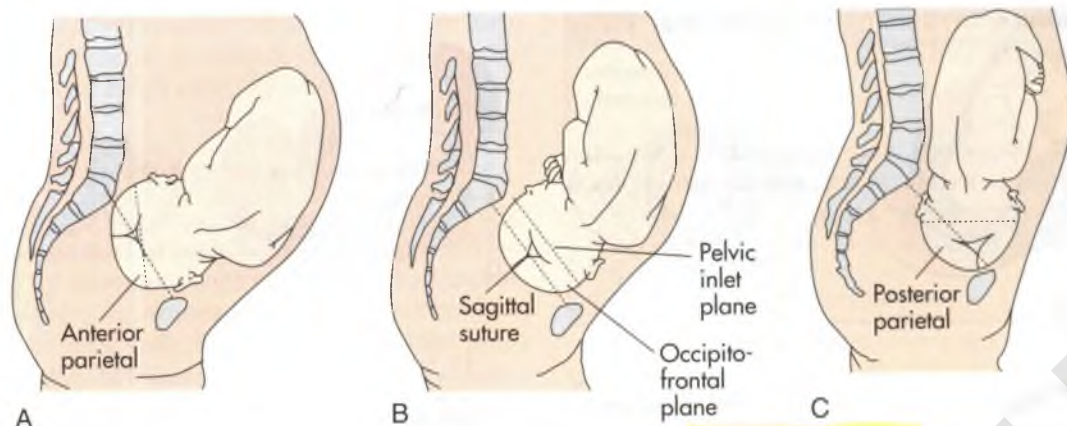

FIG 16-13 Synclitism and asynclitism. **A**, Anterior asynclitism. **B**, Normal synclitism. **C**, Posterior asynclitism.

Asynclitism. The head usually engages in the pelvis in a synclitic position—one that is parallel to the anteroposterior plane of the pelvis. Frequently asynclitism occurs (the head is deflected anteriorly or posteriorly in the pelvis), which can facilitate descent because the head is being positioned to accommodate to the pelvic cavity (Fig. 16-13). Extreme asynclitism can cause cephalopelvic disproportion, even in a normal-size pelvis, because the head is positioned so that it cannot descend.

Descent

Descent refers to the progress of the presenting part through the pelvis. Descent depends on at least four forces: (1) pressure exerted by the amniotic fluid, (2) direct pressure exerted by the contracting fundus on the fetus, (3) force of the contraction of the maternal diaphragm and abdominal muscles in the second stage of labor, and (4) extension and straightening of the fetal body. The effects of these forces are modified by the size and shape of the maternal pelvic planes and the size of the fetal head and its capacity to mold.

The degree of descent is measured by the station of the presenting part (see Fig. 16-6). As mentioned, little descent occurs during the latent phase of the first stage of labor. Descent accelerates in the active phase when the cervix has dilated to 5 to 6 cm. It is especially apparent when the membranes have ruptured.

In a first-time pregnancy descent is usually slow but steady; in subsequent pregnancies it may be rapid. Progress in descent of the presenting part is assessed by abdominal palpation and vaginal examination until the presenting part can be seen at the introitus (see Chapter 19).

Flexion

As soon as the descending head meets resistance from the cervix, pelvic wall, or pelvic floor, it normally flexes so that the chin is brought into closer contact with the fetal chest (see Fig. 16-12, B). Flexion permits the smaller suboccipitobregmatic diameter (9.5 cm) rather than the larger diameters to present to the outlet.

Internal Rotation

The maternal pelvic inlet is widest in the transverse diameter; therefore, the fetal head passes the inlet into the true pelvis in the occipitotransverse position. The outlet is widest in the anteroposterior

diameter; for the fetus to exit, the head must rotate. Internal rotation begins at the level of the ischial spines but is not completed until the presenting part reaches the lower pelvis. As the occiput rotates anteriorly, the face rotates posteriorly. With each contraction the fetal head is guided by the bony pelvis and the muscles of the pelvic floor. Eventually the occiput will be in the midline beneath the pubic arch. The head is almost always rotated by the time it reaches the pelvic floor (see Fig. 16-12, C). Both the levator ani muscles and the bony pelvis are important for achieving anterior rotation. A previous childbirth injury or regional anesthesia may compromise the function of the levator sling.

Extension

When the fetal head reaches the perineum for birth, it is deflected anteriorly by the perineum. The occiput passes under the lower border of the symphysis pubis first, and then the head emerges by extension: first the occiput, then the face, and finally the chin (see Fig. 16-12, D).

Restitution and External Rotation

After the head is born it rotates briefly to the position it occupied when it was engaged in the inlet. This movement is referred to as restitution (see Fig. 16-12, E). The 45-degree turn realigns the infant's head with the back and shoulders. The head can then be seen to rotate further. This external rotation occurs as the shoulders engage and descend in maneuvers similar to those of the head (see Fig. 16-12, F). As noted, the anterior shoulder descends first. When it reaches the outlet, it rotates to the midline and is delivered from under the pubic arch. The posterior shoulder is guided over the perineum until it is free of the vaginal introitus.

Expulsion

After birth of the shoulders, the head and shoulders are lifted up toward the mother's pubic bone and the trunk of the baby is born by flexing it laterally in the direction of the symphysis pubis. When the baby has completely emerged, birth is complete, and the second stage of labor ends.

PHYSIOLOGIC ADAPTATION TO LABOR

In addition to the maternal and fetal anatomic adaptations that occur during birth, physiologic adaptations must occur.

Accurate assessment of the laboring woman and fetus requires knowledge of these expected adaptations.

Fetal Adaptation

Several important physiologic adaptations occur in the fetus. These changes occur in fetal heart rate, fetal circulation, respiratory movements, and other behaviors.

Fetal Heart Rate

Fetal heart rate (FHR) monitoring provides reliable and predictive information about the condition of the fetus related to oxygenation. The average FHR at term is 140 beats/minute; the normal range is 110 to 160 beats/minute. Earlier in gestation the FHR is higher, with an average of approximately 160 beats/minute at 20 weeks of gestation. The rate decreases progressively as the maturing fetus reaches term. However, temporary accelerations and slight early decelerations of the FHR can be expected in response to spontaneous fetal movement, vaginal examination, fundal pressure, uterine contractions, abdominal palpation, and fetal head compression. Stresses to the uterofetoplacental unit result in characteristic FHR patterns (see Chapter 18 for further discussion).

Fetal Circulation

Fetal circulation can be affected by many factors, including maternal position, uterine contractions, blood pressure, and umbilical cord blood flow. Uterine contractions during labor tend to decrease circulation through the spiral arterioles and subsequent perfusion through the intervillous space. Most healthy fetuses are well able to compensate for this stress and exposure to increased pressure while moving passively through the birth canal during labor. Usually the umbilical cord moves freely in the amniotic fluid. However, it can be compressed during uterine contractions (Blackburn, 2013; Miller, Miller, & Tucker, 2013).

Fetal Respiration

Certain changes stimulate chemoreceptors in the aorta and carotid bodies to prepare the fetus for initiating respirations immediately after birth (Blackburn, 2013; Rozance & Rosenberg, 2012). These changes include the following:

- Fetal lung fluid is cleared from the air passages as the infant passes through the birth canal during labor and (vaginal) birth.
- Fetal oxygen pressure (PO_2) decreases.
- Arterial carbon dioxide pressure (PCO_2) increases.
- Arterial pH decreases.
- Bicarbonate level decreases.
- Fetal respiratory movements decrease during labor.

Maternal Adaptation

As the woman progresses through the stages of labor, various body system adaptations cause her to exhibit both objective signs and subjective symptoms (Box 16-2).

Cardiovascular Changes

During each contraction an average of 400 ml of blood is emptied from the uterus into the maternal vascular system. By the end of the first stage of labor cardiac output during contractions

BOX 16-2 Maternal Physiologic Changes During Labor

- Cardiac output increases 10% to 15% in first stage, 30% to 50% in second stage.
- Heart rate increases slightly in first and second stages.
- Blood pressure (both systolic and diastolic) increases during contractions and returns to baseline levels between contractions. Systolic values increase more than diastolic values.
- White blood cell (WBC) count increases.
- Respiratory rate increases.
- Temperature may be slightly elevated.
- Proteinuria may occur.
- Gastric motility and absorption of solid food are decreased; nausea and vomiting may occur during transition to secondstage labor.
- Blood glucose level decreases.

is increased by 51% above baseline pregnancy values at term. Cardiac output peaks about 10 to 30 minutes after both vaginal and cesarean birth and returns to its prelabor baseline within the first postpartum hour. A drop in maternal heart rate accompanies this increase in cardiac output (Gordon, 2012).

Changes in blood pressure also occur. In general, both systolic and diastolic pressures increase during contractions and return to baseline levels between contractions. Systolic values increase more than diastolic values (Blackburn, 2013).

Supine hypotension (see Fig. 19-5) occurs when the ascending vena cava and descending aorta are compressed. The laboring woman is at greater risk for supine hypotension when the uterus is particularly large because of multifetal pregnancy, hydramnios, or obesity or when the woman is dehydrated or hypovolemic. In addition, anxiety and pain, as well as some medications, can cause hypotension.

The woman should be discouraged from using the Valsalva maneuver (holding one's breath and tightening abdominal muscles) for pushing during the second stage. This activity increases intrathoracic pressure, reduces venous return, and increases venous pressure. The cardiac output and blood pressure increase and the pulse slows temporarily. During the Valsalva maneuver fetal hypoxia may occur. The process is reversed when the woman takes a breath.

The white blood cell (WBC) count can increase (Blackburn, 2013). Although the mechanism leading to this increase in WBCs is unknown, it may be secondary to physical or emotional stress or to tissue trauma. Labor is strenuous, and physical exercise alone can increase the WBC count.

Some peripheral vascular changes occur, perhaps in response to cervical dilation or to compression of maternal vessels by the fetus passing through the birth canal. Flushed cheeks, hot or cold feet, and eversion of hemorrhoids may result.

Respiratory Changes

Increased physical activity with greater oxygen consumption is reflected in an increase in the respiratory rate. Hyperventilation may cause respiratory alkalosis (an increase in pH), hypoxia, and hypocapnia (decrease in carbon dioxide). In the unmedicated woman in the second stage of labor, oxygen consumption almost doubles. Anxiety also increases oxygen consumption.

Renal Changes

During labor, spontaneous voiding may be difficult for various reasons: tissue edema caused by pressure from the presenting part, discomfort, analgesia, and embarrassment. Proteinuria of 1+ is a normal finding because it can occur in response to the breakdown of muscle tissue from the physical work of labor.

Integumentary Changes

The integumentary system changes are evident, especially in the great stretching of tissue that occurs in the area of the vaginal introitus. The degree of distensibility varies with the individual. Despite this ability to stretch, even in the absence of episiotomy or lacerations minute tears in the skin around the vaginal introitus do occur.

Musculoskeletal Changes

The musculoskeletal system is stressed during labor. Diaphoresis, fatigue, proteinuria (1+), and possibly an increased temperature accompany the marked increase in muscle activity. Backache and joint aches (unrelated to fetal position) occur as a result of increased joint laxity at term. The labor process itself and the woman's pointing her toes can cause leg cramps.

Neurologic Changes

Sensorial changes occur as the woman moves through the phases of the first stage of labor and as she moves from one stage

to the next. Initially she may be euphoric. Euphoria gives way to increased seriousness, then to amnesia between contractions during the second stage, and finally to elation or fatigue after giving birth. Endogenous endorphins (morphine-like chemicals produced naturally by the body) raise the pain threshold and produce sedation. In addition, physiologic anesthesia of perineal tissues, caused by pressure of the presenting part, decreases perception of pain.

Gastrointestinal Changes

During labor gastrointestinal motility and absorption of solid foods are decreased, and stomach-emptying time is slowed. Nausea and vomiting of undigested food eaten after the onset of labor are common. Nausea and belching also occur as a reflex response to full cervical dilation. The woman may state that diarrhea accompanied the onset of labor, or the nurse may palpate the presence of hard or impacted stool in the rectum.

Endocrine Changes

The onset of labor may be triggered by decreasing levels of progesterone and increasing levels of estrogen, prostaglandins, and oxytocin (Simpson & O'Brien-Abel, 2014). Metabolism increases, and blood glucose levels may decrease with the work of labor.

KEY POINTS

- Labor and birth are affected by the five P's: *passenger, passageway, powers, position* of the woman, and *psychologic response*.
- Because of its size and relative rigidity, the fetal head is a major factor in determining the course of birth.
- The diameters at the plane of the pelvic inlet, the midpelvis, and the outlet plus the axis of the birth canal determine whether vaginal birth is possible and the manner in which the fetus passes down the birth canal.
- Involuntary uterine contractions act to expel the fetus and placenta during the first stage of labor; these are augmented by voluntary bearing-down efforts during the second stage.
- The first stage of labor lasts from the time dilation begins to the time when the cervix is fully dilated.
- The second stage of labor lasts from the time of full cervical dilation to the birth of the infant.
- The third stage of labor lasts from the infant's birth to the expulsion of the placenta.
- The fourth stage of labor begins with the delivery of the placenta and includes at least the first 2 hours after birth.
- The cardinal movements of the mechanism of labor are engagement, descent, flexion, internal rotation, extension, restitution and external rotation, and expulsion of the infant.
- Although the events precipitating the onset of labor are unknown, many factors, including changes in the maternal uterus, cervix, and pituitary gland, are thought to be involved.
- A healthy fetus with an adequate uterofetoplacental circulation is able to compensate for the stress of uterine contractions.
- As the woman progresses through labor, various body systems adapt to the birth process.

Maximizing Comfort for the Laboring Woman

Cheryl R. Zauderer

<http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Identify nonpharmacologic strategies, including breathing and relaxation techniques, used to enhance relaxation and promote comfort during labor and birth.
- Compare pharmacologic methods used to relieve discomfort in different stages of labor and for vaginal or cesarean birth.
- Discuss the effects of medication management for the mother and its effect on the newborn both during and after birth.
- Construct an evidence-based plan to manage the discomfort that a woman experiences during childbirth.
- Explain the nurse's role and responsibilities while providing care for a woman receiving analgesia or anesthesia during labor.
- Describe the nurse's role in promoting comfort and safety throughout the labor and birth process.

Although labor and birth are considered to be natural processes, laboring women experience a significant amount of discomfort and pain, as well as a variety of other challenging sensations. Pain is a highly individualized phenomenon with sensory and emotional components. Even though most women experience discomfort or pain during labor and birth it is the intensity of discomfort that is unique to the individual. Pregnant women are generally concerned about the discomfort and pain that they will experience during labor and birth and about how they will respond to and cope with it. A large variety of nonpharmacologic and pharmacologic methods are available to help the woman or the couple maximize her comfort during the labor process. The methods that are selected depend on the situation, availability, and preferences of the woman, her partner, and her health care provider.

PAIN DURING LABOR AND BIRTH

Neurologic Origins

The pain and discomfort of labor have two origins: visceral and somatic. During the first stage of labor, uterine contractions cause cervical dilation and effacement. Uterine ischemia (decreased blood flow and therefore local oxygen deficit) results from compression of the arteries supplying the myometrium during uterine contractions. Pain impulses during the first stage of labor are transmitted via the T1 to T12 spinal nerve segment and accessory lower thoracic and upper lumbar sympathetic

nerves. These nerves originate in the uterine body and cervix (Blackburn, 2013).

The pain from distention of the lower uterine segment, stretching of cervical tissue as it effaces and dilates, pressure and traction on adjacent structures (e.g., uterine tubes, ovaries, ligaments) and nerves, and uterine ischemia during the first stage of labor is visceral pain. It is located over the lower portion of the abdomen. Referred pain occurs when pain that originates in the uterus radiates to the abdominal wall, lumbosacral area of the back, iliac crests, gluteal area, thighs, and lower back (Blackburn, 2013).

During most of the first stage of labor the woman usually has discomfort only during contractions, and is free of pain between contractions. Some women, especially those whose fetus is in a posterior position, experience continuous contraction-related low back pain, even in the interval between contractions. As labor progresses and pain becomes more intense and persistent, women become fatigued and discouraged, often experiencing difficulty coping with contractions (Blackburn, 2013; Burke, 2014).

During the second stage of labor the woman has somatic pain, which is often described as intense, sharp, burning, and well localized. This pain results from:

- Distention and traction on the peritoneum and uterocervical supports during contractions
- Pressure against the bladder and rectum
- Stretching and distention of perineal tissues and the pelvic floor to allow passage of the fetus
- Lacerations of soft tissue (e.g., cervix, vagina, and perineum)

As women concentrate on the work of bearing down to give birth, they may report a decrease in pain intensity (Blackburn, 2013; Burke, 2014). Pain impulses during the second stage of labor are transmitted via the pudendal nerve through S2 to S4 spinal nerve segments and the parasympathetic system (Blackburn).

Pain experienced during the third stage of labor, and the afterpains of the early postpartum period are uterine, similar to the pain experienced early in the first stage of labor. Areas of discomfort during labor are shown in Figure 17-1.

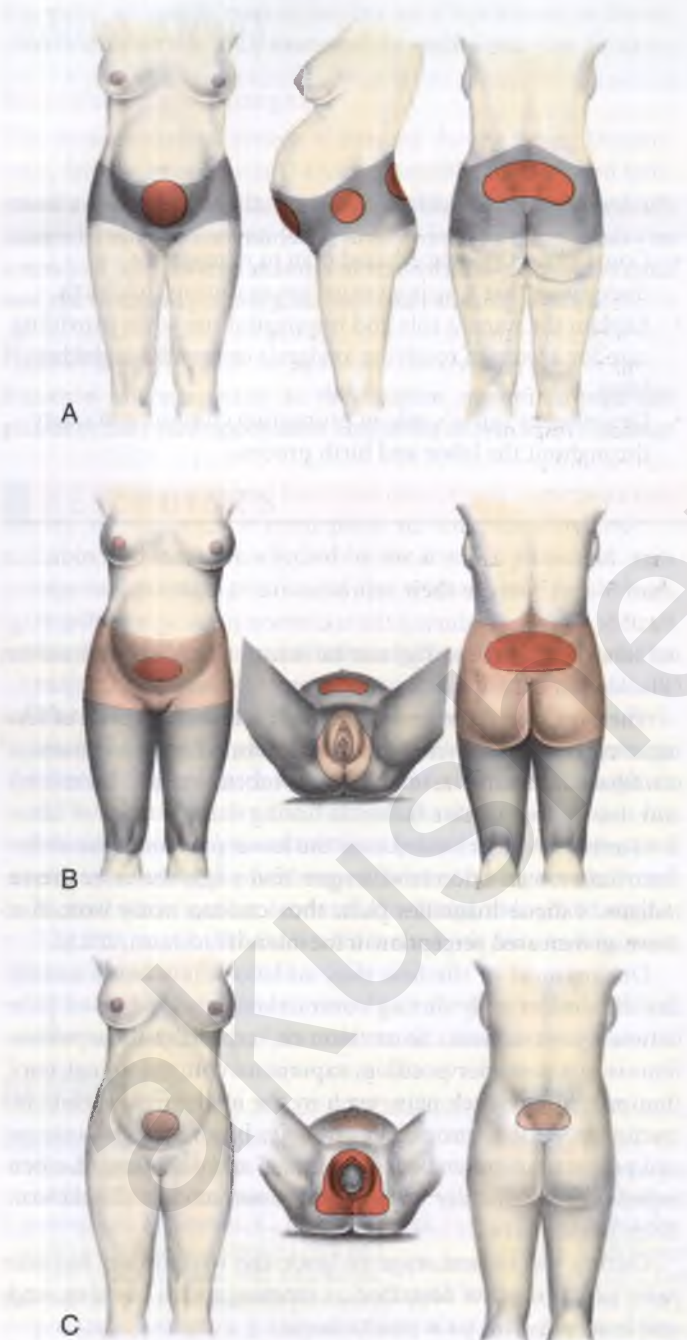

FIG 17-1 Discomfort during labor. **A**, Distribution of labor pain during first stage. **B**, Distribution of labor pain during transition and early phase of second stage. **C**, Distribution of pain during late second stage and actual birth. (Gray areas indicate mild discomfort; light pink areas indicate moderate discomfort; dark red areas indicate intense discomfort.)

Perception of Pain

Although the pain threshold is remarkably similar in everyone regardless of gender and social, ethnic, or cultural differences, these differences play a definite role in the person's perception of and behavioral responses to pain. Fear and lack of information can certainly increase the amount of pain and discomfort a laboring woman experiences. On the other hand, knowledge, a positive attitude, and support result in decreased pain perception and less use of medication during labor (Weatherspoon, 2011).

Pain tolerance refers to the level of pain a laboring woman is willing to endure. When this level is exceeded, she will seek measures to relieve the pain. Factors that influence her pain tolerance level and her request for pharmacologic pain relief measures include her desire for a natural, vaginal birth; her preparation for childbirth; her level of anxiety; the nature of her support during labor; and her willingness and ability to participate in nonpharmacologic measures for comfort (Weatherspoon, 2011).

Expression of Pain

Pain results in physiologic effects and sensory and emotional (affective) responses. During childbirth the pain or discomfort experienced gives rise to identifiable physiologic effects. Sympathetic nervous system activity is stimulated in response to intensifying pain, resulting in increased catecholamine levels. Blood pressure and heart rate increase. Maternal respiratory patterns change in response to an increase in oxygen consumption. Hyperventilation, sometimes accompanied by respiratory alkalosis, can occur as pain intensifies and more rapid, shallow breathing techniques are used during contractions. Pallor and diaphoresis may be seen. Gastric acidity increases, and nausea and vomiting are common in the active and transition phases of the first stage of labor. Placental perfusion may decrease, and uterine activity may diminish, potentially prolonging labor and affecting fetal well-being.

Certain emotional (affective) expressions of pain often are seen. Such changes include increasing anxiety with lessened perceptual field, writhing, crying, groaning, gesturing (hand clenching and wringing), and excessive muscular excitability throughout the body

FACTORS INFLUENCING PAIN RESPONSE

Pain during childbirth is unique to each woman. How she perceives or interprets that pain is influenced by a variety of physiologic, psychologic, emotional, social, cultural, and environmental factors.

Physiologic Factors

A variety of physiologic factors can affect the intensity of the childbirth experience. Uterine contractions, cervical dilation, and effacement are important aspects of labors, and can be the cause of discomfort and pain (Nur Rachmawati, 2012). Fatigue, anxiety, the interval and duration of contractions, fetal size and position, rapidity of fetal descent, maternal position, and maternal mobility during labor also affect a woman's perception of the intensity of childbirth contractions.

Beta-endorphins are endogenous opioids secreted by the pituitary gland that act on the central and peripheral nervous

systems to reduce pain. The level of beta-endorphins increases during pregnancy and birth in humans. Beta-endorphins are associated with feelings of euphoria and analgesia. The pain threshold may rise as beta-endorphin levels increase, enabling women in labor to tolerate acute pain (Blackburn, 2013).

Culture

The population of pregnant women reflects the increasingly multicultural nature of society in the United States. As nurses care for women and families from a variety of cultural backgrounds, they must have knowledge and understanding of how culture mediates pain. Although all women expect to experience at least some pain and discomfort during childbirth, it is their culture and religious belief system that determine how they will perceive, interpret, respond to, and manage the pain. Cultural influences may impose certain behavioral expectations regarding acceptable and unacceptable behavior when experiencing pain (Burke, 2014). Women with strong religious beliefs, for example, often accept pain as a necessary and inevitable part of bringing a new life into the world, whereas others tend to vocalize their pain by moaning, breathing rhythmically, or shouting (Andrews & Boyle, 2012).

An understanding of the beliefs, values, expectations, and practices of various cultures narrows the cultural gap and helps the nurse assess the laboring woman's pain experience more accurately. The nurse can then provide appropriate, culturally sensitive care by using pain relief measures that preserve the woman's sense of control and self-confidence (see Cultural Considerations box). Recognize that although a woman's behavior in response to pain may vary according to her cultural background, it may not accurately reflect the intensity of the pain she is experiencing. Assess the woman for the physiologic effects of pain, and listen to the words she uses to describe the sensory and affective qualities of her pain.

CULTURAL CONSIDERATIONS

Some Cultural Beliefs About Childbirth and Pain

The following examples demonstrate how women of different cultural backgrounds may react to pain. Because they are generalizations, the nurse must assess each woman experiencing pain related to childbirth.

- Chinese women may not exhibit reactions to pain, although exhibiting pain during childbirth is acceptable. They consider accepting something when it is first offered as impolite; therefore, pain interventions must be offered more than once. Acupuncture may be used for pain relief.
- Arab or Middle Eastern women may be vocal in response to labor pain. They may prefer medication for pain relief.
- Japanese women may be stoic in response to labor pain, but they may request medication when pain becomes severe.
- Southeast Asian women may endure severe pain before requesting relief.
- Hispanic women may be stoic until late in labor, when they may become vocal and request pain relief.
- Native-American women may use medications or remedies made from indigenous plants. They are often stoic in response to labor pain.
- African-American women may express pain openly. Use of medication for pain relief varies.

Anxiety

Anxiety is commonly associated with increased pain during labor. Mild anxiety is considered normal for a woman during labor and birth. However, excessive anxiety and fear cause more **catecholamine** secretion, which increases the stimuli to the brain from the pelvis because of decreased blood flow and increased muscle tension. This action, in turn, magnifies pain perception. Therefore, as anxiety and fear heighten, muscle tension increases, the effectiveness of uterine contractions decreases, the experience of discomfort increases, and a cycle of increased fear and anxiety begins (Blackburn, 2013). Ultimately this cycle will slow the progress of labor. The woman's confidence in her ability to cope with pain will be diminished, potentially resulting in reduced effectiveness of the pain relief measures being used.

Previous Experience

Previous experience with pain and childbirth may affect a woman's description of her pain and her ability to cope with the pain. Childbirth for a healthy young woman may be her first experience with significant pain, and as a result, she may not have developed effective pain coping strategies. She may describe the intensity of even early labor pain as pain "as bad as it can be." The nature of previous childbirth experiences also may affect a woman's responses to pain. For women who have had a difficult and painful previous birth experience, anxiety and fear from this past experience may lead to increased pain perception.

Sensory labor pain for nulliparous women is often greater than for multiparous women during early labor (dilation less than 5 cm) because their reproductive tract structures are less flexible. However, during the transition phase of the first stage of labor and during the second stage of labor, multiparous women may experience greater sensory pain than nulliparous women because their flexible tissue increases the speed of fetal descent and thereby intensifies discomfort. The firmer tissue of nulliparous women results in a slower, more gradual descent (Archie & Roman, 2013).

Parity may affect the perception of labor pain because nulliparous women often have longer labors and therefore greater fatigue. Fatigue magnifies pain, thus causing many women to have an increased perception of the intensity of pain during labor.

Gate-Control Theory of Pain

Intense pain stimuli can at times be ignored. This is possible because certain nerve cell groupings within the spinal cord, brainstem, and cerebral cortex have the ability to modulate the pain impulse through a blocking mechanism. This **gate-control theory of pain** helps explain the way hypnosis and the pain relief techniques taught in childbirth preparation classes work to relieve the pain of labor. According to this theory pain sensations travel along sensory nerve pathways to the brain, but only a limited number of sensations, or messages, can travel through these nerve pathways at one time. Using distraction techniques such as massage or effleurage, stroking, music, focal points, and imagery reduces or completely blocks the capacity of nerve pathways to transmit pain. These distractions are thought to work by closing down a hypothetical gate in the spinal cord, thus preventing pain signals from reaching the brain. The perception of pain is thereby diminished (Dean, Gwilym, & Carr, 2013).

In addition, when the laboring woman engages in neuromuscular and motor activity, activity within the spinal cord itself further modifies the transmission of pain. Cognitive work involving concentration on breathing and relaxation requires selective and directed cortical activity that activates and closes the gating mechanism as well. As labor intensifies, more complex cognitive techniques are required to maintain effectiveness. The main impetus behind the gate-control theory as it relates to pain is to introduce the brain to a positive stimulus by using all of the five senses. The brain then begins to accept the more positive stimulus, while paying less attention to negative stimuli such as discomfort or pain. Stimulating the senses will not create a pain-free environment, but it can help decrease the discomforts of labor.

Comfort

Although the predominant medical approach to labor is that it is painful, and the pain must be removed, an alternative view is that labor is a natural process in which women can experience comfort and transcend the discomfort or pain to reach the joyful outcome of birth. Having needs and desires met promotes a feeling of comfort. The most helpful interventions in enhancing comfort are a caring nursing approach and a supportive presence.

Support

Evidence indicates that a woman's satisfaction with her labor and birth experience is determined by how well her personal expectations of childbirth were met and the quality of support and interaction she received from her caregivers and partners (Box 17-1). In addition, satisfaction is influenced by the degree to which she was able to stay in control of her labor and to participate in decision making regarding her labor, including the nonpharmacologic and pharmacologic pain relief measures to be used (Devereaux & Sullivan, 2013).

The value of the continuous supportive presence of a person (e.g., doula, childbirth educator, family member, friend, nurse, or partner) during labor who provides physical comforting, facilitates communication, and offers information and guidance to the woman in labor has long been known. Emotional support is demonstrated by giving praise and reassurance and conveying a positive, calm, and confident demeanor when caring for the woman

in labor (Borders, Wendland, Haozous, et al., 2013). Women who have continuous support beginning early in labor are less likely to use pain medications or epidural analgesia or anesthesia and are more likely to experience a spontaneous vaginal birth and express satisfaction with their childbirth experience. Interestingly, research findings concluded that a more positive effect was achieved when continuous support was provided by people other than hospital staff members (Hodnett, Gates, Hofmeyr, & Sakala, 2013).

Environment

When the childbearing woman experiences discomfort in labor, the quality of her environment can contribute to her having a more positive experience. The woman's environment includes the individuals present (e.g., how they communicate; their philosophy of care, including a belief in the value of nonpharmacologic pain relief measures; practice policies; and quality of support) and the physical space in which the labor occurs. Women who are in a supportive environment feel more in control and therefore are more likely to have a better labor and birth experience. Studies have shown a correlation between control in childbirth and increased satisfaction with the entire childbirth experience (Meyer, 2013).

Women usually prefer to be cared for by familiar caregivers in a comfortable, homelike setting. The environment should be safe and private, allowing a woman to feel free to be herself as she tries out different comfort measures. Stimuli such as light, noise, and temperature should be adjusted according to her preferences. The environment should have space for movement, position changes, ambulation, and equipment such as birthing balls. Comfortable chairs, tubs, and showers should be readily available to facilitate participation in a variety of nonpharmacologic pain relief measures. Bringing items from home such as pillows, objects for a focal point, music, iPad, or DVDs can enhance the familiarity of the environment.

NONPHARMACOLOGIC PAIN MANAGEMENT

Relieving or reducing pain is important. Commonly it is not the amount of pain the woman experiences but whether she meets the goals she set for herself to cope with the pain that influences her perception of the birth experience as good or bad. The observant nurse looks for clues to the woman's desired level of control in the management of pain and its relief.

The labor and birth nurse can use a variety of nonpharmacologic methods for pain relief while providing support and encouragement to the laboring woman and her partner. Nonpharmacologic measures are often simple and safe, have few if any major adverse reactions, are relatively inexpensive, and can be used throughout labor. Additionally, they provide the woman with a sense of control over her childbirth as she makes choices about the measures that are best for her. During the prenatal period she should explore a variety of nonpharmacologic measures. Techniques she usually finds helpful in relieving stress and enhancing relaxation (e.g., music, meditation, massage, warm baths) may be very effective as components of a plan for managing labor pain. The woman should be encouraged to communicate to her health care providers her preferences for relaxation and pain relief measures and to actively participate in their implementation (see Clinical Reasoning Case Study).

BOX 17-1 Suggested Measures for Supporting a Woman in Labor

- Provide companionship and reassurance.
- Offer positive reinforcement and praise for her efforts.
- Encourage participation in distracting activities and nonpharmacologic measures for comfort.
- Give nourishment (if allowed by primary health care provider).
- Assist with personal hygiene.
- Offer information and advice.
- Involve the woman in decision making regarding her care.
- Interpret the woman's wishes to other health care providers and to her support group.
- Create a relaxing environment.
- Use a calm and confident approach.
- Support and encourage the woman's support people by role-modeling labor support measures and providing time for breaks.

**CLINICAL REASONING CASE STUDY****Making Decisions Regarding Pain Management for Labor**

Diana is a 33-year-old G 2 P 1, who has just been admitted to the labor and birth unit in active labor at 39 weeks of gestation. Her cervix is dilated to 7 cm on admission. Diana attended childbirth classes and is considered to have a low risk pregnancy. According to her birth plan, she wants to have a natural childbirth, without pharmacologic interventions. Diana was not satisfied with her experience during the labor and birth of her first child. For that birth she had an epidural, which required an IV and an indwelling urinary catheter. Because Diana was unable to push effectively during second stage labor she had a vacuum-assisted birth and a third-degree episiotomy. Diana does not want to repeat her prior birth experience this time. She is also very concerned about receiving medications that could harm her baby. Soon after admission Diana expresses discomfort and states, "I don't know if I can do this. I think I need an epidural!"

1. Evidence—Is there sufficient evidence regarding nonpharmacologic and pharmacologic pain relief measures in labor to make recommendations to Diana?
2. Assumptions—Describe the underlying assumptions about each of the following issues:
 - a. Timing of transitional phase of first stage labor and possible epidural
 - b. Effectiveness of physical and emotional support on the labor process
 - c. Approaches that are proven to reduce the use of pharmacologic measures
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

Many of the nonpharmacologic methods for relief of discomfort are taught in different types of prenatal preparation classes, or the woman or couple may have read various books and magazine articles on the subject in advance. Many of these methods require practice for best results (e.g., hypnosis, patterned breathing and controlled relaxation techniques, biofeedback, focal point, distraction), although the nurse may use some of them successfully without the woman or couple having prior knowledge (e.g., slow-paced breathing, massage and touch, effleurage, counterpressure, relaxation, music, hot or cold packs, movement or positioning). Women should be encouraged to try a variety of methods and to seek alternatives, including pharmacologic methods, when the measure being used is no longer effective (Burke, 2014).

Because of the increased use of epidural analgesia or anesthesia, nurses may be less likely to encourage women to use nonpharmacologic pain relief measures, in part because these methods may be viewed as more complex and time consuming than monitoring a woman receiving an epidural. In addition, new nurses may not have had the opportunity to develop skill in the implementation of these methods. It is imperative that perinatal nurses develop a commitment to and expertise in using a variety of nonpharmacologic pain relief strategies in order for women in labor to be comfortable using them. Although research data to support the effectiveness of many of these nonpharmacologic measures are limited, there are sufficient reports of their benefits from women and health care providers to recommend that nurses encourage their use. These methods are

less invasive and safer for mother and baby. Nonpharmacologic methods of pain relief also allow the normal course of labor to progress more efficiently, as opposed to pharmacologic methods, which tend to interrupt or even slow the labor process. Pharmacologic methods may also influence subsequent neonatal behavior and its effect on breastfeeding. The analgesic effect of many nonpharmacologic measures is comparable to or even superior to opioids that are administered parenterally (Jones, Othman, Dowswell, et al., 2012) (Box 17-2).

Childbirth Preparation Methods

The childbirth education movement began in the 1950s. Today most health care providers recommend or offer childbirth preparation classes for expectant parents. Historically, popular childbirth methods taught in the United States were the Dick-Read method, the Lamaze (psychoprophylaxis) method, and the Bradley (husband-coached childbirth) method. Although these three organizations continue to exist, they are now less focused on a "method" approach. Rather, women are assisted to develop their birth philosophy and inner knowledge and then choose from a variety of skills to use to cope with the labor process. Many childbirth educators teach a variety of techniques that originated in several different organizations or publications. Women are encouraged to choose the techniques that work best for them.

Gaining popularity are methods developed and promoted by Birthing From Within (www.birthingfromwithin.com), Birthworks (www.birthworks.org), Association of Labor Assistants and Childbirth Educators (ALACE) (www.alace.org), Childbirth and Postpartum Professional Association (CAPPA) (www.cappa.net), and HypnoBirthing (www.hypnobirthing.com), to name a few. These methods offer classes and other services that focus on fostering a woman's confidence in her innate ability

BOX 17-2 Nonpharmacologic Strategies to Encourage Relaxation and Relieve Pain**Cutaneous Stimulation Strategies**

- Counterpressure
- Effleurage (light massage)
- Therapeutic touch and massage
- Walking
- Rocking
- Changing positions
- Application of heat or cold
- Transcutaneous electrical nerve stimulation (TENS)
- Acupressure
- Water therapy (showers, whirlpool baths)
- Intradermal water block

Sensory Stimulation Strategies

- Aromatherapy
- Breathing techniques
- Music
- Imagery
- Use of focal points

Cognitive Strategies

- Childbirth education
- Hypnosis
- Biofeedback

to give birth. The woman or couple is helped to recognize the uniqueness of their pregnancy and childbirth experience.

Relaxation and Breathing Techniques

Focusing and Relaxation Techniques

By reducing tension and stress, focusing and relaxation techniques allow a woman in labor to rest and conserve energy for the task of giving birth. *Attention-focusing* and *distraction* techniques are forms of care that are effective to some degree in relieving labor pain (Jones et al., 2012). Some women bring a favorite object such as a photograph or stuffed animal to the labor room and focus their attention on this object during contractions. Others choose to fix their attention on some object in the labor room. As the contraction begins, they focus on their chosen object and perform a breathing technique to reduce their perception of pain.

With *imagery* the woman focuses her attention on a pleasant scene, a place where she feels relaxed, or an activity she enjoys. She can imagine walking through a restful garden or breathing in light, energy, and a healing color and breathing out worries and tension. Choosing the subject for the imagery and practicing the technique during pregnancy enhance effectiveness during labor.

During childbirth preparation classes the coach can learn how to palpate a woman's body to detect tense and contracted muscles. The woman then learns how to relax the tense muscle in response to the gentle stroking of the muscle by the coach (Fig. 17-2). In a common feedback mechanism, the woman and her coach say the word "relax" at the onset of each contraction and throughout it as needed. With practice the coach can effectively use support, feedback, and touch to facilitate the woman's relaxation and thereby reduce tension and stress and enhance the progress of labor (Burke, 2014).

Women may find that drinking herbal tea during labor can help them to relax (e.g., chamomile), to reduce nausea (e.g., lemon balm, peppermint), and to enhance energy and reduce fatigue (e.g., ginger, ginseng). Drinking tea can have the additional benefit of maintaining fluid balance (Walls, 2009).

The nurse can assist the woman by providing a quiet and relaxed environment, offering cues as needed, and recognizing

signs of tension (e.g., frowning, change in tone of voice, clenching of fists). A relaxed environment for labor is created by controlling sensory stimuli (e.g., light, noise, temperature), and reducing interruptions. Nurses should remain calm and unhurried in their approach and sit rather than stand at the bedside whenever possible (Burke, 2014).

Breathing Techniques

Different approaches to childbirth preparation stress varying breathing techniques to provide distraction, thereby reducing the perception of pain and helping the woman maintain control throughout contractions. In the first stage of labor such breathing techniques can promote relaxation of the abdominal muscles and thereby increase the size of the abdominal cavity. This lessens discomfort generated by friction between the uterus and abdominal wall during contractions. Because the muscles of the genital area also become more relaxed, they do not interfere with fetal descent. In the second stage, breathing is used to increase abdominal pressure and thereby assist in expelling the fetus. Breathing also can be used to relax the pudendal muscles to prevent precipitate expulsion of the fetal head (Fig. 17-3).

For couples who have prepared for labor by practicing relaxing and breathing techniques, a simple review with occasional reminders may be all that is necessary to help them along. For those who have had no preparation, instruction and practice in simple breathing and relaxation techniques can be given early in labor and often are surprisingly successful. Nurses can also model breathing techniques and breathe in synchrony with the woman and her partner. Motivation is high, and readiness to learn is enhanced by the reality of labor.

Various breathing techniques can be used for controlling pain during contractions (Box 17-3). The nurse needs to determine what, if any, techniques the laboring couple know before giving them instruction. Simple patterns are more easily learned. **Paced breathing** is most associated with prepared childbirth and includes slow-paced, modified-paced, and patterned-paced (pant-blow) breathing techniques. Each labor is different, and nursing support includes assisting

FIG 17-2 A laboring woman using focusing and breathing techniques during a uterine contraction with coaching from her partner. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

FIG 17-3 Expectant parents learning relaxation techniques. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

couples to adapt breathing techniques to their individual labor experience.

All patterns begin with a deep, relaxing, cleansing breath to “greet the contraction” and end with another deep breath exhaled to “gently blow the contraction away.” These deep breaths ensure adequate oxygen for mother and baby and signal that a contraction is beginning or has ended. As the breath is exhaled, respiratory and voluntary muscles relax (Burke, 2014). In general, *slow-paced breathing* is performed at approximately half the woman’s normal breathing rate and is initiated when she can no longer walk or talk through contractions. The woman should take approximately six to eight breaths per minute. Slow-paced breathing aids in relaxation and provides optimum oxygenation. The woman should continue to use this technique for as long as it is effective in reducing the perception of pain and maintaining control. As contractions increase in frequency and intensity, the woman often needs to change to a more complex breathing technique, which is shallower and faster than her normal rate of breathing, but should not exceed twice her resting respiratory rate. This *modified-paced breathing* pattern requires that she remain alert and concentrate more fully on breathing, thus blocking more painful stimuli than the simpler slow-paced breathing pattern does (Perinatal Education Associates, 2014).

The most difficult time to maintain control during contractions comes during the transition phase of the first stage of labor, when the cervix dilates from 8 cm to 10 cm. Even for the

woman who has prepared for labor, concentration on breathing techniques is difficult to maintain. *Patterned-paced (pant-blow) breathing* is suggested during this phase. It is performed at the same rate as modified-paced breathing and consists of panting breaths combined with soft blowing breaths at regular intervals. The patterns may vary (i.e., *pant, pant, pant, pant, blow* [4:1 pattern] or *pant, pant, pant, blow* [3:1 pattern]) (Perinatal Education Associates, 2014). An undesirable reaction to this type of breathing is hyperventilation. The woman and her support person must be aware of and watch for symptoms of the resultant respiratory alkalosis: lightheadedness, dizziness, tingling of the fingers, or circumoral numbness. Having the woman breathe into a paper bag held tightly around her mouth and nose may eliminate respiratory alkalosis. This enables her to rebreathe carbon dioxide and replace the bicarbonate ions. The woman also can breathe into her cupped hands if no bag is available. Maintaining a breathing rate that is no more than twice the normal rate will lessen chances of hyperventilation. The partner can help the woman maintain her breathing rate with visual, tactile, or auditory cues.

As the fetal head reaches the pelvic floor, the woman may feel the urge to push and may automatically begin to exert downward pressure by contracting her abdominal muscles. During second-stage pushing, the woman should find a breathing pattern that is relaxing and feels good to her and is safe for her baby. Any regular or rhythmic breathing that avoids prolonged breath holding during pushing should maintain a good oxygen flow to the fetus (Perinatal Education Associates, 2014).

The woman can control the urge to push by taking panting breaths or by slowly exhaling through pursed lips (as though blowing out a candle). This type of breathing can be used to overcome the urge to push when the cervix is not fully prepared (e.g., less than 8 cm dilated, not retracting) and to facilitate a slow birth of the fetal head.

Effleurage and Counterpressure

Effleurage (light massage) and counterpressure have brought relief to many women during the first stage of labor. The gate-control theory may supply the reason for the effectiveness of these measures. **Effleurage** is light stroking, usually of the abdomen, in rhythm with breathing during contractions. It is used to distract the woman from contraction pain. Often the presence of monitor belts makes it difficult to perform effleurage on the abdomen; therefore, a thigh or the chest may be used. As labor progresses, hyperesthesia (hypersensitivity to touch) may make effleurage uncomfortable and thus less effective.

Counterpressure is steady pressure applied by a support person to the sacral area with a firm object (e.g., tennis ball) or the fist or heel of the hand. Pressure can also be applied to both hips (double hip squeeze) or to the knees (Burke, 2014). Application of counterpressure helps the woman cope with the sensations of internal pressure and pain in the lower back. It is especially helpful for back pain caused by pressure of the occiput against spinal nerves when the fetal head is in a posterior position. Counterpressure lifts the occiput off these nerves, thereby providing pain relief. The support person will need to be relieved occasionally because application of counterpressure is hard work.

BOX 17-3 Paced Breathing Techniques

Cleansing Breath

- Relaxed breath in through nose and out through mouth. Used at the beginning and end of each contraction.

Slow-Paced Breathing (Approximately 6 to 8 Breaths per Minute)

- Performed at approximately half the normal breathing rate (number of breaths per minute divided by 2)
- IN-2-3-4/OUT-2-3-4/IN-2-3-4/OUT-2-3-4 ...

Modified-Paced Breathing (Approximately 32 to 40 Breaths per Minute)

- Performed at about twice the normal breathing rate (number of breaths per minute multiplied by 2)
- IN-OUT/IN-OUT/IN-OUT/IN-OUT ...
- For more flexibility and variety, the woman may combine the slow and modified breathing by using the slow breathing for beginnings and ends of contractions and modified breathing for more intense peaks. This technique conserves energy, lessens fatigue, and reduces risk for hyperventilation.

Patterned-Paced or Pant-Blow Breathing (Same Rate as Modified)

- Enhances concentration
- 3:1 Patterned breathing IN-OUT/IN-OUT/IN-OUT/IN-BLOW (repeat through contraction)
- 4:1 Patterned breathing IN-OUT/IN-OUT/IN-OUT/IN-OUT/IN-BLOW (repeat through contraction)

Philadelphia: Saunders; Perinatal Education Associates. (2014). *Breathing*. Available at www.birthsource.com/scripts/article.asp?articleid=211.

Touch and Massage

Touch and massage have been an integral part of the traditional care process for women in labor. A variety of massage techniques have been shown to be safe and effective during labor (Jones et al., 2012).

Touch can be as simple as holding the woman's hand, stroking her body, and embracing her. When using touch to communicate caring, reassurance, and concern, it is important that the woman's preferences for touch (e.g., who can touch her, where they can touch her, and how they can touch her) and responses to touch be determined. A woman with a history of sexual abuse or certain cultural beliefs may be uncomfortable with touch. Women who perceive touch during labor as positive have less pain, anxiety, and need for pain medication (Weatherspoon, 2011). Touch also can involve very specialized techniques that require manipulation of the human energy field.

Therapeutic touch (TT) uses the concept of energy fields within the body called *prana*. Prana are thought to be deficient in some people who are in pain. TT uses laying-on of hands by a specially trained person to redirect energy fields associated with pain. Research has demonstrated the effectiveness of TT to enhance relaxation, reduce anxiety, and relieve pain (Jones et al., 2012); however, little is known about the use or effectiveness of TT for relieving labor pain.

Head, hand, back, and foot massage may be very effective in reducing tension and enhancing comfort. Some evidence suggests that massage may improve management of labor pain (Jones et al., 2012). Hand and foot massage may be especially relaxing in advanced labor when hyperesthesia limits a woman's tolerance for touch on other parts of her body. Combining massage with aromatherapy oil or lotion enhances relaxation both during and between contractions. The woman and her partner should be encouraged to experiment with different types of massage during pregnancy to determine which might feel best and be most relaxing during labor.

Application of Heat and Cold

Warmed blankets, warm compresses, heated rice bags, a warm bath or shower, or a moist heating pad can enhance relaxation and reduce pain during labor. Heat relieves muscle ischemia and increases blood flow to the area of discomfort. Heat application is effective for back pain caused by a posterior position or general backache from fatigue.

Cold application such as cold cloths, frozen gel packs, or ice packs applied to the back, the chest, or the face during labor may be effective in increasing comfort when the woman feels warm. They also may be applied to areas of musculoskeletal pain. Cooling relieves pain by reducing the muscle temperature and relieving muscle spasms (Burke, 2014). However, a woman's culture may make the use of cold during labor unacceptable.

Heat and cold may be used alternately for a greater effect. Neither heat nor cold should be applied over ischemic or anesthetized areas because tissues can be damaged. One or two layers of cloth should be placed between the skin and a hot or cold pack to prevent damage to the underlying integument.

Acupressure and Acupuncture

Acupressure and acupuncture can be used in pregnancy, in labor, and postpartum to relieve pain and other discomforts.

Pressure, heat, or cold is applied to acupuncture points called *tsubos*. These points have an increased density of neuroreceptors and increased electrical conductivity. Acupressure is said to promote circulation of blood, the harmony of yin and yang, and the secretion of neurotransmitters, thus maintaining normal body functions and enhancing well-being (Gisin, Poat, Fierz, & Frei, 2013; Melchart, Jack, & Kashanian, 2011). Acupressure is best applied over the skin without using lubricants. Pressure is usually applied with the heel of the hand, fist, or pads of the thumbs and fingers (Fig. 17-4). Tennis balls or other devices also may be used. Pressure is applied with contractions initially and then continuously as labor progresses to the transition phase at the end of the first stage of labor (Gisin et al.; Hawkins & Bucklin, 2012; Melchart et al.). Synchronized breathing by the caregiver and the woman is suggested for greater effectiveness. Acupressure points are found on the neck, the shoulders, the wrists, the lower back including sacral points, the hips, the area below the kneecaps, the ankles, the nails on the small toes, and the soles of the feet. Acupressure may help to reduce pain and decrease the use of pharmacologic pain relief measures during labor. More research on its use is suggested (Arendt & Tessmer-Tuck, 2013).

Acupuncture is the insertion of fine needles into specific areas of the body to restore the flow of *qi* (energy) and to decrease pain, which is thought to obstruct the flow of energy. Effectiveness may be attributed to the alteration of chemical neurotransmitter levels in the body or to the release of endorphins as a result of hypothalamic activation. A trained certified therapist should do acupuncture. Arranging to have a qualified and credentialed acupuncture provider available during labor and birth may be challenging (Hawkins & Bucklin, 2012). Evidence indicates that acupuncture may be beneficial for relief of labor pain; however, further study is indicated (Gisin et al., 2013; Hawkins & Bucklin).

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) involves the placing of two pairs of flat electrodes on either side of the woman's thoracic and sacral spine (Fig. 17-5). These electrodes

FIG 17-4 Ho-Ku acupressure point (back of hand where thumb and index finger come together) used to enhance uterine contractions without increasing pain. (Courtesy Julie Perry Nelson, Loveland, CO.)

Hyper sensitivity to touch

provide continuous low-intensity electrical impulses or stimuli from a battery-operated device. During a contraction the woman increases the stimulation from low to high intensity by turning control knobs on the device. High intensity should be

FIG 17-5 Placement of transcutaneous electrical nerve stimulation (TENS) electrodes on back for relief of labor pain.

maintained for at least 1 minute to facilitate release of endorphins. Women describe the resulting sensation as a tingling or buzzing. TENS is most useful for lower back pain during the early first stage of labor. Women tend to rate the device as helpful although its use does not decrease pain. It appears that the electrical impulses or stimuli somehow make the pain less disturbing. There are no serious safety concerns associated with the use of TENS (Francis, 2012; Hawkins & Bucklin, 2012).

Water Therapy (Hydrotherapy)

Bathing, showering, and jet hydrotherapy (whirlpool baths) with warm water (e.g., at or below body temperature) are non-pharmacologic measures that can promote comfort and relaxation during labor (Fig. 17-6). The warm water stimulates the release of endorphins, relaxes fibers to close the gate on pain, promotes better circulation and oxygenation, and helps soften the perineal tissues. Most women find immersion in water to be soothing, relaxing, and comforting. While immersed, they may find it easier to let go and allow labor to take its course (Gilbert, 2011). Some evidence suggests that immersion in water may improve management of labor pain (Arendt & Tessmer-Tuck, 2013; Jones et al., 2012).

FIG 17-6 Water therapy during labor. **A**, Use of shower during labor. **B**, Woman experiencing back labor relaxes as partner sprays warm water on her back. **C**, Laboring woman relaxes in Jacuzzi. Note that fetal monitoring can continue during time in the Jacuzzi. (A and B, Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA; C, courtesy Spacelabs Medical, Redmond, WA.)

Prior to initiating hydrotherapy measures, agency policy should be consulted to determine if the approval of the laboring woman's primary health care provider is required and if criteria need to be met in terms of the status of the maternal and fetal unit (e.g., stable vital signs and fetal heart rate [FHR] and pattern, stage of labor, etc.). In order to reduce the risk of a prolonged labor, hydrotherapy is usually initiated when the woman is in active labor, at approximately 5 cm. It is at this time that she may be getting discouraged and will welcome the change that hydrotherapy offers. Remember to preserve her modesty because she may be shy about the exposure of her body when getting into a tub or shower (Creehan, 2008).

In addition to pain relief and relaxation, hydrotherapy offers other benefits. If a woman is having "back labor" as the result of an occiput posterior or transverse position, assuming a hands-and-knees or a side-lying position in the tub enhances spontaneous fetal rotation to the occiput anterior position as a result of increased buoyancy. Because less effort is needed to change positions while in the water, women are encouraged to assume upright positions and to alter positions more frequently, facilitating the progress of their labors and helping them cope with labor-associated stressors (see Community Activity box) (Smith, Levett, Collins, & Jones, 2012). Additionally, hydrotherapy results in less use of pharmacologic pain relief measures, decreased use of epidural anesthesia, fewer forceps- or vacuum-assisted births, fewer episiotomies, less perineal trauma, and increased maternal satisfaction with the birth experience (Arendt & Tessmer-Tuck, 2013; Burke, 2014).

COMMUNITY ACTIVITY

Interview several women who have given birth, and explore the positions they used while in labor. Which positions were most helpful, and why? Which did they find least helpful? Did any of the women use hydrotherapy? Share your findings with your fellow students.

When hydrotherapy is in use, FHR monitoring is done by Doppler, fetoscope, or wireless external monitor (see Fig. 17-6, C). Placement of internal electrodes is contraindicated for jet hydrotherapy. Several studies have investigated the risks of using hydrotherapy with ruptured membranes. Findings have shown no increases in chorioamnionitis, postpartum endometritis, neonatal infections, or antibiotic use (Burke, 2014). However, care must be taken to use tubs that can be cleansed easily and thoroughly. A unit protocol should be developed for cleaning the tubs.

There is no limit to the time women can stay in the bath, and often they are encouraged to stay in it as long as desired. However, most women use jet hydrotherapy for 30 to 60 minutes at a time. During the bath, if the woman's temperature and the FHR increase, if the labor process becomes less effective (e.g., slows or becomes too intense), or if relief of pain is reduced, the woman can come out of the bath and return at a later time. Repeated baths with occasional breaks may be more effective in relieving pain in long labors than extended amounts of time in the water. The water temperature should be maintained at 36° to 37° C (96.8° to 98.6° F), with the water covering the woman's abdomen to gain maximum effect from the hydrostatic pressure

and buoyancy of the water. Her shoulders should remain out of the water to facilitate the dissipation of heat (Burke, 2014; Creehan, 2008).

The American Academy of Pediatrics Committee on Fetus and Newborn has expressed concerns about actual birthing in water because of the lack of research demonstrating its safety. There are rare but reported instances of asphyxia or infection that have occurred during or as a result of underwater birth (Arendt & Tessmer-Tuck, 2013; Hawkins & Bucklin, 2012). This group believes that underwater birth should be considered an experimental procedure, performed only after informed parental consent has been obtained (Hawkins & Bucklin).

In a joint statement, the Royal College of Obstetricians & Gynaecologists (RCOG) and the Royal College of Nurse Midwives support laboring in water for healthy women with uncomplicated pregnancies at term (RCOG, 2006). While these groups acknowledge safety concerns related to respiratory problems in newborns, cord avulsion, and waterborne infection when women give birth under water, they state that these complications appear to occur rarely if good practice guidelines related to infection control, management of cord rupture, and strict adherence to eligibility criteria are followed (RCOG).

Using a shower provides comfort through the application of heat as the handheld showerhead is directed to areas of discomfort (see Fig. 17-6, A and B). The coach or partner can participate in this comfort measure by holding and directing the showerhead.

SAFETY ALERT

Because warm water can cause dizziness, a shower stool should be available, and the woman should be assisted when getting in and out of the tub.

Intradermal Water Block

An intradermal water block involves the injection of small amounts of sterile water (e.g., 0.05 to 0.1 ml) by using a fine needle (e.g., 25 gauge) into four locations on the lower back to relieve low back pain (Fig. 17-7). It is a simple procedure to perform, and there is evidence that it is effective, perhaps because of the gate-control mechanism (Hawkins & Bucklin, 2012). Other possible explanations for the effectiveness of the intradermal water block are the mechanism of counterirritation (i.e., reducing localized pain in one area by irritating the skin in an area nearby) or an increase in the level of endogenous opioids (endorphins) produced by the injections. Intense stinging will occur for about 20 to 30 seconds after injection, but relief of back pain for up to 2 hours has been reported (Burke, 2014). The procedure can be repeated, although the woman may find that the stinging that occurs with administration creates too much discomfort.

Aromatherapy

Aromatherapy uses oils distilled from plants, flowers, herbs, and trees to promote health and to treat and balance the mind, body, and spirit. These essential oils are highly concentrated, complex essences, and are mixed with lotions or creams before they are applied to the skin (e.g., for a back massage). Certain essential

FIG 17-7 Intradermal injections of 0.1 ml of sterile water in the treatment of women with back pain during labor. Sterile water is injected into four locations on the lower back, two sites lateral to the lumbosacral spine and two sites 2 to 3 cm below and 1 to 2 cm medial to the original two injection sites; 0.1 ml of sterile water is injected between the dermal layers to raise a small bleb on the skin surface at each of the four sites. Simultaneous injections administered by two clinicians will decrease the pain of the injections. During labor the injections are administered consecutively during a contraction, with the total number of injections being completed within 20 to 30 seconds (From Leeman, L., Fontaine, P., King, V., Klein, M., & Ratcliffe, S. [2003]. *The nature and management of labor pain: Part I. Nonpharmacologic pain relief. American Family Physician* 68[6], 1109-1112. Copyright 2003 Michael Norviel.)

oils can tone the uterus, encourage contractions, reduce pain, relieve tension, diminish fear and anxiety, and enhance the feeling of well-being. Lavender, rose, and jasmine oils can promote relaxation and reduce pain. Rose oil also acts as an antidepressant and uterine tonic, and jasmine oil strengthens contractions and decreases feelings of panic in addition to reducing pain. Essential oils of bergamot or rosemary can be diffused or used in a massage oil to relieve exhaustion (Gilbert, 2011). Oils may be used by adding a few drops to a warm bath or to warm water used for soaking compresses that can be applied to the body. Drops of essential oils can be put on a pillow or on a woman's brow or palms or used as an ingredient in creating massage oil. They may also be inhaled as a steam or a smoke (Arendt & Tessmer-Tuck, 2013; Gilbert). Certain odors or scents can evoke pleasant memories and feelings of love and security. As a result, it's helpful for a woman to choose the scents that she will use. Aromatherapy has not been shown to improve labor outcomes. However, there is likely little harm associated with its use, other than the possibility of an allergic reaction (Arendt & Tessmer-Tuck).

Music

Music, recorded or live, can provide a distraction, enhance relaxation, and lift spirits during labor, thereby reducing the woman's level of stress, anxiety, and perception of pain. It can be used to promote relaxation in early labor and to stimulate movement as labor progresses. Music can help to create a more relaxed atmosphere in the birth room, leading to a more relaxed approach by health care providers (Burke, 2014). Women should be encouraged to prepare their musical preferences in advance and to bring an electronic music device to the hospital or birthing center. They should choose familiar music that is associated with pleasant memories, which can also facilitate the process of guided imagery. Use of a headset or earphones may increase the effectiveness of the music because other sounds

will be shut out. Live music provided at the bedside by a support person may be very helpful in transmitting energy that decreases tension and elevates mood. Changing the tempo of the music to coincide with the rate and rhythm of each breathing technique may facilitate proper pacing. Although promising, there is insufficient evidence at the present time to support the effectiveness of music as a method of pain relief during labor. Further research is recommended (Smith et al., 2012).

Hypnosis

Hypnosis is a form of deep relaxation, similar to daydreaming or meditation (see www.hypnobirthing.com). While under hypnosis women are in a state of focused concentration and the subconscious mind can be more easily accessed. Women who attend certain childbirth preparation classes may be taught to perform self-hypnosis. Hypnosis techniques used for labor and birth place an emphasis on enhancing relaxation and diminishing fear, anxiety, and perception of pain. A few negative effects of hypnosis have been reported, including mild dizziness, nausea, and headache. These negative effects seem to be associated with failure to dehypnotize the woman properly. Although some initial small studies found hypnosis to be beneficial, a Cochrane systematic review showed no difference between women who were hypnotized and those who were not in regard to their use of pain medication during labor or their satisfaction with pain relief or the overall birth experience (Arendt & Tessmer-Tuck, 2013).

Biofeedback

Biofeedback may provide another relaxation technique that can be used for labor. Biofeedback is based on the theory that if a person can recognize physical signals, certain internal physiologic events can be changed (i.e., whatever signs the woman has that are associated with her pain). For biofeedback to be effective, the woman must be educated during the prenatal period to become aware of her body and its responses and how to relax. The woman must learn how to use thinking and mental processes (e.g., focusing) to control body responses and functions. Informational biofeedback helps couples develop awareness of their bodies and use strategies to change their responses to stress. If the woman responds to pain during a contraction with tightening of muscles, frowning, moaning, and breath holding, her partner uses verbal and touch feedback to help her relax. Formal biofeedback, which uses machines to detect skin temperature, blood flow, or muscle tension, also can prepare women to intensify their relaxation responses. Biofeedback-assisted relaxation techniques are not always successful in reducing labor pain. They may initially reduce pain or discomfort in labor, but as labor progresses women often need pain medication as well. There is insufficient evidence at this time to show that biofeedback is effective for managing labor pain (Barragan Loayza, Solá, & Juandó Prats, 2011).

PHARMACOLOGIC PAIN MANAGEMENT

Pharmacologic measures for pain management should be implemented before pain becomes so severe that catecholamines increase and labor is prolonged. Pharmacologic and nonpharmacologic measures, when used together, increase the

level of pain relief and create a more positive labor experience for the woman and her family. Nonpharmacologic measures can be used for relaxation and pain relief, especially in early labor. Pharmacologic measures can be implemented as labor becomes more active and discomfort and pain intensify. Less pharmacologic intervention often is required because nonpharmacologic measures enhance relaxation and potentiate the analgesic effect. However, women in the United States are increasingly using pharmacologic measures, especially epidural analgesia, to relieve their pain during labor and birth. In one survey, nearly two-thirds of women received regional anesthesia to relieve pain during labor or during vaginal or cesarean birth (Cunningham, Leveno, Bloom, et al., 2014). Pharmacologic measures for pain management are generally used in hospital settings rather than in birthing centers or for home births.

SAFETY ALERT

Whenever medications are administered, nurses must remain alert for adverse reactions (e.g., difficulty breathing) and be prepared to administer antidotes or summon assistance if necessary. Remember that adverse reactions can occur even if the woman has received the same medication in the past without problems.

Sedatives

Sedatives relieve anxiety and induce sleep. They can be given to a woman experiencing a prolonged latent phase of labor when there is a need to lessen the intensity of the contractions, decrease anxiety, or promote sleep. They can also be given to augment analgesics and reduce nausea when an opioid is used.

Barbiturates such as secobarbital sodium (Seconal) can cause undesirable side effects including respiratory and vasomotor depression, affecting the woman and newborn. Because of the potential for neonatal central nervous system (CNS) depression, barbiturates should be avoided if birth is anticipated within 12 to 24 hours. The depressant effects are increased if a barbiturate is administered with another CNS depressant such as an opioid analgesic. However, pain will be magnified if a barbiturate is given without an analgesic to women experiencing pain because normal coping mechanisms may be blunted. As a result of these disadvantages, barbiturates are seldom used during labor (Burke, 2014; Hawkins & Bucklin, 2012).

Phenothiazines (e.g., promethazine [Phenergan]) do not relieve pain. In the past, promethazine was often given with opioids to enhance the analgesic effects of opioids, as well as to decrease anxiety and apprehension, increase sedation, and reduce nausea and vomiting. However, research has shown that promethazine actually impairs the analgesic efficacy of opioids. Metoclopramide (Reglan), an antiemetic, has been found to effectively potentiate the effects of analgesics. Therefore, its use is recommended, rather than promethazine (Hawkins & Bucklin, 2012).

Benzodiazepines (e.g., diazepam [Valium], lorazepam [Ativan]), when given with an opioid analgesic, seem to enhance pain relief and reduce nausea and vomiting. Because benzodiazepines cause significant maternal amnesia, however, their use should be avoided during labor. A major disadvantage of diazepam is that it disrupts thermoregulation in newborns, making them less able to maintain body temperature. Flumazenil

(Romazicon) is a specific benzodiazepine antagonist that can be administered if necessary to effectively reverse benzodiazepine-induced sedation and respiratory depression (Hawkins & Bucklin, 2012).

Analgesia and Anesthesia

The use of analgesia and anesthesia was not generally accepted as part of obstetric management until Queen Victoria used chloroform during the birth of her son in 1853. Since then much study has gone into the development of pharmacologic measures for controlling discomfort during the birth period. The goal of researchers is to develop methods that will provide adequate pain relief to women without increasing maternal or fetal risk or affecting the progress of labor.

Nursing management of obstetric analgesia and anesthesia combines the nurse's expertise in maternity care with a knowledge and understanding of anatomy and physiology and of medications and their therapeutic effects, adverse reactions, and methods of administration.

Anesthesia encompasses analgesia, amnesia, relaxation, and reflex activity. Anesthesia abolishes pain perception by interrupting the nerve impulses to the brain. The loss of sensation may be partial or complete, sometimes with the loss of consciousness.

The term **analgesia** refers to the alleviation of the sensation of pain or the raising of the threshold for pain perception without loss of consciousness.

The type of analgesic or anesthetic chosen is determined in part by the stage of labor of the woman and by the method of birth planned (Box 17-4).

BOX 17-4 Pharmacologic Control of Discomfort by Stage of Labor and Method of Birth

First Stage

- Opioid agonist analgesics
- Opioid agonist-antagonist analgesics
- Epidural (block) analgesia
- Combined spinal-epidural (CSE) analgesia
- Nitrous oxide

Second Stage

- Nerve block analgesia and anesthesia
 - Local infiltration anesthesia
 - Pudendal block
 - Spinal (block) anesthesia
 - Epidural (block) analgesia
 - CSE analgesia
- Nitrous oxide

Vaginal Birth

- Local infiltration anesthesia
- Pudendal block
- Epidural (block) analgesia and anesthesia
- Spinal (block) anesthesia
- CSE analgesia and anesthesia
- Nitrous oxide

Cesarean Birth

- Spinal (block) anesthesia
- Epidural (block) anesthesia
- General anesthesia

Systemic Analgesia

Systemic analgesics (opioids) can be administered as intermittent intravenous (IV) or intramuscular (IM) doses by health care providers or by the woman herself using patient-controlled analgesia (PCA). With PCA, the woman self-administers small doses of an opioid analgesic by using a pump programmed for dose and frequency. Overall, a lower total amount of analgesic is used. Women appreciate the sense of autonomy provided by this method of pain relief, as well as the elimination of treatment delays while the nurse obtains and administers the medication (Hawkins & Bucklin, 2012).

Opioids provide sedation and euphoria, but their analgesic effect in labor is limited. The pain relief they provide is incomplete, temporary, and more effective in the early part of active labor (Anderson, 2011). All opioids cause side effects, the most serious of which is respiratory depression. Other undesirable opioid side effects include sedation, nausea and vomiting, dizziness, altered mental status, euphoria, decreased gastric motility, delayed gastric emptying, and urinary retention (Anderson). Prolonged gastric emptying time increases the risk for aspiration if general anesthesia becomes necessary in a woman who has received opioids (Hawkins & Bucklin, 2012). Bladder and bowel elimination can be inhibited. Because heart rate (e.g., bradycardia, tachycardia), blood pressure (e.g., hypotension), and respiratory effort (e.g., depression) can be adversely affected, opioid analgesics should be used cautiously in women with respiratory and cardiovascular disorders. Safety precautions should be taken after opioid administration, because several opioid side effects increase the risk for injury.

Opioids readily cross the placenta. Effects on the fetus and newborn can be profound, including absent or minimal FHR variability during labor and significant neonatal respiratory depression requiring treatment after birth (Hawkins & Bucklin, 2012).

SAFETY ALERT

Opioids decrease maternal heart and respiratory rate and blood pressure, which affects fetal oxygenation. Therefore, maternal vital signs and FHR and pattern must be assessed and documented before and after administration of opioids for pain relief.

Classifications of analgesic drugs used to relieve the pain of childbirth include **opioid (narcotic) agonists** and **opioid (narcotic) agonist-antagonists**. Choice of which medication to use often depends on the primary health care provider's preferences and the characteristics of the laboring woman. The type of systemic analgesic used therefore often varies among obstetric units.

Opioid Agonist Analgesics. Opioid (narcotic) agonist analgesics commonly used in obstetrics are meperidine (Demerol) and fentanyl (Sublimaze) (Hawkins & Bucklin, 2012). As pure opioid agonists they stimulate major opioid receptors, mu and kappa. They have no amnesic effect but create a feeling of well-being or euphoria and enhance a woman's ability to rest between contractions. Because opioids can inhibit uterine contractions, prolonging labor, they should not be administered until labor is well established unless they

are being used to enhance therapeutic rest during a prolonged latent phase of labor (Burke, 2014).

Meperidine hydrochloride is a synthetic opioid that is the most widely used systemic medication for labor pain (Cunningham et al., 2014). Its widespread use is probably related to its low cost, the fact that care providers are quite familiar with the drug, and studies that were done many years ago that found that it caused less respiratory depression than morphine (see Medication Guide: Meperidine Hydrochloride [Demerol]). However, its use during labor is becoming more controversial because of undesirable side effects, particularly in the neonate (Anderson, 2011). Both meperidine and normeperidine, an active metabolite of meperidine, cross the placenta and cause prolonged neonatal sedation and neurobehavioral changes. These metabolite-related effects cannot be reversed with naloxone (Anderson). Because meperidine and normeperidine have long half-lives, the neonatal effects can persist for the first 2 to 3 days of life (Hawkins & Bucklin, 2012).

MEDICATION GUIDE

Meperidine Hydrochloride (Demerol)

Classification

Opioid agonist analgesic

Action

Synthetic opioid agonist analgesic that stimulates both mu and kappa opioid receptors to decrease the transmission of pain impulses. Meperidine 100 mg is roughly equivalent in analgesic effect to morphine 10 mg, but it is reported to cause less maternal respiratory depression. Intravenously, the onset of action begins in 5 minutes and the duration of action is 2 to 4 hours.

Indication

Moderate to severe labor pain and postoperative pain after cesarean birth

Dosage and Route

IV: 25 to 50 mg every 1 to 2 hours

PCA Pump: 15 mg every 10 minutes as needed until birth

Adverse Effects

Tachycardia, sedation, nausea and vomiting, dizziness, altered mental status, euphoria, decreased gastric motility, delayed gastric emptying, and urinary retention

Nursing Considerations

Implement safety measures as appropriate, including use of side rails and assistance with ambulation; continue use of nonpharmacologic pain relief measures. Do not give if birth is expected to occur within 1 to 4 hours after administration because infants born to women who received meperidine during labor may have respiratory depression, peaking at 2 to 3 hours after administration of the drug. Respiratory depression caused by normeperidine, an active metabolite of meperidine, cannot be reversed by naloxone. Both meperidine and normeperidine have long half-lives. Therefore, neonates whose mothers received meperidine during labor can exhibit sedation and neurobehavioral changes for the first 2 to 3 days of life.

Data from Anderson, D. (2011). A review of systemic opioids commonly used for labor pain relief. *Journal of Midwifery & Women's Health*, 56(3), 222-239; Hawkins, J., Bucklin, B. (2012). Obstetrical anesthesia. In S. Gabbe, J. Niebyl, J. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (6th ed.). Philadelphia: Saunders.

Fentanyl citrate (Sublimaze) is a potent short-acting opioid agonist analgesic (see Medication Guide: Fentanyl Citrate [Sublimaze]). It rapidly crosses the placenta, so it is present in fetal blood within 1 minute after IV maternal administration (Anderson, 2011). As compared with meperidine, fentanyl provides equivalent analgesia with fewer neonatal effects and less maternal sedation and nausea. Fentanyl is used as a labor analgesic because of its rapid onset of action, short half-life, and lack of a metabolite (Anderson). A disadvantage of fentanyl is that more frequent dosing is required because of its relatively short duration of action (Hawkins & Bucklin, 2012). As a result, this medication is most commonly administered by PCA pump, intrathecally, or epidurally, alone or in combination with a local anesthetic agent.

Opioid (Narcotic) Agonist-Antagonist Analgesics. An **agonist** is an agent that activates or stimulates a receptor to act; an **antagonist** is an agent that blocks a receptor or a medication designed to activate a receptor. Butorphanol (Stadol) and nalbuphine (Nubain) are commonly used **opioid (narcotic) agonist-antagonist analgesics** (Hawkins & Bucklin, 2012). These medications are agonists at kappa opioid receptors and either antagonists or weak agonists at mu opioid receptors. In the doses used during labor, these mixed opioids provide adequate analgesia without causing significant respiratory depression in the mother or neonate. Their major advantage is their ceiling effect for respiratory depression; higher doses do not produce additional

respiratory depression. They are less likely to cause nausea and vomiting, but sedation may be as great or greater when compared with pure opioid agonists (Anderson, 2011; Hawkins & Bucklin). As a result of these effects, parenteral opioid agonist-antagonist analgesics are used more commonly during labor than the opioid agonist analgesics. IM, subcutaneous, and IV routes of administration can be used, but the IV route is preferred. This classification of opioid analgesics, especially nalbuphine, is not suitable for women with an opioid dependence because the antagonist activity could precipitate withdrawal symptoms (abstinence syndrome) in both the mother and her newborn (Hawkins & Bucklin) (see the Medication Guide: Butorphanol Tartrate [Stadol], Medication Guide: Nalbuphine Hydrochloride [Nubain], and the Signs of Potential Complications box).

MEDICATION GUIDE

Fentanyl Citrate (Sublimaze)

Classification

Opioid agonist analgesic

Action

Opioid agonist analgesic that stimulates both mu and kappa opioid receptors to decrease the transmission of pain impulses. Has a rapid onset of action with a short duration (0.5 to 1 hour IV; 1 to 2 hours IM).

Indication

Moderate to severe labor pain and postoperative pain after cesarean birth

Dosage and Route

IV: 50 to 100 mcg every hour
IM: 50 to 100 mcg every hour

Adverse Effects

Sedation, respiratory depression, nausea, and vomiting

Nursing Considerations

Assess for respiratory depression; naloxone should be available as an antidote. Implement safety measures as appropriate, including use of side rails and assistance with ambulation; continue use of nonpharmacologic pain relief measures. Because of its short duration of action, frequent dosing will be necessary when given intravenously. Maximum total dose for labor is usually 500 to 600 mcg.

Data from Anderson, D. (2011). A review of systemic opioids commonly used for labor pain relief. *Journal of Midwifery & Women's Health*, 56(3), 222-239.

MEDICATION GUIDE

Butorphanol Tartrate (Stadol)

Classification

Opioid agonist-antagonist analgesic

Action

Mixed agonist-antagonist analgesic that stimulates kappa opioid receptors and blocks or weakly stimulates mu opioid receptors, resulting in good analgesia but with less respiratory depression and nausea and vomiting when compared with opioid agonist analgesics. Butorphanol produces a maternal ceiling effect on pain relief and respiratory depression. IV administration of 2 mg of butorphanol produces respiratory depression similar to that of 10 mg of morphine IV or 70 mg of meperidine IV, but 4 mg of butorphanol will produce less respiratory depression than 20 mg of morphine or 140 mg of meperidine. Whether given intravenously or intramuscularly, the drug's duration of action is 4 to 6 hours.

Indication

Moderate to severe labor pain and postoperative pain after cesarean birth

Usual Dosage and Route

IV: 1 to 2 mg every 3 to 4 hours as needed
IM: 1 to 2 mg every 3 to 4 hours as needed

Adverse Effects

Confusion, sedation, hallucinations, "floating" feeling, drowsiness, transient nonpathologic sinusoidal-like fetal heart rate pattern, respiratory depression, nausea and vomiting

Nursing Considerations

May precipitate withdrawal symptoms in opioid-dependent women and their newborns. Assess maternal vital signs, degree of pain, fetal heart rate (FHR), and uterine activity before and after administration. Observe for maternal respiratory depression, notifying primary health care provider if maternal respirations are ≤ 12 breaths/minute. Encourage voiding every 2 hours, and palpate for bladder distention. If birth occurs within 1 to 4 hours of dose administration, observe newborn for respiratory depression. Implement safety measures as appropriate, including use of side rails and assistance with ambulation. Continue use of nonpharmacologic pain relief measures.

Data from Anderson, D. (2011). A review of systemic opioids commonly used for labor pain relief. *Journal of Midwifery & Women's Health*, 56(3), 222-239.

MEDICATION GUIDE

Nalbuphine Hydrochloride (Nubain)

Classification

Opioid agonist-antagonist analgesic

Action

Mixed agonist-antagonist analgesic that stimulates kappa opioid receptors and blocks or weakly stimulates mu opioid receptors, resulting in good analgesia but with less respiratory depression and nausea and vomiting when compared with opioid agonist analgesics. Nalbuphine's analgesic effect is equivalent to morphine, on a milligram-to-milligram basis. Produces a maternal ceiling effect on pain relief and respiratory depression after 30 mg of the drug has been administered. Duration of action is 2 to 4 hours when given intravenously and 4 to 6 hours when given intramuscularly.

Indication

Moderate to severe labor pain and postoperative pain after cesarean birth

Dosage and Route

IV: 10 mg every 3 hours as needed

IM: 10 mg every 3 hours as needed

Adverse Effects

Sedation, drowsiness, nausea, vomiting, dizziness, respiratory depression, temporary absent or minimal fetal heart rate (FHR) variability

Nursing Considerations

May precipitate withdrawal symptoms in opioid-dependent women and their newborns. Assess maternal vital signs, degree of pain, FHR, and uterine activity before and after administration. Observe for maternal respiratory depression, notifying primary health care provider if maternal respirations are ≤ 12 breaths/minute. Encourage voiding every 2 hours, and palpate for bladder distention. If birth occurs within 1 to 4 hours of dose administration, observe newborn for respiratory depression. Implement safety measures as appropriate, including use of side rails and assistance with ambulation. Continue use of nonpharmacologic pain relief measures.

Data from Anderson, D. (2011). A review of systemic opioids commonly used for labor pain relief. *Journal of Midwifery & Women's Health*, 56(3), 222-239.

SIGNS OF POTENTIAL COMPLICATIONS

Maternal Opioid Abstinence Syndrome (Opioid/Narcotic Withdrawal)

- Yawning, rhinorrhea (runny nose), sweating, lacrimation (tearing), mydriasis (dilation of pupils)
- Anorexia
- Irritability, restlessness, generalized anxiety
- Tremors
- Chills and hot flashes
- Piloerection ("gooseflesh" or "chill bumps")
- Violent sneezing
- Weakness, fatigue, and drowsiness
- Nausea and vomiting
- Diarrhea, abdominal cramps
- Bone and muscle pain, muscle spasms, kicking movements

Opioid (Narcotic) Antagonists. Opioids such as meperidine and fentanyl can cause excessive CNS depression in the mother, the newborn, or both, although the current practice of giving lower doses of opioids intravenously has reduced the incidence and severity of opioid-induced CNS depression.

Opioid (narcotic) antagonists such as naloxone (Narcan) can promptly reverse the CNS depressant effects, especially respiratory depression, in most situations. As stated earlier, however, naloxone cannot reverse the effects of normeperidine, an active metabolite of meperidine. In addition, the antagonist counters the effect of the stress-induced levels of endorphins. An opioid antagonist is especially valuable if labor is more rapid than expected and birth is anticipated when the opioid is at its peak effect. The antagonist may be given intravenously, or it can be administered intramuscularly (see the Medication Guide: Naloxone Hydrochloride [Narcan]). The woman should be told that the pain that was relieved with the use of the opioid analgesic will return with the administration of the opioid antagonist.

MEDICATION GUIDE

Naloxone Hydrochloride (Narcan)

Classification

Opioid antagonist

Action

Blocks both mu and kappa opioid receptors from the effects of opioid agonists

Indication

Reverses opioid-induced respiratory depression in woman or newborn; may be used to reverse pruritus from epidural opioids

Dosage and Route

Adult

Opioid overdose: 0.4 to 2 mg IV, may repeat IV at 2- to 3-min intervals until a maximum of 10 mg has been given; if IV route unavailable, IM or subcutaneous administration may be used

Newborn

Opioid-induced depression: 0.1 mg/kg (concentration is 1.0 mg/ml solution). IV is the preferred route of administration. May also be given IM, but the onset of action will be delayed compared to IV administration.

Adverse Effects

Maternal hypotension or hypertension, tachycardia, hyperventilation, nausea and vomiting, sweating, and tremulousness

Nursing Considerations

The woman should delay breastfeeding until medication is out of her system (approximately 2 hours after the last dose is given). Do not give to the woman or the newborn if the woman is opioid dependent—may cause abrupt withdrawal in the woman and newborn. If given to the woman for reversal of respiratory depression caused by opioid analgesic, pain will return suddenly. The duration of action of naloxone is shorter than that of most opioids. Therefore, the woman must be monitored closely for the return of opioid depression when the effects of naloxone are gone. Additional doses of naloxone may be necessary to maintain reversal.

Data on newborn administration from American Academy of Pediatrics (AAP) & American Heart Association (AHA). (2011). *Textbook of neonatal resuscitation* (6th ed.). Dallas, TX: AHA.

MEDICATION ALERT

An opioid antagonist (e.g., naloxone [Narcan]) is contraindicated for opioid-dependent women because it may precipitate abstinence syndrome (withdrawal symptoms). For the same reason, opioid agonist-antagonist analgesics such as butorphanol (Stadol) and nalbuphine (Nubain) should not be given to opioid-dependent women (see the Signs of Potential Complications box).

Nerve Block Analgesia and Anesthesia

A variety of local anesthetic agents are used in obstetrics to produce **regional analgesia** (some pain relief and motor block) and **regional anesthesia** (complete pain relief and motor block). Most of these agents are related chemically to cocaine and end with the suffix *-caine*. This helps to identify a local anesthetic.

The principal pharmacologic effect of local anesthetics is the temporary interruption of the conduction of nerve impulses, notably pain. Examples of common agents given are bupivacaine (Marcaine), chloroprocaine (Nesacaine), lidocaine (Xylocaine), ropivacaine (Naropin), and mepivacaine (Carbocaine). Rarely, people are sensitive (allergic) to one or more local anesthetics. Such a reaction may include respiratory depression, hypotension, and other serious adverse effects. Epinephrine, antihistamines, oxygen, and supportive measures should reverse these effects. Administering tiny amounts of the drug to test for an allergic reaction may identify sensitivity.

Local Perineal Infiltration Anesthesia. **Local perineal infiltration anesthesia** may be used when an episiotomy is to be performed or when lacerations must be sutured after birth in a woman who does not have regional anesthesia. Rapid anesthesia is produced by injecting approximately 10 to 20 ml of 1% lidocaine or 2% chloroprocaine into the skin and then subcutaneously into the region to be anesthetized. Epinephrine often is added to the solution to localize and intensify the effect of the anesthesia in a region and to prevent excessive bleeding and systemic absorption by constricting local blood vessels. Injections can be repeated to keep the woman comfortable while post-birth repairs are completed.

Pudendal Nerve Block. **Pudendal nerve block**, administered late in the second stage of labor, is useful if an episiotomy is to be performed or if forceps or a vacuum extractor is to be used to facilitate birth. It can also be administered during the third stage of labor if an episiotomy or lacerations must be repaired (American Academy of Pediatrics [AAP] & American College of Obstetricians and Gynecologists [ACOG], 2012). A pudendal nerve block is considered to be a reasonably safe and simple procedure to provide pain relief for vaginal birth (Cunningham et al., 2014; Hawkins & Bucklin, 2012). Although a pudendal nerve block does not relieve the pain from uterine contractions, it does relieve pain in the lower vagina, the vulva, and the perineum (Fig. 17-8, A). A pudendal nerve block should be administered 10 to 20 minutes before perineal anesthesia is needed.

The pudendal nerve traverses the sacrosacral notch just medial to the tip of the ischial spine on each side. Injection

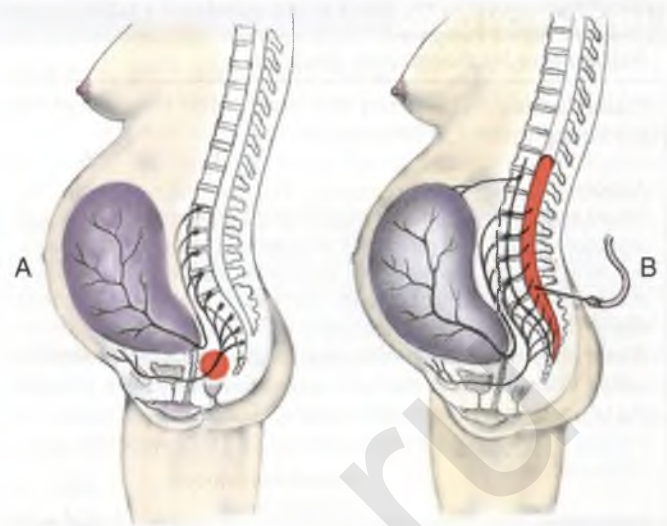

FIG 17-8 Pain pathways and sites of pharmacologic nerve blocks. **A**, Pudendal nerve block: suitable during second and third stages of labor and for repair of episiotomy or lacerations. **B**, Epidural block: suitable for all stages of labor and types of birth, and for repair of episiotomy and lacerations.

FIG 17-9 Pudendal nerve block. Use of introducer (needle guide) and Luer-Lok syringe to inject medication.

of an anesthetic solution at or near these points anesthetizes the pudendal nerves peripherally (Fig. 17-9). The transvaginal approach is generally used because it is less painful for the woman, has a higher rate of success in blocking pain, and tends to cause fewer fetal complications (Hawkins & Bucklin, 2012). Pudendal block does not change maternal hemodynamic or respiratory functions, vital signs, or the FHR. However, the bearing-down reflex is lessened or lost completely.

Spinal Anesthesia. In **spinal anesthesia (block)**, a solution containing a local anesthetic alone or in combination with an opioid agonist analgesic is injected through the third, fourth, or fifth lumbar interspace into the subarachnoid space (Fig. 17-10, A and B), where the anesthetic solution mixes with cerebrospinal fluid (CSF). Low spinal anesthesia (block) may

be used for vaginal birth, but it is not suitable for labor. Spinal anesthesia (block) used for cesarean birth provides anesthesia from the nipple (T6) to the feet. If it is used for vaginal birth, the anesthesia level is from the hips (T10) to the feet (see Fig. 17-10, C).

For spinal anesthesia (block), the woman sits or lies on her side (e.g., modified Sims position) with back curved to widen the intervertebral space to facilitate insertion of a small-gauge spinal needle and injection of the anesthetic solution into the spinal canal. The nurse supports the woman and encourages

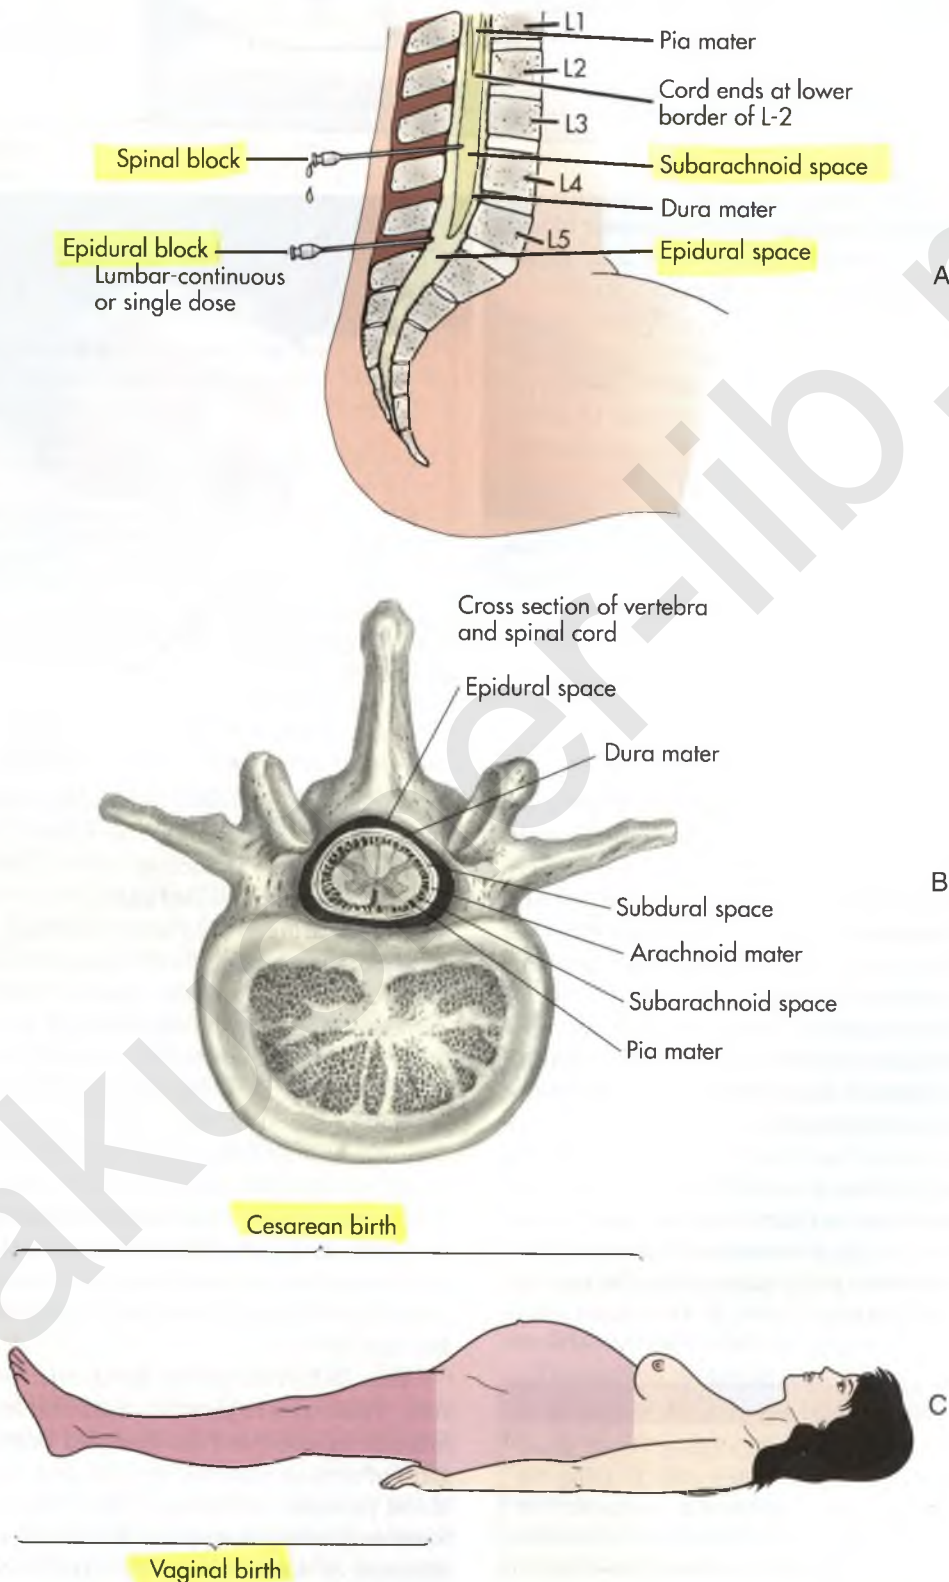

FIG 17-10 A, Membranes and spaces of spinal cord and levels of sacral, lumbar, and thoracic nerves. B, Cross section of vertebra and spinal cord. C, Level of anesthesia necessary for cesarean birth and for vaginal births.

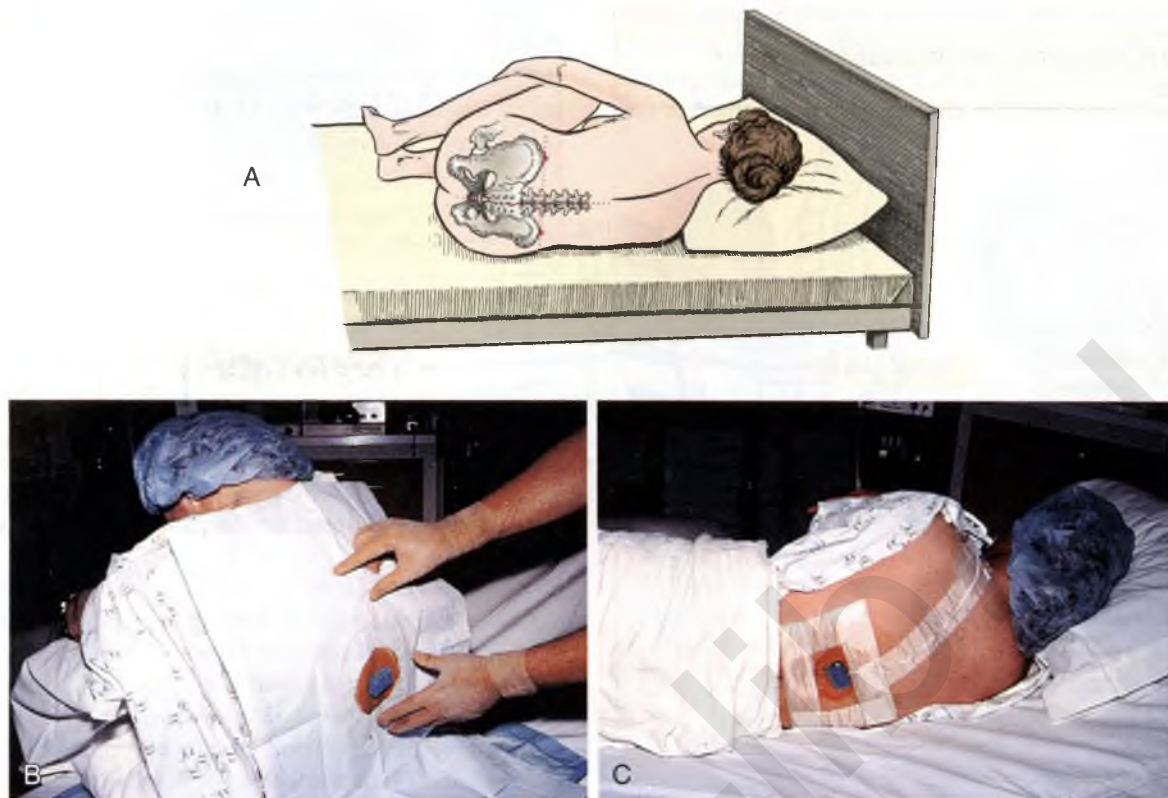

FIG 17-11 Positioning for spinal and epidural blocks. **A**, Lateral position. **B**, Upright position. **C**, Catheter for epidural is taped to the woman's back with the port segment located near her shoulder. (B and C, Courtesy Michael S. Clement, MD, Mesa, AZ.)

her to use breathing and relaxation techniques because she must remain still during the placement of the spinal needle. The needle is inserted and the anesthetic injected between contractions. After the anesthetic solution has been injected, the woman may be positioned upright to allow the heavier (hyperbaric) anesthetic solution to flow downward to obtain the lower level of anesthesia suitable for a vaginal birth. To obtain the higher level of anesthesia desired for cesarean birth she will be positioned supine with head and shoulders slightly elevated. In order to prevent supine hypotensive syndrome, the uterus is displaced laterally by tilting the operating table or placing a wedge under one of her hips. Usually the level of the block will be complete and fixed within 5 to 10 minutes after the anesthetic solution is injected but it can continue to creep upward for 20 minutes or longer (Hawkins & Bucklin, 2012). The anesthetic effect will last 1 to 3 hours, depending on the type of agent used (Fig. 17-11).

Marked hypotension, impaired placental perfusion, and an ineffective breathing pattern may occur during spinal anesthesia. Before induction of the spinal anesthetic, maternal vital signs are assessed and a 20- to 30-minute electronic fetal monitoring (EFM) strip is obtained and evaluated. In addition, the woman's fluid balance is assessed. A bolus of IV fluid (usually 500 to 1000 ml of lactated Ringer's or normal saline solution) may be administered 15 to 30 minutes before induction of the anesthetic to decrease the potential for hypotension caused by sympathetic blockade (vasodilation with pooling of blood in the lower extremities decreases cardiac output). Although the practice guidelines for obstetric anesthesia published by the American Society of Anesthesiologists (2007) state that this preanesthetic fluid bolus is not required, it is still usually administered in most clinical settings. Fluid that is used for the bolus should not contain dextrose, which could contribute to neonatal hypoglycemia (Hawkins & Bucklin, 2012).

After induction of the anesthetic, maternal blood pressure, pulse, and respirations and fetal heart rate and pattern must be assessed and documented every 5 to 10 minutes. If signs of serious maternal hypotension (e.g., a drop in systolic blood pressure to 100 mm Hg or less or below 20% of the baseline blood pressure) or fetal distress (e.g., bradycardia, minimal or absent variability, late decelerations) develop, emergency care must be given (Burke, 2014) (see the Emergency box).

⚡ SAFETY ALERT

To reduce the risk for transmission of pathogens, (1) the woman's back is cleansed before the procedure, and (2) during the induction of spinal and epidural anesthesia or analgesia, the anesthesia care provider wears sterile gloves and a face mask. Also, spinal or epidural anesthesia or analgesia should not be initiated if the woman has a tattoo at the site where the needle would be inserted.

EMERGENCY**Maternal Hypotension with Decreased Placental Perfusion****Signs and Symptoms**

- Maternal hypotension (20% decrease from preblock baseline level or ≤ 100 mm Hg systolic)
- Fetal bradycardia
- Absent or minimal FHR variability

Interventions

- Turn woman to lateral position or place pillow or wedge under hip to displace uterus
- Maintain IV infusion at rate specified, or increase administration per hospital protocol
- Administer oxygen by nonrebreather face mask at 10 to 12 L/minute or per protocol.
- Elevate the woman's legs.
- Notify the primary health care provider, anesthesiologist, or nurse anesthetist.
- Administer IV vasopressor (e.g., ephedrine 5 to 10 mg or phenylephrine 50 to 100 mcg) per protocol if previous measures are ineffective.
- Remain with woman; continue to monitor maternal blood pressure and fetal heart rate (FHR) every 5 minutes until her condition is stable or per primary health care provider's order.

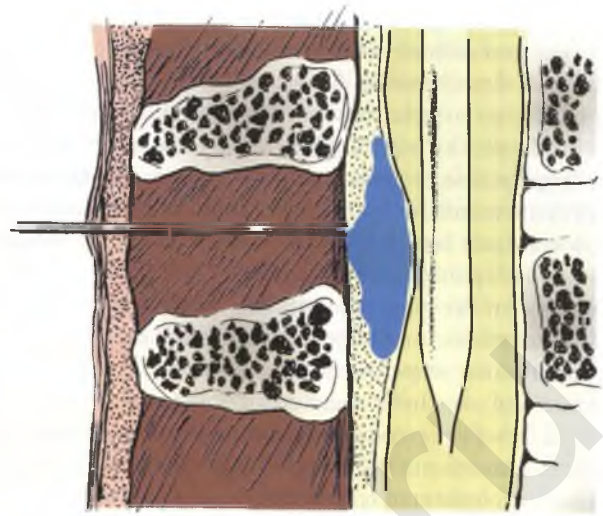

FIG 17-12 Blood-patch therapy for spinal headache.

Because the woman is unable to sense her contractions, she must be instructed when to bear down during a vaginal birth. Use of a combination of local anesthetic agent and an opioid reduces the degree of motor function loss, enhancing a woman's ability to push effectively. If the birth occurs in a delivery room (rather than a labor-delivery-recovery room), the woman will need assistance in the transfer to a recovery bed after expulsion of the placenta and perineal repair if required.

Advantages of spinal anesthesia include ease of administration and absence of fetal hypoxia with maintenance of maternal blood pressure within a normal range. Maternal consciousness is maintained, excellent muscular relaxation is achieved, and blood loss is not excessive.

Disadvantages of spinal anesthesia include possible medication reactions (e.g., allergy), hypotension, and an ineffective breathing pattern; cardiopulmonary resuscitation may be needed. When a spinal anesthetic is given, the need for operative birth (e.g., episiotomy, forceps-assisted birth, or vacuum-assisted birth) tends to increase because voluntary expulsive efforts are reduced or eliminated. After birth the incidence of bladder and uterine atony, as well as postdural puncture headache, is higher.

Leakage of CSF from the site of puncture of the dura mater (membranous covering of the spinal cord) is thought to be the major causative factor in *postdural puncture headache* (PDPH), commonly referred to as a spinal headache. Spinal headache is much more likely to occur when the dura is accidentally punctured during the process of administering an epidural block. The needle used for an epidural block has a much larger gauge than the one used for spinal anesthesia and thus creates a bigger opening in the dura, resulting in a greater loss of CSF (i.e., "wet tap"). Presumably, postural changes cause the diminished volume of CSF to exert traction on pain-sensitive CNS structures.

Characteristically, assuming an upright position triggers or intensifies the headache, whereas assuming a supine position achieves relief (Hawkins & Bucklin, 2012). The resulting headache, auditory problems (e.g., tinnitus), and visual problems (e.g., blurred vision, photophobia) begin within 2 days of the puncture and may persist for days or weeks.

The likelihood of headache after dural puncture can be reduced, however, if the anesthesia care provider uses a small-gauge spinal needle and avoids making multiple punctures of the meninges. Passing an epidural catheter through the dural opening at the time of puncture to provide continuous spinal anesthesia, with removal of the catheter 24 hours later, may help prevent spinal headache. Injecting preservative-free saline through the spinal catheter before removing it also may decrease the incidence of headache. Hydration and bed rest in the prone position have been recommended as preventive measures, but have not been proven to be of much value (Hawkins & Bucklin, 2012).

Conservative management for a PDPH includes administration of oral analgesics and methylxanthines (e.g., caffeine or theophylline). Methylxanthines cause constriction of cerebral blood vessels and may provide symptomatic relief. An autologous epidural blood patch is the most rapid, reliable, and beneficial relief measure for PDPH. The woman's blood (i.e., 20 ml) is injected slowly into the lumbar epidural space, creating a clot that patches the tear or hole in the dura mater. Treatment with a blood patch is considered if the headache is severe or debilitating and does not resolve after conservative management. The blood patch is remarkably effective and is nearly complication free (Hawkins & Bucklin, 2012) (Fig. 17-12).

The woman should be observed for alteration in vital signs, pallor, clammy skin, and leakage of CSF for 1 to 2 hours after the blood patch is performed. If no complications occur she may then resume normal activity. She should, however, be instructed to avoid coughing or straining for the first day after the blood patch (Hawkins & Bucklin, 2012). She is also taught to avoid analgesics that affect platelet aggregation (e.g., nonsteroidal antiinflammatory drugs [NSAIDs]) for 2 days, drink plenty of fluids, and observe for signs of infection at the site and

for neurologic symptoms such as pain, numbness and tingling in the legs, and difficulty with walking or elimination.

Epidural Anesthesia or Analgesia (Block). Relief from the pain of uterine contractions and birth (vaginal and cesarean) can be achieved by injecting a suitable local anesthetic agent (e.g., bupivacaine, ropivacaine), an opioid analgesic (e.g., fentanyl, sufentanil), or both into the epidural (peridural) space. Injection is made between the fourth and fifth lumbar vertebrae for a lumbar epidural block (see Figs. 17-8, B, and 17-10, A). Depending on the type, amount, and number of medications used, an anesthetic or analgesic effect will occur with varying degrees of motor impairment. The combination of an opioid with the local anesthetic agent reduces the dose of anesthetic required, thereby preserving a greater degree of motor function.

Epidural anesthesia and analgesia is currently the most effective pharmacologic pain relief method for labor. As a result, it is used by most women in the United States (Hawkins & Bucklin, 2012). For relieving the discomfort of labor and vaginal birth, a block from T10 to S5 is required. For cesarean birth, a block from at least T8 to S1 is essential. The diffusion of epidural anesthesia depends on the location of the catheter tip, the dose and volume of the anesthetic agent used, and the woman's position (e.g., horizontal or head-up). The woman must cooperate and maintain her position without moving during the insertion of the epidural catheter in order to prevent misplacement, neurologic injury, or hematoma formation.

MEDICATION ALERT

Epidural anesthesia effectively relieves the pain caused by uterine contractions. For most women, however, it does not completely remove the pressure sensations that occur as the fetus descends in the pelvis.

For the induction of an epidural block, the woman is positioned as for a spinal block. She may sit with her back curved or assume a modified Sims position with her shoulders parallel, legs slightly flexed, and back arched. It is important to avoid severe spinal flexion because it could compress the epidural space, increasing the risk for dural puncture (Burke, 2014) (see Fig. 17-11). A large-bore needle is inserted into the epidural space. A catheter is then threaded through the needle until its tip rests in the epidural space. The needle is then removed and the catheter is taped in place. After the epidural catheter is inserted and secured, a small amount of medication, called a test dose, is injected to be sure that the catheter has not been accidentally placed in the subarachnoid (spinal) space or in a blood vessel (Hawkins & Bucklin, 2012).

Initiating epidural anesthesia may be difficult when the woman is obese. She may find it harder to assume a position necessary for catheter placement. In addition, excess adipose tissue can obscure the anatomic landmarks used to identify the location of the appropriate insertion site. Morbidly obese women are also more likely to have accidental dural puncture (Jevitt, 2009). Although epidural catheter placement can present technical challenges, use of regional anesthesia can provide adequate pain management for the obese woman during labor and birth. Placing the catheter in early labor when the woman is more

comfortable and is able to fully cooperate is a recommended solution (Burke, 2014; Hawkins & Bucklin, 2012). Early placement of a functioning epidural may reduce the potential complications associated with intubation during an emergent delivery. Note that epidural anesthesia presents less risk for the obese woman than does general anesthesia (AAP & ACOG, 2012).

After the epidural has been initiated, the woman is positioned preferably on her side so that the uterus does not compress the ascending vena cava and descending aorta, which can impair venous return, reduce cardiac output and blood pressure, and decrease placental perfusion. Her position should be alternated from side to side every hour. Upright positions and ambulation may be possible, depending on the degree of motor impairment. Oxygen should be available if hypotension occurs despite maintenance of hydration with IV fluid and displacement of the uterus to the side. Ephedrine or phenylephrine (vasopressors used to increase maternal blood pressure) and increased IV fluid infusion may be needed (see the Emergency box: Maternal Hypotension with Decreased Placental Perfusion). The fetal heart rate and pattern, contraction pattern, and progress in labor must be monitored carefully because the woman may not be aware of changes in the strength of the uterine contractions or the descent of the presenting part.

Several methods can be used for an epidural block. An intermittent block is achieved by using repeated injections of anesthetic solution; it is the least common method. The most common method is the continuous block, achieved by using a pump to infuse the anesthetic solution through an indwelling plastic catheter. Patient-controlled epidural analgesia (PCEA) is the newest method; it uses an indwelling catheter and a programmed pump that allows the woman to control the dosing. This method has been found to provide optimal analgesia with higher maternal satisfaction and enhanced sense of control during labor while decreasing the total amount of medication, including local anesthetic, used (Capogna & Stirparo, 2013). The advantages of an epidural block are numerous:

- The woman remains alert and is more comfortable and able to participate.
- Good relaxation is achieved.
- Airway reflexes remain intact.
- Only partial motor paralysis develops.
- Gastric emptying is not delayed.
- Blood loss is not excessive.

Fetal complications are rare but may occur in the event of rapid absorption of the medication or marked maternal hypotension. The dose, volume, type, and number of medications used can be modified (1) to allow the woman to push, to assume upright positions, and even to walk; (2) to produce perineal anesthesia; and (3) to permit forceps-assisted, vacuum-assisted, or cesarean birth if required.

The disadvantages of epidural block also are numerous. The woman's ability to move freely and to maintain control of her labor is limited, related to the use of numerous medical interventions (e.g., an intravenous infusion and electronic monitoring) and the occurrence of orthostatic hypotension and dizziness, sedation, and weakness of the legs. CNS effects (Box 17-5) can occur if a solution containing a local anesthetic agent is accidentally injected into a blood vessel or if excessive amounts of local anesthetic are given. High spinal or "total spinal" anesthesia,

BOX 17-5 Side Effects of Epidural and Spinal Anesthesia

- Hypotension
- Local anesthetic toxicity
 - Lightheadedness
 - Dizziness
 - Tinnitus (ringing in the ears)
 - Metallic taste
 - Numbness of the tongue and mouth
 - Bizarre behavior
 - Slurred speech
 - Convulsions
 - Loss of consciousness
- Fever
- Urinary retention
- Pruritus (itching)
- Limited movement
- Longer second stage labor
- Increased use of oxytocin
- Increased likelihood of forceps- or vacuum-assisted birth
- High or total spinal anesthesia

resulting in respiratory arrest, can occur if the relatively high dosage used with an epidural block is accidentally injected into the subarachnoid space. Women who receive an epidural have a higher rate of fever (i.e., intrapartum temperature of 38° C [100.4° F] or higher), especially when labor lasts longer than 12 hours; the temperature elevation most likely is related to thermoregulatory changes, although infection cannot be ruled out. The elevation in temperature can result in fetal tachycardia and neonatal workup for sepsis, whether or not signs of infection are present (see Box 17-5).

Hypotension as a result of sympathetic blockade can occur in about 10% to 30% of women who receive regional (spinal or epidural) analgesia during labor (Witcher & McLendon, 2013) (see Emergency box: Maternal Hypotension with Decreased Placental Perfusion). Hypotension can result in a significant decrease in uteroplacental perfusion and oxygen delivery to the fetus. Urinary retention and stress incontinence can occur in the immediate postpartum period. This temporary difficulty in urinary elimination could be related not only to the effects of the epidural block and the need for catheterization but also the increased duration of labor and need for forceps- or vacuum-assisted birth associated with the block. Pruritus (itching) is a side effect that often occurs with the use of an opioid, especially fentanyl. A relationship between epidural analgesia and longer second-stage labor, use of oxytocin, and forceps- or vacuum-assisted birth has been documented (Cunningham et al., 2014). Research findings have been unable to demonstrate a significant increase in cesarean birth associated with epidural analgesia (Hawkins & Bucklin, 2012). For some women the epidural block is not effective, and a second form of analgesia is required to establish effective pain relief. When women progress rapidly in labor, pain relief may not be obtained before birth occurs.

Combined Spinal-Epidural Analgesia. In the **combined spinal-epidural (CSE) analgesia** technique, sometimes referred to as a *walking epidural*, an epidural needle is inserted into the epidural space. Before the epidural catheter is

placed, a smaller-gauge spinal needle is inserted through the bore of the epidural needle into the subarachnoid space. A small amount of opioid or combination of opioid and local anesthetic is then injected intrathecally to rapidly provide analgesia. Afterward the epidural catheter is inserted as usual. The CSE technique is an increasingly popular approach that can be used to block pain transmission without compromising motor ability. The concentration of opioid receptors is high along the pain pathway in the spinal cord, in the brainstem, and in the thalamus. Because these receptors are highly sensitive to opioids, a small quantity of an opioid-agonist analgesic produces marked pain relief lasting for several hours. If additional pain relief is needed, medication can be injected through the epidural catheter (see Fig. 17-10, A). The most common side effects of CSE are pruritus, urinary retention, immediate or delayed respiratory depression, and nausea. Naloxone can be given intravenously to manage these side effects without decreasing the degree of analgesia achieved (Hawkins & Bucklin, 2012). CSE analgesia is also associated with a greater incidence of FHR abnormalities than is epidural analgesia alone, necessitating close assessment of fetal heart rate and pattern (Cunningham et al., 2014).

Although women can walk (hence the term walking epidural), they often choose not to do so because of sedation and fatigue, abnormal sensations in and weakness of the legs, and a feeling of insecurity. Often health care providers are reluctant to encourage or assist women to ambulate for fear of injury. However, women can be assisted to change positions and use upright positions during labor and birth.

Epidural and Intrathecal (Spinal) Opioids. Opioids also can be used alone, eliminating the effect of a local anesthetic altogether. The use of epidural or intrathecal opioids without the addition of a local anesthetic agent during labor has several advantages. Opioids administered in this manner produce a rapid onset of pain relief but do not cause maternal hypotension or affect vital signs. The woman feels contractions but not pain. Her ability to bear down during the second stage of labor is preserved because the pushing reflex is not lost, and her motor power remains intact.

Fentanyl, sufentanil, or preservative-free morphine can be used. Fentanyl and sufentanil produce short-acting analgesia (1.5 to 3.5 hours), and morphine can provide pain relief for 4 to 7 hours. Morphine can be combined with fentanyl or sufentanil. Using short-acting opioids with multiparous women and morphine with nulliparous women or women with a history of long labors is appropriate. Because opioids alone usually do not provide adequate analgesia, however, they are most often given in combination with a local anesthetic (Cunningham et al., 2014).

A more common indication for the administration of epidural or intrathecal analgesics is the relief of postoperative pain. For example, a woman who gives birth by cesarean can receive fentanyl or morphine through a catheter. The catheter can then be removed, and the woman is usually free of pain for 24 hours. Occasionally the catheter is left in place in the epidural space in case another dose is needed.

Women receiving epidurally administered morphine after a cesarean birth can ambulate sooner than women who do not. The early ambulation and freedom from pain also

facilitate bladder emptying, enhance peristalsis, and prevent clot formation (e.g., thrombophlebitis) in the lower extremities. Women may require additional medication for breakthrough pain during the first 24 hours after surgery. If so, they will usually be given an NSAID such as ketorolac (Toradol), indomethacin (Indocin), or ibuprofen (Motrin) rather than a narcotic.

Side effects of opioids administered by the epidural and intrathecal routes include nausea, vomiting, diminished peristalsis, pruritus, urinary retention, and delayed respiratory depression. These effects are more common when morphine is administered. Antiemetics, antipruritics, and opioid antagonists are used to relieve these symptoms. For example, naloxone or metoclopramide may be administered. Hospital protocols or detailed physician orders should provide specific instructions for the treatment of these side effects. Use of epidural opioids is not without risk. Respiratory depression is a serious concern; for this reason the woman's respiratory status should be assessed and documented every hour for 24 hours or as designated by hospital protocol. Naloxone should be readily available for use if the respiratory rate decreases to less than 10 breaths per minute or if the oxygen saturation rate decreases to less than 89%. Administration of oxygen by nonrebreather face mask also can be initiated, and the anesthesia care provider should be notified.

Contraindications to Subarachnoid and Epidural Blocks.

Contraindications to epidural analgesia (Burke, 2014; Cunningham et al., 2014; Hawkins & Bucklin, 2012) include the following:

- Active or anticipated serious maternal hemorrhage. Acute hypovolemia leads to increased sympathetic tone to maintain the blood pressure. Any anesthetic technique that blocks the sympathetic fibers can produce significant hypotension that can endanger the mother and fetus.
- Maternal hypotension
- Coagulopathy: If a woman is receiving anticoagulant therapy (e.g., last dose of low-molecular-weight heparin within 12 hours) or has a bleeding disorder, injury to a blood vessel may cause the formation of a hematoma that may compress the cauda equina or the spinal cord and lead to serious CNS complications.
- Infection at the injection site. Infection can be spread through the peridural or subarachnoid spaces if the needle traverses an infected area.
- Increased intracranial pressure caused by a mass lesion
- Allergy to the anesthetic drug
- Maternal refusal or inability to cooperate
- Some types of maternal cardiac conditions

Epidural Block Effects on Newborn. Analgesia or anesthesia during labor and birth has little or no lasting effect on the physiologic status of the newborn. There is no evidence that the administration of maternal analgesia or anesthesia during labor and birth has a significant effect on the child's later mental and neurologic development (AAP & ACOG, 2012).

Nitrous Oxide for Analgesia

Nitrous oxide was used more widely for labor analgesia in the United States in the past but never as extensively as in other countries. However, interest in using nitrous oxide during labor

has increased in the United States (Rooks, 2011). Nitrous oxide mixed with oxygen can be inhaled in a low concentration (50% or less) to provide analgesia during the first and second stages of labor. At the lower doses used for analgesia, it helps women relax, gives them a sense of control, and reduces their perception of pain even though they may still be aware that pain is present (Rooks, 2011).

A face mask is used to self-administer the gas. The woman places the mask over her mouth and nose as soon as a contraction begins. When she inhales, a valve opens and the gas is released. When inhalation stops, the valve closes, which prevents accidental overdosing. Scavenging equipment collects the woman's exhalations to protect health care workers from repetitive occupational exposure to nitrous oxide (Rooks, 2012).

The nurse should observe the woman for nausea, vomiting, dizziness, and drowsiness, the most common side effects of nitrous oxide (Klomp, van Poppel, Jones, et al., 2012). The use of nitrous oxide does not appear to depress uterine contractions or cause adverse reactions in the fetus and newborn. Its ease of use and rapid onset of action make it a good option for labor analgesia (Rooks, 2011; Rooks, 2012).

General Anesthesia

General anesthesia rarely is used for uncomplicated vaginal birth. It is used for only about 10% of cesarean births in the United States (Hawkins & Bucklin, 2012). General anesthesia may be necessary if a spinal or epidural block is contraindicated or if circumstances necessitate rapid birth (vaginal or emergent cesarean) without sufficient time or available personnel in the birth setting to perform a block (Witcher & McLendon, 2013). In addition, being awake and aware during major surgery may be unacceptable for some women having a cesarean birth. The major risks associated with general anesthesia are difficulty with or inability to intubate and aspiration of gastric contents (Cunningham et al., 2014; Hawkins and Bucklin). Anesthesia care providers are more likely to encounter difficulty with intubating morbidly obese women, especially in an emergency situation, than women of normal weight (Witcher & McLendon).

If general anesthesia is being considered, give the woman nothing by mouth and ensure that an IV infusion is in place. If time allows, premedicate the woman with a nonparticulate (clear) oral antacid (e.g., sodium citrate/citric acid [Bicitra]) to neutralize the acidic contents of the stomach. Aspiration of highly acidic gastric contents will damage lung tissue. Some anesthesia care providers also order the administration of a histamine (H_2)-receptor blocker such as famotidine (Pepcid) or ranitidine (Zantac) to decrease gastric acid production and metoclopramide (Reglan) to accelerate gastric emptying (Cunningham et al., 2014; Hawkins & Bucklin, 2012). Before the anesthesia is given, a wedge should be placed under one of the woman's hips to displace the uterus. Uterine displacement prevents compression of the aorta and vena cava, which maintains cardiac output and placental perfusion (Cunningham et al.; Hawkins & Bucklin).

Prior to anesthesia induction, the woman will be preoxygenated with 100% oxygen by nonrebreather face mask for 2 to 3 minutes. This is especially important in pregnant women,

EVIDENCE-BASED PRACTICE

Nitrous Oxide: Laughing Gas for Labor**Ask the Question**

Is nitrous oxide a safe and effective form of pain relief that can be recommended for laboring women?

Search for the Evidence

Search Strategies English language research-based publications since 2011 on nitrous oxide, laughing gas, labor pain relief were included.

Databases Used Cochrane Collaborative Database, National Guideline Clearinghouse (AHRQ), CINAHL, PubMed, UpToDate, and the professional websites for ACOG and AWHONN.

Critical Appraisal of the Evidence

Nitrous oxide is a patient-controlled analgesia/anesthesia used for pain relief since the 1880s. It has been commonly used for labor analgesia in Canada and the United Kingdom for decades. It is delivered via mask, which the laboring woman holds to her face during contractions. Its recent introduction into practice in the United States is limited by the supply of equipment to blend the mixture of 50/50 nitrous oxide and oxygen (Likis, Andrews, Collins, et al., 2014).

- Nitrous oxide increases endorphin and dopamine levels, diminishing pain and anxiety.
- Systematic analyses comparing epidural to nitrous oxide have not shown a difference between the Apgar scores or special care admission rates between the two groups (Likis et al., 2014). Further research is needed for long-term effects.
- When compared with nitrous oxide, epidurals were associated with more hypotension, fever, motor blockade, urinary retention, and instrumental and cesarean births for fetal distress, although there was no difference in cesarean rates overall (Jones, Othman, Doswell, et al., 2012).
- Although nitrous oxide does not relieve pain as well as an epidural, it does provide other benefits: it is inexpensive, less invasive than epidural, requires less intensive monitoring, and does not limit mobility (Likis et al., 2014).
- The most common side effects of nitrous oxide are nausea, vomiting, dizziness, and drowsiness (Klomp, van Poppel, Jones, et al., 2012).

Apply the Evidence: Nursing Implications

- Some women will want the maximum pain relief of epidurals, while others may be willing to trade that for the benefits of sense of control, mobility, and limited monitoring of nitrous oxide (Rooks, 2012).
- Because nitrous has a rapid onset and clearance, it can be an excellent choice for women who want to wait for an epidural,

whose epidural is not effective, or who come in too late for an epidural (Likis et al., 2014).

- Nitrous oxide is effective within a minute (Klomp et al., 2012). Women can start with nitrous oxide and easily move to another pain relief method, as needed.
- Health care providers are exposed to ambient gas vapors in close settings. The effects of this are unknown. Appropriate ventilation greatly diminishes this exposure (Likis et al., 2014).
- Because nitrous oxide produces euphoria and dissociation with pain, future research on women's satisfaction with the method may be a better measure than "pain relief" (Likis et al., 2014).

Quality and Safety Competencies: Evidence-Based Practice* Knowledge

Describe how the strength and relevance of available evidence influence the choice of interventions in provision of client-centered care.

Nurses use high-level evidence to offer pain relief options to women in labor, based on the client's preferences.

Skills

Participate in structuring the work environment to facilitate integration of new evidence into standards of practice.

Nurses and health care providers learn safe and effective nitrous oxide administration, and educate clients.

Attitudes

Value the need for continuous improvement in clinical practice based on new knowledge.

Nurses advocate for appropriate pain relief, and collaborate in research on outcomes, including client satisfaction.

who are more likely than other adults to rapidly become hypoxic if there is a delay in successful intubation. For many years, thiopental, a short-acting barbiturate, was widely used to induce anesthesia. However, the drug is no longer available in the United States. Its manufacturer stopped production because the drug was also used for capital punishment. Propofol (Diprivan), etomidate, or ketamine are now used instead. They are administered intravenously to render the woman unconscious (Cunningham et al., 2014). Next, succinylcholine, a muscle relaxer, is administered to facilitate passage of an endotracheal tube (Cunningham et al.; Hawkins & Bucklin,

2012). Sometimes the nurse is asked to assist with applying cricoid pressure before intubation as the woman begins to lose consciousness. This maneuver blocks the esophagus and prevents aspiration should the woman vomit or regurgitate (Fig. 17-13). Pressure is released once the endotracheal tube is securely in place.

After the woman is intubated, nitrous oxide and oxygen in a 50:50 mixture are administered. A low concentration of a volatile halogenated agent (e.g., isoflurane) also may be administered to increase pain relief and to reduce maternal awareness and recall (Cunningham et al., 2014; Hawkins & Bucklin, 2012).

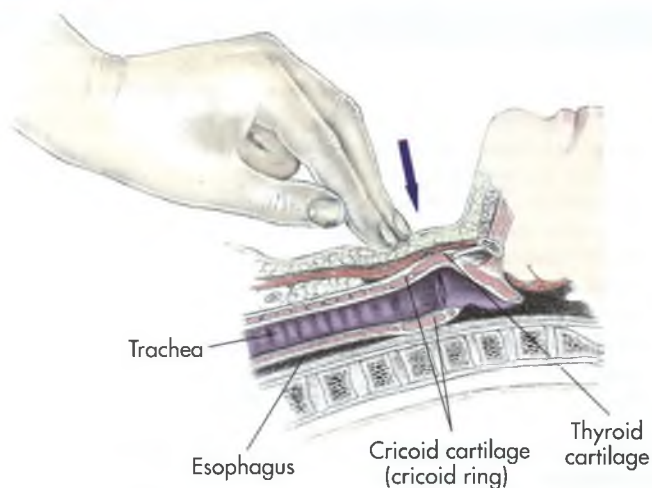

FIG 17-13 Technique of applying pressure on cricoid cartilage to occlude esophagus to prevent pulmonary aspiration of gastric contents during induction of general anesthesia.

In higher concentrations, isoflurane or methoxyflurane relaxes the uterus quickly and facilitates intrauterine manipulation, version, and extraction. However, at higher concentrations these agents cross the placenta readily and can produce narcosis in the fetus and could reduce uterine tone after birth, increasing the risk for hemorrhage. Because of this risk for neonatal narcosis, it is critical that the baby be delivered as soon as possible after inducing anesthesia to reduce the degree of fetal exposure to the anesthetic agents and the CNS depressants administered.

Priorities for recovery room care are to maintain an open airway and cardiopulmonary function and to prevent postpartum hemorrhage. Women who had surgery under general anesthesia will require pain medication soon after regaining consciousness. Routine postpartum care is organized to facilitate parent-infant attachment as soon as possible and to answer the mother's questions. When appropriate, the nurse assesses the mother's readiness to see her baby, as well as her response to the anesthesia and to the event that necessitated general anesthesia (e.g., emergency cesarean birth when vaginal birth was anticipated).

CARE MANAGEMENT

The choice of pain relief interventions depends on a combination of factors, including the woman's special needs and wishes, the availability of the desired method or methods, the knowledge and expertise in nonpharmacologic and pharmacologic methods of the health care providers involved in the woman's care, and the phase and stage of labor. (See the Nursing Care Plan for possible nursing diagnoses and interventions.)

Nonpharmacologic Interventions

The nurse supports and assists the woman as she uses nonpharmacologic interventions for pain relief and relaxation. During labor the nurse should ask the woman how she feels to evaluate the effectiveness of the specific pain management techniques used. Appropriate interventions can then be planned or continued for effective care, such as trying other nonpharmacologic methods or combining nonpharmacologic methods with medications. A pain scale, in which 0 represents no pain and 10 represents pain as bad as it could possibly be, is often used

to evaluate a woman's pain before and after pain relief interventions are implemented. Comparing the woman's answers provides a way to objectively evaluate the effectiveness of pain relief interventions. Sometimes a coping scale, rather than a pain scale, is used to evaluate how well the woman is dealing with the discomfort of labor.

Pharmacologic Interventions

Informed Consent

Pregnant women have the right to be active participants in determining the best pain care approach to use during labor and birth. The primary health care provider and anesthesia care provider are responsible for fully informing women of the alternative methods of pharmacologic pain relief available in the birth setting. A description of the various anesthetic techniques and what they entail is essential to informed consent, even if the woman received information about analgesia and anesthesia earlier in her pregnancy. The initial discussion of pain management options ideally should take place in the third trimester so the woman has time to consider alternatives. Nurses play a part in the informed consent by clarifying and describing procedures or by acting as the woman's advocate and asking the primary health care provider for further explanations. The three essential components of an informed consent are:

- First, the procedure and its advantages and disadvantages must be thoroughly explained.
- Second, the woman must agree with the plan of labor pain care as explained to her.
- Third, her consent must be given freely without coercion or manipulation from her health care provider.

LEGAL TIP: Informed Consent for Anesthesia

The woman receives (in an understandable manner) the following:

- Explanation of alternative methods of anesthesia and analgesia available
- Description of the anesthetic, including its effects and the procedure for its administration
- Description of the benefits, discomforts, risks, and consequences for the mother, the fetus, and the newborn
- Explanation of how complications can be treated
- Information that the anesthetic is not always effective
- Indication that the woman may withdraw consent at any time
- Opportunity to have any question answered
- Opportunity to have components of the consent explained in the woman's own words

The consent form will:

- Be written or explained in the woman's primary language
- Have the woman's signature
- Have the date of consent
- Carry the signature of the anesthetic care provider, certifying that the woman has received and expresses understanding of the explanation

! NURSING ALERT

In some cultures a husband is expected to consent to procedures performed on his wife. Although in the United States the woman gives consent and signs any necessary forms, she may not be willing to do so unless her husband also approves.

 **NURSING CARE PLAN**
Nonpharmacologic Pain Management

NURSING DIAGNOSIS	EXPECTED OUTCOME	INTERVENTIONS	RATIONALES
<i>Anxiety related to lack of confidence in ability to cope effectively with pain during labor</i>	Woman will express decrease in anxiety and experience satisfaction with her labor and birth performance.	<p>Assess whether woman and significant other have attended childbirth classes, their knowledge of labor process, and their current level of anxiety.</p> <p>Encourage support person to remain with woman in labor.</p> <p>Teach or review nonpharmacologic techniques available to decrease anxiety and pain during labor (e.g., focusing, relaxation and breathing techniques, effleurage, and sacral pressure).</p> <p>Explore other techniques that woman or significant other may have learned in childbirth classes (e.g., hypnosis, hydrotherapy, acupressure, biofeedback, therapeutic touch, aromatherapy, imaging, music).</p> <p>Explore use of transcutaneous electrical nerve stimulation if ordered by primary health care provider.</p> <p>Assist woman to change positions and to use pillows.</p> <p>Assess bladder for distention, and encourage voiding often.</p> <p>Encourage rest between contractions.</p> <p>Keep woman and significant other informed about progress.</p> <p>Guide couple through labor stages and phases, helping them use and modify comfort techniques that are appropriate to each phase.</p> <p>Support couple if pharmacologic measures are required to increase pain relief, explaining safety and effectiveness.</p>	<p>To plan supportive strategies that address couple's specific needs</p> <p>To provide support and increase probability of positive response to comfort measures</p> <p>To enhance chances of success in using techniques</p> <p>To provide more options for coping strategies</p> <p>To provide increased perception of control over pain and increase in release of endogenous opiates (endorphins)</p> <p>To reduce stiffness, aid circulation, and promote comfort</p> <p>To avoid bladder distention, subsequent discomfort, and potential for suppression of uterine contractions</p> <p>To minimize fatigue</p> <p>To allay anxiety</p> <p>To ensure greatest effectiveness of techniques used</p> <p>To reduce anxiety and maintain self-esteem and sense of control over labor process</p>
<i>Readiness for Enhanced Childbearing Process related to desire for healthy outcome of labor and birth</i>	Woman will participate in planning care for labor.	<p>Discuss woman's birth plan and knowledge about birth process.</p> <p>Provide information about labor process.</p> <p>Inform woman about her labor status and the fetus's well-being.</p> <p>Discuss rationales for all interventions.</p> <p>Incorporate nonpharmacologic interventions into plan of care.</p> <p>Provide emotional support and ongoing positive feedback.</p>	<p>To collect data for nursing plan of care</p> <p>To correct any misconceptions</p> <p>To promote comfort and confidence</p> <p>To incorporate woman into plan of care</p> <p>To increase woman's sense of control during labor</p> <p>To enhance positive coping mechanisms</p>

Timing of Administration

Nonpharmacologic measures can be used to relieve pain and stress and enhance progress at any time in labor.

It is often the nurse who notifies the primary health care provider that the woman is in need of pharmacologic measures to relieve her discomfort. Orders are often written for the administration of pain medication as needed by the woman and based on the nurse's clinical judgment. In the past, pharmacologic measures for pain relief were usually not implemented until labor had advanced to the active phase of the first stage of labor and the cervix had dilated approximately 4 to 5 cm, to avoid suppressing the progress of labor. However, it is now known that epidural anesthesia in early labor does not increase the rate of cesarean birth. Whereas it may shorten the duration of first-stage labor in some women, epidural anesthesia lengthens it in others (Hawkins & Bucklin, 2012). It is no longer recommended that women in labor reach a certain level of cervical dilation or fetal station before receiving epidural anesthesia (AAP & ACOG, 2012; Cunningham et al., 2014). It is, however, still recommended that the administration of systemic opioid analgesics be delayed until labor is well established (Burke, 2014).

Preparation for Procedures

The methods of pain relief available to the woman are reviewed and information is clarified as necessary. The procedure and what will be asked of the woman (e.g., to maintain flexed position during insertion of epidural needle) must be explained.

The woman also can benefit from knowing the way that the medication is to be given, the interval before the medication takes effect, and the expected pain relief from the medication. Skin-preparation measures are described, and an explanation is given for the need to empty the bladder before the analgesic or anesthetic is administered and the reason for keeping the bladder empty. When an indwelling catheter is to be threaded into the epidural space, the woman should be told that she may have a momentary twinge down her leg, hip, or back and that this feeling is not a sign of injury (Box 17-6).

Administration of Medication

Accurate monitoring of the progress of labor forms the basis for the nurse's judgment that a woman needs pharmacologic control of discomfort. Knowledge of the medications used during childbirth is essential. The most effective route of administration is selected for each woman; then the medication is prepared and administered correctly.

Any medication can cause a minor or severe allergic reaction. As part of the assessment for such allergic reactions, the nurse should monitor the woman's vital signs, respiratory effort, cardiovascular status, integument, and platelet and white blood cell count. The woman is observed for side effects of drug therapy, especially drowsiness and dyspnea. Minor reactions can consist of rash, rhinitis, fever, shortness of breath, or pruritus. Management of the less acute allergic response is not an emergency.

Severe allergic reactions (anaphylaxis) may occur suddenly and lead to shock or death. The most dramatic form of anaphylaxis is sudden, severe bronchospasm, upper airway obstruction, and hypotension (Norred, 2012). Signs of anaphylaxis are largely caused by contraction of smooth muscles

and may begin with irritability, extreme weakness, nausea, and vomiting. This may lead to dyspnea, cyanosis, convulsions, and cardiac arrest. Anaphylaxis must be diagnosed and treated immediately. Initial treatment usually consists of placing the woman in a supine position, injecting epinephrine intramuscularly, administering fluid intravenously, supporting the airway with ventilation if necessary, and giving oxygen. If the response to these measures is inadequate, IV epinephrine should be given (Norred). Cardiopulmonary resuscitation may be necessary (see Chapter 30).

Intravenous Route. The preferred route of administration of medications such as meperidine, fentanyl, butorphanol, or nalbuphine is through IV tubing, administered into the port nearest the point of insertion of the infusion (proximal port). The medication is given slowly, in small doses, during a contraction. It may be given over a period of three to five consecutive contractions if needed to complete the dose. It is given during contractions to decrease fetal exposure to the medication because uterine blood vessels are constricted during contractions and the medication stays within the maternal vascular system for several seconds before the uterine blood vessels reopen. The IV infusion is then restarted slowly to prevent a bolus of medication from being administered. With this method of injection, the amount of medication crossing the placenta to the fetus is minimized. The IV route has the following advantages:

- Onset of pain relief is rapid and more predictable.
- Pain relief is obtained with small doses of the drug.
- Duration of effect is more predictable.

Intramuscular Route. Although analgesics are still sometimes given intramuscularly (IM), it is not the preferred route of administration for the woman in labor. The advantages of using the IM route are quick administration and no need to start an IV line.

Disadvantages of the IM route include:

- Onset of pain relief is delayed.
- Higher doses of medication are required.
- Medication is released at an unpredictable rate from the muscle tissue and is available for transfer across the placenta to the fetus.

The maternal medication levels (after IM injections) are unequal because of uneven distribution (maternal uptake) and metabolism. IM injections given in the upper arm (deltoid muscle) seem to result in more rapid absorption and higher blood levels of the medication than when administered in other sites (Bricker & Lavender, 2002). If regional anesthesia is planned later in labor, the deltoid muscle is the preferred site. The autonomic blockade from the regional (e.g., epidural) anesthesia increases blood flow to the gluteal region and accelerates absorption of medication that may be sequestered there. Administration of opioids subcutaneously in the upper arm avoids this risk and, as a result, is often used as an alternative to an IM injection.

Regional (Epidural or Spinal) Anesthesia. According to professional standards (Association of Women's Health, Obstetric and Neonatal Nurses [AWHONN], 2012), the nonanesthetist registered nurse is permitted to monitor the status of the woman receiving regional anesthesia, the fetus, and the progress of labor; replace empty infusion syringes or

BOX 17-6 Nursing Interventions for the Woman Receiving Epidural or Spinal Anesthesia**Prior to the Block**

- Assist primary health care provider or anesthesia care provider with explaining the procedure and obtaining the woman's informed consent.
- Assess maternal vital signs, level of hydration, labor progress, and fetal heart rate (FHR) and pattern.
- Start an IV line and infuse a bolus of fluid (Ringer's lactate or normal saline) if ordered (e.g., 500 to 1000 ml 15 to 30 minutes prior to induction of the anesthesia).
- Obtain laboratory results (hematocrit or hemoglobin level, other tests as ordered).
- Assess the woman's level of pain using a pain scale (from 0 [no pain] to 10 [pain as bad as it could possibly be]).
- Assist the woman to void.

During Initiation of the Block

- Assist the woman with assuming and maintaining the proper position.
- Verbally guide the woman through the procedure, explaining sounds and sensations as she experiences them.
- Assist the anesthesia care provider with documentation of vital signs, time and amount of medications given, etc.
- Monitor maternal vital signs (especially blood pressure) and FHR as ordered.
- Have oxygen and suction readily available.
- Monitor for signs of local anesthetic toxicity (see Box 17-5) as the test dose of medication is administered.

While the Block Is in Effect

- Continue to monitor maternal vital signs and FHR as ordered (continuous monitoring of maternal heart rate [electrocardiogram (ECG)] and blood pressure may be ordered to monitor for accidental intravenous injection of medication).

- Continue to assess the woman's level of pain with every check of vital signs using a pain scale (from 0 [no pain] to 10 [pain as bad as it could possibly be]).
- Monitor for bladder distention.
 - Assist with spontaneous voiding on a bedpan or toilet.
 - Insert a urinary catheter if necessary.
- Encourage or assist the woman to change positions from side to side every hour.
- Promote safety.
 - Keep the side rails up on the bed.
 - Place the telephone and call light within easy reach.
 - Instruct the woman not to get out of bed without help.
 - Make sure there is no prolonged pressure on anesthetized body parts.
- Keep the epidural catheter insertion site clean and dry.
- Continue to monitor for anesthetic side effects (see Box 17-5).

While the Block Is Wearing Off After Birth

- Assess regularly for the return of sensory and motor function.
- Continue to monitor maternal vital signs as ordered.
- Monitor for bladder distention.
 - Assist with spontaneous voiding on the bedpan or toilet.
 - Insert a urinary catheter if necessary.
- Promote safety.
 - Keep the side rails up on the bed.
 - Place the telephone and call light within easy reach.
 - Instruct the woman not to get out of bed without help.
 - Make sure there is no prolonged pressure on anesthetized body parts.
- Keep the epidural catheter insertion site clean and dry.
- Continue to monitor for anesthetic side effects (see Box 17-5).

bags with the same medication and concentration; stop the infusion and initiate emergency measures if the need arises; and remove the catheter if properly educated to do so. Only qualified, licensed anesthesia care providers are permitted to insert a catheter and initiate epidural anesthesia, verify catheter placement, inject medication through the catheter, or alter the medication or medications, including the type, the amount, or the rate of infusion.

SAFETY ALERT

Safe regional anesthesia administration requires specialized education, experience, and competence. There is potential for significant maternal and fetal morbidity and mortality associated with some obstetric anesthesia complications. Therefore, a licensed, credentialed anesthesia care provider should manage regional anesthesia and analgesia during labor and birth and be readily available to manage obstetric anesthesia-related emergencies (AWHONN, 2012).

Because spinal nerve blocks can reduce bladder sensation, resulting in difficulty voiding, the woman should empty her bladder before the induction of the block and should be encouraged to void at least every 2 hours thereafter. The nurse should palpate for bladder distention and measure urinary output to ensure that the bladder is being completely emptied. A distended bladder can inhibit uterine contractions and fetal

descent, resulting in a slowing of the progress of labor. For this reason, an indwelling urinary catheter (Foley) is often routinely inserted immediately after epidural or spinal anesthesia is initiated and left in place for the remainder of the first stage of labor.

The status of the maternal-fetal unit and the progress of labor must be established before the block is performed. The nurse must assist the woman to assume and maintain the correct position for induction of epidural and spinal anesthesia (see Fig. 17-11, A and B).

Depending on the level of motor blockade, the woman should be assisted to remain as mobile as possible. When in bed, her position should be alternated from side to side every hour to ensure adequate distribution of the anesthetic solution and to maintain circulation to the uterus and placenta.

SAFETY ALERT

After receiving an epidural block or opioid intravenously for pain, the woman should not be allowed to ambulate alone. She must either remain in bed or request assistance before attempting to get out of bed. The nurse assesses the woman for signs of orthostatic hypotension and return of sensation and motor function of the lower extremities prior to ambulation.

Health care providers should be aware that effective epidural anesthesia prolongs the second stage of labor by 15 to 30 minutes. A longer second stage of labor does not negatively affect maternal or fetal outcome, however, as long as the FHR tracing is normal,

maternal hydration and analgesia are adequate, and there is ongoing progress in the descent of the fetal head. Therefore, operative interventions (e.g., the use of forceps or vacuum) to hasten the birth solely because the second stage is prolonged are unnecessary. Reducing the density of the epidural block during the second stage of labor, delaying pushing until the woman feels the urge to do so, and avoiding arbitrary definitions for the “normal” duration of second-stage labor are suggested as interventions to decrease the risk of operative vaginal birth (Hawkins & Bucklin, 2012). (See Chapter 19 for a full discussion of second-stage labor management.) Box 17-6 summarizes the nursing interventions for women receiving epidural or spinal anesthesia.

Safety and General Care

The nurse monitors and records the woman’s response to non-pharmacologic pain relief methods and to medication(s). This includes the degree of pain relief, the level of apprehension, the return of sensations and perception of pain, and allergic or adverse reactions (e.g., hypotension, respiratory depression,

fever, pruritus, and nausea and vomiting). The nurse continues to monitor maternal vital signs and fetal heart rate and pattern at frequent intervals, the strength and frequency of uterine contractions, changes in the cervix and station of the presenting part, the presence and quality of the bearing-down reflex, bladder filling, and state of hydration. Determining the fetal response after administration of analgesia or anesthesia is vital. The woman is asked if she (or the family) has any questions. The nurse also assesses the woman’s and her family’s understanding of the need for ensuring her safety (e.g., keeping side rails up, calling for assistance as needed).

The time that elapses between the administration of an opioid and the baby’s birth is documented. Medications given to the newborn to reverse opioid effects are recorded. After birth, the woman who has had spinal, epidural, or general anesthesia is assessed for return of sensory and motor function in addition to the usual postpartum assessments. Both the nurse and the anesthesia provider are responsible for documenting assessments and care in relation to the epidural.

KEY POINTS

- Nonpharmacologic pain and stress management strategies are valuable for managing labor discomfort alone or in combination with pharmacologic methods.
- The gate-control theory of pain and the stress response are the bases for many of the nonpharmacologic methods of pain relief.
- The type of analgesic or anesthetic to be used is determined by maternal and health care provider preference, the stage of labor, and the method of birth.
- Sedatives may be appropriate for women in prolonged early labor when there is a need to decrease anxiety or promote sleep or therapeutic rest.
- Naloxone (Narcan) is an opioid (narcotic) antagonist that can reverse narcotic effects, especially respiratory depression.
- Pharmacologic control of pain during labor requires collaboration among the health care providers and the laboring woman.
- The nurse must understand medications, their expected effects, potential side effects, and methods of administration.
- Maintenance of maternal fluid balance is essential during spinal and epidural nerve blocks.
- Maternal analgesia or anesthesia potentially affects neonatal neurobehavioral response.
- The use of opioid agonist-antagonist analgesics in women with preexisting opioid dependence may cause symptoms of abstinence syndrome (opioid withdrawal).
- Epidural anesthesia and analgesia is the most effective available pharmacologic pain relief method for labor. It is used by the majority of women in the United States.
- General anesthesia is rarely used for vaginal birth but may be used for cesarean birth or whenever rapid anesthesia is needed in an emergency childbirth situation.

Fetal Assessment During Labor

Kitty Cashion

© <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Identify typical signs of normal and abnormal fetal heart rate (FHR) patterns.
- Compare FHR monitoring performed by intermittent auscultation with external and internal electronic methods.
- Explain the baseline FHR and evaluate periodic changes.
- Describe nursing measures that can be used to maintain FHR patterns within normal limits.
- Differentiate among the nursing interventions used for managing specific FHR patterns, including tachycardia and bradycardia, absent or minimal variability, and late and variable decelerations.
- Review the documentation of the monitoring process necessary during labor.

The ability to assess the fetus by auscultation of the fetal heart was initially described more than 300 years ago. With the advent of the fetoscope and stethoscope after the turn of the 20th century, the listener could hear clearly enough to count the FHR. When electronic FHR monitoring made its debut for clinical use in the early 1970s, the anticipation was that its use would result in less intrapartum asphyxia and thus fewer cases of cerebral palsy. Consequently the use of electronic fetal monitoring (EFM) rapidly expanded (Garite, 2012). However, the rate of cerebral palsy has not declined since that time and is not likely to decrease, because more preterm infants are surviving (Gilbert, 2011). Prematurity is the leading cause of cerebral palsy. Intrapartum asphyxia accounts for 25% of cases or less of this disorder (Garite).

Still, EFM is a useful tool for visualizing FHR patterns on a monitor screen or printed tracing. It continues to be the primary mode of intrapartum fetal assessment in the United States and is the most commonly performed obstetric procedure in that country (American College of Obstetricians and Gynecologists [ACOG], 2009; Miller, Miller, & Tucker, 2013). Pregnant women should be informed about the equipment and procedures used and the risks, benefits, and limitations of intermittent auscultation (IA) and EFM. This chapter discusses the basis for intrapartum fetal monitoring, the types of monitoring, and nursing assessment and management of abnormal fetal status.

BASIS FOR MONITORING

Fetal Response

Because labor is a period of physiologic stress for the fetus, frequent monitoring of fetal status is part of the nursing care

during labor. The fetal oxygen supply must be maintained during labor to prevent fetal compromise and to promote newborn health after birth. The fetal oxygen supply can decrease in a number of ways:

- Reduction of blood flow through the maternal vessels as a result of maternal hypertension (chronic hypertension, preeclampsia, or gestational hypertension), hypotension (caused by supine maternal position, hemorrhage, or epidural analgesia or anesthesia), or hypovolemia (caused by hemorrhage)
 - Reduction of the oxygen content in the maternal blood as a result of hemorrhage or severe anemia
 - Alterations in fetal circulation, occurring with compression of the umbilical cord (transient, during uterine contractions [UCs], or prolonged, resulting from cord prolapse), placental separation or complete abruption, or head compression (head compression causes increased intracranial pressure and vagal nerve stimulation with an accompanying decrease in the FHR)
 - Reduction in blood flow to the intervillous space in the placenta secondary to uterine hypertonus (generally caused by excessive exogenous oxytocin) or secondary to deterioration of the placental vasculature associated with post-term gestation or maternal disorders such as hypertension or diabetes mellitus
- Fetal well-being during labor can be measured by the response of the FHR to UCs. A group of fetal monitoring experts recommended that FHR tracings demonstrating certain reassuring characteristics be described as *normal* (category I) (Box 18-1).

Uterine Activity

Table 18-1 describes normal uterine activity (UA) during labor.

BOX 18-1 Three-Tier Fetal Heart Rate Classification System

Category I

Category I fetal heart rate (FHR) tracings include all of the following:

- Baseline rate 110 to 160 beats/minute (bpm)
- Baseline FHR variability: moderate
- Late or variable decelerations: absent
- Early decelerations: either present or absent
- Accelerations: either present or absent

Category II

Category II FHR tracings include all FHR tracings not categorized as category I or category III. Examples of category II tracings include any of the following:

- Baseline rate
 - Bradycardia not accompanied by absent baseline variability
 - Tachycardia
- Baseline FHR variability
 - Minimal baseline variability
 - Absent baseline variability not accompanied by recurrent decelerations
 - Marked baseline variability
- Accelerations
 - No acceleration produced in response to fetal stimulation
- Periodic or episodic decelerations
 - Recurrent variable decelerations accompanied by minimal or moderate baseline variability
 - Prolonged decelerations (≥ 2 minutes but < 10 minutes)
 - Recurrent late decelerations with moderate baseline variability
 - Variable decelerations with other characteristics, such as slow return to baseline, "overshoots" or "shoulders"

Category III

Category III FHR tracings include:

- Absent baseline variability and any of the following:
 - Recurrent late decelerations
 - Recurrent variable decelerations
 - Bradycardia
- Sinusoidal pattern

Fetal Compromise

The goals of intrapartum FHR monitoring are to identify and differentiate the normal (reassuring) patterns from the abnormal (nonreassuring) patterns, which can be indicative of fetal compromise. Although the 2008 National Institute of Child Health and Human Development (NICHD) workshop (Macones, Hankins, Spong, et al., 2008) and the ACOG (2009) recommend use of the terms *normal* and *abnormal* to describe FHR tracings, the terms *reassuring* and *nonreassuring* are still frequently used clinically.

Abnormal FHR patterns are those associated with fetal **hypoxemia**, which is a deficiency of oxygen in the arterial blood. If uncorrected, hypoxemia can deteriorate to severe fetal **hypoxia**, an inadequate supply of oxygen at the cellular level that can cause metabolic acidosis. The term **asphyxia** is used when fetal hypoxia results in metabolic acidosis (Garite, 2012) (see Box 18-1 for examples of abnormal [category III] FHR tracings).

TABLE 18-1 Normal Uterine Activity During Labor

CHARACTERISTIC	DESCRIPTION
Frequency	Contraction frequency overall generally ranges from two to five per 10 minutes during labor, with lower frequencies seen in first stage of labor and higher frequencies (up to five contractions in 10 minutes) seen during second stage of labor
Duration	Contraction duration remains fairly stable throughout first and second stages, ranging from 45-80 seconds, not generally exceeding 90 seconds
Strength	Uterine contractions generally range from peaking at 40-70 mm Hg in first stage of labor to more than 80 mm Hg in second stage. Contractions palpated as "mild" will likely peak at less than 50 mm Hg if measured internally, whereas contractions palpated as "moderate" or greater will likely peak at 50 mm Hg or greater if measured internally.
Resting tone	Average resting tone during labor is 10 mm Hg; if using palpation, should palpate as "soft" (i.e., easily indented, no palpable resistance)
Relaxation time	Relaxation time is commonly 60 seconds or more in first stage and 45 seconds or more in second stage
Montevideo units (MVUs)	MVUs usually range from 100-250 in first stage; may rise to 300-400 in the second stage. Contraction intensities of 40 mm Hg or more and MVUs of 80-120 are generally sufficient to initiate spontaneous labor. MVUs are used only with internal monitoring of contractions.

[2013]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* (7th ed.). St. Louis: Mosby.

MONITORING TECHNIQUES

The ideal method of fetal assessment during labor, IA or EFM, continues to be debated. Although IA is a high-touch, low-technology method of assessing fetal status during labor that places fewer restrictions on maternal activity, more than 85% of laboring women in the United States are monitored electronically for at least part of their labor (ACOG, 2009; Miller et al., 2013). The continued use of EFM in place of IA is thought to be because of concerns about liability and the increased nurse-client ratio required with IA. Because all surveillance methods, including EFM, have limitations, some health care providers believe that the evidence supports a return to the use of IA for low risk laboring women (ACOG, 2009; Miller et al.).

Intermittent Auscultation

Intermittent auscultation (IA) involves listening to fetal heart sounds at periodic intervals to assess the FHR. IA of the fetal heart can be performed with a Pinard fetoscope (see Fig. 14-7, C), Doppler ultrasound (see Fig. 18-1, A), an ultrasound stethoscope (see Fig. 18-1, B), or a DeLee-Hillis fetoscope (see Fig. 18-1, C). Doppler ultrasound and ultrasound stethoscopes transmit ultrahigh-frequency sound waves, reflecting movement of the fetal heart, and convert these sounds into an electronic signal that can be counted. The fetoscope is applied to the listener's forehead because bone conduction amplifies the fetal heart sounds for counting. Box 18-2 describes how to perform IA.

EVIDENCE-BASED PRACTICE

Fetal Cardiac Assessment During Labor: How Are You Doing in There?**Ask the Question**

For low risk women, which assessments of fetal cardiac function during labor provide better outcomes?

Search for the Evidence

Search Strategies English language research-based publications on fetal assessment, monitoring, labor, labour, cardiotocography, auscultation, pulse oximetry, electrocardiogram, scalp pH, scalp lactate were included.

Exclusions included preterm, postterm, high risk

Databases Used Cochrane Collaborative Database, Joanna Briggs Institute, National Guideline Clearinghouse (AHRQ), CINAHL, PubMed, UpToDate, and the professional websites for AWHONN and SOGC

Critical Appraisal of the Evidence

Intermittent auscultation of fetal heart rate can be accomplished with a fetal stethoscope, a Pinard fetoscope, or a hand-held Doppler ultrasound device. Admission electronic fetal monitoring for 20 to 30 minutes is intended to identify risk for fetal distress.

- Routine admission 20-minute electronic fetal monitoring (EFM) assessment is associated with higher rates of continuous fetal monitoring, fetal scalp blood sampling, and a 20% higher risk for cesarean birth than intermittent auscultation. There are no significant differences in instrumental vaginal births, artificial rupture of membranes, labor augmentation, or perinatal death. These findings do not support routine admission EFM strips for low-risk term laboring women, due to the risk for overtreatment (Devane, Lalor, Daly, et al., 2012).

Inadequate fetal oxygenation leads to abnormal fetal heart rate and electrocardiogram (ECG) patterns, including elevation or suppression of the ST segment. Monitoring the fetal ECG requires cervical dilation of at least 3 cm, and ruptured membranes, in order to directly access the fetal presenting part.

- EFM plus ECG results in fewer fetal scalp blood samples, fewer instrumental deliveries, and fewer admissions to special care nursery units than EFM alone. However, there are no differences in cesarean births, and no differences in these neonatal outcomes: severe acidosis, encephalopathy, low Apgar scores at 5 minutes, or need for intubation. The reviewers suggest that fetal ECG may be useful in decision making when contemplating continuous EFM (Neilson, 2013).

A poorly oxygenated fetus will develop acidosis, lower pH, and increased blood lactate. Fetal blood sampling requires cervical dilation and ruptured membranes. Fetal lactate sampling requires much less blood volume than pH, making it more successful.

- Fetal lactate sampling (also called fetal scalp blood sampling) can be done using a point-of-care machine, like a glucometer, and reliably correlates with cord artery pH, Apgar scores <7 at 5 minutes, and metabolic acidemia, regardless of large or growth-restricted status of the fetus (Holzmann, Cnattingius, & Nordstrom, 2012).

Apply the Evidence: Nursing Implications

- Evidence that a routine admission EFM strip is not recommended for low risk term labor may meet with resistance in institutions that have made this their practice for decades. Evaluating and communicating the evidence becomes paramount for changing long-term institutional habits.
- Overtreatment, such as unnecessary cesarean births, may be a result of fear of litigation, and create additional risks and costs.

New evidence of client safety of intermittent auscultation should reassure caregivers and low risk laboring women.

- A limited assessment of ECG plus EFM is probably not any better than EFM alone, except when continuous EFM is being contemplated. The decision to initiate continuous EFM usually greatly decreases the mobility of laboring women, and may prolong labor and increase the cascade of interventions.
- Both ECG and scalp blood sampling require rupture of membranes. If this does not occur spontaneously, there is debate about the benefits versus risks of artificially rupturing membranes (increased maternal contraction pain, fetal infection, fetal distress). It falls to nurses to maintain perineal hygiene, including minimizing cervical examinations and documenting invasive procedures (Hastings-Toma, Bernard, Brody, et al., 2013).
- Fetal lactate sampling uses a very narrow capillary tube of blood, which is collected after a small incision in the fetal scalp or presenting part. Parents will probably find this distressing, and need to understand the reasons for it, the small risk for infection, and the puncture site they may notice on their newborn.

Quality and Safety Competencies: Quality Improvement* Knowledge

Recognize that nursing and other health profession students are parts of systems of care and care processes that affect outcomes for clients and families.

Nurses can use evidence to advocate for change in institutional habits, such as overtesting that leads to overtreatment.

Skills

Seek information about outcomes of care for populations served in care setting.

Seek out the highest level evidence and demonstrate its relevance to this setting.

Attitudes

Appreciate the value of what individuals and teams can do to improve care.

Education of the whole health care team is necessary to improve buy-in for institutional change.

IA is easy to use, inexpensive, and less invasive than EFM. It is often more comfortable for the woman and gives her more freedom of movement. Other care measures, such as ambulation and the use of baths or showers, are easier to carry out when IA is used. However, IA may be difficult to perform in obese women. A transvaginal fetal Doppler probe is available. It provides closer proximity to the uterus, making it easier to auscultate the FHR when the woman is obese or early in gestation (Miller et al., 2013). Because IA is intermittent, significant events may occur during a time when the FHR is not being auscultated. Also IA does not provide a permanent documented visual record of the FHR and cannot be used to assess visual patterns of the FHR variability or periodic changes (Miller et al.). When using IA the nurse can assess

FIG 18-1 A, Ultrasound Doppler. B, Ultrasound stethoscope. C, DeLee-Hillis fetoscope. (Courtesy Michael S. Clement, MD, Mesa, AZ.)

BOX 18-2 Procedure for Intermittent Auscultation of the Fetal Heart Rate

1. Palpate maternal abdomen to identify fetal presentation and position.
2. Apply ultrasonic gel to device if using Doppler ultrasound. Place listening device (see Fig. 18-1, A) over area of maximal intensity and clarity of fetal heart sounds to obtain clearest and loudest sound, which is easiest to count. This location is usually over the fetal back. If using fetoscope, firm pressure may be needed.
3. Count maternal radial pulse while listening to FHR to differentiate it from fetal rate.
4. Palpate abdomen for presence or absence of UA to count FHR between contractions.
5. Count FHR for 30 to 60 seconds after a uterine contraction to identify auscultated baseline rate and changes (increases or decreases) in it.
6. Auscultate FHR before, during, and after contraction to identify FHR during the contraction or as a response to the contraction and to assess for absence or presence of increases or decreases in FHR.
7. When distinct discrepancies in FHR are noted during listening periods, auscultate for longer period during, after, and between contractions to identify significant changes that may indicate need for another mode of FHR monitoring.

FHR, Fetal heart rate; UA, uterine activity.

the baseline FHR, rhythm, and increases and decreases from baseline.

Nursing Interventions

The American College of Nurse-Midwives (ACNM) reviewed references from the United States, Great Britain, and Canada regarding the recommended frequency of IA in low risk women and found consistent recommendations for every 15 minutes in the active phase of the first stage of labor and every 5 minutes in the second stage of labor (Miller et al., 2013). The seventh edition of *Guidelines for Perinatal Care* (American Academy of Pediatrics [AAP] & ACOG, 2012) suggests performing IA every 30 minutes in the active phase of the first stage of labor and every 15 minutes in the second stage. The Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) recommends auscultation of the FHR every 15 to 30 minutes in the active phase of the first stage labor, and every 5 to 15 minutes in the active phase of the second stage of labor (Lyndon, O'Brien-Abel, & Simpson, 2014). However, the optimal frequency for IA in low risk women during labor has not been determined (Nageotte, 2014).

! NURSING ALERT

When the FHR is auscultated and documented the descriptive terms associated with EFM (e.g., moderate variability, variable deceleration) cannot be used because most of the terms are visual descriptions of the patterns produced on the monitor tracing. However, terms that are numerically defined such as bradycardia and tachycardia can be used. When the FHR is auscultated, it should be described as a baseline number or range and as having a regular or irregular rhythm. The presence or absence of accelerations or decelerations both during and after contractions should also be noted (Lyndon et al., 2014; Miller et al., 2013).

Every effort should be made to use the method of fetal assessment the woman desires, if possible. However, auscultation of the FHR in accordance with the frequency guidelines suggested earlier may be difficult in today's busy labor and birth units. When used as the primary method of fetal assessment, auscultation requires a one-to-one nurse-to-client staffing ratio. If acuity and census change so that auscultation standards are no longer met, the nurse must inform the physician or nurse-midwife that continuous EFM will be used until staffing can be arranged to meet the standards.

The woman can become anxious if the examiner cannot readily count the fetal heartbeats. It often takes time for the inexperienced listener to locate the heartbeat and find the area of maximal intensity. To allay the mother's concerns, she can be told that the nurse is "finding the spot where the sounds are loudest." If it takes considerable time to locate the fetal heartbeat, the examiner can reassure the mother by offering her an opportunity to listen, too. If the examiner cannot locate the fetal heartbeat, assistance should be requested. In some cases ultrasound can be used to help locate the fetal heartbeat. Seeing the FHR on the ultrasound screen will be reassuring to the mother if there was initial difficulty in locating the best area for auscultation.

When using IA, uterine activity is assessed by palpation. The examiner should keep his or her fingertips placed over the fundus before, during, and after contractions. The contraction **intensity** is usually described as mild, moderate, or strong. **Duration** is measured in seconds, from the beginning to the end of the contraction. The **frequency** of contractions is measured in minutes, from the beginning of one contraction to the beginning of the next. The examiner should keep his or her hand on the fundus after the contraction is over to evaluate uterine resting tone or relaxation between contractions. **Resting tone** between contractions is usually described as soft or hard (Lyndon et al., 2014).

Accurate and complete documentation of fetal status and uterine activity is especially important when IA and palpation

are being used because no paper tracing record or computer storage of these assessments is provided as is the case with continuous EFM. Labor flow records or computer charting systems that prompt notations of all assessments are useful for ensuring such comprehensive documentation.

Electronic Fetal Monitoring

The purpose of electronic FHR monitoring is the ongoing assessment of fetal oxygenation. FHR tracings are analyzed for characteristic patterns that suggest fetal hypoxic events and metabolic acidosis during labor. When hypoxia or metabolic acidosis is suspected in labor, interventions to resolve the problem can be implemented in a timely manner before permanent damage or death occurs (Garite, 2012). The two modes of EFM are the external mode, which uses external transducers placed on the maternal abdomen to assess FHR and UA, and the internal mode, which uses a **spiral electrode** applied to the fetal presenting part to assess the FHR and an **intrauterine pressure catheter (IUPC)** to assess UA and uterine resting tone. The differences between the external and internal modes of EFM are summarized in Table 18-2.

External Monitoring

Separate transducers are used to monitor the FHR and UCs (Fig. 18-2). The **ultrasound transducer** works by reflecting high-frequency sound waves off a moving interface: in this case, the fetal heart and valves. It is sometimes difficult to reproduce a continuous and precise record of the FHR because of artifact introduced by fetal and maternal movement. Maternal obesity, occiput posterior position of the fetus, and anterior attachment of the placenta can cause weak or absent signals (AWHONN, 2009). The FHR is printed on specially formatted paper and simultaneously displayed on a screen if the fetal monitor is connected to a computer. Once the area of maximal intensity of the FHR has been located, conductive gel is applied to the surface of the ultrasound transducer, and the transducer is then positioned over this area and held securely in place using an elastic belt.

The **tocotransducer** (tocodynamometer) measures UA transabdominally. The device is placed over the fundus above the umbilicus and held securely in place using an elastic belt (see Fig. 18-2, B). UCs or fetal movements depress a

TABLE 18-2 External and Internal Modes of Monitoring

EXTERNAL MODE	INTERNAL MODE
<p>Fetal Heart Rate</p> <p><i>Ultrasound transducer:</i> High-frequency sound waves reflect mechanical action of the fetal heart. Noninvasive. Does not require rupture of membranes or cervical dilation. Used during both the antepartum and intrapartum periods.</p>	<p><i>Spiral electrode:</i> Converts the fetal ECG as obtained from the presenting part to the FHR via a cardiometer. Can be used only when membranes are ruptured and the cervix is sufficiently dilated during the intrapartum period. Electrode penetrates the fetal presenting part by 1.5 mm and must be attached securely to ensure a good signal.</p>
<p>Uterine Activity</p> <p><i>Tocotransducer:</i> Monitors frequency and duration of contractions by means of a pressure-sensing device applied to the maternal abdomen. Used during both the antepartum and intrapartum periods.</p>	<p><i>Intrauterine pressure catheter (IUPC):</i> Monitors the frequency, duration, and intensity of contractions. The two types of IUPCs are a fluid-filled system and a solid catheter. Both measure intrauterine pressure at the catheter tip and convert the pressure into millimeters of mercury on the uterine activity panel of the strip chart. Both can be used only when membranes are ruptured and the cervix is sufficiently dilated during the intrapartum period.</p>

A

B

FIG 18-3 The Monica AN24 is a wireless and beltless device that can be used with existing monitors to obtain fetal heart rate via abdominal electrocardiogram (ECG). **B**, Electrodes placed on maternal abdomen monitor ECG from fetal and maternal heart and electromyogram (EMG) from uterine muscle. (Courtesy Monica Healthcare Ltd., Nottingham, UK.)

pressure-sensitive surface on the side next to the abdomen. The tocotransducer can measure and record the frequency and approximate duration of UCs but not their intensity. This method is especially valuable for measuring UA during the first stage of labor in women with intact membranes or for antepartum testing. If the woman is obese, the tocotransducer may be unable to detect the exact frequency and duration of UCs.

Because the tocotransducer of most electronic fetal monitors is designed for assessing UA in a term pregnancy, it may not be sensitive enough to detect preterm UA. When monitoring the woman in preterm labor, remember that the fundus may be located below the level of the umbilicus. The nurse may need to rely on the woman to indicate when UCs are occurring and to use palpation as an additional way of assessing contraction frequency and validating the monitor tracing.

The external transducers are easily applied by the nurse but often must be repositioned as the woman or fetus changes position. The woman is asked to assume a semi-Fowler or lateral position. Use of external transducers confines the woman to bed or chair.

A

B

FIG 18-4 A, Woman sitting on birthing ball, and B, woman ambulating, both wearing Monica AN24. (Courtesy Monica Healthcare Ltd., Nottingham, UK.)

Portable telemetry monitors allow observation of the FHR and UC patterns by means of centrally located electronic display stations. These portable units permit the woman to walk around during electronic monitoring.

In 2011 another type of external monitor became available for use in the United States. It was used in several European countries before its debut in the United States. The Monica AN24 uses abdominally obtained electronic impulses to

monitor both FHR and UA (Fig. 18-3, A and B). The monitor uses five electrodes placed on the woman's abdomen to directly monitor the electrocardiogram from the maternal and fetal hearts and the electromyogram from the uterine muscle. This information is transmitted wirelessly, via Bluetooth technology, to an interface device that allows the FHR and UA data to print or display on a standard fetal monitor (Miller et al., 2013).

The Monica AN24 eliminates much of the problem caused by signal loss resulting from maternal or fetal movement or maternal obesity that often occurs with traditional external monitors. The monitor also more accurately measures the frequency, peak, and duration of UCs than does the traditional tocotransducer, although it does not provide actual intensity measurement in millimeters of mercury (mm Hg) as an IUPC does. Other advantages of the Monica AN24 are that it eliminates the need for abdominal belts and frequent readjustment of the tocotransducer and ultrasound transducer and provides some client mobility. The woman may move up to 50 feet away from the interface device without signal loss (Fig. 18-4, A and B). In the United States the Monica AN24 is approved for use only in pregnancies that have reached 36 completed weeks or more of gestation (Miller et al., 2013). The Monica AN24 monitor may not be readily available for use in all labor and birth settings.

Internal Monitoring

The technique of continuous internal FHR or UA monitoring provides a more accurate appraisal of fetal well-being during labor than external monitoring because it is not interrupted by fetal or maternal movement or affected by maternal size (Fig. 18-5). For this type of monitoring the membranes must be ruptured, the cervix sufficiently dilated (at least 2 to 3

cm), and the presenting part low enough to allow placement of the spiral electrode or IUPC or both. Internal and external modes of monitoring (i.e., internal FHR with external UA or external FHR with internal UA) may be combined without difficulty.

Internal monitoring of the FHR is accomplished by attaching a small spiral electrode to the presenting part. For UA to be monitored internally an IUPC is introduced into the uterine cavity. The catheter has a pressure-sensitive tip that measures changes in intrauterine pressure. As the catheter is compressed during a contraction, pressure is placed on the pressure transducer. This pressure is then converted into a pressure reading in mm Hg. The IUPC can objectively measure the frequency, duration, and intensity of UCs, as well as uterine resting tone.

Because it can precisely measure the intensity of individual UCs, the IUPC can be used to evaluate the adequacy of UA for achieving progress in labor. **Montevideo units (MVUs)** are calculated by subtracting the baseline uterine pressure from the peak contraction pressure for each contraction that occurs in a 10-minute window, and then adding together the pressures generated by each contraction that occurs during that period of time. Spontaneous labor usually begins when MVUs are between 80 and 120. Uterine activity during normal labor rarely exceeds 250 MVUs (see Table 18-1) (Cunningham, Leveno, Bloom, et al., 2014; Miller et al., 2013).

CLINICAL REASONING CASE STUDY

Monitoring the Fetus of an Obese Woman

Tameka is a 23-year-old G 4 P 2 0 1 2 at 35 weeks of gestation. She has had chronic hypertension since age 16 and is morbidly obese. Today she weighs 305 pounds. Tameka was sent from the antepartum testing area to the labor and birth unit for prolonged monitoring because she had a nonreactive nonstress test (NST) and her blood pressure was elevated at her appointment today. You are Tameka's nurse. After spending half an hour admitting her to the unit you walk out to the nurses' station and announce to your colleagues, "I am so frustrated! No matter what I do, I just can't keep that baby on the monitor!"

1. Evidence—Is there sufficient evidence at this time to draw a conclusion about the best way to monitor Tameka's fetus?
2. Assumptions—Describe an underlying assumption regarding use of the following modes of monitoring for Tameka's fetus:
 - a. Intermittent auscultation
 - b. External (ultrasound transducer)
 - c. Internal (spiral electrode)
 - d. Monica AN24
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

FIG 18-5 Diagrammatic representation of internal invasive fetal monitoring with intrauterine pressure catheter and spiral electrode in place (membranes ruptured and cervix dilated).

Display

The FHR and UA are displayed on the monitor paper or computer screen, with the FHR in the upper section and UA in the lower section. Figure 18-6 contrasts the internal and external modes of electronic monitoring. Note that each small square on the monitor paper or screen represents 10 seconds; each larger box of six squares equals 1 minute

FIG 18-6 Display of fetal heart rate (FHR) and uterine contractions (UC) as seen using the external mode of monitoring (A) as compared to the internal mode of monitoring (B). (From Miller, L., Miller, D., & Tucker, S. [2013]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [7th ed.]. St. Louis: Mosby.)

(when paper is moving through the monitor at the rate of 3 cm/minute).

FETAL HEART RATE PATTERNS

Characteristic FHR patterns are associated with fetal and maternal physiologic processes and have been identified for many years. Because EFM was introduced into clinical practice before consensus was reached in regard to standardized terminology, however, variations in the description and interpretation of common fetal heart rate patterns were often great. In 1997 the NICHD published a proposed nomenclature system for EFM interpretation with standardized definitions for FHR monitoring. The NICHD recommendations were not widely incorporated into clinical practice, however, until they were endorsed by the ACOG in 2005. AWHONN and ACNM also endorsed use of the NICHD standard terminology. All three organizations cited concerns regarding client safety and the need for improved communication among caregivers as reasons for using standard EFM definitions in clinical practice (Miller et al., 2013).

In April 2008 the NICHD, the ACOG, and the Society for Maternal-Fetal Medicine partnered to sponsor another workshop to revisit the FHR definitions recommended by the NICHD in 1997. The 1997 FHR definitions were reaffirmed at this workshop. In addition, new definitions related to UA were recommended, as well as a three-tier system of FHR pattern interpretation and categorization (see Box 18-1) (Macones et al., 2008).

Baseline Fetal Heart Rate

The intrinsic rhythmicity of the fetal heart, the central nervous system (CNS), and the fetal autonomic nervous system control the FHR. An increase in sympathetic response results

in acceleration of the FHR, whereas an increase in parasympathetic response produces a slowing of the FHR. Usually a balanced increase of sympathetic and parasympathetic response occurs during contractions, with no observable change in the baseline FHR.

The **baseline fetal heart rate** is the average rate during a 10-minute segment that excludes periodic or episodic changes, periods of marked variability, and segments of the baseline that differ by more than 25 beats/minute. There must be at least 2 minutes of interpretable baseline data in a 10-minute segment of tracing in order to determine the baseline FHR (Macones et al., 2008). After 10 minutes of tracing is observed the approximate mean rate is rounded to the closest 5 beats/minute interval (AWHONN, 2009). For example, if the FHR rate varies between 130 and 140 beats/minute over a 10-minute period, the baseline is recorded as 135 beats/minute. The normal range at term is 110 to 160 beats/minute. In the preterm fetus the baseline rate is slightly higher.

Variability

Variability of the FHR can be described as irregular waves or fluctuations in the baseline FHR of two cycles per minute or greater (Macones et al., 2008). It is a characteristic of the baseline FHR and does not include accelerations or decelerations of the FHR. Variability is quantified in beats per minute and is measured from the peak to the trough of a single cycle. Four possible categories of variability have been identified: absent, minimal, moderate, and marked (Fig. 18-7). In the past, variability was described as either long term or short term (beat to beat). The NICHD definitions do not distinguish between long- and short-term variability, however, because in actual practice they are visually determined as a unit (NICHD, 1997).

Depending on other characteristics of the FHR tracing, absent or minimal variability is classified as either abnormal

FIG 18-7 Fetal heart rate variability. A, Absent: amplitude range undetectable. B, Minimal: amplitude range detectable ≤ 5 beats/minute. C, Moderate: amplitude range 6-25 beats/minute. D, Marked: amplitude range ≥ 25 beats/minute. FHR, Fetal heart rate. (From Miller, L., Miller, D., & Tucker, S. [2013]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [7th ed.]. St. Louis: Mosby.)

or indeterminate (Macones et al., 2008) (see Fig. 18-7, A and B). It can result from fetal hypoxemia and metabolic acidemia. Other possible causes of absent or minimal variability include congenital anomalies and preexisting neurologic injury. CNS depressant medications, including analgesics, narcotics (meperidine [Demerol]), barbiturates (secobarbital [Seconal], and pentobarbital [Nembutal]), tranquilizers (diazepam [Valium]), phenothiazines (promethazine [Phenergan]), and general anesthetics are other possible causes of minimal variability. In addition, minimal variability can occur with

tachycardia, prematurity, or when the fetus is temporarily in a sleep state (Miller et al., 2013). These sleep states do not usually last longer than 30 minutes.

Moderate variability is considered normal (see Fig. 18-7, C). Its presence is highly predictive of a normal fetal acid-base balance (absence of fetal metabolic acidemia). Moderate variability indicates that FHR regulation is not significantly affected by fetal sleep cycles, tachycardia, prematurity, congenital anomalies, preexisting neurologic injury, or CNS depressant medications (Macones et al., 2008; Miller et al., 2013).

FIG 18-8 Sinusoidal pattern. FHR, Fetal heart rate. (From Miller, L., Miller, D., & Tucker, S. [2013]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [7th ed.]. St. Louis: Mosby.)

FIG 18-9 Fetal tachycardia. (From Miller, L., Miller, D., & Tucker, S. [2013]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [7th ed.]. St. Louis: Mosby.)

The significance of marked variability (see Fig. 18-7, D) is unknown due to limited scientific evidence (Macones et al., 2008).

A sinusoidal pattern—a regular smooth, undulating wavelike pattern—is not included in the definition of FHR variability. This uncommon pattern classically occurs with severe fetal anemia (Fig. 18-8). Variations of the sinusoidal pattern have been described in association with chorioamnionitis, fetal sepsis, and administration of narcotic analgesics (Miller et al., 2013).

Tachycardia

Tachycardia is a baseline FHR greater than 160 beats/minute for 10 minutes or longer (Fig. 18-9). It can be considered an early sign of fetal hypoxemia, especially when associated with late decelerations and minimal or absent variability. Fetal tachycardia can result from maternal or fetal infection, such as prolonged rupture of membranes with amnionitis; from maternal hyperthyroidism or fetal anemia; or in response to medications such as atropine, hydroxyzine (Vistaril), terbutaline (Brethine), or illicit drugs such as cocaine or methamphetamines. Table 18-3 lists causes, clinical significance, and nursing interventions for tachycardia.

Bradycardia

Bradycardia is a baseline FHR of fewer than 110 beats/minute for 10 minutes or longer (Fig. 18-10). True bradycardia occurs

TABLE 18-3 Tachycardia and Bradycardia

TACHYCARDIA

Definition

FHR >160 beats/minute lasting >10 minutes

Possible Causes

Early fetal hypoxemia
Fetal cardiac arrhythmias
Maternal fever
Infection (including chorioamnionitis)
Parasympatholytic drugs (atropine, hydroxyzine)
Beta-sympathomimetic drugs (terbutaline)
Maternal hyperthyroidism
Fetal anemia
Drugs (caffeine, cocaine, methamphetamines)

BRADYCARDIA

FHR <110 beats/minute lasting >10 minutes

Atrioventricular dissociation (heart block)
Structural defects
Viral infections (e.g., cytomegalovirus)
Medications
Fetal heart failure
Maternal hypoglycemia
Maternal hypothermia

Clinical Significance

Persistent tachycardia in absence of periodic changes does not appear serious in terms of neonatal outcome (especially true if tachycardia is associated with maternal fever); tachycardia is abnormal when associated with late decelerations, severe variable decelerations, or absent variability.

Baseline bradycardia alone is not specifically related to fetal oxygenation. The clinical significance of bradycardia depends on the underlying cause and the accompanying FHR patterns, including variability, accelerations, or decelerations.

Nursing Interventions

Dependent on cause; reduce maternal fever with antipyretics as ordered and cooling measures; oxygen at 10 L/minute by nonrebreather face mask may be of some value; carry out health care provider's orders based on alleviating cause

Dependent on cause

FHR, Fetal heart rate.

FIG 18-10 Fetal bradycardia. (From Miller, L., Miller, D., & Tucker, S. [2013]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [7th ed.]. St. Louis: Mosby.)

rarely and is not specifically related to fetal oxygenation. It must be distinguished from a prolonged deceleration because the causes and management of these two conditions are very different. Bradycardia is often caused by some type of fetal cardiac problem such as structural defects involving the pacemakers or conduction system or fetal heart failure. Other causes of

FIG 18-11 Accelerations of fetal heart rate in a term pregnancy. (From Miller, L., Miller, D., & Tucker, S. [2013]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [7th ed.]. St. Louis: Mosby.)

bradycardia include viral infections (e.g., cytomegalovirus), maternal hypoglycemia, and maternal hypothermia. The clinical significance of the bradycardia depends on the underlying cause and accompanying FHR patterns, including variability and the presence of accelerations or decelerations (Miller et al., 2013). (See Table 18-3 for a list of causes, clinical significance, and nursing interventions for bradycardia.)

Periodic and Episodic Changes in Fetal Heart Rate

Changes in FHR from the baseline are categorized as periodic or episodic. **Periodic changes** are those that occur with UCs. **Episodic changes** are those that are not associated with UCs. These patterns include both accelerations and decelerations (Macones et al., 2008).

Accelerations

Acceleration of the FHR is defined as a visually apparent abrupt (onset to peak less than 30 seconds) increase in FHR above the baseline rate (Fig. 18-11). The peak is at least 15 beats/minute above the baseline, and the acceleration lasts 15 seconds or more, with a return to baseline less than 2 minutes from the beginning of the acceleration. Before 32 weeks of gestation the definition of an acceleration is a peak of 10 beats/minute or more above the baseline and a duration of at least 10 seconds. Acceleration of the FHR for more than 10 minutes is considered a change in baseline rate (Miller et al., 2013).

Accelerations can be either periodic or episodic. They may occur in association with fetal movement or spontaneously. If accelerations do not occur spontaneously, they can be elicited by fetal scalp stimulation or vibroacoustic stimulation. Similar to moderate variability, accelerations are considered an indication of fetal well-being. Their presence is highly predictive of a normal fetal acid-base balance (absence of fetal metabolic acidemia) (Miller et al., 2013). Box 18-3 lists causes, clinical significance, and nursing interventions for accelerations.

Decelerations

A **deceleration** (caused by dominance of a parasympathetic response) may be **benign** or **abnormal**. FHR decelerations are categorized as early, late, variable, or prolonged. They are described by their visual relation to the onset and end of a contraction and by their shape.

Early Decelerations. **Early deceleration** of the FHR is a visually apparent gradual (onset to lowest point ≥ 30 seconds) decrease in and return to baseline FHR associated with UCs.

BOX 18-3 Accelerations

Causes

- Spontaneous fetal movement
- Vaginal examination
- Electrode application
- Fetal scalp stimulation
- Fetal reaction to external sounds
- Breech presentation
- Occiput posterior position
- Uterine contractions
- Fundal pressure
- Abdominal palpation

Clinical Significance

Normal pattern. Acceleration with fetal movement signifies fetal well-being representing fetal alertness or arousal states.

Nursing Interventions

None required

It is thought to be caused by transient fetal head compression and is considered a normal and benign finding (Macones et al., 2008; Miller et al., 2013). Generally the onset, *nadir* (lowest point), and recovery of the deceleration correspond to the beginning, peak, and end of the contraction (Figs. 18-12 and 18-13). For this reason, an early deceleration is sometimes called the “mirror image” of a contraction.

Early decelerations may occur during UCs, during vaginal examinations, as a result of fundal pressure, and during placement of the internal mode of fetal monitoring. When present, they usually occur during the first stage of labor when the cervix is dilated 4 to 7 cm. Early decelerations are also sometimes seen during the second stage when the woman is pushing.

Because early decelerations are considered to be benign, interventions are not necessary. The value of identifying early decelerations is so they can be distinguished from late or variable decelerations, which can be abnormal and for which interventions are appropriate. Box 18-4 lists causes, clinical significance, and nursing interventions for early decelerations.

Late Decelerations. **Late deceleration** of the FHR is a visually apparent gradual decrease in and return to baseline FHR associated with UCs (Macones et al., 2008). The deceleration begins after the contraction has started, and the nadir of the deceleration occurs after the peak of the contraction. The deceleration usually does not return to baseline until after the contraction is over (Figs. 18-14 and 18-15).

FIG 18-12 Line drawing illustrating early decelerations. *FHR*, Fetal heart rate. (From Tucker, S. [2004]. *Pocket guide to fetal monitoring and assessment* [5th ed.]. St. Louis: Mosby.)

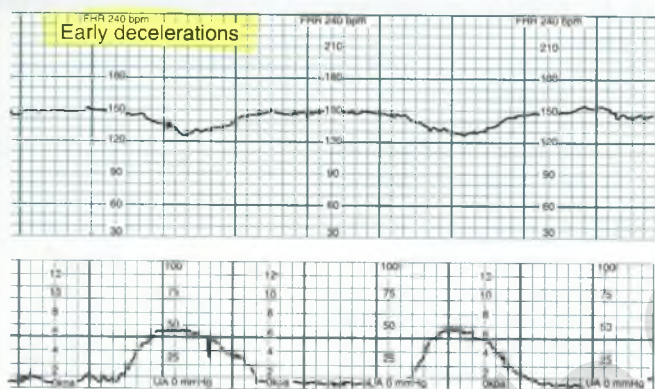

FIG 18-13 Electronic fetal monitor tracing showing early decelerations. *FHR*, Fetal heart rate; *UA*, uterine activity. (From Miller, L., Miller, D., & Tucker, S. [2013]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [7th ed.]. St. Louis: Mosby.)

BOX 18-4 Early Decelerations

Cause

Head compression resulting from the following:

- Uterine contractions
- Vaginal examination
- Fundal pressure
- Placement of internal mode of monitoring

Clinical Significance

Normal pattern; not associated with fetal hypoxemia, acidemia, or low Apgar scores

Nursing interventions

None required

Traditionally late decelerations have been attributed to uteroplacental insufficiency. However, in reality a number of factors can disrupt oxygen transfer to the fetus, even with mild UCs and a normally functioning placenta (Miller et al., 2013). These factors include maternal hypotension, *uterine tachysystole* (e.g., more than five contractions in 10 minutes averaged

over a 30-minute window), preeclampsia, late term or postterm pregnancy, amnionitis, small for gestational age fetuses, maternal diabetes, placenta previa, placental abruption, conduction anesthetics, maternal cardiac disease, and maternal anemia. Rarely fetal oxygenation can be interrupted sufficiently to result in metabolic acidemia. For that reason late decelerations should be considered an ominous sign when they are associated with absent or minimal variability (Miller et al.). The most common cause of late decelerations is uterine tachysystole, usually caused by oxytocin (Pitocin) administration (Garite, 2012). The clinical significance and nursing interventions for late decelerations are described in Box 18-5.

Variable Decelerations. **Variable deceleration** of the FHR is defined as a visually abrupt (onset to nadir less than 30 seconds) decrease in FHR below the baseline. The decrease is at least 15 beats/minute or more below the baseline, lasts at least 15 seconds, and returns to baseline in less than 2 minutes from the time of onset (Macones et al., 2008). Variable decelerations occur any time during the UC phase and are caused by compression of the umbilical cord (Figs. 18-16 and 18-17).

The appearance of variable decelerations differs from those of early and late decelerations, which closely approximate the shape of the corresponding UC. Instead, variable decelerations have a U, V, or W shape, characterized by a rapid descent and ascent to and from the nadir of the deceleration (see Figs. 18-16 and 18-17). Some variable decelerations are preceded and followed by brief accelerations of the FHR known as *shoulders*, which is an appropriate compensatory response to compression of the umbilical vein.

Occasional variables have little clinical significance. Recurrent variable decelerations, however, indicate repetitive disruption in the fetus's oxygen supply. This can result in hypoxemia and metabolic acidemia. Variable decelerations are most commonly found during the transition phase of first stage labor or the second stage of labor as a result of umbilical cord compression and stretching during fetal descent (Garite, 2012). Box 18-6 lists causes, clinical significance, and nursing interventions for variable decelerations.

FIG 18-14 Line drawing illustrating late decelerations. *FHR*, Fetal heart rate. (Modified from Tucker, S. [2004]. *Pocket guide to fetal monitoring and assessment* [5th ed.]. St. Louis: Mosby.)

FIG 18-15 Electronic fetal monitor tracing showing late decelerations. *FHR*, Fetal heart rate; *UA*, uterine activity. (From Miller, L., Miller, D., & Tucker, S. [2013]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [7th ed.]. St. Louis: Mosby.)

Prolonged Decelerations. A **prolonged deceleration** is a visually apparent decrease (may be either gradual or abrupt) in *FHR* of at least 15 beats/minute below the baseline and lasting more than 2 minutes but less than 10 minutes. A deceleration lasting more than 10 minutes is considered a baseline change (Macones et al., 2008) (Fig. 18-18).

Prolonged decelerations are caused when the mechanisms responsible for late or variable decelerations last for an extended period (more than 2 minutes). Examples of conditions that can cause an interruption in the fetal oxygen supply long enough to produce a prolonged deceleration include maternal hypotension, uterine tachysystole or rupture, extreme placental insufficiency, and prolonged cord compression or prolapse (Garite, 2012; Miller et al., 2013). The presence and degree of hypoxia are thought to correlate with the depth and duration of the deceleration, how abruptly it returns to the baseline, how much variability is lost during the deceleration, and whether rebound tachycardia and loss of variability occur after the deceleration (Garite).

BOX 18-5 Late Decelerations

Cause

Disruption of oxygen transfer from environment to fetus caused by the following:

- Uterine tachysystole
- Maternal supine hypotension
- Epidural or spinal anesthesia
- Placenta previa
- Placental abruption
- Hypertensive disorders
- Postmaturity
- Intrauterine growth restriction
- Diabetes mellitus
- Intraamniotic infection

Clinical Significance

Abnormal pattern associated with fetal hypoxemia, acidemia, and low Apgar scores; considered ominous if persistent and uncorrected, especially when associated with absent or minimal baseline variability

Nursing Interventions

The usual priority is as follows:

1. Change maternal position (lateral).
2. Correct maternal hypotension by elevating legs.
3. Increase rate of maintenance IV solution.
4. Palpate uterus to assess for tachysystole.
5. Discontinue oxytocin if infusing.
6. Administer oxygen at 8 to 10 L/minute by nonrebreather face mask.
7. Notify physician or nurse-midwife.
8. Consider internal monitoring for a more accurate fetal and uterine assessment.
9. Assist with birth (cesarean or vaginal assisted) if the pattern cannot be corrected.

IV, Intravenous.

! NURSING ALERT

Nurses should notify the physician or nurse-midwife immediately and initiate appropriate treatment of abnormal patterns when they see a prolonged deceleration.

CARE MANAGEMENT

Care of the woman receiving EFM in labor begins with evaluation of the EFM equipment. The nurse must ensure that the monitor is recording *FHR* and *UA* accurately and that the

FIG 18-16 Line drawing illustrating variable decelerations. *FHR*, Fetal heart rate. (From Tucker, S. [2004]. *Pocket guide to fetal monitoring and assessment* [5th ed.]. St. Louis: Mosby.)

FIG 18-18 Prolonged decelerations. *FHR*, Fetal heart rate; *UA*, uterine activity. (From Miller, L., Miller, D., & Tucker, S. [2013]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [7th ed.]. St. Louis: Mosby.)

BOX 18-6 Variable Decelerations

Cause

Umbilical cord compression caused by the following:

- Maternal position with cord between fetus and maternal pelvis
- Cord around fetal neck, arm, leg, or other body part
- Short cord
- Knot in cord
- Prolapsed cord

Clinical Significance

Variable decelerations occur in approximately 50% of all labors and usually are transient and correctable

Nursing Interventions

The usual priority is as follows:

1. Change maternal position (side to side, knee-chest).
2. Discontinue oxytocin if infusing.
3. Administer oxygen at 8 to 10 L/minute by nonrebreather face mask.
4. Notify physician or nurse-midwife.
5. Assist with vaginal or speculum examination to assess for cord prolapse.
6. Assist with amnioinfusion if ordered.
7. Assist with birth (vaginal assisted or cesarean) if the pattern cannot be corrected.

tracing is interpretable. If external monitoring is not adequate, changing to a fetal spiral electrode or IUPC may be necessary. A checklist for fetal monitoring equipment can be used to evaluate the equipment functions (Box 18-7).

After ensuring that the monitor is recording properly, the FHR and UA tracings are evaluated regularly throughout labor. *Guidelines for Perinatal Care*, published jointly by the American Academy of Pediatrics (AAP) and ACOG (2012), recommends that the FHR tracing be evaluated at least every 30 minutes during the first stage of labor and every 15 minutes during the second stage of labor in low risk women. If risk factors are present, the FHR tracing should be evaluated more frequently: every 15 minutes in the first stage of labor and every 5 minutes in the second stage of labor.

BOX 18-7 Checklist for Fetal Monitoring Equipment

Preparation of Monitor

1. Is the paper inserted correctly (if using paper)?
2. Are transducer cables plugged securely into the appropriate port on the monitor?
3. Is the paper speed set to 3 cm/minute?
4. Was the monitor date and time verified (when using electronic documentation)?

Ultrasound Transducer

1. Has ultrasound transmission gel been applied to the transducer?
2. Was the fetal heart rate (FHR) tested and noted on the monitor strip?
3. Was the FHR compared with the maternal pulse and noted?
4. Does a signal light flash or an audible beep occur with each heartbeat?
5. Is the belt secure and snug but comfortable for the laboring woman?

Tocotransducer

1. Is the tocotransducer firmly positioned at the site of the least maternal tissue?
2. Has it been applied without gel or paste?
3. Was the uterine activity (UA) baseline adjusted between contractions to print at the 20-mm Hg line?
4. Is the belt secure and snug but comfortable for the laboring woman?

Spiral Electrode

1. Is the connector attached firmly to the electrode pad (on the leg plate or abdomen)?
2. Is the spiral electrode attached to the presenting part of the fetus?
3. Is the inner surface of the electrode pad pre-gelled or covered with electrode gel?
4. Is the electrode pad properly secured to the woman's thigh or abdomen?

Internal Catheter or Strain Gauge

1. Is the length line on the catheter visible at the introitus?
2. Is it noted on the monitor paper that a UA test or calibration was performed?
3. Has the monitor been set to zero according to the manufacturer's directions?
4. Is the intrauterine pressure catheter properly secured to the woman?
5. Is the baseline resting tone of the uterus documented?

From Miller, L., Miller, D., & Tucker, S. (2013). *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* (7th ed.). St. Louis: Mosby.

Assessing FHR and UA patterns, implementing independent nursing interventions, documenting observations and actions according to the established standard of care, and reporting abnormal patterns to the primary care provider (e.g., physician, nurse-midwife) are the responsibilities of the nurse providing care to women in labor.

Technology has made access to and communication regarding electronic FHR tracings much more convenient for health care providers. Many hospitals use central monitor displays, which provide the opportunity to view the tracings of several

FIG 18-19 Providers can access near real-time fetal heart rate tracings and review client data using their mobile phones. (© 2014 AirStrip Technologies. All rights reserved. Trademarks not belonging to AirStrip Technologies are the property of their respective companies.)

women at the same time at the nurses' station. Health care providers can also access the FHR tracings of one woman or several clients from remote locations, including office and home. It is also possible to access FHR tracings and other client data using mobile phones (Fig. 18-19) (Miller et al., 2013).

Electronic Fetal Monitoring Pattern Recognition and Interpretation

Nurses must evaluate many factors to determine whether an FHR pattern is normal or abnormal. They evaluate these factors based on the presence of other obstetric complications, progress in labor, and use of analgesia or anesthesia. They also must consider the estimated time interval until birth. Therefore, interventions are based on clinical judgment of a complex, integrated process. Several different organizations offer EFM courses for nurses and other health care professionals. It is also possible to earn certification in EFM.

Categorizing Fetal Heart Rate Tracings

As mentioned, a three-tier system of categorizing FHR tracings is recommended (see Box 18-1). Category I FHR

LEGAL TIP: Fetal Monitoring Standards

Nurses who care for women during childbirth are legally responsible for correctly interpreting FHR patterns, initiating appropriate nursing interventions based on those patterns, and documenting the outcomes of those interventions. Perinatal nurses are responsible for the timely notification of the physician or nurse-midwife in the event of abnormal FHR patterns. They also are responsible for initiating the institutional chain of command should differences in opinion arise among health care providers concerning the interpretation of the FHR pattern and the intervention required.

tracings are normal and strongly predictive of normal fetal acid-base status at the time of observation. These tracings may be followed in a routine manner and do not require any specific action. Category II FHR tracings are indeterminate. This category includes all tracings that do not meet category I or category III criteria. Category II tracings require continued observation and evaluation. Category III FHR tracings are abnormal. Immediate evaluation and prompt intervention are required when these patterns are identified (Macones et al., 2008).

Nursing Management of Abnormal Patterns

The five essential components of the FHR tracing that must be evaluated regularly are baseline rate, baseline variability, accelerations, decelerations, and changes or trends over time. Whenever one of these five essential components is assessed as abnormal, corrective measures must be taken immediately. The purpose of these actions is to improve fetal oxygenation (Miller et al., 2013). The term *intrauterine resuscitation* is sometimes used to refer to specific interventions initiated when an abnormal FHR pattern is noted. Basic corrective measures include providing supplemental oxygen, instituting maternal position changes, and increasing intravenous fluid administration. These interventions are implemented to improve uterine and intervillous space blood flow and increase maternal oxygenation and cardiac output (Miller et al.). Box 18-8 lists basic interventions to improve maternal and fetal oxygenation status.

Depending on the underlying cause of the abnormal FHR pattern, other interventions, such as correcting maternal hypotension, reducing UA, and altering second-stage pushing techniques also may be instituted (Miller et al., 2013). Box 18-8 lists interventions for these specific problems. Some of the items listed are not independent nursing interventions. Any medications administered, for example, must be authorized either through inclusion in a specific unit protocol or by a written or verbal order. Some interventions are specific to the FHR pattern. (See Table 18-3 and Boxes 18-5 and 18-6 for nursing interventions for tachycardia, late decelerations, and variable decelerations.) Based on the FHR response to these interventions the primary health care provider decides whether additional interventions should be instituted or whether immediate assisted vaginal or cesarean birth should be performed.

OTHER METHODS OF ASSESSMENT AND INTERVENTION

A major shortcoming of EFM is its high rate of false-positive results. Even the most abnormal patterns are poorly predictive of neonatal morbidity. Therefore, other methods of assessment have been developed to evaluate fetal status. Fetal scalp stimulation and vibroacoustic stimulation and umbilical cord acid-base determination are frequently performed. Fetal scalp blood sampling is another available assessment technique. Amnioinfusion and tocolytic therapy are interventions often used in an attempt to improve abnormal FHR patterns.

BOX 18-8 Management of Abnormal Fetal Heart Rate Patterns

Basic Interventions

- Administer oxygen by nonrebreather face mask at a rate of 10 L/minute for approximately 15 to 30 minutes.
- Assist the woman to a side-lying (lateral) position.
- Increase maternal blood volume by increasing the rate of the primary IV infusion.

Interventions for Specific Problems

- Maternal hypotension
 - Increase the rate of the primary IV infusion.
 - Change to lateral or Trendelenburg positioning.
 - Administer ephedrine or phenylephrine per unit protocol or standing order if other measures are unsuccessful in increasing blood pressure.
- Uterine tachysystole
 - Reduce or discontinue the dose of any uterine stimulants in use (e.g., oxytocin [Pitocin]).
 - Administer a uterine relaxant (tocolytic) (e.g., terbutaline [Brethine]).
- Abnormal fetal heart rate pattern during the second stage of labor
 - Use open-glottis pushing.
 - Use fewer pushing efforts during each contraction.
 - Make individual pushing efforts shorter.
 - Push only with every other or every third contraction.
 - Push only with a perceived urge to push (in women with regional anesthesia).

IV, Intravenous.

Assessment Techniques

Fetal Scalp Stimulation and Vibroacoustic Stimulation

Several research studies undertaken in the 1980s found that an FHR acceleration in response to digital or vibroacoustic stimulation was highly predictive of a normal scalp blood pH. The two methods of fetal stimulation used most often in clinical practice are scalp stimulation (using digital pressure during a vaginal examination) and vibroacoustic stimulation (using an artificial larynx or fetal acoustic stimulation device on the maternal abdomen over the fetal head for 1 to 5 seconds). Another stimulation method is placing a specialized halogen light source on the maternal abdomen. The desired result of these stimulation methods is an acceleration in the FHR of at least 15 beats/minute for at least 15 seconds (Miller et al., 2013). An FHR acceleration indicates the absence of metabolic acidemia. If the fetus does not respond to stimulation with an acceleration, fetal compromise is not necessarily indicated; however, further evaluation of fetal well-being is needed. Fetal stimulation should be performed at times when the FHR is at baseline. Neither fetal scalp stimulation nor vibroacoustic stimulation should be instituted if FHR decelerations or bradycardia is present (Miller et al.).

Umbilical Cord Blood Acid-Base Determination

In assessing the immediate condition of the newborn after birth, a sample of cord blood is a useful adjunct to the Apgar score, especially if there has been an abnormal or confusing FHR tracing during labor or neonatal depression at birth.

TABLE 18-4 Approximate Normal Values for Cord Blood

VESSEL	pH	Pco ₂ (mm Hg)	Po ₂ (mm Hg)	BASE DEFICIT (mmol/L)
Artery	7.2-7.3	45-55	15-25	<12
Vein	7.3-7.4	35-45	25-35	<12

From Miller, L., Miller, D., & Tucker, S. (2013). *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* (7th ed.). St. Louis: Mosby.

TABLE 18-5 Types of Acidemia

VALUE	RESPIRATORY	METABOLIC	MIXED
pH	<7.20	<7.20	<7.20
Pco ₂	Elevated	Normal	Elevated
Base deficit	<12 mmol/L	≥12 mmol/L	≥12 mmol/L

From Miller, L., Miller, D., & Tucker, S. (2013). *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* (7th ed.). St. Louis: Mosby.

Generally the procedure is performed by withdrawing blood from both the umbilical artery and the umbilical vein. Both samples are then tested for pH, carbon dioxide pressure (Pco₂), oxygen pressure (Po₂), and base deficit or base excess (Garite, 2012; Miller et al., 2013). Umbilical arterial values reflect fetal condition, whereas umbilical vein values indicate placental function (Miller et al.).

The ACOG (2012) suggests obtaining cord blood values in the following clinical situations: cesarean birth for fetal compromise, low 5-minute Apgar score, severe intrauterine growth restriction, abnormal FHR tracing, maternal thyroid disease, intrapartum fever, and multifetal gestation. Normal umbilical artery and vein cord blood values are listed in Table 18-4. Normal findings preclude the presence of acidemia at or immediately before birth. If acidemia is present (e.g., pH less than 7.20), the type of acidemia is determined (respiratory, metabolic, or mixed) by analyzing the blood gas values (Table 18-5) (Miller et al., 2013).

Fetal Scalp Blood Sampling

Sampling of the fetal scalp blood for pH determination was first described in the 1960s and performed extensively in the 1970s. The procedure is performed by obtaining a sample of fetal scalp blood through the dilated cervix after the membranes have ruptured. Its use is limited by many factors, including the requirement for cervical dilation and membrane rupture, technical difficulty of the procedure, need for repetitive pH determinations, and uncertainty regarding interpretation and application of results. This procedure is now seldom used in the United States but remains a common practice in many other countries (Miller et al., 2013).

Interventions

Amnioinfusion

Amnioinfusion is infusion of room-temperature isotonic fluid (usually normal saline or lactated Ringer's solution) into the uterine cavity if the volume of amniotic fluid is low. Without the buffer of amniotic fluid the umbilical cord

can easily become compressed during contractions or fetal movement, diminishing the flow of blood between the fetus and placenta. The purpose of amnioinfusion is to relieve intermittent umbilical cord compression that results in variable decelerations and transient fetal hypoxemia by restoring the amniotic fluid volume to a normal or near-normal level (Miller et al., 2013). Women with an abnormally small amount of amniotic fluid (oligohydramnios) or no amniotic fluid (anhydramnios) are candidates for this procedure. Conditions that can result in oligohydramnios or anhydramnios include uteroplacental insufficiency, premature rupture of membranes, and anomalies that prevent or reduce fetal urine production.

Risks of amnioinfusion are overdistention of the uterine cavity and increased uterine tone. Fluid is administered through an IUPC either by gravity flow or by an infusion pump. Usually a bolus of fluid is administered over 20 to 30 minutes, and then the infusion is slowed to a maintenance rate. Likely no more than 1000 ml of fluid will need to be administered. The fluid can be warmed for the preterm fetus by infusing it through a blood warmer (Miller et al., 2013).

Intensity and frequency of UCs should be continually assessed during the procedure. The recorded uterine resting tone during amnioinfusion appears higher than normal because of resistance to outflow and turbulence at the end of the catheter. Uterine resting tone should not exceed 40 mm Hg during the procedure. The amount of fluid return must be estimated and documented during amnioinfusion to prevent overdistention of the uterus. The volume of fluid returned should be approximately the same as the amount infused (Miller et al., 2013).

Tocolytic Therapy

Tocolysis (relaxation of the uterus) can be achieved by administering drugs that inhibit UCs. This therapy can be used as an adjunct to other interventions in managing fetal stress when the fetus is exhibiting abnormal patterns associated with increased UA. Tocolysis improves blood flow through the placenta by inhibiting UCs. It may be implemented by the primary health care provider when other interventions to reduce UA such as maternal position change and discontinuance of an oxytocin infusion have not diminished the UCs effectively. Tocolytics can be administered when women are having excessive spontaneous UCs. They are also frequently administered after a decision for cesarean birth has been made while preparations for surgery are under way. The most commonly used tocolytic in these situations is terbutaline (Brethine) given subcutaneously. Terbutaline works quickly and has been demonstrated to improve Apgar scores and cord pH values without apparent complications such as postpartum hemorrhage (Garite, 2012). If the FHR and UC patterns improve, the woman may be allowed to continue labor; if no improvement is seen, immediate cesarean birth may be needed.

CLIENT AND FAMILY TEACHING

Although the use of EFM can be reassuring to many parents, it can be a source of anxiety to some. Therefore, the nurse must be particularly sensitive and respond appropriately to the

FIG 18-20 Nurse explains electronic fetal monitoring as ultrasound transducer monitors the fetal heart rate. (Courtesy Julie Perry Nelson, Loveland, CO.)

BOX 18-9 Client and Family Teaching When Electronic Fetal Monitor Is Used

The following guidelines relate to client teaching and the functioning of the monitor.

- Explain the purpose of monitoring.
- Explain each procedure.
- Provide rationale for maternal position other than supine.
- Explain that fetal status can be continuously assessed by electronic fetal monitoring (EFM), even during contractions.
- Explain that the lower tracing on the monitor strip paper shows uterine activity (UA); the upper tracing shows the fetal heart rate (FHR).
- Reassure woman and partner that prepared childbirth techniques can be implemented without difficulty.
- Explain that during external monitoring effleurage can be performed on sides of abdomen or upper portion of thighs.
- Explain that breathing patterns based on the time and intensity of contractions can be enhanced by the observation of uterine activity on the monitor strip, which shows the onset of contractions.
- Note peak of contraction; knowing that the contraction will not get stronger and is halfway over is usually helpful.
- Note diminishing intensity.
- Coordinate with appropriate breathing and relaxation techniques.
- Reassure woman and partner that the use of internal monitoring does not restrict movement, although she is confined to bed.*
- Explain that use of external monitoring usually requires the woman's cooperation during positioning and movement.
- Reassure woman and partner that use of monitoring does not imply fetal jeopardy.

*Portable telemetry monitors allow the FHR and uterine contraction patterns to be observed on centrally located display stations. These portable units permit ambulation during electronic monitoring.

emotional, informational, and comfort needs of the woman in labor and those of her family (Fig. 18-20 and Box 18-9).

Part of the nurse's role includes acting as a partner with the woman to achieve a high-quality birthing experience. In addition to teaching and supporting the woman and her family with understanding of the labor and birth process, breathing techniques, use of equipment, and pain management techniques,

the nurse can assist with two factors that have an effect on fetal status: positioning and pushing. The nurse should ask for the woman's cooperation in avoiding the supine position. Instead, the woman should be encouraged to maintain a side-lying position or semi-Fowler position with a lateral tilt to the uterus. In addition, the nurse should instruct the woman to keep her mouth and glottis open and to let air escape from her lungs during the pushing process. Both of these interventions help to improve fetal oxygenation. See Chapter 19 for further discussion of maternal positioning and pushing techniques.

DOCUMENTATION

Clear and complete documentation in the woman's medical record is essential. Each FHR and UA assessment must be completely documented in the woman's medical record. More and more hospitals are moving to use of the electronic medical record and computerized charting. With computerized charting, each required component usually appears on the screen so it will be addressed routinely. Computerized charting often includes forced choices that greatly increase the use of standardized FHR terminology by all members of the health care team. In the past, nurses were often encouraged to chart both on the monitor strip and in the medical record. However, charting directly on the monitor strip is unnecessary when an electronic medical record is used (Fig. 18-21). Any information that is handwritten on the monitor strip will not be recorded in the computer record. Furthermore, given that the EFM tracing is stored on a computer, the paper strips are destroyed after the woman is discharged. No permanent record of the handwritten charting exists.

In institutions that still use a paper chart, documentation on the woman's monitor strip is started before initiating monitoring and consists of identifying information plus other relevant data. This documentation is continued and updated according to institutional protocol as monitoring continues and labor progresses.

In some institutions observations noted and interventions implemented are recorded on the monitor strip to produce a comprehensive document that chronicles the course of labor and the care rendered. In other institutions this documentation is confined to the labor flow record. Advocates of documenting on both the medical record and the EFM strip cite as advantages of this approach the ease of writing directly on the strip while at the bedside and the improved accuracy in documenting critical events and the interventions implemented. Others believe that charting on the EFM strip constitutes duplicate documentation of the information noted in the medical record, and thus it is unnecessary additional paperwork for the nurse.

A disadvantage of documenting on both the EFM strip and the medical record is that the times noted for events and interventions on the EFM strip frequently do not correlate with what is later documented in the medical record. These inaccuracies can lead people involved in the retrospective review process carried out during litigation to infer that documentation errors have occurred. Therefore, if institutional policy mandates documentation both on the monitor strip and in the medical record, the nurse must make sure the times and notations of events and interventions recorded in each place agree.

Fetal Monitor Integration

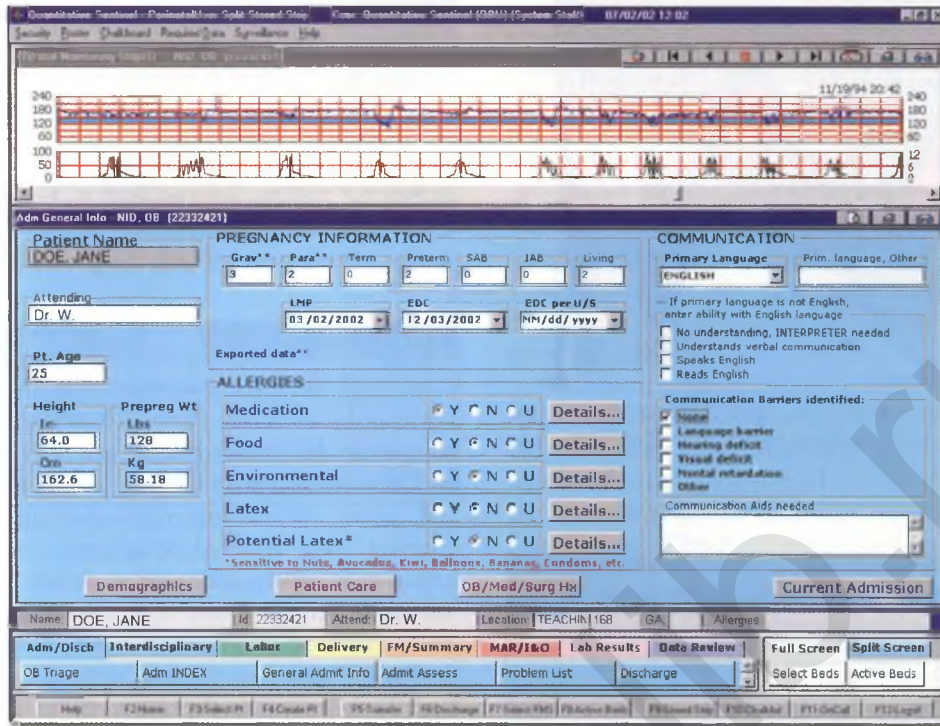

FIG 18-21 With integration of the fetal monitor tracing into the electronic medical record, the nurse can view the fetal tracing while charting. (Courtesy General Electric Healthcare Technologies, Barrington, IL.)

KEY POINTS

- Fetal well-being during labor is gauged by the response of the FHR to UCs.
- Standardized definitions for many common FHR patterns have been adopted for use in clinical practice by the ACNM, ACOG, and AWHONN.
- The five essential components of the FHR tracing are baseline rate, baseline variability, accelerations, decelerations, and changes or trends over time.
- The monitoring of fetal well-being includes FHR and UA assessment and assessment of maternal vital signs.
- The FHR can be monitored by either IA or EFM. The FHR and UA can be assessed by EFM using either the external or internal monitoring mode.
- Assessing FHR and UA patterns, implementing independent nursing interventions, and reporting abnormal patterns to the physician or nurse-midwife are the nurse's responsibilities.
- The AWHONN and ACOG have established and published health care provider standards and guidelines for FHR monitoring.
- The emotional, informational, and comfort needs of the woman and her family must be addressed when the mother and her fetus are being monitored.
- Documentation of fetal assessment is initiated and updated according to institutional protocol.

Nursing Care of the Family During Labor and Birth

Deborah S. Walker

© <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Review the data included in the initial assessment of the woman in labor.
- Describe the ongoing assessment of maternal progress during the first, second, third, and fourth stages of labor.
- Recognize the physical and psychosocial findings indicative of maternal progress during labor.
- Describe fetal assessment during labor.
- Identify signs of developing complications during labor and birth.
- Incorporate evidence-based nursing interventions into a comprehensive plan of care relevant to each stage of labor.
- Recognize the importance of support (family, partner, doula, nurse) in fostering maternal confidence and facilitating the progress of labor and birth.
- Analyze the influence of cultural and religious beliefs and practices on the process of labor and birth.
- Describe the role and responsibilities of the nurse during emergency childbirth.
- Evaluate the effect of perineal trauma on the woman's reproductive and sexual health.

The labor and childbirth processes are natural phenomena during which most women benefit from a philosophy of minimal intervention. The minimal intervention philosophy acknowledges that most pregnancies, labors, and births are normal and that intervention creates the potential for iatrogenic maternal-fetal injuries (Simpson & O'Brien-Abel, 2014). This is an exciting and potentially anxious time for the woman and her significant others (support persons, family members). In a relatively short period of time, they experience one of the most profound changes in their lives. Birth may take place in the hospital, birth center, or home setting or unexpectedly at any number of locations. The woman and her significant others may be cared for by a team of caregivers including nurses, doulas, nurse-midwives, and physicians. During labor and birth, nurses provide comprehensive care for women and families by using evidence-based knowledge of physiologic and psychosocial processes and selected pharmacologic and nonpharmacologic measures.

For most women labor begins with regular uterine contractions, continues with hours of hard work during cervical dilation and birth, and ends as the woman begins to recover physically from birth and she and her significant others begin the attachment process with the newborn. Nursing care management focuses on assessment and support of the woman and her significant others throughout labor and birth, with the goal of ensuring the best possible outcome for all involved. The focus of this chapter is on nursing care that facilitates normal birth processes.

COMMUNITY ACTIVITY

- Compare and contrast childbirth education classes offered by a hospital with those offered by a community group.
- Visit the website of a hospital that offers childbirth education classes in your community. Review the client information about the childbirth classes. If you are not able to find this information on their website, contact one of the instructors. What is the philosophy of the class? Is a specific type of childbirth method taught? Are the classes offered by nurses, nurse-midwives, physicians, or someone else? How long are the classes; one class versus a series of classes? What information is covered in the class(es)? Are significant others welcome to attend? Is breastfeeding information given? Is skin-to-skin contact immediately following birth discussed? How much of the information relates to hospital policies and practices rather than to childbirth coping strategies and newborn care? Are women encouraged to develop a birth plan?
- Visit the website of a community group offering childbirth education classes in your city or state that teaches a specific method such as Lamaze or Bradley. If you cannot find the information on the website, contact one of the instructors. What is the philosophy of the method? What are the credentials and education of the instructor? Are the classes offered as a series or one time only? Are significant others and children welcome? Where do women/families attending these classes plan to give birth? Are women encouraged to develop a birth plan?

FIRST STAGE OF LABOR

The **first stage of labor** begins with the onset of regular uterine contractions and ends with full cervical effacement and dilation. The first stage of labor consists of three phases: the **latent (early) phase** (through 3 cm of dilation), the **active phase** (4 to 7 cm of dilation), and the **transition phase** (8 to 10 cm of dilation).

CARE MANAGEMENT

Most nulliparous women planning a hospital or birth center birth seek admission in the latent (early) phase because they have not experienced labor before and are unsure of the “right” time to come in. Multiparous women usually do not come to the birth center or hospital until they are in the active phase of the first stage of labor. Even though no two labors are identical, women who have given birth before often are less anxious about the process, unless their previous experience was negative.

Assessment

Assessment begins at the first contact with the woman, whether by telephone or in person. Many women call the hospital or birthing center first for validation that it is all right for them to come in for evaluation or admission or that they can remain at home. Many hospitals, however, discourage the nurse from giving advice regarding what to do because of legal liability. Nurses are often instructed to tell women who call with questions to call their nurse-midwife or physician or to come to the hospital if they feel the need to be checked. The nature of the telephone conversation, including any advice or instructions given, should be documented in the woman’s record (Gilbert, 2011).

A pregnant woman may first call her nurse-midwife or physician or go to the hospital or birth center while in false labor or early in the latent phase of the first stage of labor. She may feel discouraged, angry, or confused on learning that the contractions that feel so strong and regular to her are not true contractions because they are not causing cervical dilation or that they are still not strong or frequent enough for admission. During the third trimester of pregnancy, women should be instructed about the stages of labor and the signs indicating its onset. They should be informed that they will usually not be admitted if the cervix is dilated 3 cm or less (see Teaching for Self-Management).

If the woman lives near the hospital or birth center and has adequate support and transportation, she may be encouraged to stay at home or return home to allow labor to progress (e.g., until the uterine contractions are more frequent and intense). The ideal setting at this time for the woman at low risk for obstetric complications is usually the familiar environment of her home, where she can move around freely and eat and drink at will. The woman who lives at a considerable distance from the hospital or birth center, who lacks adequate support and transportation, or who has a history of rapid labors in the past, however, may be admitted in latent labor. The same measures used by the woman at home should be offered to the woman admitted in early labor.

A warm shower is often relaxing during early labor. However, warm baths before labor is well established could inhibit uterine contractions and prolong the labor process (Waterbirth

TEACHING FOR SELF-MANAGEMENT

How to Distinguish True Labor from False Labor

True Labor

Contractions

- Occur regularly, becoming stronger, lasting longer, and occurring closer together
- Become more intense with walking
- Are usually felt in the lower back, radiating to the lower portion of the abdomen
- Continue despite use of comfort measures

Cervix (by Vaginal Examination)

- Shows progressive change (softening, effacement, and dilation signaled by the appearance of bloody show)
- Moves to an increasingly anterior position

Fetus

- Presenting part usually becomes engaged in the pelvis, which results in increased ease of breathing; at the same time, the presenting part presses downward and compresses the bladder, resulting in urinary frequency

False Labor

Contractions

- Occur irregularly or become regular only temporarily
- Often stop with walking or position change
- Can be felt in the back or the abdomen above the umbilicus
- Can often be stopped through the use of comfort measures

Cervix (by Vaginal Examination)

- May be soft but with no significant change in effacement or dilation or evidence of bloody show
- Is often in a posterior position

Fetus

- Presenting part is usually not engaged in the pelvis

International, 2013). Soothing back, foot, and hand massage or a warm drink of preferred liquids such as tea or milk can help the woman rest and even sleep, especially if false or early labor is occurring at night. Diversional activities such as walking outdoors or in the house, reading, watching television, “playing” on a computer or smart phone, or talking with friends can reduce the perception of early discomfort, help the time pass, and decrease anxiety.

When the woman arrives at the birth center or hospital perinatal unit, assessment is the top priority (Fig. 19-1). The nurse first performs a screening assessment by using the techniques of interview and physical assessment and reviews the laboratory and diagnostic test findings to determine the health status of the woman and her fetus and the progress of her labor. The nurse also notifies the nurse midwife or physician. If the woman is admitted, a detailed systems assessment is done.

When the woman is admitted to a hospital, she is usually moved from an observation area to the labor room; the labor, delivery, and recovery (LDR) room; or the labor, delivery, recovery, and postpartum (LDRP) room. If the woman wishes, include her partner in the assessment and admission process. The nurse can direct significant other(s) not participating in this process to the appropriate waiting area. In the hospital setting the woman undresses and puts on her own gown

FIG 19-1 Woman being assessed for admission to the labor and birth unit. (Courtesy Julie Perry Nelson, Loveland, CO.)

LEGAL TIP: Obstetric Triage and EMTALA

The Emergency Medical Treatment and Active Labor Act (EMTALA) is a federal regulation enacted to protect pregnant women during an emergency regardless of their insurance status or ability to pay for care. According to the EMTALA, pregnant women who present with contractions or who may be in labor are considered unstable and must be assessed, stabilized, and treated at the hospital where they present regardless of their insurance status or ability to pay (Wilson-Griffin, 2014). Nurses working in labor and birth units must be familiar with their responsibilities according to the EMTALA regulations, which include providing services to pregnant women when they experience an urgent pregnancy problem (e.g., labor, decreased fetal movement, rupture of membranes, or recent trauma) and fully documenting all relevant information (e.g., assessment findings, interventions implemented, and client responses to care measures provided). A pregnant woman presenting in an obstetric triage area is considered to be in “true” labor until a qualified health care provider certifies that she is not. Agencies need to have specific policies and procedures in place so that compliance with the EMTALA regulations is achieved while safe and efficient care is provided (Miller, Miller, & Tucker, 2013).

or a hospital gown. The nurse places an identification band on the woman’s wrist. Her personal belongings are put away safely or given to family members, according to agency policy. Women who participate in expectant parents classes often bring a birth bag or Lamaze bag with them. The nurse then shows the woman and her partner the layout and operation of the unit and room, how to use the call light and telephone system, and how to adjust lighting in the room and the different bed positions.

The nurse assures the woman that she is in competent, caring hands and that she and those to whom she gives permission can ask questions related to her care and status and that of her fetus at any time during labor. The nurse can minimize the woman’s anxiety by explaining terms commonly used during labor. The woman’s interest, response, and prior experience guide the depth and breadth of these explanations.

Most hospitals have specific forms, whether paper or electronic, that are used to obtain important assessment information when a woman in labor is being evaluated or admitted

(Fig. 19-2, A and B). More and more hospitals now use an electronic health record (EHR); almost all documentation is done on a computer. Sources of data include the prenatal record, the initial interview, physical examination to determine baseline physiologic parameters (e.g., vital signs), laboratory and diagnostic test results, select psychosocial and cultural factors, and the clinical evaluation of labor status.

Prenatal Data

The nurse reviews the prenatal record to identify the woman’s individual needs and risks. Copies of prenatal records are generally filed in the hospital’s perinatal unit at some time during the woman’s pregnancy (usually in the third trimester) or accessed by computer so that they are readily available on admission. If the woman has had no prenatal care or her prenatal records are unavailable, the nurse must obtain certain baseline information. If the woman is having discomfort, the nurse should ask questions between contractions when the woman can concentrate more fully on her answers. At times, the partner or support person(s) may need to be secondary sources of essential information. According to the Health Insurance Portability and Accountability Act (HIPAA), the woman must give permission for other individuals to be involved in the exchange of information regarding her care. Ideally, this permission should be obtained during pregnancy and a signed form included in her health records.

Knowing the woman’s age is important so that the nurse can individualize care to the needs of her age group. For example, a 14-year-old girl and a 40-year-old woman have different but specific needs, and their ages place them at risk for different problems. Accurate height and weight measurements are important. A pregnancy weight gain greater than recommended may place the woman at a higher risk for cephalopelvic disproportion and cesarean birth. This is especially true for women who are petite and have gained 16 kg (35 lb) or more. A prepregnancy body mass index (BMI) greater than 30 is also a cause for concern. Other factors to consider are the woman’s general health status, current medical conditions or allergies, respiratory status, and previous surgical procedures.

The nurse should carefully review the woman’s prenatal records, taking note of her obstetric and pregnancy history including gravidity; parity; and problems such as history of vaginal bleeding, gestational hypertension, anemia, pregestational or gestational diabetes, infections (e.g., bacterial, viral, sexually transmitted), and immunodeficiency status. In addition, the expected date of birth (EDB) should be confirmed. Other important data found in the prenatal record include patterns of maternal weight gain, physiologic measurements such as maternal vital signs (blood pressure, temperature, pulse, respirations), fundal height, baseline fetal heart rate (FHR), and laboratory and diagnostic test results. See Table 14-1 for a list of common prenatal laboratory tests. Common diagnostic and fetal assessment tests performed prenatally include amniocentesis, nonstress test (NST), biophysical profile (BPP), and ultrasound examination. See Chapter 26 for more information.

If this labor and birth experience is not the woman’s first, the nurse needs to note the characteristics of her previous

experiences. This information includes the duration of previous labors, the types of pain relief measures, including anesthesia used, the type of birth (e.g., spontaneous vaginal, forceps-assisted, vacuum-assisted, or cesarean birth), and the condition of the newborn. Explore the woman's perception of her previous labor and birth experiences because this perception may influence her attitude toward her current experience.

Interview

The woman's primary reason for coming to the hospital is determined in the interview. Her primary reason may be, for example, that her bag of waters (BOW, amniotic membranes) ruptured, with or without contractions. The woman may also have come in for a period of observation reserved for women who are unsure about the onset of their labor. This allows time for the diagnosis of labor without official hospital admission

BOX 19-1 Procedure: Tests for Rupture of Membranes

Nitrazine Test for pH

- Explain procedure to the woman or couple.

Procedure

- Wash hands and put on sterile gloves.
- Use a cotton-tipped applicator impregnated with Nitrazine dye for determining pH (differentiates amniotic fluid, which is slightly alkaline, from urine and purulent material [pus], which are acidic).
- Dip the cotton-tipped applicator deep into the vagina to pick up fluid (procedure may be performed during speculum examination).

Read Results

- Membranes probably intact: identifies vaginal and most body fluids that are acidic:

Yellow	pH 5
Olive-yellow	pH 5.5
Olive-green	pH 6

- Membranes probably ruptured: identifies amniotic fluid that is alkaline:

Blue-green	pH 6.5
Blue-gray	pH 7
Deep blue	pH 7.5

- Realize that false test results are possible because of presence of bloody show, insufficient amniotic fluid, or semen.

- Provide pericare as needed.
- Remove gloves and wash hands.

Document Results

- Results are reported as positive or negative.

Test for Ferning or Fern Pattern

- Explain procedure to woman or couple.

Procedure

- Wash hands, put on sterile gloves, obtain specimen of fluid (usually during sterile speculum examination).
- Spread a drop of fluid from vagina on clean glass slide with sterile cotton-tipped applicator.
- Allow fluid to dry.
- Examine the slide under microscope; observe for appearance of ferning (a frondlike crystalline pattern) (do not confuse with cervical mucus test, when high levels of estrogen cause ferning).
- Observe for absence of ferning (alerts staff to possibility that amount of specimen was inadequate or that specimen was urine, vaginal discharge, or blood).
- Provide pericare as needed.
- Remove gloves and wash hands.

Document Results

- Results are reported as positive or negative.

and minimizes or avoids cost to the woman when used by the hospital and approved by her health insurance plan.

Even the experienced woman may have difficulty determining the onset of labor. She is asked to recall the events of the previous days and to describe the following:

- Time and onset of contractions and progress in terms of frequency, duration, and intensity
- Location and character of discomfort from contractions (e.g., back pain, abdominal or suprapubic discomfort)
- Persistence of contractions despite changes in maternal position and activity (e.g., walking or lying down)
- Presence and character of vaginal discharge or “show”
- The status of amniotic membranes, such as a gush or seepage of fluid (**spontaneous rupture of membranes [SRM]**). If there has been a discharge that may be amniotic fluid, she is asked the date and time the fluid was first noted and the fluid’s characteristics (e.g., amount, color, unusual odor). In many instances, a sterile speculum examination and **Nitrazine** (pH) and **fern tests** can confirm that the membranes are ruptured (Box 19-1).

These descriptions help the nurse assess the degree of progress in the process of labor. **Bloody show** is distinguished from bleeding by the fact that it is pink and feels sticky because of its mucoid nature. There is very little bloody show in the beginning, but the amount increases with effacement and dilation of the cervix. A woman may report a small amount of brownish to bloody discharge that may be attributed to cervical trauma resulting from vaginal examination or coitus (intercourse) within the past 48 hours.

Assessing the woman’s respiratory status is important in case general anesthesia is needed in an emergency. The nurse

determines this status by asking the woman if she has a “cold” or related symptoms (e.g., stuffy nose, sore throat, or cough).

The status of allergies, including allergies to latex and tape, and medications routinely used in obstetrics, such as opioids (e.g., hydromorphone [Dilaudid], butorphanol [Stadol], fentanyl [Sublimaze], nalbuphine [Nubain]), anesthetic agents (e.g., bupivacaine, lidocaine, ropivacaine), and antiseptics (Betadine) is reviewed. Some allergic responses cause swelling of the mucous membranes of the respiratory tract, which could interfere with breathing and the administration of inhalation anesthesia. Because vomiting and subsequent aspiration into the respiratory tract can complicate an otherwise normal labor, the nurse records the time and type of the woman’s most recent solid and liquid intake.

The nurse obtains any information not found in the prenatal record during the admission assessment. Pertinent data include the birth plan (Box 19-2), the choice of infant feeding method, the type of pain management (including nonpharmacologic comfort measures) preferred, and the name of the pediatric health care provider. She or he obtains a client profile that identifies the woman’s preparation for childbirth, the support person or family members desired during childbirth and their availability, and ethnic or cultural expectations and needs. The nurse also determines the woman’s use of alcohol, drugs, and tobacco during pregnancy.

The nurse reviews the birth plan. If no written plan has been prepared, the nurse helps the woman formulate a birth plan by describing options available and determining the woman’s wishes and preferences. As caregiver and advocate, the nurse integrates the woman’s desires into the nursing care plan while explaining what may or may not be possible given the hospital’s

BOX 19-2 The Birth Plan

The birth plan should include the woman's or couple's preferences related to:

- Presence of birth companions such as the partner, older children, parents, friends, and doula, and the role each will play
- Presence of other persons such as students, male attendants, and interpreters
- Clothing to be worn
- Environmental modifications such as lighting, music, privacy, focal point, items from home such as pillows
- Labor activities such as preferred positions for labor and for birth, ambulation, birth balls, showers and whirlpool baths, oral food and fluid intake
- List of comfort and relaxation measures
- Labor and birth medical interventions such as pharmacologic pain relief measures, intravenous therapy, electronic monitoring, induction or augmentation measures, and episiotomy
- Care and handling of the newborn immediately after birth such as immediate skin-to-skin contact, cutting of the cord, eye care, breastfeeding
- Cultural and religious requirements related to the care of the mother, newborn, and placenta

The childbirth website—www.childbirth.org—provides couples with an interactive birth plan along with examples of birth plans and descriptions of the options that can be included.

policies. She or he also prepares the woman for the possibility that her plan may change as labor progresses and assures her that the staff will provide information so that she can make informed decisions. The woman must also understand that the longer her “wish list”, the less is the likelihood that all of her expectations will be met.

The nurse should discuss with the woman and her partner their plans for preserving childbirth memories through the use of photography and videotaping. Information should be provided about the agency's policies regarding these practices and under what circumstances they are allowed. Protection of privacy and safety and infection control are major concerns for the expectant parents and the agency. To avoid future embarrassment and distress, the nurse should clarify with the woman exactly what parts of her childbirth she wishes to have photographed and the degree of detail. Remind women and their families that pictures should not be posted on social media sites without the knowledge and consent of every person who appears in the picture.

LEGAL TIP: Recording of Childbirth

The woman's record should reflect that the childbirth was recorded. Some hospitals and health care providers do not allow videotaping of the birth because of concerns related to legal liability.

Psychosocial Factors

The woman's general appearance and behavior (and that of her partner) provide valuable clues to the type of supportive care she will need. However, keep in mind that general appearance and behavior may vary, depending on the stage and phase of labor (Table 19-1 and Box 19-3).

Women with a History of Sexual Abuse. Labor can trigger memories of sexual abuse, especially during intrusive procedures such as vaginal examinations. Monitors, intravenous (IV) lines, and epidurals can make the woman feel a loss of control or feel as if she is being confined to bed and “restrained.” Being observed by students and having intense sensations in the uterus and genital area, especially at the time when she must push the baby out, can also trigger negative memories.

The nurse can help the abuse survivor associate the sensations she is experiencing with the process of childbirth and not with her past abuse. Help maintain her sense of control by explaining all procedures and why they are needed, validating her needs, and paying close attention to her requests. Wait for the woman to give permission before touching her, and accept her often extreme reactions to labor (Simpson & O'Brien-Abel, 2014). Avoid words and phrases that can cause the woman to recall the words of her abuser (e.g., “open your legs,” “relax and it won't hurt so much”). Limit the number of procedures that invade her body (e.g., vaginal examinations, urinary catheter, internal monitor, forceps or vacuum extractor) as much as possible. Encourage her to choose a person (e.g., doula, friend, family member) to be with her during labor to provide continuous support and comfort and to act as her advocate. Nurses are advised to care for all laboring women in this manner because it is not unusual for a woman to choose not to reveal a history of sexual abuse. Careful attention to these care measures can help a woman perceive her childbirth experience in positive terms.

Stress in Labor

The way in which women and their support persons or family members approach labor is related to how they have been socialized to the childbearing process as well as how they deal with other stressors in their lives. Their reactions reflect their life experiences regarding childbirth—physical, social, cultural, and religious. Society communicates its expectations regarding acceptable and unacceptable maternal behaviors during labor and birth. These expectations may be used by some women as the basis for evaluating their own actions during childbirth. An idealized perception of labor and birth may be a source of guilt and cause a sense of failure if the woman finds the process less than joyous, especially when the pregnancy is unplanned or is the product of a dysfunctional or terminated relationship. Often women have heard horror stories or have seen friends or relatives going through labors that appear anything but easy. Multiparous women often base their expectations of the present labor on their previous childbirth experiences.

Discuss the feelings a woman has about her pregnancy and fears regarding childbirth. This discussion is especially important if the woman is a primigravida who has not attended childbirth classes but has obtained information on childbirth from reality birth television shows or is a multiparous woman who has had a previous negative childbirth experience. Women in labor usually have a variety of concerns that they will voice if asked but may not volunteer. Major fears and concerns relate to the process and effects of childbirth, maternal and fetal well-being, and the attitude and actions of the health care staff. Every effort should be made to provide support and to encourage those with her to be supportive. Women who have continuous labor support are more likely to have a spontaneous vaginal birth and are less

TABLE 19-1 Expected Maternal Progress During First Stage of Labor

PHASES MARKED BY CERVICAL DILATION*

CRITERION	0-3 cm (LATENT)	4-7 cm (ACTIVE)	8-10 cm (TRANSITION)
Duration†	About 6-8 hours	About 3-6 hours	About 20-40 minutes
Contractions			
Strength	Mild to moderate	Moderate to strong	Strong to very strong
Rhythm	Irregular	More regular	Regular
Frequency	5-30 minutes apart	3-5 minutes apart	2-3 minutes apart
Duration	30-45 seconds	40-70 seconds	45-90 seconds
Descent			
Station of presenting part	Nulliparous: 0 Multiparous: -2 cm to 0	Varies: +1 to +2 cm Varies: +1 to +2 cm	Varies: +2 to +3 cm Varies: +2 to +3 cm
Show			
Color	Brownish discharge, mucus plug, or pale pink mucus	Pink to bloody mucus	Bloody mucus
Amount	Scant	Scant to moderate	Copious
Behavior and appearance‡	Excited; thoughts center on self, labor, and baby; may be talkative or silent, calm or tense; some apprehension; pain controlled fairly well; alert, follows directions readily; open to instructions	Becomes more serious, doubtful of pain control, more apprehensive; desires companionship and encouragement; attention more inwardly directed; fatigue evidenced; malar (cheeks) flush; has some difficulty following directions	Pain described as severe; backache common; frustration, fear of loss of control, and irritability may be voiced; expresses doubt about ability to continue; vague in communications; amnesia between contractions; writhing with contractions; nausea and vomiting, especially if hyperventilating; hyperesthesia; circumoral pallor, perspiration of forehead and upper lip; shaking tremor of thighs; feeling of need to defecate, pressure on anus

*In the nullipara, effacement is often complete before dilation begins; in the multipara it occurs simultaneously with dilation.

†Duration of each phase is influenced by such factors as parity, maternal emotions, position, level of activity, and fetal size, presentation, and position. For example, the labor of a nullipara tends to last longer, on average, than the labor of a multipara. Women who ambulate and assume upright positions or change positions frequently during labor tend to experience a shorter first stage. Descent is often prolonged in breech presentations and occiput posterior positions.

‡Women who have epidural analgesia for pain relief may not demonstrate some of these behaviors.

BOX 19-3 Psychosocial Assessment of the Laboring Woman

Verbal Interactions

- Does the woman ask questions?
- Can she ask for what she needs?
- Does she talk to her support person(s)?
- Does she talk freely with the nurse or respond only to questions?

Body Language

- Does she change positions or lie rigidly still?
- What is her anxiety level?
- How does she react to being touched by the nurse or support person?
- Does she avoid eye contact?
- Does she look tired? If she appears tired, ask her how much rest she has had in the past 24 hours.

Perceptual Ability

- Is there a language barrier?
- Are repeated explanations necessary because her anxiety level interferes with her ability to comprehend?
- Can she repeat what she has been told or otherwise demonstrate her understanding?

Discomfort Level

- To what degree does the woman describe what she is experiencing including her pain experience?
- How does she react to a contraction?
- How does she react to assessment and care measures?
- Are any nonverbal pain messages noted?
- Can she ask for comfort measures?

likely to have intrapartum analgesia or anesthesia, a cesarean or an operative vaginal birth, and a baby with a low 5-minute Apgar score; or to report dissatisfaction with their childbirth experiences (Hodnett, Gates, Hofmeyr, & Sakala, 2013).

The father, coach, or significant other also experiences stress during labor. The nurse can assist and support these individuals by identifying their needs and expectations, helping to make sure these are met, and interpreting events that are occurring. The nurse can determine what role the support person intends to fulfill and whether he or she is prepared for that role by making observations and asking herself or himself such questions as, "Has the couple attended childbirth classes?" "What role does this person expect to play?" "Does he or she do all the talking?" "Is he or she nervous, anxious, aggressive, or hostile?" "Does he or she look hungry, tired, worried, or confused?" "Does he or she watch television, sleep, or stay out of the room instead of paying attention to the woman?" "Where does he or she sit?" "Does he or she touch the woman; what is the character of the touch?" Be sensitive to the needs of support persons and provide teaching and support as appropriate. In many instances the support these people provide to the laboring woman may be in direct proportion to the support they receive from the nurses and other health care providers.

Cultural Factors

Nearly 1 million immigrants come to the United States each year, half of whom are women of childbearing age. More than 30% of the U.S. population belongs to a cultural group other than non-Hispanic white. It is expected that by the year

FIG 19-3 Birthing room specific to a Native-American population. Note the arrow pointing east, the rug on the wall, and the rope or sash belt hanging from the ceiling. (Courtesy Patricia Hess, San Francisco, CA; Chinle Comprehensive Health Care Center, Chinle, AZ.)

2050 members of cultural groups other than non-Hispanic white will make up more than half of the U.S. population (Callister, 2014). As the population becomes more diverse, it is increasingly important to note the woman's ethnic or cultural and religious values, beliefs, and practices in order to anticipate nursing interventions to add or eliminate from an individualized, mutually acceptable plan of care that provides a feeling of safety and control (Fig. 19-3). Nurses should be committed to providing culturally sensitive care and to developing an appreciation and respect for cultural diversity (Callister). Encourage the woman to request specific caregiving behaviors and practices that are important to her. In some cases if a special request contradicts usual practices in that setting, the woman or the nurse can ask the woman's nurse-midwife or physician to write an order to accommodate the special request. For example, in many cultures, it is unacceptable to have a male caregiver examine a pregnant woman. In some cultures it is traditional to take the placenta home; in others, the woman has only certain nourishments during labor. Some women believe that cutting the body, as with an episiotomy, allows her spirit to leave her body and that rupturing the membranes prolongs, not shortens, labor. It is always important to listen respectfully and carefully explain the rationale for recommended care measures (see the Cultural Considerations box).

CULTURAL CONSIDERATIONS BOX

Birth Practices in Different Cultures

Somalia: Because Somalis in general do not like to show any sign of weakness, women are extremely stoic during childbirth

Japan: Natural childbirth methods practiced; may labor silently; may eat during labor; father may be present

China: Stoic response to pain; father not usually present; side-lying position preferred for labor and birth because this position is thought to reduce infant trauma

India: Natural childbirth methods preferred; father not usually present; female relatives usually present

Iran: Father not present; female support and female caregivers preferred

Mexico: May be stoic about discomfort until second stage, and then may request pain relief; father and female relatives may be present

Laos: May use squatting position for birth; father may or may not be present; female attendants preferred

Data from D'Avanzo, C. (2008). *Mosby's pocket guide to cultural health assessment* (4th ed.). St. Louis: Mosby.

Within cultures, women may have an idea of the “right” way to behave in labor and may react to the pain experienced in that way. These behaviors can range from total silence to moaning or screaming, but they do not necessarily indicate the degree of pain being experienced. A woman who moans with contractions may not be in as much physical pain as a woman who is silent but winces during contractions. Some women believe that screaming or crying out in pain is shameful if a man is present. If the woman's support person is her mother, she may perceive the need to “behave” more strongly than if her support person is the father of the baby. She will perceive herself as failing or succeeding based on her ability to follow these “standards” of behavior. Conversely, a woman's behavior in response to pain may influence the support received from significant others. In some cultures, women who lose control and cry out in pain may be scolded, whereas in other cultures, support persons will become more helpful.

Culture and Father Participation. A companion is an important source of support, encouragement, and comfort for women during childbirth. The woman's cultural and religious background influences her choice of birth companion as do trends in the society in which she lives. For example, in Western societies the father is often viewed as the ideal birth companion. For many years European-American couples traditionally attended childbirth classes together as an expected activity, although this is not as common today. Laotian (Hmong) husbands also traditionally participate actively in the labor process. In some other cultures the father may be available, but his presence in the labor room with the mother may not be considered appropriate, or he may be present but resist active involvement in her care. Such behavior could be perceived by the nursing staff to indicate a lack of concern, caring, or interest. Women from many cultures prefer female caregivers and want to have at least one female companion present during labor and birth. They are also usually very concerned about modesty. If couples from these cultures immigrate to the United States or Canada, their roles may change. The nurse needs to talk to the woman and her support persons to determine the roles they will assume.

The Non-English-Speaking Woman in Labor. A woman's level of anxiety in labor increases when she does not understand what is happening to her or what is being said. Non-English-speaking women often feel a complete loss of control over their situation if no health care provider is present who speaks their language. They can panic and withdraw or become physically abusive when someone tries to do something they perceive might harm them or their babies. A support person is sometimes able to serve as an interpreter. However, caution is warranted because the interpreter may not be able to convey exactly what the nurse or others are saying or what the woman is saying, which can increase the woman's stress level even more.

Ideally, a bilingual or bicultural nurse will care for the woman. Alternatively a hospital employee or volunteer interpreter may be contacted for assistance (see Box 2-2). Ideally, the interpreter is from the woman's culture. For some women, a female is more acceptable than a male interpreter. If no one in the hospital is able to interpret, call a service so that interpretation can take place over the telephone. Even when the nurse has limited ability to communicate verbally with the woman, in most instances the woman appreciates his or her efforts to do so. Speaking slowly, avoiding complex words and medical terms, and using gestures can help a woman and her partner understand. Often the woman understands English much better than she speaks it.

Physical Examination

The initial physical examination includes a general systems assessment and an assessment of fetal status. During the examination uterine contractions are assessed and a vaginal examination is performed. The findings of the admission physical examination serve as a baseline for assessing the woman's progress from that point. The information obtained from a complete and accurate assessment during the initial examination serves as the basis for determining whether the woman should be admitted and what her ongoing care should be. Expected

maternal progress and minimal assessment guidelines during the first stage of labor are presented in Tables 19-1 and 19-2.

Birth is a time when nurses and other health care providers may be exposed to a great deal of maternal and newborn blood and body fluids. Therefore, Standard Precautions should guide all assessment and care measures (Box 19-4). Hand hygiene (e.g., washing hands with soap or application of an alcohol-based antiseptic rub) before and after assessing the

BOX 19-4 Standard Precautions During Childbirth

- Wash hands before and after putting on gloves and performing procedures; cleansing alcohol rubs can be used if hands are not visibly soiled.
- Wear gloves (clean or sterile, as appropriate) when performing procedures that require contact with the woman's genitalia and body fluids, including bloody show (e.g., during vaginal examination, amniotomy, hygienic care of the perineum, insertion of an internal scalp electrode and intrauterine pressure monitor, and urinary catheterization).
- Wear a mask that has a shield or protective eyewear, and cover gown when assisting with the birth. Cap and shoe covers are worn for cesarean birth but are optional for vaginal birth in a birthing room. Gowns worn by the nurse-midwife or physician who is attending the birth should have a waterproof front and sleeves and should be sterile. Mask also should be worn during spinal puncture or insertion of an epidural catheter.
- Drape the woman with sterile towels and sheets as appropriate. Explain to the woman what can and cannot be touched.
- Help the woman's partner put on appropriate coverings for the type of birth, such as cap, mask, gown, and shoe covers. Show the partner where to stand and what can and cannot be touched.
- Wear gloves and gown when handling the newborn immediately after birth.
- Use an appropriate method to suction the newborn's airway, such as a bulb syringe or mechanical wall suction.

TABLE 19-2 Nursing Assessments in First-Stage Labor

LABOR PHASE	TIME FRAME	SPECIFIC ASSESSMENTS
Latent	Every 30-60 minutes	Maternal blood pressure, pulse, and respirations Fetal heart rate (FHR) and pattern Uterine activity Presence of vaginal show
	Every 30 minutes	Changes in maternal appearance, mood, affect, energy level, and condition of partner or coach
	Every 2-4 hours	Temperature (every 4 hours until membranes rupture, then every 2 hours)
	As needed	Vaginal examination to identify progress in labor
Active	Every 30 minutes	Maternal blood pressure, pulse, and respirations
	Every 15-30 minutes	FHR and pattern Uterine activity Presence of vaginal show
	Every 15 minutes	Changes in maternal appearance, mood, affect, energy level, and condition of partner or coach
	Every 2-4 hours	Temperature (every 4 hours until membranes rupture, then every 2 hours)
Transition	As needed	Vaginal examination to identify progress in labor
	Every 15-30 minutes	Maternal blood pressure, pulse, and respirations
	Every 15-30 minutes	FHR and pattern Uterine activity Presence of vaginal show
	Every 10-15 minutes	Changes in maternal appearance, mood, affect, energy level, and condition of partner or coach
	Every 5 minutes	Temperature (every 4 hours until membranes rupture, then every 2 hours)
	Every 2-4 hours	Vaginal examination to identify progress in labor
	As needed	

woman and providing care is critical in preventing infection transmission. The nurse should explain assessment findings to the woman and her partner whenever possible. Throughout labor, accurate documentation, following agency policy, is done as soon as possible after a procedure has been performed (Fig. 19-4). If in-room computer stations are used, make sure to turn the computer so that your back is not to the woman while you are documenting.

General Systems Assessment. On admission, the nurse should perform a brief systems assessment. This includes an

FIG 19-4 Nurse documenting assessment findings on computer in a labor, delivery, recovery, postpartum room. (Courtesy Shannon Perry, Phoenix, AZ.)

assessment of the heart, lungs, and skin and an examination to determine the presence and extent of edema of the face, hands, sacrum, and legs. It also includes testing of deep tendon reflexes and for clonus, if indicated. Also note the woman's weight. Increasing numbers of women are overweight or obese. Excessive size can make nursing care during labor and birth more difficult and places the woman at risk for complications such as operative birth, infection, and blood clots. See Chapter 32 for further information.

Vital Signs. Assess vital signs (temperature, pulse, respirations, and blood pressure using a correct size cuff) on admission. The initial values are used as the baseline for comparison for all future measurements. If the blood pressure is elevated, reassess it 30 minutes later, between contractions, to obtain a reading after the woman has relaxed. Encourage the woman to lie on her side to prevent supine hypotension and the resulting fetal hypoxemia (Fig. 19-5). Monitor her temperature so you can identify signs of infection or a fluid deficit (e.g., dehydration associated with inadequate intake of fluids).

Leopold Maneuvers (Abdominal Palpation). Leopold maneuvers are performed with the woman briefly lying on her back (Box 19-5). These maneuvers help to answer three important questions: (1) What fetal part is in the uterine fundus? (2) Where is the fetal back located? (3) What is the presenting fetal part?

FIG 19-5 Supine hypotension. Note relation of pregnant uterus to ascending vena cava in standing position (A), and in the supine position (B). C, Compression of aorta and inferior vena cava with woman in supine position. D, Compression of these vessels is relieved by placement of a wedge pillow under the woman's right side.

BOX 19-5 Procedure: Leopold Maneuvers

- Wash hands.
- Ask woman to empty bladder.
- Position woman supine with one pillow under her head and with her knees slightly flexed.
- Place small rolled towel under woman's right or left hip to displace uterus off major blood vessels (prevents supine hypotensive syndrome; see Fig. 19-5, D).
- If right-handed, stand on woman's right, facing her (if left-handed, stand on woman's left):
 - Identify fetal part that occupies the fundus. The head feels round, firm, freely movable, and palpable by ballottement; the breech feels less regular and softer. This maneuver identifies fetal lie (longitudinal or transverse) and presentation (cephalic or breech) (Fig. A).
 - Using palmar surface of one hand, locate and palpate the smooth convex contour of the fetal back and the irregularities that identify the small parts (feet, hands, elbows). This maneuver helps identify fetal presentation (Fig. B).
 - With right hand, determine which fetal part is presenting over the inlet to the true pelvis. Gently grasp the lower pole

- of the uterus between the thumb and fingers, pressing in slightly (Fig. C). If the head is presenting and not engaged, determine the attitude of the head (flexed or extended).
- Turn to face the woman's feet. Using both hands, outline the fetal head (Fig. D) with the palmar surface of the fingertips. When the presenting part has descended deeply, only a small portion of it may be outlined. Palpation of the cephalic prominence helps identify the attitude of the head. If the cephalic prominence is found on the same side as the small parts, this means that the head must be flexed and the vertex is presenting (see Fig. D). If the cephalic prominence is on the same side as the back, this indicates that the presenting head is extended and the face is presenting.
- Document fetal presentation, position, and lie and whether presenting part is flexed or extended, engaged, or free floating. Use agency's protocol for documentation (e.g., "Vtx, LOA, floating").

Assessment of Fetal Heart Rate and Pattern. The point of maximal intensity (PMI) of the FHR is the location on the maternal abdomen at which the FHR is heard the loudest. It is usually directly over the fetal back. In a vertex presentation you can usually hear the FHR below the mother's umbilicus in either the right or the left lower quadrant of the abdomen. In a breech presentation you usually hear the FHR above the mother's umbilicus. Table 19-2 summarizes the assessments recommended for determining fetal status. In addition, you must assess the FHR after ROM because this is the most common time for the umbilical cord to prolapse, after any change in the contraction pattern or maternal status, and before and after the woman receives medication or a procedure is performed.

Assessment of Uterine Contractions. A general characteristic of effective labor is regular uterine activity (i.e., contractions becoming more frequent with increased duration), but uterine activity is not directly related to labor progress. Uterine contractions are the primary powers that act involuntarily to expel the fetus and the placenta from the uterus. Several methods are used to evaluate uterine contractions, including the woman's subjective description, palpation and timing of contractions by a health care provider, and electronic monitoring.

Each contraction exhibits a wavelike pattern. It begins with a slow increment (the "building up" of a contraction from its onset), gradually reaches a peak, and then diminishes rapidly (decrement, the "letting down" of the contraction). An interval

of rest ends when the next contraction begins. The outward appearance of the woman's abdomen during and between contractions and the pattern of a typical uterine contraction are shown in Figure 19-6.

A uterine contraction is described in terms of the following characteristics:

- **Frequency:** How often uterine contractions occur; the time that passes from the beginning of one contraction to the beginning of the next contraction
- **Intensity:** The strength of a contraction at its peak
- **Duration:** The time that passes between the onset and the end of a contraction
- **Resting tone:** The tension in the uterine muscle between contractions; relaxation of the uterus

Uterine contractions are assessed by palpation or by using external or internal electronic monitors (see Chapter 18 for further discussion). Frequency and duration can be measured by all three methods of uterine activity monitoring. The accuracy of determining intensity and resting tone varies by the method used. The woman's description and examiner's palpation are more subjective and less precise ways of determining the intensity of uterine contractions and resting tone than are the external or internal electronic monitors. The following terms describe what is felt on palpation:

- **Mild:** Slightly tense fundus that is easy to indent with fingertips (feels like pressing finger to tip of nose)

EVIDENCE-BASED PRACTICE

Correcting Fetal Malpresentations: Version and Moxibustion**Ask the Question**

For women near term with noncephalic fetal presentation, what are the options to maximize the chance of a vaginal birth?

Search for the Evidence

Search Strategies English language research-based publications since 2011 on external cephalic version, moxibustion, postural, obesity, and tocolytics were included.

Databases Used Cochrane Collaborative Database, National Guideline Clearinghouse (AHRQ), CINAHL, PubMed, UpToDate, and the professional websites for ACOG and AWHONN

Critical Appraisal of the Evidence

Noncephalic presentation (breech or transverse) makes vaginal birth risky or impossible and is a common reason for scheduled cesarean birth. Malpresentations can sometimes be corrected. Ideally correction occurs before engagement of the presenting part in the pelvis (“dropping”), yet close enough to term to maintain the position until birth and minimize the risk of preterm birth.

External cephalic version (ECV) is an ultrasound-guided, hands-on procedure to externally manipulate the fetus into a cephalic lie. It is done at 36 to 37 weeks, in the hospital setting.

- Beta stimulants to relax the uterus, such as terbutaline, have the best evidence for premedication (Cluver, Hofmeyr, Gyte, & Sinclair, 2012).
- Successful outcome of a vaginal birth is most likely for multiparous women with adequate amniotic fluid (Mowat & Gardener, 2013).
- Even with successful ECV, women are still at a greater risk for cesarean birth, especially if they are nulliparous and labor is induced (Kuppens, Hutton, Hasaart, et al., 2013).

Postural management, the practice of positioning women with their pelvis elevated, does not have sufficient evidence to support it as an effective corrective technique (Hofmeyr & Kulier, 2012).

Moxibustion, the Chinese practice of burning lungwort close to acupuncture point 67, the tip of the fifth toe, has promising evidence. Meta-analysis of eight trials found that moxibustion was associated with less need for oxytocin. When combined with acupuncture or postural management, moxibustion may result in fewer cesarean births (Coyle, Smith, & Peat, 2012).

Apply the Evidence: Nursing Implications

Promoting cephalic vaginal birth is protective against the complications of cesarean birth, which includes a high risk for future cesarean births.

- Even with uterine relaxers, ECV is very uncomfortable or painful, and carries its own risks for placental abruption, cord accident, and emergent cesarean birth. Women benefit from having a support person present.
- Moxibustion is a welcome noninvasive technique that shows promise and does no harm. Proper training is required to avoid

burns and respiratory reaction. Of practical concern to consider is the venting of smoke, to avoid triggering smoke alarms. Lack of familiarity probably impedes its uptake.

Women with malposition need to understand the mechanics of vaginal birth, and the risk factors for all options. Some women may prefer a cesarean birth, even with its increased risks.

Quality and Safety Competencies: Evidence-Based Practice* Knowledge

Discriminate between valid and invalid reasons for modifying evidence-based clinical practice based on clinical expertise or patient or family preferences.

ECV is well accepted, but painful and risky. Postural management has insufficient evidence, but moxibustion may be a noninvasive and safe way to correct malposition.

Skills

Consult with clinical experts before deciding to deviate from evidence-based protocols.

The skill and preparation of the practitioner and team are paramount for client safety and efficacy.

Attitudes

Acknowledge your own limitations in knowledge and clinical expertise before determining when to deviate from evidence-based best practices.

Keeping knowledge and skills up-to-date is essential for all members of the health team.

• **Moderate:** Firm fundus that is difficult to indent with fingertips (feels like pressing finger to chin)

• **Strong:** Rigid boardlike fundus that is almost impossible to indent with fingertips (feels like pressing finger to forehead)

Women in labor tend to describe the pain of contractions in terms of the sensations they are experiencing in the lower abdomen

or back, which are sometimes unrelated to the firmness of the uterine fundus. Therefore, their assessment of the strength of their contractions can be less accurate than that of the health care provider, although the amount of discomfort reported is valid.

External electronic monitoring provides some information about the strength of uterine contractions when the appearance

FIG 19-6 Assessment of uterine contractions. A, Abdominal contour before and during uterine contraction. B, Wavelike pattern of contractile activity.

of contractions on admission is compared with those that occur later in labor. Internal electronic monitoring with an intrauterine pressure catheter, however, is the most accurate way of assessing the intensity of uterine contractions and uterine resting tone.

On admission to a hospital, uterine contractions and FHR and pattern are usually monitored electronically for at least a 20- to 30-minute period as a baseline. The minimal times for assessing uterine activity during the various phases of stage one labor are listed in Table 19-2. The findings expected as the first stage of labor progresses are summarized in Table 19-1.

SAFETY ALERT

If you find the characteristics of contractions to be abnormal, either exceeding or falling below what is considered acceptable in terms of the standard characteristics, report this finding to the nurse-midwife or physician.

You must consider uterine activity in the context of its effect on cervical effacement and dilation and on the degree of descent of the presenting part (see Chapter 16). You must also consider the effect on the fetus. You can verify the progress of labor effectively through the use of graphic charts (partograms) on which you plot cervical dilation and station (descent). This type of graphic charting assists in early identification of deviations from expected labor patterns. Figure 19-7 provides examples of partograms. Hospitals and birthing centers may develop their own assessment graphs that may include data not only on dilation and descent but also maternal vital signs, FHR, and uterine activity.

SAFETY ALERT

The nurse should recognize that active labor can actually last longer than the expected labor patterns because all women are different. This finding is not a cause for concern unless the maternal-fetal unit exhibits signs of stress (e.g., abnormal FHR patterns, maternal fever).

Vaginal Examination. The vaginal examination reveals whether the woman is in true labor and enables the examiner to determine whether the membranes have ruptured (Fig. 19-8). Because this examination is often stressful and uncomfortable for the woman and may introduce microorganisms into the vagina if the membranes are ruptured, perform it only when indicated by the status of the woman and her fetus. For example, perform a vaginal examination on admission, prior to administering medications (e.g., analgesics, increasing oxytocin infusion), when significant change has occurred in uterine activity, on maternal request or perception of perineal pressure or the urge to bear down, when membranes rupture, or when you note variable decelerations of the FHR. A full explanation of the examination and support of the woman are important in reducing the stress and discomfort associated with the examination (Simpson & O'Brien-Abel, 2014) (Box 19-6).

Laboratory and Diagnostic Tests

Analysis of Urine Specimen. A clean-catch urine specimen may be obtained to gather further data about the pregnant woman's health. Analysis of the specimen is a convenient and simple procedure that can provide information about her hydration status (e.g., specific gravity, color, amount), nutritional status (e.g.,

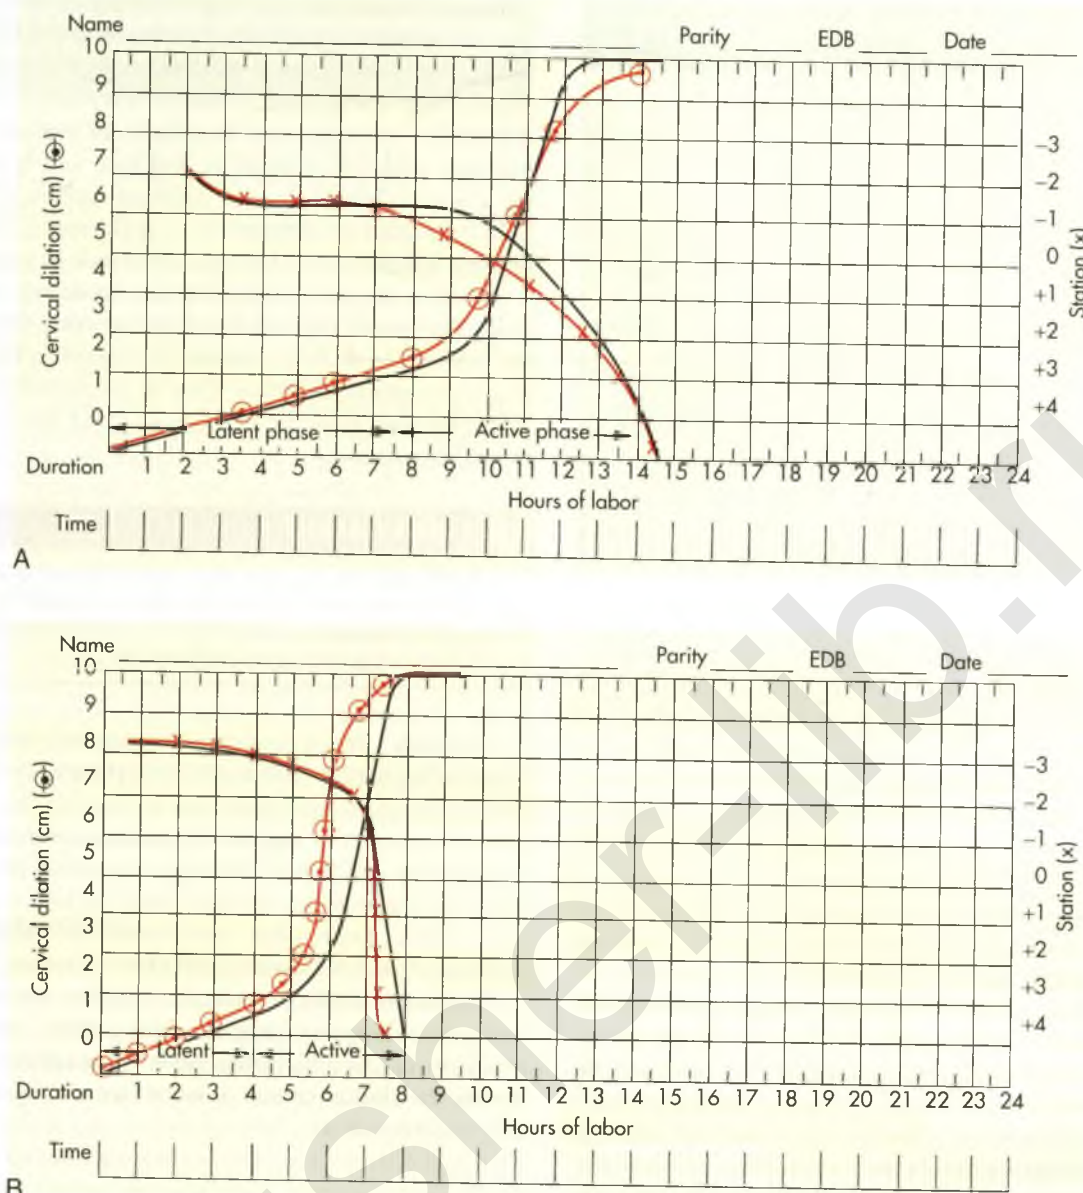

FIG 19-7 Partograms for assessment of patterns of cervical dilation and descent. Individual woman's labor patterns (colored) are superimposed on prepared labor graph (black) for comparison. **A**, Labor of a nulliparous woman. **B**, Labor of a multiparous woman. The rate of cervical dilation is plotted with the circled plot points. A line drawn through these symbols depicts the slope of the curve. Station is plotted with X's. A line drawn through the X's reveals the pattern of descent.

FIG 19-8 Vaginal examination. **A**, Undilated, uneffaced cervix; membranes intact. **B**, Palpation of sagittal suture line. Cervix effaced and partially dilated.

BOX 19-6 Procedure: Vaginal Examination of the Laboring Woman

- Use a sterile glove and antiseptic solution or soluble gel for lubrication.
- Position the woman to prevent supine hypotension. Drape to ensure privacy.
- Cleanse the perineum and vulva, if needed.
- After obtaining the woman's permission to touch her, gently insert the index and middle fingers into the woman's vagina.
- Determine:
 - Cervical dilation, effacement, and position (e.g., posterior, mid, anterior)
 - Presenting part, position, and station; molding of the head with development of caput succedaneum (may affect accuracy of determination of station)
 - Status of membranes (intact, bulging, or ruptured)
 - Characteristics of amniotic fluid (e.g., color, clarity, and odor), if membranes are ruptured
- Explain the findings of the examination to the woman.
- Document your findings and report them to the nurse-midwife or physician.

ketones), infection status (e.g., leukocytes), or the status of possible complications such as preeclampsia, shown by finding protein in the urine. In many hospitals this test must be done in the laboratory rather than at the bedside, even if a urine dipstick is used.

Blood Tests. The blood tests performed vary with the hospital protocol and the woman's health status. Currently, all blood tests must be performed in the hospital laboratory rather than on the perinatal unit. Often blood samples are obtained from the hub of the catheter when an IV is started or a heparin or saline lock is inserted. A hematocrit will likely be ordered. More comprehensive blood assessments such as white blood cell count, red blood cell count, hemoglobin level, hematocrit, and platelet values are included in a complete blood count (CBC). A CBC may be ordered for women with a history of infection, anemia, gestational hypertension, or other disorders. Many hospitals require that a CBC be done before epidural anesthesia is initiated. Any woman whose human immunodeficiency virus (HIV) status is undocumented at the time of labor should be screened with a rapid HIV test unless she declines (opts-out) testing (Centers for Disease Control and Prevention [CDC], Branson, Handsfield, et al., 2006).

Most hospitals require that a "type and screen," to determine the woman's blood type and Rh status, be performed on admission. Even if these tests have already been performed during pregnancy, the hospital's laboratory or blood bank must verify the results in-house. If the woman had no prenatal care or if her prenatal records are not available, a prenatal screen will likely be drawn on admission. The prenatal screen includes laboratory tests that would normally have been drawn at the initial prenatal visit (see Table 14-1).

Other Tests. If the woman's group B streptococcus status is not known, a rapid test may be done on admission. The rapid test results are usually available within an hour or so and will determine if the woman must be given antibiotics during labor.

Assessment of Amniotic Membranes and Fluid. Labor is initiated at term by SROM in approximately 25% of pregnant women. A lag period, rarely exceeding 24 hours, may precede the onset of labor. Membranes (the BOW) also can rupture spontaneously any time during labor, but most commonly in the

transition phase of the first stage of labor. Box 19-1 explains how to determine if membranes are ruptured. If the membranes do not rupture spontaneously, the BOW may be ruptured artificially at some time during labor. However, this practice is discouraged if there is no medical reason because it can increase the laboring woman's sensation of pressure and pain and is not necessary for a normal birth to occur. Artificial rupture of membranes (AROM), called an **amniotomy**, is performed by the physician or nurse-midwife using a plastic AmniHook or a surgical clamp.

Whether the membranes rupture spontaneously or artificially, the time of rupture should be recorded. Other necessary documentation includes information regarding the FHR before and after rupture, the color (clear or meconium stained), estimated amount, and odor of the fluid. (See Chapter 32 for additional information.)

SAFETY ALERT

The umbilical cord may prolapse when the membranes rupture. The FHR and pattern should be monitored closely for several minutes immediately after ROM to determine fetal well-being, and the findings should be documented.

Infection. When membranes rupture, microorganisms from the vagina can then ascend into the amniotic sac, causing chorioamnionitis and placentitis to develop. For this reason, limit the number of vaginal examinations and assess maternal temperature and vaginal discharge frequently (at least every 2 hours) so that you can quickly identify an infection developing after ROM. Even when membranes are intact, however, microorganisms may ascend and cause infection.

Assessment findings serve as a baseline for evaluating the woman's subsequent progress during labor. Although some problems can be anticipated, others may appear unexpectedly during the clinical course of labor (see the Signs of Potential Complications box).

SIGNS OF POTENTIAL COMPLICATIONS

Labor

- Intrauterine pressure of ≥ 80 mm Hg or resting tone of ≥ 20 mm Hg (both determined by internal monitoring with intrauterine pressure catheter [IUPC])
- Contractions lasting ≥ 90 seconds
- More than five contractions in a 10-minute period (contractions occur more frequently than every 2 minutes)
- Relaxation between contractions lasting < 30 seconds
- Fetal bradycardia or tachycardia; absent or minimal variability not associated with fetal sleep cycle or temporary effects of central nervous system (CNS) depressant drugs given to the woman; late, variable, or prolonged fetal heart rate (FHR) decelerations
- Irregular FHR; suspected fetal arrhythmias
- Appearance of meconium-stained or bloody fluid from the vagina
- Arrest in progress of cervical dilation or effacement, descent of the fetus, or both
- Maternal temperature of $\geq 38^\circ\text{C}$ (100.4°F)
- Foul-smelling vaginal discharge
- Persistent bright or dark red vaginal bleeding

BOX 19-7 Evidence-Based Care Practices Designed to Promote, Protect, and Support Normal Labor and Birth

- Allow labor to begin on its own: encourage spontaneous labor rather than fostering elective labor inductions.
- Encourage freedom of movement throughout labor to facilitate the progress of labor and enhance maternal comfort and control of the labor process.
- Provide labor support beginning early in labor and continuing throughout the process of childbirth to relieve maternal anxiety and stress and decrease the risk for epidural anesthesia and cesarean birth; support should be provided by someone not employed by the hospital (e.g., doula).
- Avoid routine implementation of interventions (e.g., intravenous fluids, oral intake restrictions, continuous electronic fetal monitoring, labor augmentation measures [amniotomy, oxytocin administration], and epidural anesthesia).
- Support the practice of spontaneous, nondirected pushing in nonsupine positions (e.g., lateral, squatting, standing, kneeling, and semisitting) to facilitate the progress of fetal descent and shorten the second stage of labor.
- Avoid separation of the mother from her healthy baby after birth by encouraging skin-to-skin contact of mother and baby to keep newborn warm, prevent neonatal infection, enhance the newborn's physiologic adjustment to extrauterine life, and foster early breastfeeding.

Adapted from Romano, A.M. & Lothian, J.A. (2008). Promoting, protecting, and supporting normal birth: A look at the evidence. *Journal of Obstetric, Gynecologic, and Neonatal Nursing*, 37(1), 94-105.

Nursing Interventions

The nursing process provides the framework for the nursing care management of women in labor. The physical nursing care given to a woman in labor is an essential component of her care. The current emphasis on evidence-based practice supports the management of care by using this approach to enhance the safety, effectiveness, and acceptability of the physical care measures chosen to support the woman during labor and birth (Box 19-7). The various physical needs, the necessary nursing actions, and the rationale for care are presented in Table 19-3 and the Nursing Care Plan.

General Hygiene

Offer women in labor the use of showers or warm-water baths, if they are available, to enhance the feeling of well-being and to minimize the discomfort of contractions. Water immersion during active labor is associated with a decrease in the use of analgesia and reports of less maternal pain (Arendt & Tessmer-Tuck, 2013; Berghella, Baxter, & Chauhan, 2008). Also encourage women to wash their hands or use cleansing foam after voiding and performing self-hygiene measures. Change the linen if it becomes wet or stained with blood and use linen savers (Chux), changing them as needed.

Nutrient and Fluid Intake

Oral Intake. Before the 1940s women were allowed to eat and drink during labor to maintain the energy required to sustain labor and the stamina required to give birth. This practice changed, allowing the laboring woman only clear liquids or ice chips or nothing by mouth during the active phase of labor when

concern arose regarding the risk of anesthesia complications and their secondary effects, if general anesthesia were required in an emergency. These secondary effects include the aspiration of gastric contents and resultant compromise in oxygen perfusion, which could endanger the lives of the mother and fetus (Sharts-Hopko, 2010; Simpson & O'Brien-Abel, 2014). There have been no randomized trials evaluating the ingestion of solid foods in labor, so current management is based mostly on expert opinion. The American College of Obstetricians and Gynecologists (ACOG), the American Society of Anesthesiologists, and the Canadian Anesthesiologists' Society recommend avoiding solid food during labor (Simpson & O'Brien-Abel). This practice is being challenged by many health care providers, however, because regional anesthesia is used more often than general anesthesia, even for emergency cesarean births. Women are awake during regional anesthesia and are able to participate in their own care and protect their airway.

An adequate intake of fluids and calories is required to meet the energy demands and fluid losses associated with childbirth. The progress of labor slows, with a more rapid development of hypoglycemia and ketosis if these demands are not met and fat is metabolized. Reduced energy for bearing-down efforts (pushing) increases the risk for a forceps- or vacuum-assisted birth. This is most likely to occur in women who begin to labor early in the morning after a night without caloric intake. When women are permitted to consume fluid and food freely, they typically regulate their own oral intake, eating light foods (e.g., eggs, yogurt, ice cream, dry toast and jelly, fruit) and drinking fluids during early labor and tapering off to the intake of clear fluids and sips of water or ice chips as labor intensifies and the second stage approaches (Sharts-Hopko, 2010).

Common hospital practice is to allow clear liquids (e.g., water, tea, fruit juices without pulp, clear sodas, coffee, sports drinks, fruit ice, Popsicles, gelatin, broth) during early labor, tapering off to ice chips and sips of water as labor progresses and becomes more active. Herbal teas can provide not only hydration but also other beneficial effects. Chamomile tea can enhance relaxation, lemon balm or peppermint tea can reduce nausea, and teas of ginger or ginseng root are energizing (Walls, 2009). A woman's culture may influence what she will eat and drink during labor. In addition, women who use nonpharmacologic pain relief measures and labor at home or in birthing centers are more likely to eat and drink during labor. The amount of solid and liquid carbohydrates to offer a woman in labor is still unclear. Although it is known that energy needs increase as labor becomes prolonged, there is limited evidence regarding the effect of oral carbohydrate intake in enhancing the progress of labor and reducing the risk for dystocia (Sharts-Hopko, 2010).

A Cochrane database review of this topic concluded that there is no justification for restricting food or fluid intake during labor in women at low risk for complications (Singata, Tranmer, & Gyte, 2013). Nurses should follow the orders of the woman's primary health care provider when offering the woman food or fluid during labor. However, as advocates, nurses can facilitate change by informing others of the current research findings that support the safety and effectiveness of the oral intake of food and fluid during labor and initiating such research themselves.

 **NURSING CARE PLAN**
Care of the Woman in Labor

NURSING DIAGNOSIS	EXPECTED OUTCOME	INTERVENTIONS	RATIONALES
<i>Anxiety related to labor and the birthing process</i>	Woman reports decreased anxiety level using an anxiety scale (from 0 [no anxiety] to 10 [anxiety as bad as it could possibly be]).	<p>Orient woman and significant others to labor and birth unit and explain admission protocol.</p> <p>Assess woman's knowledge, experience, and expectations of labor; note any signs or expressions of anxiety, nervousness, or fear.</p> <p>Discuss expected progression of labor and describe what to expect during process.</p> <p>Identify specific source(s) of anxiety.</p> <p>Actively involve woman in care decisions during labor, interpret sights and sounds of environment (monitor sights and sounds, unit activities), and share information on progression of labor (vital signs, fetal heart rate [FHR], dilation, effacement).</p>	<p>To allay initial feelings of anxiety</p> <p>To establish baseline for intervention</p> <p>To decrease anxiety associated with the unknown</p> <p>To better target interventions</p> <p>To increase her sense of control and lessen fears</p>
<i>Acute Pain related to increasing frequency and intensity of contractions</i>	Woman reports decreased pain level using a pain scale (from 0 [no pain] to 10 [pain as bad as it could possibly be]).	<p>Assess woman's level of pain and strategies that she has used to cope with it.</p> <p>Encourage significant other to remain as support person during labor process.</p> <p>Assist the woman and support person(s) in use of specific nonpharmacologic pain methods such as conscious relaxation, breathing techniques, hypnosis, music, distraction, imagery, massage, and touch.</p> <p>Provide comfort measures such as frequent mouth care to prevent dry mouth, application of damp cloth to forehead, and changing of damp gown or bed covers.</p> <p>Help the woman to move around and change position such as squatting or using a birthing ball or birthing stool.</p> <p>Explain which analgesics and anesthesia are available for use during labor and birth.</p> <p>Administer analgesics or assist with regional anesthesia (e.g., epidural) as ordered or desired.</p>	<p>To establish baseline for intervention</p> <p>To assist with support and comfort measures because measures are often more effective when delivered by a familiar person</p> <p>To increase relaxation, help woman cope with the intensity of contractions, and promote use of controlled thought and direction of energy</p> <p>To relieve discomfort associated with diaphoresis</p> <p>To reduce stiffness, promote comfort, and facilitate progress of birth</p> <p>To provide knowledge to help woman make decisions about pain control</p> <p>To provide effective pain relief during labor and birth</p>
<i>Impaired Urinary Elimination related to sensory impairment secondary to labor</i>	Woman's bladder is emptied at least every 2 hours, either by spontaneous voiding or urinary catheter.	<p>Palpate bladder superior to symphysis frequently (at least every 2 hours).</p> <p>Encourage frequent voiding (at least every 2 hours) and catheterize if necessary.</p> <p>Help woman to bathroom or commode to void, if appropriate; provide privacy, and use techniques to stimulate voiding such as running water.</p>	<p>To detect full bladder that occurs from increased fluid intake and inability to feel urge to void</p> <p>To avoid bladder distention because it impedes progress of fetus down birth canal and may result in trauma to bladder</p> <p>To facilitate bladder emptying with an upright position (natural) and relaxation</p>

 NURSING CARE PLAN—cont'd

Care of the Woman in Labor

NURSING DIAGNOSIS	EXPECTED OUTCOME	INTERVENTIONS	RATIONALES
<i>Ineffective Coping related to the birthing process</i>	Woman actively participates in birth process with no evidence of injury to her or her fetus.	Constantly monitor events of labor and birth, including physiologic responses of woman and fetus and emotional responses of woman and partner.	To ensure maternal, partner, and fetal well-being
		Provide ongoing feedback to woman and partner.	To decrease anxiety and enhance participation
		Continue to provide comfort measures and minimize distractions (e.g., dim the room lights and speak quietly).	To decrease discomfort and aid in focus on birth process
		Encourage woman to experiment with various positions.	To assist downward movement of fetus
		Ensure that woman takes deep cleansing breaths before and after each contraction.	To enhance gas exchange and oxygen transport to fetus
		Encourage woman to push spontaneously when urge to bear down is perceived during contraction.	To aid descent and rotation of fetus
		Encourage woman to exhale, holding breath for short periods while bearing down.	To avoid holding breath and triggering Valsalva maneuver, thereby increasing intrathoracic and cardiovascular pressure and decreasing the amount of oxygen that reaches uterus and placenta, placing fetus at risk
		Have woman take deep breaths and relax between contractions.	To reduce fatigue and increase effectiveness of pushing efforts
		Have mother pant as fetal head crowns.	To control birth of head and reduce risk for perineal trauma or fetal head injury
		Explain to woman and labor partner what is expected in the third stage of labor.	To enlist cooperation
<i>Fatigue related to energy expenditure required during labor and birth</i>	Woman's energy levels are restored.	Have woman maintain her position.	To facilitate delivery of placenta
		Educate woman and partner about need for rest and help them plan strategies (e.g., restricting visitors, increasing role of support systems performing functions associated with daily routines) that allow specific times for rest and sleep.	To ensure that woman can restore depleted energy levels in preparation for caring for new infant
		Monitor woman's fatigue level and amount of rest received.	To ensure restoration of energy
		Group care activities as much as possible.	To allow for periods of uninterrupted rest

Intravenous Intake. Fluids commonly are administered intravenously to the laboring woman to maintain hydration, especially if labor is long and the woman is unable to ingest a sufficient amount of fluid orally or if she is receiving epidural or intrathecal anesthesia. In most cases an electrolyte solution without glucose (e.g., Ringer's lactate or normal saline) is adequate and does not introduce excess glucose into the bloodstream. The latter is important because an excessive maternal glucose level results in fetal hyperglycemia and fetal hyperinsulinism. After birth the neonate's high level of insulin reduces his or her glucose stores, and hypoglycemia results. Infusions containing glucose can also reduce sodium levels

in the woman and the fetus, leading to transient neonatal tachypnea. If maternal ketosis occurs, the nurse-midwife or physician can order an IV solution containing a small amount of dextrose to provide the glucose needed to assist in fatty acid metabolism.

 SAFETY ALERT

Nurses should carefully monitor the intake and output of laboring women receiving IV fluids because they face an increased danger of hypervolemia as a result of the fluid retention that occurs during pregnancy.

TABLE 19-3 Physical Nursing Care During Labor

NEED	NURSING ACTIONS	RATIONALE
General Hygiene		
Showers or bed baths, Jacuzzi bath	Assess for progress in labor Supervise showers closely if woman is in true labor Suggest allowing warm water to flow over back	Determines appropriateness of the activity Prevents injury from fall; labor may be accelerated Aids relaxation; increases comfort
Perineum	Cleanse frequently, especially after rupture of membranes and when show increases	Enhances comfort and reduces risk of infection
Oral hygiene	Offer toothbrush or mouthwash, or wash the teeth with an ice-cold wet washcloth as needed	Refreshes mouth; helps counteract dry, thirsty feeling
Hair	Brush, braid per woman's wishes	Improves morale; increases comfort
Handwashing	Offer washcloths or cleansing foam before and after voiding and as needed	Maintains cleanliness; prevents infection
Face	Offer cool washcloth	Provides relief from diaphoresis; cools and refreshes
Gowns and linens	Change as needed	Improves comfort; enhances relaxation
Nutrient and Fluid Intake		
Oral	Offer fluids and solid foods as ordered by nurse-midwife or physician and desired by laboring woman	Provides hydration and calories; enhances positive emotional experience and maternal control
Intravenous (IV)	Establish and maintain IV line as ordered	Maintains hydration; provides venous access for medications
Elimination		
Voiding	Encourage voiding at least every 2 hours	A full bladder may impede descent of presenting part; overdistention may cause bladder atony and injury, as well as postpartum voiding difficulty
Ambulatory woman	Allow ambulation to bathroom according to orders of nurse-midwife or physician, if: The presenting part is engaged The membranes are not ruptured The woman is not medicated	Reinforces normal process of urination Precautionary measure to protect against prolapse of umbilical cord Precautionary measure to protect against injury
Woman on bed rest	Offer bedpan Encourage upright position on bedpan, allow tap water to run; place woman's hands in warm water; pour warm water over the vulva; give positive suggestion Provide privacy Put up side rails on bed Place call bell and telephone within reach Offer washcloth or cleansing foam for hands Wash vulvar area	Prevents complications of bladder distention and ambulation Encourages voiding Shows respect for woman Prevents injury from fall Reinforces safe care Maintains cleanliness; prevents infection Maintains cleanliness; enhances comfort; prevents infection
Catheterization	Catheterize according to orders of nurse-midwife or physician or hospital protocol if measures to facilitate voiding are ineffective Insert catheter between contractions Avoid force if obstacle to insertion is noted	Prevents complications of bladder distention Minimizes discomfort "Obstacle" may be caused by compression of urethra by presenting part
Bowel elimination— sensation of rectal pressure	Perform vaginal examination Help the woman ambulate to bathroom, or offer bedpan if rectal pressure is not from presenting part Cleanse perineum immediately after passage of stool	Prevents misinterpretation of rectal pressure from the presenting part as the need to defecate Determines degree of descent of presenting part Reinforces normal process of bowel elimination and safe care Reduces risk of infection and sense of embarrassment

Elimination

Voiding. Encourage voiding every 2 hours. A distended bladder may impede descent of the presenting part, slow or stop uterine contractions, and lead to decreased bladder tone or uterine atony after birth. Women who receive epidural analgesia or anesthesia are especially at risk for the retention of urine. Therefore, the need to void should be assessed more frequently with them.

Assist the woman to the bathroom to void or use a bedside commode, unless any of the following apply: the nurse-midwife or physician has ordered bed rest; the woman is receiving epidural analgesia or anesthesia; internal monitoring is being used; or ambulation will compromise the status of the laboring woman or her fetus. External monitoring can usually be interrupted long enough for the woman to go to the bathroom.

If using a bedpan is necessary, encourage spontaneous voiding by providing privacy and having the woman sit upright (as she would on a toilet). Other interventions to encourage urination, either in the bathroom or on the bedpan, are having the woman listen to the sound of water slowly running from a faucet, placing her hands in warm water, having her blow bubbles into a glass of water using a straw, or pouring warm water over the vulva and perineum using a peri bottle.

Catheterization. If the woman is unable to void and her bladder is distended, she may need to be catheterized. Many hospitals have protocols or standing orders that rely on the nurse's judgment concerning the need for catheterization. Before performing the catheterization, clean the vulva and perineum because vaginal show and amniotic fluid may be

present. If an obstacle that prevents advancement of the catheter is present, this obstacle is most likely the presenting part. If you cannot advance the catheter, stop the procedure and notify the nurse-midwife or physician of the difficulty.

Bowel Elimination. Most women do not have bowel movements during labor because of decreased intestinal motility. Stool that has formed in the large intestine often moves downward toward the anorectal area as a result of pressure exerted by the fetal presenting part as it descends. This stool is often expelled during second-stage pushing and birth. However, the passage of stool with bearing-down efforts increases the risk of infection and may embarrass the woman, thereby reducing the effectiveness of her pushing efforts. To prevent these problems, the nurse should immediately cleanse the perineal area to remove any stool, while reassuring the woman that the passage of stool at this time is a normal and expected event, because the same muscles used to expel the baby also expel stool.

Routine use of enemas on hospital admission for women at term has shown only modest benefits. There is a trend toward lower infection rates and the newborns have fewer lower respiratory tract infections and less need for antibiotics. However, because enemas cause discomfort for women and increase the costs of giving birth, the small benefits do not outweigh the disadvantages of this practice (Berghella et al., 2008). In addition, a Cochrane review of this topic found that the evidence does not support the routine use of enemas during labor (Revez, Gaitan, & Cuervo, 2013).

When the presenting part is deep in the pelvis, even in the absence of stool in the anorectal area, the woman may feel rectal pressure and think she needs to defecate. If the woman expresses the urge to defecate, the nurse should perform a vaginal examination to assess cervical dilation and station. When a multiparous woman experiences the urge to defecate, this often means birth will follow quickly.

Ambulation and Positioning

Upright positions and mobility during labor may be more pleasant for laboring women. These practices have also been associated with improved uterine contraction intensity and shorter labors, less need for pain medications, reduced rate of operative birth (e.g., cesarean birth, forceps- and vacuum-assisted birth), increased maternal autonomy and control, distraction from the discomforts of labor, and an opportunity for close interaction with the woman's partner and care provider as they help her assume upright positions and remain mobile (Lawrence, Lewis, Hofmeyr, & Styles, 2013; Simpson & O'Brien-Abel, 2014; Zwelling, 2010). No harmful effects have been observed from maternal activity and position changes. However, confinement to bed is the norm for laboring women in U.S. hospitals. The increased use of epidurals during childbirth accompanied by multiple medical interventions (e.g., electronic fetal monitors, IV infusions) and reduced motor control contribute to this practice, thereby interfering with a woman's freedom of movement and often slowing labor progress.

It is important to encourage ambulation if membranes are intact, after ROM if the fetal presenting part is engaged, and if the woman has not received medication for pain (Fig. 19-9). The woman also may find it comfortable to stand and lean forward on her partner, doula, or nurse for support at times during

FIG 19-9 Woman preparing to walk with partner. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

labor (Fig. 19-10, A). In some circumstances, ambulation may be contraindicated because of maternal or fetal status.

When the woman lies in bed, she usually changes her position spontaneously as labor progresses. If she does not change position every 30 to 60 minutes, assist her to do so. The side-lying (lateral) position is preferred because it promotes optimal uteroplacental and renal blood flow and increases fetal oxygen saturation (Fig. 19-11, B). If the woman wants to lie supine, the nurse should place a pillow under one hip as a wedge to prevent the uterus from compressing the aorta and vena cava (see Fig. 19-5). Sitting is not contraindicated unless it adversely affects fetal status, which you can determine by checking the FHR and pattern. If the fetus is in the occiput posterior position, it may be helpful to encourage the woman to squat during contractions because this position increases the pelvic diameter, allowing the head to rotate to a more anterior position (see Fig. 19-11, A). A hands-and-knees position during contractions (see Fig. 19-10, B) or a lateral position on the same side as the fetal spine also are recommended to facilitate the rotation of the fetal occiput from a posterior to an anterior position, as gravity pulls the fetal back forward. These positions also provide access to the back for application of counterpressure by the partner, doula, or nurse (Hanson, 2009; Simpson & O'Brien-Abel, 2014; Simpson, Cesario, Morin, et al., 2008; Zwelling, 2010) (see Fig. 19-11, B). Women with epidural anesthesia may not be able to squat or assume a hands-and-knees position depending on the degree of motor involvement resulting from the epidural.

Much research continues to focus on acquiring a better understanding of the physiologic and psychologic effects of maternal position in labor. Box 19-8 describes a variety of positions that are commonly used and recommended.

The woman can use a birth ball (gymnastic ball, physical therapy ball) to support her body as she assumes a variety of labor and birth positions (Fig. 19-12). She can sit on the ball while leaning over the bed or lean over the ball to support her upper body and reduce stress on her arms and hands when she assumes a hands-and-knees position. The birth ball can encourage pelvic mobility and pelvic and perineal relaxation when the

FIG 19-10 A, Woman standing and leaning forward with support. B, Woman in hands-and-knees position. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

woman sits on the firm yet pliable ball and rocks in rhythmic movements. Warm compresses applied to the perineum and lower back can maximize this relaxation and comfort effect. The birth ball should be large enough that, when the woman sits, her knees are bent at a 90-degree angle and her feet are flat on the floor and approximately 2 feet apart.

SAFETY ALERT

A woman may experience dizziness as she changes upright positions during labor. It is essential that the nurse or support person be present to provide assistance should dizziness occur.

Supportive Care During Labor and Birth

Support during labor and birth involves emotional support, physical care and comfort measures, and advice and information. The value of the continuous supportive presence of a person (e.g., doula, childbirth educator, family member, friend, nurse, partner) during labor has long been known. Women who have continuous support beginning in early labor are less likely to use pain medication or epidurals, more likely to have a spontaneous vaginal birth, and less likely to report dissatisfaction with their birth experience. No harmful effects from continuous labor support have been identified. To the contrary, there is good evidence that labor support improves important health outcomes (Association of Women's Health, Obstetric and Neonatal Nurses [AWHONN], 2011; Berghella et al., 2008; Hodnett et al., 2013).

Labor rooms should be airy, clean, and homelike. The laboring woman should feel safe in this environment and free to be herself and to use the comfort and relaxation measures she prefers. To enhance relaxation, turn off bright overhead lights when not needed, and keep noise and intrusions to a minimum. Control the temperature to ensure the laboring woman's comfort. The room

FIG 19-11 Maternal positions for labor. A, Squatting. B, Lateral position. Support person is applying sacral pressure while partner provides encouragement. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

BOX 19-8 Common Maternal Positions* During Labor and Birth**Semirecumbent Position (See Figs. 19-14, B, and 19-15, B)**

With the woman sitting with her upper body elevated to at least a 30-degree angle, place a wedge or small pillow under her hip to prevent vena cava compression and reduce the likelihood of supine hypotension (see Fig. 19-5).

- The greater the angle of elevation, the more gravity or pressure is exerted that promotes fetal descent, the progress of contractions, and the widening of pelvic dimensions.
- This position is convenient for providing care measures and for external fetal monitoring.

Lateral Position (See Figs. 19-11, B, and 19-14, A)

Have the woman alternate between a left and right side-lying position, and provide abdominal and back support as needed for comfort.

- Removes pressure from the vena cava and back, enhances uteroplacental perfusion, and relieves backache
- Facilitates internal rotation of fetus in a posterior position to an anterior position (woman should lie on same side as fetal spine)
- Makes it easier to perform back massage or counterpressure
- Associated with less frequent, but more intense, contractions
- May be more difficult to obtain good external fetal monitor tracings
- May be used as a birthing position
- Takes pressure off perineum, allowing it to stretch gradually
- Reduces risk for perineal trauma

Upright Position

The gravity effect enhances the contraction cycle and fetal descent: the weight of the fetus places increasing pressure on

the cervix; the cervix is pulled upward, facilitating effacement and dilation; impulses from the cervix to the pituitary gland increase, causing more oxytocin to be secreted; and contractions are intensified, thereby applying more forceful downward pressure on the fetus, but they are less painful.

- Fetus is aligned with pelvis, and pelvic diameters are widened slightly
- Effective upright positions include:
 - Ambulation (see Fig. 19-9)
 - Standing and leaning forward with support provided by coach (see Fig. 19-10, A), end of bed, back of chair, or birth ball; relieves backache and facilitates application of counterpressure or back massage
 - Sitting up in bed, in chair, in birthing chair, on toilet, or on bedside commode (see Fig. 19-14, B)
 - Squatting (see Figs. 19-11, A, and 19-15, E)

Hands-and-Knees Position—Position for Posterior Positions of the Presenting Part (See Figs. 19-10, B, and 19-12)

Assume an “all fours” position or lean over an object (e.g., birth ball) while on the knees in bed or on a covered floor; this allows for pelvic rocking.

- Relieves backache characteristic of “back labor”
- Facilitates internal rotation of the fetus by increasing mobility of the coccyx, increasing the pelvic diameters, and using gravity to turn the fetal back and rotate the head (NOTE: A side-lying position, double hip squeeze, or knee squeeze also can facilitate internal rotation.)

*Assess the effect of each position on the laboring woman’s comfort and anxiety level, progress of labor, and fetal heart rate and pattern. Alternate positions every 30 to 60 minutes, allowing the woman to take control of her position changes.

FIG 19-12 Woman laboring using birth ball. (Courtesy Polly Perez, Cutting Edge Press, Johnson, VT.)

should be large enough to accommodate a comfortable chair for the woman’s support person, the monitoring equipment, and hospital personnel. Encourage women to bring their own pillows to make the hospital surroundings more homelike and to facilitate position changes. Environmental modifications should reflect the preferences of the woman, including the number of visitors and availability of a telephone, television, and music.

Labor Support by the Nurse. Supportive nursing care for a woman in labor includes:

- Helping her maintain control and participate to the extent she wishes in the birth of her infant
- Providing continuity of care that is nonjudgmental and respectful of her cultural and religious values and beliefs
- Meeting her expected outcomes for her labor
- Listening to her concerns and encouraging her to express her feelings
- Acting as her advocate, supporting her decisions and respecting her choices as appropriate, and relating her wishes as needed to other health care providers
- Helping her conserve her energy and cope effectively with her pain and discomfort by using a variety of comfort measures that are acceptable to her
- Helping control her discomfort
- Acknowledging her efforts during labor including her strength and courage, as well as those of her partner, and providing positive reinforcement
- Protecting her privacy, modesty, and dignity

Women who have attended childbirth education programs that teach the psychoprophylactic (Lamaze) approach will know something about the labor process, coaching techniques, and comfort measures. The nurse plays a supportive role and keeps the woman and her partner informed of the labor progress. If necessary, review the methods learned in class and practiced at home because it may be difficult for the woman to effectively

FIG 19-13 Partner providing comfort measures. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

use these methods and techniques now that she is in labor and in an unfamiliar setting.

Even when a laboring woman has not attended childbirth classes, the nurse can teach her simple breathing and relaxation techniques during the early phase of labor. In this case the nurse provides more of the coaching and supportive care until the support person feels ready to take on a more active coaching role (see Chapter 17). The nurse can demonstrate comfort measures while encouraging the support person to assist and the laboring woman to express her needs and feelings. Observing the comforting approaches of the nurse can help the partner learn effective comfort measures.

Comfort measures vary with the situation (Fig. 19-13). The nurse can draw on the woman's list of comfort measures and relaxation techniques learned during the pregnancy and through life experiences. Such measures include maintaining a comfortable, calm, supportive atmosphere in the labor and birth area; using touch therapeutically (e.g., heat or cold applied to the lower back in the event of back labor, a cool cloth applied to the forehead, massage); providing nonpharmacologic measures to relieve discomfort (e.g., hydrotherapy); and most important, just being there (see Tables 19-1 and 19-4). See Chapter 17 for a full discussion of pharmacologic and nonpharmacologic comfort measures.

Most women in labor respond positively to touch, but you should obtain permission before using any touching measures. Women appreciate gentle assistance by staff members. Back rubs and counterpressure may be offered, especially if the woman is experiencing back labor. Teach the support person to exert counterpressure against the woman's sacrum over the occiput of the head of a fetus in a posterior position (see Fig. 19-11, B). Double hip or knee squeezes can also be helpful in reducing back pain. The back pain is caused by the occiput pressing on spinal nerves, and counterpressure lifts the occiput off these nerves, providing some relief from pain. The partner will need to be relieved after a while, however, because exerting counterpressure is hard work. Hand and foot massage also can be soothing and relaxing.

The woman's perception of the soothing qualities of touch may change as labor progresses. Many women become more sensitive to touch (hyperesthesia) as labor progresses. This is a typical

response during the transition phase (see Table 19-1). They may tell their coach to leave them alone or not to touch them. The partner who is unprepared for this normal response may feel rejected and may react by withdrawing active support. The nurse can reassure him or her that this response is a positive indication that the first stage is ending and the second stage is approaching. Women with increased sensitivity to touch may tolerate it better on surfaces of the body where hair does not grow, such as the forehead, the palms of the hands, and the soles of the feet.

Labor Support by the Father or Partner. Although a woman or a man other than the father may be the woman's partner, the father of the baby is usually the support person during labor. He is often able to provide the comfort measures and touch that the laboring woman needs. When the woman becomes focused on her pain, sometimes the partner can persuade her to try nonpharmacologic variations of comfort measures. In addition, he usually is able to interpret the woman's needs and desires for staff members.

The feelings of a first-time father change as labor progresses. Although he is often calm at the onset of labor, feelings of fear and helplessness begin to dominate as labor becomes more active and the father realizes that it is more stressful than he anticipated. A study of Swedish fathers' birth experiences found that although about three quarters of the men reported positive or very positive experiences, less positive experiences were associated with emergency cesarean birth, assisted vaginal birth, and dissatisfaction with their partners' medical care. The interactions of health care providers with the fathers and the fathers' perception of the health care providers' competence were also related to the fathers' birth experiences (Johansson, Rubertsson, Radestad, & Hildingsson, 2012). Staff members should tell the father that his presence is helpful and encourage him to be involved in the care of the woman to the extent to which he and his partner are comfortable. He should be reassured that he is not assuming the responsibility for observation and management of his partner's labor, but that his responsibility is to support her as the labor progresses. The nurse can suggest alternative comfort measures when those he is using are no longer helpful or are rejected by his partner.

The first-time father may feel excluded as birth preparations begin during the transition phase. Once the second stage begins and birth nears, the father's focus changes from the woman to the baby who is about to be born. The father will be exposed to many sights and smells he may never have experienced. Therefore, the nurse needs to tell him what to expect and make him comfortable about leaving the room to regain his composure should something occur that surprises him, but make sure that someone else is available to support the woman during his absence.

Nursing actions that support the father convey several important concepts: first, he is a person of value; second, he can be a partner in the woman's care; and third, childbearing is a team effort. Box 19-9 details ways in which the nurse can support the father-partner. A well-informed father can make an important contribution to the health and well-being of the mother and child, their family interrelationship, and his self-esteem.

Labor Support by Doulas. Continuity of care has been cited by women as a critical component of a satisfying childbirth

BOX 19-9 Guidelines for Supporting the Father*

- Orient him to the labor room and the unit; explain location of the cafeteria, toilet, waiting room, and nursery; give information about visiting hours; introduce personnel by name and describe their functions.
- Inform him of sights and smells he can expect; encourage him to leave the room if necessary.
- Respect his or the couple's decision about the degree of his involvement. Offer them freedom to make decisions.
- Tell him when his presence has been helpful, and continue to reinforce this throughout labor.
- Offer to teach him comfort measures; demonstrate or role-play these measures.
- Inform him frequently of the progress of the labor and the woman's needs. Keep him informed about procedures to be performed.
- Prepare him for changes in the woman's behavior and physical appearance.
- Remind him to eat; offer him snacks and fluids if possible.
- Relieve him of the job of support person as necessary. Offer him blankets if he is to sleep in a chair by the bedside.
- Acknowledge the stress experienced by each partner during labor and birth, and identify normal responses.
- Attempt to modify or eliminate unsettling stimuli, such as extra noise and extra light; create a relaxing and calm environment.

*These guidelines are appropriate for any support person or partner.

experience. A specially trained, experienced female labor attendant called a doula can meet this need. The doula is a professional or lay labor-support person who is present during labor in addition to the labor and birth nurse (Burke, 2014). The primary role of the doula is to focus on the laboring woman and to provide physical and emotional support by using soft, reassuring words of praise and encouragement; touching; stroking; and hugging. The doula also administers comfort measures to reduce pain and enhance relaxation and coping, walks with the woman, helps her to change positions, and coaches her bearing-down efforts. Doulas provide information about labor progress and explain procedures and events. They advocate for the woman's right to participate actively in managing her labor.

The doula also supports the woman's partner, who often feels unqualified to be the sole labor support and may find it difficult to watch the woman when she is experiencing pain. The doula can encourage and praise the partner's efforts, create a partnership as caregivers, and provide respite care. Doulas also facilitate communication between the laboring woman and her partner, as well as between the couple and the health care team (Simkin, 2012).

Doula support during labor is associated with decreased use of analgesia, decreased incidence of operative birth, increased incidence of spontaneous vaginal birth, and increased maternal satisfaction with the childbirth experience (Berghella et al., 2008).

The roles of the nurse and the doula are complementary. They should work together as a team, recognizing and respecting the role each plays in supporting and caring for the woman and her partner during the childbirth process. Both the nurse and the doula provide supportive care measures. The nurse also focuses on monitoring the status of the maternal-fetal unit,

implementing clinical care protocols (including pharmacologic interventions), and documenting assessment findings, actions, and responses (Simkin, 2012).

Labor Support by Grandparents. When grandparents act as labor coaches, it is especially important to support and treat them with respect. They may have ways to deal with pain based on their experience. Grandparents should be encouraged to help as long as their actions do not compromise the status of the mother or the fetus. The nurse treats grandparents with dignity and respect by acknowledging the value of their contributions to parental support and recognizing the difficulty parents have in witnessing the woman's discomfort or crisis. If they have never witnessed a birth, the nurse may need to provide explanations of what is happening. Many of the activities used to support fathers also are appropriate for grandparents (see Box 19-9).

Siblings During Labor and Birth

Preparing siblings for acceptance of the new child helps promote the attachment process and may help older children accept this change. The older child or children who know they are important to the family become active participants. Rehearsal for the event before labor is essential.

The age and developmental level of children influence their responses; therefore, preparation for the children to be present during labor is adjusted to meet each child's needs (see Box 14-2). The child younger than 2 years shows little interest in pregnancy and labor. However, for the older child, such preparation may reduce fears and misconceptions. Parents need to be prepared for labor and birth themselves and feel comfortable about the process and the presence of their children. Most parents have a "feel" for their children's maturational level and their physical and emotional ability to observe and cope with the events of the labor and birth process. Preparation can include a description of the anticipated sights, events (e.g., ROM, monitors, IV infusions), smells, and sounds; a labor and birth demonstration; a tour of the birthing unit; and an opportunity to be around a real newborn. Storybooks about the birth process can be read to or by children to prepare them for the event. Films are available for preparing preschool and school-age children to participate in the labor and birth experience. Children must learn that their mother will be working hard during labor and birth. She will not be able to talk to them during contractions. She may groan, scream, grunt, and pant at times as well as say things she would not say otherwise (e.g., "I can't take this anymore," "Take this baby out of me," or "This pain is killing me"). You can tell them that labor is uncomfortable, but that their mother's body is made for the job.

Most agencies require that a specific person be designated to watch over the children who are participating in their mother's childbirth experience, to provide them with support, explanations, diversions, and comfort as needed. Health care providers involved in attending women during birth must be comfortable with the presence of children and the unpredictability of their questions, comments, and behaviors.

Emergency Interventions

Although rare, emergency conditions that require immediate nursing intervention can arise with startling speed. See Chapter 18 for information on management of abnormal

FHR. Management of other emergency situations, including meconium-stained amniotic fluid, shoulder dystocia, prolapsed umbilical cord, ruptured uterus, and amniotic fluid embolus, is discussed in Chapter 32.

SECOND STAGE OF LABOR

The **second stage of labor** is the stage in which the infant is born. This stage begins with full cervical dilation (10 cm) and complete effacement (100%) and ends with the baby's birth. The force exerted by uterine contractions, gravity, and maternal bearing-down efforts facilitates achievement of the expected outcome of a spontaneous, uncomplicated vaginal birth. The median duration of second-stage labor is 50 to 60 minutes in nulliparous women and 20 to 30 minutes in multiparous women. In addition to parity, maternal size and fetal weight, position, and descent influence the length of this stage. The use of epidural anesthesia often increases the length of the second stage of labor because the epidural blocks or reduces the woman's urge to bear down and limits her ability to attain an upright position to push. The upper limits for the duration of normal second-stage labor are (Wing & Farinelli, 2012):

- Nulliparous women: 2 hours with no regional anesthesia use
3 hours with use of regional anesthesia
- Multiparous women: 1 hour with no regional anesthesia use
2 hours with regional anesthesia

A prolonged second stage is diagnosed after these time limits are reached. A thorough assessment of the status of the maternal-fetal unit should be made as well as a determination regarding the likely effectiveness and safety of further bearing-down efforts (Simpson et al., 2008).

The second stage of labor is composed of two phases: the latent phase and the active pushing phase. Maternal verbal and nonverbal behaviors, uterine activity, the urge to bear down, and fetal descent characterize these phases (Hanson, 2009; Simpson et al., 2008).

The **latent ("laboring down") phase** is a period of rest and relative calm. During this phase the fetus continues to descend passively through the birth canal and rotate to an anterior position as a result of ongoing uterine contractions. The woman is quiet and often relaxes with her eyes closed between contractions. The urge to bear down is not strong, and some women do not experience it at all or only during the acme (peak) of a contraction. Delayed pushing has been shown to result in significant decreases in pushing time, significant increases in the duration of second-stage labor, and a reduction in the number of operative vaginal births. On the other hand, no differences in the number of cesarean births, perineal lacerations or episiotomies, or fetal complications have been linked to delayed pushing (Kelly, Johnson, Lee, et al., 2010). In a randomized clinical trial, allowing a woman to rest during this phase and waiting until the urge intensified to begin pushing significantly reduced the amount of time spent pushing but did not significantly increase the total length of second-stage labor. In this study maternal fatigue scores, perineal injuries, and FHR decelerations were similar in the immediate- and delayed-pushing groups (Gillesby, Burns, Dempsey, et al., 2010). Another study also found a significant decrease in pushing time in nulliparous women with

epidural anesthesia who practiced delayed pushing during second-stage labor (Gillesby et al.).

Careful monitoring with assurance of normal fetal status should be used during delayed pushing. If descent is slow and the woman becomes anxious, she should be encouraged to change positions frequently or to stand by the bedside to use the advantage of gravity and movement to facilitate descent and progress to the active pushing phase signaled by a perception of the need to bear down (Hanson, 2009).

During the **active pushing (descent) phase** the woman has strong urges to bear down as the Ferguson reflex is activated when the presenting part presses on the stretch receptors of the pelvic floor. At this point the fetal station is usually +1 and the position is anterior. This stimulation causes the release of oxytocin from the posterior pituitary gland, which provokes stronger expulsive uterine contractions. The woman becomes more focused on bearing-down efforts, which become rhythmic. She changes positions frequently to find a more comfortable pushing position. The woman often announces the onset of contractions and becomes more vocal as she bears down. The urge to bear down intensifies as descent progresses and the presenting part reaches the perineum. The woman may be more verbal about the pain she is experiencing; she may scream or swear and may act out of control.

The nurse encourages the woman to "listen" to her body as she progresses through the phases of the second stage of labor. When a woman listens to her body to tell her when to bear down, she is using an internal locus of control and often feels more satisfied with her efforts to give birth to her baby. This enhances her sense of self-esteem and accomplishment and her efforts become more effective. Always encourage the woman's trust in her own body and her ability to give birth to her baby. Validate the woman's experience of pressure, stretching, and straining as normal and a signal that the descent of the fetus is progressing and that her body is capable of withstanding birth. Honestly explain what is happening and describe the progress being made.

CARE MANAGEMENT

Box 19-10 describes nursing care during the second stage of labor. The only certain objective sign that the second stage of labor has begun is the inability to feel the cervix during vaginal examination, indicating that the cervix is fully dilated and effaced. The precise moment that this occurs is not easily determined because it depends on when a vaginal examination is performed to validate full dilation and effacement. This makes timing of the actual duration of the second stage difficult. Other signs that suggest the onset of the second stage include the urge to push or feeling the need to have a bowel movement. These signs commonly appear at the time the cervix reaches full dilation. However, they can appear earlier in labor. Women with an epidural block may not exhibit such signs.

Women who are laboring without regional anesthesia can experience an irresistible urge to bear down before full dilation. For some, this occurs as early as 5 cm dilation. This is most often related to the station of the presenting part below the level of the ischial spines of the maternal pelvis. This occurrence creates a conflict between the woman, whose body is telling her to

BOX 19-10 Nursing Care in Second-Stage Labor**Assessment****Signs That Suggest the Onset of the Second Stage**

Urge to push or feeling need to have a bowel movement
 Sudden appearance of sweat on upper lip
 An episode of vomiting
 Increased bloody show
 Shaking of extremities
 Increased restlessness; verbalization (e.g., "I can't go on.")
 Involuntary bearing-down efforts

Physical Assessment

Assess every 5 to 30 minutes: maternal blood pressure, pulse, and respirations.
 Assess every 5 to 15 minutes, depending on risk status: fetal heart rate and pattern.
 Assess every 10 to 15 minutes: vaginal show, signs of fetal descent, and changes in maternal appearance, mood, affect, energy level, and condition of partner/coach.
 Assess every contraction and bearing-down effort.

Interventions**Latent ("Laboring Down") Phase**

Help to rest in a position of comfort; encourage relaxation to conserve energy.
 Promote progress of fetal descent and onset of urge to bear down by encouraging position changes, pelvic rock, ambulation, showering.

Active Pushing (Descent) Phase

Help to change position and encourage spontaneous bearing-down efforts.
 Help to relax and conserve energy between contractions.
 Provide comfort and pain-relief measures as needed.
 Cleanse perineum promptly if fecal material is expelled.
 Coach to pant during contractions and to gently push between contractions when head is emerging.
 Provide emotional support, encouragement, and positive reinforcement of efforts.
 Keep woman informed regarding progress.
 Create a calm and quiet environment.
 Offer mirror to watch birth.

push, and her health care providers, who may believe that pushing the fetal presenting part against an incompletely dilated cervix will result in cervical edema and lacerations, as well as slow the labor progress. Evaluate the premature urge to bear down as a sign of labor progress, possibly indicating the onset of the second stage of labor. Base the timing of when a woman pushes in relation to whether her cervix is fully dilated on research evidence rather than on tradition or routine practice. Pushing with the urge to bear down at the acme of a contraction may be safe and effective for a woman if her cervix is soft, retracting, and 8 cm or more dilated and if the fetus is at +1 station and rotating to an anterior position (Roberts, 2002).

Assessment continues during the second stage of labor. Professional standards and agency policy determine the specific type and timing of assessments, as well as the way in which findings are documented (see Box 19-10). Signs and symptoms of impending birth (Table 19-4) may appear unexpectedly, requiring immediate action by the nurse (Box 19-11).

The nurse continues to monitor maternal-fetal status and events of the second stage and provide comfort measures for the

mother. This includes helping her change position; providing mouth care; maintaining clean, dry bedding; and keeping extraneous noise, conversation, and other distractions (e.g., laughing, talking of attending personnel in or outside the labor area) to a minimum. The woman is encouraged to indicate other support measures she would like (see Table 19-3; Nursing Care Plan).

In the hospital, birth may occur in an LDR, LDRP, or delivery room. If the mother is to be transferred to the delivery room for birth, perform the transfer early enough to avoid rushing her. The birth area also is readied (see later discussion).

Preparing for Birth**Maternal Position**

No single position for childbirth exists. Labor is a dynamic, interactive process involving the woman's uterus, pelvis, and voluntary muscles. In addition, angles between the baby and the woman's pelvis constantly change as the infant turns and flexes down the birth canal. The woman may want to assume various positions for childbirth. She should be encouraged to change positions frequently and assisted in attaining and maintaining her position(s) of choice (Figs. 19-14 and 19-15). Supine, semirecumbent, or lithotomy positions are still widely used in Western societies despite evidence that an upright position shortens labor (Chang, Chou, Lin, et al., 2011).

Birth attendants play a major role in influencing a woman's choice of positions for birth, with nurse-midwives tending to advocate nonlithotomy positions (e.g., upright, lateral) for the second stage of labor. An upright position (walking, sitting, kneeling, or squatting) offers a number of advantages. Gravity can promote the descent of the fetus. Uterine contractions are generally stronger and more efficient in effacing and dilating the cervix, resulting in shorter labor (Blackburn, 2013; Lawrence et al., 2013; Zwelling, 2010). An upright position also is beneficial to the mother's cardiac output, thereby increasing perfusion of the uterus. The use of upright and lateral positions is also associated with less pain and perineal damage, fewer episiotomies and abnormal FHR patterns, and fewer operative vaginal births (Berghella et al., 2008; Chang et al., 2011; Simpson et al., 2008; Zwelling, 2010). The benefits of upright positions may be related to:

- Straightening of the longitudinal axis of the birth canal and improving the alignment of the fetus for passage through the pelvis
- Application of gravity to direct the fetal head toward the pelvic inlet, thereby facilitating descent
- Enlargement of pelvic dimensions and restriction of the encroachment of the sacrum and coccyx into the pelvic outlet
- Increased uteroplacental circulation, resulting in more intense, efficient uterine contractions
- Enhancement of the woman's ability to bear down effectively, thereby minimizing maternal exhaustion

Squatting is highly effective in facilitating the descent and birth of the fetus. It is one of the best and most natural positions for second stage labor and has been associated with the same benefits as other upright and lateral positions (Simpson et al., 2008). Women should assume a modified, supported squat until the fetal head is engaged, at which time a deep squat can be

TABLE 19-4 Expected Maternal Progress in the Second Stage of Labor

CRITERION	LATENT ("LABORING DOWN") PHASE (AVERAGE DURATION, 10-30 MINUTES)	ACTIVE PUSHING (DESCENT) PHASE (AVERAGE DURATION VARIES)*
Contractions		
Intensity	Period of physiologic lull for all criteria; period of peace and rest	Significant increase becoming overwhelmingly strong and expulsive
Frequency		Every 2 to 2.5 minutes progressing to every 1 to 2 minutes
Duration		90 seconds
Descent, station	0 to +2	+2 to +4; rate of descent increases and Ferguson reflex† is activated; fetal head becomes visible at introitus, and birth occurs
Show: color and amount		Significant increase in dark red bloody show; bloody show accompanies emergence of head
Spontaneous bearing-down efforts	Slight to absent, except at peak of strongest contractions	Increased urge to bear down, becomes stronger as fetus descends to vaginal introitus and reaches perineum
Vocalization	Quiet; concern over progress	Grunting sounds or expiratory vocalizations; announces contractions; may scream or swear
Maternal behavior	Experiences sense of relief that transition to second stage is finished Feels fatigued and sleepy Feels a sense of accomplishment and optimism because the "worst is over" Feels in control	Senses increased urge to push and describes increasing pain; describes <i>ring of fire</i> (burning sensation of acute pain as vagina stretches and fetal head crowns) Expresses feeling of powerlessness Shows decreased ability to listen to or concentrate on anything but giving birth Alters respiratory pattern: has short 4- to 5-second breath holds with regular breaths in between, 5 to 7 times per contraction Frequent repositioning Often shows excitement immediately after birth of head

*Duration of descent phase can vary, depending on maternal parity, effectiveness of bearing-down efforts, and presence of spinal anesthesia or epidural analgesia.

†Pressure of presenting part on stretch receptors of pelvic floor stimulates release of oxytocin from posterior pituitary, resulting in more intense uterine contractions.

Data from Hanson, L. (2009). Second-stage labor care. *Journal of Perinatal & Neonatal Nursing*, 23(1), 31-39; AWHONN. (2008). *Nursing care and management of the second stage of labor: Evidence-based clinical practice guideline* (2nd ed.). Washington, DC: Author; Roberts, J.E. (2002). The "push" for evidence: Management of the second stage. *Journal of Midwifery & Women's Health*, 1, 2-15; Simkin, P., & Anчета, R. (2000). *The labor progress*. Malden, MA: Blackwell Science.

used. A firm surface is required for this position, and the woman will need side support (see Fig. 19-11, A). In a birthing bed, a squat bar is available that she can use to help support herself (Fig. 19-15, E). A birth ball can also help a woman maintain the squatting position. The fetus will be aligned with the birth canal, and pelvic and perineal relaxation is facilitated as she sits on the ball or holds it in front of her for support as she squats (see Box 19-8).

When a woman uses the supported standing position for bearing down, her weight is borne on both femoral heads, allowing the pressure in the acetabulum to cause the transverse diameter of the pelvic outlet to increase by up to 1 cm. This can be helpful if descent of the head is delayed because the occiput has not rotated from the lateral (transverse diameter of pelvis) to the anterior position. Birthing chairs or rocking chairs may be used to provide women with a good physiologic position to enhance bearing-down efforts during childbirth (see Box 19-8), although some women may feel restricted by a chair. The upright position also provides a potential psychologic advantage in that it allows the mother to see the birth as it occurs and to maintain eye contact with the attendant.

Oversized beanbag chairs and large floor pillows can be used for both labor and birth. They can mold around and support the mother in whatever position she selects. These chairs are of particular value for mothers who wish to be actively involved in the birth process. Birthing stools can be used to support the woman in an upright position similar to squatting. Some women may feel more comfortable sitting on the toilet or commode during pushing because they are concerned about stool incontinence during this stage. Encourage them to empty their bladder to avoid the effects of a distended bladder. You must closely monitor these women, however, and ask them to move

from the toilet before birth becomes imminent. Because sitting on chairs, stools, toilets, or commodes can increase perineal edema and blood loss, assist the woman to change her position frequently (e.g., every 10 to 15 minutes).

The side-lying, or lateral, position, with the upper part of the woman's leg held by the nurse or coach or placed on a pillow, is an effective position for the second stage of labor (see Fig. 19-14, A, and Box 19-8). Some women prefer a semisitting (semirecumbent) position instead (see Fig. 19-15, B, and Box 19-8). If the semirecumbent position is used, do not force the woman's legs against her abdomen as she bears down. This position will increase perineal stretching and the risk for perineal trauma as well as spinal and lower extremity neurologic injuries (Simpson & O'Brien-Abel, 2014; Simpson et al., 2008). The hands-and-knees position is yet another effective position for birth (see Fig. 19-10, B, and Box 19-8).

The birthing bed can be set for different positions according to the woman's needs (see Fig. 19-15; Fig. 19-16). The woman can squat, kneel, sit, recline, or lie on her side, choosing the position most comfortable for her without having to climb into bed for the birth. At the same time, the birthing bed provides excellent access and visualization for the attendant to perform examinations, place electrodes, and assist the woman giving birth. You can position the bed for the administration of anesthesia and it is ideal to help women receiving an epidural to assume different positions to facilitate birth. You can also use the bed to transport the woman to the operating room if a cesarean birth is necessary. The woman can use squat bars, over-the-bed tables, birth balls, and pillows for support.

BOX 19-11 Guidelines for Assistance at the Emergency Birth of a Fetus in the Vertex Presentation

1. The woman usually assumes the position most comfortable for her. A lateral position is often recommended to facilitate a controlled birth of the head, thereby minimizing the risk for perineal trauma and neonatal head injury.
2. Reassure the woman that birth is usually uncomplicated in these situations. Use eye-to-eye contact and a calm, relaxed manner. If there is someone else available, such as the partner, that person could help support the woman in the position, assist with coaching, and provide positive reinforcement and praise of her efforts.
3. Wash your hands and put on gloves, if available.
4. Place under the woman's buttocks whatever clean material is available.
5. Avoid touching the vaginal area to decrease the possibility of infection.
6. As the head begins to crown, you should perform the following tasks:
 - a. Tear the amniotic membranes if they are still intact.
 - b. Instruct the woman to pant or pant-blow, thus minimizing the urge to push.
 - c. Place the flat side of your hand on the exposed fetal head and apply *gentle* pressure toward the vagina to prevent the head from "popping out." The mother may participate by placing her hand under yours on the emerging head. **Note:** Rapid birth of the fetal head must be prevented because a rapid change of pressure within the molded fetal skull follows, which may result in dural or subdural tears. Rapid birth also may cause vaginal or perineal lacerations.
7. After the birth of the head, check to see if the umbilical cord is around the baby's neck. If it is, *gently* try to slip it over the baby's head or pull it *gently* to get some slack so that you can slip it over the shoulders.
8. Support the baby's head as external rotation occurs. Then with one hand on each side of the baby's head, exert *gentle* pressure downward so that the anterior shoulder emerges under the symphysis pubis and acts as a fulcrum; then, as *gentle* pressure is exerted upward, the posterior shoulder, which has passed over the sacrum and coccyx, emerges.
9. Be alert! Hold the baby securely because the rest of the body may emerge quickly. The baby will be slippery!
10. Cradle the baby's head and back in one hand and the buttocks in the other. Keep the baby's head down to drain away the mucus. Use a bulb syringe, if needed, to remove mucus from the baby's mouth and then from the nose.
11. Dry the baby quickly to prevent rapid heat loss and immediately place the baby on the mother's abdomen. Keep the baby at the same level as the mother's uterus until the cord stops pulsating. **Note:** The baby should be kept at the same level as the mother's uterus to prevent the baby's blood from flowing to or from the placenta and resulting in hypovolemia or hypervolemia. Also, do not "milk" the cord.
12. With the baby on the mother's abdomen, cover the baby (remember to keep the head warm, too) with a warmed blanket or the mother's clothing, and have her cuddle the baby. Compliment her (them) on a job well done, and on the baby, if appropriate.
13. Wait for the placenta to separate. *Do not* tug on the cord. **Note:** Inappropriate traction may tear the cord, separate the placenta, or invert the uterus. Signs of placental separation include a slight gush of dark blood from the introitus, lengthening of the cord, and change in the uterine contour from a discoid to globular shape.
14. Instruct the mother to push to deliver the separated placenta. Gently ease out the placental membranes using an up-and-down motion until the membranes are removed. If birth occurs outside a hospital setting, to minimize complications, do not cut the cord without proper clamps and a sterile cutting tool. Inspect the placenta for intactness. Place the baby on the placenta and wrap the two together for additional warmth.
15. Check the firmness of the uterus. Gently massage the fundus and demonstrate to the mother how she can massage her own fundus properly.
16. If supplies are available, clean the mother's perineal area and apply a peripad.
17. In addition to gentle massage of the fundus, the following measures can be taken to prevent or minimize hemorrhage:
 - a. Put the baby to the mother's breast as soon as possible. Sucking or nuzzling and licking the nipple stimulates the release of oxytocin from the posterior pituitary. **Note:** If the baby does not or cannot nurse, manually stimulate the mother's nipples.
 - b. Do not allow the mother's bladder to become distended. Assess the bladder for fullness and encourage her to void if fullness is found.
 - c. Expel any clots from the mother's uterus after ensuring that the fundus is firm.
18. Comfort or reassure the mother and her family or friends. Keep the mother and the baby warm. Give her fluids if available and tolerated.
19. If there is more than one baby, identify the infants in order of birth (using letters A, B, etc.).
20. Make notations regarding the following aspects of the birth:
 - a. Fetal presentation and position
 - b. Presence of cord around neck (nuchal cord) or other parts and number of times cord encircled part
 - c. Color, character, and estimated amount of amniotic fluid, if rupture of membranes occurred immediately before birth
 - d. Time of birth
 - e. Estimated time of determination of Apgar score (e.g., 1 and 5 minutes after birth), resuscitation efforts implemented, and ultimate condition of baby
 - f. Gender of baby
 - g. Time of placental expulsion, as well as the appearance and completeness of the placenta
 - h. Maternal condition: affect, behavior, and demeanor, amount of bleeding, and status of uterine tonicity
 - i. Any unusual occurrences during the birth (e.g., maternal or paternal response, verbalizations, or gestures in response to birth of baby)

Bearing-Down Efforts

As the fetal head reaches the pelvic floor, most women experience the urge to bear down. Reflexively the woman will begin to exert downward pressure by contracting her abdominal muscles while relaxing her pelvic floor. This bearing down is an involuntary response to the Ferguson reflex. A strong expiratory

grunt or groan (vocalization) often accompanies pushing when the woman exhales as she pushes. This natural vocalization by women during open-glottis bearing-down efforts should not be discouraged.

When coaching women to push, encourage them to push as they feel like pushing (instinctive, spontaneous pushing)

FIG 19-14 A, Pushing, side-lying position. Perineal bulging can be seen. B, Pushing, semisitting position. Nurse-midwife assists mother to feel top of fetal head. (A, Courtesy Michael S. Clement, MD, Mesa, AZ. B, Courtesy Roni Wernik, Palo Alto, CA.)

rather than to give a prolonged push on command (directed, closed-glottis pushing). Prolonged breath-holding, or sustained, directed bearing down is still a common practice, often beginning at 10-cm dilation and before the urge to bear down is perceived. The woman is coached to hold her breath, closing her glottis, and to push while the nurse or partner counts to 10. This method of bearing down is strongly discouraged because it may trigger the **Valsalva maneuver**, which occurs when the woman closes her glottis (closed-glottis pushing), which increases intrathoracic and cardiovascular pressure. This reduces cardiac output and decreases perfusion of the uterus and the placenta. Adverse effects associated with prolonged breath-holding and forceful pushing efforts include fetal hypoxia and subsequent acidosis, increased risk for pelvic floor damage (structural and neurogenic), and perineal trauma (Blackburn, 2013; Hanson, 2009; Simpson & O'Brien-Abel, 2014; Simpson et al., 2008). The benefits of spontaneous pushing efforts rather than sustained Valsalva pushes include less fatigue and enhanced comfort. In addition, these more effective bearing-down efforts result in less time spent actively pushing (Hanson, 2009; James, 2011; Simpson & O'Brien-Abel, 2014). Based on this evidence, it is essential that labor and birth nurses advocate for the practice of delayed and spontaneous bearing-down efforts with the woman in an upright or lateral position (Hanson, 2009).

A woman can become confused and anxious when she is being told to do something in conflict with what her body is telling her. Using phrases such as “You are doing so well; do it again,” “You are moving the baby down,” and “Follow what your body is telling you,” rather than “Push, push, push,” encourages a woman to feel confident in her body and what she is feeling (Hanson, 2009).

Monitor the woman’s breathing so that she does not hold her breath for more than 6 to 8 seconds at a time followed by a slight exhale (a combination of open-glottis and voluntary

closed-glottis pushing). Remind her to ventilate her lungs fully by taking deep cleansing breaths before and after each contraction. Bearing down while exhaling (open-glottis pushing) and taking breaths between bearing-down efforts help to maintain adequate oxygen levels for the mother and fetus, thus enhancing fetal well-being. The active pushing phase of the second stage of labor is considered to be the most physiologically stressful part of labor. Therefore, every effort should be made to ensure that women use nondirected spontaneous pushing to conserve energy and maximize the effect of each bearing-down effort. A woman’s bearing-down efforts naturally will become more forceful and frequent as the second stage progresses to birth (Simpson et al., 2008).

A woman may reach the second stage of labor and then experience a lack of readiness to complete the process and give birth to her baby. She may have doubts about her readiness to be a mother or may desire to wait for her support person or nurse-midwife or physician to arrive. Fear, anxiety, or embarrassment regarding unfamiliar or painful sensations and behaviors during pushing (e.g., sounds made, passage of stool) may be other inhibiting factors. Fear that the baby will be in danger once it emerges from the protective intrauterine environment also may be present. By recognizing that a woman may experience a need to hold back the birth of her baby, you can address the woman’s concerns and effectively coach her during this stage of labor.

To ensure the slow birth of the fetal head, encourage the woman to control the urge to bear down by coaching her to take panting breaths or exhale slowly through pursed lips as the baby’s head crowns. At this point the woman needs simple, clear directions from one person. Amnesia between contractions often occurs in the second stage of labor; therefore, you may have to rouse the woman to get her to cooperate in the bearing-down process. Parents who have attended childbirth

FIG 19-15 The versatility of today's birthing bed makes it practical in a variety of settings. **NOTE:** Obstetric (OB) table used for lithotomy position. **A,** Labor bed. **B,** Birth chair. **C,** Birth bed. **D,** OB table. **E,** Squatting or birth bar. education classes may have devised a set of verbal cues for the laboring woman to follow.

Fetal Heart Rate and Pattern

As noted, you must check the fetal heart rate regularly (see Chapter 18 for further discussion). If the baseline rate begins to slow, if absent or minimal variability occurs, or if deceleration patterns (e.g., late, variable, or prolonged decelerations) develop, initiate interventions promptly. Turn the woman onto her side to reduce the pressure of the uterus against the ascending vena cava and descending aorta (see Fig. 19-5). Oxygen can be administered by nonrebreather mask at 10 L/min

(Miller et al., 2013). These interventions are often all that is necessary to restore a normal pattern. If the FHR and pattern do not become normal immediately, notify the nurse-midwife or physician because the woman may need medical intervention to give birth. See Chapter 18 for more interventions related to abnormal FHR.

Support of the Father or Partner

During the second stage the woman needs continuous support and coaching (see Table 19-4 and Box 19-10). Because the coaching process is often physically and emotionally tiring for support persons, the nurse offers them nourishment and

fluids and encourages them to take short breaks as needed (see Box 19-9). If birth occurs in an LDR or LDRP room, the support person usually wears street clothes. Instruct the support person who attends the birth in a delivery or operating room to put on a cover gown or scrub clothes, mask, hat, and shoe covers, if required by agency policy. The nurse also specifies support measures that can be used for the laboring woman and points out areas of the room in which the partner can move freely.

Encourage partners to be present at the birth of their infants if doing so is in keeping with their cultural and personal expectations and beliefs. The presence of partners maintains the psychologic closeness of the family unit, and the partner can continue to provide the supportive care given during labor. The woman and her partner need to have an equal opportunity to initiate the attachment process with the baby.

LEGAL TIP: Documentation

Documentation of all observations (e.g., maternal vital signs, FHR and pattern, progress of labor) and nursing interventions, including the woman's response, should be done concurrent with care. The course of labor and the maternal-fetal response may change without warning. All documentation must be accurate, complete, timely, and according to agency policy.

Supplies, Instruments, and Equipment

To prepare for birth in any setting, the birthing table is usually set up during the transition phase of first stage labor for nulliparous women and during the active phase for multiparous women.

Prepare the birthing bed or table, and arrange instruments on the instrument table or delivery cart (Fig. 19-17). Follow standard procedures for gloving, identifying and opening sterile packages, adding sterile supplies to the instrument table, unwrapping sterile instruments, and handing them to the nurse-midwife or physician. Ready the crib or radiant warmer and equipment for the support and stabilization of the infant (Fig. 19-18).

The items used for birth may vary among different facilities; therefore, consult each facility's procedure manual to determine the protocols specific to that facility.

The nurse estimates the time until the birth will occur and notifies the nurse-midwife or physician if he or she is not in the woman's room. Even the most experienced nurse can miscalculate the time left before birth occurs; therefore, every nurse who attends a woman in labor must be prepared to assist with an emergency birth if the physician or nurse-midwife is not present (see Box 19-11).

Birth in a Delivery Room or Birthing Room

The woman will need assistance if she must move from the labor bed to the delivery table (Fig. 19-19). The various positions assumed for birth in a delivery room are the Sims or lateral

FIG 19-17 Instrument table. (Courtesy Marjorie Pyle, RNC, Life-circle, Costa Mesa, CA.)

FIG 19-16 Birth bed. (Courtesy Hill-Rom, Batesville, IN.)

position in which the attendant supports the upper part of the woman's leg, the dorsal position (supine position with one hip elevated), and the lithotomy position.

The lithotomy position makes dealing with some complications that arise more convenient for the nurse-midwife or physician (see Fig. 19-15, D). To place the woman in this position, bring her buttocks to the edge of the bed or table and place her legs in stirrups. Take care to pad the stirrups, to raise and place both legs simultaneously, and to adjust the shanks of the stirrups so that the calves of the legs are supported. No pressure should be placed on the popliteal space. Stirrups that are not the same height will strain ligaments in the woman's back as she bears down, leading to considerable discomfort in the postpartum period. The lower portion of the table may be dropped down and rolled back under the table.

The maternal position for birth in a birthing room varies from a lithotomy position with the woman's feet in stirrups or resting on footrests or with her legs held and supported by the nurse or support person, to one in which her feet rest on footrests while she holds on to a squat bar, to a side-lying position with the woman's upper leg supported by the coach, nurse, or squat bar. Once the woman is positioned, the foot of the bed is removed so that the nurse-midwife or physician attending the birth can gain better perineal access for performing an episiotomy, delivering a large baby, using forceps or vacuum extractor, or getting access to the emerging head to facilitate suctioning. Alternately, the foot of the bed can be left in place and lowered

FIG 19-19 Delivery room. (Courtesy Michael S. Clement, MD, Mesa, AZ.)

slightly to form a ledge that allows access for birth and serves as a place to lay the newborn (see Fig. 19-15, A).

Once the woman is positioned for birth either in a delivery room or birthing room, the vulva and perineum are cleansed. Hospital or birthing center protocols and the preferences of nurse-midwives or physicians for cleansing may vary.

The nurse continues to coach and encourage the woman and monitor the fetal status. Keep the nurse-midwife or physician informed of the FHR and pattern. Prepare or obtain an oxytocic medication such as oxytocin (Pitocin) so that it is ready to be administered immediately after expulsion of the placenta. Always follow Standard Precautions as care is administered during the process of labor and birth (see Box 19-4).

In the hospital delivery room, the nurse-midwife or physician may put on a cap, a mask that has a shield or protective eyewear, and shoe covers. After washing hands, the provider puts on a sterile gown (with waterproof front and sleeves) and sterile gloves. Nurses attending the birth also may need to wear caps, protective eyewear, masks, gowns, and gloves. The woman may then be draped with sterile drapes. In the birthing room, Standard Precautions are observed, but the amount and types of protective coverings worn by those in attendance may vary.

Maintain contact with the parents by touching, verbal comforting, describing progress, explaining the reasons for care, and sharing in the parents' joy at the birth of their baby.

Mechanism of Birth: Vertex Presentation. The three phases of the spontaneous birth of a fetus in a vertex presentation are (1) birth of the head, (2) birth of the shoulders, and (3) birth of the body and extremities (see Chapter 16).

With voluntary bearing-down efforts, the head appears at the introitus (Fig. 19-20, A to D). **Crowning** occurs when the widest part of the head (the biparietal diameter) distends the vulva just before birth. Immediately before birth, the perineal musculature becomes greatly distended. If an **episiotomy** (incision into the perineum to enlarge the vaginal outlet) is necessary, it is done at this time to minimize soft-tissue damage. A local anesthetic may be administered if necessary before performing an episiotomy. Box 19-12 shows the process of normal vaginal childbirth using a series of photographs.

The physician or nurse-midwife may use a hands-on approach to control the birth of the head, believing that guarding the perineum results in a gradual birth that will prevent fetal intracranial injury, protect maternal tissues, and reduce

FIG 19-21 Birth of head with modified Ritgen maneuver. Note control to prevent too-rapid birth of head.

postpartum perineal pain. This approach involves (1) applying pressure against the rectum, drawing it downward to aid in flexing the head as the back of the neck catches under the symphysis pubis; (2) applying upward pressure from the coccygeal region (modified *Ritgen maneuver*) (Fig. 19-21) to extend the head during the actual birth, thereby protecting the musculature of the perineum; and (3) assisting the mother with voluntary control of the bearing-down efforts by coaching her to pant while letting uterine forces expel the fetus.

Some health care providers use a hands-poised (hands-off) approach when attending a birth. In this approach, hands are prepared to place light pressure on the fetal head to prevent rapid expulsion. The provider does not place hands on the perineum or use them to assist with birth of the shoulders and body.

The hands-on and hands-poised approaches have similar results in terms of perineal and vaginal tears, but the hands-on technique is associated with a higher incidence of third-degree tears and episiotomies. In one study the hands-poised approach resulted in fewer third-degree tears (Berghella et al., 2008). However, the hands-on approach may result in less perineal pain.

The umbilical cord often encircles the neck (nuchal cord) but rarely so tightly as to cause hypoxia. After the head is born, gentle palpation is used to feel for the cord. If present, the health care provider slips the cord gently over the head if possible. If

the loop is tight or if there is a second loop, he or she will probably clamp the cord twice, cut between the clamps, and unwind the cord from around the neck before the birth is allowed to continue. Mucus, blood, or meconium in the nasal or oral passages may prevent the newborn from breathing. To eliminate this problem, moist gauze sponges are used to wipe the nose and mouth. A bulb syringe may be inserted first into the mouth and oropharynx and then into both nares to aspirate contents.

Fundal Pressure. Fundal pressure is the application of gentle, steady pressure against the fundus of the uterus to facilitate the vaginal birth. Use of fundal pressure by nurses is *not* advised because there is no standard technique available for this maneuver. Historically it has been used when the administration of analgesia and anesthesia decreased the woman's ability to push during the birth, in cases of shoulder dystocia, and when second-stage fetal bradycardia or other abnormal FHR patterns were present. However, no legal, professional, or regulatory standards exist for its use and no evidence related to its effectiveness in facilitating a safe vaginal birth is available (Simpson et al., 2008).

Immediate Assessments and Care of the Newborn

The time of birth is the precise time when the entire body is out of the mother and must be recorded. In the case of multiple births, each birth is noted in the same way. If the newborn's condition is not compromised, he or she should be dried and placed on the mother's abdomen immediately after birth and covered with a warm, dry blanket. The cord may be clamped at this time, and the nurse-midwife or physician may ask if the woman's partner would like to cut the cord. If so, the partner is given a sterile pair of scissors and instructed to cut the cord 1 inch (2.5 cm) above the clamp.

The care given immediately after the birth focuses on assessing and stabilizing the newborn. AWHONN (2010) recommends that at least two nurses be present for each birth. One nurse is responsible for care of the newborn while the other nurse assists the nurse-midwife or physician with delivery of the placenta and care of the mother. The "baby nurse" must watch the infant for any signs of distress and initiate appropriate interventions. AWHONN also recommends that, in cases of multiple births, each baby has his own nurse (AWHONN).

Perform a brief assessment of the newborn immediately while the mother is holding the infant. This assessment includes assigning Apgar scores at 1 and 5 minutes after birth (see Table 24-1). Maintaining a patent airway, supporting respiratory effort, and preventing cold stress by drying and, preferably, covering the newborn with a warmed blanket while on his mother's abdomen skin-to-skin or, less optimally, placing him or her under a radiant warmer are the major priorities in terms of the newborn's immediate care. You can postpone further examination, identification procedures, and care until later in the third stage of labor or early in the fourth stage.

Perineal Trauma Related to Childbirth

Most acute injuries and lacerations of the perineum, vagina, uterus, and their support tissues occur during childbirth. Alternative measures for perineal management, such as application of warm compresses and gentle perineal massage and stretching have been suggested to lessen the degree of perineal lacerations

and trauma. Perineal massage during the last month of pregnancy has clear benefits of reducing perineal trauma during birth and pain afterward for women who had not given birth vaginally before. A Cochrane review found that warm compresses during the second stage of labor may be beneficial in reducing the incidence of third- and fourth-degree lacerations (Aasheim, Nilsen, Lukasse, & Reinar, 2011).

Some degree of trauma to the soft tissues of the birth canal and adjacent structures occurs during every birth. The tendency to sustain lacerations varies with each woman; that is, the soft tissue in some women may be less distensible. Damage usually is more pronounced in nulliparous women because the tissues are firmer and more resistant than are those in multiparous women. Heredity is also a factor. For example, the tissue of light-skinned women, especially those with reddish hair, is not as readily distensible as that of darker-skinned women, and healing may be less efficient. Other risk factors associated with perineal trauma include maternal nutritional status, birth position, pelvic anatomy (e.g., narrow subpubic arch with a constricted outlet), fetal malpresentation and position (e.g., breech, occiput posterior position), large (macrosomic) infants, use of forceps or vacuum to facilitate birth, prolonged second-stage labor, and rapid labor in which there is insufficient time for the perineum to stretch.

Some injuries to the supporting tissues, whether they are acute or nonacute and whether they were repaired or not, may lead to genitourinary and sexual problems later in life (e.g., pelvic relaxation, uterine prolapse, cystocele, rectocele, dyspareunia, urinary and bowel dysfunction) (see Chapter 11). Performing Kegel exercises in the prenatal and postpartum periods improves and restores the tone and strength of the perineal muscles (see Chapter 4, Teaching for Self-Management box: Kegel Exercises). Health practices, including good nutrition and appropriate hygienic measures, help maintain the integrity and suppleness of the perineal tissues, enhance healing, and prevent infection.

Perineal Lacerations. Perineal lacerations usually occur as the fetal head is being born. The extent of the laceration is defined in terms of its depth (Cunningham, Leveno, Bloom, et al., 2014):

First degree: Laceration that extends through the skin and vaginal mucous membrane but not the underlying fascia and muscle

Second degree: Laceration that extends through the fascia and muscles of the perineal body, but not the anal sphincter

Third degree: Laceration that involves the external anal sphincter

Fourth degree: Laceration that extends completely through the rectal mucosa, disrupting both the external and internal anal sphincters

Perineal injury often is accompanied by small lacerations on the medial surfaces of the labia minora below the pubic rami and to the sides of the urethra (periurethral) and clitoris. Lacerations in this highly vascular area often result in profuse bleeding. Third- and fourth-degree lacerations must be carefully repaired so that the woman retains fecal continence. Simple perineal injuries usually heal without permanent disability, regardless of whether they were repaired. However, repairing a new perineal injury to prevent future complications is easier than correcting long-term damage.

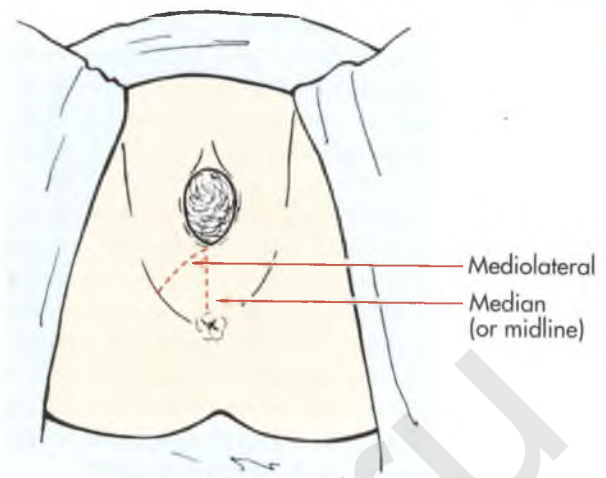

FIG 19-22 Types of episiotomies.

Vaginal and Urethral Lacerations. Vaginal lacerations often occur in conjunction with perineal lacerations. Vaginal lacerations tend to extend up the lateral walls (sulci) and, if deep enough, involve the levator ani muscle. Additional injury may occur high in the vaginal vault near the level of the ischial spines. Vaginal vault lacerations are often circular and may result from use of forceps to rotate the fetal head, rapid fetal descent, or precipitous birth.

Cervical Injuries. Cervical injuries occur when the cervix retracts over the advancing fetal head. These cervical lacerations occur at the lateral angles of the external os. Most lacerations are shallow and bleeding is minimal. Larger lacerations may extend to the vaginal vault or beyond it into the lower uterine segment; serious bleeding may occur. Extensive lacerations may follow hasty attempts to enlarge the cervical opening artificially or to deliver the fetus before full cervical dilation is achieved. Injuries to the cervix can have adverse effects on future pregnancies and childbirths.

Episiotomy. An episiotomy is an incision in the perineum used to enlarge the vaginal outlet (Fig. 19-22). Its use has steadily declined in recent years due to a lack of sound, rigorous research to support its benefits. Episiotomies are performed in approximately 10% of births in the United States (Martin, Hamilton, Ventura, et al., 2011). This practice is even less common in Europe and Canada, probably because of the more routine use in those countries of the side-lying position for birth. This position places less tension on the perineum, making possible a gradual stretching of the perineum with fewer indications for episiotomy. Whenever possible, giving birth over an intact perineum provides the best outcomes (e.g., less blood loss, less risk of infection, and less postpartum pain).

Different types of episiotomies may be performed, classified by the site and direction of the incision (see Fig. 19-22); the type that provides the best outcome is unknown (Berghella et al., 2008). Midline (median) episiotomy is most commonly used in the United States. It is effective, easily repaired, and generally the least painful. However, midline episiotomies also are associated with a higher incidence of third- and fourth-degree lacerations (Cunningham et al., 2014). Sphincter tone is usually restored after primary healing and a good repair. Medioloateral episiotomy is used in operative births when the need for

posterior extension is likely. Although a fourth-degree laceration may be prevented, a third-degree laceration may occur. The blood loss is also greater and the repair more difficult and painful than with midline episiotomies (Cunningham et al.). It is also more painful in the postpartum period, and the pain lasts longer.

An increasingly common practice in many settings now is to support the perineum manually during birth rather than performing an episiotomy with the goal of minimizing trauma. If tears occur, they are often smaller than an episiotomy, are repaired easily or do not need to be repaired at all, and heal quickly with less pain. Episiotomies are associated with more posterior perineal trauma, suturing and healing complications, and later pain with intercourse. Therefore, episiotomy should be avoided whenever possible (Berghella et al., 2008).

THIRD STAGE OF LABOR

The **third stage of labor** lasts from the birth of the baby until the placenta is expelled.

CARE MANAGEMENT

The goal in the management of the third stage of labor is the prompt separation and expulsion of the placenta, achieved in the easiest, safest manner. The third stage is generally by far the shortest stage of labor. The placenta is usually expelled within 10 to 15 minutes after the birth of the baby. If the third stage has not been completed within 30 minutes, the placenta is considered to be retained and interventions to hasten its separation and expulsion are usually instituted (Wing & Farinelli, 2012).

Under normal circumstances the placenta is attached to the decidual layer of the basal plate's thin endometrium by numerous fibrous anchor villi—much in the same way a postage stamp is attached to a sheet of postage stamps. After the birth of the fetus, strong uterine contractions and the sudden decrease in uterine size cause the placental site to shrink. This causes the anchor villi to break and the placenta to separate from its attachments. Normally the first few strong contractions that occur after the baby's birth cause the placenta to shear away from the basal plate. A placenta cannot detach itself from a flaccid (relaxed) uterus because the placental site is not reduced in size.

Placental Separation and Expulsion

Depending on preference, the nurse-midwife or physician may use either a passive or an active approach to manage the third stage of labor. Passive management involves patiently watching for signs that the placenta has separated from the uterine wall spontaneously and monitoring for spontaneous expulsion. This approach is commonly practiced in the United States (Burke, 2010). Active management of third-stage labor is practiced in many countries around the world. Components of active management include administering an oxytocic medication (e.g., oxytocin [Pitocin]) when the anterior shoulder is birthed or immediately following the birth of the fetus, clamping and cutting the umbilical cord within 3 minutes after birth, and gently controlling cord traction following uterine contraction and separation of the placenta. Evidence-based literature and the

World Health Organization now recommend active management of the third stage of labor because its use decreases the rate of postpartum hemorrhage caused by uterine atony (Burke, 2010; Cunningham et al., 2014).

To assist in the delivery of the placenta, the woman is instructed to push when signs of separation have occurred (Fig. 19-23). If possible, the woman should expel the placenta during a uterine contraction. Alternate compression and elevation of the fundus along with minimal, controlled traction on the umbilical cord may also be used to facilitate delivery of the placenta and amniotic membranes. Oxytocics are usually administered after the placenta is removed when active management of third stage labor is not implemented because they stimulate the uterus to contract, thereby helping to prevent hemorrhage (Box 19-13).

Whether the placenta first appears by its shiny fetal surface (Schultze mechanism) or turns to show its dark roughened maternal surface first (Duncan mechanism) is of no clinical importance.

After the placenta and the amniotic membranes emerge, the nurse-midwife or physician examines them for intactness to ensure that no portion remains in the uterine cavity (i.e., no fragments of the placenta or membranes are retained) (Fig. 19-24). At this time the nurse will obtain a sample of blood from the umbilical cord to be used for determining the baby's blood type and Rh status. Some parents will also have made arrangements to have blood from the cord collected for storage and possible future use.

When the third stage of labor has been completed the nurse-midwife or physician examines the woman for any perineal, vaginal, or cervical lacerations requiring repair. The nurse may need to assist by providing adequate lighting or exposure of the woman's perineum and vagina so that a thorough examination can be performed. If an episiotomy was performed, it will be sutured. Immediate repair promotes healing, limits residual damage, and decreases the possibility of infection. The woman usually feels some discomfort while the nurse-midwife or physician carries out the postbirth vaginal examination. Help the woman to use breathing and relaxation or distraction techniques to assist her in dealing with the discomfort. During this time the "baby nurse" performs a quick assessment of the newborn's physical condition and places matching identification bands on baby and mother. Weighing the baby, eye prophylaxis, and a vitamin K injection can be delayed until after the initial bonding time with the parents.

After any necessary repairs have been completed, cleanse the vulvar area gently with warm water or normal saline, and apply a perineal pad or an ice pack to the perineum. Reposition the birthing bed or table, and lower the woman's legs simultaneously from the stirrups if she gave birth in a lithotomy position. Remove any drapes, and place dry linen under the woman's buttocks. Provide her with a clean gown and a blanket, which is warmed, if needed.

Some women and their families may have culturally based beliefs regarding the care of the placenta and the manner of its disposal after birth, viewing the care and disposal of the placenta as a way of protecting the newborn from bad luck and illness. In Spanish the placenta is referred to as *el compañero* or "the companion" of the child (Callister, 2014). A request by the woman to take the placenta home and dispose of it according to her

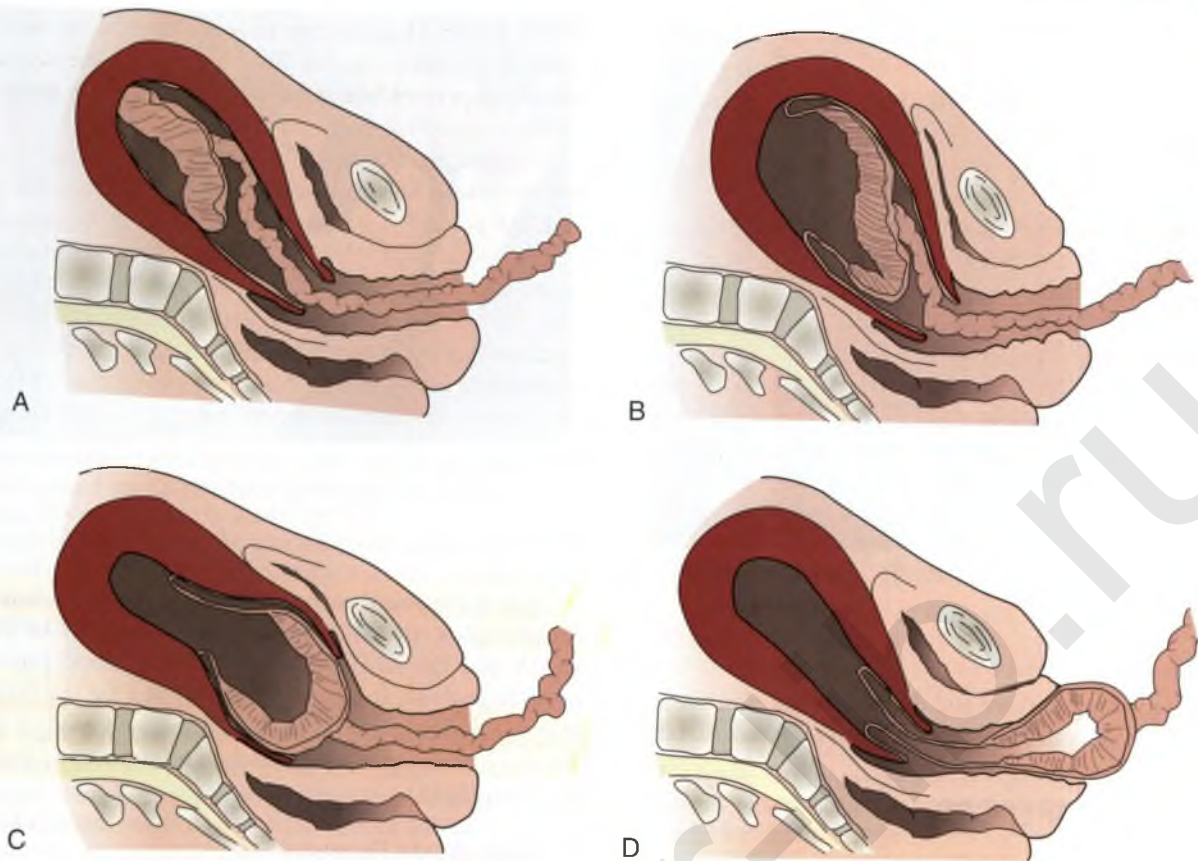

FIG 19-23 Third stage of labor. **A**, Placenta begins to separate in central portion, accompanied by retroplacental bleeding. Uterus changes from discoid to globular shape. **B**, Placenta completes separation and enters lower uterine segment. Uterus has globular shape. **C**, Placenta enters vagina, cord is seen to lengthen, and there may be an increase in bleeding. **D**, Expulsion (delivery) of placenta and completion of third stage.

BOX 19-13 Nursing Care in Third-Stage Labor

Assessment

Signs That Suggest the Onset of the Third Stage

- A firmly contracting fundus
- A change in the uterus from a discoid to a globular ovoid shape as the placenta moves into the lower uterine segment
- A sudden gush of dark blood from the introitus
- Apparent lengthening of the umbilical cord as the placenta descends to the introitus
- The finding of vaginal fullness (the placenta) on vaginal or rectal examination or of fetal membranes at the introitus

Physical Assessment

- Assess every 15 minutes: maternal blood pressure, pulse, and respirations.
- Assess for signs of placental separation and amount of bleeding.
- Assist with determination of Apgar score at 1 and 5 minutes after birth (see Table 24-1).
- Assess maternal and paternal response to completion of child-birth process and their reaction to the newborn.

Interventions

- Assist to bear down to facilitate expulsion of the separated placenta.
- Administer an oxytocic medication as ordered to ensure adequate contraction of the uterus, thereby preventing hemorrhage.
- Provide nonpharmacologic and pharmacologic comfort and pain relief measures.
- Perform hygienic cleansing measures.
- Keep mother/partner informed of progress of placental separation and expulsion and perineal repair if appropriate.
- Explain purpose of medications administered.
- Introduce parents to their baby and facilitate the attachment process by delaying eye prophylaxis; wrap mother and baby together for skin-to-skin contact.
- Provide private time for parents to bond with new baby; help them create memories.
- Encourage breastfeeding if desired.

customs sometimes conflicts with health care agency policies, especially those related to infection control and the disposal of biologic wastes. Many cultures follow specific rules regarding the disposal of the placenta in terms of method (burning, drying, burying, eating), site for disposal (in or near the home), and timing of disposal (immediately after birth, time of day, astrologic

signs). Disposal rituals may vary according to the gender of the child and the length of time before another child is desired. Some cultures believe that eating the placenta is a means of restoring a woman's well-being after birth or ensuring high-quality breast milk. Health care providers can provide culturally sensitive health care by encouraging women and their families to express

FIG 19-24 Examination of the placenta. (Courtesy Michael S. Clement, MD, Mesa, AZ.)

their wishes regarding the care and disposal of the placenta and by establishing a policy to fulfill these requests (D'Avanzo, 2008).

FOURTH STAGE OF LABOR

The first 1 to 2 hours after birth, sometimes called the **fourth stage of labor**, is a crucial time for mother and newborn. Both are not only recovering from the physical process of birth but also becoming acquainted with each other and additional family members. During this time maternal organs undergo their initial readjustment to the nonpregnant state, and the functions of body systems begin to stabilize.

CARE MANAGEMENT

In most hospitals the mother remains in the labor and birth area during this recovery time. In an institution where LDR rooms are used, the woman stays in the same room where she gave birth. In traditional settings women are taken from the delivery room to a separate recovery area for observation. Arrangements for care of the newborn vary during the fourth stage of labor. In many settings the baby remains with the mother, and the labor or birth nurse cares for both of them. In other institutions the baby is taken to the nursery for several hours of observation after an initial bonding period with the parents, siblings, and perhaps other family members (Fig. 19-25).

Assessment

If the recovery nurse has not previously cared for the new mother, he or she begins with an oral report from the nurse who attended the woman during labor and birth and a review of the prenatal, labor, and birth records. Of primary importance are conditions that could predispose the mother to hemorrhage, such as precipitous labor, a large baby, grand multiparity (i.e., having given birth to five or more viable infants), or induced labor. For healthy women, hemorrhage is the most dangerous potential complication during the fourth stage of labor.

FIG 19-25 Big brother becomes acquainted with new baby sister. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

During the fourth stage of labor the mother is assessed frequently (Box 19-14). The American Academy of Pediatrics (AAP) and the ACOG recommend that blood pressure and pulse be assessed at least every 15 minutes for the first 2 hours after birth. Temperature should be assessed every 4 hours for the first 8 hours after birth and then at least every 8 hours (AAP & ACOG, 2012).

Postanesthesia Recovery

The woman who has given birth by cesarean or has received regional anesthesia for a vaginal birth requires special attention during the recovery period. Obstetric recovery areas are held to the same standard of care that would be expected of any other postanesthesia recovery (PAR) unit (AAP & ACOG, 2012). A PAR score is determined for each woman on arrival and is updated as part of every 15-minute assessment. Components of the PAR score include activity, respirations, blood pressure, level of consciousness, and color.

If the woman received general anesthesia, she should be awake and alert and oriented to time, place, and person. Her respiratory rate should be within normal limits, and her oxygen saturation level at least 95%, as measured by a pulse oximeter. If the woman received epidural or spinal anesthesia, she should be able to raise her legs, extended at the knees, off the bed, or flex her knees, place her feet flat on the bed, and raise her buttocks well off the bed. The numb or tingling, prickly sensation should be entirely gone from her legs. The length of time required to recover from regional anesthesia varies greatly. Often it takes several hours for these anesthetic effects to disappear completely.

SAFETY ALERT

Regardless of her obstetric status, no woman should be discharged from the recovery area until she has completely recovered from the effects of anesthesia.

Nursing Interventions

Care of the New Mother

If food and fluids were restricted, especially if excessive fluid loss occurred during labor and birth (blood, perspiration, or

BOX 19-14 Assessment During the Fourth Stage of Labor**Blood Pressure**

- Measure blood pressure every 15 minutes for the first 2 hours.

Pulse

- Assess rate and regularity. Measure every 15 minutes for the first 2 hours.

Temperature

- Determine temperature at the beginning of the recovery period. Temperature should then be assessed every 4 hours for the first 8 hours after birth and then at least every 8 hours.

Fundus

- Position woman with knees flexed and head flat.
- Just below umbilicus, cup hand and press firmly into abdomen. At the same time, stabilize the uterus at the symphysis with the opposite hand (see Fig. 20-1).
- If fundus is firm (and bladder is empty), with uterus in midline, measure its position relative to woman's umbilicus. Lay fingers flat on abdomen under umbilicus; measure how many fingerbreadths (fb) or centimeters (cm) fit between umbilicus and top of fundus. Fundal height is documented according to agency guidelines. For example, if the fundus is 1 fb or 1 cm above the umbilicus, fundal height may be recorded as either +1, u+1, or 1/u. If the fundus is 1 fb or 1 cm below the umbilicus, fundal height may be recorded as either -1, u-1, or u/1.
- If fundus is not firm, massage it gently to contract and expel any clots before measuring distance from umbilicus.
- Place hands appropriately; massage gently only until firm.
- Expel clots while keeping hands placed as in Figure 20-1. With upper hand, firmly apply pressure downward toward vagina; observe perineum for amount and size of expelled clots.

Bladder

- Assess distention by noting location and firmness of uterine fundus and by observing and palpating bladder. A distended bladder is seen as a suprapubic rounded bulge that is dull to percussion and fluctuates like a water-filled balloon. When the bladder is distended, the uterus is usually boggy in consistency, well above the umbilicus, and to the woman's right side.
- Assist woman to void spontaneously. Measure amount of urine voided.
- Catheterize as necessary.
- Reassess after voiding or catheterization to make sure the bladder is not palpable and the fundus is firm and in the midline.

Lochia

- Observe lochia on perineal pads and on linen under the mother's buttocks. Determine amount and color; note size and number of clots; note odor.
- Observe perineum for source of bleeding (e.g., episiotomy, lacerations).

Perineum

- Ask or assist woman to turn onto her side and flex upper leg on hip.
- Lift upper buttock.
- Observe perineum in good lighting.
- Assess episiotomy or laceration repair for redness (erythema), edema, ecchymosis (bruising), drainage, and approximation (REEDA).
- Assess for presence of hemorrhoids.

emesis), the woman will be very hungry and thirsty soon after birth. In the absence of complications, a woman who has given birth vaginally may have fluids and a regular diet as soon as she desires (AAP & ACOG, 2012). In the immediate postpartum period, women who give birth by cesarean are usually restricted to clear liquids and ice chips.

As soon as they have had a chance to bond with the baby and eat, most new mothers are ready for a nap or at least a quiet period of rest. Following this rest period, the woman may want to shower and change clothes. Most new mothers are capable of self-management or are assisted in these activities by family members or support persons.

Care of the Family

Most parents enjoy being able to hold, explore, and examine the baby immediately after birth. Both parents can assist with thoroughly drying the infant. Usually the infant is wrapped in a receiving blanket and given to the mother or father/partner to hold. Skin-to-skin contact is encouraged. The nurse places the unwrapped infant on the woman's chest or abdomen and then covers the baby and mother with a warm blanket. Holding the newborn next to her skin helps the mother maintain the baby's body heat and provides skin-to-skin contact. Stockinette caps are often used to keep the newborn's head warm and prevent heat loss.

Many women wish to begin breastfeeding their newborns at this time to take advantage of the infant's alert state (*first period*

of reactivity) and to stimulate the production of oxytocin that promotes contraction of the uterus and prevents hemorrhage. In Baby Friendly hospitals, breastfeeding is initiated within the first hour after birth, and any unnecessary separation of mother and baby is strongly discouraged. However, some women prefer to wait to breastfeed until they have had time to rest. Be aware that in some cultures breastfeeding is not acceptable to some women until the milk comes in. In the Hispanic culture, for example, the colostrum is thought to be bad or old milk (Callister, 2014). Therefore, women may wait several days after giving birth before initiating breastfeeding.

Family-Newborn Relationships. The woman's reaction to the sight of her newborn may range from excited outbursts of laughing, talking, and even crying, to apparent apathy. A polite smile and nod may be her only acknowledgment of the comments of nurses and the nurse-midwife or physician. Occasionally the reaction is one of anger or indifference; the woman turns away from the baby, concentrates on her own pain, and sometimes makes hostile comments. These varied reactions can arise from pleasure, exhaustion, or deep disappointment. When evaluating parent-newborn interactions after birth, the nurse should consider the cultural characteristics of the woman and her family and the expected behaviors of that culture. In some cultures the birth of a male child is preferred, and women may grieve when a female child is born (Callister, 2014).

CLINICAL REASONING CASE STUDY

Encouraging Skin-to-Skin Contact Immediately After Birth

A nurse returning from international travel during which she was able to observe childbirth in different cultures noted that generally babies were cradled naked on the mother's abdomen or chest immediately after birth. She noted that the babies were calm, breastfed readily, and had stable vital signs. She also noted that the nurses respected the time that mothers and babies spent together and delayed any unnecessary interventions until at least an hour after birth.

The nurse approached her unit manager to discuss what she learned regarding how skin-to-skin contact immediately following birth promotes, protects, and supports well-being, attachment, and breastfeeding. The manager expressed great interest, and asked the nurse to present an in-service program for the medical and nursing staff regarding this issue as a first step in implementing skin-to-skin contact. What should this nurse include in her in-service program to convince the medical and nursing staff that there is evidence to support skin-to-skin contact immediately following birth and that delaying unnecessary interventions can be safe and effective for women and their newborns?

1. Evidence—Is there sufficient evidence to support the safety and effectiveness of immediate skin-to-skin contact?
2. Assumptions—What assumptions can be made about the following issues related to skin-to-skin contact?
 - a. Benefits of an approach that promotes, protects, and supports skin-to-skin contact
 - b. Management approaches that should be emphasized during the labor and birth
 - c. Necessity of gaining the support of both the medical and nursing staff to effectively implement this change in practice on the unit.
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

Whatever the reaction and its cause, the woman needs continuing acceptance and support from all staff. Make a notation regarding the parents' reaction to the newborn in the recovery record. Assess this reaction by asking yourself such questions as, "How do the parents look?" "What do they say?" "What do they do?" Conduct further assessment of the parent-newborn relationship as you give care during the period of recovery. This assessment is especially important if you notice warning signs (e.g., passive or hostile reactions to the newborn, disappointment with gender or appearance of the newborn, absence of eye contact, or limited interaction of parents with each other) immediately after birth. Nurses should discuss any warning signs with the woman's nurse-midwife or physician.

Siblings, who may have appeared only remotely interested in the final phases of the second stage, tend to experience renewed interest and excitement when the newborn appears. They can be encouraged to hold the baby (see Fig. 19-25).

Parents usually respond to praise of their newborn. Many need to be reassured that the dusky appearance of their baby's hands and feet immediately after birth is normal until circulation is well established. If appropriate, explain the reason for the molding of the newborn's head. Communicate information about hospital routine. Recognize, however, that the cultural background of the parents may influence their expectations regarding the care and handling of their newborn immediately after birth. For example, Korean mothers may believe that the head should not be touched because it is the most sacred part of a person's body. Hispanic mothers may believe that the "evil eye" or too much praise of the baby will cause illness, restlessness, or excessive crying (Callister, 2014). Hospital staff members, by their interest and concern, can provide the environment for making this a satisfying experience for parents, family, and significant others.

KEY POINTS

- The onset of labor may be difficult to determine for both nulliparous and multiparous women.
- The familiar environment of her home is most often the ideal place for a woman during the latent phase of the first stage of labor.
- The nurse assumes much of the responsibility for assessing the progress of labor and for keeping the nurse-midwife or physician informed about that progress and deviations from expected findings.
- The fetal heart rate and pattern reveal the fetal response to the stress of the labor process.
- Assessing the laboring woman's urinary output and bladder is critical to ensure her progress and to prevent bladder injury.
- Regardless of the actual labor and birth experience, the woman's or couple's perception of the birth experience is most likely to be positive when events and performances are consistent with expectations, especially in terms of maintaining control and adequacy of pain relief.
- The woman's level of anxiety may increase when she does not understand what is being said to her about her labor because of the medical terminology used or because of a language barrier.
- Coaching, emotional support, and comfort measures assist the woman to use her energy constructively in relaxing and working with the contractions.
- The progress of labor is enhanced when a woman changes her position frequently during the first stage of labor.
- Doula's provide a continuous, supportive presence during labor that can have a positive effect on the process of childbirth and its outcome.
- The cultural beliefs and practices of a woman and her significant others, including her partner, can have a profound influence on their approach to labor and birth.
- Siblings present for labor and birth need preparation and support for the event.
- Women with a history of sexual abuse often experience profound stress and anxiety during childbirth.
- Inability to palpate the cervix during vaginal examination indicates that complete effacement and full dilation have occurred and is the only certain, objective sign that the second stage has begun.
- Women may have an urge to bear down at various times during labor; for some it may be before the cervix is fully dilated and for others it may not occur until the active phase of the second stage of labor.

KEY POINTS—cont'd

- When encouraged to respond to the rhythmic nature of the second stage of labor, the woman normally changes body positions, bears down spontaneously, and vocalizes (open-glottis pushing) when she perceives the urge to push (Ferguson reflex).
- Women should bear down several times during a contraction using the open-glottis pushing method. They should avoid sustained closed-glottis pushing because this will inhibit oxygen transport to the fetus.
- Nurses can use the role of advocate to prevent routine use of episiotomy and reduce the incidence of lacerations by empowering women to take an active role in their birth and

- by educating health care providers about approaches to managing childbirth that reduce the incidence of perineal trauma.
- Objective signs indicate that the placenta has separated and is ready to be expelled; excessive traction (pulling) on the umbilical cord before the placenta has separated can result in maternal injury.
- During the fourth stage of labor, the woman's fundal tone, lochial flow, and vital signs should be assessed frequently to ensure that she is physically recovering well after giving birth.
- Most parents and families enjoy being able to hold, explore, and examine the baby immediately after the birth.

Postpartum Physiologic Changes

Kathryn R. Alden

© <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Describe the anatomic and physiologic changes that occur during the postpartum period.
- Discuss characteristics of uterine involution and lochial flow and describe ways to measure them.
- List expected values for vital signs and blood pressure, deviations from normal findings, and probable causes of the deviations.

The postpartum period is the interval between birth and the return of the reproductive organs to their normal nonpregnant state. This period is sometimes referred to as the **puerperium**, or *fourth trimester of pregnancy*. Although the puerperium has traditionally been considered to last 6 weeks, this time frame varies among women. The physiologic changes that occur during the reversal of the processes of pregnancy are distinctive, but they are normal. To provide care during the recovery period that is beneficial to the mother, her infant, and her family, the nurse must synthesize knowledge of maternal anatomy and physiology of the recovery period, the newborn's physical and behavioral characteristics, infant care activities, and the family's response to the birth. This chapter focuses on anatomic and physiologic changes that occur in the mother during the postpartum period.

REPRODUCTIVE SYSTEM AND ASSOCIATED STRUCTURES

Uterus

Involution Process

The return of the uterus to a nonpregnant state after birth is called **involution**. This process begins immediately after expulsion of the placenta with contraction of the uterine smooth muscle.

At the end of the third stage of labor, the uterus is in the midline, approximately 2 cm below the level of the umbilicus, with the fundus resting on the sacral promontory. At this time the uterus weighs approximately 1000 g.

Within 12 hours the fundus can rise to approximately 1 cm above the umbilicus (Fig. 20-1). By 24 hours after birth the uterus is about the same size as it was at 20 weeks of gestation. Involution progresses rapidly during the next few days. The

fundus descends 1 to 2 cm every 24 hours. By the sixth postpartum day the fundus is normally located halfway between the umbilicus and the symphysis pubis. The uterus should not be palpable abdominally after 2 weeks and should have returned to its nonpregnant location by 6 weeks after birth (Blackburn, 2013).

The uterus, which at full term weighs approximately 11 times its prepregnancy weight, involutes to approximately 500 g by 1 week after birth and to 350 g by 2 weeks after birth. At 6 weeks postpartum, it weighs 60 to 80 g.

Increased estrogen and progesterone levels are responsible for stimulating the massive growth of the uterus during pregnancy. Prenatal uterine growth results from both hyperplasia (an increase in the number of muscle cells) and hypertrophy (an enlargement of the existing cells). After birth the decrease in these hormones causes **autolysis**—the self-destruction of excess hypertrophied tissue. The additional cells laid down during pregnancy remain and account for the slight increase in uterine size after each pregnancy.

Subinvolution is the failure of the uterus to return to a nonpregnant state. The most common causes of subinvolution are retained placental fragments and infection (see Chapter 33).

Contractions

Postpartum hemostasis is achieved primarily by compression of intramyometrial blood vessels as the uterine muscle contracts rather than by platelet aggregation and clot formation. The hormone *oxytocin*, released from the pituitary gland, strengthens and coordinates these uterine contractions, which compress blood vessels and promote hemostasis. During the first 1 to 2 postpartum hours, uterine contractions can decrease in intensity and become uncoordinated. Because it is vital that the uterus remains firm and well contracted, exogenous oxytocin

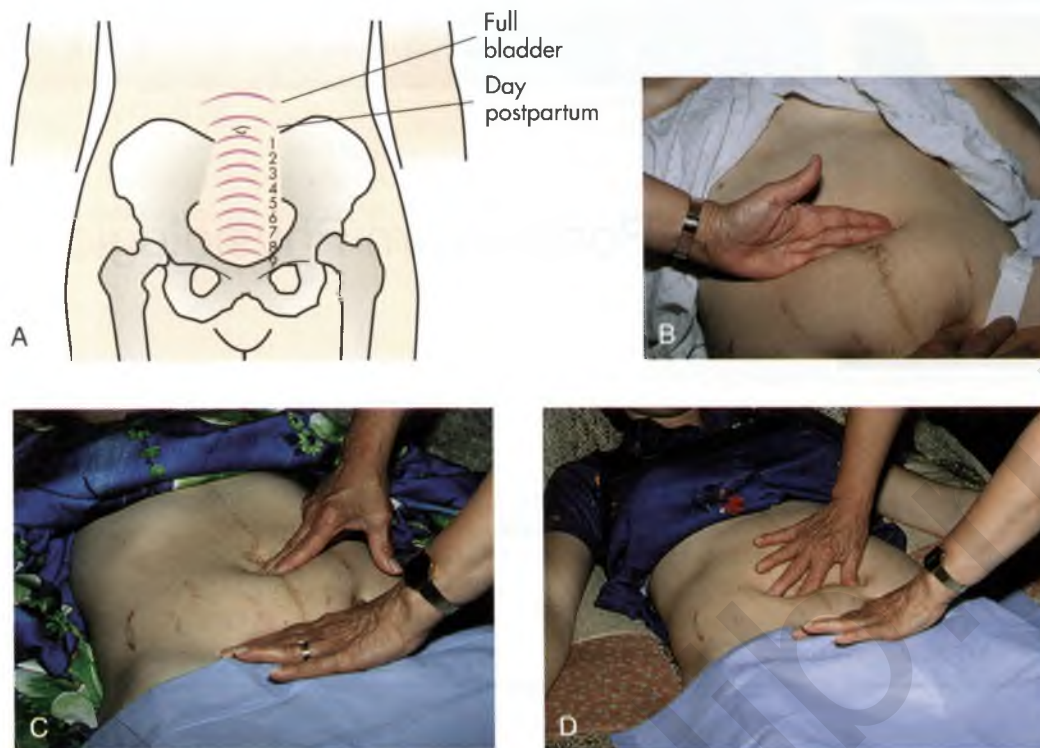

FIG 20-1 Assessment of involution of uterus after birth. A, Normal progress, days 1 through 9. B, Size and position of uterus 2 hours after birth. C, Two days after birth. D, Four days after birth. (B through D, Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

(Pitocin) is usually administered intravenously or intramuscularly immediately after expulsion of the placenta. The uterus is very sensitive to oxytocin during the first week or so after birth. Breastfeeding immediately after birth and in the early days postpartum increases the release of oxytocin, which decreases blood loss and reduces the risk for postpartum hemorrhage (Lawrence & Lawrence, 2011).

In first-time mothers uterine tone is good, the fundus generally remains firm, and the woman usually perceives only mild uterine cramping. Periodic relaxation and vigorous contractions are more common in subsequent pregnancies and can cause uncomfortable cramping called **afterpains** (afterbirth pains), which typically resolve in 3 to 7 days. Afterpains are more noticeable after births in which the uterus was overdistended (e.g., macrosomic infant, multifetal gestation, polyhydramnios). Breastfeeding and exogenous oxytocic medication usually intensify these afterpains because both stimulate uterine contractions.

Placental Site

Immediately after the placenta and membranes are expelled, vascular constriction and thromboses reduce the placental site to an irregular nodular and elevated area. Upward growth of the endometrium causes sloughing of necrotic tissue and prevents the scar formation characteristic of normal wound healing. This unique healing process enables the endometrium to resume its usual cycle of changes and permit implantation and placentation in future pregnancies. Endometrial regeneration is completed by postpartum day 16, except at the placental site. Regeneration at the placental site usually is not complete until 6 weeks after birth (Blackburn, 2013).

Lochia

Postbirth uterine discharge, commonly called **lochia**, initially is bright red (lochia rubra) and may contain small clots. For the first 2 hours after birth the amount of uterine discharge should be about that of a heavy menstrual period. After that time the lochial flow should steadily decrease.

Lochia rubra is dark red and consists mainly of blood and decidual and trophoblastic debris. The flow pales, becoming pink or brown (**lochia serosa**) after 3 to 4 days. Lochia serosa consists of old blood, serum, leukocytes, and tissue debris. In most women, about 10 to 14 days after birth the drainage becomes yellow to white (**lochia alba**). Lochia alba consists of leukocytes, decidua, epithelial cells, mucus, serum, and bacteria. Lochia can persist up to 4 to 8 weeks after birth. If the woman receives an oxytocic medication, regardless of the route of administration, the flow of lochia is often scant until the effects of the medication wear off. The amount of lochia is usually less after a cesarean birth because the surgeon suctions the blood and fluids from the uterus or wipes the uterine lining before closing the incision. Flow of lochia usually increases with ambulation and breastfeeding. Lochia tends to pool in the vagina when the woman is lying in bed; the woman then can experience a gush of blood when she stands. This gush should not be confused with hemorrhage.

Persistence of lochia rubra in the postpartum period suggests continued bleeding as a result of retained fragments of the placenta or membranes. It is not uncommon for women to experience a sudden, but brief, increase in bleeding 7 to 14 days after birth when sloughing of eschar over the placental site occurs. If this increase in bleeding does not subside within 1 to 2 hours, the woman needs to be evaluated for possible retained placental fragments (Katz, 2012).

BOX 20-1 Lochial and Nonlochia Bleeding**Lochia Bleeding**

Lochia usually trickles from the vaginal opening. The steady flow is greater as the uterus contracts.

A gush of lochia can appear as the uterus is massaged. If it is dark in color, it has been pooled in the relaxed vagina, and the amount soon lessens to a trickle of bright red lochia (in the early puerperium).

Nonlochia Bleeding

If the bloody discharge spurts from the vagina, and the uterus is firmly contracted, there can be cervical or vaginal tears in addition to the normal lochia.

If the amount of bleeding continues to be excessive and bright red, a tear can be the source.

About 10% to 15% of women still have normal lochia serosa discharge at their 6-week postpartum examination (Katz, 2012). However, the continued flow of lochia serosa or lochia alba by 3 to 4 weeks after birth can indicate endometritis, particularly if the woman has fever, pain, or abdominal tenderness. Lochia should smell like normal menstrual flow; an offensive odor usually indicates infection.

Not all postpartal vaginal bleeding is lochia; vaginal bleeding after birth can be caused by unrepaired vaginal or cervical lacerations. Box 20-1 distinguishes between lochia and nonlochia bleeding.

Cervix

The cervix is soft immediately after birth. The ectocervix (portion of the cervix that protrudes into the vagina) appears bruised and has some small lacerations, creating optimal conditions for the development of infection. Over the next 12 to 18 hours it shortens and becomes firmer. The cervical os, which dilated to 10 cm during labor, closes gradually. Within 2 to 3 days postpartum, it has shortened, become firm, and regained its form. The cervix up to the lower uterine segment remains edematous, thin, and fragile for several days after birth. By the second or third postpartum day, the cervical dilation has decreased to 2 to 3 cm, and by 1 week after birth, it is approximately 1 cm dilated (Blackburn, 2013). The external cervical os never regains its prepregnancy appearance; it no longer has a circular shape but, instead, appears as a jagged slit often described as a “fish mouth” (see Fig. 13-2). Lactation delays the production of cervical and other estrogen-influenced mucus and affects mucosal characteristics.

Vagina and Perineum

Postpartum estrogen deprivation is responsible for the thinness of the vaginal mucosa and the absence of rugae. The smooth-walled vagina that was greatly distended during birth gradually decreases in size and regains tone, although it never completely returns to its prepregnancy state. Rugae reappear within 3 weeks, but they are never as prominent as in the nulliparous woman. Most rugae are permanently flattened. The mucosa remains atrophic in the lactating woman, at least until menstruation resumes. Thickening of the vaginal mucosa occurs with the return of ovarian function. Estrogen deficiency is responsible for a decreased amount of vaginal lubrication; vaginal

dryness is more prevalent among breastfeeding mothers. Localized dryness and coital discomfort (dyspareunia) can persist until ovarian function returns and menstruation resumes. The use of a water-soluble lubricant during sexual intercourse is usually recommended.

Immediately after birth the introitus is erythematous and edematous, especially in the area of an episiotomy or laceration repair. It is barely distinguishable from that of a nulliparous woman if lacerations or an episiotomy have been carefully repaired, hematomas are prevented or treated early, and the woman practices good hygiene during the first 2 weeks after birth.

Most episiotomies and laceration repairs are visible only if the woman is lying on her side with her upper buttock raised or if she is placed in the lithotomy position. A good light source is essential for visualization of some repairs. Healing of an episiotomy or laceration is the same as any surgical incision. Signs of infection (pain, redness, warmth, swelling, or discharge) or lack of approximation (separation of the edges of the incision) can occur. Initial healing occurs within 2 to 3 weeks, but 4 to 6 months can be required for the repair to heal completely (Blackburn, 2013). If forceps were used for the birth, the woman may have experienced vaginal or cervical lacerations; hematomas of the pelvic soft tissues can also occur with forceps-assisted birth (see Chapter 32).

Hemorrhoids (anal varicosities) are commonly seen. Internal hemorrhoids can evert while the woman is pushing during birth. Women often experience associated symptoms such as itching, discomfort, and bright red bleeding with defecation. Hemorrhoids usually decrease in size within 6 weeks of childbirth.

Pelvic Muscular Support

The supporting structure of the uterus and vagina can be injured during birth; this can contribute to later gynecologic problems. Supportive tissues of the pelvic floor that are torn or stretched during birth can require up to 6 months to regain tone. Kegel exercises, which help strengthen perineal muscles and encourage healing, are recommended after birth (see Teaching for Self-Management: Kegel Exercises, Chapter 4). Later in life, women can experience pelvic relaxation—the lengthening and weakening of the fascial supports of pelvic structures. These structures include the uterus, upper posterior vaginal wall, urethra, bladder, and rectum. Although relaxation can occur in any woman, it is commonly a direct but delayed complication of birth (see Chapter 11).

ENDOCRINE SYSTEM**Placental Hormones**

Significant hormonal changes occur during the postpartum period. Expulsion of the placenta results in dramatic decreases in the hormones produced by that organ.

Estrogen and progesterone levels drop markedly after expulsion of the placenta and reach their lowest levels 1 week after birth. Decreased estrogen levels are associated with the diuresis of excess extracellular fluid accumulated during pregnancy. In nonlactating women, estrogen levels begin to increase by 2 weeks after birth and by postpartum day 17 are higher than in women who breastfeed (Katz, 2012).

Human chorionic gonadotropin (hCG) disappears fairly quickly from maternal circulation. However, because removing hCG from the extravascular and intracellular spaces takes

additional time, the hormone can be detected in the maternal system for 3 to 4 weeks after birth (Blackburn, 2013).

Metabolic Changes

Decreases in human chorionic somatomammotropin (formerly called *human placental lactogen*), estrogens, cortisol, and the placental enzyme *insulinase* reverse the diabetogenic effects of pregnancy, resulting in significantly lower blood glucose levels in the immediate puerperium. Mothers with type 1 diabetes will likely require much less insulin for several days after birth. Because these normal hormonal changes make the puerperium a transitional period for carbohydrate metabolism, it is more difficult to interpret results of glucose tolerance tests at this time.

Thyroid volume gradually returns to normal by 3 months after birth. Levels of thyroxine and triiodothyronine decrease to prepregnant levels within 4 weeks. There is an increased risk of a transient autoimmune thyroiditis in the postpartum period (Katz, 2012).

The basal metabolic rate remains elevated for the first 1 to 2 weeks after birth (James, 2014). It gradually returns to prepregnancy levels.

Pituitary Hormones and Ovarian Function

Prolactin levels in blood rise progressively throughout pregnancy. After birth, as levels of progesterone decrease, prolactin levels increase. In a woman who breastfeeds, prolactin levels are highest during the first month after birth and remain elevated above nonpregnant levels as long as she is breastfeeding. Serum prolactin levels are influenced by the frequency of breastfeeding, the duration of each feeding, and the degree to which supplementary feedings are used. Individual differences in the strength of an infant's sucking stimulus also affect prolactin levels. In nonlactating women, prolactin levels decline after birth and reach the prepregnant range by the third postpartum week (Katz, 2012).

Lactating and nonlactating women differ considerably in the timing of their first ovulation and when menstruation resumes. Ovulation occurs as early as 27 days after birth in nonlactating women, with a mean time of about 7 to 9 weeks. About 70% of nonbreastfeeding women resume menstruating by 12 weeks after birth. The mean time to ovulation in women who breastfeed is about 6 months (Katz, 2012). The persistence of elevated serum prolactin levels in breastfeeding women appears to be responsible for suppressing ovulation. In lactating women both the resumption of ovulation and the return of menses are determined in large part by breastfeeding patterns. For example, ovulation is delayed longer in women who breastfeed exclusively compared with women who breastfeed and offer supplemental infant formula to their infants. Because of the uncertainty about the return of ovulation and menstruation, discussion of contraceptive options early in the puerperium is necessary. The first menstrual flow after birth is usually heavier than normal. Within three or four cycles, the amount of menstrual flow returns to the prepregnancy volume.

URINARY SYSTEM

The hormonal changes of pregnancy (i.e., high steroid levels) contribute to an increase in renal function; diminishing steroid levels after birth may partly explain the reduced renal function

that occurs during the puerperium. Kidney function returns to normal within 1 month after birth. About 6 to 8 weeks are required for the pregnancy-induced hypotonia and dilation of the ureters and renal pelves to return to the nonpregnant state. In a small percentage of women dilation of the urinary tract can persist for 3 months or longer, increasing the risk of developing a urinary tract infection.

Urine Components

The renal glycosuria induced by pregnancy disappears by 1 week postpartum, but lactosuria can occur in lactating women. The blood urea nitrogen increases during the puerperium as autolysis of the involuting uterus occurs. Plasma creatinine levels return to normal by 6 weeks postpartum. Pregnancy-associated proteinuria resolves by 6 weeks after birth (Blackburn, 2013). Ketonuria can occur in women with an uncomplicated birth or after a prolonged labor with dehydration.

Fluid Loss

Within 12 hours of birth women begin to lose excess tissue fluid accumulated during pregnancy. Postpartal diuresis, caused by decreased estrogen levels, removal of increased venous pressure in the lower extremities, and loss of the remaining pregnancy-induced increase in blood volume, aids the body in ridding itself of excess fluid. Urine output of 3000 ml or more each day during the first 2 to 3 days is common. Profuse diaphoresis often occurs, especially at night, for the first 2 to 3 days after birth. Fluid loss through perspiration and increased urinary output accounts for a weight loss of approximately 2.25 kg (5 lb) during the early puerperium.

Urethra and Bladder

Birth-induced trauma, increased bladder capacity after birth, and the effects of conduction anesthesia can result in a decreased urge to void. In addition, pelvic soreness caused by the forces of labor, vaginal or perineal lacerations, or episiotomy can reduce or alter the voiding reflex. Decreased voiding combined with postpartal diuresis can result in bladder distention.

Immediately after birth, excessive bleeding can occur if the bladder becomes distended because it pushes the uterus up and to the side and prevents it from contracting firmly. Later in the puerperium, overdistention can make the bladder more susceptible to infection and impede the resumption of normal voiding. With adequate bladder emptying, bladder tone is usually restored by 5 to 7 days after birth.

Some women experience *stress incontinence* during the postpartum period. This is more likely to occur after vaginal than cesarean birth. Stress incontinence can be related to tissue trauma to the pelvic floor occurring with maternal expulsive efforts and increased size of the neonate. Coached pushing versus uncoached (non-Valsalva) pushing can increase the risk of damage to the pelvic floor and subsequent stress incontinence (James, 2014) (see Chapter 11).

GASTROINTESTINAL SYSTEM

Most new mothers are very hungry after full recovery from analgesia, anesthesia, and fatigue. Requests for extra portions of food and frequent snacks are common.

A spontaneous bowel evacuation may not occur for 2 to 3 days after birth. This delay can be explained by slowed peristalsis related to decreased muscle tone in the intestines during labor and the immediate puerperium, prelabor diarrhea, lack of food, or dehydration. The mother often anticipates discomfort during the bowel movement because of perineal tenderness as a result of an episiotomy, lacerations, or hemorrhoids and resists the urge to defecate. Regular bowel habits should be reestablished when bowel tone returns.

Third- and fourth-degree perineal lacerations that involve the anal sphincter are associated with an increased risk for postpartum anal incontinence. Women with this problem are more often incontinent of flatus than of stool. If anal incontinence lasts more than 6 months, studies should be conducted to determine the specific cause and appropriate treatment (Katz, 2012).

BREASTS

Promptly after birth, a decrease occurs in the concentrations of hormones (i.e., estrogen, progesterone, hCG, prolactin, cortisol, and insulin) that stimulated breast development during pregnancy. The time required for these hormones to return to prepregnancy levels is determined in part by whether or not the mother breastfeeds her infant.

Breastfeeding Mothers

During the first 24 hours after birth, there is little if any change in the breast tissue. Colostrum, or early milk, a clear yellow fluid, can be expressed from the breasts. The breasts gradually become fuller and heavier as the colostrum transitions to mature milk by about 72 to 96 hours after birth; this is often referred to as the “milk coming in,” or lactogenesis II. The breasts can feel warm, firm, and somewhat tender. Bluish white milk with a skim-milk appearance (true milk) can be expressed from the nipples. As milk glands and milk ducts fill with milk, breast tissue can feel somewhat nodular or lumpy. Unlike the lumps associated with fibrocystic breast changes or cancer (which can be palpated consistently in the same location), the nodularity associated with milk production tends to shift in position. Some women experience engorgement at this time due to an increase in blood and lymphatic fluid as milk production increases. Engorged breasts are hard and uncomfortable; the fullness of the nipple tissue can make it difficult for the infant to latch on and feed. With frequent breastfeeding and proper care, engorgement is a temporary condition that typically lasts only 24 to 48 hours (see Chapter 25).

Nonbreastfeeding Mothers

The breasts generally feel nodular in contrast to the granular feel of breasts in nonpregnant women. The nodularity is bilateral and diffuse. Prolactin levels drop rapidly. Colostrum is present for the first few days after birth. Palpation of the breasts on the second or third day as milk production begins can reveal tissue tenderness in some women. On the third or fourth postpartum day, engorgement can occur. The breasts are distended (swollen), firm, tender, and warm to the touch. Breast distention is caused primarily by the temporary congestion of veins and lymphatics rather than by an accumulation of milk. Milk is present but should not be expressed. Axillary breast tissue (the tail of Spence)

and any accessory breast or nipple tissue along the milk line can be involved. Engorgement resolves spontaneously, and discomfort decreases usually within 24 to 36 hours. A breast binder or well-fitted supportive bra, ice packs, fresh cabbage leaves, and/or mild analgesics may be used to relieve discomfort. Nipple stimulation is avoided. If suckling or milk expression is never begun (or is discontinued), lactation ceases within a few days to a week.

CARDIOVASCULAR SYSTEM

Blood Volume

Changes in blood volume after birth depend on several factors, such as blood loss during birth and the amount of extravascular water (physiologic edema) mobilized and excreted. Pregnancy-induced hypervolemia (an increase in blood volume to 40% to 45% above nonpregnancy levels) allows most women to tolerate considerable blood loss during birth. The average blood loss for a vaginal birth of a single fetus ranges from 300 to 500 ml (10% of blood volume). The typical blood loss for women who give birth by cesarean is 500 to 1000 ml (15% to 30% of blood volume). During the first few days after birth the plasma volume decreases further as a result of diuresis (Blackburn, 2013).

Maternal physiologic changes in the puerperium enable the woman to cope with the blood loss that normally occurs during birth by increasing her circulation blood volume. These changes are: (1) elimination of uteroplacental circulation that reduces the size of the maternal vascular bed by 10% to 15%; (2) loss of placental endocrine function that removes the stimulus for vasodilation; and (3) mobilization of extravascular water stored during pregnancy. By the third postpartum day, the plasma volume has been replenished as extravascular fluid returns to the intravascular space (Katz, 2012) (see Clinical Reasoning Case Study).

CLINICAL REASONING CASE STUDY

Maternal Postpartum Blood Loss and Fatigue

You are caring for four women on the postpartum unit: two had vaginal births and two had cesarean births. Each of the women has complained about feeling tired and has expressed concern about the amount of blood she lost during birth. Before providing client education related to fatigue after birth and blood loss, you review the clients' records with attention to estimated blood loss, hemoglobin and hematocrit values, intake and output, and nursing notes.

1. Evidence—Is there sufficient evidence to draw conclusions about the relation between tiredness (fatigue) after birth and blood loss?
2. Assumptions—What assumptions can be made about the following factors?
 - a. Comparison of amount of blood loss between women who give birth vaginally and by cesarean
 - b. Postpartum norms for hematocrit and hemoglobin for women who give birth vaginally and by cesarean
 - c. Causes of fatigue after birth
 - d. Interventions to alleviate fatigue and replace blood lost at birth
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

Cardiac Output

Pulse rate, stroke volume, and cardiac output increase throughout pregnancy. Dramatic changes in maternal hemodynamic status occur with birth of the newborn and delivery of the placenta. The immediate blood loss reduces plasma volume without reducing cardiac output. This is due to the compensatory influx of nearly 500 ml of blood into the maternal system from the uteroplacental bed, a rapid decrease in uterine blood flow, and mobilization of extracellular fluid. Typically cardiac output is increased immediately after birth by 60% to 80% over prelabor values; it returns to prelabor values within 1 hour. By 2 weeks after birth, cardiac output decreases by 30% and gradually decreases to prepregnant levels by 6 to 8 weeks postpartum in the majority of women (Blackburn, 2013).

Vital Signs

Few alterations in vital signs are seen under normal circumstances (Table 20-1). Heart rate is increased immediately after birth and can remain elevated for the first hour. Puerperal bradycardia is common, with heart rate decreasing to 40 to 50 beats/minute (James, 2014).

There is a transient increase in blood pressure of approximately 5% during the first few days after birth (Katz, 2012). It can take weeks or months for pulse and blood pressure to return to prepregnancy levels. Increase in blood pressure greater than 140/90 when measured on two or more occasions at least 6 hours apart can indicate preeclampsia.

Respiratory function rapidly returns to nonpregnant levels after birth. After the uterus is emptied, the diaphragm descends, the normal cardiac axis is restored, and the point of maximal impulse and the electrocardiogram are normalized.

Blood Components

Hematocrit and Hemoglobin

In women with an average blood loss during birth, the hematocrit level drops moderately for 3 to 4 days, then begins to increase, and reaches nonpregnant levels by 8 weeks postpartum (Katz, 2012). A postpartum hematocrit can be lower than normal if the blood loss was increased or if the hypovolemia of pregnancy was less than normal.

White Blood Cell Count

Normal leukocytosis of pregnancy averages approximately 12,000/mm³. During the first 4 to 7 days after birth, values between 20,000 and 25,000/mm³ are common. Leukocytosis, coupled with the increase in erythrocyte sedimentation rate that normally occurs, can obscure the diagnosis of acute infection.

Coagulation Factors

Clotting factors and fibrinogen are normally increased during pregnancy and remain elevated in the immediate puerperium. When combined with vessel damage and immobility, this hypercoagulable state causes an increased risk for venous thromboembolism, especially after a cesarean birth. Fibrinolytic activity also increases during the first few days after birth (Katz, 2012). Factors I, II, VIII, IX, and X decrease to nonpregnant levels

TABLE 20-1 Vital Signs After Childbirth

NORMAL FINDINGS	DEVIATIONS FROM NORMAL FINDINGS AND PROBABLE CAUSES
<p>Temperature</p> <p>During first 24 hours, temperature can increase to 38° C (100.4° F) as a result of dehydrating effects of labor. After 24 hours, the woman should be afebrile.</p>	<p>A diagnosis of puerperal sepsis is suggested if an increase in maternal temperature to 38° C (100.4° F) is noted after the first 24 hours after birth and recurs or persists for 2 days. Other possible causes are mastitis, endometritis, urinary tract infections, and other systemic infections.</p>
<p>Pulse</p> <p>Pulse, along with stroke volume and cardiac output, remains elevated for the first hour or so after birth. It gradually decreases over the first 48 hours postpartum. Puerperal bradycardia (40-50 beats/min) is common.</p>	<p>A rapid pulse rate or one that is increasing can indicate hypovolemia as a result of hemorrhage.</p>
<p>Respirations</p> <p>The respiratory rate, which was unchanged or slightly increased during pregnancy, should be within the woman's normal prepregnancy range soon after birth.</p>	<p>Hypoventilation (respiratory depression) can occur after an unusually high subarachnoid (spinal) block or epidural opioid medication after a cesarean birth.</p>
<p>Blood Pressure</p> <p>Blood pressure shows a transient increase of approximately 5% over the first few days after birth, returning to prepregnancy levels over weeks or months. Orthostatic hypotension, as indicated by feelings of faintness or dizziness immediately after standing up, can develop in the first 48 hours as a result of the splanchnic engorgement that can occur after birth.</p>	<p>A low or decreasing blood pressure can indicate hypovolemia secondary to hemorrhage; however, it is a late sign, and other symptoms of hemorrhage usually are present. An increased reading can result from excessive use of vasopressor or oxytocic medications. Because gestational hypertension can persist into or occur first in the postpartum period, routine evaluation of blood pressure is needed. If a woman complains of headache, hypertension must be ruled out as a cause before analgesics are administered.</p>

within a few days. Fibrin split products, probably released from the placental site, can be found in maternal blood.

Varicosities

Varicosities (varices) of the legs (Fig. 20-2) and around the anus (hemorrhoids) are common during pregnancy. All varices, even the less common vulvar varices, regress (empty) rapidly immediately after birth. Total or nearly total regression of varicosities is expected in the postpartum period.

RESPIRATORY SYSTEM

When birth occurs there is an immediate decrease in intraabdominal pressure, which allows for greater excursion of the diaphragm. With decreased pressure on the diaphragm and reduced pulmonary blood flow, chest wall compliance increases. Rib cage elasticity can take months to return to a prepregnancy state. The costal angle that was increased during pregnancy may

FIG 20-2 Varicosities in legs. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

not completely return to the prepregnancy level. The decline in progesterone that occurs with loss of the placenta causes PaCO_2 levels to rise (Blackburn, 2013).

NEUROLOGIC SYSTEM

Neurologic changes during the puerperium result from a reversal of maternal adaptations to pregnancy and from trauma during labor and birth.

Pregnancy-induced neurologic discomforts disappear after birth. Elimination of physiologic edema through the diuresis that follows birth relieves carpal tunnel syndrome by easing compression of the median nerve. The periodic numbness and tingling of fingers usually disappear after the birth unless lifting and carrying the baby aggravate the condition. Nasal stuffiness, tinnitus, and laryngeal changes resolve within a few days postpartum.

Headaches are common in the first postpartum week; they are usually bilateral and frontal (Blackburn, 2013). However, headache requires careful assessment. Postpartum headaches can be caused by various conditions, including postpartum-onset preeclampsia, stress, and leakage of cerebrospinal fluid into the extradural space during placement of the needle for administration of epidural or spinal anesthesia.

MUSCULOSKELETAL SYSTEM

Abdomen

When the woman stands during the first days after birth, her abdomen protrudes and gives her a still-pregnant appearance. During the first 2 weeks after birth, the abdominal wall is relaxed. It takes about 6 weeks for the abdominal wall to

FIG 20-3 Abdominal wall 6 weeks after vaginal birth is almost back to prepregnancy appearance. Note that the linea nigra is still visible. (Courtesy Jodi Brackett, Phoenix, AZ.)

return almost to its prepregnancy state (Fig. 20-3). The return of muscle tone depends on previous tone, proper exercise, and the amount of adipose tissue. Occasionally, with or without overdilatation because of a large fetus or multiple fetuses, the abdominal wall muscles separate, a condition termed *diastasis recti abdominis* (see Fig. 13-13, B). Persistence of this separation can be disturbing to the woman, but surgical correction rarely is necessary. With time the separation becomes less apparent.

Other adaptations of the mother's musculoskeletal system that occur during pregnancy are reversed in the puerperium. These adaptations include the relaxation and subsequent hypermobility of the joints and the change in the mother's center of gravity in response to the enlarging uterus. The joints are completely stabilized by 6 to 8 weeks after birth. Although all other joints return to their normal prepregnancy state, those in the parous woman's feet do not. The new mother may notice a permanent increase in her shoe size. Back pain usually resolves in a few weeks or months following birth.

INTEGUMENTARY SYSTEM

Melasma (chloasma or "mask of pregnancy") usually disappears in the postpartum period but persists in about 30% of women (Kroumpouzou, 2012). Hyperpigmentation of the areolae and linea nigra may not regress completely after birth. Some women will have permanent darker pigmentation of those areas. Striae gravidarum (stretch marks) on the breasts, abdomen, and thighs may fade but usually do not disappear completely.

Vascular abnormalities such as spider angiomas (nevi) and palmar erythema generally regress in response to the rapid decline in estrogens after birth. For some women, spider nevi persist indefinitely.

For the first 3 months after birth, women often report hair loss when they brush or comb their hair. The abundance of fine hair seen during pregnancy usually disappears after giving

birth; however, any coarse or bristly hair that appears during pregnancy usually remains. Fingernails return to their prepregnancy consistency and strength.

IMMUNE SYSTEM

In the postpartum period the woman's immune (lymphoreticular) system, which was mildly suppressed during pregnancy,

gradually returns to its prepregnant state, although the exact timeline is unclear (Blackburn, 2013). This rebound of the immune system can trigger "flare-ups" of autoimmune conditions such as multiple sclerosis or lupus erythematosus (Katz, 2012).

KEY POINTS

- The rapid decrease in estrogen and progesterone levels after expulsion of the placenta is responsible for triggering many of the anatomic and physiologic changes in the puerperium.
- Within 6 weeks after birth, the physiologic changes induced by pregnancy have reverted to their normal state.
- Assessing lochia and fundal height is essential to monitor the progress of normal involution and to identify potential problems.
- The uterus involutes rapidly after birth and returns to the true pelvis within 2 weeks.
- The return of ovulation and menses is determined in part by whether the woman breastfeeds her infant.
- Few alterations in vital signs are seen after birth under normal circumstances.
- Hypercoagulability, vessel damage, and immobility predispose the woman to venous thromboembolism.
- Marked diuresis, decreased bladder sensitivity, and overdistention of the bladder can lead to problems with urinary elimination.
- Pregnancy-induced hypervolemia, combined with several postpartum physiologic changes, allows the woman to tolerate considerable blood loss at birth.

Nursing Care of the Family During the Postpartum Period

Jennifer T. Alderman

© <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Describe components of a systematic postpartum assessment.
- Recognize signs of potential complications in the postpartum woman.
- Formulate a nursing care plan for a woman and her family in the postpartum period.
- Explain the influence of cultural beliefs and practices on postpartum care.
- Identify psychosocial needs of the woman and family in the early postpartum period.
- Prepare a plan for postpartum teaching for self-management.
- Describe the nurse's role in these postpartum follow-up strategies: home visits, telephone follow-up, warm lines and help lines, support groups, and referrals to community resources.

At no other time is family-centered maternity care more important than in the postpartum period. Nursing care is provided in the context of the family unit and focuses on assessment and support of the woman's physiologic and emotional adaptation after birth. During the early postpartum period, components of nursing care include assisting the mother with rest and recovery from labor and birth, assessing physiologic and psychologic adaptation after birth, preventing complications, educating regarding self-management and infant care, and supporting the mother and her partner during the initial transition to parenthood. In addition, the nurse considers the needs of other family members and includes strategies in the nursing care plan to assist the family in adjusting to the new baby.

The approach to the care of women after birth is wellness oriented. In the United States most women remain hospitalized no more than 1 or 2 days after vaginal birth, and some as few as 6 hours. Because so much important information needs to be shared with these women in a very short time, their care must be thoughtfully planned and provided. This chapter discusses nursing care of the woman and her family in the postpartum period extending into the fourth trimester—the first 3 months after birth.

TRANSFER FROM THE RECOVERY AREA

After the initial recovery period has been completed, and provided that her condition is stable, the woman may be transferred to a postpartum room in the same or another nursing unit. In facilities with labor, delivery, recovery, postpartum

(LDRP) rooms, the woman is not moved and the nurse who provides care during the recovery period usually continues caring for the woman. In many settings, women who have received general or regional anesthesia must be cleared for transfer from the recovery area by a member of the anesthesia care team. In other settings, a nurse makes the determination.

In preparing the transfer report, the recovery nurse uses information from the records of admission, birth, and recovery (Fig. 21-1). Information that must be communicated to the postpartum nurse includes the woman's name, age, identity of the health care provider; gravidity and parity; anesthetic used; any medications given; duration of labor and time of rupture of membranes; whether labor was induced or augmented; type of birth and perineal repair; blood type and Rh status; group B streptococcus (GBS) status; status of rubella immunity; human immunodeficiency virus (HIV), hepatitis B, and syphilis serology test results; other infections identified during pregnancy (e.g., gonorrhea, chlamydia), and whether these were treated; type and amount of intravenous fluids; physiologic status since birth; description of fundus, lochia, bladder, and perineum; sex and weight of infant; time of birth; name of pediatric care provider; chosen method of feeding; any abnormalities noted; and assessment of initial parent-infant interaction.

Most of this information is also documented for the nursing staff in the newborn nursery if the infant is transferred to that unit (in some settings, the newborn never leaves the mother's room). In addition, specific information should be provided regarding the newborn's Apgar scores (see Chapter 24), weight, voiding, stooling, and whether fed since birth. Nursing

POSTPARTUM DISCHARGE INSTRUCTIONS

Notify your provider if:

- Elevated temperature above 100.4(F)
- Increased pain not relieved with suggested therapies or pain medications
- Vaginal bleeding saturating the peripad requiring pad change every hour or passing large clots (size of a golf ball)
- Discharge has foul odor
- Incision is red, swollen, draining or has increasing discomfort
- Perineum is red, swollen, draining or has increasing discomfort
- Burning or difficulty urinating or feeling that you are not completely emptying your bladder.
- If no bowel movement in 4 days
- Nipples are bleeding, sore or cracked or you notice any redness, hot spot or lump on the breast
- Feelings of panic, anxiety, depression or sadness or if feel unable to adequately care for your infant

Additional Instructions

Additional Instructions

ADDITIONAL INSTRUCTIONS:

Medications

- Resume prenatal vitamins as directed by your physician
- Take medications as directed by provider

Activity

- Rest frequently, try to nap when the baby is sleeping
- Resume your normal activity and exercise very gradually over 6 weeks.
- Obtain help for general household duties (cleaning, cooking, laundry, shopping, and caring for older children).
- Avoid driving for 1-2 weeks after delivery and when taking medications that may impair your judgement

Nutrition

- Drink 8 to 10 glasses of water per day
- Eat plenty of proteins, fruits, and vegetables, and drink plenty of milk
- Eat a high fiber diet to help relieve constipation

Hygiene

- You may take tub baths or showers-use plain water-no bubble baths or oils or you may run the risk of infection

Care

- Stitches will dissolve on their own and need little additional care. Keep the area as clean as possible.
- Warm sitz baths or tub soaks 2-3 times per day may help relieve soreness
- Keep incision clean and dry. Pat dry following bath or shower. No bandage is necessary
- Wear a good supportive bra 24 hours a day for 1-2 weeks if not nursing, and continuously if nursing
- Change pad with every void
- Use of peri-bottle with each void

FIG 21-2 Part of a postpartum discharge teaching screen in an electronic medical record. (Courtesy Kitty Cashion, Memphis, TN.)

interventions that have been completed (e.g., eye prophylaxis, vitamin K injection) as well as identification procedures done (e.g., footprints, armbands) must be recorded.

In recent years many inpatient nursing units, including perinatal care areas, have changed the way the nurse-to-nurse handoff report is given. Bedside reporting is increasingly being used instead of the traditional report given at the nurses' station. Bedside reporting has been shown to improve client safety and client satisfaction. Clients feel more involved in their plan of care, which increases their satisfaction. Additionally, holding report at the bedside has enabled many nurses

to both visualize and communicate with the client at the time of report, which improves client safety (Novak & Fairchild, 2012).

PLANNING FOR DISCHARGE

From their initial contact with the postpartum woman, nurses prepare the new mother for her return to home. Planning for discharge begins with the first interaction between the nurse, the woman, and her family and continues until they leave the hospital or birthing facility (Fig. 21-2).

The length of hospital stay after giving birth depends on many factors, including the physical condition of the mother and the newborn, mental and emotional status of the mother, social support at home, client education needs for self-management and infant care, and financial constraints.

Women who give birth in birthing centers may be discharged within a few hours, after the woman's and infant's conditions are stable. Mothers and newborns who are at low risk for complications may be discharged from the hospital within 24 to 36 hours after vaginal birth. This short time frame is often called early postpartum discharge, shortened hospital stay, and 1-day maternity stay. Early discharge was popular in the late 1980s and early 1990s, but concerns related to the health and safety of mothers and newborns led to legislation promoting longer hospital stays. The passage of the Newborns' and Mothers' Health Protection Act of 1996 provided minimum federal standards for health plan coverage for mothers and their newborns (American Academy of Pediatrics [AAP] Committee on Fetus and Newborn, 2010). Under this act all health plans are required to allow the new mother and newborn to remain in the hospital for a minimum of 48 hours after an uncomplicated vaginal birth and for 96 hours after a cesarean birth, unless the attending provider in consultation with the mother decides on early discharge.

Criteria for Discharge

The American Academy of Pediatrics (AAP) recommends that the hospital stay for a mother with a healthy term newborn should be of sufficient length to identify early problems and determine that the mother and family are prepared and able to care for the neonate at home. The health of the mother and her newborn should be stable, the mother should be able and confident to provide care for her infant, and there should be adequate support systems in place and access to follow-up care (AAP Committee on Fetus and Newborn, 2010).

It is essential that nurses consider the individual needs of the woman and her newborn and provide care that is intentionally planned to meet these needs. Hospital-based maternity nurses continue to play key roles as caregivers, teachers, and advocates for mothers, newborns, and families in developing and implementing effective home-care strategies. Postpartum order sets and maternal-newborn teaching checklists that address the mother's learning needs can be used to accomplish client care tasks and educational outcomes.

CARE MANAGEMENT: PHYSICAL NEEDS

The nursing plan of care includes both the postpartum woman and her infant. It is also family centered, considering the needs and concerns of the family and focusing on family unity (Waller-Wise, 2012). Although in some hospitals the nursery nurse retains primary responsibility for the infant, most perinatal settings use the **couplet** or mother/baby model of care (Association of Women's Health, Obstetric and Neonatal Nurses [AWHONN], 2010). Nurses in these settings have been educated in both mother and infant care and function as primary nurses for both mother and infant, even if the infant is

kept in the nursery. This approach is a variation of rooming-in, in which the mother and infant room together and mother and nurse share the infant's care. The organization of the mother's care must take the newborn's feeding and care needs into consideration.

Ongoing Physical Assessment

Ongoing assessments are performed throughout hospitalization. In addition to vital signs, physical assessment of the postpartum woman focuses on evaluation of the breasts, uterine fundus, lochia, perineum, bladder and bowel function, vital signs, and legs (Table 21-1).

Routine Laboratory Tests

Several laboratory tests may be performed in the immediate postpartum period. Hemoglobin and hematocrit values are often evaluated on the first postpartum day to assess blood loss during birth, especially after cesarean birth. In some hospitals a clean-catch or catheterized urine specimen is obtained and sent for routine urinalysis or culture and sensitivity, especially if an indwelling urinary catheter was inserted during the intrapartum period. In addition, if the woman's rubella immunity and Rh status are unknown, tests to determine her status and need for possible treatment should be performed at this time.

Nursing Interventions

Based on the available data (e.g., medical record) and assessment findings, the nurse plans with the woman which nursing measures are appropriate and which are to be given priority. The nursing care plan includes periodic assessments to detect deviations from normal physical changes, measures to relieve discomfort or pain, safety measures to prevent injury and infection, and education and counseling measures designed to promote the woman's feelings of competence in self-management and infant care. The nurse evaluates continually and is ready to change the plan if indicated. Almost all hospitals use standardized care plans as a base. Nurses individualize care of the postpartum woman and neonate according to their specific needs (see the Nursing Care Plan). Signs of potential problems that may be identified during the assessment process are listed in Table 21-1.

Nurses assume many roles while implementing the nursing care plan. They provide direct physical care, educate new mothers and their families, and provide anticipatory guidance and counseling. Perhaps most important, they nurture the woman by providing encouragement and support as she begins to assume the many tasks of motherhood. Nurses who take the time to "mother the mother" do much to increase feelings of self-confidence in new mothers. Nurses are careful to include the woman's spouse or partner and other primary support persons in education and counseling.

The first step in providing individualized care is to confirm the woman's identity by checking her wristband. At the same time the infant's identification number is matched with the corresponding band on the mother's wrist and in some instances the father's or partner's wrist. The nurse determines how the mother wishes to be addressed and notes her preference in her medical record and her nursing care plan.

 **NURSING CARE PLAN**
Postpartum Care—Vaginal Birth

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Risk for Fluid Volume Deficit related to uterine atony/hemorrhage</i>	Fundus is firm, lochia is moderate, and there is no evidence of hemorrhage.	<p>Monitor lochia (color, amount, consistency) and count sanitary pads if lochia is heavy.</p> <p>Monitor and palpate fundus for location and tone to determine status of uterus and direct further interventions.</p> <p>Monitor intake and output, assess for bladder fullness, and encourage voiding.</p> <p>Monitor vital signs (increased pulse and respirations, decreased blood pressure) and skin temperature and color.</p> <p>Monitor postpartum hematology studies.</p> <p>If the fundus is boggy, apply gentle massage and assess tone response.</p> <p>Express uterine clots.</p> <p>Explain to woman process of involution and teach her to assess and massage fundus and report any persistent bogginess.</p> <p>Administer uterotonic agents per health care provider's order and evaluate effectiveness.</p> <p>Administer fluids, blood, blood products, or plasma expanders as ordered.</p>	<p>To evaluate amount of bleeding</p> <p>To assess for uterine atony, the most common cause of postpartum hemorrhage</p> <p>To prevent bladder distention because a full bladder interferes with involution of uterus</p> <p>To detect signs of hemorrhage/shock</p> <p>To assess effects of blood loss</p> <p>To promote uterine contractions and increase uterine tone (do not overstimulate because doing so can cause fundal relaxation)</p> <p>To promote uterine contraction</p> <p>To involve her in self-management and increase sense of self-control</p> <p>To promote continuing uterine contraction</p> <p>To replace lost fluid and lost blood volume</p>
<i>Acute Pain related to postpartum physiologic changes (hemorrhoids, episiotomy, breast engorgement, sore/damaged nipples)</i>	Woman exhibits signs of decreased discomfort.	<p>Assess location, type, and quality of pain.</p> <p>Explain to woman source and reasons for pain, its expected duration, and treatments.</p> <p>Administer prescribed pain medications and monitor effectiveness.</p> <p>If pain is perineal (lacerations, episiotomy, hemorrhoids), apply ice packs in first 24 hours.</p> <p>Encourage sitz baths using cool water the first 24 hours.</p> <p>Use warm water for sitz baths after 24 hours.</p> <p>Apply witch hazel compresses.</p> <p>Teach woman to use prescribed perineal creams, sprays, or ointments.</p> <p>Teach woman to tighten buttocks before sitting and to sit on flat, hard surfaces.</p> <p>If nipples are sore or damaged, assess infant positioning and latch; assist mother to correct problems.</p> <p>If nipples are sore, have woman rub expressed milk into them after feeding and leave nipples open to air.</p> <p>Apply hydrogel pads between feedings.</p> <p>Wear breast shells over sore nipples.</p> <p>If breasts are engorged, have breastfeeding woman feed frequently, hand express or pump as needed, and apply ice packs and/or cabbage leaves intermittently between feedings.</p>	<p>To direct intervention</p> <p>To decrease anxiety and increase sense of control</p> <p>To provide pain relief</p> <p>To reduce edema and vulvar irritation and reduce discomfort</p> <p>To reduce edema and discomfort</p> <p>To promote circulation and reduce discomfort</p> <p>To reduce edema</p> <p>To depress response of peripheral nerves</p> <p>To compress buttocks and reduce pressure on perineum (avoid donuts and soft pillows because they separate buttocks and decrease venous blood flow, increasing pain)</p> <p>To prevent further nipple soreness and damage</p> <p>To promote healing</p> <p>To promote comfort</p> <p>To prevent irritation</p> <p>To reduce tissue swelling and promote milk flow</p>

 **NURSING CARE PLAN—cont'd**
Postpartum Care—Vaginal Birth

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Sleep Pattern Disturbance related to excitement, discomfort, and environmental interruptions</i>	Woman sleeps for uninterrupted periods of time and feels rested after waking.	<p>Suggest that woman take a warm shower before breastfeeding.</p> <p>If pain is from breast and woman is not breastfeeding, encourage use of well-fitting supportive bra or breast binder and application of ice packs or cold cabbage leaves.</p> <p>Establish woman's routine sleep patterns and compare with current sleep pattern, exploring things that interfere with sleep.</p> <p>Individualize nursing routines to fit woman's natural body rhythms (i.e., sleep-wake cycles); provide a sleep-promoting environment (i.e., darkness, quiet, adequate ventilation, appropriate room temperature); prepare for sleep using woman's usual routines (i.e., back rub, soothing music, warm milk); teach use of guided imagery and relaxation techniques.</p> <p>Avoid things or routines that can interfere with sleep (i.e., caffeine, foods that induce heartburn, fluids, strenuous mental/physical activity).</p> <p>Administer sedative or pain medication as prescribed.</p> <p>Advise woman/partner to limit visitors and activities.</p> <p>Teach woman to use infant nap time as a nap time to rest.</p>	<p>To stimulate milk flow and relieve stasis</p> <p>To suppress milk production and reduce tissue swelling from engorgement</p> <p>To determine scope of problem and direct interventions</p> <p>To promote optimal conditions for sleep</p> <p>To enhance quality of sleep</p> <p>To enhance quality of sleep</p> <p>To avoid further taxation and fatigue</p>
<i>Risk for Altered Patterns of Urinary Elimination related to perineal trauma and effects of anesthesia</i>	Woman will void within 3 to 4 hours after birth and empty bladder completely.	<p>Assess position and character of uterine fundus and bladder.</p> <p>Measure intake and output.</p> <p>Encourage voiding by assisting woman to bathroom, running water over perineum, running water in sink, and providing privacy.</p> <p>Encourage oral fluid intake.</p> <p>Catheterize as necessary with indwelling or straight method.</p>	<p>To nap and replenish energy and decrease fatigue</p> <p>To ascertain if any further interventions are indicated because of displacement of fundus or distention of bladder</p> <p>To assess adequacy of fluid intake and urine output; a full or distended bladder increases the risk for uterine atony</p> <p>To encourage voiding</p> <p>To replace any fluids lost during birth and prevent dehydration</p> <p>To ensure bladder emptying and prevent uterine atony</p>

The woman and her family are oriented to their surroundings. Familiarity with the unit, routines, resources, and personnel reduces one potential source of anxiety—the unknown. The mother is reassured through knowing whom and how she can call for assistance and what she can expect in the way of supplies and services. If the woman's usual daily routine before admission differs from the routine of the facility, the nurse works with the woman to develop a mutually acceptable routine.

Nurses discuss infant security precautions with the mother and her family because infant abductions are an ongoing concern. Between 1983 and 2013, 132 infants were abducted from health care facilities in the United States; 58% of the babies were taken from the mother's room and 13% were taken from the nursery (National Center for Missing and Exploited Children, 2014). The Joint Commission (1999) calls for hospitals to have a management plan to prevent infant abductions. As a result, many units have special limited-entry systems.

TABLE 21-1 Postpartum Assessment and Signs of Potential Complications

ASSESSMENT	NORMAL FINDINGS	SIGNS OF POTENTIAL COMPLICATIONS
Blood pressure (BP)	Consistent with BP baseline during pregnancy; can have orthostatic hypotension for 48 hours	Hypertension: anxiety, preeclampsia, essential hypertension Hypotension: hemorrhage
Temperature	36.2°–38° C (97.2°–100.4° F)	>38° C (100.4° F) after 24 hours: infection
Pulse	50–90 beats/min	Tachycardia: pain, fever, dehydration, hemorrhage
Respirations	16–24 breaths/min	Bradypnea: effects of opioid medications Tachypnea: anxiety; may be sign of respiratory disease
Breath sounds	Clear to auscultation	Crackles: possible fluid overload
Breasts	Days 1–2: soft Days 2–3: filling Days 3–5: full, soften with breastfeeding (milk is “in”)	Firmness, heat, pain: engorgement
Nipples	Skin intact; no soreness reported	Redness, bruising, cracks, fissures, abrasions, blisters: usually associated with latching problems
Uterus (fundus)	Firm, midline; first 24 hours at level of umbilicus; involutes ≈1 cm/day	Soft, boggy, higher than expected level: uterine atony Lateral deviation: distended bladder
Lochia	Days 1–3: rubra (dark red) Days 3–10: serosa (brownish red or pink) After 10 days: alba (yellowish white) Amount: scant to moderate Few clots Fleshy odor	Large amount of lochia, large clots: uterine atony, vaginal or cervical laceration Foul odor: infection
Perineum	Minimal edema Laceration or episiotomy: edges approximated Pain minimal to moderate: controlled by analgesics, nonpharmacologic techniques, or both	Pronounced edema, bruising, hematoma Redness, warmth, drainage: infection Excessive discomfort first 1–2 days: hematoma; after day 3: infection
Rectal area	No hemorrhoids; if hemorrhoids are present, soft and pink	Discolored hemorrhoidal tissue, severe pain: thrombosed hemorrhoid
Bladder	Able to void spontaneously; no distention; able to empty completely; no dysuria	Overdistended bladder possibly causing uterine atony, excessive lochia
Abdomen and bowels	Diuresis begins ≈12 hours after birth; can void 3000 ml/day Abdomen soft, active bowel sounds in all quadrants Bowel movement by day 2 or 3 after birth Cesarean: incision dressing clean and dry; suture line intact	Dysuria, frequency, urgency: infection No bowel movement by day 3 or 4: constipation; diarrhea
Legs	Deep tendon reflexes (DTRs) 1+ to 2+ Peripheral edema possibly present Homan sign* negative	Abdominal incision—redness, edema, warmth, drainage: infection DTRs ≥3+: preeclampsia
Energy level	Able to care for self and infant; able to sleep	Redness, tenderness, pain, thrombophlebitis*
Emotional status	Excited, happy, interested or involved in infant care	Lethargy, extreme fatigue, difficulty sleeping: postpartum depression Sad, tearful, disinterested in infant care: postpartum blues or depression

*Homan sign was traditionally included in routine postpartum assessments; however, it is no longer common practice due to concern about its limited sensitivity and specificity in diagnosing venous thromboembolism and the potential risk of dislodging a clot when the test is performed.

Nurses teach mothers and their families to check the identity of any person who comes to remove the baby from their room. Hospital personnel usually wear picture identification badges. On some units all staff members wear matching scrubs or special badges. Other units use closed-circuit television, computer monitoring systems, or fingerprint identification pads. As a rule, the infant is never carried in a staff member's arms outside the mother's room, but is always wheeled in a bassinet.

SAFETY ALERT

Nurses play a critical role in educating parents about measures to prevent infant abduction. Parents should be instructed how to identify legitimate hospital personnel, to never leave the newborn in the hospital room without direct supervision, and to request a second staff member to verify the identity of any questionable person who wants to take the baby from the mother's room. Parents should be instructed to use caution when posting photos of the new baby on the Internet and publishing public notices about the birth (AAP and American College of Obstetricians and Gynecologists [ACOG], 2012).

Nurses and new parents must work together to ensure the safety of newborns in the hospital environment (Hiner, Pyka, Burks, et al., 2012).

Preventing Excessive Bleeding

All women who have given birth are at risk for excessive bleeding that can progress to postpartum hemorrhage (see Chapter 33). The most frequent cause of excessive bleeding after birth is uterine atony (i.e., failure of the uterine muscle to contract firmly). The two most important interventions for preventing excessive bleeding are maintaining good uterine tone and preventing bladder distention. If uterine atony occurs, the relaxed uterus distends with blood and clots, blood vessels in the placental site are not clamped off, and excessive bleeding results. Although the cause of uterine atony is not always clear, it often results from retained placental fragments.

Excessive blood loss after birth can also be caused by vaginal or vulvar hematomas or unrepaired lacerations of the vagina or cervix. These potential sources might be suspected if excessive vaginal bleeding occurs in the presence of a firmly contracted uterus.

FIG 21-3 Blood loss after birth is assessed by the extent of perineal pad saturation as (from left to right) scant (<2.5 cm), light (<10 cm), moderate (>10 cm), or heavy (one pad saturated within 2 hours).

⚡ SAFETY ALERT

A perineal pad saturated in 15 minutes or less and pooling of blood under the buttocks are indications of excessive blood loss, requiring immediate assessment, intervention, and notification of the primary health care provider.

Accurate visual estimation of blood loss is an important nursing responsibility. Blood loss is usually described subjectively as scant, light, moderate, or heavy (profuse). Figure 21-3 shows examples of perineal pad saturation corresponding to each of these descriptions.

Although postpartal blood loss can be estimated by observing the amount of drainage on a perineal pad, judging the amount of lochial flow is difficult if based only on observation of perineal pads. More objective estimates of blood loss include measuring serial hemoglobin or hematocrit values, weighing blood clots and items saturated with blood (1 ml equals 1 g), and establishing how many milliliters are required to saturate the perineal pads being used.

Any estimation of lochial flow is inaccurate and incomplete without considering the time factor. The woman who saturates a perineal pad in 1 hour or less is bleeding much more heavily than the woman who saturates one perineal pad in 8 hours.

Nurses in general tend to overestimate rather than underestimate blood loss. Different brands of perineal pads vary in their saturation volume and soaking appearance. For example, blood placed on some brands tends to soak down into the pad, whereas on other brands it tends to spread outward. Nurses should determine saturation volume and soaking appearance for the brands used in their institution so that they can improve accuracy of blood loss estimation.

⚡ SAFETY ALERT

The nurse always checks for blood under the mother's buttocks as well as on the perineal pad. Although the amount on the perineal pad can appear to be small, blood can flow between the buttocks onto the linens under the mother. When this happens, excessive bleeding can go undetected.

When excessive bleeding occurs, vital signs are monitored closely. Blood pressure is not a reliable indicator of impending shock from early postpartum hemorrhage because

compensatory mechanisms prevent a significant drop in blood pressure until the woman has lost 30% to 40% of her blood volume (see Chapter 33). Respirations, pulse, skin condition, urinary output, and level of consciousness are more sensitive means of identifying hypovolemic shock (see the Emergency box). The frequent physical assessments performed during the fourth stage of labor are designed to provide prompt identification of excessive bleeding. Nurses maintain vigilance for excessive bleeding throughout the hospital stay as they perform periodic assessment of the uterine fundus and lochia.

+ EMERGENCY

Hypovolemic Shock

Signs and Symptoms

- Persistent significant bleeding occurs—perineal pad is soaked within 15 minutes; may not be accompanied by a change in vital signs or maternal color or behavior.
- The woman states she feels weak, lightheaded, “funny,” or nauseated or that she “sees stars.”
- The woman begins to act anxious or exhibits air hunger.
- The woman's skin color turns ashen or grayish.
- Skin feels cool and clammy.
- Pulse rate increases.
- Blood pressure decreases.

Interventions

- Notify the primary health care provider.
- If the uterus is atonic, massage gently and expel clots to cause it to contract; compress uterus manually, as needed, using two hands. Add oxytocic agent to intravenous drip, as ordered.
- Give oxygen by nonrebreather face mask at 10 L/min.
- Tilt the woman onto her side or elevate the right hip; elevate her legs to at least a 30-degree angle.
- Provide additional or maintain existing intravenous (IV) infusion of lactated Ringer's solution or normal saline solution to restore circulatory volume (woman should have two patent IV lines; insert second IV using 16- to 18-gauge IV catheter).
- Administer blood or blood products, as ordered.
- Monitor vital signs.
- Insert an indwelling urinary catheter to monitor kidney perfusion.
- Administer emergency drugs, as ordered.
- Prepare for possible surgery or other emergency treatments or procedures.
- Document the incident, medical and nursing interventions instituted, and the woman's response to interventions.

Maintaining Uterine Tone

A major intervention to alleviate uterine atony and restore uterine muscle tone is stimulation by gently massaging the fundus until firm (Fig. 21-4). Fundal massage can cause a temporary increase in the amount of vaginal bleeding seen as pooled blood leaves the uterus. Clots can also be expelled. The uterus can remain boggy even after massage and clot expulsion.

Fundal massage can be a very uncomfortable procedure. If the nurse explains the purpose of fundal massage as well as the causes and dangers of uterine atony, the woman will likely be more cooperative. Teaching the woman to massage her own fundus enables her to maintain some control and decreases her anxiety.

(muscle loses strength)

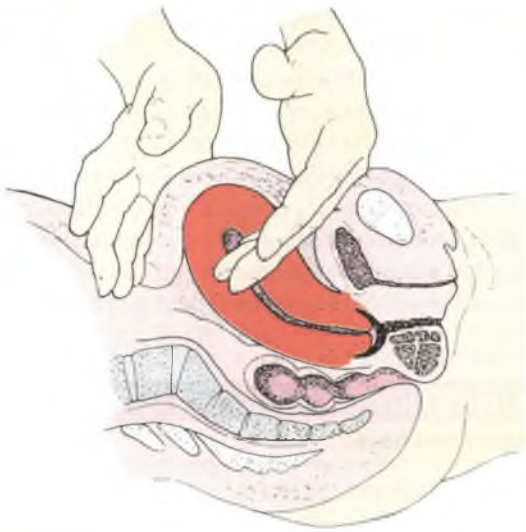

FIG 21-4 Palpating fundus of uterus during the postpartum period. Note that upper hand is cupped over fundus; lower hand dips in above symphysis pubis and supports uterus while it is massaged gently.

When uterine atony and excessive bleeding occur, additional interventions likely to be used are administration of intravenous fluids and oxytocic medications (drugs that stimulate contraction of the uterine smooth muscle). (See Medication Guide in Chapter 33 for information about common oxytocic medications.)

Preventing Bladder Distention

Uterine atony and excessive bleeding after birth can be the result of bladder distention. A full bladder causes the uterus to be displaced above the umbilicus and well to one side of midline in the abdomen. It also prevents the uterus from contracting normally.

Women can be at risk of bladder distention resulting from urinary retention based on intrapartum factors including epidural anesthesia, episiotomy, extensive vaginal or perineal lacerations, instrument-assisted birth, or prolonged labor. Women who have had indwelling catheters, such as with cesarean birth, can experience some difficulty as they initially attempt to void after the catheter is removed. Nurses who are aware of these risk factors can be proactive in preventing complications.

Nursing interventions for a postpartum woman focus on helping the woman empty her bladder spontaneously as soon as possible. The first priority is to assist the woman to the bathroom or onto a bedpan if she is unable to ambulate. Having the woman listen to running water, placing her hands in warm water, or pouring water from a squeeze bottle over her perineum may stimulate voiding. Other techniques include assisting the woman into the shower or sitz bath and encouraging her to void; relaxation techniques can also be helpful. Administering analgesics, if ordered, may be indicated because some women fear voiding because of anticipated pain. If these measures are unsuccessful, a sterile catheter may be inserted to drain the urine.

Preventing Infection

Nurses in the postpartum setting are acutely aware of the importance of preventing infection. One important means of preventing infection is by maintaining a clean environment. Bed linens

should be changed as needed. Disposable pads and drawsheets are changed frequently. Women should wear slippers when walking about to prevent contamination of the linens when they return to bed. Personnel must be conscientious about their hand hygiene to prevent cross-infection. Standard Precautions must be practiced. Staff members with colds, coughs, or skin infections (e.g., a cold sore on the lip [herpes simplex virus, type 1]) must follow hospital protocol when in contact with postpartum women. In many hospitals, staff members with open herpetic lesions, strep throat, conjunctivitis, upper respiratory infections, or diarrhea are encouraged to avoid contact with mothers and infants by staying home until the condition is no longer contagious. Visitors with signs of illness are not permitted to enter the postpartum unit.

Perineal lacerations and episiotomies can increase the risk of infection as a result of interruption in skin integrity. Proper perineal care helps prevent infection in the genitourinary area and aids the healing process. Educating the woman to wipe from front to back (urethra to anus) after voiding or defecating is a simple first step. In many hospitals a squeeze bottle filled with warm water or an antiseptic solution is used after each voiding to cleanse the perineal area. The woman should change her perineal pad from front to back each time she voids or defecates and wash her hands thoroughly before and after doing so (Box 21-1).

Promoting Comfort

Most women experience some degree of discomfort during the postpartum period. Common causes of discomfort include pain from uterine contractions (afterpains), perineal lacerations or episiotomy, hemorrhoids, sore nipples, and breast engorgement. The woman's description of the location, type, and severity of her pain is the best guide in choosing appropriate interventions. To confirm the location and extent of discomfort, the nurse inspects and palpates areas of pain as appropriate for redness, swelling, discharge, and heat, and observes for body tension, guarded movements, and facial tension. Blood pressure, pulse, and respirations can be elevated in response to acute pain. Diaphoresis can accompany severe pain. A lack of objective signs does not necessarily mean there is no pain because there can be a cultural component to the expression of pain. Nursing interventions are intended to eliminate the pain sensation entirely or reduce it to a tolerable level that allows the woman to care for herself and her newborn. Nurses may use nonpharmacologic and pharmacologic interventions to promote comfort. Pain relief is enhanced by using more than one method or route.

Nonpharmacologic Interventions. Various nonpharmacologic measures are used to reduce postpartum discomfort. These include distraction, imagery, therapeutic touch, relaxation, acupressure, aromatherapy, hydrotherapy, massage therapy, music therapy, and transcutaneous electrical nerve stimulation (TENS).

For women who are experiencing discomfort associated with uterine contractions, application of warmth (e.g., heating pad) or lying prone can be helpful. Interaction with the infant can also provide distraction and decrease this discomfort. Because afterpains are more severe during and after breastfeeding, interventions are planned to provide the most timely and effective relief. Simple interventions that can decrease the discomfort associated with an episiotomy or perineal

BOX 21-1 Interventions for Episiotomy, Lacerations, and Hemorrhoids

Explain procedure and rationale before implementation.

Cleansing

- Wash hands before and after cleansing perineum and changing pads.
- Wash perineum with mild soap and warm water at least once daily.
- Cleanse from symphysis pubis to anal area.
- Apply peripad from front to back, protecting inner surface of pad from contamination.
- Wrap soiled pad and place in covered waste container.
- Change pad with each void or defecation or at least four times per day.
- Assess amount and character of lochia with each pad change.

Ice Pack

- Apply a covered ice pack to perineum from front to back:
 - During first 24 hours to decrease edema formation and increase comfort
 - After first 24 hours following birth as needed to provide anesthetic effect

Squeeze Bottle

- Demonstrate use and assist woman; explain rationale.
- Fill bottle with tap water warmed to approximately 38° C (100.4° F) (comfortably warm on wrist).
- Instruct woman to position nozzle between her legs so squirts of water reach perineum as she sits on toilet seat. Explain that it will take whole bottle of water to cleanse the perineum.
- Remind her to blot dry with toilet paper or clean wipes.
- Remind her to avoid contamination from anal area by wiping “front to back.”
- Apply clean pad.

Sitz Bath**Built-in Type**

- Prepare bath by thoroughly scrubbing with cleaning agent and rinsing.
- Pad with towel before filling.
- Fill one third to one half full with water of correct temperature 38° to 40.6° C (100.4° to 105.1° F). Some women prefer cool sitz baths. Ice is added to water to lower temperature to a comfortable level.
- Encourage woman to use at least twice a day for 20 minutes.
- Place call bell within easy reach.
- Teach woman to enter bath by tightening gluteal muscles and keeping them tightened and then relaxing them after she is in bath.
- Place dry towels within reach.
- Ensure privacy.
- Check woman in 15 minutes.

Disposable Type

- Clamp tubing and fill bag with warm water.
- Raise toilet seat; place bath in bowl with overflow opening directed toward back of toilet.
- Place container above toilet bowl.
- Attach tube into groove at front of bath.
- Loosen tube clamp to regulate rate of flow; fill bath to about one half full; continue as for built-in sitz bath.

Topical Applications

- Apply anesthetic cream or spray after cleansing perineal area: use sparingly three or four times per day.
- Apply witch hazel pads (Tucks) after voiding or defecating; woman pats perineum dry from front to back and applies witch hazel pads.
- Apply hemorrhoidal cream as ordered to anal area after cleansing.

lacerations include encouraging the woman to lie on her side whenever possible. Other interventions include application of an ice pack; topical application (if ordered) of anesthetic spray or cream; cleansing with water from a squeeze bottle; and a cleansing shower, tub bath, or sitz bath. Many of these interventions are also effective for hemorrhoids, especially ice packs, sitz baths, and topical applications (such as witch hazel pads). (Box 21-1 gives additional specific information about these interventions.)

Sore nipples in breastfeeding mothers are most likely related to ineffective latch technique. Assessment and assistance with feeding can help alleviate the cause. To ease discomfort associated with sore nipples, the mother may apply topical preparations such as purified lanolin or hydrogel pads (see Chapter 25).

Breast engorgement can occur whether the woman is breastfeeding or formula feeding. The discomfort associated with engorged breasts may be reduced by applying ice packs or cabbage leaves (or both) to the breasts, and wearing a well-fitted support bra. Antiinflammatory medications such as ibuprofen can also be helpful in relieving some of the discomfort. Decisions about specific interventions for engorgement are based on whether the woman chooses breastfeeding or bottle feeding (see Chapter 25).

Pharmacologic Interventions. Pharmacologic interventions are commonly used to relieve or reduce postpartum discomfort. Most health care providers routinely order a variety of

analgesics to be administered as needed, including both opioid and nonopioid (e.g., nonsteroidal antiinflammatory drugs [NSAIDs]). In some hospitals NSAIDs are administered on a scheduled basis, especially if the woman had perineal repair. Topical application of antiseptic or anesthetic ointment or spray can be used for perineal pain. Patient-controlled analgesia (PCA) pumps and epidural analgesia are commonly used to provide pain relief after cesarean birth.

**MEDICATION ALERT**

The nurse should carefully monitor all women receiving opioids because respiratory depression and decreased intestinal motility are side effects.

Many women want to participate in decisions about analgesia. Severe pain, however, can interfere with active participation in choosing pain relief measures. If an analgesic is to be given, the nurse must make a clinical judgment of the type, appropriate dosage, and frequency from the medications ordered. The woman is informed of the prescribed analgesic and its common side effects; this teaching is documented.

Breastfeeding mothers often have concerns about the effects of an analgesic on the infant. Although nearly all drugs present in maternal circulation are also found in breast milk, many analgesics commonly used during the postpartum

period are considered relatively safe for breastfeeding mothers and infants. Often the timing of medications can be adjusted to minimize infant exposure. A mother may be given pain medication immediately after breastfeeding so that the interval between medication administration and the next breastfeeding session is as long as possible. The decision to administer medications of any kind to a breastfeeding mother must always be made by carefully weighing the woman's need against actual or potential risks to the infant. Resources are readily accessible for nurses and health care providers to examine the safety of medications for breastfeeding mothers (e.g., LactMed [<http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT>]).

If acceptable pain relief has not been obtained in 1 hour and there is no change in the initial assessment, the nurse may need to contact the primary care provider for additional pain relief orders or further directions. Unrelieved pain results in fatigue, anxiety, and a worsening perception of the pain. It might also indicate the presence of a previously unidentified or untreated problem.

Promoting Rest. *Postpartum fatigue* (PPF) is more than just feeling tired; it is a common complex physiologic and psychologic phenomenon. Physical fatigue or exhaustion can be associated with long labor or cesarean birth; hospital routines and infant care demands such as breastfeeding also contribute to maternal fatigue. Fatigue can also be associated with anemia, infection, or thyroid dysfunction. The excitement and exhilaration experienced after the birth of the infant makes resting difficult. Physical discomfort can interfere with sleep. Well-intentioned visitors can interrupt periods of rest in the hospital and at home.

Symptoms of PPF and depressive symptoms are interrelated. Depressive symptoms can affect fatigue, whereas fatigue can lead to or worsen depressive symptoms. Depression-related PPF can be differentiated from nondepression-related fatigue based on whether depressive symptoms are reduced when fatigue is decreased (Doering & Durfor, 2011).

Fatigue is likely to worsen over the first 6 weeks after birth, often because of situational factors. After discharge from the hospital, fatigue increases as the woman provides care and feeding for the newborn in combination with other family and household responsibilities such as caring for other children, preparing meals, and doing laundry. Many women have partners, family members, or friends to provide much-needed assistance, whereas others can be without any help at all. The nurse needs to inquire about resources available to the woman after discharge and help her plan accordingly.

Interventions are planned to meet the woman's individual needs for sleep and rest while she is in the hospital. Comfort measures and medications to promote sleep may be necessary. The side-lying position for breastfeeding minimizes fatigue in nursing mothers. Support and encouragement of mothering behaviors help reduce anxiety. Hospital and nursing routines can be adjusted to meet needs of individual mothers. In addition, the nurse can help the family limit visitors and provide a comfortable chair or bed for the partner or other family member who is staying with the new mother.

Because PPF can be very debilitating, follow-up after hospital discharge is important. Screening for PPF can be accomplished with a nurse-initiated telephone call at 2 weeks, as well as at the routine 6-week postpartum visit with the health care provider. Nurses in the pediatric care provider's office or clinic should also be alert for signs of PPF. The infant will be seen within the first few days after birth—before the woman sees her obstetric care provider.

Some physiologic factors contributing to PPF are amenable to intervention and can be identified even before birth. These include sleeping problems during pregnancy, anemia, infection or inflammation, and thyroid dysfunction. The medical records of women with known risk factors can be flagged to alert hospital staff to their special needs (Doering & Durfor, 2011).

Promoting Ambulation. Early ambulation is associated with a reduced incidence of venous thromboembolism (VTE); it also promotes the return of strength. Free movement is encouraged once anesthesia wears off unless an opioid analgesic has been administered. After the initial recovery period the mother is encouraged to ambulate frequently.

In the early postpartum period women can feel lightheaded or dizzy when standing. The rapid decrease in intraabdominal pressure after birth results in a dilation of blood vessels supplying the intestines (splanchnic engorgement) and causes blood to pool in the viscera. This condition contributes to the development of orthostatic hypotension when the woman who has recently given birth sits or stands up, first ambulates, or takes a warm shower or sitz bath. When assisting a woman to ambulate, the nurse needs to consider the baseline blood pressure, amount of blood loss, and type, amount, and timing of analgesic or anesthetic medications administered.

Women who have had regional (epidural or spinal) anesthesia can experience slow return of sensory and motor function in their lower extremities, increasing the risk of falls with early ambulation. Careful assessment by the postpartum nurse can prevent falls. Factors that the nurse should consider are the time lapse since epidural or spinal medication was given; the woman's ability to bend both knees, place both feet flat on the bed, and lift buttocks off the bed without assistance; medications since birth; vital signs; and estimated blood loss with birth. Before allowing the woman to ambulate the nurse assesses the ability of the woman to stand unassisted beside her bed, simultaneously bending both knees slightly, and then standing with knees locked. If the woman is unable to balance herself, she can be safely eased back into bed without injury (Lockwood & Anderson, 2013).

SAFETY ALERT

To promote safety and prevent injury it is important to have hospital personnel present the first time the woman gets out of bed after birth because she can feel weak, dizzy, faint, or lightheaded. The woman is instructed to call for assistance before getting out of bed the first time and any time thereafter if she feels dizzy or weak. The partner or family members who are present are instructed as well.

Preventing VTE is important. Women who must remain in bed after giving birth are at increased risk for this complication. Antiembolic stockings (TED hose) or a sequential compression device (SCD boots) may be ordered prophylactically. If a woman remains in bed longer than 8 hours (e.g., for postpartum magnesium sulfate therapy for preeclampsia), exercise to promote circulation in the legs is indicated, using the following routine:

- Alternate flexion and extension of the feet.
- Rotate the ankles in a circular motion.
- Alternate flexion and extension of the legs.
- Press the back of the knees to the bed surface; relax.

If the woman is susceptible to VTE, she is encouraged to walk about actively for true ambulation and is discouraged from sitting immobile in a chair. Women with varicosities are encouraged to wear support hose. If a thrombus is suspected, as evidenced by warmth, redness, or tenderness in the suspected leg, the primary health care provider should be notified. Meanwhile the woman should be confined to bed, with the affected limb elevated on pillows.

Promoting Exercise. Postpartum exercise can begin soon after birth, although the woman should be encouraged to start with simple exercises and gradually progress to more strenuous ones. Figure 21-5 illustrates a number of exercises appropriate for the new mother. Abdominal exercises are postponed until approximately 4 to 6 weeks after cesarean birth.

Kegel exercises to strengthen muscle tone are extremely important, particularly after vaginal birth. Kegel exercises help women regain the muscle tone that is often lost as pelvic tissues are stretched and torn during pregnancy and birth. Women who maintain muscle strength benefit years later by retaining urinary continence.

Women must learn to perform Kegel exercises correctly (see Teaching for Self-Management box: Kegel Exercises, Chapter 4). Some women perform the exercises incorrectly and can increase the risk of incontinence, which can occur when inadvertently bearing down on the pelvic floor muscles, thrusting the perineum outward. The health care provider can assess the woman's technique during the pelvic examination at her follow-up visit by inserting two fingers intravaginally and noting whether the pelvic floor muscles correctly contract and relax.

Promoting Nutrition

During the hospital stay most women have a good appetite and eat well. They may request that family members bring favorite or culturally appropriate foods. Cultural dietary preferences must be respected. This interest in food presents an ideal opportunity for nutritional counseling on dietary needs after pregnancy, with specific information related to breastfeeding, preventing constipation and anemia, promoting weight loss, and promoting healing and well-being (see Chapter 15).

A well-balanced diet helps promote healing and health in the postpartum period. The recommended caloric intake for the moderately active, nonlactating postpartum woman is 1800 to 2200 kcal/day. Lactating women need an additional 450 to 500 kcal/day, which can usually be met with simple adjustments in a normally balanced diet. Women who are underweight, exercise excessively, or are breastfeeding more than one infant need additional calories. Dietary intake for lactating women should include 200 to 300 mg of the omega-3 long-chain

polyunsaturated fatty acids (docosahexaenoic acid [DHA]) so that there is adequate DHA in the breast milk. The addition of one or two portions of fish with low mercury content provides the additional DHA. Women on selected vegan diets and those who are poorly nourished may need to take DHA and multivitamin supplements (AAP Section on Breastfeeding, 2012).

Prenatal vitamins may be continued until 6 weeks after birth or until the supply has been used. Iron supplements may be prescribed for women with low hemoglobin and hematocrit levels.

Promoting Normal Bladder and Bowel Patterns

Bladder Function. The mother should void spontaneously within 6 to 8 hours after giving birth. The first several voidings should be measured to document adequate emptying of the bladder. A volume of at least 150 ml is expected for each voiding. Some women experience difficulty in emptying the bladder, possibly as a result of diminished bladder tone, edema from trauma, or fear of discomfort. Nursing interventions for inability to void and bladder distention are discussed in the section "Preventing Bladder Distention."

Bowel Function. After birth, women can be at risk for constipation related to side effects of medications (opioid analgesics, iron supplements, magnesium sulfate), dehydration, immobility, or the presence of episiotomy, perineal lacerations, or hemorrhoids. The woman can be fearful of pain with the first bowel movement.

Nursing interventions to promote normal bowel elimination include educating the woman about measures to prevent constipation, such as ambulation and increasing the intake of fluids and fiber. Alerting the woman to side effects of medications such as opioid analgesics (e.g., decreased gastrointestinal tract motility) can encourage her to implement measures to reduce the risk of constipation. Stool softeners or laxatives may be necessary during the early postpartum period. These are used only at the direction of the health care provider.

SAFETY ALERT

Rectal suppositories and enemas should not be administered to women with third- or fourth-degree perineal lacerations. These measures to treat constipation can be very uncomfortable and can cause hemorrhage or damage to the suture line. They can also predispose the woman to infection.

Some mothers experience gas pains; this is more common following cesarean birth. Ambulation or rocking in a rocking chair can stimulate passage of flatus and provide relief. Antiflatulent medications may be ordered. The mother can avoid foods (e.g., legumes, beans, broccoli) that tend to produce gas.

Promoting Breastfeeding

The ideal time to initiate breastfeeding is within the first 1 to 2 hours after birth. Newborns should be placed in skin-to-skin contact with their mothers as soon as possible after birth and remain there for at least an hour. Nurses can encourage mothers to observe their babies for signs that they are ready to breastfeed and then assist the mothers as needed to initiate breastfeeding (Baby-Friendly USA, 2011). During this first hour most infants

Abdominal Breathing. Lie on back with knees bent. Inhale deeply through nose. Keep ribs stationary and allow abdomen to expand upward. Exhale slowly but forcefully while contracting the abdominal muscles; hold for 3 to 5 seconds while exhaling. Relax.

Reach for the Knees. Lie on back with knees bent. While inhaling deeply, lower chin onto chest. While exhaling, raise head and shoulders slowly and smoothly and reach for knees with arms outstretched. The body should rise only as far as the back will naturally bend while waist remains on floor or bed (about 6 to 8 inches). Slowly and smoothly lower head and shoulders back to starting position. Relax.

Double Knee Roll. Lie on back with knees bent. Keeping shoulders flat and feet stationary, slowly and smoothly roll knees over to the right to touch floor or bed. Maintaining a smooth motion, roll knees back over to the left until they touch floor or bed. Return to starting position and relax.

Leg Roll. Lie on back with legs straight. Keeping shoulders flat and legs straight, slowly and smoothly lift left leg and roll it over to touch the right side of floor or bed and return to starting position. Repeat, rolling right leg over to touch left side of floor or bed. Relax.

Combined Abdominal Breathing and Supine Pelvic Tilt (Pelvic Rock). Lie on back with knees bent. While inhaling deeply, roll pelvis back by flattening lower back on floor or bed. Exhale slowly but forcefully while contracting abdominal muscles and tightening buttocks. Hold for 3 to 5 seconds while exhaling. Relax.

Buttocks Lift. Lie on back with arms at sides, knees bent, and feet flat. Slowly raise buttocks and arch back. Return slowly to starting position.

Single Knee Roll. Lie on back with right leg straight and left leg bent at the knee. Keeping shoulders flat, slowly and smoothly roll left knee over to the right to touch floor or bed and then back to starting position. Reverse position of legs. Roll right knee over to the left to touch floor or bed and return to starting position. Relax.

Arm Raises. Lie on back with arms extended at 90-degree angle from body. Raise arms so they are perpendicular and hands touch. Lower slowly.

FIG 21-5 Postpartum exercise should begin as soon as possible. The woman should start with simple exercises and gradually progress to more strenuous ones.

are alert and ready to nurse. Breastfeeding aids in contracting the uterus and preventing maternal hemorrhage. This initial breastfeeding session allows the nurse to assess the mother's basic knowledge of breastfeeding and the physical appearance of the breasts and nipples. Throughout the hospital stay, nurses provide education and assistance for the breastfeeding mother, making appropriate referrals to lactation consultants as needed. Nurses also provide information about community breastfeeding support groups (see Chapter 25 for further information on assisting the breastfeeding woman.)

COMMUNITY ACTIVITY

Women breastfeed longer if they feel supported in their breastfeeding efforts. Nurses and lactation consultants provide support during inpatient stays after birth. Women can find support in the community in various groups. Social support interventions that include peer support are successful in increasing the duration of exclusive breastfeeding and satisfaction with breastfeeding. In their discharge planning nurses can refer breastfeeding mothers to community groups such as La Leche League for support. Community and home health care nurses can facilitate breastfeeding efforts through organizing or facilitating support groups. Mothers experienced in breastfeeding can facilitate these efforts.

Identify sources of breastfeeding support in your community. Are these resources free and available in various parts of the community? What form does the support take? Are there group classes? Individual consultation? Who provides the consultation? Make a list of the resources you identified and share the list with your clinical group.

Lactation Suppression. Lactation suppression is necessary when a woman has decided not to breastfeed or in the case of neonatal death. The woman wears a well-fitted support bra continuously for at least the first 72 hours after giving birth. She should avoid breast stimulation, including running warm water over the breasts, newborn suckling, or expressing milk. Some nonbreastfeeding mothers experience severe breast **engorgement** (swelling of breast tissue caused by increased blood and lymph supply to the breasts as the body produces milk, occurring about 72 to 96 hours after birth). Breast engorgement can usually be managed satisfactorily with nonpharmacologic interventions.

Periodic application of ice packs to the breasts can help decrease the discomfort associated with engorgement. Although there is lack of scientific evidence to support effectiveness, cabbage leaves are often recommended to help relieve engorgement; formula-feeding mothers may be told to place fresh green cabbage leaves over their breasts and to replace the leaves when they are wilted. A mild analgesic or anti-inflammatory medication can reduce discomfort associated with engorgement. Medications that were once prescribed for lactation suppression (e.g., estrogen, estrogen and testosterone, and bromocriptine) are no longer used.

Health Promotion for Planning Future Pregnancies and Children

Rubella Vaccination. For women who have not had rubella or who are serologically non-immune (titer of 1:8 or enzyme

immunoassay level less than 0.8), a subcutaneous injection of rubella vaccine is recommended in the postpartum period prior to hospital discharge to prevent the possibility of contracting rubella in future pregnancies; this is given as the measles, mumps, rubella (MMR) vaccine. Women are cautioned to avoid becoming pregnant for 28 days after receiving the rubella vaccine because of the potential teratogenic risk to the fetus (CDC, 2014). The live attenuated rubella virus is not communicable in breast milk; therefore, breastfeeding mothers can be vaccinated. However, because the virus is shed in urine and other body fluids, the vaccine should not be given if the mother or other household members are immunocompromised. Fever, transient arthralgia, rash, and lymphadenopathy are common side effects of the rubella vaccine (McLean, Fiebelkorn, Temte, & Wallace, 2013).

Varicella Vaccination. The Centers for Disease Control and Prevention (CDC) recommend that varicella vaccine be administered before discharge in postpartum women who have no immunity. A second dose is given at the postpartum follow-up visit (4 to 8 weeks after the first dose) (CDC, 2014).

LEGAL TIP: Rubella and Varicella Vaccination

Informed consent for rubella and varicella vaccination in the postpartum period includes information about possible side effects and the risk of teratogenic effects on the fetus. Women must understand that they must not become pregnant for 28 days after being vaccinated (CDC, 2014).

Tetanus-Diphtheria-Acellular Pertussis Vaccine. Tetanus-diphtheria-acellular pertussis (Tdap) vaccine is recommended for postpartum women who have not previously received the vaccine; it is given before discharge from the hospital or as early as possible in the postpartum period to protect women from pertussis and to decrease the risk of infant exposure to pertussis. Women should be advised that other adults and children who will be around the newborn should be vaccinated with Tdap if they have not previously received the vaccine. Women who receive the vaccine can continue to breastfeed (CDC, 2013).

Preventing Rh Isoimmunization. Injection of Rh immune globulin (a solution of gamma globulin that contains Rh antibodies) within 72 hours after birth prevents sensitization in the Rh-negative woman who has had a fetomaternal transfusion of Rh-positive fetal red blood cells (RBCs) (see the Medication Guide). Rh immune globulin promotes lysis of fetal Rh-positive blood cells before the mother forms her own antibodies against them.

The administration of 300 mcg (1 vial) of Rh immune globulin is usually sufficient to prevent maternal sensitization. If a large fetomaternal transfusion is suspected, however, the dosage needed should be determined by performing a Kleihauer-Betke test, which detects the amount of fetal blood in the maternal circulation. If more than 30 ml of fetal blood is present in maternal circulation, the dosage of Rh immune globulin must be increased (AAP & ACOG, 2012).

MEDICATION GUIDE***Rh Immune Globulin, RhoGAM, Gamulin Rh, HypRho-D, Rhophylac*****Action**

Suppression of immune response in nonsensitized women with Rh-negative blood who receive Rh-positive blood cells because of fetomaternal hemorrhage, transfusion, or accident

Indications

Routine antepartum prevention at 28 weeks of gestation in women with Rh-negative blood; suppress antibody formation after birth, miscarriage, pregnancy termination, abdominal trauma, ectopic pregnancy, amniocentesis, version, or chorionic villus sampling

Dosage and Route

Standard dose: 1 vial (300 mcg) IM in deltoid or gluteal muscle; microdose: 1 vial (50 mcg) IM in deltoid muscle; Rh₀(D) immune globulin (Rhophylac) can be given IM or IV (available in prefilled syringes).

Adverse Effects

Myalgia, lethargy, localized tenderness and stiffness at injection site, mild and transient fever, malaise, headache; rarely nausea, vomiting, hypotension, tachycardia, possible allergic response

Nursing Considerations

- Give standard dose to mother at 28 weeks of gestation as prophylaxis or after an incident or exposure risk that occurs after 28 weeks of gestation (e.g., amniocentesis, second-trimester miscarriage or abortion, and after version).
- Give standard dose within 72 hours after birth if neonate is Rh+.
- Give microdose for first trimester miscarriage or abortion, ectopic pregnancy, chorionic villus sampling.
- Verify that the woman is Rh negative and has not been sensitized, if postpartum that Coombs' test is negative, and that baby is Rh positive. Provide explanation to the woman about the procedure, including the purpose, possible side effects, and effect on future pregnancies. Have the woman sign a consent form if required by agency. Verify correct dosage and confirm lot number and woman's identity before giving injection (verify with another registered nurse or by other procedure per agency policy); document administration per agency policy. Observe client for at least 20 minutes after administration for allergic response.
- Document lot number and expiration date in the client record.
- The medication is made from human plasma (a consideration if woman is a Jehovah's Witness). The risk of transmitting infectious agents, including viruses, cannot be eliminated completely.

IM, Intramuscular; IV, intravenous.

There is some disagreement about whether Rh immune globulin should be considered a blood product. Health care providers need to discuss the most current information about this issue with women whose religious beliefs conflict with having blood products administered to them (e.g., Jehovah's Witnesses).

CARE MANAGEMENT: PSYCHOSOCIAL NEEDS

Meeting the psychosocial needs of new parents involves assessing their reactions to the birth experience, feelings about themselves, and interactions with the new baby (Fig. 21-6) and other family members. Specific interventions are planned to increase the parents' knowledge and self-confidence as they assume the care and responsibility of the new baby and integrate this new member into their existing family structure in a way that meets their cultural expectations (see Chapters 22 and 24).

Taking time to assess maternal emotional needs and to address concerns before discharge can promote better psychologic health and adjustment to parenting. Ongoing support for postpartum women is also needed. Even though issues such as fatigue are often evident during the hospital stay, this type of support will likely be an ongoing concern after discharge when the woman is providing care for the newborn, herself, and other family members. **Postpartum support is especially beneficial to at-risk populations such as low-income primiparas, those at risk for family dysfunction and child abuse, and those at risk for postpartum depression (PPD).**

Sometimes the psychosocial assessment indicates serious actual or potential problems that must be addressed. The Signs of Potential Complications box identifies psychosocial characteristics and behaviors that warrant ongoing evaluation after hospital discharge. Women exhibiting these needs should be referred to appropriate community resources for assessment and management.

Effect of the Birth Experience

Many women need to review and reflect on labor and birth and to look retrospectively at their own intrapartal behavior. Their

FIG 21-6 Parents getting acquainted with their new son. (Courtesy Julie and Darren Nelson, Loveland, CO.)

MEDICATION ALERT

Rh immune globulin suppresses the immune response. Therefore, the woman who receives both Rh immune globulin and a live virus immunization such as rubella must be tested in 3 months to see if she has developed rubella immunity. If not, she will need another dose of the vaccine (McLean et al., 2013).

SIGNS OF POTENTIAL COMPLICATIONS

Postpartum Psychosocial Concerns

The following signs suggest potentially serious complications and should be reported to the health care provider or clinic (these may be noticed by the partner or other family members):

- Unable or unwilling to discuss labor and birth experience
- Refers to self as ugly and useless
- Excessively preoccupied with self (body image)
- Markedly depressed
- Lacks a support system
- Partner or other family members react negatively to the baby
- Refuses to interact with or care for baby; for example, does not name baby, does not want to hold or feed baby, is upset by vomiting and wet or soiled diapers (cultural appropriateness of actions must be considered)
- Expresses disappointment over baby's sex
- Sees baby as messy or unattractive
- Baby reminds mother of family member or friend she does not like
- Has difficulty sleeping
- Experiences loss of appetite

partners can have similar needs. If their birth experience was different from their birth plan (e.g., induction, epidural anesthesia, cesarean birth), both partners may need to mourn the loss of their expectations before they can adjust to the reality of their actual birth experience. Inviting them to review the events and describe how they feel helps the nurse assess how well they understand what happened and how well they have been able to put their birth experience into perspective.

Maternal Self-Image

An important assessment concerns the woman's self-concept, body image, and sexuality. How the new mother feels about herself and her body during the postpartum period can affect her behavior and adaptation to parenting. The woman's self-concept and body image can also affect her sexuality.

Feelings related to sexual adjustment after birth are often a cause of concern for new parents. Women who have recently given birth can be reluctant to resume sexual intercourse for fear of pain or may worry that coitus will damage healing perineal tissue. Because many new parents are anxious for information but reluctant to bring up the subject, postpartum nurses can matter-of-factly include the topic of postpartum sexuality during their routine physical assessment and teaching. Partners often have questions and concerns as well; it is helpful to include them in teaching sessions or discussions regarding sexuality in the postpartum period.

Adaptation to Parenthood and Parent-Infant Interactions

The psychosocial assessment includes evaluating adaptation to parenthood as evidenced by the mother's and father's (partner's) reactions to and interactions with the new baby. Clues indicating successful adaptation begin to appear early in the postbirth period as parents react positively to the newborn infant and continue the process of establishing a relationship with their child.

Parents are adapting well to their new roles when they exhibit a realistic perception and acceptance of their newborn's needs and limited abilities, immature social responses, and helplessness.

Examples of positive parent-infant interactions include taking pleasure in the infant and in providing care, responding appropriately to infant cues, and providing comfort (see Chapter 24). If these indicators are missing, the nurse needs to investigate further in an attempt to identify what is hindering the normal adaptation process. The nurse can ask questions to determine if the woman is experiencing the normal "baby blues" or if there is a more serious underlying condition. Screening for PPD through use of a simple tool such as the Edinburgh Postnatal Depression Scale (EPDS) can be done before hospital discharge. Screening for PPD should also be done after discharge (see Chapter 31). The AAP recommends that pediatric care providers routinely perform maternal screening for PPD during infant follow-up visits at 1, 2, and 4 months (AAP Committee on Psychosocial Aspects of Child and Family Health, 2010) (see Clinical Reasoning Case Study).

CLINICAL REASONING CASE STUDY

Risk for Postpartum Depression

Elisabeth, a 38-year old multipara, has just given birth to her fourth baby. The ages of her other children are 8, 4, and 2. During the morning nursing assessment, Elisabeth was noted to be tearful and stated that she was feeling "overwhelmed" and "very unsure" of herself and how to take care of the new baby, although she has three previous children. She shared that her mother was diagnosed with cancer 2 months ago and is undergoing treatment. Her husband will be starting a much-needed new job next week and will not be able to get any time off for a while. Other family members do not live close by except for her sister, who is out of town often due to her job responsibilities. Elisabeth is concerned about how she will manage taking care of a newborn and three other children with a seemingly depleted support system.

1. Evidence—Is there sufficient evidence to support counseling women with psychosocial concerns in the immediate postpartum period?
2. Assumptions—What assumptions can be made about the following issues?
 - a. Elisabeth is at risk for postpartum depression
 - b. Elisabeth's lack of a support system
 - c. Elisabeth's ability to connect with community resources after discharge
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

Family Structure and Functioning

A woman's adjustment to her role as mother is affected greatly by her relationships with her partner, her mother and other relatives, and any other children (Fig. 21-7). Nurses can help ease the new mother's return home by identifying possible conflicts among family members and by helping the woman plan strategies for dealing with these problems before discharge. Such a conflict can arise when couples have very different ideas about parenting. Dealing with the stresses of sibling rivalry and unsolicited grandparent advice also can affect the woman's transition to motherhood. Only by asking about other nuclear and extended family members can the nurse discover potential problems in such relationships and help plan workable solutions for them.

FIG 21-7 Older sibling cuddles with mother and new baby. (Courtesy Jennifer Hobgood, Creedmoor, NC.)

Effect of Cultural Diversity

The final component of a complete psychosocial assessment is the woman's cultural beliefs, values, and practices. Cultural beliefs and traditions strongly influence the behaviors of the woman and her family during the postpartum period. Nurses are likely to come into contact with women from many different countries and cultures. All cultures have developed safe and satisfying methods of caring for new mothers and babies. The nurse can identify some cultural beliefs and practices through observation and interaction with the mother and her family. Only by understanding and respecting the values and beliefs of each woman can the nurse design a plan of care to meet the individual's needs.

To identify cultural beliefs and practices when planning and implementing care, the nurse conducts a cultural assessment. It can be accomplished most easily through conversation with the mother and her partner. Some hospitals have assessment tools designed to identify cultural beliefs and practices that can influence care. Components of the cultural assessment include the ability to read and write English, primary language spoken, family involvement and support, dietary preferences, infant care, attachment, religious or cultural beliefs, folk medicine practices, nonverbal communication, and personal space preferences.

Postpartum care occurs within a sociocultural context. Rest, seclusion, dietary restraints, and ceremonies honoring the mother are common traditional practices that are followed for the promotion of the health and well-being of the mother and baby. In some cultures the postpartum period is considered a time of increased vulnerability for the mother. To protect her there are restrictions on activity, diet, bathing, and infant caretaking.

The postpartum period is seen by some cultures as a time of impurity for the mother. For as many days or weeks as she has lochial flow, she is considered "impure" and has limited contact with others. Sexual activity is prohibited during this time (Mattson, 2011).

In many Asian cultures the balance between yin and yang (cold and hot) is necessary for balance and harmony with the environment. Postpartum practices focus on helping the

mother achieve this balance. Pregnancy is considered a "hot" condition. It is believed that birth depletes the mother's body of heat through loss of blood and inner energy; this places her in a "cold" state for about 40 days until her womb is healed. The woman consumes only "hot" foods and beverages. Examples of foods that are considered "hot" include rice, eggs, beef, and chicken soup. Seaweed soup is consumed by postpartum women for the purpose of increasing milk production and helping to rid the body of lochia. Family members often bring in foods from home (Callister, 2014). To help prevent the loss of heat from the body, the mother may be discouraged from showering or bathing for several days or weeks; however, there is attention to perineal care and hygiene. The temperature of the hospital room is warmer than usual. The mother likely spends most of the time in bed to prevent cold air from entering the body and she has minimal contact with the infant. Family members provide care for the mother and the newborn. For example, in the Korean culture, the mother-in-law is charged with caring for her daughter-in-law and newly born grandchild during the postpartum period (Callister).

! NURSING ALERT

Women whose cultural beliefs involve achieving balance between hot and cold prefer warm or hot beverages. They will not drink cold beverages or ice water. They are likely to refuse routine application of cold packs or pads to the perineum because this conflicts with beliefs about preventing loss of heat.

Hispanic and Latino women who have immigrated to the United States or other Western nations often observe the period of 40 days (6 weeks) after birth as *la cuarentena*. During this time the woman's body is perceived to be "open" and vulnerable to drafts; *la cuarentena* is about "closing the body." Traditional practices associated with *la cuarentena* include a liquid diet of nutritious drinks, soups, and broths in the early postpartum period; binding the abdomen; avoiding cool air; and maintaining sexual abstinence. Activity is restricted and the mother stays at home (Waugh, 2011). A common concern of Hispanic and Latino women is the "evil eye" or *mal de ojo*. They believe that if someone admires or covets the infant but does not touch him or her, it can cause bad luck, illness, or even death. In an attempt to ward off the evil eye, some mothers place a bracelet with a black onyx hand, *la manita de azabache*, on or near the newborn (Callister, 2014).

The nurse should not assume that a mother desires to use traditional health practices that represent a particular cultural group merely because she is a member of that culture. Many young women who are first- or second-generation Americans follow their cultural traditions only when older family members are present or not at all.

It is important that nurses consider all cultural aspects when planning care and not use their own cultural beliefs as the framework for that care. Although the beliefs and behaviors of other cultures can seem different or strange, they should be encouraged as long as the mother wants to conform to them and she and the baby have no ill effects.

MEDICATION ALERT

The nurse needs to determine whether a woman is using any complementary or alternative therapies (i.e., "folk medicine") during the postpartum period because active ingredients in some herbal preparations can have adverse physiologic effects when used in combination with prescribed medicines.

The Cultural Considerations box lists some common cultural beliefs about the postpartum period and family planning.

DISCHARGE TEACHING**Self-Management and Signs of Complications**

Discharge planning begins at the time of admission to the unit and should be reflected in the nursing care plan developed for each woman. For example, a great deal of time during the hospital stay is usually spent in teaching about maternal self-management and care of the newborn because the goal is for all women to be capable of providing basic care for themselves and their infants at the time of discharge. In addition, every woman must be taught to recognize physical and psychologic signs and symptoms that might indicate problems and how to obtain advice and assistance quickly if these signs appear. Table 21-1 and the Signs of Potential Complications box: Postpartum Psychosocial Concerns earlier in this chapter list several common indications of maternal physical and psychosocial problems in the postpartum period. (See Chapter 31 and Chapter 33 for more information on postpartum complications.) Before discharge, women need basic instruction regarding a variety of self-management topics such as nutrition, exercise, family planning, the resumption

of sexual intercourse, prescribed medications, and routine mother-baby follow-up care.

Because of the limited time available for teaching, nurses must target their teaching on expressed needs of the woman. Giving the woman a list of topics and asking her to indicate her learning needs help the nurse maximize teaching efforts and can increase retention of information. Providing written materials on postpartum self-management, breastfeeding, and infant care that the woman can consult after discharge is helpful.

Just before the time of discharge the nurse reviews the woman's records to see that laboratory reports, medications, signatures, and other items are in order. Some hospitals have a checklist to use before the woman's discharge. The nurse verifies that medications, if ordered, have arrived on the unit; that any valuables kept secured during the woman's stay have been returned to her and that she has signed a receipt for them; and that the infant is ready to be discharged. The woman's and the baby's identification bands are checked carefully.

SAFETY ALERT

No medication that can cause drowsiness should be administered to the mother before discharge if she is the one who will be holding the baby when they leave the hospital. In most instances the woman is seated in a wheelchair and given the baby to hold. Some families leave unescorted and ambulatory, depending on hospital protocol. The newborn must be secured in a car seat for the drive home.

In many hospitals new mothers (breastfeeding and formula feeding) are routinely presented with gift bags that contain samples of infant formula. This practice is not consistent with

CULTURAL CONSIDERATIONS**Examples of Cultural Beliefs and Practices in the Postpartum Period****Postpartum Care**

- *Chinese, Mexican, Korean, and Southeast Asian women* may wish to consume only warm foods and hot drinks to replace blood loss and restore the balance of hot and cold in their bodies. These women desire to stay warm and avoid bathing, exercises, and hair washing for 7 to 30 days after childbirth. Self-management is usually not a priority; care by family members is preferred. The woman has respect for elders and authority. Some women wear abdominal binders. They may prefer not to give their babies colostrum.
- *Chinese women* follow specific restrictions on diet and activity for the first month; this is referred to as "doing the month."
- *Arabic women* eat special meals designed to restore their energy. They are expected to stay at home for 40 days after birth to avoid illness resulting from exposure to the outside air.
- *Haitian women* often wear a belt or piece of linen pulled tightly around the waist to prevent gas from entering the body; they may request to take the placenta home to bury or burn. For 6 to 11 weeks after birth, they typically follow a strict regimen of baths, vapor baths, teas, and dressing warmly.
- *Muslim women* follow strict religious laws on modesty and diet. A Muslim woman must keep her hair, body, arms to the wrist, and legs to the ankles covered at all times. She cannot be alone in the presence of a man other than her husband or a male relative. Observant Muslims will not eat pork or pork

products and are obligated to eat meat slaughtered according to Islamic laws (halal meat). If halal meat is not available, kosher meat, seafood, or a vegetarian diet is usually accepted.

- *Ethiopian women* stay secluded for a minimum of 40 days after birth. They consume special foods such as a gruel of oats and honey to increase breast milk production.

Family Planning

- Birth control is government mandated in mainland *China*. Most *Chinese women* have an intrauterine device (IUD) inserted after the birth of their first child. Women do not want hormonal methods of contraception because they fear putting these medications into their bodies.
- *Hispanic women* may choose the rhythm method or natural family planning because most are Catholic.
- *(East) Indian men* are encouraged to have voluntary sterilization by vasectomy.
- *Muslim couples* may practice contraception by mutual consent as long as its use is not harmful to the woman. Acceptable contraceptive methods include foam and condoms, the diaphragm, and natural family planning.
- *Hmong women* highly value and desire large families, which limits birth control practices.
- *Arabic women* value large families, and sons are especially prized.

the Baby-Friendly Hospital USA Initiative (2011). Prepackaged formula should not be given to mothers who are breastfeeding. Such “gifts” are associated with earlier cessation of breastfeeding.

Sexual Activity and Contraception

Discussing sexual activity with women and their partners is important before they leave the hospital because many couples resume sexual activity before the traditional postpartum follow-up visit with the health care provider 6 weeks after birth. For most women the risk of hemorrhage or infection is minimal by approximately 2 weeks postpartum. Couples may be anxious about the topic but uncomfortable and unwilling to bring it up. The nurse needs to discuss the physical and psychologic effects that giving birth can have on sexual activity (see Teaching for Self-Management).

Many factors can influence the timing and quality of sexual activity after birth. Postpartum perineal pain and dyspareunia (painful intercourse) are common among women with perineal lacerations or episiotomy. Some women who had an episiotomy report discomfort with intercourse for months after birth.

TEACHING FOR SELF-MANAGEMENT

Resuming Sexual Activity After Birth

- Unless your health care provider indicates otherwise, you can safely resume sexual activity (intercourse) by the second to fourth week after birth, when bleeding has stopped and the perineum is healed. Most women resume sexual activity by 5 to 6 weeks after birth, although this varies and is often related to perineal discomfort. Perineal lacerations or episiotomy increases the chances of discomfort with intercourse. For the first 6 weeks to 6 months, vaginal lubrication might be decreased, especially among breastfeeding women. Your physiologic reactions to sexual stimulation for the first 3 months after birth may be slower and less intense. The strength of the orgasm may be reduced.
- A water-soluble gel or contraceptive cream or jelly might be recommended for lubrication. If some vaginal tenderness is present, your partner can be instructed to insert one or more clean, lubricated fingers into the vagina and rotate them to help the vagina relax and identify possible areas of discomfort. A position in which you have control of the depth of the insertion of the penis also is useful. The side-by-side or female-on-top position may be most comfortable.
- The presence of the baby influences sexual activity and enjoyment. Parents hear every sound made by the baby; conversely you may be concerned that the baby hears every sound you make. In either case any phase of the sexual response cycle can be interrupted by hearing the baby cry or move, leaving both of you frustrated and unsatisfied. In addition, the amount of psychologic energy expended by you in child-care activities can lead to fatigue. Newborns require a great deal of attention and time.
- Some women have reported feeling sexual stimulation and orgasms when breastfeeding their babies. This is not abnormal. Breastfeeding mothers often are interested in returning to sexual activity before nonbreastfeeding mothers.
- You should be instructed to perform the Kegel exercises correctly to strengthen your pubococcygeal muscle. This muscle is associated with bowel and bladder function and vaginal feeling during intercourse.

Discomfort is more severe and lasts longer with third- and fourth-degree lacerations (see Evidence-Based Practice box). Breastfeeding mothers often experience vaginal dryness related to high levels of prolactin and low estrogen levels. Changes in family structure and altered sleep patterns can make it difficult for a couple to find time for privacy and intimacy. Postpartum depression is associated with decreased sexual desire; medication used to treat PPD can reduce sexual desire and inhibit orgasm (Leeman & Rogers, 2012).

Contraceptive options should also be discussed with heterosexual women (and their partners, if present) before discharge so that they can make informed decisions about fertility management before resuming sexual activity. Waiting to discuss contraception at the 6-week checkup can be too late. Ovulation can occur as soon as 1 month after birth, particularly in women who formula-feed their infants. Breastfeeding mothers should be informed that breastfeeding is not a reliable means of contraception and that other methods should be used; non-hormonal methods are best because oral contraceptives can interfere with milk production. Women who are undecided about contraception at the time of discharge need information about using condoms with spermicidal foam or creams until the first postpartum checkup. Contraceptive options are discussed in detail in Chapter 8.

Medications

Women routinely continue to take their prenatal vitamins during the postpartum period. Breastfeeding mothers may continue prenatal vitamins for the duration of breastfeeding. Supplemental iron may be prescribed for mothers with lower than normal hemoglobin levels. Women with extensive episiotomies or perineal lacerations (third or fourth degree) are usually prescribed stool softeners to take at home. Pain medications (opioid and nonopioid) may be prescribed, especially for women who had cesarean births. The nurse should make certain that the woman knows the route, dosage, frequency, and common side effects of all medications that she will be taking at home. Written information about the medications is usually included in the discharge instructions.

Follow-Up After Discharge

Routine Schedule of Care

Women who have experienced uncomplicated vaginal births are commonly scheduled for the traditional 6-week postpartum examination. Women who have had a cesarean birth are often seen in the health care provider's office or clinic within 2 weeks after hospital discharge. The date and time for the follow-up appointment should be included in the discharge instructions. If an appointment has not been made before the woman leaves the hospital, she should be encouraged to call the health care provider's office or clinic to schedule one.

Parents who have not already done so need to make plans for newborn follow-up at the time of discharge. Breastfeeding infants are routinely seen by the pediatric health care provider or clinic within 3 to 5 days after birth or 48 to 72 hours after hospital discharge and again at approximately 2 weeks of age (AAP Section on Breastfeeding, 2012). Formula-feeding infants may be seen for the first time at 2 weeks of age. If an appointment for a specific date and time

EVIDENCE-BASED PRACTICE

Perineal Trauma and Postpartum Sexual Function**Ask the Question**

Which perinatal interventions for perineal trauma minimize pain and prevent sexual dysfunction?

Search for the Evidence

Search Strategies English language research-based publications on perineal trauma, birth, postpartum, sexual were included.

Databases Used Cochrane Collaborative Database, National Guideline Clearinghouse (AHRQ), CINAHL, PubMed, and UpToDate

Critical Appraisal of the Evidence

- Sexual dysfunction can affect more than half of all women at 2 to 3 months after birth. One major cause is dyspareunia (painful intercourse) after perineal trauma, especially third- and fourth-degree lacerations requiring repair. Other causes may include decreased libido and lower estrogen resulting from breastfeeding, postpartum depression, and fatigue.
- Both episiotomy and second-degree lacerations with repair are associated with lower libido, orgasm, sexual satisfaction, and greater dyspareunia than in women with intact perineums (Rathfisch, Dikencik, Kazilkaya, et al., 2010). Routine episiotomy during birth is not recommended.
- Warm compresses and perineal massage during first- and second-stage birth significantly decrease third- and fourth-degree tears (Aasheim, Nilsen, Lukasse, et al., 2011).
- Evidence is still mixed for whether to suture or not suture first- and second-degree lacerations. Although small studies find little difference between groups for pain and wound complications, despite slower wound healing the unsutured group still experiences greater satisfaction than the sutured group (Elharmeel, Chaudhary, Tan, et al., 2011).

Apply the Evidence: Nursing Implications

Women can be embarrassed to discuss sexual function with their partners and/or with their health care team. Nurses are ideally placed to initiate and keep the dialog going throughout childbearing. Leeman and Rogers (2012) recommend the following clinical approach for assessing and preventing postpartum sexual dysfunction:

- Discussion of anatomy, physiology, and sexual function should begin in early pregnancy and continue throughout the postpartum period, including a brief valid and reliable sexual function survey.
- Antenatal perineal massage should be taught to minimize perineal damage.
- Perineal management at birth should include limited use of instrumental delivery, especially forceps, and avoiding

episiotomy, along with careful assessment and repair of anal sphincter lacerations with synthetic, absorbable sutures.

- Before hospital discharge initiate discussions with woman and partner regarding pain, dyspareunia, resumption of intercourse, and contraception. Women should know the hypoestrogenic and sensitivity changes that they can experience as a result of breastfeeding and the need for additional vaginal lubrication.
- At postpartum visits assess urine, bowel, and sexual function; inspect perineum; and assess and discuss mood and intimacy challenges such as fatigue and timing issues. Suggesting alternate positions may help increase comfort during intercourse. Evaluate satisfaction with contraceptive method.

Quality and Safety Competencies: Evidence-Based Practice* Knowledge

Describe evidence-based practice to include the components of research evidence, clinical expertise, and patient/family values.

Sexuality is affected by birth. Nurses can sensitively initiate discussion of sexual intimacy.

Skills

Base individualized care plan on client values, clinical expertise, and evidence.

The nurse models a view of human sexuality as a healthy and normal part of one's quality of life.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice.

The nurse can educate the woman and partner and dispel myths about sexuality.

was not made for the infant before leaving the hospital, the parents should be encouraged to call the office or clinic soon after their arrival home.

Home Visits

Home visits to mothers and babies within a few days of discharge can help bridge the gap between hospital care and routine visits to health care providers. Nurses can assess the mother, the infant, and the home environment; answer questions and provide education and emotional support; and make referrals to community resources if necessary. Some families hire

postpartum doula to help during the early postpartum period. The support provided by nurses and other trained community health workers can enhance parent-infant interaction and parenting skills; home visits also help to promote mutual support between the mother and her partner. Breastfeeding outcomes can be enhanced through home visitation programs (Paul, Beiler, Schaefer, et al., 2012; Yonemoto, Dowswell, Nagai, & Mori, 2013).

Home nursing care may not be available, even if needed, because no agencies are available to provide the service or no coverage is in place for payment by third-party payers. If care

is available, a referral form containing information about the mother and baby should be completed at hospital discharge and sent immediately to the home care agency.

The home visit is most commonly scheduled on the woman's second day home from the hospital, but it can be scheduled on any of the first 4 days at home, depending on the individual family's situation and needs. Additional visits are planned throughout the first week, as needed. The home visits may be extended beyond that time if the family's needs warrant it and if a home visit is the most appropriate option for carrying out the follow-up care required to meet the specific needs identified.

During the home visit the nurse conducts a systematic assessment of mother and newborn to determine physiologic adjustment and identify any existing complications. The assessment also focuses on the mother's emotional adjustment and her knowledge of self-management and infant care. Conducting the assessment in a private area of the home provides an opportunity for the mother to ask questions on potentially sensitive topics such as breast care, constipation, sexual activity, or family planning. The nurse assesses family adjustment to the newborn and addresses any concerns during the home visit.

During the newborn assessment the nurse can demonstrate and explain normal newborn behavior and capabilities and encourage the mother and family to ask questions or express concerns they have. The home care nurse verifies if the blood sample for newborn screening has been drawn (see Chapter 24). If the baby was discharged from the hospital before 24 hours of age, a blood sample for the newborn screen may be drawn by the home care nurse, or the family will need to take the infant to the health care provider's office or clinic.

Telephone Follow-Up

In addition to or instead of a home visit, many providers are implementing one or more postpartum telephone follow-up calls to their clients for assessment, health teaching, and identification of complications to effect timely intervention and referrals. Telephone follow-up may be offered by hospitals, private physicians, clinics, or private agencies. It may be either a separate service or combined with other strategies for extending postpartum care. Telephone nursing assessments are frequently used as follow-up to postpartum home visits to reassess a woman's knowledge about the signs and symptoms of adequate

intake by the breastfeeding infant or, after initiating home phototherapy, to assess the caregiver's knowledge regarding equipment complications.

Warm Lines. The **warm line** is another type of telephone link between the new family and concerned caregivers or experienced parent volunteers. A warm line is a help line or consultation service, not a crisis intervention line. The warm line is appropriately used for dealing with less extreme concerns that seem urgent at the time the call is placed but are not actual emergencies. Calls to warm lines commonly relate to infant feeding, prolonged crying, or sibling rivalry. Families are encouraged to call when concerns arise. Telephone numbers for warm lines should be given to parents before hospital discharge.

Support Groups

The woman adjusting to motherhood may desire interaction and conversation with other women who are having similar experiences. Postpartum women who have met earlier in prenatal clinics or on the hospital unit can begin to associate for mutual support. Members of childbirth classes who attend a postpartum reunion may decide to extend their relationship during the fourth trimester. Fathers or partners also benefit from participation in support groups.

A postpartum support group enables mothers and partners/fathers to share with and support each other as they adjust to parenting. Many new parents find it reassuring to discover that they are not alone in their feelings of confusion and uncertainty. An experienced parent can often impart concrete information that is valuable to other group members. Inexperienced parents can imitate the behavior of others in the group whom they perceive as particularly capable.

Referral to Community Resources

To develop an effective referral system the nurse should have an understanding of the needs of the woman and family and of the organization and community resources available for meeting those needs. Locating and compiling information about available community services contributes to the development of a referral system. The nurse also needs to develop his or her own resource file of local and national services that are frequently useful to postpartum families.

KEY POINTS

- Postpartum care is family centered and modeled on the concept of health.
- Cultural beliefs and practices affect the maternal and family response to the postpartum period.
- The nursing care plan includes assessments to detect deviations from normal, comfort measures to relieve discomfort or pain, and safety measures to prevent injury or infection.
- Common nursing interventions in the postpartum period focus on preventing excessive bleeding, bladder distention, infection; providing nonpharmacologic and pharmacologic relief of discomfort associated with the episiotomy, lacerations, or breastfeeding; and instituting measures to promote or suppress lactation.
- Teaching and counseling measures are designed to promote the woman's feelings of competence in self-management and infant care.
- Meeting the psychosocial needs of new mothers involves taking into consideration the composition and functioning of the entire family.
- Early discharge classes, telephone follow-up, home visits, warm lines, and support groups are effective means of facilitating physiologic and psychologic adjustments in the postpartum period.

Transition to Parenthood

Diana McCarty

Ⓜ <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Identify parental and infant behaviors that facilitate and those that inhibit parental attachment.
- Describe sensual responses that strengthen attachment.
- Examine the process of becoming a mother and becoming a father.
- Compare maternal adjustment and paternal adjustment to parenthood.
- Describe nursing interventions that facilitate parent-infant adjustment.
- Examine the effects of the following on parenting responses and behavior: parental age (i.e., adolescence and older than 35 years), social support, culture, same sex parenting, socioeconomic conditions, personal aspirations, and sensory impairment.
- Describe sibling adjustment.
- Discuss grandparent adaptation.

Becoming a parent brings great joy and amazement to most people. The **transition to parenthood** involves change and adaptation as the family adjusts to life with a new baby. It is the first months of having a child when parents define their parental roles and adjust to parenthood. It can create a period of instability, whether parenthood is biologic or adoptive and whether the parents are married husband-wife couples, cohabiting couples, single mothers, single fathers, or same sex couples. Parenting is a process of role attainment and role transition. The transition is an ongoing process as the parents and infant develop and change.

PARENTAL ATTACHMENT, BONDING, AND ACQUAINTANCE

The process by which a parent comes to love and accept a child and a child comes to love and accept a parent is known as **attachment**. Attachment occurs through the process of **bonding**. In their bonding theory, Klaus and Kennell (1976) proposed that there is a sensitive period during the first few minutes or hours after birth when mothers and fathers must have close contact with their infants to optimize the child's later development. Klaus and Kennell (1982) later revised their theory of parent-infant bonding, modifying their claim of the critical nature of immediate contact with the infant after birth. They acknowledged the adaptability of human parents, stating that more than minutes or hours are needed for parents to form an emotional relationship with their infants. The terms *attachment* and *bonding* continue to be used interchangeably.

Attachment is developed and maintained by proximity and interaction with the infant, through which the parent becomes

acquainted with the infant, identifies the infant as an individual, and claims the infant as a member of the family. Positive feedback between the parent and the infant through social, verbal, and nonverbal responses (whether real or perceived) facilitates the attachment process. Attachment occurs through a mutually satisfying experience. A mother commented on her son's grasp reflex, "I put my finger in his hand, and he grabbed right on. It is just a reflex, I know, but it felt good anyway" (Fig. 22-1).

The concept of attachment includes **mutuality**; that is, the infant's behaviors and characteristics elicit a corresponding set of parental behaviors and characteristics. The infant displays signaling behaviors such as crying, smiling, and cooing that initiate the contact and bring the caregiver to the child. These behaviors are followed by executive behaviors such as rooting, grasping, and postural adjustments that maintain the contact. Most caregivers are attracted to an alert, responsive, cuddly infant but find it less desirable to interact with an irritable, apparently disinterested infant. Attachment occurs more readily with the infant whose temperament, social capabilities, appearance, and sex fit the parent's expectations. If the infant does not meet these expectations, the parent's disappointment can delay the attachment process. Table 22-1 presents a comprehensive list of classic infant behaviors affecting parental attachment. Table 22-2 presents a corresponding list of parental behaviors that affect infant attachment.

An important part of attachment is **acquaintance**. Parents use eye contact (Fig. 22-2), touching, talking, and exploring to become acquainted with their infant during the immediate postpartum period. Adoptive parents undergo the same process when they first meet their new child. During this period families engage in the **claiming process**, which is the identification of the new baby

FIG 22-1 Hands. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

FIG 22-2 Early acquaintance between parents and newborn as mother holds infant in en face position. (Courtesy Kathryn Alden, Chapel Hill, NC.)

TABLE 22-1 Infant Behaviors Affecting Parental Attachment

FACILITATING BEHAVIORS

Visually alert; eye-to-eye contact; tracking or following parent's face
Appealing facial appearance; randomness of body movements reflecting helplessness

Smiles

Vocalization; crying only when hungry or wet

Grasp reflex

Anticipatory approach behaviors for feedings; sucks well; feeds easily

Enjoys being cuddled and held

Easily consolable

Activity and regularity somewhat predictable

Attention span sufficient to focus on parents

Differential crying, smiling, and vocalizing; recognizes and prefers parents

Approaches through locomotion

Clings to parent; puts arms around parent's neck

Lifts arms to parents in greeting

INHIBITING BEHAVIORS

Sleepy; eyes closed most of the time; gaze aversion

Resemblance to person parent dislikes; hyperirritability or jerky body movements when touched

Bland facial expression; infrequent smiles

Crying for hours on end; colicky

Exaggerated motor reflex

Feeds poorly; regurgitates; vomits often

Resists holding and cuddling by crying, stiffening body

Inconsolable; unresponsive to parenting, caretaking tasks

Unpredictable feeding and sleeping schedule

Inability to attend to parent's face or offered stimulation

Shows no preference for parents over others

Unresponsive to parent's approaches

Seeks attention from any adult in room

Ignores parents

Adapted from Gerson, E. (1973). *Infant behavior in the first year of life*. New York: Raven Press.

TABLE 22-2 Parental Behaviors Affecting Infant Attachment

FACILITATING BEHAVIORS

Looks; gazes; takes in physical characteristics of infant; assumes en face position; eye contact

Hovers; maintains proximity; directs attention to, points to infant

Identifies infant as unique individual

Claims infant as family member, names infant

Touches; progresses from fingertip to fingers to palms to encompassing contact

Smiles at infant

Talks to, coos, or sings to infant

Expresses pride in infant

Relates infant's behavior to familiar events

Assigns meaning to infant's actions and sensitively interprets infant's needs

Views infant's behaviors and appearance in positive light

INHIBITING BEHAVIORS

Turns away from infant; ignores infant's presence

Avoids infant; does not seek proximity; refuses to hold infant when given opportunity
Identifies infant with someone parent dislikes; fails to recognize any of infant's unique features

Fails to place infant in family context or identify infant with family member; has difficulty naming

Fails to move from fingertip touch to palmar contact and holding

Maintains bland countenance or frowns at infant

Wakes infant when infant is sleeping; handles roughly; hurries feeding by moving nipple continually

Expresses disappointment, displeasure in infant

Does not incorporate infant into life

Makes no effort to interpret infant's actions or needs

Views infant's behavior as exploiting, deliberately uncooperative; views appearance as distasteful, ugly

Adapted from Mercer, R. (1983). Parent-infant attachment. In L. Sonstegard, K. Kowalski, & B. Jennings (Eds.), *Women's health* (vol. 2). New York: Grune & Stratton.

FIG 22-3 Father looks for resemblance between newborns and older daughter. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

(Fig. 22-3). The child is first identified in terms of “likeness” to other family members, then in terms of “differences,” and finally in terms of “uniqueness.” The unique newcomer is thus incorporated into the family. Mothers and fathers examine their infant carefully and point out characteristics that the child shares with other family members and that are indicative of a relationship between them. Maternal comments such as the following reveal the claiming process: “Everyone says, ‘He’s the image of his father,’ but I found one part like me—his toes are shaped like mine.”

On the other hand, some mothers react negatively. They “claim” the infant in terms of the discomfort or pain the baby causes. The mother interprets the infant’s normal responses as being negative toward her and reacts to her child with dislike or indifference. She does not hold the child close or touch the child in a comforting way. For example, “The nurse put the baby into Lydia’s arms. She promptly laid him across her knees and glanced up at the television. ‘Stay still until I finish watching; you’ve been enough trouble already.’”

Nursing interventions related to the promotion of parent-infant attachment are numerous and varied (Table 22-3).

TABLE 22-3 Examples of Parent-Infant Attachment Interventions

INTERVENTION LABEL AND DEFINITION	ACTIVITIES
<p>Attachment Promotion Facilitation of development of parent-infant relationship</p>	<p>Provide opportunity for parent or parents to see, hold, and examine newborn immediately after birth. Encourage parent or parents to hold infant close to body. Assist parent or parents to participate in infant care. Provide rooming-in while in hospital.</p>
<p>Environmental Management: Attachment Process Manipulation of individuals’ surroundings to facilitate development of parent-infant relationship</p>	<p>Create environment that fosters privacy. Individualize daily routine to meet parents’ needs. Permit father or significant other to sleep in room with mother. Develop policies that permit presence of significant others as much as desired.</p>
<p>Family Integrity Promotion: Childbearing Family Facilitation of growth of individuals or families who are adding infant to family unit</p>	<p>Prepare parent or parents for expected role changes involved in becoming a parent. Prepare parent or parents for responsibilities of parenthood. Monitor effects of newborn on family structure. Reinforce positive parenting behaviors.</p>
<p>Lactation Counseling Use of interactive helping process to assist in achieving and maintaining successful breastfeeding</p>	<p>Correct misconceptions, misinformation, and inaccuracies about breastfeeding. Assess feeding techniques and assist as needed. Evaluate parents’ understanding of infant’s feeding cues (e.g., rooting, sucking, alertness). Determine frequency of feedings in relation to infant’s needs. Demonstrate breast massage and discuss its advantages to increasing milk supply. Provide education, encouragement, and support.</p>
<p>Parent Education: Infant Instruction on nurturing and physical care needed during first year of life</p>	<p>Determine parents’ knowledge, readiness, and ability to learn about infant care. Provide anticipatory guidance about developmental changes during first year of life. Teach parent or parents skills to care for newborn. Demonstrate ways in which parent or parents can stimulate infant’s development. Discuss infant’s capabilities for interaction. Demonstrate quieting techniques.</p>
<p>Risk Identification: Childbearing Family Identification of individual or family likely to experience difficulties in parenting and assigning priorities to strategies to prevent parenting problems</p>	<p>Determine developmental stage of parent or parents. Review prenatal history for factors that predispose individuals or family to complications. Ascertain understanding of English or other language used in community. Monitor behavior that may indicate problem with attachment. Plan for risk-reduction activities in collaboration with individual or family.</p>

They can enhance positive parent-infant contacts by heightening parental awareness of an infant's responses and ability to communicate. As the parent attempts to become competent and loving in that role, nurses can bolster the parent's self-confidence and ego. Nurses can identify actual and potential problems and collaborate with other health care professionals who will provide care for the parents after discharge. Nursing considerations for fostering maternal-infant bonding among special populations can vary (see the Cultural Considerations box).

CULTURAL CONSIDERATIONS

Fostering Bonding in Women of Varying Ethnic and Cultural Groups

Childbearing practices and rituals of other cultures are not always congruent with standard practices associated with bonding in the Anglo-American culture. For example, Chinese families traditionally use extended family members to care for the newborn so that the mother can rest and recover, especially after a cesarean birth. Some Native-American, Asian, and Hispanic women do not initiate breastfeeding until their breast milk comes in. Haitian families do not name their babies until after the confinement month. The amount of eye contact varies among cultures as well. Yup'ik Eskimo mothers almost always position their babies so that they can make eye contact.

Nurses should become knowledgeable about the childbearing beliefs and practices of diverse cultural and ethnic groups. Because individual cultural variations exist within groups, nurses need to clarify with the client and family members or friends what cultural norms they follow. Incorrect judgments can be made about parent-infant bonding if nurses do not practice culturally sensitive care.

Modified from D'Avanzo, C. (2008). *Mosby's pocket guide to cultural health assessment* (4th ed.). St. Louis: Mosby.

Assessment of Attachment Behaviors

One of the most important areas of assessment is careful observation of specific behaviors thought to indicate the formation of emotional bonds between the newborn and the family, especially the mother. Unlike physical assessment of the neonate, which has concrete guidelines to follow, assessment of parent-infant attachment relies more on skillful observation and interviewing. Rooming-in of mother and infant and liberal visiting privileges for father or partner, siblings, and grandparents provide nurses with excellent opportunities to observe interactions and identify behaviors that demonstrate positive or negative attachment. Attachment behaviors can be easily observed during infant feeding sessions. Box 22-1 presents guidelines for assessment of attachment behaviors.

During pregnancy, and often even before conception occurs, parents develop an image of the "ideal" or "fantasy" infant. At birth the fantasy infant becomes the real infant. How closely the dream child resembles the real child influences the bonding process. Assessing such expectations during pregnancy and at the time of the infant's birth allows identification of discrepancies in the parents' view of the fantasy child versus the real child.

The labor process significantly affects the immediate attachment of mothers to their newborn infants. Factors such as a long labor, feeling tired or "drugged" after birth, and problems

BOX 22-1 Assessing Attachment Behavior

- When the infant is brought to the parents, do they reach out for the infant and call the infant by name? (Recognize that in some cultures parents may not name the infant in the early newborn period.)
- Do the parents speak about the infant in terms of identification—who the infant resembles, and what appears special about their infant over other infants?
- When parents are holding the infant, what kind of body contact is seen—do parents feel at ease in changing the infant's position, are fingertips or whole hands used, and does the infant have parts of the body they avoid touching or parts of the body they investigate and scrutinize?
- When the infant is awake, what kinds of stimulation do the parents provide—do they talk to the infant, to each other, or to no one, and how do they look at the infant—direct visual contact, avoiding eye contact, or looking at other people or objects?
- How comfortable do the parents appear in terms of caring for the infant? Do they express any concern regarding their ability or disgust for certain activities, such as changing diapers?
- What type of affection do they demonstrate to the newborn, such as smiling, stroking, kissing, or rocking?
- If the infant is fussy, what kinds of comforting techniques do the parents use, such as rocking, swaddling, talking, or stroking?

with breastfeeding, preterm birth, and being separated from the infant at birth can delay the development of initial positive feelings toward the newborn (Flacking, Lehtonen, Thomson, et al., 2012; Hoffenkamp, Tooten, Hall, et al., 2012). Referral to groups such as La Leche League International (www.llli.org) or Postpartum Support International (www.Postpartum.net) can be helpful.

PARENT-INFANT CONTACT

Early Contact

Early close contact can facilitate the attachment process between parent and child. Although a delay in contact does not necessarily mean that attachment will be inhibited, additional psychologic energy can be necessary to achieve the same effect. To date, no scientific evidence has demonstrated that immediate contact after birth is essential for the human parent-child relationship.

Early skin-to-skin contact between the mother and newborn immediately after birth and during the first hour facilitates maternal affectionate and attachment behaviors (Hung & Berg, 2011; Thukral, Sankar, Agarwal, et al., 2012). The newborn is placed in the prone position on the mother's bare chest; the baby and mother are covered with a warm blanket and a cap is placed on the infant's head to prevent heat loss. This practice promotes early and effective breastfeeding and increases breastfeeding duration. It is also associated with less infant crying, improved thermoregulation (especially in low birth weight infants), and improved cardiorespiratory stability in late preterm infants (Moore, Anderson, Bergman, & Dowswell, 2012).

Parents who are unable to have early contact with their newborn (e.g., the infant was transferred to the intensive care nursery) can be reassured that such contact is not essential for

parent-infant attachment. Otherwise, adopted infants would not form affectionate ties with their parents. Nurses need to stress that the parent-infant relationship is a process that occurs over time.

Extended Contact

Rooming-in is common in family-centered care. With this practice the infant stays in the room with the mother. In some facilities the newborn never leaves the mother's presence; nurses perform the initial assessment and care in the room with the parents. In other hospitals the infant is transferred to the postpartum or mother-baby unit from the transitional nursery (if the facility uses one) after showing satisfactory extrauterine adjustment. Nurses encourage the father or partner to actively participate in caring for the infant. They can also encourage siblings and grandparents to visit and become acquainted with the infant. Whether the method of family-centered care is rooming-in, mother-baby or couplet care, or a family birth unit, mothers, their partners, and family members are equal and integral parts of the developing family.

Extended contact with the infant should be available for all parents but especially for those at risk for parenting inadequacies, such as adolescents and low-income women. Postpartum nurses need to consider and encourage activities that optimize family-centered care (Welch, Hofer, Brunelli, et al., 2012).

COMMUNICATION BETWEEN PARENT AND INFANT

The parent-infant relationship is strengthened through the use of sensual responses and abilities by both partners in the interaction. The nurse should keep in mind that cultural variations are often seen in these interactive behaviors.

The Senses

Touch

Touch, or the tactile sense, is used extensively by parents as a means of becoming acquainted with the newborn. Many mothers reach out for their infants as soon as they are born. Mothers lift their infants to their breasts, enfold them in their arms, and cradle them. Once the infant is close, the mother begins the exploration process with her fingertips, one of the most touch-sensitive areas of the body. Within a short time she uses her palm to caress the baby's trunk and eventually enfolds the infant. Similar progression of touching is demonstrated by fathers, partners, and other caregivers. Gentle stroking motions are used to soothe and quiet the infant; patting or gently rubbing the infant's back is a comfort after feedings. Infants also pat the mother's breast as they nurse. Both seem to enjoy sharing each other's body warmth. Parents seem to have an innate desire to touch, pick up, and hold the infant (Fig. 22-4). They comment on the softness of the baby's skin and note details of the baby's appearance. As parents become increasingly sensitive to the infant's like or dislike for different types of touch, they draw closer to the baby.

Touching behaviors by mothers vary in different cultural groups. For example, minimal touching and cuddling is a traditional Southeast Asian practice thought to protect the infant from evil spirits. Because of tradition and spiritual beliefs,

FIG 22-4 Father interacts with his newborn son. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

women in India and Bali have practiced infant massage since ancient times.

Eye Contact

Parents repeatedly demonstrate interest in having eye contact with the baby. Some mothers remark that once their babies have looked at them, they feel much closer to them. Parents are intent on getting their babies to open their eyes and look at them. In North American culture, eye contact appears to reinforce the development of a trusting relationship and is an important factor in human relationships at all ages. In other cultures, eye contact is perceived differently. For example, in Mexican culture, sustained direct eye contact is considered to be rude, immodest, and dangerous for some. This danger can arise from the *mal de ojo* (evil eye), resulting from excessive admiration. Women and children are thought to be more susceptible to *mal de ojo*.

As newborns become functionally able to sustain eye contact with their parents, they spend time in mutual gazing, often in the **en face** position, in which the parent's and infant's faces are approximately 30 cm (12 inches) apart and on the same plane (see Fig. 22-2). Nurses, physicians, or nurse midwives can facilitate eye contact immediately after birth by positioning the infant on the mother's abdomen or chest with the mother's and the infant's faces on the same plane. Dimming the lights encourages the infant's eyes to open. To promote eye contact, instillation of prophylactic antibiotic ointment in the infant's eyes can be delayed until the infant and parents have had some time together in the first hour after birth.

Voice

The shared response of parents and infants to each other's voices is remarkable. Parents wait tensely for the first cry. Once that cry has reassured them of the baby's health, they begin comforting behaviors. As the parents speak, the infant is alerted and turns toward them. Infants respond to higher-pitched voices and can distinguish their mother's voice from others soon after birth.

Odor

Another behavior shared by parents and infants is a response to each other's odor. Mothers comment on the smell of their

FIG 22-5 Infant in alert state. (Courtesy Kathryn Alden, Chapel Hill, NC.)

babies when first born and have noted that each infant has a unique odor. Infants learn rapidly to distinguish the odor of their mother's breast milk.

Entrainment

Newborns move in time with the structure of adult speech, which is termed **entrainment**. They wave their arms, lift their heads, and kick their legs, seemingly "dancing in tune" to a parent's voice. Culturally determined rhythms of speech are ingrained in the infant long before he or she uses spoken language to communicate. This shared rhythm also gives the parent positive feedback and establishes a positive setting for effective communication.

Biorhythmicity

Biorhythmicity refers to the infant being in tune with the mother's natural rhythms. The mother's heartbeat or a recording of a heartbeat can soothe a crying infant. One of the newborn's tasks is to establish a personal biorhythm. Parents can help in this process by giving consistent loving care and using their infant's alert state to develop responsive behavior and increase social interactions and opportunities for learning (Fig. 22-5).

Reciprocity and Synchrony

Reciprocity is a type of body movement or behavior that provides the observer with cues. The observer or receiver interprets those cues and responds to them. Reciprocity often takes several weeks to develop with a new baby. For example, when the newborn fusses and cries, the mother responds by picking up and cradling the infant, the baby becomes quiet and alert and establishes eye contact, and the mother verbalizes, sings, and coos while the baby maintains eye contact. The baby then averts the eyes and yawns; the mother decreases her active response. If the parent continues to stimulate the infant, the baby can become fussy.

The term **synchrony** refers to the "fit" between the infant's cues and the parent's response. When parent and infant experience a synchronous interaction, it is mutually rewarding (Fig. 22-6). Parents need time to interpret the infant's cues correctly. For example, the infant develops a specific cry in response to

FIG 22-6 Sharing a smile: an example of synchrony. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

different situations such as boredom, loneliness, hunger, and discomfort. The parent may need assistance in interpreting these cries, along with trial and error interventions, before synchrony develops.

PARENTAL ROLE AFTER BIRTH

Adaptation involves stabilizing tasks, a coming to terms with commitments. Parents demonstrate growing competence in child care activities and become increasingly more attuned to their infant's behavior.

Transition to Parenthood

Historically the transition to parenthood was viewed as a crisis. The current perspective is that parenthood is a developmental transition rather than a major life crisis. The transition to parenthood is a time of disorder and disequilibrium, as well as satisfaction and joy, for mothers and their partners. Usual methods of coping often seem ineffective during this time. Some parents are so distressed that they are unable to be supportive of each other. Because men typically identify their spouses or partners as their primary or only source of support, the transition can be comparatively harder for the fathers. They often feel deprived when the mothers, who are also experiencing stress, cannot provide their usual level of support. Many parents are unprepared for the strong emotions such as helplessness, inadequacy, and anger that arise when dealing with a crying infant. However, the parenthood role allows adults to develop and display a selfless, warm, and caring side of themselves that may not otherwise be expressed.

For the majority of mothers and their partners the transition to parenthood is an opportunity rather than a time of crisis. Parents try new coping strategies as they work to master their new roles and reach new developmental levels. As they work through the transition, they often find personal strength and resourcefulness.

Parental Tasks and Responsibilities

Parents need to reconcile the actual child with the fantasy and dream child. This process means coming to terms with the

infant's physical appearance, sex, innate temperament, and physical status. If the real child differs greatly from the fantasy child, some parents delay acceptance of the child. In some instances, they never accept the child.

Many parents know the sex of the infant before birth because of the use of ultrasound assessments. For those who do not have this information, disappointment over the baby's sex can take time to resolve. The parents may provide adequate physical care but have difficulty in being sincerely involved with the infant until this internal conflict has been resolved. As one mother remarked, "I really wanted a boy. I know it is silly and irrational, but when they said, 'She's a lovely little girl,' I was so disappointed and angry—yes, angry—I could hardly look at her. Oh, I looked after her okay, her feedings and baths and things, but I couldn't feel excited. To tell the truth, I felt like a monster not liking my child. Then one day, she was lying there and she turned her head and looked right at me. I felt a flooding of love for her come over me, and we looked at each other a long time. It's okay now. I wouldn't change her for all the boys in the world."

The normal appearance of the neonate—size, color, molding of the head, or bowed appearance of the legs—is startling for some parents. Nurses can encourage parents to examine their babies and to ask questions about newborn characteristics.

Parents need to become adept in the care of the infant, including caregiving activities, noting the communication cues given by the infant to indicate needs, and responding appropriately to the infant's needs. The more quickly parents become competent in child care activities, the more quickly they can direct their psychologic energy toward observing and responding to these communication cues. Self-esteem grows with competence. Breastfeeding helps mothers believe that they are contributing in a unique way to the welfare of the infant. The parent may interpret the infant's response to the parental care and attention as a comment on the quality of that care. Infant behaviors that parents interpret as positive responses to their care include being consoled easily, enjoying being cuddled, and making eye contact. Spitting up frequently after feedings, crying, and being unpredictable are often perceived as negative responses to parental care. Continuation of these infant responses that parents view as negative can result in alienation of parent and infant.

Some people view assistance, including advice by husbands, partners, wives, mothers, mothers-in-law, and health care professionals, as supportive. Others view advice as criticism or an indication of how inept these people judge the new parents to be. Criticism, real or imagined, of the new parents' ability to provide adequate physical care, nutrition, or social stimulation for the infant can be devastating. By providing encouragement and praise for parenting efforts, nurses can enhance the new parents' confidence.

Parents must establish a place for the newborn within the family group. Whether the infant is the firstborn or the last born, all family members must adjust their roles to accommodate the newcomer.

Becoming a Mother

Rubin (1961) identified three phases of maternal role attainment in which the mother adjusts to her parental role. These

TABLE 22-4 Phases of Maternal Postpartum Adjustment

PHASE	CHARACTERISTICS
Dependent: taking-in phase	First 24 hours (range, 1 to 2 days) Focus: self and meeting of basic needs: Reliance on others to meet needs for comfort, rest, closeness, and nourishment Excited and talkative Desire to review birth experience
Dependent-independent: taking-hold phase	Starts second or third day; lasts 10 days to several weeks Focus: care of baby and competent mothering: Desire to take charge Still has need for nurturing and acceptance by others Eagerness to learn and practice—optimal period for teaching by nurses Handling of physical discomforts and emotional changes Possible experience with "blues"
Interdependent: letting-go phase	Focus: forward movement of family as unit with interacting members: Reassertion of relationship with partner Resumption of sexual intimacy Resolution of individual roles

Data from Rubin, R. (1961). Basic maternal behavior. *Nursing Outlook*, 9(11), 683-686.

phases extend over the first several weeks and are characterized by dependent behavior, dependent-independent behavior, and interdependent behavior (Table 22-4). Rubin's research was conducted when the length of stay in the hospital was longer (3 to 5 or more days). With today's early discharge, women seem to move through the phases faster.

Mercer (2004) suggested that the concept of *maternal role attainment* be replaced with *becoming a mother* to signify the transformation and growth of the mother's identity. Becoming a mother implies more than attaining a role. It includes learning new skills and increasing her confidence in herself as she meets new challenges in caring for her child or children.

Mercer and Walker (2006) identified four stages in the process of becoming a mother: "(a) commitment, attachment to the unborn baby, and preparation for delivery and motherhood during pregnancy; (b) acquaintance/attachment to the infant, learning to care for the infant, and physical restoration during the first 2 to 6 weeks following birth; (c) moving toward a new normal; and (d) achievement of a maternal identity through redefining self to incorporate motherhood (around 4 months)" (Mercer & Walker, pp. 568-569). The time of achievement of the stages is variable and the stages can overlap. Achievement is influenced by maternal and infant variables and the social environment.

Maternal sensitivity or maternal responsiveness is an important determinant of the maternal-infant relationship. It can be defined as the quality of a mother's sensitive behaviors that are based on her awareness, perception, and responsiveness to infant cues and behaviors. Maternal sensitivity significantly influences the infant's physical, psychologic, and cognitive development. Maternal qualities inherent to this sensitivity include awareness and responsiveness to infant cues, affect, timing, flexibility, acceptance, and conflict negotiation. Maternal sensitivity develops over time in a reciprocal give-and-take relationship with the infant (Tharner, Luijk, Raat, et al., 2012).

The transition to motherhood requires adjustment for the mother and her family. Not all mothers experience the transition to motherhood in the same way. Circumstances such as problems in postpartum recovery or giving birth to a high risk infant add to the disruption. For some women becoming a mother entails multiple losses. For example, for a single woman a loss of the family of origin can occur when the family does not accept her decision to have the child. There can be loss of a relationship with the father of the baby, with friends, and with her own sense of self. Some women describe a loss of dreams that includes loss of job, financial security, and a future profession. Accompanying these losses is a loss of support.

Reality-based perinatal education programs help to prepare mothers and decrease their anxiety. Live classes allow time for questions to be answered and for mothers to lend support to one another. Mothers need to know that during the first months of parenthood it is common to feel overwhelmed and insecure and to experience physical and mental fatigue. They need to be assured that this situation is temporary and that 3 to 6 months can be needed to become comfortable in caregiving and in being a mother. Maternal support by professionals should not end with hospital discharge but, instead, extend over the next 4 to 6 months. Nurses can advocate for the extension of support services well into the postpartum period (Mercer & Walker, 2006; Shapiro, Nahm, Gottman, & Content, 2011).

During pregnancy and after birth nurses can discuss the usual postpartum concerns that mothers experience. They can provide anticipatory guidance on coping strategies, such as resting when the infant sleeps and planning with an extended family member or friend to do the housework for the first week or two after the baby is born. Once a mother is home, periodic telephone calls from a nurse who cared for her in the birth setting can provide the mother with an opportunity to vent her concerns and get support and advice from “her” nurse. Nurses should plan additional supportive counseling for first-time mothers inexperienced in child care, women whose careers had provided outside stimulation, women who lack friends or family members with whom to share delights and concerns, and adolescent mothers. When, possible, postpartum home visits should be included in the postpartum care.

In summary, nurses have the unique opportunity to experience the miracle of a birth and provide valuable client and family education and emotional support that will help during and after this exciting and overwhelming time of transition to parenthood (Husmillo, 2013).

Postpartum “Blues”

The “pink” period surrounding the first day or two after birth, characterized by heightened joy and feelings of well-being, is often followed by a “blue” period. Approximately 50% to 80% of women of all ethnic and racial groups experience the **postpartum blues**, or “baby blues.” During the blues, women are emotionally labile and often cry easily for no apparent reason. This lability seems to peak around the fifth day and subsides by the tenth day. Other symptoms of postpartum blues include depression, a let-down feeling, restlessness, fatigue, insomnia, headache, anxiety, sadness, and anger. Biochemical, psychologic, social, and cultural factors have been explored

as possible causes of postpartum blues; however, the cause remains unknown.

Whatever the cause, the early postpartum period appears to be one of emotional and physical vulnerability for new mothers, who are often psychologically overwhelmed by the reality of parental responsibilities. Mothers feel deprived of the supportive care they received from family members and friends during pregnancy. Some mothers regret the loss of the mother–unborn child relationship and mourn its passing. Still others experience a let-down feeling when labor and birth are complete. The majority of women experience fatigue after birth, which is compounded by the around-the-clock demands of the new baby. Postpartum fatigue increases the risk of postpartum depressive symptoms and can have a negative effect on maternal role attainment (Kurth, Spichiger, Stutz, et al., 2010). A few questions on a discharge checklist can help mothers assess their level of blues and decide when to seek advice from their nurse, nurse-midwife, or physician. Home visits and telephone follow-up calls by a nurse are important to assess the mother’s pattern of blue feelings and behavior over time. To help mothers cope with postpartum blues, nurses can suggest various strategies (see Teaching for Self-Management box).

TEACHING FOR SELF-MANAGEMENT

Coping with Postpartum Blues

- Remember that the “blues” are normal and that both the mother and the father or partner can experience them.
- Get plenty of rest; nap when the baby does if possible. Go to bed early and let friends and family know when to visit and how they can help. (Remember, you are not Supermom.)
- Use relaxation techniques learned in birthing classes (or ask the nurse to teach you and your partner some techniques).
- Do something for yourself. Take advantage of the time your partner or family members care for the baby—soak in the tub (a 20-minute soak can be the equivalent of a 2-hour nap), or go for a walk.
- Plan a day out of the house—go to the mall with the baby, being sure to take a stroller or carriage, or go out to eat with friends without the baby. Many communities have churches or other agencies that provide child care programs such as Mothers’ Morning Out.
- Talk to your partner about the way you feel—for example, about feeling tied down, how the birth met your expectations, and things that will help you (do not be afraid to ask for specifics).
- If you are breastfeeding, give yourself and your baby time to learn.
- Seek out and use community resources such as La Leche League or community mental health centers. One nationally recognized resource is:
Postpartum Support International
 927 North Kellogg Ave.
 Santa Barbara, CA 93111
 (805) 967-7636
 www.postpartum.net

Although the postpartum blues are usually mild and short-lived, approximately 10% to 15% of women experience a more severe syndrome termed *postpartum depression* (PPD). Symptoms of PPD can range from mild to severe, with women having

good days and bad days. Fathers can also experience PPD. Screening for PPD should be performed with both mothers and fathers. PPD can go undetected because new parents generally do not voluntarily admit to this kind of emotional distress out of embarrassment, guilt, or fear. Nurses need to include teaching about how to differentiate symptoms of the blues and PPD and urge parents to report depressive symptoms promptly if they occur (see Chapter 31).

Becoming a Father

The realities of the first few weeks at home with a newborn cause fathers to change their expectations, set new priorities, and redefine their role. They develop strategies for balancing work, their own needs, and the needs of their partner and infant. Men become increasingly more comfortable with infant care. During this time they may struggle for recognition and positive feedback from their partner, the infant, and others. They can feel excluded from support and attention by health care providers. Infant smiles enhance involvement and the father-infant relationship (Table 22-5).

First-time fathers often perceive the first 4 to 10 weeks of parenthood in much the same way that mothers do. It is a period characterized by uncertainty, increased responsibility, disruption of sleep, and inability to control time needed to care for the infant while reestablishing the relationship with their partner (Yu, Hung, Chan, et al., 2012). The realities of these first few weeks at home with a newborn often cause fathers to change their expectations, set new priorities, and redefine their roles. They begin to develop strategies for balancing work with their own needs and the needs of their partner and infant (de Montigny, Lacharité, & Devault, 2012)

Research on paternal adjustment to parenthood suggests that men go through predictable phases during their transition to parenthood as they seek to become involved fathers (Goodman, 2005). In the first phase men enter parenthood with intentions of being an emotionally involved father with deep connections to the infant. They consider how they were parented by their own father. Many desire to parent differently from their own father, whereas others plan to adopt the parenting style of their father (Chin, Hall, & Daiches, 2011).

The second phase is a time of confronting reality, when men realize that their expectations were inconsistent with the realities of life with a newborn during the first few weeks. During this period fathers experience intense emotions. Many acknowledge that their expectations were of limited value once

they were immersed in the reality of parenthood. Feelings that often accompany this reality are sadness, ambivalence, jealousy, frustration, and an overwhelming desire to be more involved. Some men are surprised that establishing a relationship with the infant is more gradual than expected. Fathers often feel alone, having no one with whom to discuss their feelings during this time because mothers are often preoccupied with infant care and their own transition to parenting.

The third phase is working to create the role of involved father. Men strive to become increasingly more comfortable with infant care. Uncertainty about child care skills can lead to feelings of anxiety (Goodman, 2005). Communicating with other new fathers about their experiences can help alleviate some of this anxiety (Chin et al., 2011). During this time they may struggle for recognition and positive feedback from their partner, the infant, and others and may feel excluded from support and attention by health care providers. Leaving their partner and the newborn to return to work after the birth can be difficult for fathers; many find it challenging to balance their time between work and spending time with their families. Some men reprioritize their activities or negotiate work hours to allow them to be at home more often (Chin et al.).

The final phase of becoming an involved father is one of reaping rewards, the most significant being reciprocity from the infant, such as a smile. This phase typically occurs around 6 weeks to 2 months. Increased sociability of the infant enhances this father-infant relationship (Goodman, 2005).

In North American culture, neonates have a powerful effect on their fathers who become intensely involved with their babies. The term used for the father's absorption, preoccupation, and interest in the infant is **engrossment**. Characteristics of engrossment include some of the sensual responses relating to touch and eye-to-eye contact that were discussed earlier and the father's keen awareness of features both unique and similar to himself that validate his claim to the infant. The father feels strong attraction to the newborn. Fathers spend considerable time "communicating" with the infant and taking delight in the infant's response to them (Fig. 22-7). Fathers experience increased self-esteem and a sense of being proud, bigger, more mature, and older after seeing their baby for the first time.

FIG 22-7 Engrossment. Father is absorbed in looking at his newborn. (Courtesy Kathryn Alden, Chapel Hill, NC.)

TABLE 22-5 Early Development of the Involved Father Role

PHASES	CHARACTERISTICS
Expectations and intentions	Desire for emotional involvement and deep connection with infant
Confronting reality	Dealing with unrealistic expectations, frustration, disappointment, feelings of guilt, helplessness, and inadequacy
Creating the role of involved father	Altering expectations, establishing new priorities, redefining role, negotiating changes with partner, learning to care for infant, increasing interaction with infant, struggling for recognition
Reaping rewards	Infant smile, sense of meaning, completeness and immortality

From Goodman, J. (2005). Becoming an involved father of an infant. *Journal of Obstetric, Gynecologic and Neonatal Nursing*, 34(2), 190-200.

Fathers spend less time than mothers with infants, and their interactions with infants tend to be characterized by stimulating social play rather than caretaking. The variations in infant stimulation from both parents provide a wider social experience for the infant.

Fathers receive less interpersonal and professional support compared with mothers and can feel excluded from prenatal appointments and perinatal classes (Chin et al., 2011; Steen, Downe, Bamford, & Edozien, 2012). They need information and encouragement during pregnancy and in the postpartum period related to infant care, parenting, and relationship changes. During the postpartum hospital stay, nurses can arrange to teach infant care when the father is present and provide anticipatory guidance for fathers about the transition to parenthood. Separate prenatal and parenting classes and parenting support groups for fathers can provide them with an opportunity to discuss their concerns and have some of their needs met. To prepare fathers for the transition to parenthood, perinatal education should include information on role changes associated with parenting, the importance of parenting “teamwork,” the increased risk of mental distress and depression, the mother’s experience and how to provide support, how to interpret and respond to infant behaviors, and how to deal with infant crying (May & Fletcher, 2013). Postpartum telephone calls and home visits by the nurse should include time for assessment of the father’s adjustment and needs (Chin et al.).

Adjustment for the Couple

The transition to parenthood brings about changes in the relationship between the mother and her partner. A strong, healthy marriage or couple relationship is the best foundation for parenthood, although even the best relationships are often shaken with the addition of a new baby. During the first few weeks after birth, parents experience many emotions. Even though they may feel an overwhelming love and a sense of amazement toward their newborn, they can also feel a great responsibility. Even if the mother and her partner have been to prenatal classes, read books or Internet sources, or sought advice from family or friends, they are usually surprised by the realities of life with a new baby and the changes in their relationship. Because men and women experience pregnancy and birth differently, the expectation is that they will also vary in their transition to parenthood.

Common issues that couples face as they become parents include changes in their relationship with one another, division of household and infant care responsibilities, financial concerns, balancing work and parental responsibilities, and social activities (Menéndez, Hidalgo, Jiménez, & Moreno, 2011). To assist new parents in their transition, nurses can encourage them during pregnancy and in the postpartum period to share personal expectations with each other and to assess their relationship periodically. Couples need to schedule time into their busy lives for one-on-one conversation and try to have regular “dates” or time apart from the infant. The mother and her partner need to express appreciation for one another and for their baby. Support from family, friends, and community health professionals should be identified early and used as needed during pregnancy and in the postpartum period and beyond. The couple who is willing to experiment with new approaches to their

lifestyle and habits can find the transition to parenthood less difficult.

Resuming Sexual Intimacy

Nurses can provide opportunities for parents to discuss concerns and ask questions about resuming sexual intimacy. The couple may begin to engage in sexual intercourse during the second to fourth week after the baby is born. Some couples begin earlier, as soon as it can be accomplished without discomfort, depending on factors such as timing and vaginal dryness. Sexual intimacy enhances the adult aspect of the family, and the adult pair shares a closeness denied to other family members. Changes in a woman’s sexual desire after birth are related to hormonal shifts, increased breast size, uneasiness with a body that has yet to return to a prepregnant size, chronic fatigue related to sleep deprivation, and physical exhaustion. Partners can feel alienated when they observe the intimate mother-infant relationship, and some are frank in expressing feelings of jealousy toward the infant. The resumption of sexual intimacy seems to bring the parents’ relationship back into focus. Before and after birth, nurses should review with new parents their plans for other pregnancies and their preferences for contraception. (See Teaching for Self-Management box: Resuming Sexual Intimacy in Chapter 21.)

Infant-Parent Adjustment

It has long been recognized that newborns participate actively in shaping their parents’ reaction to them. Behavioral characteristics of the infant influence parenting behaviors. The infant and the parent each have unique rhythms, behaviors, and response styles that are brought to every interaction. Infant-parent interactions can be facilitated in any of the following three ways: (1) modulation of rhythm, (2) modification of behavioral repertoires, and (3) mutual responsivity. Nurses can teach parents about these three aspects of infant-parent interaction through discussions, written materials, and media resources describing infant capabilities. A creative approach is to make a video recording of the parent-infant pair during an interaction and then use that recording to discuss the pair’s rhythm, behavioral repertoire, and responsivity.

Rhythm. To modulate rhythm, both parent and infant must be able to interact. Therefore, the infant must be in the alert state, one of the most difficult of the sleep-wake states to maintain. The alert state (Fig. 22-8) occurs most often during a feeding or in face-to-face play. The parent must work hard to help the infant maintain the alert state long enough and often enough for interactions to take place. The en face position is usually assumed (see Fig. 22-8, D). Multiparous mothers in particular are very sensitive and responsive to the infant’s feeding rhythms.

Mothers learn to reserve stimulation for pauses in sucking activity and not to talk or smile excessively while the infant is sucking because the infant will stop feeding to interact with her. With maturity the infant can sustain longer interactions by modulating activity rhythms, that is, limb movement, sucking, gaze alternation, and habituation. Meanwhile, the parent becomes more attuned to the infant’s rhythms and learns to modulate the rhythms, facilitating a rhythmic turn-taking interaction.

FIG 22-8 Holding newborn in en face position, mother interacts with her daughter, 6 hours old. A, Infant is quiet and alert. B, Mother begins talking to daughter. C, Infant responds, opens mouth like her mother. D, Infant gazes at her mother. E, Infant waves hand. F, Infant glances away, resting; hands relax. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

Behavioral Repertoires. Both the infant and the parent have a repertoire of behaviors they can use to facilitate interactions. Fathers and mothers engage in these behaviors depending on the extent of contact and caregiving of the infant. Nurses can teach parents to recognize, interpret, and respond to infant behaviors. An innovative program called HUG Your Baby (Help, Understanding and Guidance for Young Families: www.hugyourbaby.org) is designed to prepare health care professionals to teach parents how to understand their newborns and prevent problems related to crying, sleeping, eating, attachment, and bonding.

The infant's behavioral repertoire includes gazing, vocalizing, and facial expressions. From birth the infant is able to focus, follow the human face, and alternate the gaze voluntarily, looking away from the parent's face when understimulated or overstimulated (see Fig. 22-8, F). One of the key responses for the parents to learn is to be sensitive to the infant's capacity for attention and inattention. Developing this sensitivity is especially important when interacting with preterm infants.

Body gestures form a part of the infant's "early language." Babies greet parents with waving hands (see Fig. 22-8, E) or by reaching out. They can raise an eyebrow or soften their expression to elicit loving attention. Game-playing can stimulate them to smile or laugh. Pouting or crying, arching of the back, and general squirming usually signal the end of an interaction.

The parents' repertoire includes various types of interactive behaviors such as constantly looking at the infant and noting the infant's response. New parents often remark that they are exhausted from looking at the baby and smiling. Adults also "infantilize" their speech to help the infant "listen." They do this by slowing the tempo, speaking loudly and rhythmically, and emphasizing key words. Phrases are repeated frequently. Infantilizing does not mean using "baby talk," which involves distortion of sounds.

To communicate emotions to the infant, parents often use facial expressions such as slow and exaggerated looks of

surprise, happiness, and confusion. Games such as peek-a-boo and imitation of the infant's behaviors are other means of interaction. For example, if the baby smiles, so does the parent; if the baby frowns, the parent responds in kind.

Responsivity. Contingent responses (responsivity) are those that occur within a specific time and are similar in form to a stimulus behavior. The adult has the feeling of having an influence on the interaction. Infant behaviors such as smiling, cooing, and sustained eye contact, usually in the en face position, are viewed as contingent responses. The infant's responses act as rewards to the initiator and encourage the adult to continue with the game when the infant responds positively. When the adult imitates the infant, the infant appears to enjoy it. A progression occurs in the types of behaviors that parents present for the baby to imitate; for example, in early interactions, the parent will grimace rather than laugh, which is in keeping with the infant's developmental level. Such "turnabout" behaviors sustain interactions and promote harmony in the relationship.

DIVERSITY IN TRANSITIONS TO PARENTHOOD

Various factors, including age, social networks, socioeconomic conditions, and personal aspirations for the future, influence how parents respond to the birth of a child. Cultural beliefs and practices also affect parenting behaviors. Factors that are recognized to increase the risk of parenting problems include age (adolescent or older than 35 years), same sex parenting, social support, culture, socioeconomic conditions, and personal aspirations.

Age

Maternal age has a definite effect on the transition to parenting. The mother, fetus, and newborn are at highest risk when the mother is an adolescent or older than 35 years.

The Adolescent Mother

Although becoming a parent is biologically possible for the adolescent female, her egocentricity and concrete thinking often interfere with the ability to parent effectively. Adolescent mothers are more likely to give birth to preterm and/or low-birth-weight infants (Martin, Hamilton, Osterman, et al., 2013). Mortality rates are higher among infants of adolescent mothers. This can be related to inherent problems associated with preterm birth or other conditions, but it is also influenced by the mother's inexperience, lack of knowledge, and immaturity. In the United States, adolescent mothers are often poorer, less educated, and receive less prenatal care than older mothers (Geoghegan, 2013). Nevertheless, in most instances, with adequate support and developmentally appropriate teaching, adolescents can learn effective parenting skills. Strong social and functional support promotes positive outcomes for adolescent mothers.

Contrary to popular beliefs related to the detrimental effects of adolescent pregnancy, research evidence suggests that the life course for adolescent mothers is similar to that of their socioeconomic peers. In some families or communities, adolescent parenthood is considered a normal or positive life event. Even so, adolescent pregnancy and parenting are important public health concerns.

The transition to parenthood can be difficult for adolescents. Because many adolescents have their own unmet developmental needs, coping with the developmental tasks of parenthood is often difficult. Some young parents experience difficulty accepting a changing self-image and adjusting to new roles related to the responsibilities of infant care. Adolescent mothers are at increased risk for postpartum depression; this is often associated with a lack of social support and poor relations with their partner (Mollborn & Jacobs, 2011). There is an increased risk of child abuse and neglect by adolescent mothers; the risk increases when the mother experienced abuse as a child (Bartlett & Easterbrooks, 2012).

As adolescent parents move through the transition to parenthood, they can feel "different" from their peers, excluded from "fun" activities, and prematurely forced to enter an adult social role. The conflict between their own desires and the infant's demands, in addition to the low tolerance for frustration that is typical of adolescence, further contribute to the normal psychosocial stress of birth and parenting. Maintaining a relationship with the baby's father is often beneficial for the teen mother and her infant, although in adolescent pregnancy it is often found that the young father departs from the relationship.

Adolescent mothers provide warm and attentive physical care; however, they use less verbal interaction than older parents, tend to be less responsive, and interact less positively with their infants than older mothers. Interventions emphasizing verbal and nonverbal communication skills between mother and infant are important. Such intervention strategies must be concrete and specific because of the cognitive and developmental level of adolescents. In comparison with older mothers, teenage mothers have a limited knowledge of child development. They tend to expect too much of their infants too soon and often characterize their infants as being fussy. This limited knowledge can cause teenagers to respond to their infants inappropriately.

Many young mothers pattern their maternal role on what they experienced with their own mothers. Therefore, nurses need to determine the type of support that people close to the young mother are able and prepared to give, as well as the kinds of community assistance available to supplement this support. Many teen mothers can identify a source of social support, with the predominant source being their own mothers.

The need for continued assessment of the new mother's parenting abilities during this postpartum period is essential. Continued support is facilitated by involving the grandparents and other family members, as well as through home visits and group sessions for discussion of infant care and parenting concerns (Schaffer, Goodhue, Stennes, & Lanigan, 2012). Community-based programs for pregnant adolescents and adolescent parents improve access to health care, education, and other support services. Many school-based programs include a parenting and life skills curriculum as well as pregnancy prevention strategies. Serious problems can be prevented through outreach programs concerned with self-management, parent-child interactions, infant development, and child safety. As the adolescent performs her mothering role within the framework of her family, she may need to address dependence versus independence issues. The adolescent's family members also need help adapting to their new roles. Some mothers and fathers of adolescents feel they are too young and unprepared to be grandparents (see Clinical Reasoning Case Study).

The Adolescent Father

The adolescent father and mother face immediate developmental tasks that include completing the developmental tasks of

CLINICAL REASONING CASE STUDY

Transition to Parenthood for the Adolescent Couple

You are the mother/baby nurse caring for Sherika, a 16-year-old who gave birth to a baby girl 24 hours ago. John, the baby's father, is Sherika's 17-year-old "on again, off again" boyfriend who has visited once since the baby was born, but only for a couple of hours. John has held the baby briefly twice but seems to stand in the background most of the time. Sherika's mother has been at the hospital with her since admission and has been very involved in her care. Her mother has raised six children and has very strong opinions about how to take care of the baby and Sherika as she recovers from the birth. Sherika would like to breastfeed the baby, but her mother states that when she was raising her children she did not have enough milk to feed them, and insists that Sherika start with formula feeding.

- Evidence—Is evidence sufficient to draw conclusions about the education and care needed for this family?
- Assumptions—What assumptions can be made about the following factors?
 - The relationship of maternal age and transition to parenthood
 - The relationship of paternal age and transition to parenthood
 - The need for postpartum and discharge teaching
 - The role of family dynamics and postpartum adaptation
 - Short- and long-term goals that would promote positive outcomes
- What nursing care priorities can be determined at this time?
- Does the evidence objectively support your conclusion?

adolescence, making a transition to parenthood, and sometimes adapting to marriage. These transitions are often stressful. In addition, relationships between adolescent mothers and fathers tend to be less stable than among adults and often deteriorate or dissolve soon after birth. The involvement of the father with the infant is dependent on his relationship with the mother, who also controls his access to the infant (Farrie, Lee, & Fagan, 2011).

The nurse can initiate interaction with the adolescent father during prenatal visits, labor and birth, and the postpartum hospitalization. The nurse can assess the relationship between the two adolescents and encourage them to discuss their plans for the father's involvement with the mother and infant after birth (Fagan, 2013). During the hospital stay the nurse can include the adolescent father in teaching sessions about infant care and parenting. The nurse can ask him to be present during postpartum home visits and to accompany the mother and the baby to well-baby follow-up visits at the clinic or pediatrician's office. With the adolescent mother's approval, the nurse may contact the father directly.

Adolescent fathers need support to discuss their emotional responses to the pregnancy, birth, and fatherhood. The nurse needs to be aware of the father's feelings of guilt, powerlessness, or bravado because these feelings can have negative consequences for both the parents and the child. Counseling of adolescent fathers needs to be reality oriented and should include topics such as finances, child care, parenting skills, and the father's role in the parenting experience. Teenage fathers also need to know about reproductive physiology and birth control options, as well as sexual practices that lower the risk of pregnancy and sexually transmitted infections.

The adolescent father may continue to be involved in an ongoing relationship with the young mother and his baby. In those instances he plays an important role in the decisions about child care and raising the child. He may need help to develop realistic perceptions of his role as "father to a child" and is encouraged to use coping mechanisms that are not harmful to his own, his partner's, or his child's well-being. The nurse may enlist support systems, parents, and professional agencies on his behalf.

Maternal Age Older Than 35 Years

Women older than 35 years have always continued their child-bearing either by choice or because of a lack of or a failure of contraception during the perimenopausal years. Added to this group are women who have postponed pregnancy because of careers or other reasons, as well as women of infertile couples who finally become pregnant with the aid of assisted reproductive technology.

Support from partners aids in the adjustment of older mothers to changes involved in becoming a parent and seeing themselves as competent. Support from other family members and friends is also important for positive self-evaluation of parenting, a sense of well-being and satisfaction, and help in dealing with stress. Women of advanced maternal age can experience social isolation. Older mothers may have less family and social support than younger mothers. They are less likely to live near family, and their own parents may

be unable to provide assistance or support because of age or health issues. Mothers of advanced maternal age are often caught in the "sandwich generation," taking on responsibility for care of aging parents while parenting young children. Social support can be lacking because their peers are probably busy with their careers and have limited time to help. Their friends are likely to have older children and have less in common with the new mother (Morgan, Merrell, Rentschler, & Chadderton, 2012).

Changes in the sexual aspect of a relationship can create stress for new midlife parents. Mothers report that it is difficult to find time and energy for a romantic rendezvous. They attribute much of this difficulty to the reality of caring for an infant, but the decreasing libido that normally accompanies getting older also contributes.

Work and career issues are sources of conflict for older mothers. Conflicts emerge over being disinterested in work, worrying about giving enough attention to work with the distractions of a new baby, and anticipating what returning to work will entail. Child care is a major factor in causing stress about work.

Another major issue for older mothers with careers is the perception of loss of control. Mothers older than 35 years, when compared with younger mothers, are at a different stage in their careers, having attained high levels of education, career, and income. The loss of control experienced when going from the consistency of a work role to the inconsistency of the parent role comes as a surprise to many older women. Helping the older mother have realistic expectations of herself and of parenthood is essential.

New mothers who are also perimenopausal can experience difficulty distinguishing fatigue, loss of sleep, decreased libido, or other physiologic symptoms as the causes of the change in their sex lives. Although many women view menopause as a natural stage of life, for midlife mothers, this cessation of menstruation coincides with the state of parenthood. The changes of midlife and menopause can add more emotional and physical stress to older mothers' lives because of the time- and energy-consuming aspects of raising a young child.

Paternal Age Older Than 35 Years

Although many older fathers describe their experience of midlife parenting as wonderful, they also recognize drawbacks. Positive aspects of fatherhood in older years include increased love and commitment between the two parents, a reinforcement of why one married in the first place, a feeling of being complete, experiencing "the child" again in oneself, more financial stability than in younger years, and more freedom to focus on parenting rather than on career. A common drawback of midlife parenting is the change that it brings about in the relationships with their partners.

Parenting in Same Sex Couples

The transition to parenting for same sex couples can present unique challenges. Whether the couple consists of two women or two men, issues such as a lack of family acceptance and support, public ignorance, and social and legal invisibility influence their ability to adapt as new parents. Attitudes of health care professionals can either positively or negatively affect the care provided to same-sex couples.

Lesbian Couple

The transition to parenting for many lesbian couples is unique in that there are two women with maternal status, one who gave birth and the other who may be referred to as “the other mother,” “nonbiologic mother,” “co-parent,” or other term preferred by the couple. It is important for health care providers to determine the couple’s preference about how they wish to be identified.

Among lesbian couples the decision to become parents is intentional. There are several methods to achieve a pregnancy. One woman can be artificially inseminated and conceive a child who is genetically related to her. The fertilized egg of one partner can be implanted into the uterus of the other who carries the pregnancy. Alternatively, one woman can be implanted with the fertilized egg from a donor so that the child is not biologically related to either partner. Evidence suggests that the birth mother has chosen to be the one to carry the baby because of a greater desire to experience the pregnancy and birth and to be genetically related to the child. Other factors that influence the decision are age, health, infertility, and career considerations. Some lesbian couples who wish to become parents use a surrogate to carry the pregnancy or they may adopt. If the couple adopts a newborn, the nurse may be involved in educating them about infant care.

Health care providers demonstrate a variety of reactions to lesbian couples ranging from rejection and exclusion to complete acceptance and inclusion. Judgmental attitudes, confusion, or lack of understanding can affect the quality of care provided to these families (Dahl, Fylkesnes, Sorlie, & Malterud, 2013). Although the traditional roles of the mother and father in heterosexual relationships are well recognized, the role of the lesbian co-parent can be questioned, misunderstood, and ignored by society and by health care providers. Intentionally or accidentally, health care providers can exclude partners or fail to acknowledge their roles in pregnancy, birth, and parenting (O’Neill, Hamer, & Dixon, 2012).

Integration of the nonchildbearing partner into care includes offering opportunities afforded male partners of heterosexual women such as “cutting the cord” and rooming in with the mother and baby during hospitalization. An option not available to male partners is to actually breastfeed the infant. The nonchildbearing female partner can stimulate milk production through induced lactation using medications and regular pumping. A supplemental feeding device containing expressed breast milk or formula can be used to provide additional milk to the breastfeeding infant (see Fig. 25-8). Women who choose not to induce lactation yet desire to have the breastfeeding experience can put the baby to breast using a supplemental feeding device.

Similar to heterosexual parents, lesbian couples face challenges in adjusting to life with a new baby. The birth mother tends to be the one most responsible for child care because she is likely to be working fewer hours than her partner. Tensions can arise between the partners in relation to their roles. This can be compounded by the lack of a formal, recognized relationship between the co-parent and the infant and the issues surrounding her legal rights in relation to her partner and the infant (Mortensen, Torsheim, Melkevik, & Thuen, 2012).

Lesbian couples face strong social sanctions regarding pregnancy and parenting. Their families may not have resolved the initial dismay and guilt over learning of their daughters’

homosexuality, or they may disagree with the lesbian couple’s decision to conceive and be parents. Lesbian parents deal with public ignorance, social and legal invisibility, and the lack of biologic connection to the child by using various techniques. These techniques include carefully planning and accomplishing their transition to parenthood, displaying public acts of equal mothering, sharing parenting at home, establishing a distinct parenting role within the family, and supporting each partner’s sense of identity as a mother. In situations in which family support is limited or absent, the nurse can help lesbian couples locate supportive social groups, lesbian or heterosexual.

Gay Couples

Some men in same-sex relationships, or gay couples, choose to become parents by adoption or through assisted reproduction in which a gestational carrier is impregnated by artificial insemination or in vitro fertilization (Greenfield & Seli, 2011). Female-to-male transgender individuals in gay relationships have been known to become pregnant. Same-sex male couples face the same social sanctions regarding pregnancy and parenting that lesbian couples encounter.

Nurses are likely to encounter gay couples in the hospital setting if they are present for birth by a surrogate or if they are adopting a newborn and visit the hospital to spend time with the neonate and learn about infant care. Nurses can help these men locate support groups that will address their needs. They need to ensure that these families receive effective health care. Data on gay parenting are limited and focus more on developmental outcomes of the children than on parenting styles or parental caregiving. Research is needed to identify the needs of gay parents and ways to support them in their parenting endeavors.

Social Support

Social support is strongly related to positive adaptation by new parents during the transition to parenthood. Social support is multidimensional and includes the number of members in a person’s social network, types of support, perceived general support, actual support received, and satisfaction with support available and received. Partner support in pregnancy has a positive influence on adaptation in the postpartum period (Goldberg & Smith, 2011; Westling, Glynn, Sandman, et al., 2012).

Across cultural groups, families and friends of new parents form an important dimension of the parent’s social network. Through seeking help within the social network, new mothers learn culturally valued practices and develop role competency.

Social networks provide a support system on which parents can rely for assistance, but they also can be a source of conflict. Sometimes a large network can cause problems because it results in conflicting advice that comes from numerous people. Grandparents or in-laws are most appreciated when they assist with household responsibilities and do not intrude into the parents’ privacy or judge them critically.

Because of the extent of restructuring and reorganization that occurs in a family with the birth of another child, the mothers’ moods and fatigue in the postpartum period can be helped more by situation-specific support from family and friends than by general support. Situation-specific support relates to practice concerns such as physical needs and child care. For example, the practical support of a grandparent bathing the infant can help

lessen a second-time mother's feelings of loss by providing her time to be with her first-born child. General support addresses the feelings of being loved, supported, and valued.

Culture

Cultural beliefs and practices are important determinants of parenting behaviors. Culture influences the interactions with the baby, as well as the parents' or the family's caregiving style.

All cultures place importance on desiring and valuing children. In Asian families, children are a source of family strength and stability, are perceived as wealth, and are objects of parental love and affection. Infants are almost always given an affectionate "cradle" name that is used during the first years of life. Differing cultural values can influence parents' interactions with health care professionals. For example, Asians are taught to be humble and obedient, to refrain from questioning authority figures (e.g., a nurse), to avoid confrontation, and to respect the yin/yang balance in nature. Because of these learned values, an Asian mother might not confront the nurse about the length of time taken to receive the medication requested for her episiotomy pain. A mother may nod and say, "Yes," in response to the nurse's directions for using an iced sitz bath but then will not use the sitz bath. The "yes," in this case, is a gesture of courtesy, meaning, "I'm listening"; it is not an indication of agreement to comply. The mother does not use the iced sitz bath because of her traditional avoidance of bathing and cold after birth. Because not all members of a cultural group adhere to traditional practices, it is necessary to validate which cultural practices are important to individual parents. This can be easily accomplished by asking the parents specific questions about their cultural beliefs and practices.

Knowledge of cultural beliefs can help the nurse make more accurate assessments and analyses of observed parenting behaviors. For example, nurses can become concerned when they observe cultural practices that appear to reflect poor maternal-infant bonding. Algerian mothers may not unwrap and explore their infants as part of the acquaintance process because in Algeria, babies are wrapped tightly in swaddling clothes to protect them physically and psychologically. The nurse may observe a Vietnamese woman who gives minimal care to her infant but refuses to cuddle or further interact with her baby. This apparent lack of interest in the newborn is this cultural group's attempt to ward off "evil spirits" and actually reflects an intense love and concern for the infant. An Asian mother might be criticized for almost immediately relinquishing the care of the infant to the grandmother and not even attempting to hold her baby when it is brought to her room. However, in Asian extended families, members show their support for a new mother's rest and recuperation by assisting with the care of the baby. Contrary to the guidance that is sometimes given to mothers in the United States about exclusive breastfeeding, a mix of breastfeeding and bottle feeding is standard practice for Japanese mothers. This tradition is related to concern for the mother's rest during the first 2 to 3 months and does not usually lead to problems with lactation; breastfeeding is widespread and successful among Japanese women.

Cultural beliefs and values give perspective to the meaning of childbirth for a new mother. Nurses can provide an opportunity

for a new mother to talk about her perception of the meaning of childbearing. In helping new families adjust to parenthood, nurses must provide culturally sensitive care by following principles that facilitate nursing practice within transcultural situations (Chalmers, 2012).

Socioeconomic Conditions

Socioeconomic conditions often determine access to available resources. Parents whose economic condition is made worse with the birth of each child and who are unable to use an effective method of fertility management can find birth complicated by concern for their own health and a sense of helplessness. Mothers who are single, separated, or divorced from their husbands or without a partner, family, and friends can view the birth of a child with dread. **Serious financial problems can negatively affect mothering behaviors. Similarly, fathers who are overwhelmed with financial stresses may lack effective parenting skills and behaviors.**

Personal Aspirations

For some women parenthood interferes with or blocks plans for personal freedom or career advancement. **Unresolved resentment affects caregiving activities and adjustment to parenting. This situation can result in indifference and neglect of the infant or in excessive concerns; the mother may set impossibly high standards for her own behavior or the child's performance.**

Nursing interventions include providing opportunities for mothers to express their feelings freely to an objective listener, to discuss measures to permit personal growth, and to learn about the care of their infant. Referring the woman to a support group of other mothers "in the same situation" may also be helpful.

Nurses can be proactive in influencing changes in work policies related to maternity and paternity leaves, varying models of work sharing and family-friendly work environments. Some corporations already structure their worksites to support new mothers (e.g., by providing on-site day care facilities and lactation rooms).

PARENTAL SENSORY IMPAIRMENT

In early interactions between the parent and child, each one uses all senses—sight, hearing, touch, taste, and smell—to initiate and sustain the attachment process. A parent who has an impairment of one or more of the senses needs to maximize use of the remaining senses. Mothers with disabilities tend to value the importance of performing parenting tasks in the perceived culturally usual way.

Visually Impaired Parent

Visual impairment alone does not seem to have a negative effect on early parenting experiences. These parents, just as sighted parents, express the wonders of parenthood and encourage other visually impaired people to become parents.

Although visually impaired parents can initially feel pressure to conform to traditional, sighted ways of parenting, they soon adapt and develop methods better suited to themselves. Examples of activities that visually impaired parents perform differently include preparation of the infant's nursery, clothes, and

supplies. Some parents put an entire clothing outfit together and hang it in the closet rather than keeping items separate in drawers. Some develop a labeling system for the infant's clothing and place diapering, bathing, and other care supplies where they will be easy to locate. A strength that visually impaired parents have is a heightened sensitivity to other sensory outputs. Visually impaired parents can tell when their infant is facing them because they notice the baby's breath on their faces.

One of the major difficulties that visually impaired parents experience is the skepticism, open or hidden, of health care professionals. Visually impaired people may sense reluctance on the part of others to acknowledge that they have a right to be parents. All too often nurses and physicians lack the experience to deal with the childbearing and childrearing needs of visually impaired parents, as well as parents with other disabilities, such as the hearing impaired, physically impaired, and mentally challenged. The nurse's best approach is to assess the parents' capabilities and to use that information as a basis for making plans to assist them, often in much the same way as for parents without impairments. Visually impaired mothers have made suggestions about providing care for women such as themselves during childbearing (Box 22-2). Such approaches can help avoid a sense of increased vulnerability on the parent's part. Materials for perinatal education are available in Braille.

Eye contact is important in U.S. culture. With a parent who is visually impaired, this critical factor in the parent-child attachment process is obviously missing. However, the blind parent, who may never have experienced this method of strengthening relationships, does not miss it. The infant will need other sensory input from that parent. An infant looking into the eyes of a parent who is blind can be unaware that the eyes are unseeing. Other people in the newborn's environment can also participate in active eye-to-eye contact to supply this need. A problem may arise, however, if the visually impaired parent has little facial expression. The infant, after making repeated unsuccessful attempts to engage in face play with the mother, will abandon the behavior with her and intensify it with the father or other people in the household. Nurses can provide anticipatory guidance regarding this situation and help the mother learn to nod and smile while talking and cooing to the infant.

Hearing-Impaired Parent

A parent who has a hearing impairment faces challenges in caregiving and parenting, particularly if the deafness dates from birth or early childhood. Whether one or both parents are hearing impaired, they are likely to have established an independent household. Devices that transform sound into light flashes can be placed in the infant's room to permit immediate detection of crying. Even if the parent is not speech trained, vocalizing can serve as both a stimulus and a response to the infant's early vocalizing. Deaf parents can provide additional vocal training by use of recordings and television so that from birth the child is aware of the full range of the human voice. Young children acquire sign language readily, and the first sign used is as varied as the first word.

Section 504 of the Rehabilitation Act of 1973 requires that hospitals and other institutions receiving funds from the U.S. Department of Health and Human Services use various

BOX 22-2 Nursing Approaches for Working with Visually Impaired Parents

- A visually impaired parent needs an orientation to the hospital room that allows the parent to move about the room independently. For example, "Go to the left of the bed and trail the wall until you feel the first door. That is the bathroom."
- Parents who are visually impaired need explanations of routines.
- Parents who are visually impaired need to feel devices (e.g., portable sitz bath equipment, breast pump) and to hear descriptions of the devices.
- Visually impaired parents need a chance to ask questions.
- Visually impaired parents need the opportunity to hold and touch the newborn after birth.
- Nurses need to demonstrate infant care by touch and to follow with, "Now show me how you would do it."
- Nurses need to give instructions such as, "I'm going to give you the baby. The head is to your left side."

communication techniques and resources with the deaf, including having staff members or certified interpreters who are proficient in sign language. For example, provision of written materials with demonstrations and having nurses stand where the parent can read their lips (if the parent practices lip reading) are two techniques that can be used. A creative approach is for the nursing unit to develop videos in which information on postpartum care, infant care, and parenting issues is signed by an interpreter and spoken by a nurse. A video recording in which a nurse signs while speaking is ideal. With the advent of the Internet, many resources are available to deaf parents. Box 22-3 lists suggestions for working with hearing-impaired parents.

SIBLING ADAPTATION

Because the family is an interactive, open unit, the addition of a new family member affects everyone in the family. Siblings have to assume new positions within the family hierarchy. Parents often face the task of caring for the neonate while also attending to the needs of other children, and attempting to distribute their attention equitably. When the newborn is preterm or has special needs, this task can be difficult.

Reactions of siblings result from temporary separation from the mother, changes in the mother's or father's behavior, or the infant coming home. Positive behavioral changes of siblings include interest in and concern for the baby (Fig. 22-9) and increased independence. Regression in toileting and sleep habits, aggression toward the baby, and increased seeking of attention and whining are examples of negative behaviors.

The parents' attitudes toward the arrival of the baby can set the stage for the other children's reactions. Because the baby absorbs the time and attention of the important people in the other children's lives, jealousy (**sibling rivalry**) is common once the initial excitement of having a new baby in the home is over.

Parents, especially mothers, spend much time and energy promoting sibling acceptance of a new baby. Sibling preparation classes can help children adjust. Older children may be actively involved in preparing for the infant, and this involvement can intensify after the birth. Parents have to manage the

BOX 22-3 Nursing Approaches for Working with Hearing-Impaired Parents

- Before initiating communication, the nurse needs to be aware of the parents' preferences and capabilities: Do they wear a hearing aid? Do they read lips? Do they wish to have an interpreter?
- The nurse should make certain that the parent(s) sees the nurse approaching to avoid startling the parent.
- Before speaking, the nurse needs to be directly in front of the parent and should have that person's full attention.
- When speaking, the nurse should face the parent directly and should be at the same level.
- It is best to avoid standing in front of a light or a window while speaking to the parent.
- Keep hands away from the face while speaking to minimize distractions.
- If the parent relies on lip reading, the nurse should sit close enough so that the parent can easily see lip movements.
- The nurse should speak clearly with a regular voice volume and lip movements, while maintaining eye contact.
- Speak in short, simple sentences to facilitate understanding.
- If the parent does not understand something, it is better to find a different way to say what needs to be communicated rather than repeating the same words over and over.
- Written messages aid in communication. A small white or black erasable board can be useful.
- Educational materials should be given to hearing-impaired parents and they should be asked to read the materials prior to a teaching session. They can refer to the materials after discharge.
- Visual aids such as pictures, diagrams, or other devices should be used when doing client teaching.
- When doing parent teaching, it is helpful for a hearing person (partner or family member) to be present.
- The nurse should allow ample time to communicate with the hearing-impaired parent; being in a rush can evoke stress and create barriers to effective communication.

feeling of guilt that the older children are being deprived of parental time and attention and monitor the behavior of older children toward the more vulnerable infant and divert aggressive behavior. Box 22-4 presents strategies that parents have used to facilitate sibling acceptance of a new baby.

Siblings demonstrate acquaintance behaviors with the newborn. The acquaintance process depends on the information given to the child before the baby is born and on the child's cognitive and developmental levels. The initial behaviors of siblings with the newborn include looking at the infant and touching the head (see Fig. 22-9). **The initial adjustment of older children to a newborn takes time, and parents should allow children to interact at their own pace rather than forcing them to interact.** To expect a young child to accept and love a rival for the parents' affection assumes an unrealistic level of maturity. Sibling love grows as does other love, that is, by being with another person and sharing experiences. The bond between siblings involves a secure base in which one child provides support for the other, is missed when absent, and is looked to for comfort and security.

GRANDPARENT ADAPTATION

Becoming a grandparent is most often associated with great joy and happiness. Yet it is a time of transition as roles and relationships change and new opportunities arise. Emotions are varied and can change from day to day; feelings of joy, anticipation, and excitement are often intermingled with some degree of anxiety and uncertainty. **Circumstances surrounding the pregnancy and birth influence the feelings, reactions, and responses of grandparents.**

Pregnancy and birth necessitate redefining of intergenerational roles and relationships within the family. A primary role of the grandparents is to support, nurture, and empower their children in the parenting role. Grandparents must acknowledge that things have changed since they first became parents as they deal with changes in practices and attitudes toward pregnancy, birth, childrearing, and men's and women's roles at home and in the workplace. **The degree to which grandparents understand**

FIG 22-9 First meeting. Sister with mother during first meeting with new sibling. **A**, First tentative touch with fingertip. **B**, Relationship is more secure; touching with whole hand is now okay. **C**, Smiles indicate acceptance. (Courtesy Sara Kossuth, Los Angeles, CA.)

BOX 22-4 Strategies for Facilitating Sibling Acceptance of a New Baby

- Take your older child (or children) on a tour of your hospital room and point out similarities between this birth and his or her birth. "This is like the room I was in with you, and the baby is in the same kind of bassinet that you were in."
- Have a small gift from the baby to give to your older child each day he or she visits in the hospital.
- Give the older child a T-shirt that says "I'm a big brother" [or "sister"].
- Arrange for your children to be among the first to see the newborn. Let them hold the baby in the hospital.
- When the older child visits for the first time, make sure you are not holding the new baby. Your arms need to be open and available for the older child. Instruct the person accompanying the older child to call ahead or give a warning knock to give you time to lay the baby down or have someone else hold the baby.
- Plan individual time with each child. The father or partner can spend time with the older siblings while the mother is taking care of the baby and vice versa. Siblings like to have time and attention from both parents.
- Give preschool and early school-age siblings a newborn doll as "their baby." Give the sibling a photograph of the new baby to take to school to show off "his" or "her" baby. Older siblings may enjoy the responsibility of helping care for the newborn, such as learning how to give the baby a bottle or change a diaper. Remember to supervise interactions between the siblings and new baby.

and accept current practices can influence how supportive they are to their adult children.

At the same time that they are adjusting to grandparenthood, many grandparents are experiencing typical life transitions and events, such as retirement and a move to smaller housing, and need support from their adult children. Some may feel regret about their limited involvement because of poor health or geographic distance.

The extent of grandparent involvement in the care of the newborn depends on many factors such as the willingness to become involved, the proximity of the grandparents, and cultural expectations of the grandparents' role. For example, if the new parents live in the United States, Asian grandparents will typically come to the United States to care for the baby and the mother after birth and to care for the children once the parents return to work. In the United States, paternal grandparents, in contrast to those in other cultures, frequently consider themselves secondary to the maternal grandparents. Less seems expected of them, and they are initially less involved. Nevertheless, these grandparents are eager to help and express great pleasure in their son's fatherhood and his involvement with the baby (Fig. 22-10).

Relationships between grandparents and parents can change with the birth of a new baby. For first-time parents, pregnancy and parenthood can reawaken old issues related to dependence versus independence. Couples often do not plan on their parents' help immediately after the baby arrives. They want time "to be a family," implying a couple-baby unit, not the intergenerational family network. Contrary to their expectations, however, new parents do call on their

FIG 22-10 Father, grandfather, and new grandson get acquainted. (Courtesy Sharon Johnson, Petaluma, CA.)

parents for help, especially the maternal grandmother. Many grandparents are aware of their adult children's wishes for autonomy, respect these wishes, and remain available to help when asked.

Grandparents' classes can be used to bridge the generation gap and to help the grandparents understand their adult children's parenting concepts. The classes include information on up-to-date childbearing practices; family-centered care; infant care, feeding, and safety (car seats); and exploration of roles that grandparents play in the family unit.

Increasing numbers of grandparents are providing permanent care for their grandchildren as a result of divorce, substance abuse, child abuse or neglect, abandonment, teenage pregnancy, death, human immunodeficiency virus and acquired immunodeficiency syndrome, unemployment, incarceration, and mental health problems. This emerging trend requires the nurse to evaluate the role of the grandparent in parenting the infant. Educational and financial considerations must be addressed and available support systems identified for these families.

CARE MANAGEMENT

Numerous changes occur during the first weeks of parenthood. Nursing care management should be directed toward helping parents cope with infant care, role changes, altered lifestyle, and change in family structure resulting from the addition of a new baby. Developing skill and confidence in caring for an infant can be anxiety provoking. Anticipatory guidance can help prevent a shock of reality in the transition from hospital or birthing center to home that might negate the parents' joy or cause them undue stress.

Through education, support, and encouragement, nurses are instrumental in assisting mothers and their partners in the transition to parenthood, whether they are first-time parents or parents of several other children. Early and ongoing assessment and intervention promotes positive outcomes for parents, infants, and family members (see Nursing Care Plan).

 **NURSING CARE PLAN**
Home Care Follow-Up: Transition to Parenthood

NURSING DIAGNOSIS	EXPECTED OUTCOME	INTERVENTIONS	RATIONALES
<i>Deficient Knowledge of infant care related to lack of experience or lack of support</i>	Parents provide safe and adequate care, and infant appears healthy.	<p>Observe infant care routines (bathing, diapering, feeding, play).</p> <p>Observe infant's appearance (height-weight ratio, head circumference, fontanel, skin tone and turgor), and assess vital signs, overall tone, reflexes, and age-appropriate developmental skills.</p> <p>Explore available support systems for infant care.</p> <p>Demonstrate care routines that pose difficulties, and have involved family members return demonstration.</p> <p>Provide ongoing follow-up and referrals as needed.</p>	<p>To evaluate parental ease with care and adequacy of techniques</p> <p>To evaluate for signs indicative of inadequate care</p> <p>To determine adequacy of existing system</p> <p>To facilitate improvements in care</p> <p>To ensure that identified potential and actual care deficits are addressed and resolved</p>
<i>Disturbed Sleep Pattern related to infant demands and environmental interruptions</i>	Woman sleeps for uninterrupted periods and states that she feels rested on waking.	<p>Discuss woman's routine, and specify factors that interfere with sleep.</p> <p>Explore ways woman and significant others can make environment more conducive to sleep (e.g., privacy, darkness, quiet, back rubs, soothing music, warm milk), and teach use of guided imagery and relaxation techniques.</p> <p>Eliminate factors or routines that can interfere with sleep (e.g., caffeine, foods that induce heartburn, strenuous mental or physical activity).</p> <p>Advise family to limit visitors and activities.</p> <p>Have family plan specific times to care for newborn.</p> <p>Have mother learn to use infant nap time as time for her to nap as well.</p> <p>Assist family to identify persons such as family members or friends who can help with household tasks, infant care, and care of other children.</p>	<p>To determine scope of problem and direct interventions</p> <p>To promote optimal conditions for sleep</p> <p>To prevent interference with sleep</p> <p>To prevent further stress and fatigue</p> <p>To allow mother time to sleep</p> <p>To replenish energy and decrease fatigue</p> <p>To allow mother more time to rest</p>
<i>Impaired Home Maintenance related to addition of new family member, inadequate resources, or inadequate support systems</i>	Home exhibits signs of safe and functional environment.	<p>Observe home environment (e.g., available living space and sleeping arrangements; adequacy of facilities for food preparation and storage, hygiene, and toileting; overall state of repair; cleanliness; presence of safety hazards).</p> <p>Observe arrangements for newborn, such as sleeping space, care equipment, and supplies (bathing, changing, feeding, transportation).</p> <p>Explore who is responsible for cooking, cleaning, child care, and newborn care, and determine whether mother seems adequately rested.</p> <p>Identify and arrange referrals to needed social agencies (e.g., Temporary Assistance for Needy Families [TANF]; Special Supplemental Nutrition Program for Women, Infants and Children [WIC]; food pantries).</p>	<p>To determine adequacy and effective use of resources</p> <p>To determine adequacy of resources</p> <p>To determine adequacy of support systems</p> <p>To address resource deficits (finances, supplies, equipment)</p>
<i>Interrupted Family Processes related to inclusion of new family member</i>	Infant is successfully incorporated into family structure.	<p>Explore with family ways that birth and neonate have changed family structure and function.</p> <p>Observe family's interaction with newborn, and note degree of bonding, evidence of sibling rivalry, and involvement in newborn care.</p> <p>Clarify identified misinformation and misperceptions.</p> <p>Assist family in exploring options for solutions to identified problems.</p> <p>Support family's efforts as they move toward adjusting and incorporating new member.</p> <p>If needed, make referrals to appropriate social services or community agencies.</p>	<p>To evaluate functional and role adjustment</p> <p>To evaluate acceptance of newest family member</p> <p>To promote clear communication</p> <p>To promote effective problem resolution</p> <p>To reinforce new functions and roles</p> <p>To ensure ongoing support and care</p>

COMMUNITY ACTIVITY

- Visit the website of a hospital that provides maternity services in your community. Does the hospital offer prepared childbirth, parenting, sibling or infant/child cardiorespiratory resuscitation (CPR) classes? Are group tours of the birthing center provided for expectant parents?
- Visit the website babycenter.com, which provides information for parents about pregnancy, parenting, and children's health. Review the information about postpartum emotional health, causes and treatments of baby blues, and baby blues versus postpartum depression.
- Visit the FamilyandHomeNetwork.com website, and research the availability of support groups for parents in your community.

In collaboration with the family, incorporating their priorities and preferences to meet their specific needs, nurses can:

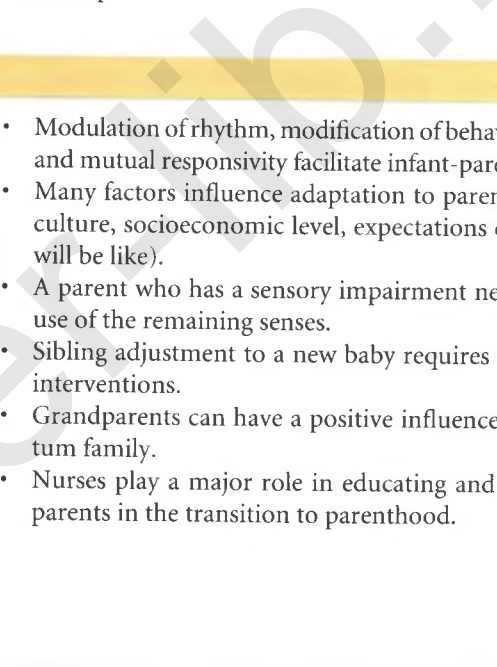

- Provide opportunities for parent-infant interaction.
- Implement strategies to facilitate sibling acceptance of the infant (see Box 22-4).

KEY POINTS

- The birth of a child necessitates changes in the existing interactional structure of a family.
- Attachment is the process by which the parent and infant come to love and accept each other.
- Attachment is strengthened through the use of sensory responses or interactions by both partners in the parent-infant interaction.
- Women go through predictable stages in becoming a mother.
- Many mothers exhibit signs of postpartum blues (baby blues).
- Fathers experience emotions and adjustments during the transition to parenthood that are similar to, and also distinctly different from, those of mothers.
- Modulation of rhythm, modification of behavioral repertoires, and mutual responsivity facilitate infant-parent adjustment.
- Many factors influence adaptation to parenthood (e.g., age, culture, socioeconomic level, expectations of what the child will be like).
- A parent who has a sensory impairment needs to maximize use of the remaining senses.
- Sibling adjustment to a new baby requires creative parental interventions.
- Grandparents can have a positive influence on the postpartum family.
- Nurses play a major role in educating and supporting new parents in the transition to parenthood.

Physiologic and Behavioral Adaptations of the Newborn

Kathryn R. Alden

<http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Analyze the physiologic adaptations that the neonate must make during the transition intrauterine to extrauterine life.
- Describe the behavioral adaptations that are characteristic of the newborn during the transition period.
- Explain the mechanisms of thermoregulation in the neonate and the potential consequences of hypothermia and hyperthermia.
- Recognize newborn reflexes and differentiate characteristic responses from abnormal responses.
- Discuss the sensory and perceptual functioning of the neonate.
- Identify signs that the neonate is at risk related to problems with each body system.

The neonatal period includes the time from birth through day 28 of life. During this time the neonate must make many physiologic and behavioral adaptations to extrauterine life. Physiologic adjustment tasks are those that involve: (1) establishing and maintaining respirations; (2) adjusting to circulatory changes; (3) regulating temperature; (4) ingesting, retaining, and digesting nutrients; (5) eliminating waste; and (6) regulating weight. Behavioral tasks include: (1) establishing a regulated behavioral tempo independent of the mother, which involves self-regulating arousal, self-monitoring changes in state, and patterning sleep; (2) processing, storing, and organizing multiple stimuli; and (3) establishing a relationship with caregivers and the environment. The term infant usually makes these adjustments with little or no difficulty.

TRANSITION TO EXTRAUTERINE LIFE

The major adaptations associated with transition from intrauterine to extrauterine life occur during the first 6 to 8 hours after birth. The predictable series of events during transition are mediated by the sympathetic nervous system and result in changes that involve heart rate, respirations, temperature, and gastrointestinal function. This transition period represents a time of vulnerability for the neonate and warrants careful observation by nurses. To detect disorders in adaptation soon after birth, nurses must be aware of normal features of the transition period.

In their classic work on newborn adaptation to extrauterine life, Desmond, Rudolph, and Phitaksphraiwan (1966) proposed

three stages of newborn transition. The stages are still considered valid today.

The first stage of the transition period lasts up to 30 minutes after birth and is called the *first period of reactivity*. The newborn's heart rate increases rapidly to 160 to 180 beats/minute but gradually falls after 30 minutes or so to a baseline rate of 100 to 120 beats/minute. Respirations are irregular, with a rate between 60 and 80 breaths/minute. Fine crackles can be present on auscultation. Audible grunting, nasal flaring, and retractions of the chest also can be present, but these should cease within the first hour of birth. The infant is alert and may have spontaneous startles, tremors, crying, and head movement from side to side. Bowel sounds are audible, and meconium may be passed.

After the first period of reactivity the newborn either sleeps or has a marked decrease in motor activity. This *period of decreased responsiveness* lasts from 60 to 100 minutes. During this time the infant is pink, and respirations are rapid and shallow (up to 60 breaths/minute) but unlabored. Bowel sounds are audible, and peristaltic waves may be noted over the rounded abdomen.

The *second period of reactivity* occurs roughly between 2 and 8 hours after birth and lasts from 10 minutes to several hours. Brief periods of tachycardia and tachypnea occur, associated with increased muscle tone, changes in skin color, and mucus production. Meconium is commonly passed at this time. Most healthy newborns experience this transition, regardless of gestational age or type of birth; extremely and very preterm infants do not because of physiologic immaturity.

Physiologic Adjustments

Respiratory System

As the infant emerges from the intrauterine environment and the umbilical cord is severed, profound adaptations are necessary for survival. The most critical of these is the establishment of effective respirations. Most newborns breathe spontaneously after birth and are able to maintain adequate oxygenation. Preterm infants often encounter respiratory difficulties related to their immature lungs.

Initiation of Breathing. During intrauterine life oxygenation of the fetus occurs through transplacental gas exchange. However, at birth the lungs must be established as the site of gas exchange. In utero fetal blood was shunted away from the lungs, but when birth occurs the pulmonary vasculature must be fully perfused for this purpose. Clamping the umbilical cord causes a rise in blood pressure (BP), which increases circulation and lung perfusion.

It has been recognized that there is no single trigger for newborn respiratory function. The initiation of respirations in the neonate is the result of a combination of chemical, mechanical, thermal, and sensory factors (Blackburn, 2013).

Chemical Factors. The activation of chemoreceptors in the carotid arteries and aorta results from the relative state of hypoxia associated with labor. With each labor contraction there is a temporary decrease in uterine blood flow and transplacental gas exchange, resulting in transient fetal hypoxia and hypercarbia. Although the fetus is able to recover between contractions, there appears to be a cumulative effect that results in progressive decline in PO_2 , increased PCO_2 , and lowered blood pH. Decreased levels of oxygen and increased levels of carbon dioxide seem to have a cumulative effect that is involved in initiating neonatal breathing by stimulating the respiratory center in the medulla. Another chemical factor may also play a role; it is thought that as a result of clamping the cord, there is a drop in levels of a prostaglandin that can inhibit respirations.

Mechanical Factors. Respirations in the newborn can be stimulated by changes in intrathoracic pressure resulting from compression of the chest during vaginal birth. As the infant passes through the birth canal, the chest is compressed. With birth this pressure on the chest is released, and the negative intrathoracic pressure helps draw air into the lungs. Crying increases the distribution of air in the lungs and promotes expansion of the alveoli. The positive pressure created by crying helps keep the alveoli open.

Thermal Factors. With birth the newborn enters the extrauterine environment, in which the temperature is significantly lower. The profound change in environmental temperature stimulates receptors in the skin, resulting in stimulation of the respiratory center in the medulla.

Sensory Factors. Sensory stimulation occurs in a variety of ways with birth. Some of these include handling the infant by the physician or nurse-midwife, suctioning the mouth and nose, and drying by the nurses. Pain associated with birth also can be a factor. The lights, sounds, and smells of the new environment also can be involved in stimulation of the respiratory center.

At term the lungs hold approximately 20 ml of fluid per kilogram. Air must be substituted for the fluid that filled the fetal respiratory tract. Traditionally it had been thought that the thoracic squeeze occurring during normal vaginal birth

resulted in significant clearance of lung fluid. However, it appears that this event plays a minor role. In the days preceding labor there is reduced production of fetal lung fluid and concomitant decreased alveolar fluid volume. Shortly before the onset of labor there is a catecholamine surge that seems to promote fluid clearance from the lungs, which continues during labor (Goldsmith, 2011). The movement of lung fluid from the air spaces occurs through active transport into the interstitium, with drainage occurring through the pulmonary circulation and lymphatic system. Retention of lung fluid can interfere with the infant's ability to maintain adequate oxygenation, especially if other factors (e.g., meconium aspiration, congenital diaphragmatic hernia, esophageal atresia with fistula, choanal atresia, congenital cardiac defect, immature alveoli) that compromise respirations are present. Infants born by cesarean in which labor did not occur before birth can experience some lung fluid retention, although it typically clears without harmful effects on the infant (Hillman, Kallapur, & Jobe, 2012). These infants are also more likely to develop transient tachypnea of the newborn (TTNB) caused by the lower levels of catecholamines (Abu-Shaweesh, 2011).

The alveoli of the term infant's lungs are lined with **surfactant**, a protein manufactured in type II lung cells. Lung expansion depends largely on chest wall contraction and adequate surfactant secretion. Surfactant lowers surface tension, therefore reducing the pressure required to keep the alveoli open with inspiration, and prevents total alveolar collapse on exhalation, thereby maintaining alveolar stability. The decreased surface tension results in increased lung compliance, helping to establish the functional residual capacity of the lungs (Blackburn, 2013). With absent or decreased surfactant, more pressure must be generated for inspiration, which can soon tire or exhaust preterm or sick term infants.

Breathing movements that began in utero as intermittent become continuous after birth, although the mechanism for this is not well understood. Once respirations are established, breaths are shallow and irregular, ranging from 30 to 60 breaths/minute, with periods of breathing that include pauses in respirations lasting less than 20 seconds. These episodes of periodic breathing occur most often during the active (rapid eye movement [REM]) sleep cycle and decrease in frequency and duration with age. Apneic periods longer than 20 seconds indicate a pathologic process and should be evaluated.

Newborn infants are by preference nose breathers. The reflex response to nasal obstruction is to open the mouth to maintain an airway. This response is not present in most infants until 3 weeks after birth; therefore cyanosis or asphyxia can occur with nasal blockage.

In most newborns, auscultation of the chest reveals loud, clear breath sounds that seem very near because little chest tissue intervenes. Breath sounds should be clear and equal bilaterally, although fine rales for the first few hours are not unusual (Gardner & Hernandez, 2011). The ribs of the infant articulate with the spine at a horizontal rather than a downward slope; consequently the rib cage cannot expand with inspiration as readily as that of an adult. Because neonatal respiratory function is largely a matter of diaphragmatic contraction, abdominal breathing is characteristic of newborns. The newborn infant's chest and abdomen rise simultaneously with inspiration. Characteristics

of the respiratory system of the neonate and the effects of these characteristics on respiratory function are listed in Table 23-1.

Signs of Respiratory Distress. Signs of respiratory distress can include nasal flaring, intercostal or subcostal retractions (in-drawing of tissue between the ribs or below the rib cage), or grunting with respirations. Suprasternal or subclavicular retractions with stridor or gasping most often represent an upper airway obstruction. Seesaw or paradoxical respirations (exaggerated rise in abdomen with respiration as the chest falls) instead of abdominal respirations are abnormal and should be reported. A respiratory rate of less than 30 or greater than 60 breaths/minute with the infant at rest must be evaluated. The respiratory rate of the infant can be slowed, depressed, or absent as a result of the effects of analgesics or anesthetics administered to the mother during labor and birth. Apneic episodes can be related to several events (rapid increase in body temperature, hypothermia, hypoglycemia, or sepsis) that require thorough evaluation. Tachypnea can result from inadequate clearance of lung fluid, or it can be an indication of newborn respiratory distress syndrome (RDS). Tachypnea can be the first sign of respiratory, cardiac, metabolic, or infectious illnesses (Gardner & Hernandez, 2011).

Changes in the infant's color can indicate respiratory distress. **Acrocyanosis**, the bluish discoloration of hands and feet, is a normal finding in the first 24 hours after birth. Transient

periods of duskiess while crying are common immediately after birth; however, central cyanosis is abnormal and signifies hypoxemia. With central cyanosis the lips and mucous membranes are bluish. It can be the result of inadequate delivery of oxygen to the alveoli, poor perfusion of the lungs that inhibits gas exchange, or cardiac dysfunction. Because central cyanosis is a late sign of distress, newborns usually have significant hypoxemia when cyanosis appears.

Infants who experience mild TTNB often have signs of respiratory distress during the first 1 to 2 hours after birth as they transition to extrauterine life. Tachypnea with rates up to 100 breaths/minute can be present along with intermittent grunting, nasal flaring, and mild retractions. Supplemental oxygen may be needed. TTNB usually resolves in 24 to 48 hours (Soltau & Carlo, 2014).

In neonates with more serious respiratory problems, symptoms of distress are more pronounced and tend to last beyond the first 2 hours after birth. Respiratory rates can exceed 120 breaths/minute. Moderate to severe retractions, grunting, pallor, and central cyanosis can occur. The respiratory symptoms can be accompanied by hypotension, temperature instability, hypoglycemia, acidosis, and signs of cardiac problems. Common respiratory complications affecting neonates include RDS, meconium aspiration, pneumonia, and persistent pulmonary hypertension of the newborn (PPHN) (see Chapter 34).

Cardiovascular System

The cardiovascular system changes significantly after birth. The infant's first breaths, combined with increased alveolar capillary distention, inflate the lungs and reduce pulmonary vascular resistance to pulmonary blood flow from the pulmonary arteries. Pulmonary artery pressure drops, and pressure in the right atrium declines. Increased pulmonary blood flow from the left side of the heart increases pressure in the left atrium, which causes a functional closure of the foramen ovale. During the first few days of life crying can temporarily reverse the flow through the foramen ovale and lead to mild cyanosis. Soon after birth cardiac output nearly doubles and blood flow increases to the lungs, heart, kidney, and gastrointestinal (GI) tract (Hillman et al., 2012).

In utero fetal P_{O_2} is 20 to 30 mm Hg. After birth, when the P_{O_2} level in the arterial blood approximates 50 mm Hg, the ductus arteriosus constricts in response to increased oxygenation. Circulating prostaglandin E (PGE_2) levels also have an important role in closing the ductus arteriosus. In term infants it functionally closes within the first 24 hours after birth; permanent (anatomic) closure usually occurs within 3 to 4 weeks, and the ductus arteriosus becomes a ligament. The ductus arteriosus can open in response to low oxygen levels in association with hypoxia, asphyxia, or prematurity. With auscultation of the chest a patent ductus arteriosus can be detected as a heart murmur (Lott, 2014).

When the cord is clamped and severed, the umbilical arteries, the umbilical vein, and the ductus venosus are functionally closed; they are converted into ligaments within 2 to 3 months. The hypogastric arteries also occlude and become ligaments. Table 23-2 summarizes the cardiovascular changes at birth.

Heart Rate and Sounds. The heart rate for a term newborn ranges from 110 to 160 beats/minute, with brief fluctuations

TABLE 23-1 Characteristics of the Respiratory System of the Neonate

CHARACTERISTIC	EFFECT ON FUNCTION
Immature alveoli; decreased size and number of alveoli	Risk of respiratory insufficiency and pulmonary problems
Thicker alveolar wall; decreased alveolar surface area	Less efficient gas transport and exchange
Continued development of alveoli until childhood	Possible opportunity to reduce effects of discrete lung injury
Decreased lung elastic tissue and recoil	Decreased lung compliance requiring higher pressures and more work to expand; increased risk of atelectasis
Reduced diaphragm movement and maximal force potential	Less effective respiratory movement; difficulty generating negative intrathoracic pressures; risk of atelectasis
Tendency to nose breathe; altered position of larynx and epiglottis	Enhanced ability to synchronize swallowing and breathing; risk of airway obstruction; possibly more difficult to intubate
Small compliant airway passages with higher airway resistance; immature reflexes	Risk of airway obstruction and apnea
Increased pulmonary vascular resistance with sensitive pulmonary arterioles	Risk of ductal shunting and hypoxemia with events such as hypoxia, acidosis, hypothermia, hypoglycemia, and hypercarbia
Increased oxygen consumption	Increased respiratory rate and work of breathing; risk of hypoxia
Increased intrapulmonary right-left shunting	Increased risk of atelectasis with wasted ventilation; lower P_{CO_2}
Immaturity of pulmonary surfactant system in immature infants	Increased risk of atelectasis and respiratory distress syndrome; increased work of breathing
Immature respiratory control	Irregular respirations with periodic breathing; risk of apnea; inability to rapidly alter depth of respirations

P_{CO_2} , Partial pressure of carbon dioxide.

From Blackburn, S. (2013). *Maternal, fetal, and neonatal physiology: A clinical perspective* (4th ed.). St. Louis: Mosby.

TABLE 23-2 Cardiovascular Changes at Birth

PRENATAL STATUS	POSTBIRTH STATUS	ASSOCIATED FACTORS
Primary Changes		
Pulmonary circulation: High pulmonary vascular resistance, increased pressure in right ventricle and pulmonary arteries	Low pulmonary vascular resistance; decreased pressure in right atrium, ventricle, and pulmonary arteries	Expansion of collapsed fetal lung with air
Systemic circulation: Low pressures in left atrium, ventricle, and aorta	High systemic vascular resistance; increased pressure in left atrium, ventricle, and aorta	Loss of placental blood flow
Secondary Changes		
Umbilical arteries: Patent, carrying of blood from hypogastric arteries to placenta	Functionally closed at birth; obliteration by fibrous proliferation possibly taking 2 to 3 months, distal portions becoming lateral vesicoumbilical ligaments, proximal portions remaining open as superior vesicle arteries	Closure preceding that of umbilical vein, probably accomplished by smooth muscle contraction in response to thermal and mechanical stimuli and alteration in oxygen tension Mechanically severed with cord at birth
Umbilical vein: Patent, carrying of blood from placenta to ductus venosus and liver	Closed; becoming ligamentum teres hepatis after obliteration	Closure shortly after umbilical arteries; hence blood from placenta possibly entering neonate for short period after birth Mechanically severed with cord at birth
Ductus venosus: Patent, connection of umbilical vein to inferior vena cava	Closed; becoming ligamentum venosum after obliteration	Loss of blood flow from umbilical vein
Ductus arteriosus: Patent, shunting of blood from pulmonary artery to descending aorta	Functionally closed almost immediately after birth; anatomic obliteration of lumen by fibrous proliferation requiring 1 to 3 months, becoming ligamentum arteriosum	Increased oxygen content of blood in ductus arteriosus creating vasospasm of its muscular wall High systemic resistance increasing aortic pressure; low pulmonary resistance reducing pulmonary arterial pressure
Foramen ovale: Formation of a valve opening that allows blood to flow directly to left atrium (shunting of blood from right to left atrium)	Functionally closed at birth; constant apposition gradually leading to fusion and permanent closure within a few months or years in majority of persons	Increased pressure in left atrium and decreased pressure in right atrium, causing closure of valve over foramen

Data from Blackburn, S. (2013). *Maternal, fetal, and neonatal physiology: A clinical perspective* (4th ed.). St. Louis: Mosby.

greater and less than these values usually noted during sleeping and waking states. The range of the heart rate in the term infant is about 85 to 100 beats/minute during deep sleep and can increase to 180 beats/min or higher when the infant cries. A heart rate that is either high (more than 160 beats/minute) or low (fewer than 100 beats/minute) should be reevaluated within 30 minutes to 1 hour or when the activity of the infant changes. Immediately after birth the heart rate can be palpated by grasping the base of the umbilical cord.

The apical impulse (point of maximal impulse [PMI]) in the newborn is at the fourth intercostal space and to the left of the midclavicular line (Gardner & Hernandez, 2011). The PMI is often visible and easily palpable because of the thin chest wall; this is also called *precordial activity*.

Apical pulse rates should be determined for all infants. Auscultation should be for a full minute, preferably when the infant is asleep. An irregular heart rate in newborns is not uncommon in the first few hours of life. Sinus dysrhythmia is common. After this time an irregular heart rate not attributed to changes in activity or respiratory pattern should be evaluated. Heart sounds during the neonatal period are of higher pitch, shorter duration, and greater intensity than during adult life. The first sound (S_1) is typically louder and duller than the second sound (S_2), which is sharp. The third and fourth heart sounds are not auscultated in newborns. Most heart murmurs heard during the neonatal period have no pathologic significance, and more than half of the murmurs disappear by 6 months. However, the presence of a murmur and accompanying signs such as poor feeding, apnea, cyanosis, or pallor is considered abnormal and should be investigated. There can be significant cardiac defects without a murmur or other symptoms (Smith, 2012). This reinforces the importance of ongoing assessment.

Blood Pressure. Values for newborn BP vary with gestational age, weight, state of alertness, and cuff size. The term newborn infant's average systolic BP is 60 to 80 mm Hg, and average diastolic BP is 40 to 50 mm Hg. The mean arterial pressure (MAP) should be equivalent to the weeks of gestation. For example, an infant born at 40 weeks of gestation should have a MAP of at least 40. The BP increases by the second day of life, with minor variations noted during the first month of life. A drop in systolic BP (about 15 mm Hg) in the first hour of life is common. Crying and movement usually cause increases in the systolic BP. The measurement of BP is best accomplished with an oscillometric device while the infant is at rest. A correctly sized cuff must be used for accurate measurement of an infant's BP; the cuff should cover 75% of the distance between the axilla and elbow (Fanaroff & Fanaroff, 2012).

Policies on routine assessment of neonatal BP vary. In many agencies, unless a specific indication exists, BP is not measured in the newborn on a routine basis except as a baseline. In some institutions nurses obtain four extremity BPs in the presence of any cardiovascular symptoms such as tachycardia, murmur, abnormal pulses, poor perfusion, or abnormal precordial activity. If the systolic pressure is more than 10 mm Hg higher in the upper extremities than in the lower extremities, further diagnostic testing may be needed (Kenney, Hoover, Williams, & Iskersky, 2011).

Blood Volume. Blood volume in the term newborn averages 85 ml/kg of body weight (Luchtman-Jones & Wilson, 2011). Immediately after birth the total blood volume averages 300 ml, but this volume can increase by as much as 100 ml, depending on the length of time to cord clamping and cutting. The infant born prematurely has a relatively greater blood volume than the term newborn. This occurs because the preterm infant has a

proportionately greater plasma volume, not a greater red blood cell (RBC) mass.

Early or delayed clamping of the umbilical cord changes the circulatory dynamics of the newborn. Delayed clamping expands the blood volume from the so-called placental transfusion of blood to the newborn. Delayed cord clamping (≥ 2 minutes after birth) has been reported to be beneficial in improving hematocrit and iron status and decreasing anemia; such benefits can last up to 6 months (Andersson, Hellström-Westas, Andersson, et al., 2011). Polycythemia that occurs with delayed clamping is usually not harmful, although there can be an increased risk of jaundice that requires phototherapy. The American College of Obstetricians and Gynecologists (ACOG, 2012) and the American Academy of Pediatrics (AAP, 2013) report that there is a lack of evidence to support or refute benefits of delayed cord clamping for term infants in rich resource settings. However, they recognize that preterm infants experience important benefits. Transitional circulation is improved, red blood cell volume is better established, and there is a reduced need for blood transfusion. The risk of intraventricular hemorrhage is significantly reduced in preterm infants when cord clamping is delayed (ACOG, 2012; AAP, 2013).

Signs of Cardiovascular Problems. Close monitoring of the infant's vital signs is important in detecting impending problems early. Persistent tachycardia (more than 160 beats/minute) can be associated with anemia, hypovolemia, hyperthermia, or sepsis. Persistent bradycardia (less than 100 beats/minute) can be a sign of a congenital heart block or hypoxemia.

The newborn's skin color can reflect cardiovascular problems. Pallor in the immediate postbirth period is often a sign of underlying problems such as anemia or marked peripheral vasoconstriction as a result of intrapartum asphyxia or sepsis. Any prolonged cyanosis other than in the hands or feet can indicate respiratory and/or cardiac problems. The presence of jaundice can indicate ABO or Rh factor incompatibility problems (see Chapter 36).

Congenital heart defects are the most common types of congenital malformations (see Chapter 36). Although the more serious defects such as tetralogy of Fallot are likely to have clinical manifestations such as cyanosis, dyspnea, and hypoxia, others such as small ventricular septal defects can be asymptomatic. The prenatal history can provide information regarding risk factors for congenital heart defects so the nurse knows to be more alert for symptoms. Maternal illness such as rubella, metabolic disease such as diabetes, and drug ingestion are associated with an increased risk of cardiac defects.

Hematopoietic System

Red Blood Cells. Because fetal circulation is less efficient at oxygen exchange than the lungs, the fetus needs additional RBCs for transport of oxygen in utero. Therefore, at birth the average levels of RBCs, hemoglobin, and hematocrit are higher than those in the adult; these levels fall slowly over the first month. At birth the RBC count ranges from 4.6 to 5.2 million/mm³ (Blackburn, 2013). The term newborn can have a hemoglobin concentration of 14 to 24 g/dl at birth, decreasing gradually to 12 to 20 g/dl during the first 2 weeks (Pagana & Pagana, 2011). Hematocrit levels at birth range from 51% to

56%, increase slightly in the first few hours or days as fluid shifts from intravascular to interstitial spaces (Blackburn, 2013), and by 8 weeks are between 39% and 59% (Pagana & Pagana). Polycythemia (central venous hematocrit greater than 65%) can occur in term and preterm infants as a result of delayed cord clamping, maternal hypertension or diabetes, or intrauterine growth restriction.

The source of the sample is a significant factor in levels of RBCs, hemoglobin, and hematocrit because capillary blood yields higher values than venous blood. The timing of blood sampling is also significant; the slight rise in RBCs after birth is followed by a substantial drop. At birth the infant's blood contains an average of 70% fetal hemoglobin; however, because of the shorter life span of the cells containing fetal hemoglobin, the percentage falls to 55% by 5 weeks and to 5% by 20 weeks. Iron stores generally are sufficient to sustain normal RBC production for 4 to 5 months in the term infant, at which time a transient physiologic anemia can occur.

Leukocytes. Leukocytosis, with a white blood cell (WBC) count of approximately 18,000/mm³ (range 9000 to 30,000/mm³), is normal at birth (Pagana & Pagana, 2011). The number of WBCs increases to 23,000 to 24,000/mm³ during the first day after birth. The initial high WBC count of the newborn decreases rapidly, and a stable level of 12,000/mm³ is normally maintained during the neonatal period (Blackburn, 2013). Serious infection is not tolerated well by the newborn; leukocytes are slow to recognize foreign protein and localize and fight infection early in life. Sepsis can be accompanied by a concomitant rise in neutrophils; however, some infants initially have clinical signs of sepsis without a significant elevation in WBCs. In addition, events other than infection (i.e., prolonged crying, maternal hypertension, asymptomatic hypoglycemia, hemolytic disease, meconium aspiration syndrome, labor induction with oxytocin, surgery, difficult labor, high altitude, and maternal fever) can cause neutrophilia in the newborn.

Platelets. Platelet count ranges between 150,000 and 300,000/mm³ and is essentially the same in newborns as in adults (Pagana & Pagana, 2011). The levels of factors II, VII, IX, and X found in the liver decrease during the first few days of life because the newborn cannot synthesize vitamin K. However, bleeding tendencies in the newborn are rare, and, unless the vitamin K deficiency is great, clotting is sufficient to prevent hemorrhage.

Blood Groups. The infant's blood group is determined genetically and established early in fetal life. However, during the neonatal period the strength of the agglutinogens present in the RBC membrane gradually increases. Cord blood samples may be used to identify the infant's blood type and Rh status.

Thermogenic System

Next to establishing respirations and adequate circulation, heat regulation is most critical to the newborn's survival. During the first 12 hours after birth the neonate attempts to achieve thermal balance in adjusting to the extrauterine environmental temperature. **Thermoregulation** is the maintenance of balance between heat loss and heat production. Newborns attempt to stabilize their core body temperatures within a narrow range. **Hypothermia** from excessive heat loss is a common and dangerous problem.

Anatomic and physiologic characteristics of neonates place them at risk for heat loss. Newborns have a thin layer of subcutaneous fat. The blood vessels are close to the surface of the skin. Changes in environmental temperature alter the temperature of the blood, thereby influencing temperature regulation centers in the hypothalamus. Newborns have larger body surface-to-body weight (mass) ratios than do children and adults (Blackburn, 2013).

Heat Loss. The body temperature of newborn infants depends on the heat transfer between the infant and the external environment. Factors that influence heat loss to the environment include the temperature and humidity of the air, the flow and velocity of the air, and the temperature of surfaces in contact with and around the infant. The goal of care is to provide a **neutral thermal environment** for the neonate in which heat balance is maintained. The neutral thermal environment is the ideal environmental temperature that allows the neonate to maintain a normal body temperature to minimize oxygen and glucose consumption (Ringer, 2013a). Heat loss in the newborn occurs by four modes:

1. **Convection** is the flow of heat from the body surface to cooler ambient air. Because of heat loss by convection, the ambient temperature in the nursery is kept at approximately 24° C (75.2° F), and newborns in open bassinets are wrapped to protect them from the cold. A cap may be worn to decrease heat loss from the infant's head.
2. **Radiation** is the loss of heat from the body surface to a cooler solid surface not in direct contact but in relative proximity. To prevent this type of loss, cribs and examining tables are placed away from outside windows, and care is taken to avoid direct air drafts.
3. **Evaporation** is the loss of heat that occurs when a liquid is converted to a vapor. In the newborn, heat loss by evaporation occurs as a result of moisture vaporization from the skin. This heat loss is intensified by failing to dry the newborn directly after birth or by drying the infant too slowly after a bath. The less mature the newborn, the more severe the evaporative heat loss. Evaporative heat loss, as a component of insensible water loss, is the most significant cause of heat loss in the first few days of life.
4. **Conduction** is the loss of heat from the body surface to cooler surfaces in direct contact. During the initial assessment, the newborn is placed on a prewarmed bed under a radiant warmer to minimize heat loss. The scales used for weighing the newborn should have a protective cover to minimize conductive heat loss.

Heat loss must be controlled to protect the infant. Control of such modes of heat loss is the basis of caregiving policies and techniques. Drying the infant quickly after birth is essential to prevent hypothermia. Skin-to-skin contact with the mother is an effective means of reducing conductive and radiant heat loss and enhancing newborn temperature control and maternal-infant interaction. The naked newborn is placed on the mother's bare chest and covered with a warm blanket; a cap may be placed on the infant's head to help conserve heat (Fig. 23-1) (Brown & Landers, 2011). An alternative is to place the neonate under a radiant warmer to reduce heat loss and promote thermoregulation.

Thermogenesis. In response to cold the neonate attempts to generate heat (**thermogenesis**) by increasing muscle activity.

FIG 23-1 Infant in skin-to-skin contact with mother. Note infant smile. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

Cold infants may cry and appear restless. Because of vasoconstriction the skin can feel cool to touch, and acrocyanosis can be present. There is an increase in cellular metabolic activity, primarily in the brain, heart, and liver; this also increases oxygen and glucose consumption.

In an effort to conserve heat, term newborns assume a position of flexion that helps guard against heat loss because it diminishes the amount of body surface exposed to the environment. Infants also can reduce the loss of internal heat through the body surface by constricting peripheral blood vessels.

Adults are able to produce heat through shivering; however, the shivering mechanism of heat production is rarely operable in the newborn unless there is prolonged cold exposure (Blackburn, 2013). Newborns produce heat through **nonshivering thermogenesis**. This is accomplished primarily by metabolism of **brown fat**, which is unique to the newborn; and secondarily by increased metabolic activity in the brain, heart, and liver. Brown fat is located in superficial deposits in the interscapular region and axillae and in deep deposits at the thoracic inlet, along the vertebral column, and around the kidneys. Brown fat has a richer vascular and nerve supply than ordinary fat. Heat produced by intense lipid metabolic activity in brown fat can warm the newborn by increasing heat production as much as 100%. Reserves of brown fat, usually present for several weeks after birth, are rapidly depleted with **cold stress**. The amount of brown fat reserve increases with the weeks of gestation. A full-term newborn has greater stores than a preterm infant (Ringer, 2013a).

Hypothermia and Cold Stress. When the neonate's temperature drops, vasoconstriction occurs as a mechanism to conserve heat. The infant can appear pale and mottled; the skin feels cool, especially on the extremities. If the hypothermia is not corrected it will progress to cold stress, which imposes metabolic

FIG 23-2 Effects of cold stress. When an infant is stressed by cold, oxygen consumption increases, and pulmonary and peripheral vasoconstriction occur, thereby decreasing oxygen uptake by the lungs and oxygen to the tissues; anaerobic glycolysis increases; and there is a decrease in PO_2 and pH, leading to metabolic acidosis.

and physiologic demands on all infants, regardless of gestational age and condition. The respiratory rate increases in response to the increased need for oxygen. In the cold-stressed infant, oxygen consumption and energy are diverted from maintaining normal brain and cardiac function and growth to thermogenesis for survival. If the infant cannot maintain an adequate oxygen tension, vasoconstriction follows and jeopardizes pulmonary perfusion. As a consequence the PO_2 is decreased, and the blood pH drops (Ringer, 2013b). Surfactant synthesis can be altered. These changes can prompt a transient respiratory distress or aggravate existing RDS. Moreover, decreased pulmonary perfusion and oxygen tension can maintain or reopen the right-to-left shunt across the ductus arteriosus.

The basal metabolic rate increases with cold stress. If cold stress is protracted, anaerobic glycolysis occurs, resulting in increased production of acids. Metabolic acidosis develops, and, if a defect in respiratory function is present, respiratory acidosis also develops (Fig. 23-2). Excessive fatty acids can displace the bilirubin from the albumin-binding sites and exacerbate hyperbilirubinemia. Hypoglycemia is another metabolic consequence of cold stress. The process of anaerobic glycolysis can deplete existing stores. If the infant is sufficiently stressed and low glucose stores are not replaced, hypoglycemia, which can be asymptomatic in the newborn, can develop (Brown & Landers, 2011; Sedin, 2011).

Hyperthermia. Although occurring less frequently than hypothermia, **hyperthermia** can occur and must be corrected. A body temperature greater than 37.5°C (99.5°F) is considered to be abnormally high and is typically caused by excess heat production related to sepsis or a decrease in heat loss. Hyperthermia can result from the inappropriate use of external heat sources such as radiant warmers, phototherapy, sunlight,

increased environmental temperature, and the use of excessive clothing or blankets (Brown & Landers, 2011). The clinical appearance of the infant who is hyperthermic often indicates the causative mechanism. Infants who are overheated because of environmental factors such as being swaddled in too many blankets exhibit signs of heat-losing mechanisms: skin vessels dilate, skin appears flushed, hands and feet are warm to touch, and the infant assumes a posture of extension. The newborn who is hyperthermic because of sepsis appears stressed: vessels in the skin are constricted, color is pale, and hands and feet are cool. Hyperthermia develops more rapidly in a newborn than in an adult because of the relatively larger surface area of an infant. Sweat glands do not function well. Hyperthermia can cause neurologic injury and increased risk of seizures; severe cases can result in heat stroke and death (Brown & Landers, 2011; Ringer, 2013b).

Renal System

At term the kidneys occupy a large portion of the posterior abdominal wall. The bladder lies close to the anterior abdominal wall and is both an abdominal and a pelvic organ. In the newborn almost all palpable masses in the abdomen are renal in origin.

At birth a small quantity (approximately 40 ml) of urine is usually present in the bladder of a full-term infant. Many newborns void at the time of birth, although this is easily missed and may not be recorded. During the first few days term infants generally excrete 15 to 60 ml/kg/day; output gradually increases over the first month (Blackburn, 2013). The frequency of voiding varies from 2 to 6 times per day during the first and second days of life and increases during the subsequent 24 hours. After day 4, approximately 6 to 8 voidings per day of pale straw-colored urine indicate adequate fluid intake. Noting and recording the first voiding are important. An infant who has not voided by 24 hours should be assessed for adequacy of fluid intake, bladder distention, restlessness, and symptoms of pain. The health care provider should be notified.

Full-term newborns have limited capacity to concentrate urine; therefore, the specific gravity is usually low (less than 1.004) (Vogt & Dell, 2011). The ability to concentrate urine fully is attained by about 3 months of age. After the first voiding the infant's urine can appear cloudy (because of mucus content) and have a much higher specific gravity. This decreases as fluid intake increases. Normal urine during early infancy is usually straw colored and almost odorless. Sometimes pink-tinged uric acid crystal stains or "brick dust" appears on the diaper. Uric acid crystals are normal during the first week, but thereafter can be a sign of inadequate intake (Janke, 2014). Loss of fluid through urine, feces, lungs, increased metabolic rate, and limited fluid intake results in a 5% to 10% loss of the birth weight. This usually occurs over the first 3 to 5 days of life. If the mother is breastfeeding and her milk supply has not come in yet (which occurs by the third or fourth day after birth), the neonate is somewhat protected from dehydration by its increased extracellular fluid volume. The neonate should regain the birth weight within 10 to 14 days, depending on the feeding method (breast or bottle).

Fluid and Electrolyte Balance. In the term neonate approximately 75% of body weight consists of total body water

(extracellular and intracellular). A reduction in extracellular fluid occurs with diuresis during the first few days after birth. The weight loss experienced by most newborns during the first few days after birth is caused primarily by extracellular water loss (Dell, 2011).

The daily fluid requirement for neonates weighing more than 1500 g is 60 to 80 ml/kg during the first 2 days of life. From 3 to 7 days the requirement is 100 to 150 ml/kg/day, and from 8 to 30 days it is 120 to 180 ml/kg/day (Dell, 2011).

At birth the glomerular filtration rate (GFR) of a newborn is approximately 30% to 50% of the adult GFR. This results in a decreased ability to remove nitrogenous and other waste products from the blood. The GFR rapidly increases during the first month of life as a result of postnatal physiologic changes, including decreased renal vascular resistance, increased renal blood flow, and increased filtration pressure.

Sodium reabsorption is decreased as a result of a lowered sodium- or potassium-activated adenosine triphosphatase activity. The decreased ability to excrete excess sodium results in hypotonic urine compared with plasma, leading to a higher concentration of sodium, phosphates, chloride, and organic acids and a lower concentration of bicarbonate ions. The infant has a higher renal threshold for glucose than adults.

Bicarbonate concentration and buffering capacity are decreased. This can lead to acidosis and electrolyte imbalance.

Signs of Renal System Problems. The renal system has a wide range of functions. Dysfunction resulting from physiologic abnormalities can range from the lack of a steady stream of urine to gross anomalies such as hypospadias and exstrophy of the bladder, which can be identified easily at birth. Enlarged or cystic kidneys can be identified as masses during abdominal palpation. Some kidney anomalies also can be detected by ultrasound examination during pregnancy (see Chapter 36).

Gastrointestinal System

The full-term newborn is capable of swallowing, digesting, metabolizing and absorbing proteins and simple carbohydrates and emulsifying fats. With the exception of pancreatic amylase, the characteristic enzymes and digestive juices are present even in low-birth-weight neonates.

In the adequately hydrated infant the mucous membrane of the mouth is moist and pink; the hard and soft palates are intact. The presence of moderate to large amounts of mucus is common in the first few hours after birth. Small whitish areas (Epstein pearls) may be found on the gum margins and at the juncture of the hard and soft palates. The cheeks are full because of well-developed sucking pads. These, like the labial tubercles (sucking calluses) on the upper lip, disappear around the age of 12 months when the sucking period is over.

Sucking is a reflex behavior that begins in utero as early as 15 to 16 weeks. Sucking behavior is influenced by neuromuscular maturity, maternal medications received during labor and birth, and the type of initial feeding. As early as 28 weeks some infants can coordinate sucking, swallowing, and breathing while breastfeeding. Bottle-feeding infants may not coordinate sucking, swallowing, and breathing until 32 to 34 weeks. A special mechanism present in healthy term newborns coordinates the sucking, swallowing, and breathing reflexes necessary for oral feeding. This is well developed in most infants by 37 weeks

(Gardner & Lawrence, 2011). Sucking takes place in small bursts of 3 or 4 and up to 8 to 10 sucks at a time, with a brief pause between bursts. The infant is unable to move food from the lips to the pharynx; therefore placing the nipple (breast or bottle) well inside the baby's mouth is necessary. Peristaltic activity in the esophagus is uncoordinated in the first few days of life. It quickly becomes a coordinated pattern in healthy full-term infants, and they swallow easily.

Teeth begin developing in utero, with enamel formation continuing until about 10 years of age. Tooth development is influenced by neonatal or infant illnesses and medications and by illnesses of or medications taken by the mother during pregnancy. The fluoride level in the water supply also influences tooth development. Occasionally an infant may be born with one or more teeth. These natal teeth have poorly formed roots and as they loosen place the infant at risk of aspiration. Therefore, they are usually extracted.

The mucosal barrier in the intestines is not fully mature until 4 to 6 months of age, which allows antigens and other macromolecules such as bacteria to be transported across the intestinal wall into the systemic circulation. This increases the risk of allergies and infection (Blackburn, 2013).

The neonate's intestines are sterile at birth; bacteria are not present in the infant's GI tract. Soon after birth oral and anal orifices permit entrance of bacteria and air. Generally the highest bacterial concentration is found in the lower portion of the intestine, particularly in the large intestine. Normal colonic bacteria are established within the first week after birth; and normal intestinal flora help synthesize vitamin K, folate, and biotin. Bowel sounds can usually be heard shortly after birth.

The capacity of the newborn stomach varies widely, depending on the size of the infant, from less than 30 ml on day 1 to more than 90 ml on day 3. After birth the newborn stomach becomes increasingly more compliant and relaxed to accommodate larger volumes. Several factors such as time and volume of feedings or type and temperature of food can affect the emptying time.

Because of the immaturity of the GI system, newborns are prone to regurgitation, vomiting, and gastroesophageal reflux (GER). Regurgitation is common among newborns and is most prevalent during the first 3 months. Vomiting and regurgitation can be decreased by avoiding overfeeding, burping the infant, and positioning him or her with the head slightly elevated.

Regurgitation is not equivalent to GER, although it often accompanies GER, which is the backflow of gastric contents into the esophagus. In some infants GER is severe enough to cause dysphagia, esophagitis, and aspiration. These infants may be treated with medications to reduce gastric acidity such as antacids, histamine-blocking agents, or proton-pump inhibitors (Barksdale, Chwals, Magnuson, & Parry, 2011).

Digestion. The infant's ability to digest carbohydrates, fats, and proteins is regulated by the presence of certain enzymes. Most of these enzymes are functional at birth except for pancreatic amylase and lipase. Amylase is produced by the salivary glands after approximately 3 months and by the pancreas at approximately 6 months of age. This enzyme is necessary to convert starch into maltose and occurs in high amounts in colostrum. The other exception is lipase, also secreted by the pancreas; it is necessary for the digestion of fat. Therefore, the

normal newborn is capable of digesting simple carbohydrates and proteins but has a limited ability to digest fats. Mammary lipase in human milk aids in digestion of fats by the neonate.

Lactase levels in newborns are higher than in older infants. This enzyme is necessary for digestion of lactose, the major carbohydrate in human milk and commercial infant formula.

Stools. Meconium fills the lower intestine at birth. It is formed during fetal life from the amniotic fluid and its constituents, intestinal secretions (including bilirubin), and cells (shed from the mucosa). **Meconium** is greenish black and viscous and contains occult blood. The first meconium stool passed is usually sterile, but within hours all meconium passed contains bacteria. Most healthy term infants pass meconium within the first 12 to 24 hours of life, and almost all do so by 48 hours. The number of stools passed varies during the first week, being most numerous between the third and sixth days. Newborns fed early pass stools sooner. Progressive changes in the stooling pattern indicate a properly functioning GI tract (Box 23-1).

Feeding Behaviors. Variations occur among infants regarding interest in food, signs of hunger, and amount ingested at one time. The amount of food that the infant takes in at any feeding depends on the infant's size, hunger level, and alertness. When put to breast some infants feed immediately, whereas others require a longer learning period. Random hand-to-mouth movement and sucking of fingers are well developed at birth and intensify when the infant is hungry. Caregivers should be alert and responsive to these hunger cues (Lawrence & Lawrence, 2011).

Signs of Gastrointestinal Problems. The time, color, and character of the infant's first stool should be noted. Failure to pass meconium can indicate bowel obstruction related to conditions such as an inborn error of metabolism (e.g., cystic fibrosis) or a congenital disorder (e.g., Hirschsprung's disease or an imperforate anus). An active rectal "wink" reflex

(contraction of the anal sphincter muscle in response to touch) is a sign of good sphincter tone.

Fullness of the abdomen above the umbilicus can be caused by hepatomegaly, duodenal atresia, or distention. Abdominal distention at birth usually indicates a serious disorder such as a ruptured viscus (from abdominal wall defects) or tumors. Distention that occurs later can be the result of overfeeding or signal GI disorders. A scaphoid (sunken) abdomen, with bowel sounds heard in the chest and signs of respiratory distress, indicates a diaphragmatic hernia. Fullness below the umbilicus can indicate a distended bladder.

Some infants are intolerant of certain commercial infant formulas. If an infant is allergic or unable to digest a formula, the stools can become very soft with a high water content that is signaled by a distinct water ring around the stool on the diaper. Forceful ejection of stool and a water ring around the stool are signs of diarrhea. Care must be taken to avoid misinterpreting transitional stools for diarrhea. The loss of fluid in diarrhea can rapidly lead to fluid and electrolyte imbalance. Passage of meconium from the vagina or urinary meatus is a sign of a possible fistulous tract from the rectum.

The amount and frequency of regurgitation ("spitting up") or vomiting after feedings should be documented. Color change, gagging, and projectile (very forceful) vomiting occur in association with esophageal and tracheoesophageal anomalies. Vomiting in large amounts, especially if it is projectile, can be a sign of pyloric stenosis. Bilious emesis is suggestive of intestinal obstruction or malrotation of the bowel (Barksdale et al., 2011).

Hepatic System

The liver and gallbladder are formed by the fourth week of gestation. In the newborn the liver can be palpated about 1 to 2 cm below the right costal margin because it is enlarged and occupies about 40% of the abdominal cavity. The infant's liver plays an important role in iron storage, carbohydrate metabolism, conjugation of bilirubin, and coagulation.

Iron Storage. The fetal liver, which serves as the site for production of hemoglobin after birth, begins storing iron in utero. The infant's iron store is proportional to total body hemoglobin content and length of gestation. At birth the term infant has an iron store sufficient to last 4 to 6 months. Iron stores of preterm and small for gestational age infants are often lower and are depleted sooner than in healthy term infants. Although both breast milk and cow's milk contain iron, the bioavailability of iron in breast milk is far superior.

The American Academy of Pediatrics (AAP) recommends that breastfed infants should receive a daily oral iron supplement (1 mg/kg) beginning at 4 months until feeding includes iron-fortified cereal or other foods fortified with iron. Formula-fed infants should receive a formula that contains supplemental iron (Baker, Greer, & the Committee on Nutrition, 2010).

Carbohydrate Metabolism. In utero the glucose concentration in the umbilical vein is approximately 80% of the maternal level. At birth the newborn is cut off from its maternal glucose supply and as a result experiences an initial decrease in serum glucose levels. Glucose levels reach a low point between 30 and 90 minutes after birth and then rise gradually. In most healthy

BOX 23-1 Changes in Stooling Patterns of Newborns

Meconium

- The infant's first stool is composed of amniotic fluid and its constituents, intestinal secretions, shed mucosal cells, and possibly blood (ingested maternal blood or minor bleeding of alimentary tract vessels).
- Passage of meconium should occur within the first 24 to 48 hours, although it can be delayed up to 7 days in very low birth weight. The passage of meconium can occur in utero and can be a sign of fetal distress.

Transitional Stools

- Usually appear by third day after initiation of feeding
- Greenish brown to yellowish brown; thin and less sticky than meconium; can contain some milk curds

Milk Stool

- Usually appears by the fourth day
- **Breastfed infants:** Stools yellow to golden, pasty in consistency; resemble a mixture of mustard and cottage cheese, with an odor similar to sour milk
- **Formula-fed infants:** Stools pale yellow to light brown, firmer consistency, with a more offensive odor

term newborns blood glucose levels stabilize at 50 to 60 mg/dl during the first several hours after birth. Within the first week they should be approximately 60 to 80 mg/dl (Kalhan & Devaskar, 2011).

The initiation of feedings helps to stabilize the newborn's blood glucose levels. In general blood glucose levels less than 40 mg/dl are considered abnormal and warrant intervention. The hypoglycemic infant can display the classic symptoms of jitteriness, lethargy, apnea, feeding problems, or seizures; or the infant can be asymptomatic. Hypoglycemia in the initial newborn period is most often transient and easily corrected through feeding. Persistent or recurrent hypoglycemia necessitates intravenous glucose therapy and possible pharmacologic intervention.

Conjugation of Bilirubin and Newborn Jaundice. Jaundice, the visible yellowish color of the skin and sclera, is caused by elevated serum levels of unconjugated (indirect) bilirubin. The liver is responsible for the conjugation of bilirubin, which results from the breakdown of RBCs. When RBCs reach the end of their life span, their membranes rupture, and hemoglobin is released. The hemoglobin is phagocytosed by macrophages; it then splits into heme and globin. The heme is broken down by the reticuloendothelial cells, converted to bilirubin, and released in an unconjugated form. The unconjugated (indirect) bilirubin is relatively insoluble and almost entirely bound to circulating albumin, a plasma protein. Bilirubin that is not bound to albumin, or free bilirubin, can easily cross the blood-brain barrier and cause neurotoxicity (acute bilirubin encephalopathy or kernicterus).

The unconjugated bilirubin must be conjugated so it becomes soluble and excretable. In the liver the unbound bilirubin is conjugated with glucuronic acid in the presence of the enzyme glucuronyl transferase. The conjugated form of bilirubin (direct bilirubin) is soluble and excreted from liver cells as a constituent of bile. Along with other components of bile, direct bilirubin is excreted into the biliary tract system that carries the bile into the duodenum. Bilirubin is converted to urobilinogen and stercobilinogen within the duodenum through the action of the bacterial flora. Urobilinogen is excreted in urine and feces; stercobilinogen is excreted in the feces. The effectiveness of bilirubin excretion through the feces depends on the stooling pattern of the newborn and the substances in the intestine that break down conjugated bilirubin. In the newborn intestine the enzyme β -glucuronidase is able to convert conjugated bilirubin into the unconjugated form, which is subsequently reabsorbed by the intestinal mucosa and transported to the liver; this is called *enterohepatic circulation*. Feeding is important in reducing serum bilirubin levels because it stimulates peristalsis and produces more rapid passage of meconium, thus diminishing the amount of reabsorption of unconjugated bilirubin. Feeding also introduces bacteria to aid in the reduction of bilirubin to urobilinogen. Colostrum, a natural laxative, facilitates the passage of meconium (Fig. 23-3).

When levels of unconjugated bilirubin exceed the ability of the liver to conjugate it, plasma levels of bilirubin increase, and jaundice appears. Jaundice is generally noticeable first in the head, especially in the sclera and mucous membranes, and progresses gradually to the thorax, abdomen, and extremities. The degree of jaundice is determined by serum total bilirubin

FIG 23-3 Formation and excretion of bilirubin.

measurements. Jaundice is likely to appear when bilirubin levels exceed 5 to 6 mg/dl (Blackburn, 2013).

The newborn is at risk for hyperbilirubinemia because of distinctive aspects of normal neonatal physiology. The higher RBC mass at birth and shorter life span of neonatal RBCs mean that there is a need for greater bilirubin synthesis. The ability of the liver to conjugate bilirubin is reduced during the first few days after birth; it can metabolize and excrete only about two thirds of the circulating bilirubin. In addition, there are fewer bilirubin binding sites because newborns have lower serum albumin levels. In the intestines conjugated bilirubin becomes unconjugated and recirculated through the enterohepatic circulation, which increases serum bilirubin levels (Blackburn, 2013).

Traditionally newborn jaundice has been categorized as either *physiologic* or *pathologic* (nonphysiologic), depending primarily on the time it appears and on serum bilirubin levels. Controversy surrounds the definitions of normal or physiologic ranges of total serum bilirubin. Total serum bilirubin levels in newborns are affected by variables such as length of gestation, age, weight, race, nutritional status, and mode of feeding (Blackburn, 2013). The time of onset of jaundice is a key factor in evaluating its cause and determining if treatment is needed. *Early-onset jaundice* is usually related to increased bilirubin production; *late-onset jaundice* is most often related to delayed elimination of bilirubin, with or without increased production (Kamath, Thilo, & Hernandez, 2011). Table 23-3 lists the varying causes of neonatal hyperbilirubinemia.

Among the factors that increase the risk of hyperbilirubinemia, prematurity is the most significant. Prematurity affects liver and brain metabolism and albumin binding sites, placing preterm and late preterm infants at greater risk for hyperbilirubinemia. Infants of Asian and Native-American

TABLE 23-3 Causes of Neonatal Unconjugated (Indirect) Hyperbilirubinemia

BASIS	CAUSES
Increased Production of Bilirubin	
Increased hemoglobin destruction	Fetomaternal blood group incompatibility (Rh, ABO) Congenital red blood cell abnormalities Congenital enzyme deficiencies (G6PD, galactosemia) Enclosed hemorrhage (cephalhematoma, bruising) Sepsis
Increased amount of hemoglobin	Polycythemia (maternal-fetal or twin-twin transfusion, SGA) Delayed cord clamping
Increased enterohepatic circulation	Delayed passage of meconium, meconium ileus, or plug Fasting or delayed initiation of feeding Intestinal atresia or stenosis
Altered Hepatic Clearance of Bilirubin	
Alteration in uridine diphosphate glucuronyl transferase production or activity	Immaturity Metabolic/endocrine disorders (e.g., Crigler-Najjar disease, hypothyroidism, disorders of amino acid metabolism)
Alteration in hepatic function and perfusion (and thus conjugating ability)	Asphyxia, hypoxia, hypothermia, hypoglycemia Sepsis (also causes inflammation) Drugs and hormones (e.g., novobiocin, pregnanediol)
Hepatic obstruction (associated with direct hyperbilirubinemia)	Congenital anomalies (biliary atresia, cystic fibrosis) Biliary stasis (hepatitis, sepsis) Excessive bilirubin load (often seen with severe hemolysis)

breakdown of RBC →

Pathologic Jaundice. Although physiologic jaundice is usually considered benign, unconjugated bilirubin (indirect) can accumulate to hazardous levels and lead to a pathologic condition. **Pathologic or nonphysiologic jaundice** is unconjugated hyperbilirubinemia that is either pathologic in origin or severe enough to warrant further evaluation and treatment. Jaundice is usually considered pathologic or nonphysiologic if it appears within 24 hours after birth, if total serum bilirubin levels increase by more than 6 mg/dl in 24 hours, and if the serum bilirubin level exceeds 15 mg/dl at any time (Blackburn, 2013). High levels of unconjugated bilirubin are usually caused by excessive production of bilirubin through hemolysis. Hemolytic disease of the newborn caused by maternal/newborn blood group incompatibility is the most common cause of hyperbilirubinemia. It can also be caused by glucose-6-phosphate dehydrogenase (G6PD) deficiency, a genetic disorder that is more common among Asian and Native-American populations. Other causes are listed in Table 23-3.

If increased levels of unconjugated bilirubin are left untreated, neurotoxicity can result as bilirubin is transferred into the brain cells. **Acute bilirubin encephalopathy** refers to the acute manifestations of bilirubin toxicity that occur during the first weeks after birth. This can include a range of symptoms such as lethargy, hypotonia, irritability, seizures, coma, and death. **Kernicterus** refers to the irreversible, long-term consequences of bilirubin toxicity such as hypotonia, delayed motor skills, hearing loss, cerebral palsy, and gaze abnormalities (AAP Subcommittee on Hyperbilirubinemia, 2004) (see Chapter 36).

Jaundice Related to Breastfeeding. Two forms of breastfeeding-related jaundice are recognized: **breastfeeding-associated jaundice** and **breast milk jaundice**. These typically occur in otherwise healthy infants. Both types can occur in the same infant and are not easily differentiated (Blackburn, 2013).

Breastfeeding-associated jaundice (early-onset jaundice) begins at 2 to 5 days of age. Breastfeeding does not cause the jaundice; rather it is a lack of effective breastfeeding that contributes to the hyperbilirubinemia. If the infant is not feeding effectively, there is less caloric and fluid intake and possible dehydration. Hepatic clearance of bilirubin is reduced. With less intake, there are fewer stools. As a result bilirubin is reabsorbed from the intestine back into the bloodstream and must be conjugated again so it can be excreted (Blackburn, 2013; Lawrence & Lawrence, 2011).

Breast milk jaundice (late-onset jaundice) usually occurs at 5 to 10 days of age. Infants are usually feeding well and gaining weight appropriately. Rising levels of bilirubin peak during the second week and gradually diminish. Despite high levels of bilirubin that can persist for 3 to 12 weeks, these infants have no signs of hemolysis or liver dysfunction. The etiology of breast milk jaundice is uncertain. However, it seems to be related to factors in the breast milk (e.g., pregnanediol, fatty acids, and β -glucuronidase) that either inhibit the conjugation of bilirubin or decrease the excretion of bilirubin (Blackburn, 2013). (See Chapter 25 for a discussion of these conditions in relation to newborn nutrition.)

Coagulation. The liver plays an important role in blood coagulation. Coagulation factors, which are synthesized in

G6PD, Glucose-6-phosphate dehydrogenase; SGA, small for gestational age. From Blackburn, S. (2013). *Maternal, fetal, and neonatal physiology: A clinical perspective* (4th ed.). St. Louis: Mosby.

ethnicity have higher bilirubin levels. Breastfeeding infants are at greater risk of hyperbilirubinemia (see later discussion).

Physiologic Jaundice. Physiologic or nonpathologic jaundice occurs in approximately 60% of newborn infants born at term and 80% of preterm infants (Kaplan, Wong, & Sibley, 2011). It appears after 24 hours of age and usually resolves without treatment.

Two phases of **physiologic jaundice** have been identified in full-term infants. In the first phase bilirubin levels of Caucasian and African-American infants gradually increase to approximately 5 to 6 mg/dl by 72 to 96 hours of life and decrease to a plateau of 2 to 3 mg/dl by the fifth day. In Asian and Asian-American infants bilirubin levels peak between 72 and 120 hours of age and gradually fall to 2 to 3 mg/dl by the seventh to tenth days. In the second phase of physiologic jaundice bilirubin levels gradually decrease between 5 and 10 days of life, reaching normal adult levels of 2 mg/dl or less by 14 days. This pattern varies according to racial group, method of feeding (breast versus formula), and gestational age. In preterm formula-fed infants serum bilirubin levels can peak as high as 10 to 12 mg/dl at 5 to 6 days of life and decrease slowly over a period of 2 to 4 weeks (Kaplan et al., 2011).

SAFETY ALERT

The appearance of jaundice during the first 24 hours of life or persistence beyond the ages previously delineated usually indicates a potential pathologic process that requires investigation.

the liver, are activated by vitamin K. The lack of intestinal bacteria needed to synthesize vitamin K results in transient blood coagulation deficiency between the second and fifth days of life. The levels of coagulation factors slowly increase to reach adult levels by the age of 9 months. The administration of intramuscular vitamin K shortly after birth helps prevent bleeding problems. Any bleeding problems noted in the newborn should be reported immediately, and tests for clotting ordered (Manco-Johnson, Rodden, & Hays, 2011).

Signs of Hepatic System Problems. Preterm infants are at risk for hepatic system problems such as hyperbilirubinemia and hypoglycemia because of their immaturity. The hematologic status of all newborns should be assessed for anemia. Because infants can develop a coagulation deficiency, a male neonate who has been circumcised must be observed closely for signs of hemorrhage. Hemorrhage also can be caused by a clotting defect, indicating a serious problem such as hemophilia.

Immune System

Beginning early in gestation the immune system of the fetus is developing the capacity to respond to foreign antigens. The development of the immune system is necessary to equip the neonate to meet the numerous environmental challenges (e.g., microorganisms) associated with life in the extrauterine world.

At birth most of the circulating antibodies in the newborn are immunoglobulin G (IgG) antibodies that were transported across the placenta from the maternal circulation. IgG is key to immunity to bacteria and viruses. This transfer of antibodies from the mother begins as early as 14 weeks of gestation and is greatest during the third trimester. By term the IgG levels in the cord blood of the infant are higher than those in maternal blood. The passive immunity afforded the infant through the placental transfer of IgG usually provides sufficient antimicrobial protection during the first 3 months of life. Production of adult concentrations of IgG is reached by 4 to 6 years of age (Kapur, Yoder, & Polin, 2011).

The fetus is capable of producing IgM by the eighth week of gestation, and low levels are present at term (less than 10% of adult levels). IgM is important for immunity to blood-borne infections and is the major immunoglobulin synthesized during the first month. By the age of 2 years IgM reaches adult levels. The production of IgA, IgD, and IgE is much more gradual, and maximal levels are not attained until early childhood (Kapur et al., 2011).

The membrane-protective IgA is missing from the respiratory and urinary tracts, and, unless the newborn is breastfed, it also is absent from the GI tract. Breast milk provides the newborn with important immunity. The secretory IgA in human milk acts locally in the intestines to neutralize bacterial and viral pathogens. It can also lessen the risk of allergy and food intolerance through modulation of exposure to foreign milk protein antigens.

The newborn is capable of producing a protective immune response to vaccines, given as early as a few hours after birth. For example, when hepatitis B vaccine is administered at birth to the infant born to a mother with hepatitis B, there is an excellent immune response. This holds true even if the infant does not receive additional hepatitis B immunoglobulin.

The WBCs of the newborn display a delayed response to invading bacteria. The influx of phagocytic cells to areas of inflammation is somewhat slowed, although the ability of these cells to attack and destroy bacteria is equivalent to that of adults (Kapur et al., 2011).

Risk for Infection. All newborns, and preterm newborns especially, are at high risk for infection during the first several months of life. During this period infection is one of the leading causes of morbidity and mortality. The newborn cannot limit the invading pathogen to the portal of entry because of the generalized hypofunctioning of the inflammatory and immune mechanisms.

Early signs of infection must be recognized so prompt diagnosis and treatment can occur. Temperature instability or hypothermia can be symptomatic of serious infection; newborns do not typically exhibit fever, although hyperthermia can occur (temperature greater than 38° C [100.4° F]). Lethargy, irritability, poor feeding, vomiting or diarrhea, decreased reflexes, and pale or mottled skin color are some of the clinical signs that suggest infection. Respiratory symptoms such as apnea, tachypnea, grunting, or retracting can be associated with infection such as pneumonia (Bodin, 2014). Any unusual discharge from the infant's eyes, nose, mouth, or other orifice must be investigated. If a rash appears, it must be evaluated closely; many normal rashes in the newborn are not associated with any infection. Infants must be protected from infections by the use of proper hand hygiene.

The greatest risk factor for neonatal infection is prematurity because of immaturity of the immune system. Other risk factors include premature rupture of membranes, chorioamnionitis, maternal fever, antenatal or intrapartum asphyxia, invasive procedures, stress, and congenital anomalies.

Integumentary System

All skin structures are present at birth. The epidermis and dermis are loosely bound and extremely thin. After 35 weeks of gestation the skin is covered by **vernix caseosa** (a cheeselike, whitish substance) that is fused with the epidermis and serves as a protective covering. Vernix caseosa is a complex substance that contains sebaceous gland secretions. It has emollient and antimicrobial properties and prevents fluid loss through the skin; it also has antioxidant properties. Removal of the vernix is followed by desquamation of the epidermis in most infants. There is evidence that leaving residual vernix intact after birth has positive benefits for neonatal skin such as decreasing the skin pH, decreasing skin erythema, and improving skin hydration (Association of Women's Health, Obstetric and Neonatal Nurses [AWHONN], 2013; Visscher, Utturkar, Pickens, et al., 2011).

The skin of a term infant is erythematous (red) for a few hours after birth, and then it fades to its normal color. The skin often appears blotchy or mottled, especially over the extremities. The hands and feet appear slightly cyanotic (acrocyanosis); this is caused by vasomotor instability and capillary stasis. Acrocyanosis is normal and appears intermittently over the first 7 to 10 days, especially with exposure to cold (Fig. 23-4).

The healthy term infant usually has a plump appearance because of large amounts of subcutaneous tissue and extracellular water content. Subcutaneous fat accumulated during the last trimester acts as insulation. Fine lanugo hair may be

FIG 23-4 Newborn infant with acrocyanosis of upper and lower extremities. (Courtesy Barbara Wilson, West Jordan, UT.)

FIG 23-5 Mongolian spot.

noted over the face, shoulders, and back. Edema of the face and ecchymosis (bruising) or petechiae may be noted as a result of face presentation, forceps-assisted birth, or vacuum extraction.

Creases are located on the palms of the hands and the soles of the feet. The simian line, a single palmar crease, is often seen in Asian infants and infants with Down syndrome. The soles of the feet should be inspected for the number of creases during the first few hours after birth; as the skin dries, more creases appear. More creases correlate with a greater maturity rating. Preterm newborns have few, if any, creases.

Sweat Glands. Distended, small, white sebaceous glands noticeable on the newborn face are known as **milium**. Although sweat glands are present at birth, term infants usually do not sweat for the first 24 hours. By day 3 sweating begins on the face, then progresses to the palms. Infants can sweat as a function of body or environmental temperature; there can also be emotional sweating from crying or pain (Hoath & Narendran, 2011).

Desquamation. **Desquamation** (peeling) of the skin of the term infant does not occur until a few days after birth. Large generalized areas of skin desquamation present at birth can be an indication of postmaturity.

Mongolian Spots. **Mongolian spots**, bluish black areas of pigmentation, can appear over any part of the exterior surface of the body, including the extremities. They are noted more commonly on the back and buttocks (Fig. 23-5). These pigmented areas occur most frequently in newborns whose ethnic origins are Latin America, Asia, Africa, or the Mediterranean area. They are more common in dark-skinned individuals but can occur in 5% to 13% of Caucasians (Blackburn, 2013). Mongolian spots fade gradually over months or years.

The presence of Mongolian spots on the newborn should be documented carefully in the medical record. These normal skin pigmentations can be mistaken for bruises once the infant is discharged, which can raise suspicion of physical abuse.

FIG 23-6 A, Nevus simplex or telangiectatic nevi (stork bite). B, Erythema toxicum. (Courtesy Mead Johnson & Co., Evansville, IN.)

Nevi. **Nevus simplex**, also known as salmon patches, telangiectatic nevi, “stork bites,” or “angel kisses,” are the result of a superficial capillary defect. They are usually small, flat, and pink and are easily blanched (Fig. 23-6, A). The most common sites are the upper eyelids, nose, upper lip, and nape of the neck (Blackburn, 2013). Salmon patches tend to be symmetric, with lesions occurring on both eyelids or both sides of midline. They have no clinical significance and require no treatment. Facial lesions usually fade between the first and second years of life, whereas neck lesions can be visible into adulthood (Morelli, 2011).

A port-wine stain, or **nevus flammeus**, is usually visible at birth and is due to an asymmetric postcapillary venule malformation. It is usually pink and flat at birth, but darkens with time, becoming red or purple and pebbly in consistency. True port-wine stains do not blanch on pressure or disappear. They are found most commonly on the face and neck (Püttgen & Cohen, 2012).

A **nevus vascularis**, or strawberry hemangioma, is a common type of capillary hemangioma that occurs more often in female infants. It consists of dilated newly formed capillaries occupying the entire dermal and subdermal layers with associated connective tissue hypertrophy. The typical lesion is a raised, sharply demarcated, bright or dark red rough-surfaced swelling, usually appearing on the head. In more than half of affected infants, lesions are present at birth; the remainder appear during the early weeks after birth. Most lesions reach maximum growth in 6 to 8 months, although deeper hemangiomas can continue to grow for up to 2 years. Hemangiomas usually fade or shrink with time (Hoath & Narendran, 2011).

Erythema Toxicum. **Erythema toxicum**, a transient rash, is also called *erythema neonatorum*, *newborn rash*, or *flea bite dermatitis*. It first appears in term neonates during the first 24 to 72 hours after birth and can last up to 3 weeks of age (Blackburn, 2013). It has lesions in different stages: erythematous macules, papules, and small vesicles (see Fig. 23-6, B). The lesions can appear suddenly anywhere on the body. The rash is thought to be an inflammatory response. Eosinophils, which help decrease inflammation, are found in the vesicles. Although the appearance is alarming, the rash has no clinical significance and requires no treatment.

Signs of Integumentary Problems. Close observation of the newborn's skin color can lead to early detection of potential problems. Any pallor, plethora (deep purplish color from increased circulating RBCs), petechiae, central cyanosis, or jaundice should be noted and described. The skin should be examined for signs of birth injuries such as forceps marks and lesions related to fetal monitoring. Bruises or petechiae can be present on the head, neck, and face of an infant born with a nuchal cord (cord around the neck) or who had a face presentation at birth. Bruising can increase the risk of hyperbilirubinemia. Petechiae can be present if increased pressure was applied to an area. Petechiae scattered over the infant's body should be reported to the health care provider because petechiae can indicate underlying problems such as low platelet count or infection.

Unilateral or bilateral periauricular papillomas (skin tags) occur fairly frequently. Their occurrence is usually a family trait and of no consequence.

Reproductive System

Female. An increase in estrogen during pregnancy followed by a drop after birth results in a mucoid vaginal discharge and even some slight bloody spotting (pseudomenstruation). External genitalia (i.e., labia majora and minora) are usually edematous with increased pigmentation. In term neonates the labia majora and minora cover the vestibule (Fig. 23-7, A). In preterm infants the clitoris is prominent, and the labia majora are small and widely separated. Vaginal or hymenal tags are

FIG 23-7 External genitalia. A, Genitalia in female term infant. B, Genitalia in uncircumcised male infant. Rugae cover scrotum, indicating term gestation. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

common findings and have no clinical significance. Vernix caseosa can be present between the labia and should not be forcibly removed during bathing.

If the girl was born in the breech position, the labia can be edematous and bruised. The edema and bruising resolve in a few days; no treatment is necessary.

Male. In the uncircumcised newborn the foreskin or prepuce completely covers the glans. The foreskin adheres to the glans and is not fully retractable for 3 to 4 years. The position of the urethra should be at the tip of the penis. With hypospadias or epispadias the urethral opening is located in an abnormal position, on or adjacent to the glans, although it can appear on the penile shaft or perineum. Small, white, firm lesions called *epithelial pearls* may be seen at the tip of the prepuce.

By 28 to 36 weeks of gestation the testes can be palpated in the inguinal canal, and a few rugae appear on the scrotum. At 36 to 40 weeks of gestation the testes are palpable in the upper scrotum, and rugae appear on the anterior portion. After 40 weeks the testes can be palpated in the scrotum, and rugae cover the scrotal sac. The postterm neonate has deep rugae and a pendulous scrotum. The incidence of undescended testes is 3.7%

FIG 23-8 Swelling of the genitals and bruising of the buttocks after a breech birth. (From O'Doherty, N. [1986]. *Neonatology: Micro atlas of the newborn*. Nutley, NJ: Hoffman-LaRoche.)

in term males and 21% in preterm males (Shulman, Palmert, & Wherrett, 2011). **Hydrocele**, caused by an accumulation of fluid around the testes, can be present. Hydroceles can be easily transilluminated with a light and usually resolve without treatment.

The scrotum is usually more deeply pigmented than the rest of the skin (see Fig. 23-7, B), particularly in darker-skinned infants. A bluish discoloration of the scrotum suggests testicular torsion, which needs immediate attention. If the male infant is born in a breech presentation, the scrotum can be very edematous and bruised (Fig. 23-8). The swelling and discoloration subside within a few days.

Swelling of Breast Tissue. Swelling of the breast tissue in term infants of both sexes is caused by the hyperestrogenism of pregnancy. In a few infants a thin discharge (witch's milk) can be seen. This finding has no clinical significance, requires no treatment, and subsides within a few days as the maternal hormones are eliminated from the infant's body.

The nipples should be symmetric on the chest. Breast tissue and areola size increase with gestation. The areola appears slightly elevated at 34 weeks of gestation. By 36 weeks a breast bud of 1 to 2 mm is palpable; this increases to 12 mm by 42 weeks.

Signs of Reproductive System Problems. The infant must be inspected closely for ambiguous genitalia and other abnormalities. Normally in a female infant the urethral opening is located behind the clitoris. Any deviation from this can incorrectly suggest that the clitoris is a small penis, which can occur in conditions such as adrenal hyperplasia. Nearly all female infants are born with hymenal tags; absence of such tags can indicate vaginal agenesis. Fecal discharge from the vagina indicates a rectovaginal fistula. Any of these findings must be reported to the neonatal or pediatric health care provider for further evaluation.

Hypospadias (urethra is located on ventral surface of the penis) or **epispadias** (urethra is located on dorsal surface), undescended or maldescended testes, and other abnormalities

FIG 23-9 Molding. A, Significant molding after vaginal birth. B, Schematic of bones of skull when molding is present. (A, Courtesy Kim Molloy, Knoxville, IA.)

of the male genitalia must be reported. Circumcision is contraindicated in the presence of hypospadias or epispadias because the foreskin is used in repair of these anomalies.

Inguinal hernias can be present and become more obvious when the infant cries. They are common, especially in African-American neonates, and usually require no treatment because they resolve with time.

Skeletal System

The infant's skeletal system undergoes rapid development during the first year of life. At birth more cartilage is present than ossified bone. Because of cephalocaudal (head-to-rump) development, the newborn looks somewhat out of proportion.

The head at term is approximately one fourth of the total body length. The arms are slightly longer than the legs. In the newborn the legs are about one third of the total body length. As growth proceeds the midpoint in head-to-toe measurements gradually descends from the level of the umbilicus at birth to the level of the symphysis pubis at maturity.

The face appears small in relation to the skull. The skull appears large and heavy. Cranial size and shape can be distorted by **molding** (the shaping of the fetal head by overlapping of the cranial bones to facilitate movement through the birth canal during labor) (Fig. 23-9).

Caput Succedaneum. **Caput succedaneum** is a generalized, easily identifiable edematous area of the scalp, most commonly

found on the occiput (Fig. 23-10, A). With vertex presentation the sustained pressure of the presenting vertex against the cervix results in compression of local vessels, slowing venous return. The slower venous return causes an increase in tissue fluids within the skin of the scalp, and edema develops. This edematous area, present at birth, extends across suture lines of the skull and usually disappears spontaneously within 3 to 4 days. Infants who are born with the assistance of vacuum extraction usually have a caput in the area where the cup was applied. Bruising of the scalp is often seen in the presence of caput succedaneum.

Cephalhematoma. Cephalhematoma is a collection of blood between a skull bone and its periosteum. Therefore, a cephalhematoma does not cross a cranial suture line (see Fig. 23-10, B). A cephalhematoma is firmer and more well defined than a caput. Often caput succedaneum and cephalhematoma occur simultaneously. A cephalhematoma usually resolves in 2 to 8 weeks. As the hematoma resolves, hemolysis of RBCs occurs, and hyperbilirubinemia can result (Bonifacio, Gonzalez, & Ferriero, 2012).

Subgaleal Hemorrhage. Subgaleal hemorrhage is bleeding into the subgaleal compartment (see Fig. 23-10, C). The subgaleal compartment is a potential space that contains loosely arranged connective tissue; it is located beneath the galea aponeurosis, the tendinous sheath that connects the frontal and occipital muscles and forms the inner surface of the scalp. Subgaleal hemorrhage is the result of traction or application of

shearing forces to the scalp, commonly associated with difficult operative vaginal birth, especially vacuum extraction. The scalp is pulled away from the bony calvarium; the vessels are torn, and blood collects in the subgaleal space. Blood loss can be severe, resulting in hypovolemic shock, disseminated intravascular coagulation (DIC), and death (Mangurten & Puppala, 2011).

Early detection of the hemorrhage is vital; serial head circumference measurements and inspection of the back of the neck for increasing edema and a firm mass are essential. A boggy scalp, pallor, tachycardia, and increasing head circumference can also be early signs of a subgaleal hemorrhage. Computed tomography or magnetic resonance imaging is useful in confirming the diagnosis. Replacement of lost blood and clotting factors is required in acute cases of hemorrhage. Another possible early sign of subgaleal hemorrhage is a forward and lateral positioning of the newborn's ears because the hematoma extends posteriorly. Monitoring the infant for changes in level of consciousness and decreases in hematocrit is also key to early recognition and management. An increase in serum bilirubin levels may be seen as a result of the degradation of blood cells within the hematoma (Mangurten & Puppala, 2011).

Spine. The bones in the vertebral column of the newborn form two primary curvatures—one in the thoracic region and one in the sacral region. Both are forward, concave curvatures. As the infant gains head control at approximately age 3 months, a secondary curvature appears in the cervical region. The newborn's spine appears straight and can be flexed easily. The newborn

FIG 23-10 A, Caput succedaneum. B, Cephalhematoma C, Subgaleal hemorrhage. (A and C, From Seidel, H., Ball, J., Dains, J., & Benedict, G. [2006]. *Mosby's guide to physical examination* [6th ed.]. St. Louis: Mosby.)

can lift the head and turn it from side to side when prone. The vertebrae should appear straight and flat. If a pilonidal dimple is noted, further inspection is required to determine whether a sinus is present. A pilonidal dimple, especially with a sinus and nevus pilosus (hairy nevus), can be associated with spina bifida.

Extremities. The infant's extremities should be symmetric and of equal length. Fingers and toes should be equal in number (five fingers on each hand and five toes on each foot) and should have nails present. Digits may be missing (*oligodactyly*). Extra digits (*polydactyly*) are sometimes found on hands or feet. Fingers or toes may be fused (*syndactyly*).

The infant is examined for **developmental dysplasia of the hips (DDH)**. In newborns with DDH the affected hip is unlikely to be dislocated at birth; instead it is easily dislocatable. Postnatal factors determine whether the hip dislocates, subluxates, or remains stable. DDH occurs more often in female infants, in breech presentations (Fig. 23-11), and in infants with family history of DDH (Cooperman & Thompson, 2011).

Signs of DDH are asymmetric gluteal and thigh skinfolds, uneven knee levels, a positive Ortolani test, and a positive Barlow test. The hips are inspected for symmetry. Gluteal and thigh

FIG 23-11 Position of infant's legs after breech birth. Note preterm genitalia. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

FIG 23-12 Signs of developmental dysplasia of the hip. **A**, Asymmetry of gluteal and thigh folds with shortening of the thigh (Galeazzi sign). **B**, Limited hip abduction, as seen in flexion (Ortolani test). **C**, Apparent shortening of the femur, as indicated by the level of the knees in flexion (Allis sign). **D**, Ortolani maneuver with femoral head moving in and out of acetabulum (in infants 1 to 2 months old). (From Hockenberry, M. J., & Wilson, D. (2013). *Wong's essentials of pediatric nursing* (9th ed.). St. Louis: Mosby.)

skinfolds should be equal and symmetric, and legs should be of equal length (Fig. 23-12, A). The level of the knees in flexion should be equal (see Fig. 23-12, C). Hip integrity is assessed by using the Barlow test and the Ortolani maneuver. For the Barlow test the examiner places the middle finger over the greater trochanter and the thumb along the midthigh. The hip is flexed to 90 degrees and adducted, followed by gentle downward pushing of the femoral head. If the hip can be dislocated with this maneuver, the femoral head moves out of the acetabulum, and the examiner feels a "clunk." The hip is then checked to determine if the femoral head can be returned into the acetabulum using the Ortolani maneuver. As the hip is abducted and upward leverage is applied, a dislocated hip returns to the acetabulum with a clunk that is felt by the examiner (White & Goldberg, 2012) (see Fig. 23-12, B and D).

⚡ SAFETY ALERT

Only expert examiners (physicians, nurse practitioners) should perform the Barlow test and Ortolani maneuver to assess for DDH. An unskilled examiner can cause injury to the newborn.

Signs of Skeletal Problems. Abnormalities of the skeletal system can be congenital, developmental, drug induced, or the result of intrapartum or postnatal factors. Signs of DDH, additional digits or webbing of digits, and any other abnormality should be documented and reported to the primary health care provider.

A fractured clavicle often occurs in macrosomic infants and in those who had a difficult birth (e.g., shoulder dystocia). Unequal movement of the upper extremities or crepitus over the clavicular area can indicate fracture.

The newborn's feet can appear to be abnormally positioned. This can indicate congenital deformity or can be related to fetal positioning in utero. For example, clubfoot (talipes equinovarus), a deformity in which the foot turns inward and is fixed in a plantar-flexion position, is a congenital condition

that warrants attention. If the foot is turned inward in the plantar-flexion position but can be moved into the normal position, it is likely caused by fetal positioning and should gradually resolve.

Neuromuscular System

The neuromuscular system is almost completely developed at birth. The term newborn is a responsive and reactive being with remarkable capacity for social interaction and self-organization.

Growth of the brain after birth follows a predictable pattern of rapid growth during infancy and early childhood; it becomes more gradual during the remainder of the first decade and minimal during adolescence. By the end of the first year the cerebellum ends its growth spurt, which began at approximately 30 gestational weeks.

The brain requires glucose as a source of energy and a relatively large supply of oxygen for adequate metabolism. The necessity for glucose requires careful assessment of neonates who are at risk for hypoglycemia (e.g., infants of mothers who have diabetes; infants who are macrosomic or small for gestational age; and newborns who experienced prolonged birth, hypoxia, or preterm birth).

Spontaneous motor activity can be seen as transient tremors of the mouth and chin, especially during crying episodes, and of the extremities, notably the arms and hands. Transient tremors are normal and can be observed in nearly every newborn. They most often involve the mouth and chin or the arms and hands. These tremors should not be present when the infant is quiet and should not persist beyond 1 month of age. Persistent tremors or tremors involving the total body can indicate pathologic conditions. Normal tremors, tremors (jitteriness) of hypoglycemia, and seizure activity must be differentiated so corrective care can be instituted as necessary (Verklan & Lopez, 2011).

To differentiate between tremors or jitteriness and seizure activity, the nurse can consider the following signs (Scher, 2012; Verklan & Lopez, 2011):

- Tremors or jitteriness are easily elicited by motions or voice and cease with gentle restraint of the body part, whereas seizure activity continues.
- Passive flexion and repositioning of the tremulous extremity reduces or stops the movement.
- Seizure activity is associated with ocular changes (eyes deviating or staring) and autonomic changes (apnea, tachycardia, pupil changes, increased salivation); these signs are not associated with jitteriness or tremors.

The posture of the term newborn demonstrates flexion of the arms at the elbows and the legs at the knees. Hips are abducted and partially flexed. Intermittent fisting of the hands is common.

Muscle tone and strength are directly related. The infant with normal tone and strength exhibits some resistance to passive movement such as when being pulled to sit or when the arm or leg is extended by the examiner. The hypotonic neonate shows little resistance and can feel like a “rag doll.” Hypertonia is evidenced by increased resistance to passive movement.

Although neuromuscular control is very limited, it can be noted. If newborns are placed face down on a firm surface, they will turn their heads to the side. They attempt to hold their heads

in line with their bodies if they are raised by their arms. Various reflexes serve to promote safety and adequate food intake.

Newborn Reflexes. The newborn has many primitive reflexes. The times at which these reflexes appear and disappear reflect the maturity and intactness of the developing nervous system. The most common reflexes found in the normal term newborn are described in Table 23-4.

Behavioral Characteristics

The healthy infant must accomplish behavioral and biologic tasks to develop normally. Behavioral characteristics form the basis of the social capabilities of the infant. Newborns progress through a hierarchy of developmental challenges as they adapt to their environment and caregivers. They must first be able to regulate their physiologic or autonomic system, including involuntary physiologic functions such as heart rate, respiration, and temperature. The next level is motor organization, in which infants regulate or control their motor behavior. This includes controlling random movements, improving muscle tone, and reducing excessive activity. The third level of behavior is *state regulation*, which refers to the ability to modulate the state of consciousness. The infant develops predictable sleep and wake states and is able to react to stress through self-regulation or communicating with the caregiver by crying and then being consoled. Finally the infant reaches the fourth level of attention and social interaction. He or she is able to attend to visual and auditory stimulation, stay alert for long periods, and engage in social interaction (Brazelton & Nugent, 2011).

This progression in behavior is the basis for the Brazelton Neonatal Behavioral Assessment Scale (NBAS) (Brazelton & Nugent, 2011). The NBAS is an interactive examination that assesses the infant’s response to 28 areas organized according to the clusters in Box 23-2. It is generally used as a research or diagnostic tool and requires special training. The NBAS helps the practitioner identify where the infant falls along the continuum of behaviors and determine the type of support needed.

The Newborn Behavioral Observations (NBO) system, based on the NBAS, is a tool that is used in clinical settings to help parents identify, understand, and respond to newborn behavior (Nugent, Keefer, Minear, et al., 2007). Karl and Keefer (2011) developed a training program using the NBO system to educate clinicians about newborn behavior, self-regulation skills, and social interaction capabilities. A major benefit of this program is that nurses and other clinicians can use the information to educate and help parents interpret newborn cues and respond appropriately, which promotes attachment (Karl & Keefer). See Chapter 22 for further discussion of attachment.

Sleep-Wake States

Healthy newborns differ in their activity levels, feeding patterns, sleeping patterns, and responsiveness. Parents’ reactions to their newborns are often determined by these differences. Showing parents the unique characteristics of their infant helps them develop a more positive perception of the infant and promotes increased interaction between infant and parent. Infant responses to environmental stimuli and to their caregivers depend on the infant’s state or state of consciousness.

In the early newborn period infants tend to alternate periods of sleep and wakefulness that resemble their fetal inactivity

TABLE 23-4 Assessment of Newborn Reflexes

REFLEX	ELICITING THE REFLEX	CHARACTERISTIC RESPONSE	COMMENTS
Sucking and rooting	Touch infant's lip, cheek, or corner of mouth with nipple or finger.	Infant turns head toward stimulus and opens mouth.	Response is difficult if not impossible to elicit after infant has been fed; if response is weak or absent, consider preterm birth or neurologic defect. Parental guidance: Avoid trying to turn head toward breast or nipple; allow infant to root; response disappears after 3-4* mo but can persist up to 1 yr. If response is weak or absent, it can indicate prematurity or neurologic defect.
Swallowing	Feed infant; swallowing usually follows sucking and obtaining fluids.	Swallowing is usually coordinated with sucking and breathing and usually occurs without gagging, coughing, apnea, or vomiting.	If response is weak or absent, this can indicate preterm birth, effects of maternal analgesics, or illness that needs investigation. Sucking, swallowing, and breathing are often uncoordinated in preterm infant.
Grasp			
Palmar	Place finger in palm of hand.	Infant's fingers curl around examiner's fingers.	Palmar response lessens by 3-4 mo; parents enjoy this contact with infant.
Plantar	Place finger at base of toes.	Toes curl downward.	Plantar response lessens by 8 mo.

Plantar grasp reflex. (From Zitelli, B. J., & Davis, H. W. [2007]. *Atlas of pediatric physical diagnosis* [5th ed.]. St. Louis: Mosby.)

Extrusion	Touch or depress tip of tongue.	Newborn forces tongue outward.	Response disappears about fourth to fifth month.
Glabellar (Myerson)	Tap over forehead, bridge of nose, or maxilla of newborn whose eyes are open.	Newborn blinks for first four or five taps.	Continued blinking with repeated taps is consistent with extrapyramidal signs.
Tonic neck or "fencing"	With infant in supine neutral position, turn head quickly to one side.	With infant facing left side, arm and leg on that side extend; opposite arm and leg flex (turn head to right, and extremities assume opposite postures).	Responses in leg are more consistent. Complete response disappears by 3-4 mo; incomplete response may be seen until third or fourth year. After 6 wk persistent response is sign of possible cerebral palsy.

Classic pose in tonic neck reflex. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

*All durations for persistence of reflexes are based on time elapsed after 40 weeks of gestation (i.e., if newborn was born at 36 weeks of gestation, add 1 month to all time limits given).

TABLE 23-4 Assessment of Newborn Reflexes—cont'd

REFLEX	ELICITING THE REFLEX	CHARACTERISTIC RESPONSE	COMMENTS
Moro	Hold infant in semisitting position, allow head and trunk to fall backward to angle of at least 30 degrees (with support). Place infant supine on flat surface; perform sharp hand clap.	Symmetric abduction and extension of arms are seen; fingers fan out and form a C with thumb and forefinger; slight tremor may be noted; arms are adducted in embracing motion and return to relaxed flexion and movement. A cry may accompany or follow motor movement. Legs may follow similar pattern of response. Preterm infant does not complete "embrace"; instead arms fall backward because of weakness.	Response is present at birth; complete response may be seen until 8 wk; body jerk only is seen between 8 and 18 wk; response is absent by 6 mo if neurologic maturation is not delayed; response may be incomplete if infant is in deep sleep state; give parental guidance about normal response. Asymmetric response can connote injury to brachial plexus, clavicle, or humerus. Persistent response after 6 mo indicates possible neurologic abnormality.

Startle

Moro reflex. (Courtesy Paul Vincent Kuntz, Texas Children's Hospital, Houston.)

Stepping or "walking"	Hold infant vertically under arms or on trunk, allowing one foot to touch table surface.	Infant will simulate walking, alternating flexion and extension of feet; term infants walk on soles of their feet, and preterm infants walk on their toes.	Response is normally present for 3-4 wk.
-----------------------	--	--	--

Stepping reflex. (From Dickason, E. J., Silverman, B. L., & Kaplan, J. A. [1998]. *Maternal-infant nursing care* [3rd ed.]. St. Louis: Mosby.)

Crawling	Place newborn on abdomen.	Newborn makes crawling movements with arms and legs.	Response should disappear about 6 wk of age.
----------	---------------------------	--	--

Crawling reflex. (Courtesy Paul Vincent Kuntz, Texas Children's Hospital, Houston.)

TABLE 23-4 Assessment of Newborn Reflexes—cont'd

REFLEX	ELICITING THE REFLEX	CHARACTERISTIC RESPONSE	COMMENTS
Deep tendon	Use finger instead of percussion hammer to elicit patellar, or knee jerk, reflex; newborn must be relaxed.	Reflex jerk is present; even with newborn relaxed, nonselective overall reaction may occur.	It is usually more difficult to elicit upper extremity reflexes than lower extremity reflexes.
Crossed extension	With infant in supine position, examiner extends one leg of infant and presses down knee. Stimulation of sole of foot of fixated limb should cause free leg to flex, adduct, and extend as if attempting to push away stimulating agent.	Opposite leg flexes, adducts, and then extends.	This reflex should be present during newborn period.

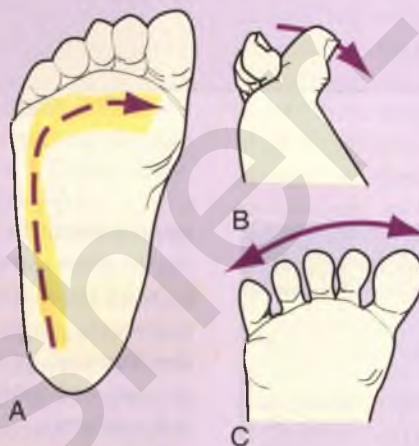

Crossed extension reflex. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

Babinski (plantar)

On sole of foot, beginning at heel, stroke upward along lateral aspect of sole; then move finger across ball of foot.

All toes hyperextend, with dorsiflexion of big toe—recorded as a positive sign.

Absence requires neurologic evaluation; should disappear after 1 yr of age. Response depends on infant's general muscle tone, maturity, and condition.

Babinski reflex. **A**, Direction of stroke. **B**, Dorsiflexion of big toe. **C**, Fanning of toes. (From Hockenberry, M. J., & Wilson, D. [2013]. *Wong's nursing care of infants and children* [9th ed.]. St. Louis: Mosby.)

Pull-to-sit (traction response); postural tone

Pull infant up by wrists from supine position with head in midline.

Head lags until infant is in upright position; then head is held in same plane with chest and shoulder momentarily before falling forward; infant attempts to right head.

Response depends on general muscle tone and maturity and condition of infant.

Truncal incurvation (Galant)

Place infant prone on flat surface; run finger down back about 4-5 cm lateral to spine, first on one side and then down the other.

Trunk is flexed, and pelvis is swung toward stimulated side.

Response disappears by fourth week. Response varies but should be obtainable in all infants, including preterm. Absence suggests general depression of nervous system. With transverse lesions of cord, no response below level of lesion is present.

Truncal incurvation reflex. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

TABLE 23-4 Assessment of Newborn Reflexes—cont'd

REFLEX	ELICITING THE REFLEX	CHARACTERISTIC RESPONSE	COMMENTS
Magnet	Place infant in supine position, partially flex both lower extremities, and apply light pressure with fingers to soles of feet (Fig. A). Normally, while examiner's fingers maintain contact with soles of feet, lower limbs extend.	Both lower limbs should extend against examiner's pressure (Fig. B).	Absence suggests damage to central nervous system. Weak reflex may be seen after breech presentation <i>without</i> extended legs or may indicate sciatic nerve stretch syndrome. Breech presentation <i>with</i> extended legs may evoke exaggerated response.
			
Magnet reflex. (Courtesy Michael S. Clement, MD, Mesa, AZ.)			
Additional newborn responses: yawn, stretch, burp, hiccup, sneeze	These are spontaneous behaviors.	Responses can be slightly depressed temporarily because of maternal analgesia or anesthesia, fetal hypoxia, or infection.	Parental guidance: Most of these behaviors are pleasurable to parents. Parents need to be assured that behaviors are normal. Sneeze is usually a response to mucus in the nose and not an indicator of a cold (upper respiratory tract infection). No treatment is needed for hiccups; sucking may help. In a preterm infant these are signs of neurodevelopmental immaturity and physiologic stress.

BOX 23-2 Clusters of Neonatal Behaviors in Brazelton Neonatal Behavioral Assessment Scale

- Habituation—Ability to respond to and then inhibit responding to discrete stimulus (e.g., light, rattle, bell, pinprick) while asleep
- Orientation—Quality of alert states and ability to attend to visual and auditory stimuli while alert
- Motor performance—Quality of movement and tone
- Range of state—Measure of general arousal level or arousability of infant
- Regulation of state—How infant responds when aroused
- Autonomic stability—Signs of stress (e.g., tremors, startles, skin color) related to homeostatic (self-regulator) adjustment of the nervous system
- Reflexes—Assessment of several neonatal reflexes

From Brazelton, T., & Nugent, J. (2011). *Neonatal behavioral assessment scale* (4th ed.). London: MacKeith.

and activity patterns. Variations in the state of consciousness of infants are called **sleep-wake states**. The six states form a continuum from deep sleep to extreme irritability (Fig. 23-13): two sleep states (deep sleep and light sleep) and four wake states (drowsy, quiet alert, active alert, and crying) (Brazelton & Nugent, 2011). Each state has specific characteristics and state-related behaviors. The optimal state of arousal is the quiet alert state. During this state infants smile, vocalize, move in synchrony with speech, watch their parents' faces, and respond to people talking to them. They respond to internal and external

environmental factors by controlling sensory input and regulating the sleep-wake states; the ability to make smooth transitions between states is called *state modulation*. The ability to regulate sleep-wake states is essential in the infant's neurobehavioral development. Term infants are better able than preterm infants to cope with external or internal factors that affect the sleep-wake patterns.

Infants use purposeful behavior to maintain the optimal arousal state as follows: (1) actively withdrawing by increasing physical distance, (2) rejecting by pushing away with hands and feet, (3) decreasing sensitivity by falling asleep or breaking eye contact by turning the head, or (4) using signaling behaviors such as fussing and crying. These behaviors permit infants to quiet themselves and reinstate readiness to interact.

The first 6 weeks of life involve a steady decrease in the proportion of active REM sleep to total sleep. A steady increase in the proportion of quiet sleep to total sleep also occurs. Periods of wakefulness increase. For the first few weeks the wakeful periods seem dictated by hunger, but soon a need for socializing appears. The newborn sleeps approximately 16 to 19 hours a day, with periods of wakefulness gradually increasing. By the fourth week of life some infants stay awake from one feeding to the next (Gardner & Goldson, 2011).

Other Factors Influencing Newborn Behavior

Gestational Age. The gestational age and level of central nervous system (CNS) maturity affect infant behavior. In the preterm neonate with an immature CNS the entire body

FIG 23-13 Newborn sleep-wake states. A, Deep sleep. B, Light sleep. C, Drowsy. D, Quiet alert. E, Active alert. F, Crying. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

responds to a pinprick of the foot, although the response may not be observed by an untrained observer. The more mature infant withdraws only the foot. CNS immaturity is reflected in reflex development, sleep-wake states, and ability (or lack thereof) to regulate or modulate a smooth transition between different states. Preterm infants have brief periods of alertness but have difficulty maintaining alertness without becoming overstimulated, which leads to autonomic instability unless intervention is implemented. Premature or sick infants show signs of fatigue or physiologic stress sooner than full-term healthy infants.

Time. The time elapsed since birth affects the behavior of infants as they attempt to become organized initially. Time elapsed since the previous feeding and time of day also can influence infants' responses.

Stimuli. Environmental events and stimuli affect the infants' behavioral responses. The newborn responds to animate and inanimate stimuli. Nurses in intensive care nurseries observe that infants respond to loud noises, bright lights, monitor alarms, and tension in the unit. If a mother is tense, nervous, or uncomfortable while feeding her infant, the infant may sense her tension and demonstrate difficulty feeding.

Medication. No conclusive evidence exists regarding the effects of maternal analgesia or anesthesia during labor on neonatal behavior. Researchers who have studied the effects of epidural medications on breastfeeding behaviors have been unable to show a cause-and-effect relationship (Hoyt, 2011).

Sensory Behaviors

From birth infants possess sensory capabilities that indicate a state of readiness for social interaction. They effectively use behavioral responses in establishing their first dialogues. These responses, coupled with the newborns' "baby appearance" (e.g., facial proportions of forehead, eyes larger than the lower portion of the face) and their small size and helplessness, rouse feelings of wanting to hold, protect, and interact with them.

Vision. At birth the eye is structurally incomplete, and the muscles are immature. The process of accommodation is not present but improves over the first 3 months of life. The pupils react to light, the blink reflex is stimulated easily, and the corneal reflex is activated by light touch. Term newborns can see objects as far away as 50 cm (2.5 feet). The clearest visual distance is 17 to 20 cm (8 to 12 inches), which is approximately the distance between the mother's and infant's faces during breastfeeding or cuddling. Newborns seem to have a preference for faces and can recognize the mother's face. This facilitates interaction and promotes bonding. They will engage the mother or caregiver with eye contact. Newborns can imitate facial expressions and motions such as protruding the tongue (Gardner & Goldson, 2011). Newborns prefer complex patterns over nonpatterned stimuli. They prefer black and white, possibly because of the greater contrast. Within 2 to 3 months they can discriminate colors (Nugent & Morell, 2011).

Hearing. Term newborns can hear and differentiate among various sounds. They will turn toward a sound and attempt to locate the source. The neonate recognizes and responds readily to the mother's voice and shows a preference for high-pitched intonation. Newborns respond to rhythmic sounds. They are accustomed to hearing the regular rhythm of the mother's heartbeat, which was a constant sound during intrauterine life. As a result they respond by relaxing and ceasing to fuss and cry if a regular heartbeat simulator is placed in their cribs; a lullaby can have the same effect (Nugent & Morell, 2011). Hearing is integral to bonding and attachment and may be more important than vision (Gardner & Goldson, 2011).

Routine hearing screening is recommended for all newborns before hospital discharge. See Chapter 24 for a discussion about screening of newborn hearing.

Smell. Newborns have a highly developed sense of smell and can detect and discriminate distinct odors. It has been shown that preterm infants as early as 28 weeks are capable of reacting to odors. They react to strong odors such as alcohol or vinegar by turning their heads away but are attracted to sweet smells. By the fifth day of life newborn infants can recognize their mother's smell. Breastfed infants are able to smell breast milk and can differentiate their mothers from other lactating women (Lawrence & Lawrence, 2011).

Taste. Young infants are particularly oriented toward the use of their mouths, both for meeting their nutritional needs for rapid growth and for releasing tension through sucking. The early development of circumoral sensation, muscle activity, and taste would seem to be preparation for survival in the extrauterine environment. The newborn can distinguish among tastes and has a preference for sweet solutions (Gardner & Goldson, 2011).

Touch. The infant is responsive to touch on all parts of the body. The face (especially the mouth), the hands, and the soles of the feet seem to be the most sensitive. Reflexes can be elicited

by stroking the infant. The newborn's responses to touch suggest that this sensory system is well prepared to receive and process tactile messages (Gardner & Goldson, 2011). Touch and motion are essential to normal growth and development. However, each infant is unique, and variations can be seen in newborns' responses to touch. Birth trauma or stress and depressant drugs taken by the mother decrease the infant's sensitivity to touch or painful stimuli.

Response to Environmental Stimuli

Temperament. Each neonate has a unique repertoire of behaviors that are influenced by various factors including temperament, sensory threshold, ability to habituate, and consolability. Temperament refers to individual variations in the reaction pattern of newborns. Newborns possess individual characteristics that affect selective responses to various stimuli present in the internal and external environments. Some infants appear to be quiet by nature and can remain still for extended periods. Their movements may be smooth and relaxed most of the time, and they have little difficulty settling down for feeding. Other infants are more active and seem to be in constant motion; they seem to be excited and interested in exploring the faces and sounds around them. These infants often need help to settle; containment (swaddling), physical contact, and boundaries surrounding the neonate in the crib can facilitate a quiet alert state (Nugent & Morell, 2011).

Habituation. Habituation is a protective mechanism that allows the infant to become accustomed to environmental stimuli. It is a psychologic and physiologic phenomenon in which the response to a constant or repetitive stimulus is decreased. In the term newborn this can be demonstrated in several ways. Shining a bright light into a newborn's eyes causes a startle or squinting the first two or three times. The third or fourth flash elicits a diminished response, and by the fifth or sixth flash the infant ceases to respond (Brazelton & Nugent, 2011). The same response pattern holds true for the sounds of a rattle or stroking the bottom of the foot.

The ability to habituate allows the healthy term newborn to select stimuli that promote continued learning about the social world, thus avoiding overload. The intrauterine environment seems to have programmed the newborn to be especially responsive to human voices, soft lights, soft sounds, and sweet tastes.

The newborn quickly learns the sounds in the home environment and is able to sleep in their midst. The selective responses of the newborn indicate cerebral organization capable of memory

and making choices. The ability to habituate depends on the state of consciousness, hunger, fatigue, and temperament. These factors also affect consolability, cuddliness, irritability, and crying.

Consolability. Newborns vary in the ability to console themselves or be consoled. In the crying state most newborns initiate one of several ways to reduce their distress. Hand-to-mouth movements with or without sucking and being alert to voices, noises, or visual stimuli are common. Some infants are consoled only if they are held and rocked (Brazelton & Nugent, 2011).

Cuddliness. Cuddliness is especially important to parents because they often gauge their ability to care for the child by the child's responses to their actions. The degree to which newborns relax and mold into the contours of the person holding them varies. One extreme is the infant who always resists being held with thrashing and stiffening of the body. This is in contrast to the infant who immediately relaxes when held and molds to the body of the person. Less extreme behavior is demonstrated by infants who are passive when held and those who gradually mold after being held for a while (Brazelton & Nugent, 2011).

Irritability. Some newborns cry longer and harder than others. For some the sensory threshold seems low. They are readily upset by unusual noises, hunger, wetness, or new experiences and thus respond intensely. Others with a high sensory threshold require a great deal more stimulation and variation to reach the active, alert state.

Crying. Crying is the language an infant uses most often to communicate needs. It can signal hunger, discomfort, pain, desire for attention, or fussiness. Infants may cry in response to environmental stimuli such as cold, being overstimulated, or being held by multiple persons. Responsiveness of the caregiver to the crying creates trust as the infant learns to associate the caregiver with comfort.

The amount and tone of crying vary based on gestational age, weight, and the reason for the cry (e.g., hunger, pain). A high-pitched cry can be a sign of a neurologic disorder. Some mothers state that they learn to distinguish among the cries. The breastfeeding mother's body responds physiologically to infant crying by stimulating the milk-ejection reflex ("let-down") (Gardner & Goldson, 2011).

The duration of crying also varies greatly in each infant; newborns may cry for as little as 5 minutes or as much as 2 hours or more per day. The amount of crying peaks in the second month and then decreases. There is a diurnal rhythm of crying, with more crying occurring in the evening hours.

KEY POINTS

- By full term the newborn's various anatomic and physiologic systems have reached a level of development and functioning that permits a physical existence apart from the mother.
- The neonate's most critical adaptation to extrauterine life is to establish effective respirations.
- Heat loss in the healthy term newborn can exceed the capacity to produce heat; this can lead to cold stress and metabolic and respiratory complications that threaten the newborn's well-being.
- Physiologic jaundice occurs in 60% of term infants and 80% of preterm infants.
- Jaundice is considered pathologic if it appears within the first 24 hours of life, if serum bilirubin levels increase by more than 6 mg/dl in 24 hours, or if serum bilirubin exceeds 15 mg/dl at any time.
- Some reflex behaviors are important for the newborn's survival.
- The healthy newborn has sensory abilities that indicate a state of readiness for social interaction. Sleep-wake states and other factors influence the newborn's behavior.
- Newborn behavior progresses from self-regulation of autonomic processes to social interaction.
- Each full-term newborn has a predisposed capacity to handle the multitude of stimuli in the external world.

Nursing Care of the Newborn and Family

Kathryn R. Alden

ⓔ <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Explain the purpose and components of the Apgar score.
- Describe how to perform a physical assessment of a newborn.
- Describe how to perform a gestational age assessment of a newborn.
- Compare the characteristics of the preterm, late preterm, early term, full term, and postterm neonate.
- Provide nursing care to assist the newborn to transition to extrauterine life.
- Explain the elements of a safe environment.
- Discuss phototherapy and the guidelines for teaching parents about this treatment.
- Explain the purposes and methods for circumcision, the postoperative care of the circumcised infant, and parent teaching regarding circumcision.
- Describe the procedures for administering an intramuscular injection, performing a heelstick, collecting urine specimens, and venipuncture.
- Evaluate pain in the newborn based on physiologic changes and behavioral observations.
- Discuss pharmacologic and nonpharmacologic interventions to reduce neonatal pain.
- Review anticipatory guidance nurses provide to parents before discharge.

Although most infants make the necessary biopsychosocial adjustments to extrauterine existence without undue difficulty, their well-being depends on the care they receive from others. This chapter describes the assessment and care of the infant immediately after birth until discharge from the birth setting, as well as important anticipatory guidance related to ongoing infant care. A discussion of pain in the neonate and its management is included.

CARE MANAGEMENT: BIRTH THROUGH THE FIRST 2 HOURS

Care begins immediately after birth and focuses on assessing and stabilizing the newborn's condition. The nurse has the primary responsibility for the infant during this period because the physician or nurse-midwife is involved with care of the mother. The nurse must be alert for any signs of distress and initiate appropriate interventions.

The foundation for providing comprehensive, family-centered newborn care is awareness of the mother's preconception and prenatal history as well as intraparturient events. Recognition of risk factors (Box 24-1) enables the nurse to be more astute in observations and assessments and more likely to identify early signs of complications. This allows for earlier intervention and promotes positive outcomes.

⚡ SAFETY ALERT

With the possibility of transmission of viruses such as hepatitis B virus (HBV) and human immunodeficiency virus (HIV) through maternal blood and blood-stained amniotic fluid, the newborn must be considered a potential contamination source until proved otherwise. As part of Standard Precautions, nurses wear gloves when handling the newborn until blood and amniotic fluid are removed by bathing.

Immediate Care after Birth

The primary goal of care in the first moments after birth is to assist the newly born infant to transition to extrauterine life by establishing effective respirations. If the infant is at term, is crying or breathing, and has good muscle tone, routine care can begin (Kattwinkel, Perlman, Aziz, et al., 2010). The infant is placed prone skin-to-skin on the mother's abdomen or chest, and the nurse assesses the airway. Slight extension of the neck helps keep the airway patent. Drying the infant with vigorous rubbing removes moisture to prevent evaporative heat loss and provides tactile stimulation to stimulate respiratory effort. The mother and her newborn are covered with a warm blanket and a cap is placed on the infant's head (Niermeyer & Clarke, 2011).

The newborn should be breathing spontaneously. The trunk and lips should be pink; acrocyanosis is a normal finding

(see Fig. 23-4) (Niermeyer & Clarke, 2011). If the neonate is apneic or has gasping respirations, positive-pressure ventilation is needed.

The heart rate is quickly assessed by grasping the base of the cord or by auscultating the left chest with a stethoscope. The nurse counts for 6 seconds and multiplies by 10 to calculate the heart rate. It should be greater than 100 beats/minute. If the newborn requires respiratory or circulatory support, the nurse and other members of the health care team (e.g., neonatologist, respiratory therapist) follow the American Heart Association guidelines for neonatal resuscitation (Kattwinkel et al., 2010). The neonatal resuscitation algorithm directs the care (Fig. 24-1).

As soon as possible after birth, the nurse places identically numbered bands on the infant's wrist and ankle, on the mother, and on the father or significant other. An electronic infant security tag or abduction system alarm should be placed on all newborns to aid in protecting against infant abduction. The infant is footprinted with ink or a scanning device within 2 hours of birth. (See later discussion of infant abduction.)

BOX 24-1 Assessment of Preconception, Prenatal, and Intrapartum Risk Factors

Preconception

- Age
- Preexisting medical conditions: diabetes, hypertension, cardiac disease, anemia, thyroid disorder, renal disease, obesity
- Genetic factors: family history
- Obstetric history: gravidity, parity, number of living children and their ages, history of stillbirth, previous infant with congenital anomalies, habitual abortion, use of assisted reproductive technology, interpregnancy spacing
- Blood type and Rh status

Prenatal

- Prenatal care: when started
- Nutrition: weight gain, diet, obesity, eating disorders
- Health-compromising behaviors: smoking, alcohol use, substance abuse
- Blood group or Rh sensitization
- Medications: prescription, over-the-counter, and complementary and alternative medications
- History of infection: sexually transmitted infections, TORCH* infections, group B streptococcus status

Intrapartum

- Length of gestation: preterm, late preterm, early term, term, or postterm
- First stage of labor: length, electronic fetal monitoring—internal or external, rupture of membranes (time, presence of meconium), signs of fetal distress (decelerations)
- Group B streptococcus status: treatment during labor
- Second stage of labor: length, vaginal or cesarean, instrument assisted—forceps or vacuum extractor, complications (shoulder dystocia, bleeding [abruptio placentae or placenta previa]), cord prolapse, maternal analgesia and/or anesthesia

*TORCH is the collective name for toxoplasmosis, other infections (e.g., hepatitis), rubella virus, cytomegalovirus (CMV), and herpes simplex virus.

Adapted from Hurst, H.M. (2015). Antepartum-intrapartum complications. In T.M. Verklan & M. Walden (Eds.), *Core curriculum for neonatal intensive care nursing* (5th ed.). St. Louis: Saunders.

Apgar Scoring and Initial Assessment

The initial assessment of the neonate is performed immediately after birth using the Apgar score (Table 24-1) and a brief physical examination (Table 24-2). A gestational age assessment is completed within the first hours of birth in a stable newborn (Fig. 24-2). A more comprehensive physical assessment is completed within 24 hours of birth (Table 24-3).

Apgar Score

The **Apgar score** permits a rapid assessment of the newborn's transition to extrauterine life based on five signs that indicate the physiologic state of the neonate: (1) heart rate, based on auscultation with a stethoscope or palpation of the umbilical cord; (2) respiratory effort, based on observed movement of the chest wall; (3) muscle tone, based on degree of flexion and movement of the extremities; (4) reflex irritability, based on response to suctioning of the nares or nasopharynx; and (5) generalized skin color, described as pallid, cyanotic, or pink (see Table 24-1). Evaluations are made at 1 and 5 minutes after birth and can be completed by the nurse or birth attendant. Scores of 0 to 3 indicate severe distress, scores of 4 to 6 indicate moderate difficulty, and scores of 7 to 10 indicate that the infant is having minimal or no difficulty adjusting to extrauterine life. Apgar scores do not predict future neurologic outcome but are useful for describing the newborn's transition to the extrauterine environment and the need for resuscitation (Box 24-2). If resuscitation is required, it should be initiated before the 1-minute Apgar score is determined (American College of Obstetricians and Gynecologists [ACOG] Committee on Obstetric Practice, 2010).

Initial Physical Assessment

The initial examination of the newborn (see Table 24-2) can occur while the nurse is drying and wrapping the infant, or observations can be made while the infant is lying on the mother's abdomen or in her arms immediately after birth. Efforts should be directed toward minimizing interference in the initial parent-infant acquaintance process. If the infant is breathing effectively, is pink, and has no apparent life-threatening anomalies or risk factors requiring immediate attention (e.g., infant of a mother with diabetes), further examination can be delayed until after the parents have had an opportunity to interact with the infant. Routine procedures and the admission process can be carried out in the mother's room or in a separate nursery.

Physical Assessment

Although the initial assessment after birth can reveal significant anomalies, birth injuries, and cardiopulmonary problems that have immediate implications, a more detailed, thorough physical examination should follow within 24 hours after birth (see Table 24-3). The parents' presence during this and other examinations encourages discussion of their concerns and actively involves them in the health care of their infant from birth. It also affords the nurse an opportunity to observe parental interactions with the infant. The findings provide a database for implementing the nursing process with newborns and providing anticipatory guidance for the parents. Ongoing assessments are made throughout the hospital stay; another detailed physical examination is performed before discharge.

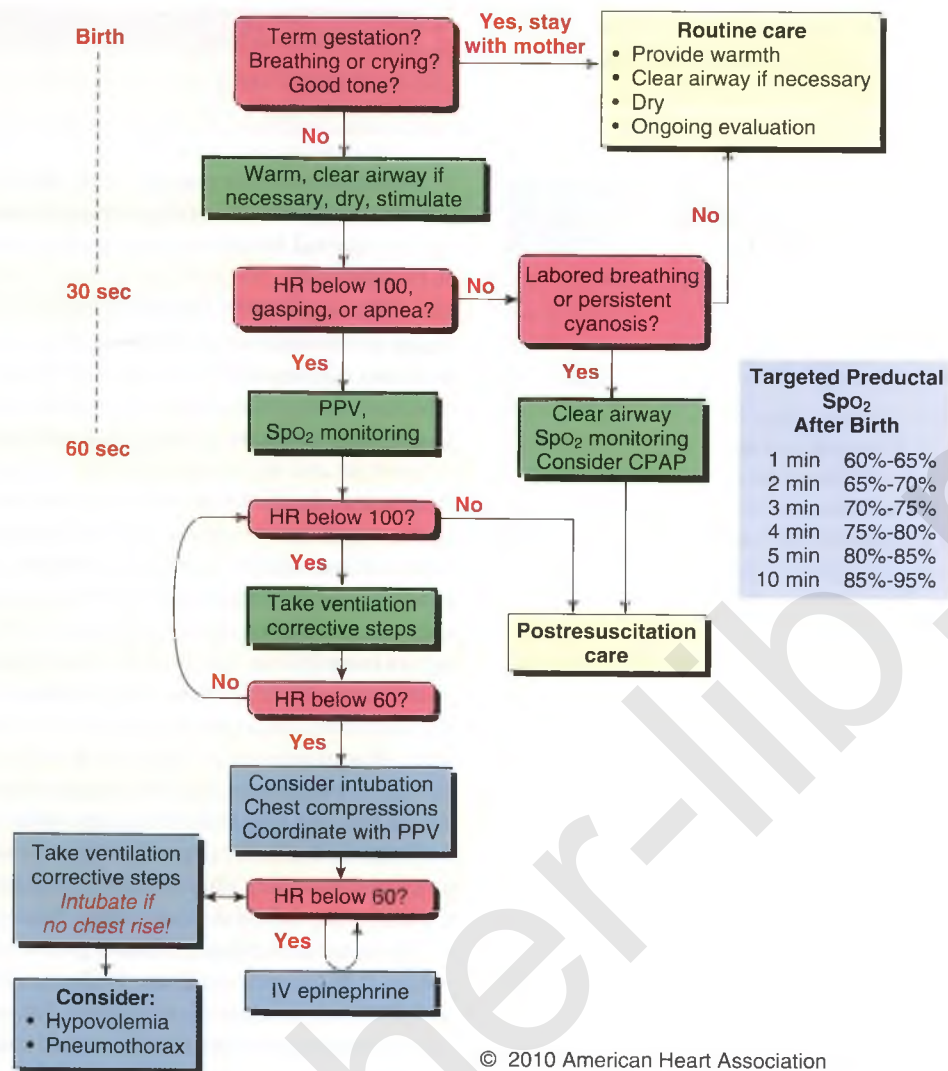

FIG 24-1 Neonatal resuscitation algorithm. CPAP, Continuous positive airway pressure; HR, heart rate; IV, intravenous; PPV, positive-pressure ventilation; SpO₂, blood oxygen saturation. (From Katwinkel, J., Perlman, J.M., Aziz, K., et al. [2010]. Part 15: Neonatal resuscitation: 2010 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care. *Circulation*, 122[Suppl 3], S909-S919. Reprinted with permission of the American Heart Association.)

TABLE 24-1 Apgar Score

SIGN	SCORE		
	0	1	2
Heart rate	Absent	Slow (<100/min)	>100/min
Respiratory effort	Absent	Slow, weak cry	Good cry
Muscle tone	Flaccid	Some flexion of extremities	Well flexed
Reflex irritability	No response	Grimace	Cry
Color	Blue, pale	Body pink, extremities blue	Completely pink

General Appearance

The neonate's maturity level can be gauged by assessing general appearance. Features to assess in the general survey include posture, activity, any overt signs of anomalies that can cause initial distress, presence of bruising or other birth trauma, and state of

alertness. The normal resting position of the neonate is one of general flexion.

Vital Signs

The temperature, heart rate, and respiratory rate are always obtained. Blood pressure (BP) is not routinely assessed unless cardiac problems are suspected. An irregular, very slow, or very fast heart rate can indicate a need for further evaluation of circulatory status including BP measurement.

The axillary temperature is a safe, accurate measurement of temperature. Electronic thermometers have expedited this task and provide a reading within 1 minute. Temporal artery, tympanic, and oral routes for measuring temperature in the newborn are not considered accurate (Brown & Landers, 2011). Taking an infant's temperature can cause the infant to cry and struggle against the placement of the thermometer in the axilla. Before taking the temperature, the examiner

can determine the apical heart rate and respiratory rate while the infant is quiet and at rest. The normal axillary temperature averages 37° C (98.6° F), with a range from 36.5° to 37.5° C (97.7° to 99.5° F).

SAFETY ALERT

Rectal temperatures should not be done on a newborn because of the risk for perforation.

TABLE 24-2 Initial Physical Assessment of the Newborn

General appearance	<input type="checkbox"/> Color pink <input type="checkbox"/> Acrocyanosis present <input type="checkbox"/> Flexed posture <input type="checkbox"/> Alert <input type="checkbox"/> Active
Respiratory system	<input type="checkbox"/> Airway patent <input type="checkbox"/> No upper airway congestion <input type="checkbox"/> No retractions or nasal flaring <input type="checkbox"/> Respiratory rate, 30-60 breaths/min <input type="checkbox"/> Lungs clear to auscultation bilaterally <input type="checkbox"/> Chest expansion symmetric
Cardiovascular system	<input type="checkbox"/> Heart rate >100 beats/min; strong and regular <input type="checkbox"/> No murmurs heard <input type="checkbox"/> Pulses strong and equal bilaterally
Neurologic system	<input type="checkbox"/> Moves extremities <input type="checkbox"/> Normotonic <input type="checkbox"/> Symmetric features, movement Reflexes present: <ul style="list-style-type: none"> <input type="checkbox"/> Sucking <input type="checkbox"/> Rooting <input type="checkbox"/> Moro <input type="checkbox"/> Grasp <input type="checkbox"/> Anterior fontanel soft and flat
Gastrointestinal system	<input type="checkbox"/> Abdomen soft, no distention <input type="checkbox"/> Cord attached and clamped <input type="checkbox"/> Anus appears patent
Eyes, nose, mouth	<input type="checkbox"/> Eyes clear <input type="checkbox"/> Palate intact <input type="checkbox"/> Nares patent
Skin	<input type="checkbox"/> No signs of birth trauma <input type="checkbox"/> No lesions or abrasions
Genitourinary system	<input type="checkbox"/> Normal genitalia
Other	<input type="checkbox"/> No obvious anomalies
Comments:	

The respiratory rate varies with the state of alertness and activity after birth. Respirations are abdominal in nature and can be counted by observing or lightly feeling the rise and fall of the abdomen. Neonatal respirations are shallow and irregular. The respirations should be counted for a full minute to obtain an accurate count because there are periods when respirations can cease for seconds (≤ 20) and resume again. The examiner should also observe for symmetry of chest movement. The average respiratory rate is 40 breaths/minute but will vary between 30 and 60 breaths/minute; respiratory rate can exceed 60 breaths/minute if the newborn is very active or crying.

An apical pulse rate should be obtained on all newborns. Auscultation should be for a full minute, preferably when the infant is asleep or in a quiet alert state. The infant may need to be held and comforted during assessment. The normal heart rate ranges from 110 to 160 beats/minute when the infant is awake (Blackburn, 2013). It is common to detect brief irregularities in the heart rate. Heart rate varies with the newborn's behavioral state. Bradycardia is a heart rate less than 100 beats/minute. However, a term infant in deep sleep can have a heart rate in the 80s or 90s; the rate should increase when the infant awakens. Tachycardia is a heart rate exceeding 160 beats/minute. It is not unusual for a crying infant to have a heart rate greater than 160; the heart rate should decrease when the crying ceases.

Assessment of neonatal blood pressure is based on agency policy. If BP is measured, an oscillometric monitor calibrated for neonatal pressures is preferred. An appropriate-size cuff (width-to-arm or width-to-calf ratio of 0.45 to 0.70, or approximately $\frac{1}{2}$ to $\frac{3}{4}$) is essential for accuracy. Neonatal BP usually is highest immediately after birth and falls to a minimum by 3 hours after birth. It then begins to rise steadily and reaches a plateau between 4 and 6 days after birth. This measurement is usually equal to that of the immediate postbirth BP. The BP varies with the neonate's activity; accurate measurement is best obtained while the newborn is at rest. Blood pressure varies with gestational age and chronologic age. Systolic pressure in a term neonate averages 60 to 80 mm Hg; diastolic pressure averages 40 to 50 mm Hg. The mean arterial pressure should approximate

BOX 24-2 Significance of the Apgar Score

The Apgar score was developed to provide a rapid systematic method of assessing an infant's condition at birth. When used correctly it is useful for standardized assessment and provides a mechanism to document the neonate's transition after birth. It is designed to be used for a limited time frame. Apgar scores are affected by factors such as gestational age, maternal medications, trauma, congenital anomalies, hypovolemia, and hypoxia.

Researchers have tried to correlate Apgar scores with various outcomes in the term infant such as intelligence and neurologic development. In some instances researchers have attempted to attribute causality to the Apgar score, that is, to suggest that the

low Apgar score caused or predicted later problems. This use of the Apgar score is inappropriate.

There is a lack of evidence regarding the significance of the Apgar score in preterm infants. It should be used with this population of infants only for ongoing assessment in the delivery room.

The Apgar score is a useful index for monitoring neonatal response to resuscitation, especially in regard to a change in the score from 1 minute to 5 minutes after birth. However, assigning an Apgar score to a neonate during resuscitation is not equivalent to assigning a score to a newborn who is breathing spontaneously. It is important that health care professionals be consistent in assigning Apgar scores during a resuscitation.

the neonate's week of gestation. According to agency protocol, four extremity blood pressures may be assessed routinely or only when a murmur is auscultated. If the upper extremity systolic pressures are more than 15 mm Hg greater than those in the lower extremities, the infant may have a cardiac defect such as coarctation of the aorta (Kenney, Hoover, Williams, & Iskersky, 2011). Peripheral pulses are also palpated as part of the assessment in any infant with a heart murmur.

Baseline Measurements of Physical Growth

Baseline measurements are taken and recorded to help assess the progress and determine the growth patterns of the neonate. These measurements may be recorded on growth charts. The following measurements are made when the neonate is assessed.

Weight. The newborn is usually weighed shortly after birth. This assessment is performed in the labor and birthing area, the mother's room, or in the nursery. Care must be taken to ensure that the scales are balanced. The totally unclothed neonate is placed in the center of the scale, which is usually covered with a disposable pad or cloth to prevent heat loss via conduction and to prevent cross-infection. The nurse should place one hand over (but not touching) the neonate to be prepared to prevent the infant from falling off the scales. Weighing the infant at the same time every day is common during the hospital stay. Birth weight of a term infant typically ranges from 2500 to 4000 g (5.5 to 8.8 lb).

Head Circumference and Body Length. The head is measured at the widest part, which is the occipitofrontal diameter. The tape measure is placed around the head just above the infant's eyebrows. The term neonate's head circumference ranges from 32 to 36.8 cm (12.6 to 14.5 in.).

The length can be difficult to obtain because of the flexed posture of the newborn. The examiner places the newborn on a flat surface and extends the leg until the knee is flat against the surface. Placing the head against a perpendicular surface and extending the leg can assist with obtaining this measurement. In the term neonate, head-to-heel length ranges from 45 to 55 cm (17.7 to 21.7 in.).

Neurologic Assessment

The physical examination includes a neurologic assessment of newborn reflexes (see Table 23-4). This assessment provides useful information about the infant's nervous system and state of neurologic maturation. Many reflex behaviors (e.g., sucking, rooting) are important for proper development. Other reflexes such as gagging and sneezing act as primitive safety mechanisms. The assessment needs to be carried out as early as possible because abnormal signs in the early neonatal period can require further investigation before the newborn is discharged home.

Gestational Age Assessment

Assessment of gestational age is important because perinatal morbidity and mortality rates are related to gestational age and birth weight. A frequently used method of determining gestational age is the New Ballard Score, which can be used to measure gestational ages of infants as young as 20 weeks of gestation (see Fig. 24-2). It assesses six external physical and six neuromuscular signs. Each sign has a numeric score, and the cumulative score correlates with a maturity rating (gestational age). The examination of infants

with a gestational age of 26 weeks or less should be performed at a postnatal age of less than 12 hours. For infants with a gestational age of at least 26 weeks, the examination can be performed up to 96 hours after birth. To ensure accuracy, experts recommend that the initial examination is performed within the first 48 hours of life. Neuromuscular adjustments after birth in extremely immature neonates require a follow-up examination to further validate neuromuscular criteria (Ballard, Khoury, Wedig, et al., 1991). Box 24-3 highlights specific maneuvers used in gestational age assessment.

Classification of Newborns by Gestational Age and Birth Weight

Classification of infants at birth by both birth weight and gestational age provides a more satisfactory method for predicting mortality risks and providing guidelines for management of the neonate than estimating gestational age or birth weight alone. The infant's birth weight, length, and head circumference are plotted on standardized graphs that identify normal values for gestational age. A normal range of birth weights exists for each gestational week (see Fig. 24-2, B).

The infant whose weight is **appropriate for gestational age (AGA)** (between the 10th and 90th percentiles) can be presumed to have grown at a normal rate regardless of the length of gestation—preterm, term, or postterm. The infant who is **large for gestational age (LGA)** (more than the 90th percentile) can be presumed to have grown at an accelerated rate during fetal life; the **small for gestational age (SGA)** infant (less than the 10th percentile) can be presumed to have grown at a restricted rate during intrauterine life. When gestational age is determined according to the New Ballard Score, the newborn will fall into one of the following nine possible categories for birth weight and gestational age: AGA—term, preterm, postterm; SGA—term, preterm, postterm; or LGA—term, preterm, postterm. Birth weight influences mortality: the lower the birth weight, the higher the mortality. The same is true for gestational age: the lower the gestational age, the higher the mortality (Gardner & Hernandez, 2011).

Infants may also be classified in the following ways according to gestation (ACOG Committee on Obstetric Practice & Society for Maternal-Fetal Medicine, 2013):

- **Preterm, or premature**—born before completion of 37 weeks of gestation, regardless of birth weight
- **Late preterm**—34 0/7 through 36 6/7 weeks
- **Early term**—37 0/7 through 38 6/7 weeks
- **Full term**—39 0/7 through 40 6/7 weeks
- **Late term**—41 0/7 through 41 6/7 weeks
- **Postterm**—42 0/7 weeks and beyond
- **Postmature**—born after completion of week 42 of gestation and showing the effects of progressive placental insufficiency

Early Term Infant

“Early term” (37 0/7 through 38 6/7 weeks) is a recent addition to the categories describing newborns according to gestational age. In 2011, 25.86% of births were considered early term (Martin, Hamilton, Ventura, et al., 2013). A recent increase in the number of early term infants is associated with elective inductions and elective cesarean births that are scheduled before 39 weeks. Compared with full-term infants, early term infants are at greater

risk for short- and long-term health problems. Early term birth is associated with higher risk of hypoglycemia, respiratory problems such as respiratory distress syndrome and transient tachypnea of the newborn (TTNB), and a greater likelihood of NICU admission (Sengupta, Carrion, Shelton, et al., 2013). These infants are also at increased risk for long-term problems such as learning difficulties (e.g., attention deficit hyperactivity disorder [ADHD]) (Lindstrom, Lindblad, & Hjern, 2011). Early term infants have higher neonatal, postnatal, and infant mortality rates (Reddy, Bettegowda, Dias, et al., 2011). Nurses and other health care providers need to be aware of the vulnerability of this population of neonates and monitor them closely (Craighead, 2012).

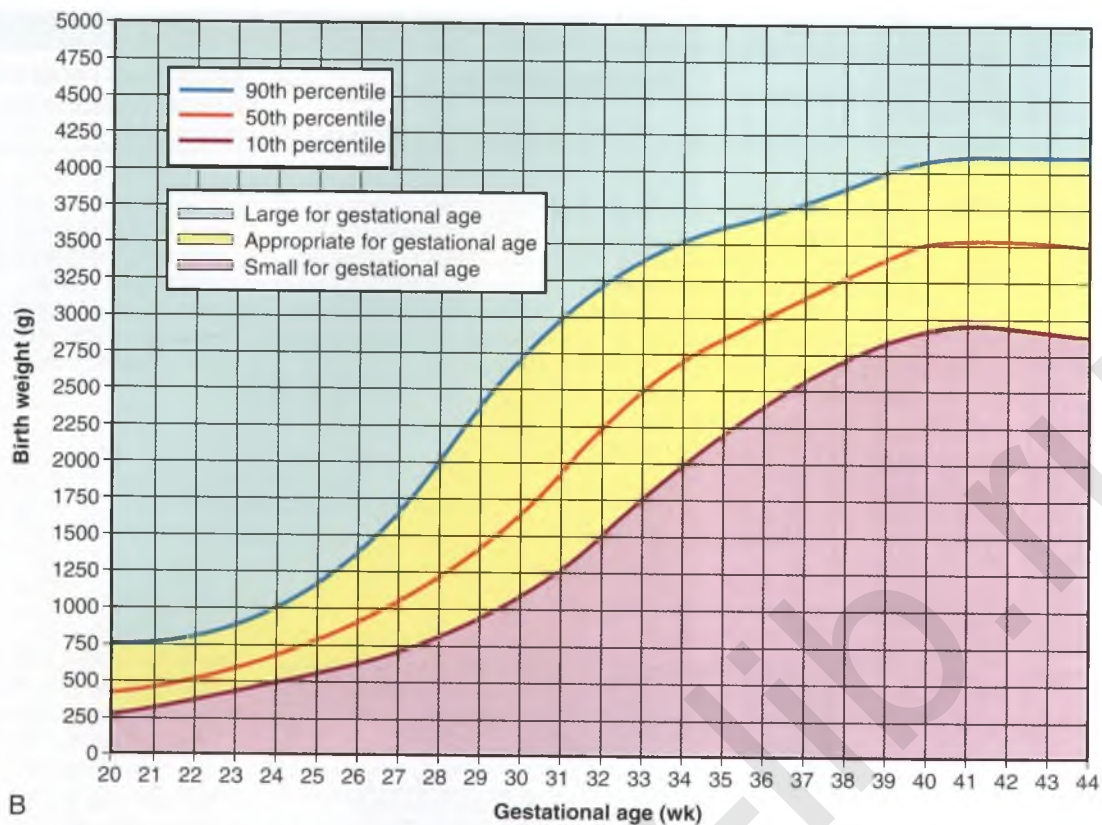

Late Preterm Infant

The rate of preterm birth in the United States was 11.73% in 2011. The majority of preterm births are considered late preterm, occurring between 34% and 36% weeks of gestation.

These late preterm infants account for 8.28% of all births (Martin et al., 2013). Elective vaginal and cesarean births before 39 weeks have contributed significantly to late preterm birth rates in the United States.

Late preterm infants have been called “the great impostors” because they are often the size and weight of term infants and are often treated as healthy newborns. Despite their appearance as term infants, late preterm infants are at increased risk for respiratory distress, temperature instability, hypoglycemia, apnea, feeding difficulties, and hyperbilirubinemia. Nurses and health care providers must be cognizant of the risk factors for late preterm infants and be continually vigilant for the development of problems related to the infant’s immaturity (Phillips, Goldstein, Hougland, et al., 2013). In an effort to identify these infants, a gestational age assessment should be performed on all newborns soon after birth (Cooper, Holditch-Davis, Verklan, et al., 2012). The late preterm infant’s care is further addressed in Chapter 34.

B

FIG 24-2, cont'd B, Intrauterine growth: birth weight percentiles based on live single births at gestational ages 20 to 44 weeks. (A, From Ballard, J., Khoury, J., Wedig, K., et al. [1991]. New Ballard score, expanded to include extremely premature infants. *Journal of Pediatrics*, 119[3], 417-423.)

BOX 24-3 Maneuvers Used in Assessing Gestational Age

Posture

With infant quiet and in a supine position, observe degree of flexion in arms and legs. Muscle tone and degree of flexion increase with maturity. Full flexion of the arms and legs = score 4.*

Square Window

With thumb supporting back of arm below wrist, apply gentle pressure with index and third fingers on dorsum of hand without rotating infant's wrist. Measure angle between base of thumb and forearm. Full flexion (hand lies flat on ventral surface of forearm) = score 4.*

Arm Recoil

With infant supine, fully flex both forearms on upper arms and hold for 5 seconds; pull down on hands to extend fully, and rapidly release arms. Observe rapidity and intensity of recoil to a state of flexion. A brisk return to full flexion = score 4.*

Popliteal Angle

With infant supine and pelvis flat on a firm surface, flex lower leg on thigh and then flex thigh on abdomen. While holding

knee with thumb and index finger, extend lower leg with index finger of other hand. Measure degree of angle behind knee (popliteal angle). An angle of less than 90 degrees = score 5.*

Scarf Sign

With infant supine, support head in midline with one hand; use other hand to pull infant's arm across the shoulder so that infant's hand touches shoulder. Determine location of elbow in relation to midline. Elbow does not reach midline = score 4.*

Heel to Ear

With infant supine and pelvis flat on a firm surface, pull foot as far as possible (without using force) up toward ear on same side. Measure distance of foot from ear and degree of knee flexion (same as popliteal angle). Knees flexed with a popliteal angle of less than 10 degrees = score 4.*

*See Fig. 24-2 for scale and interpretation of scores.

TABLE 24-3 Physical Assessment of Newborn

AREA ASSESSED AND APPRAISAL PROCEDURE	NORMAL FINDINGS		DEVIATIONS FROM NORMAL RANGE: POSSIBLE PROBLEMS (ETIOLOGY)
	AVERAGE FINDINGS	NORMAL VARIATIONS	
Posture			
Inspect newborn before disturbing for assessment	Vertex: arms, legs in moderate flexion; fists clenched	Frank breech: legs straighter and stiff, newborn assuming intrauterine position in repose for a few days	Hypotonia, relaxed posture while awake (preterm or hypoxia in utero, maternal medications, neuromuscular disorder such as spinal muscular atrophy)
Refer to maternal chart for fetal presentation, position, and type of birth (vaginal, surgical), given that newborn readily assumes in utero position	Resistance to having extremities extended for examination or measurement, crying possible when attempted Cessation of crying when allowed to resume curled-up fetal position (lateral) Normal spontaneous movement bilaterally asynchronous (legs moving in bicycle fashion) but equal extension in all extremities	Prenatal pressure on limb or shoulder possibly causing temporary facial asymmetry or resistance to extension of extremities	Hypertonia (chemical dependence, central nervous system [CNS] disorder) Limitation of motion in any of extremities
Vital Signs			
<i>Check heart rate and pulses:</i>			
Thorax (chest)			
Inspection	Visible pulsations in left midclavicular line, fifth intercostal space		
Palpation	Apical pulse, fourth intercostal space 110-160 beats/min when awake	80-100 beats/min (sleeping) to 180 beats/min (crying); possibly irregular for brief periods, especially after crying	Tachycardia: persistent, ≥ 180 beats/min (respiratory distress syndrome [RDS]; pneumonia) Bradycardia: persistent, ≤ 80 beats/min (congenital heart block, maternal lupus)
Auscultation	Quality: <i>first sound</i> (closure of mitral and tricuspid valves) and <i>second sound</i> (closure of aortic and pulmonic valves) sharp and clear	Murmur, especially over base or at left sternal border in interspace 3 or 4 (foramen ovale anatomically closing at approximately 1 yr)	Murmur (possibly functional) Dysrhythmias: irregular rate
Apex: mitral valve			Sounds: Distant (pneumopericardium) Poor quality Extra
Second interspace, left of sternum: pulmonic valve			Heart on right side of chest (dextrocardia, often accompanied by reversal of intestines)
Second interspace, right of sternum: aortic valve			Weak or absent peripheral pulses (decreased cardiac output, thrombus, possible coarctation of aorta if weak on left and strong on right)
Junction of xiphoid process and sternum: tricuspid valve			Bounding
Peripheral pulses: femoral, brachial, popliteal, posterior tibial	Peripheral pulses equal and strong		
<i>Assess temperature:</i>			
Axillary: method of choice	Axillary: 37° C (98.6° F)	36.5°-37.5° C (97.7°-100° F)	Subnormal (preterm birth, infection, low environmental temperature, inadequate clothing, dehydration)
Temporal and intraauricular thermometers not effective in measuring newborn temperature	Temperature stabilized by 8-10 hr of age	Heat loss: from evaporation, conduction, convection, radiation	Increased (infection, high environmental temperature, excessive clothing, proximity to heating unit or in direct sunshine, chemical dependence, diarrhea and dehydration) Temperature not stabilized by 6-8 hr after birth (if mother received magnesium sulfate, newborn less able to conserve heat by vasoconstriction; maternal analgesics possibly reducing thermal stability in newborn)
<i>Observe and monitor respiratory rate and effort:</i>			
Observe respirations when infant is at rest	40/min Tendency to be shallow and irregular in rate, rhythm, and depth when infant is awake	30-60/min Short periodic breathing episodes and no evidence of respiratory distress or apnea (>20 sec); periodic breathing	Apneic episodes: >20 sec (preterm infant: rapid warming or cooling of infant; CNS or blood glucose instability)
Observe respiratory effort		First period (reactivity): 50-60/min Second period: 50-70/min	Bradypnea: <25 /min (maternal narcosis from analgesics or anesthetics, birth trauma)
Count respirations for full minute		Stabilization (1-2 days): 30-40/min Crackles (fine)	Tachypnea: >60 /min (RDS, transient tachypnea of the newborn, congenital diaphragmatic hernia)
Auscultate breath sounds	Crackles may be heard after birth No adventitious sounds audible on inspiration and expiration		Breath sounds: Crackles (coarse), rhonchi, wheezing
Listen for sounds audible without stethoscope	Breath sounds: bronchial; loud, clear		Expiratory grunt (narrowing of bronchi) Distress evidenced by nasal flaring, grunting, retractions, labored breathing Stridor (upper airway occlusion)

TABLE 24-3 Physical Assessment of Newborn—cont'd

AREA ASSESSED AND APPRAISAL PROCEDURE	NORMAL FINDINGS		DEVIATIONS FROM NORMAL RANGE: POSSIBLE PROBLEMS (ETIOLOGY)
	AVERAGE FINDINGS	NORMAL VARIATIONS	
<p><i>Obtain blood pressure (BP) (usually not done in normal term infant)</i></p> <p>Check oscillometric monitor BP cuff: BP cuff width affects readings, use appropriate-size cuff and palpate brachial, popliteal, or posterior tibial pulse (depending on measurement site)</p>	<p>60-80/40-50 mm Hg (approximate ranges)</p> <p>At birth</p> <p>Systolic: 60-80 mm Hg</p> <p>Diastolic: 40-50 mm Hg</p> <p>At 2 weeks</p> <p>Systolic: 68-88 mm Hg</p> <p>Diastolic: 40-60 mm Hg</p>	<p>Variation with change in activity level: awake, crying, sleeping</p>	<p>Difference between upper and lower extremity pressures (coarctation of aorta)</p> <p>Hypotension (sepsis, hypovolemia)</p> <p>Hypertension (coarctation of aorta, renal involvement, thrombus)</p>
<p>Weight</p> <p>Put cloth or paper protective liner in place and adjust scale to 0 g or pounds and ounces</p> <p>Weigh at same time each day</p> <p>Protect newborn from heat loss</p>	<p>Female: 3400 g (7.5 lb)</p> <p>Male: 3500 g (7.7 lb)</p> <p>Regaining of birth weight within first 2 weeks</p>	<p>2500-4000 g (5.5-8.8 lb)</p> <p>Acceptable weight loss: 10% or less in first 3-5 days</p> <p>Second baby weighing more than first (on average)</p>	<p>Weight \leq2500 g (preterm, small for gestational age, rubella syndrome)</p> <p>Weight \geq4000 g (large for gestational age, maternal diabetes, heredity—normal for these parents)</p> <p>Weight loss more than 10% to 15% (growth failure, dehydration); assess breastfeeding success</p>

Weighing the infant. The nurse never leaves the infant alone on a scale. The scale is covered to protect against cross-infection. (Courtesy Wendy and Marwood Larson-Harris, Roanoke, VA.)

Length

<p>Measure length from top of head to heel; measuring is difficult in term infant because of presence of molding, incomplete extension of knees</p>	<p>50 cm (19.7 in)</p>	<p>45-55 cm (17.7-21.7 in)</p>	<p><45 cm (17.7 in) or >55 cm (21.7 in) (chromosomal abnormality, heredity—normal for these parents); some syndromes present shorter than average limb length (skeletal dysplasias, achondroplasia)</p>
---	------------------------	--------------------------------	---

Measuring length crown to heel. To determine total length, include length of legs. If measurements are taken before the infant's initial bath, wear gloves. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

TABLE 24-3 Physical Assessment of Newborn—cont'd

AREA ASSESSED AND APPRAISAL PROCEDURE	NORMAL FINDINGS		DEVIATIONS FROM NORMAL RANGE: POSSIBLE PROBLEMS (ETIOLOGY)
	AVERAGE FINDINGS	NORMAL VARIATIONS	
Head Circumference Measure head at greatest diameter: occipitofrontal circumference May need to remeasure on second or third day after resolution of molding and caput succedaneum	33-35 cm (13-13.8 in) Circumference of head and chest approximately the same for first 1 or 2 days after birth; chest rarely measured on routine basis	32-36.8 cm (12.6-14.5 in)	Microcephaly, head \leq 32 cm: (maternal rubella, toxoplasmosis, cytomegalovirus, fused cranial sutures [craniosynostosis]) Hydrocephaly: sutures widely separated, circumference \geq 4 cm more than chest circumference (infection) Increased intracranial pressure (hemorrhage, space-occupying lesion)
			
Measuring head circumference. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)			
Chest Circumference Measure at nipple line	2-3 cm (0.8-1.2 in) less than head circumference; average 30-33 cm (11.8-13 in)	\leq 30 cm	Prematurity
			
Measuring chest circumference. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)			
Skin Check color Inspect and palpate Inspect semi-naked newborn in well-lit, warm area without drafts; natural daylight best Inspect newborn when quiet and alert	Generally pink Varies with ethnic origin, skin pigmentation beginning to deepen right after birth in basal layer of epidermis Acrocyanosis common after birth	Mottling Harlequin sign Plethora Telangiectases ("stork bites" or capillary hemangiomas) (see Fig. 23-6, A) Erythema toxicum/neonatorum ("newborn rash") (see Fig. 23-6, B) Milia Petechiae over presenting part Ecchymoses from forceps in vertex births or over buttocks, genitalia, and legs in breech births	Dark red (preterm, polycythemia) Gray (hypotension, poor perfusion) Pallor (cardiovascular problem, CNS damage, blood dyscrasia, blood loss, twin-to-twin transfusion, infection) Cyanosis (hypothermia, infection, hypoglycemia, cardiopulmonary diseases, neurologic or respiratory malformations) Generalized petechiae (clotting factor deficiency, infection) Generalized ecchymoses (hemorrhagic disease)
Observe for jaundice	None at birth	Physiologic jaundice in up to 60% of term infants in first week of life	Jaundice within first 24 hr (increased hemolysis, Rh isoimmunization, ABO incompatibility)

TABLE 24-3 Physical Assessment of Newborn—cont'd

AREA ASSESSED AND APPRAISAL PROCEDURE	NORMAL FINDINGS		DEVIATIONS FROM NORMAL RANGE: POSSIBLE PROBLEMS (ETIOLOGY)
	AVERAGE FINDINGS	NORMAL VARIATIONS	
Observe for birthmarks or bruises: Inspect and palpate for location, size, distribution, characteristics, color, if obstructing airway or oral cavity		Mongolian spot (see Fig. 23-5) in infants of African-American, Asian, and Native-American origin	Hemangiomas Nevus flammeus: port-wine stain Nevus vasculosus: strawberry mark Cavernous hemangioma
Check skin condition: Inspect and palpate for intactness, smoothness, texture, edema, pressure points if ill or immobilized	Edema confined to eyelid (result of eye prophylaxis) Opacity: few large blood vessels visible indistinctly over abdomen	Slightly thick; superficial cracking, peeling, especially of hands, feet No visible blood vessels, a few large vessels clearly visible over abdomen Some fingernail scratches	Edema on hands, feet; pitting over tibia; periorbital (overhydration; hydrops) Texture thin, smooth, or of medium thickness; rash or superficial peeling visible (preterm, postterm) Numerous vessels very visible over abdomen (preterm) Texture thick, parchment-like; cracking, peeling (postterm) Skin tags, webbing Papules, pustules, vesicles, ulcers, maceration (impetigo, candidiasis, herpes, diaper rash)
Weigh infant routinely	Dehydration: loss of weight best indicator	Normal weight loss after birth: up to 10% of birth weight	
Gently pinch skin between thumb and forefinger over abdomen and inner thigh to check for turgor	After pinch released, skin returns to original state immediately		Loose, wrinkled skin (prematurity, postmaturity, dehydration: fold of skin persisting after release of pinch) Tense, tight, shiny skin (edema, extreme cold, shock, infection)
Note presence of subcutaneous fat deposits (adipose pads) over cheeks, buttocks		Variation in amount of subcutaneous fat	Lack of subcutaneous fat, prominence of clavicle or ribs (preterm, malnutrition)
Check for vernix caseosa: Observe color, amount, and odor before bath	Whitish, cheesy, odorless	Usually more found in creases, folds	Absent or minimal (postmature infant) Abundant (preterm) Green color (possible in utero release of meconium or presence of bilirubin) Odor (possible intrauterine infection) Absent (postmature) Abundant (preterm, especially if lanugo abundant, long, and thick over back)
Assess lanugo: Inspect for this fine, downy hair, amount and distribution	Over shoulders, pinnae of ears, forehead	Variation in amount	
Head			
Palpate skin	(See "Skin")	Caput succedaneum, possibly showing some ecchymosis (see Fig. 23-10, A)	Cephalhematoma (see Fig. 23-10, B) Subgaleal hemorrhage (see Fig. 23-10 C)
Inspect shape, size	Making up one fourth of body length Molding (see Fig. 23-9)	Slight asymmetry from intrauterine position Lack of molding (preterm, breech presentation, cesarean birth)	Severe molding (birth trauma) Indentation (fracture from trauma)
Palpate, inspect, and note size and status of fontanels (open vs. closed)	Anterior fontanel 5-cm diamond, increasing as molding resolves Posterior fontanel triangle, smaller than anterior	Variation in fontanel size with degree of molding Difficulty in feeling fontanels possible because of molding	Fontanels: Full, bulging (tumor, hemorrhage, infection) Large, flat, soft (malnutrition, hydrocephaly, delayed bone age, hypothyroidism) Depressed (dehydration)
Palpate sutures	Palpable and separated sutures	Possible overlap of sutures with molding	Sutures: Widely spaced (hydrocephaly) Premature closure (fused) (craniosynostosis)
Inspect pattern, distribution, amount of hair; feel texture	Silky, single strands lying flat; growth pattern toward face and neck	Variation in amount	Fine, wooly (preterm) Unusual swirls, patterns, or hairline; or coarse, brittle (endocrine or genetic disorders)
Eyes			
Check placement on face	Eyes and space between eyes each one third the distance from inner to outer canthus	Epicanthal folds: characteristic in some ethnicities	Epicanthal folds when present with other signs (chromosomal disorders such as Down, cri du chat syndromes)

Continued

TABLE 24-3 Physical Assessment of Newborn—cont'd

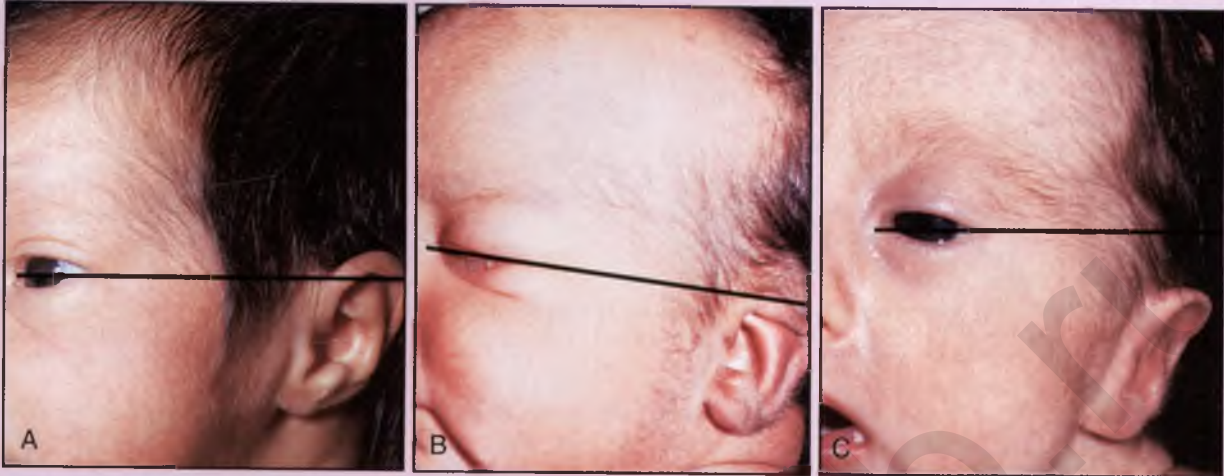

AREA ASSESSED AND APPRAISAL PROCEDURE	NORMAL FINDINGS		DEVIATIONS FROM NORMAL RANGE: POSSIBLE PROBLEMS (ETIOLOGY)
	AVERAGE FINDINGS	NORMAL VARIATIONS	
			
	<p>Eyes. In pseudostrabismus, inner epicanthal folds cause the eyes to appear misaligned; however, corneal light reflexes are perfectly symmetric. Eyes are symmetric in size and shape and are well placed.</p>		
Check for symmetry in size, shape	Symmetric in size, shape		
Check eyelids for size, movement, blink	Blink reflex	Edema if eye prophylaxis drops or ointment instilled	
Assess for discharge	None No tears	Some discharge if silver nitrate used Occasional presence of tears	Discharge: purulent (infection) Chemical conjunctivitis from eye medication is common—requires no treatment
Evaluate eyeballs for presence, size, shape	Both present and of equal size, both round, firm	Subconjunctival hemorrhage	Agnesis or absence of one or both eyeballs Lens opacity or absence of red reflex (congenital cataracts, possibly from rubella, retinoblastoma [cat's-eye reflex]) Lesions: coloboma, absence of part of iris (congenital) Pink color of iris (albinism) Jaundiced sclera (hyperbilirubinemia)
Check pupils	Present, equal in size, reactive to light		Pupils: unequal, constricted, dilated, fixed (intracranial pressure, medications, tumor)
Evaluate eyeball movement	Random, jerky, uneven, focus possible briefly, following to midline	Transient strabismus or nystagmus until third or fourth month	Persistent strabismus Doll's eyes (increased intracranial pressure) Sunset (increased intracranial pressure)
Assess eyebrows: amount of hair, pattern	Distinct (not connected in midline)		Connection in midline (Cornelia de Lange syndrome)
Nose			
Observe shape, placement, patency, configuration	Midline Some mucus but no drainage Preferential nose breather Sneezing to clear nose	Slight deformity (flat or deviated to one side) from passage through birth canal	Copious drainage (rarely congenital syphilis; blockage membranous or bone with cyanosis at rest and return of pink color with crying [choanal atresia]) Malformed (congenital syphilis, chromosomal disorder) Flaring of nares (respiratory distress)
Ears			
Observe size, placement on head, amount of cartilage, open auditory canal	Correct placement line drawn through inner and outer canthi of eyes reaching to top notch of ears (at junction with scalp) Well-formed, firm cartilage	Size: small, large, floppy Darwin tubercle (nodule on posterior helix)	Agnesis Lack of cartilage (preterm) Low placement (chromosomal disorder, intellectual disability, kidney disorder) Preauricular tag or sinus Size: possibly overly prominent or protruding ears

TABLE 24-3 Physical Assessment of Newborn—cont'd

AREA ASSESSED AND APPRAISAL PROCEDURE	NORMAL FINDINGS		DEVIATIONS FROM NORMAL RANGE: POSSIBLE PROBLEMS (ETIOLOGY)
	AVERAGE FINDINGS	NORMAL VARIATIONS	
			
	<p>Placement of ears on the head in relation to a line drawn from the inner to the outer canthus of the eye. A, Normal position. B, Abnormally angled ear. C, True low-set ear. (Courtesy Mead Johnson Nutritionals, Evansville, IN.)</p>		
Assess hearing	Responds to voice and other sounds	State (e.g., alert, asleep) influencing response	Lack of response to loud noise should <i>not</i> imply deafness
Perform universal newborn hearing screening to identify deficits (see Fig. 24-11)	Both ears pass		One or both ears fail
Facies			
Observe overall appearance and symmetry of face	Rounded and symmetric; influenced by birth type, molding, or both	Positional deformities	Usually accompanied by other features such as low-set ears, other structural disorders (hereditary, chromosomal aberration)
Mouth			
Inspect and palpate	Symmetry of lip movement	Transient circumoral cyanosis	Gross anomalies in placement, size, shape (cleft lip or palate [or both], gums)
Assess buccal mucosa			Cyanosis, circumoral pallor (respiratory distress, hypothermia)
Dry or moist			Asymmetry in movement of lips (seventh cranial nerve paralysis)
Pink			
Status intact			
Assess lips for color, configuration, movement			
Check gums	Pink gums	Inclusion cysts (Epstein pearls—Bohn nodules, whitish, hard nodules on gums or roof of mouth)	Teeth: predeciduous or deciduous (hereditary)
Assess tongue for color, mobility, movement, size	Tongue not protruding, freely movable, symmetric in shape, movement	Short lingual frenulum (ankyloglossia)	Macroglossia (preterm, chromosomal disorder)
	Sucking pads inside cheeks		Thrush: white plaques on cheeks or tongue that bleed if touched (<i>Candida albicans</i>)
Assess palate (soft, hard):	Soft and hard palates intact	Anatomic groove in palate to accommodate nipple, disappearance by 3 to 4 yr of age	Cleft hard or soft palate
Arch	Uvula in midline	Epstein pearls	
Uvula			
Assess chin	Distinct chin		Micrognathia—recessed chin with prominent overbite (Pierre Robin or other syndrome)
Evaluate saliva for amount, character	Mouth moist, pink		Excessive salivation and choking or turning blue (esophageal atresia, tracheoesophageal fistula)
Check reflexes:	Reflexes present	Reflex response dependent on state of wakefulness and hunger	Absent (preterm)
Rooting			
Sucking			
Extrusion			
Neck			
Inspect and palpate for movement, flexibility, masses, bruising	Short, thick, surrounded by skin folds; no webbing		Webbing (Turner syndrome)

TABLE 24-3 Physical Assessment of Newborn—cont'd

AREA ASSESSED AND APPRAISAL PROCEDURE	NORMAL FINDINGS		DEVIATIONS FROM NORMAL RANGE: POSSIBLE PROBLEMS (ETIOLOGY)
	AVERAGE FINDINGS	NORMAL VARIATIONS	
Check sternocleidomastoid muscles, movement and position of head	Head held in midline (sternocleidomastoid muscles equal), no masses Freedom of movement from side to side and flexion and extension, no movement of chin past shoulder	Transient positional deformity apparent when newborn is at rest: passive movement of head possible	Restricted movement, holding of head at angle (torticollis [wryneck], opisthotonos) Absence of head control (preterm birth, Down syndrome, hypotonia [spinal muscular atrophy])
Assess trachea for position and thyroid gland	Thyroid not palpable		Masses (enlarged thyroid) Distended veins (cardiopulmonary disorder) Skin tags
Chest			
<i>Inspect and palpate</i>			
Shape	Almost circular, barrel shaped	Tip of sternum possibly prominent	Bulging of chest, unequal movement (pneumothorax, pneumomediastinum) Malformation (funnel chest—pectus excavatum)
Observe respiratory movements	Symmetric chest movements, chest and abdominal movements synchronized during respirations	Occasional retractions, especially when crying	Retractions with or without respiratory distress (preterm, RDS) Paradoxical breathing
Evaluate clavicles	Clavicles intact		Fracture of clavicle (trauma); crepitus
Assess ribs	Rib cage symmetric, intact; moves with respirations		Poor development of rib cage and musculature (preterm)
Assess nipples for size, placement, number	Nipples prominent, well formed; symmetrically placed		Nipples Supernumerary, along nipple line Malpositioned or widely spaced
Check breast tissue	Breast nodule: approximately 6 mm in term infant	Breast nodule: 3-10 mm Secretion of witch's milk	Lack of breast tissue (preterm)
Auscultate: Heart sounds and rate and breath sounds (see "Vital Signs")			Sounds: bowel sounds may be heard in diaphragmatic hernia (see "Abdomen")
Abdomen			
Inspect and palpate umbilical cord	Two arteries, one vein Whitish gray Definite demarcation between cord and skin, no intestinal structures within cord Dry around base, drying Odorless Cord clamp in place for 24 to 48 hr	Reducible umbilical hernia	One artery (renal anomaly) Meconium stained (intrauterine distress) Bleeding or oozing around cord (hemorrhagic disease) Redness or drainage around cord (infection, possible persistence of urachus) Hernia: herniation of abdominal contents through cord opening (e.g., omphalocele); defect covered with thin, friable membrane, possibly extensive
Inspect size of abdomen and palpate contour	Rounded, prominent, dome shaped because abdominal musculature not fully developed Liver possibly palpable 1-2 cm (0.4-0.8 in) below right costal margin No other masses palpable No distention Few visible veins on abdominal surface	Some diastasis recti (separation) of abdominal musculature	Gastroschisis: herniation of abdominal contents to the side or above the cord, contents not covered by membranous tissue and may include liver Distention at birth: ruptured viscus, genitourinary masses or malformations: hydronephrosis, teratomas, abdominal tumors Mild (overfeeding, high gastrointestinal tract obstruction) Marked (lower gastrointestinal tract obstruction, anorectal malformation, anal stenosis), often with bilious emesis Intermittent or transient (overfeeding) Partial intestinal obstruction (stenosis of bowel) Visible peristalsis (obstruction) Malrotation of bowel or adhesions Sepsis (infection)
Auscultate bowel sounds and note number, amount, and character of stools	Sounds present within minutes after birth in healthy term infant Meconium stool passing within 24-48 hr after birth		Scaphoid, with bowel sounds in chest and severe respiratory distress (congenital diaphragmatic hernia)

TABLE 24-3 Physical Assessment of Newborn—cont'd

AREA ASSESSED AND APPRAISAL PROCEDURE	NORMAL FINDINGS		DEVIATIONS FROM NORMAL RANGE: POSSIBLE PROBLEMS (ETIOLOGY)
	AVERAGE FINDINGS	NORMAL VARIATIONS	
Assess color		Linea nigra possibly apparent and caused by hormone influence during pregnancy	
Observe movement with respiration	Respirations primarily diaphragmatic, abdominal and chest movement synchronous		Decreased or absent abdominal movement with breathing (phrenic nerve palsy, congenital diaphragmatic hernia)
Genitalia			
Female (see Fig. 23-7, A)			
Inspect and palpate			
General appearance		Increased pigmentation caused by pregnancy hormones	Ambiguous genitalia—wide variation (small phallus not well distinguished from enlarged clitoris)
Clitoris	Usually edematous		Virilized female—extremely large clitoris (congenital adrenal hyperplasia)
Labia majora	Usually edematous, covering labia minora in term newborns	Edema and ecchymosis after breech birth Some vernix caseosa between labia possible	
Labia minora	Possible protrusion over labia majora		Enlarged clitoris with urinary meatus on tip, absent scrotum, micropenis, fused labia Stenosed meatus Labia majora widely separated and labia minora prominent (preterm)
Discharge	Smegma	Blood-tinged discharge from pseudo-menstruation caused by pregnancy hormones	Fecal discharge (fistula)
Vagina	Open orifice Mucoïd discharge Hymenal/vaginal tag		Absence of vaginal orifice
Urinary meatus	Beneath clitoris, difficult to see		Bladder exstrophy (bladder outside abdominal cavity and turned inside out)
Check urination	Void within 24 hr; voiding 2-6 times per 24 hr for first 1-2 days; voiding 6-8 times per 24 hr by day 4 or 5	Rust-stained urine (uric acid crystals)	No void within first 24 hours (renal agenesis; Potter syndrome)
Male (see Fig. 23-7, B)			
Inspect and palpate			
General appearance		Increased size and pigmentation caused by pregnancy hormones, (wide variation in size of genitalia)	Ambiguous genitalia Micropenis
Penis			
Urinary meatus appearance	Foreskin covers glans (if uncircumcised), meatus at tip of penis		Urinary meatus not on tip of glans penis (hypospadias, epispadias, foreskin may be retracted or absent)
Prepuce (foreskin)—do not forcibly retract foreskin if uncircumcised	Prepuce covering glans penis and not retractable	Prepuce removed if circumcised	Round meatal opening
Scrotum: Rugae (wrinkles)	Large, edematous, pendulous in term infant; covered with rugae	Scrotal edema and ecchymosis if breech birth Hydrocele, small, noncommunicating	Scrotum smooth and testes undescended (preterm, cryptorchidism) Bifid scrotum Hydrocele Inguinal hernia
Testes	Palpable on each side	Bulge palpable in inguinal canal	Undescended (preterm)
Check urination	Voiding within 24 hr, stream adequate; voiding 2-6 times per 24 hr for first 1-2 days; voiding 6-8 times per 24 hr by day 4 or 5	Rust-stained urine (uric acid crystals)	No void in first 24 hr (renal agenesis; Potter syndrome)
Check reflexes:			
Cremasteric	Testes retracted, especially when newborn is chilled		

Continued

TABLE 24-3 Physical Assessment of Newborn—cont'd

AREA ASSESSED AND APPRAISAL PROCEDURE	NORMAL FINDINGS		DEVIATIONS FROM NORMAL RANGE: POSSIBLE PROBLEMS (ETIOLOGY)
	AVERAGE FINDINGS	NORMAL VARIATIONS	
Extremities			
Make a general check: Inspect and palpate Degree of flexion Range of motion Symmetry of motion Muscle tone	Assuming of position maintained in utero Attitude of general flexion Full range of motion, spontaneous movements	Transient positional deformities	Limited motion (malformations) Poor muscle tone (preterm, maternal medications, CNS anomalies)
Check arms and hands: Inspect and palpate Color Intactness Appropriate placement	Longer than legs in newborn period Contours and movements symmetric	Slight tremors sometimes apparent Some acrocyanosis	Asymmetry of movement (fracture/crepitus, brachial nerve trauma, malformations) Asymmetry of contour (malformations, fracture) Amelia or phocomelia (teratogens) Palmar creases Simian line with short, incurved little fingers (Down syndrome)
Count number of fingers	Five on each hand Fist often clenched with thumb under fingers		Webbing of fingers: syndactyly Absence or excess of fingers Strong, rigid flexion; persistent fists; positioning of fists in front of mouth constantly (CNS disorder) Yellowed nailbeds (meconium staining) Increased tonicity, clonus, prolonged tremors (CNS disorder)
Evaluate joints Shoulder Elbow Wrist Fingers	Full range of motion, symmetric contour		
Check reflexes Palmar grasp Plantar grasp	Infant's fingers tightly flex around examiner's finger when palm is stimulated Infant's toes flex and curl around examiner's finger when sole of foot at base of toes is stimulated	May occur spontaneously when sucking	Weak or absent reflexes can indicate CNS depression
Check legs and feet: Inspect and palpate Color Intactness Length in relation to arms and body and to each other Number of toes	Appearance of bowing because lateral muscles more developed than medial muscles Five on each foot	Feet appearing to turn in but can be easily rotated externally, positional defects tending to correct while infant is crying Acrocyanosis	Amelia, phocomelia (chromosomal defect, teratogenic effect) Temperature of one leg differing from that of the other (circulatory deficiency, CNS disorder)
Femur Head of femur as legs are flexed and abducted, placement in acetabulum (see Fig. 23-12) Major gluteal folds Soles of feet	Intact femur Major gluteal folds even Soles well lined (or wrinkled) over two thirds of foot in term infants Plantar fat pad giving flat-footed effect		Webbing, syndactyly (chromosomal defect) Absence or excess of digits (chromosomal defect, familial trait) Femoral fracture (difficult breech birth) Developmental dysplasia of the hip (DDH) Gluteal folds uneven: DDH Soles of feet: Few creases (preterm) Covered with creases (postmature) Congenital clubfoot Hypermobility of joints (Down syndrome)
Evaluate joints Hip Knee Ankle Toes Check reflexes (see Table 23-4)	Full range of motion, symmetric contour		Asymmetric movement (trauma, CNS disorder)

TABLE 24-3 Physical Assessment of Newborn—cont'd

AREA ASSESSED AND APPRAISAL PROCEDURE	NORMAL FINDINGS		DEVIATIONS FROM NORMAL RANGE: POSSIBLE PROBLEMS (ETIOLOGY)
	AVERAGE FINDINGS	NORMAL VARIATIONS	
Back			
Assess anatomy:			
Inspect and palpate			
Spine	Spine straight and easily flexed Infant able to raise and support head momentarily when prone	Temporary minor positional deformities, correction with passive manipulation	Limitation of movement (fusion or deformity of vertebra) Spina bifida cystica (meningocele, myelomeningocele)
Shoulders	Shoulders, scapulae, and iliac crests lining up in same plane		Pigmented nevus with tuft of hair, location anywhere along the spine often associated with spina bifida occulta
Scapulae			Sinus (opening to spinal cord)
Iliac crests			
Base of spine—pilonidal dimple or sinus			
Check reflexes (spinal related)			
Test trunk incurvation reflex	Trunk flexed and pelvis swings to stimulated side	May not be apparent in first few days but is usually present in 5-6 days	If transverse lesion is present, no response below lesion; absence of response: central nervous system abnormality or CNS depression
Test magnet reflex	Lower limbs extend as pressure applied to feet with legs in semiflexed position	Weak or exaggerated response with breech presentation	Absence: suggestive of CNS damage or malformation
Anus			
Inspect and palpate	One anus with good sphincter tone	Passage of meconium within 48 hr of birth	Imperforate anus without fistula
Placement	Passage of meconium within 24 hr after birth		Rectal atresia and stenosis
Patency	Anal "wink" present, anal opening patent		Absence of anal opening; drainage of fecal material from vagina in female or urinary meatus in male (rectal fistula) or along perineal raphe (midline area between base of penis and anus)—anorectal malformation
Test for sphincter response (active "wink" reflex)			
Observe for the following:			
Abdominal distention			
Passage of meconium from anal opening			
Fecal drainage from perineum, penis, vagina			
Stools			
Observe frequency, color, consistency	Meconium followed by transitional and soft yellow stool		No stool (obstruction) Frequent watery stools (infection, phototherapy)

Postterm or Postmature Infant

Infants born of a gestation that extends beyond 42 weeks are considered to be postterm, regardless of birth weight. Some infants are appropriate for gestational age, but show the characteristics of progressive placental dysfunction. These infants are labeled as postmature and are likely to have little if any vernix caseosa, absence of lanugo, abundant scalp hair, and long fingernails. The skin is often cracked, parchment-like, and desquamating. A common finding in postmature infants is a wasted physical appearance that reflects intrauterine deprivation. Depletion of subcutaneous fat gives them a thin, elongated appearance. The little vernix caseosa that remains in the skinfolds may be stained deep yellow or green, which is usually an indication of meconium in the amniotic fluid.

There is a significant increase in fetal and neonatal mortality in postmature infants compared with those born at term. They are especially prone to fetal distress associated with the decreasing efficiency of the placenta, macrosomia, and meconium aspiration syndrome. The greatest risk occurs during the stresses of labor and birth, particularly in infants of primigravidas, or

women giving birth to their first child. Close surveillance with fetal assessment and possible induction of labor is usually recommended when a pregnancy is postterm.

Immediate Interventions

Changes can occur quickly in newborns immediately after birth. Assessment must be followed by implementing appropriate care.

Airway Maintenance

Generally the healthy term infant born vaginally has little difficulty clearing the airway. Most secretions are moved by gravity and brought by the cough reflex to the oropharynx to be drained or swallowed or wiped away. If the infant has excess mucus in the respiratory tract, the mouth and nasal passages can be gently suctioned with a bulb syringe (see Teaching for Self-Management: Suctioning with a Bulb Syringe and Fig. 24-3). Routine chest percussion and suctioning of healthy term or late preterm infants are avoided; evidence is insufficient to support anything other than gentle nasopharyngeal and oropharyngeal suctioning to clear

 **NURSING CARE PLAN**
The Normal Newborn

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Ineffective Airway Clearance related to excess mucus production or improper positioning</i>	Neonate's airway remains patent; breath sounds are clear, and no respiratory distress is evident.	<p>Assess respiration and auscultate lungs.</p> <p>Observe for signs of respiratory distress.</p> <p>Teach parents that gagging, coughing, and sneezing are normal neonatal responses.</p> <p>Teach parents feeding techniques that prevent overfeeding and distention of abdomen and to burp neonate frequently.</p> <p>Position neonate on back when sleeping.</p> <p>Suction mouth and nasopharynx with bulb syringe as needed; clean nares of crusted secretions.</p> <p>Teach parents how to use bulb syringe and how to relieve airway obstruction.</p>	<p>To identify potential problems with blocked airway</p> <p>To assist neonate in clearing airways</p> <p>To prevent regurgitation and aspiration</p> <p>To prevent suffocation</p> <p>To clear airway and prevent aspiration and airway obstruction</p> <p>To clear airway</p>
<i>Risk for Imbalanced Body Temperature related to larger body surface relative to mass</i>	Neonate's temperature remains in range of 36.5° to 37.5° C (97.7° to 99.5° F).	<p>Maintain neutral thermal environment.</p> <p>Monitor neonate's axillary temperature frequently.</p> <p>Bathe neonate efficiently when temperature is stable, using warm water, drying carefully, and avoiding exposing neonate to drafts.</p> <p>Report any alterations in temperature findings promptly.</p>	<p>To identify any changes in neonate's temperature that may be related to other causes</p> <p>To identify any changes promptly and to prevent hypothermia and cold stress</p> <p>To avoid heat loss from evaporation and convection</p> <p>To assess for signs of infection or hypoglycemia and facilitate prompt treatment</p>
<i>Risk for Infection related to immature immunologic defenses and environmental exposure</i>	Neonate will be free from signs of infection.	<p>Review maternal record for evidence of any risk factors.</p> <p>Monitor temperature and other vital signs.</p> <p>Have all care providers, including parents, perform proper hand hygiene before handling newborn.</p> <p>Provide prescribed eye prophylaxis.</p> <p>Keep genital area clean and dry using proper cleansing techniques.</p> <p>Keep umbilical stump clean and dry.</p> <p>If infant is circumcised, keep site clean and apply diaper loosely.</p> <p>Teach parents to keep neonate away from crowds and environmental irritants.</p>	<p>To ascertain whether neonate is predisposed to infection</p> <p>To identify early possible evidence of infection, especially temperature instability</p> <p>To protect newborn from infection</p> <p>To prevent infection</p> <p>To prevent skin irritation, cross-contamination, and infection</p> <p>To promote drying and to minimize chance of infection</p> <p>To prevent infection and trauma</p>
<i>Risk for Injury related to sole dependence on caregiver</i>	Neonate remains free of injury.	<p>Monitor environment for hazards such as sharp objects (e.g., long fingernails, caregiver's jewelry).</p> <p>Handle neonate gently and support head, ensure use of car seat by parents, teach parents to avoid placing neonate on high surfaces unsupervised, and to supervise pet and sibling interactions with neonate.</p> <p>Assess neonate frequently for any evidence of jaundice, and teach parents to monitor for jaundice.</p>	<p>To reduce potential sources of infection</p> <p>To prevent injury</p> <p>To prevent injury</p> <p>To identify rising bilirubin levels, treat promptly, and prevent complications such as acute bilirubin encephalopathy and kernicterus</p>

NURSING CARE PLAN—cont'd

The Normal Newborn

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Readiness for Enhanced Family Coping related to anticipatory guidance regarding responses to neonate's crying</i>	Parents will verbalize their understanding of methods of coping with neonate's crying and describe increased success in interpreting neonate's cries.	<p>Alert parents to crying as neonate's form of communication and that cries can be differentiated to indicate hunger, wetness, pain, and loneliness.</p> <p>Teach parents normal patterns of infant crying and alert them to the danger of shaking a baby.</p> <p>Differentiate self-consoling behaviors from fussing or crying.</p> <p>Discuss methods of consoling the crying neonate, such as changing diapers, talking softly to neonate, holding neonate's arms close to body, swaddling, picking neonate up, rocking, using pacifier, feeding, or burping.</p>	<p>To provide reassurance that crying is not indicative of neonate's rejection of parents and that parents will learn to interpret different cries of their child</p> <p>To provide anticipatory guidance and to prevent injury to the infant</p> <p>To give parents concrete examples of interventions</p> <p>To provide anticipatory guidance and promote parental confidence</p>

secretions. The nurse should auscultate the infant's chest with a stethoscope to determine if crackles or inspiratory stridor is present. Fine crackles may be auscultated for several hours after birth, especially in neonates born by cesarean. If the bulb syringe does not clear mucus interfering with respiratory effort, mechanical suction may be used.

TEACHING FOR SELF-MANAGEMENT

Suctioning with a Bulb Syringe

- The bulb syringe should always be kept in the infant's crib.
- The mouth is suctioned first to prevent the infant from inhaling pharyngeal secretions by gasping as the nares are touched.
- The bulb is compressed (see Fig. 24-3) and the tip is inserted into one side of the mouth. The center of the infant's mouth is avoided because the gag reflex can be stimulated.
- The nasal passages are suctioned one nostril at a time.
- When the infant's cry does not sound as though it is through mucus or a bubble, suctioning can be stopped.

If the newborn has an obstruction that is not cleared with suctioning, the neonatal or pediatric care provider should be notified. Further investigation must occur to determine if a mechanical defect (e.g., tracheoesophageal fistula or choanal atresia [see Chapter 36]) is causing the obstruction.

Deeper suctioning may be needed to remove mucus from the newborn's nasopharynx or posterior oropharynx. However, this type of suctioning should be performed only after an assessment of the risks involved.

Maintaining an Adequate Oxygen Supply

Four conditions are essential for maintaining an adequate oxygen supply:

- A clear airway
- Effective establishment of respirations
- Adequate circulation, adequate perfusion, and effective cardiac function
- Adequate thermoregulation

FIG 24-3 Bulb syringe. Bulb is compressed before inserting tip into mouth. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

Newborns who encounter respiratory problems are likely to exhibit signs and symptoms that indicate some degree of distress. Preterm infants are at greatest risk for respiratory distress (see the Signs of Potential Complications box; see also Chapter 34).

SIGNS OF POTENTIAL COMPLICATIONS

Abnormal Newborn Breathing

- Bradypnea (≤ 30 respirations/min)
- Tachypnea (≥ 60 respirations/min)
- Abnormal breath sounds: coarse or fine crackles, wheezes, expiratory grunt
- Respiratory distress: nasal flaring, retractions, stridor, gasping, chin tug
- Seesaw or paradoxical respirations
- Skin color: cyanosis, mottling
- Pulse oximetry value: $< 95\%$

Maintaining Body Temperature

Effective neonatal care includes maintenance of a neutral thermal environment (see Chapter 23). Cold stress increases the need for oxygen and can deplete glucose stores. The infant can react to exposure to cold by increasing the respiratory rate and can become cyanotic.

The ideal method for promoting warmth and maintaining neonatal body temperature is early skin-to-skin contact (SSC) with the mother. The naked infant is placed prone directly on the mother's chest; both mother and infant are then covered with a warm blanket and a cap is placed on the infant's head. Early SSC has distinct short- and long-term benefits including temperature stabilization, reduced crying, improved breastfeeding initiation and duration, and maternal attachment (Moore, Anderson, Bergman, & Dowswell, 2012). Other interventions to promote warmth include drying and wrapping the newborn in warmed blankets immediately after birth, keeping the head well covered, and keeping the ambient temperature of the nursery or mother's room at 22° to 26° C (72° to 78° F) (American Academy of Pediatrics [AAP] & ACOG, 2012).

If the infant does not remain skin-to-skin with the mother during the first 1 to 2 hours after birth, the nurse places the thoroughly dried infant under a radiant warmer or in a warm incubator until the body temperature stabilizes. The infant's skin temperature is used as the point of control in a warmer with a servo-controlled mechanism. The control panel is usually maintained between 36° and 37° C (96.8° and 98.6° F). This setting should maintain the healthy term newborn's skin temperature at approximately 36.5° to 37° C (97.7° to 98.6° F). A thermistor probe (automatic sensor) is usually placed on the upper quadrant of the abdomen immediately below the right or left costal margin (never over a bone). A reflector adhesive patch can be used over the probe to provide adequate warming. This probe is designed to detect minor temperature changes resulting from external environmental factors or neonatal factors (peripheral vasoconstriction, vasodilation, or increased metabolism) before a dramatic change in core body temperature develops. The servo-controller adjusts the temperature of the warmer to maintain the infant's skin temperature within the preset range. The sensor needs to be checked periodically to make sure it is securely attached to the infant's skin. The axillary temperature of the newborn is checked every hour (or more often as needed) until the newborn's temperature stabilizes. The length of time to stabilize and maintain body temperature varies; each newborn should therefore be allowed to achieve thermal regulation as necessary, and care should be individualized.

During all procedures, heat loss must be avoided or minimized for the newborn; therefore, examinations and activities are performed with the newborn under a heat panel. The initial bath is postponed until the newborn's skin temperature is stable and can adjust to heat loss from a bath. Even a healthy term infant can become hypothermic. Inadequate drying and wrapping immediately after birth, a cold birthing room, or birth in a car on the way to the hospital can cause the newborn's temperature to fall below the normal range (hypothermia). The hypothermic infant should be warmed gradually because rapid warming can cause apneic spells and acidosis. Therefore, the warming process is monitored to progress slowly over 2 to 4 hours.

FIG 24-4 Instillation of medication into eye of newborn. Thumb and forefinger are used to open the eye; medication is placed in the lower conjunctiva from the inner to the outer canthus. (Courtesy Marjorie Pyle, Lifecircle, Costa Mesa, CA.)

Eye Prophylaxis

The U.S. Preventive Services Task Force (USPSTF, 2011) and the Canadian Paediatric Society Infectious Diseases and Immunization Committee (2002) recommend instilling a prophylactic agent in the eyes of all neonates to prevent **ophthalmia neonatorum** or neonatal conjunctivitis, which is an inflammation caused by sexually transmitted bacteria acquired during passage through the mother's birth canal. Prophylactic medication is targeted primarily toward preventing infection from *Neisseria gonorrhoeae*. Without prompt treatment this infection can lead to blindness (Smith, 2012) (Fig. 24-4). Erythromycin 0.5% ophthalmic ointment, tetracycline 1% ointment, and silver nitrate 1% solution are considered effective as preventive medications, although silver nitrate and tetracycline are not available in the United States (Canadian Paediatric Society Infectious Diseases and Immunization Committee, 2002; USPSTF, 2011). In some countries, 2.5% povidone-iodine solution is used, although this is not currently approved for use in the United States. Eye prophylaxis is usually administered within the first hour after birth. It may be delayed up to 2 hours until after the first breastfeeding so that eye contact and parent-infant attachment and bonding are facilitated. Eye prophylaxis for every newborn is mandated by law in the majority of U.S. states without regard to the mode of birth. In some states parents may refuse eye prophylaxis by signing a form that becomes part of the newborn record (Dekker, 2012).

Topical antibiotics such as erythromycin are not effective in treating chlamydial conjunctivitis; systemic treatment is needed. A 14-day course of oral erythromycin or an oral sulfonamide may be given for chlamydial conjunctivitis (AAP Committee on Infectious Diseases, 2012).

Vitamin K Prophylaxis

Administering vitamin K intramuscularly is routine in the newborn period in the United States and Canada. A single

MEDICATION GUIDE**Eye Prophylaxis: Erythromycin Ophthalmic Ointment, 0.5%, and Tetracycline Ophthalmic Ointment, 1%****Action**

These antibiotic ointments are both bacteriostatic and bactericidal caused by *Neisseria gonorrhoeae*.

Indication

These medications are applied to prevent ophthalmia neonatorum in newborns of mothers who are infected with *Neisseria gonorrhoeae*. Eye prophylaxis for ophthalmia neonatorum is required by law in all U.S. states and in some Canadian provinces.

Neonatal Dosage

Apply a 1- to 2-cm ribbon of ointment to the lower conjunctival sac of each eye; can also be used in drop form

Adverse Reactions

Can cause chemical conjunctivitis that lasts 24 to 48 hours; vision can be blurred temporarily

Nursing Considerations

Administer within 1 to 2 hours of birth. Wear gloves. Cleanse the eyes if necessary before administration. Open the eyes by putting a thumb and finger at the corner of each lid and gently pressing on the periorbital ridges. Squeeze the tube and spread the ointment from the inner canthus of the eye to the outer canthus. Do not touch the tube to the eye. After 1 minute excess ointment may be wiped off. Observe eyes for irritation. Explain the treatment to the parents.

intramuscular (IM) injection of 0.5 to 1 mg of vitamin K is given soon after birth to prevent hemorrhagic disease of the newborn. In the United States, administration can be delayed until after the first breastfeeding in the birthing room (AAP & ACOG, 2012). In Canada, newborns should receive the injection within 6 hours after birth when the infant is stable and there has been opportunity for interaction with the parents (McMillan & Canadian Paediatric Society Fetus and Newborn Committee, 2014). Vitamin K is synthesized by intestinal flora, which are not present at birth. The introduction of bacteria begins with the first feedings, and by the age of 7 days, healthy newborns are able to produce their own vitamin K.

Promoting Parent-Infant Interaction

Today's birthing practices promote the family as the focus of care. Parents generally desire to share in the birth process and have early contact with their infants. The infant can be put to breast soon after birth. Early contact between mother and newborn can be important in developing future relationships; it also has a positive effect on the initiation and duration of breastfeeding. Rooming-in during the hospital stay promotes parent-infant interaction. Early mother-infant contact produces physiologic benefits for the mother and neonate. Maternal levels of oxytocin and prolactin rise with early breastfeeding. The process of developing active immunity begins as the infant ingests antibodies from the mother's colostrum.

MEDICATION GUIDE**Vitamin K: Phytonadione (AquaMEPHYTON, Konakion)****Action**

This intervention provides vitamin K because the newborn does not have the intestinal flora to produce this vitamin in the first week after birth. It also promotes formation of clotting factors (II, VII, IX, X) in the liver.

Indication

Vitamin K is used for preventing and treating hemorrhagic disease in the newborn.

Neonatal Dosage

Administer a 0.5-mg (0.25-ml) dose to newborns weighing less than 1500 g and a 1-mg (0.5-ml) dose to newborns weighing more than 1500 g intramuscularly soon after birth; the injection can be delayed until after initial breastfeeding.* Vitamin K is never administered by the intravenous (IV) route for the prevention of hemorrhagic disease of the newborn except in some cases of a preterm infant who has no muscle mass. In such instances the medication is diluted and given over 10 to 15 minutes while closely monitoring the infant with a cardiorespiratory monitor. Rapid IV administration of vitamin K can cause cardiac arrest.

Adverse Reactions

Edema, erythema, and pain at the injection site occur rarely; hemolysis, jaundice, and hyperbilirubinemia have been reported, particularly in preterm infants.

Nursing Considerations

Follow the procedure for intramuscular injection on (see Fig. 24-15).

*Administration may be delayed up to 6 hours in Canada.

CARE MANAGEMENT: FROM 2 HOURS AFTER BIRTH UNTIL DISCHARGE

Depending on the model of care delivery, the mother/baby nurse or newborn nursery nurse is responsible for ongoing assessment and care of the newborn. Astute assessment skills and appropriate interventions promote positive outcomes, especially for newborns who experience any problems before going home. Newborn care is family centered—the nurse provides education and support for the new parents throughout the hospital stay and assists them in preparing for discharge from the birthing facility.

Common Newborn Problems**Birth Injuries**

Birth trauma includes any physical injury sustained by a newborn during labor and birth. Although most injuries are minor and resolve during the neonatal period without treatment, some types of trauma require intervention; a few are serious enough to be fatal. (See Chapter 35 for more information on birth injuries.)

Retinal and **subconjunctival hemorrhages** result from rupture of capillaries caused by increased pressure during birth. These hemorrhages usually clear within 5 days and present no further problems. Parents need explanation and reassurance that these injuries are harmless.

Erythema, ecchymoses, petechiae, abrasions, lacerations, or edema of the buttocks and extremities can be present. Localized discoloration can appear over the presenting part as a result of forceps- or vacuum-assisted birth. Ecchymoses and edema can appear anywhere on the body. Petechiae (pinpoint hemorrhagic areas) acquired during birth can extend over the upper trunk and face. These lesions are benign if they disappear within 2 or 3 days of birth and no new lesions appear. Ecchymoses and petechiae can be signs of a more serious disorder, such as thrombocytopenic purpura. To differentiate hemorrhagic areas from a skin rash or discolorations, the nurse attempts to blanch the skin by pressing with two fingers, lifting the fingers off the skin, and waiting for the return of blood. Petechiae and ecchymoses will not blanch because extravasated blood remains within the tissues, whereas skin rashes and discolorations will blanch.

Trauma to the presenting fetal part can occur during labor and birth. Caput succedaneum and cephalhematoma are discussed in Chapter 23 (see Fig. 23-10). Forceps injury and bruising from the vacuum cup occur at the site of application of the instruments. A forceps injury commonly produces a linear mark across both sides of the face in the shape of forceps blades. The affected areas are kept clean to minimize the risk for infection. These injuries usually resolve spontaneously within several days with no specific therapy.

Bruises over the face can be the result of face presentation (Fig. 24-5). In a breech presentation, bruising and swelling may be seen over the buttocks or genitalia (see Fig. 23-8). The skin over the entire head can be ecchymotic and covered with petechiae caused by a tight nuchal cord. If the hemorrhagic areas do not disappear spontaneously in 2 days or if the infant's condition changes, the primary health care provider is notified.

FIG 24-5 Marked bruising on the entire face of an infant born vaginally after face presentation. Less severe ecchymoses were present on the extremities. Phototherapy was required for treatment of jaundice resulting from the breakdown of accumulated blood. (From O'Doherty, N. [1986]. *Neonatology: Micro atlas of the newborn*. Nutley, NJ: Hoffman-La Roche.)

Accidental lacerations can be inflicted with a scalpel during a cesarean birth. These cuts can occur on any part of the body but are most often found on the scalp, buttocks, and thighs. They are usually superficial and need only to be kept clean. If skin closure is needed, an adhesive substance or strips may be applied. Sutures are rarely needed.

Physiologic Problems

Jaundice

Assessment and Screening. A majority of newborn infants experience some level of jaundice due to hyperbilirubinemia during the first few days of life, usually occurring after 24 hours. In most cases it is *physiologic jaundice*, caused by increased levels of unconjugated bilirubin; physiologic jaundice is usually self-limiting and requires no treatment. It peaks at about 3 to 5 days and resolves after 1 to 2 weeks. In some cases phototherapy is needed to lower bilirubin levels to within an acceptable range. Physiologic jaundice must be differentiated from pathologic jaundice, which is associated with higher levels of unconjugated bilirubin. This type of jaundice can appear in the first 24 hours and often requires phototherapy to resolve (see Chapter 23). Jaundice can also be associated with breastfeeding (see Chapter 25).

Every newborn should be assessed for jaundice at least every 8 to 12 hours; this can be easily done when vital signs are assessed. To differentiate cutaneous jaundice from normal skin color, the nurse applies pressure with a finger over a bony area (e.g., the nose, forehead, sternum) for several seconds to empty all the capillaries in that spot, then releases the pressure by lifting the finger. If jaundice is present, the blanched area will appear yellowish before the capillaries refill. The conjunctival sacs and buccal mucosa also are assessed, especially in darker-skinned infants. Assessing for jaundice in natural light is recommended because artificial lighting and reflection from nursery walls can distort the actual skin color.

Visual assessment of jaundice alone does not provide an accurate assessment of the level of serum bilirubin, especially in dark-skinned newborns (Burgos, Flaherman, & Newman, 2012). A more accurate noninvasive assessment of hyperbilirubinemia is accomplished using transcutaneous bilirubinometry [TcB] (Fig. 24-6). TcB devices allow for repetitive estimations

FIG 24-6 Transcutaneous monitoring of bilirubin with a transcutaneous bilirubinometry (TcB) monitor. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

of bilirubin and work well on both dark- and light-skinned infants. TcB levels demonstrate linear correlation with serum determinations of bilirubin levels in full-term infants (Dijk & Hulzebos, 2012; Maisels, DeRidder, Kring, & Balasubramaniam, 2009). TcB monitors can be used to screen for clinically significant jaundice and decrease the need for serum bilirubin measurements.

If an infant appears jaundiced in the first 24 hours of life, a TcB or total serum bilirubin (TSB) level should be measured and results interpreted based on the newborn's age in hours according to the hour-specific nomogram for infants born at 35 weeks of gestation or later (AAP Subcommittee on Hyperbilirubinemia, 2004). Repeat testing is based on the risk level (low, intermediate, or high), the age of the neonate, and the progression of jaundice.

In an effort to prevent severe hyperbilirubinemia and the neurologic complications of acute bilirubin encephalopathy and kernicterus, the AAP and the Canadian Paediatric Society recommend routine screening of all newborns before hospital discharge using TcB or serum bilirubin measurement (AAP Subcommittee on Hyperbilirubinemia, 2004; Barrington, Sankaran, & Canadian Paediatric Society Fetus and Newborn Committee, 2011). In general, if the TcB level is greater than 12 mg/dl, a serum bilirubin check is done and levels are interpreted according to the hour-specific nomogram (AAP Subcommittee on Hyperbilirubinemia, 2004) (Fig. 24-7). A tool at www.bilitool.org facilitates calculating the risk for neonatal hyperbilirubinemia.

Infants in the lower risk category are less likely to develop hyperbilirubinemia. However, the AAP warns that all infants should be considered as being at potential risk for hyperbilirubinemia, even if they were identified as being in the low risk category. This means that all newborns should be followed after hospital discharge for the development of unexpected jaundice and that parents should be given printed and oral information about newborn jaundice (Bromiker, Bin-Nun, Schimmel, et al., 2012; Maisels et al., 2009).

Adequate feeding is essential in preventing hyperbilirubinemia. Newborns should breastfeed early (within 1 to 2 hours after birth) and often (at least 8 to 12 times/24 hours) (AAP Section on Breastfeeding, 2012; AAP Subcommittee on Hyperbilirubinemia, 2004). Colostrum acts as a laxative to promote stooling, which helps rid the body of bilirubin. Formula-fed infants should be fed after birth when their physiologic status has stabilized and thereafter at least every 3 to 4 hours.

Routine assessment of risk factors for severe hyperbilirubinemia is advised. The most common risk factors include gestational age less than 38 weeks, exclusive breastfeeding (especially in association with breastfeeding difficulties and excessive weight loss), significant jaundice in a sibling, isoimmune or other hemolytic disease (e.g., glucose-6-phosphate dehydrogenase [G6PD] deficiency), cephalhematoma, significant bruising, and East Indian race (AAP Subcommittee on Hyperbilirubinemia, 2004).

Close follow-up of infants at risk for hyperbilirubinemia is essential; parents should be educated and encouraged to

FIG 24-7 Nomogram for designation of risk in 2840 well newborns at 36 or more weeks of gestational age with birth weight of 2000 g or more or 35 or more weeks of gestational age with birth weight of 2500 g or more based on the hour-specific serum bilirubin values. (This nomogram should not be used to represent the natural history of neonatal hyperbilirubinemia.) (From Bhutani, V., Johnson, L., & Sivieri, E.M. [1999]. Predictive ability of a predischarge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. *Pediatrics*, 103[1], 6-14.)

follow postdischarge recommendations (AAP Subcommittee on Hyperbilirubinemia, 2004). Follow-up should occur 48 to 72 hours after discharge from the birthing facility or sooner based on the length of stay and presence of risk factors for hyperbilirubinemia (Burgos et al., 2012).

Therapy for Hyperbilirubinemia. The decision to treat an infant for hyperbilirubinemia is based on total serum bilirubin levels, the infant's gestational age, and the presence of risk factors. Using a nomogram that plots bilirubin levels according to gestational age, the provider determines the appropriate management plan (Maisels, 2010). The AAP provides guidelines that provide direction for health care providers in determining the need for phototherapy or exchange transfusion (AAP Committee on Hyperbilirubinemia, 2004).

The goal of treatment of hyperbilirubinemia is to help reduce the newborn's serum levels of unconjugated bilirubin. There are two ways to reduce unconjugated bilirubin levels: phototherapy and exchange blood transfusion. Phototherapy is the most common treatment. Exchange transfusion is used to treat those infants whose levels of serum bilirubin are rising rapidly despite the use of intensive phototherapy.

Phototherapy. The purpose of phototherapy is to reduce the level of circulating unconjugated bilirubin or keep it from increasing. Phototherapy uses light energy to change the shape and structure of unconjugated bilirubin, converting it into a conjugated form that can be excreted through urine and stool. Phototherapy is delivered through lamp, blanket, pad, or cover-body devices. The severity of the newborn's hyperbilirubinemia determines the type of phototherapy device and strength of light, duration of treatment, and venue (hospital or home). The neonate's response to phototherapy depends on the bilirubin level, the effectiveness of the phototherapy device, and the infant's ability to excrete the bilirubin (Bhutani & Committee on Fetus and Newborn, 2011).

The dose and effectiveness of phototherapy are affected by the source of light. Phototherapy units vary in the spectrum of light they deliver and in the filters used. The most effective therapy is achieved with special blue fluorescent tubes or a specially designed light-emitting diode (LED). Phototherapy lights do not emit significant ultraviolet radiation; the small amount that is emitted does not cause erythema. Most of the ultraviolet light is absorbed by the glass wall of the fluorescent tube and by the plastic cover of the light (Bhutani & Committee on Fetus and Newborn, 2011; Kamath, Thilo, & Hernandez, 2011). Phototherapy is usually effective in treating hyperbilirubinemia that has not reached levels associated with acute bilirubin encephalopathy or kernicterus.

The effectiveness of phototherapy is related to the distance between the light and the neonate and on the surface area of skin that is exposed. To maximize skin exposure, multiple devices may be used simultaneously. For example, a neonate may be placed under a phototherapy lamp while also lying on a fiberoptic pad or LED mattress (Bhutani & Committee on Fetus and Newborn, 2011).

During phototherapy using a lamp, the infant, wearing only a diaper, is placed under a bank of lights approximately 45 to 50 cm from the light source. Phototherapy can be used for the infant in an incubator (Fig. 24-8) or in an open crib. The distance varies according to unit protocol and type of

light used. The irradiance of the light is monitored routinely with a radiometer, with measurements at several sites over the neonate's body surface during treatment to ensure efficacy of therapy (Bhutani & Committee on Fetus and Newborn, 2011).

Within 4 to 6 hours after initiation of phototherapy, the bilirubin level should begin to decrease. Phototherapy is used until the infant's serum bilirubin level decreases to within an acceptable range. The decision to discontinue therapy is based on the observation of a definite downward trend in the bilirubin values.

When a phototherapy lamp is used, the infant's eyes must be protected by an opaque mask to prevent retinal damage. The eye shield should cover the eyes completely but not occlude the nares. Before the mask is applied, the infant's eyes should be closed gently to prevent excoriation of the corneas. The mask should be removed periodically and during infant feedings so that the eyes can be assessed and cleansed with water and the parents can have visual contact with the infant.

Phototherapy can cause changes in the infant's temperature, depending partially on the bed used—bassinet, incubator, or radiant warmer. When under a phototherapy light, infants are usually clothed only with a diaper. The infant's temperature should be closely monitored. Phototherapy lights can increase the rate of insensible water loss, which contributes to fluid loss and dehydration. Therefore, the infant must be adequately hydrated. Hydration maintenance in the healthy newborn is accomplished through breastfeeding or infant formula. Feedings of glucose water or plain water have no advantage or benefit because these liquids do not promote excretion of bilirubin in the stools and can actually perpetuate enterohepatic circulation, thus delaying bilirubin excretion.

It is important to closely monitor urinary output as an indicator of hydration status while the infant is receiving phototherapy. Urine output can be decreased or unaltered; the urine can have a dark gold or brown appearance.

The number and consistency of stools are monitored. Bilirubin breakdown increases gastric motility, which results in loose stools that can cause skin excoriation and breakdown. The infant's buttocks must be cleaned after each stool to help maintain skin integrity.

FIG 24-8 Infant under phototherapy lights while in incubator. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

SAFETY ALERT

No ointments, creams, or lotions should be applied to the newborn's skin during phototherapy because they can absorb heat and cause burns.

If the infant is under phototherapy lights, maximizing skin exposure to the light is important. Infants need to be turned at least every 2 to 3 hours. A fine maculopapular rash can appear during phototherapy, but this condition is transient. In rare instances there can be bullous eruptions or the development of bronze baby syndrome in which the skin appears grayish brown. Researchers are investigating the potential long-term effects of phototherapy (e.g., retinal damage, malignant melanoma), although the evidence has yet to be evaluated (Bhutani & Committee on Fetus and Newborn, 2011; Xiong, Qu, Cambier, & Mu, 2011).

In addition to phototherapy lights, other systems are used for phototherapy. A bassinet system provides special blue light above and beneath the infant. Another phototherapy device is a fiberoptic blanket that is connected to a light source. The blanket is flexible and can be placed around the infant's torso or underneath the infant in the bassinet. There are also bilirubin beds with LED lights in a pad that covers the surface of the bassinet (Fig. 24-9). The LEDs do not produce heat and can be used with radiant warmers. These devices are usually less effective when used alone as compared with conventional phototherapy lights. They can be very useful in combination with overhead phototherapy lights. In certain instances the infant's bilirubin levels increase rapidly and intensive phototherapy is required; this situation involves the use of a combination of conventional lights and fiberoptic blankets to maximize bilirubin reduction. Although fiberoptic lights do not produce heat as do conventional lights, staff should ensure that a covering pad is placed between the infant's skin and the fiberoptic device to prevent skin burns, especially in preterm infants. The newborn can remain in the mother's room in an open crib or in her arms during treatment. The use of eye patches depends on whether the devices are used alone or in combination with phototherapy lights.

HOME PHOTOTHERAPY. The use of home phototherapy should be reserved for healthy term infants with bilirubin levels in the "optional phototherapy" range according to the nomogram. The concern is that home phototherapy units do not

FIG 24-9 Infant receiving phototherapy using bilirubin bed. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

provide the same level of irradiance or body surface coverage as phototherapy devices used in the hospital (AAP Committee on Hyperbilirubinemia, 2004).

PHOTOTHERAPY AND PARENT-INFANT INTERACTION. The traditional use of phototherapy raises concerns related to psychobehavioral issues, including parent-infant separation, potential social isolation, decreased sensorineural stimulation, altered biologic rhythms, altered feeding patterns, and activity changes. Parental anxiety can be greatly increased, particularly at the sight of the newborn with eyes covered and under special lights. The interruption of breastfeeding for phototherapy is a potential deterrent to successful maternal-infant attachment and interaction. Because research has demonstrated that bilirubin catabolism occurs primarily within the first few hours after initiating phototherapy, there is increased support for the removal of the infant from treatment for feeding and holding. Intermittent phototherapy can be just as effective as continuous therapy when used correctly. The benefits of stopping phototherapy for short periods so parents can feed and hold the newborn should be carefully considered by the health care team and the parents.

FOLLOW-UP. Close follow-up is needed for infants who have been treated for hyperbilirubinemia. Repeat testing of serum bilirubin levels and follow-up visits with the pediatric health care provider are expected. Some institutions or third-party providers pay for a home visit to evaluate the infant's condition and to monitor the mother's health. When follow-up serum bilirubin levels are needed after discharge from the hospital, a health care technician or nurse may draw the blood for the specimen or the parents may take the baby to a laboratory to have blood drawn for a serum bilirubin. In some cases parents take the newborn to an outpatient clinic or physician's office to be evaluated.

Exchange Transfusion. When phototherapy is not effective in reducing serum bilirubin levels or with severe hyperbilirubinemia such as in hemolytic disease, **exchange transfusion** may be needed. This procedure is done in an intensive care setting. The infant's blood is replaced with a combination of blood products such as red blood cells (RBCs) mixed with 5% albumin or fresh frozen plasma (Kaplan, Wong, Sibley, & Stevenson, 2011) (see Chapter 36).

Hypoglycemia. **Hypoglycemia** in a term infant during the early newborn period is defined as a blood glucose concentration less than adequate to support neurologic, organ, and tissue function; however, there is a lack of consensus among experts regarding the precise level at which this concentration occurs. Similarly, there is no consensus about when to screen for hypoglycemia or the level at which treatment should be instituted (Adamkin & Committee on Fetus and Newborn, 2011). Hypoglycemia that warrants treatment is usually defined as blood glucose levels less than 40 mg/dl, although some experts recommend treatment for levels less than 50 mg/dl (McGowan, Rozance, Price-Douglas, & Hay, 2011).

Bedside glucose monitoring is performed using reagent test strips with or without a reflectance colorimeter. Because of variations in devices and operator techniques, it is recommended that any level less than 45 mg/dl should be followed up with a serum glucose level (Kalhan & Devaskar, 2011).

At birth, the maternal source of glucose is cut off when the umbilical cord is clamped. Most healthy term newborns experience a transient decrease in glucose levels to as low as 30 mg/dl

during the first 1 to 2 hours after birth, with a subsequent mobilization of free fatty acids and ketones to help maintain adequate glucose levels (Blackburn, 2013). Infants who are asphyxiated or have other physiologic stress can experience hypoglycemia as a result of a decreased glycogen supply, inadequate gluconeogenesis, or overutilization of glycogen stored during fetal life. There is concern about neurologic injury as a result of severe or prolonged hypoglycemia, especially in combination with ischemia (Kalhan & Devaskar, 2011).

There is no need to routinely assess glucose levels of healthy term infants. Adequate feeding helps these neonates maintain normal glucose levels.

Glucose levels should be measured in neonates at 34 weeks of gestation or more if risk factors or clinical manifestations of hypoglycemia are present. Infants considered to be at risk for hypoglycemia include those who are SGA or LGA, infants of mothers with diabetes, and late preterm infants. The frequency of glucose testing is determined by the risk factors for each individual newborn. All at-risk infants should be fed within the first hour, with glucose testing done 30 minutes after feeding. For at least the first 24 hours after birth, late preterm and SGA neonates should be fed every 2 to 3 hours, with glucose levels measured before each feeding. LGA infants and infants of mothers with diabetes should have glucose screening before feedings for at least the first 12 hours after birth; further testing is done if glucose levels are less than 45 mg/dl (Adamkin & Committee on Fetus and Newborn, 2011).

Glucose testing should be done on any infant with clinical signs of hypoglycemia. The clinical signs of hypoglycemia can be transient or recurrent and include jitteriness, lethargy, poor feeding, abnormal cry, hypotonia, temperature instability (hypothermia), respiratory distress, apnea, and seizures (Kalhan & Devaskar, 2011). It is important to remember that hypoglycemia can be present in the absence of clinical manifestations.

Late preterm infants are at increased risk for hypoglycemia. They have decreased glycogen stores and lack hepatic enzymes for gluconeogenesis and glycogenolysis. Their hormonal regulation and insulin secretion are immature. The increased risk of cold stress and feeding difficulties adds to the risk for hypoglycemia (Cooper et al., 2012).

The at-risk asymptomatic neonate with glucose levels less than 25 mg/dl in the first 4 hours or less than 35 mg/dl from 4 to 24 hours of age should be fed. Glucose testing should be repeated 1 hour after feeding. If levels remain low despite feeding, IV dextrose is warranted. In such infants the treatment should be aimed at maintaining the blood glucose levels greater than 45 mg/dl. For the neonate with clinical signs of hypoglycemia, regardless of cause or age, IV dextrose infusion is usually recommended. For any infant with hypoglycemia, follow-up glucose testing at specified intervals is needed until glucose levels are stable (Adamkin & Committee on Fetus and Newborn, 2011; McGowan et al., 2011).

Hypocalcemia. Hypocalcemia is defined as serum calcium levels of less than 7.8 to 8 mg/dl in term infants and slightly lower (7 mg/dl) in preterm infants. Hypocalcemia is common in critically ill neonates but also can occur in infants of mothers with diabetes or in those who had perinatal asphyxia or trauma and in low-birth-weight and preterm infants. Infants born to mothers treated with anticonvulsants during pregnancy also are at risk (Rigo, Mohamed, & De Curtis, 2011). Early-onset hypocalcemia usually occurs within the first 24 to 48 hours after

birth. Signs of hypocalcemia include jitteriness, high-pitched cry, irritability, apnea, intermittent cyanosis, abdominal distention, and laryngospasm, although some hypocalcemic infants are asymptomatic. Jitteriness is a symptom of both hypoglycemia and hypocalcemia; therefore, hypocalcemia must be considered if the therapy for hypoglycemia proves ineffective.

In most instances early-onset hypocalcemia is self-limiting and resolves within 1 to 3 days. Treatment usually includes early feeding of an appropriate source of calcium such as fortified human milk or preterm infant formula (Jones, Hayes, Starbuck, & Porcelli, 2011).

Laboratory and Diagnostic Tests

Because newborns experience many transitional events in the first 28 days of life, laboratory samples are often collected to determine adequate physiologic adaptation and to identify disorders that can adversely affect the child's life beyond the neonatal period. Blood samples for most laboratory tests can be obtained from the neonate with a heel puncture, also known as a *heelstick*. Tests commonly performed other than blood glucose and bilirubin levels include newborn screening tests and serum drug levels. Standard laboratory values for a term newborn are listed in Table 24-4.

TABLE 24-4 Standard Laboratory Values in a Term Neonate

HEMATOLOGY		VALUES
Hemoglobin (g/dl)		14 to 24
Hematocrit (%)		44 to 64
Red blood cells (RBCs)/ μ L		4.8×10^6 to 7.1×10^6
Reticulocytes (%)		1.8 to 4.6
Fetal hemoglobin (% of total)		50 to 70
Platelet count/ mm^3		150,000 to 300,000
White blood cells (WBCs)/ μ L		9000 to 30,000
Bilirubin, total (mg/dl)*	24 hr	2 to 6
	48 hr	6 to 7
	3 to 5 days	4 to 6
Serum glucose (mg/dl)	<1 day	40 to 60
	>1 day	50-90
Arterial blood gases	pH	7.35-7.45
	P_{CO_2}	35 to 45 mm Hg
	P_{O_2}	60 to 80 mm Hg
	HCO_3	18-26 mEq/L
	Base excess	(-5) to (+5)
	O_2 saturation	92-94%

dl, Deciliter; μ L, microliter; P_{CO_2} , partial pressure of carbon dioxide; P_{O_2} , partial pressure of oxygen.

*Bilirubin levels should be interpreted according to the hour-specific nomogram (AAP Subcommittee on Hyperbilirubinemia, 2004).

Universal Newborn Screening

Mandated by U.S. law, newborn genetic screening is an important public health program aimed at early detection of genetic diseases that result in severe health problems if not treated early. The universal screening program is state-based and involves a variety of components including education, screening, follow-up, treatment, and a system for monitoring and evaluation. The U.S. Department of Health and Human Services (USDHHS) Discretionary Advisory Committee on Heritable Disorders in Newborns and Children (2013) recommends screening for 31 core disorders and 26 secondary disorders. The core disorders include hemoglobinopathies (e.g., sickle cell disease), inborn errors of metabolism (e.g., phenylketonuria [PKU], galactosemia), severe combined immunodeficiency, and critical congenital heart disease (Howell, Terry, Tait, et al., 2012). The majority of disorders included in the screening are not symptomatic at birth. Individual states select additional disorders to include in the screening. The most current list is available through the National Newborn Screening and Genetics Resource Center (NNSGRC) at <http://genes-r-us.uthscsa.edu/sites/genes-r-us/files/nbsdisorders.pdf>. In Canada, universal newborn screening policies and practices are varied. Individual provinces in Canada determine the disorders included in newborn screening; however, all provinces screen for PKU and congenital hypothyroidism (Wilson, Kennedy, Potter, et al., 2010).

Capillary blood samples are obtained from newborn infants using a heelstick; blood is collected on a special filter paper and sent to a designated state laboratory for analysis (Fig. 24-10). Samples are usually collected in the hospital after 24 hours of age and before discharge; testing may be delayed for sick or preterm infants or those born outside the hospital (ACOG Committee on Genetics, 2011). The screening test should be repeated at age 1 to 2 weeks if the initial specimen was obtained when the infant was younger than 24 hours.

The American College of Medical Genetics (2009) recommends that states retain the residual dried blood filter spots. These blood samples are useful for future testing and research purposes. However, ethical concerns are related to the need for parental consent to retain blood samples and use them for biomedical research. Nurses need to be aware of policies and procedures regarding retention and use of newborn screening

samples in the state where they practice so they are able to provide information to parents (Tluczek & De Luca, 2013).

Families should be educated about universal newborn screening during the prenatal period (ACOG Committee on Genetics, 2011). However, this is not common practice; newborn screening is not usually discussed with parents prior to birth. This may be related to the fact that in the majority of states informed consent is not required for newborn screening (Tarini & Goldenberg, 2012). In many cases discussion about newborn screening occurs in the hospital setting at the time of blood sample collection. Nurses can provide education for parents regarding the purpose of the screening, the procedure for blood sampling, when to expect results, and the importance of follow-up (Araia, Wilson, Chakraborty, et al., 2012; Tluczek & De Luca, 2013).

COMMUNITY ACTIVITY

Visit the National Newborn Screening and Genetics Resource Center (NNSGRC) website (<http://genes-r-us.uthscsa.edu>). Review the information for parents and family about resources, disorders tested, and screening programs.

At the NNSGRC website, visit the newborn screening program site for your state. What types of disorders are included in newborn screening? Does your state require newborn hearing screening? Review the information for parents about diagnostic testing and community support services.

Newborn Hearing Screening. Hearing loss is the most commonly diagnosed genetic disorder of all the core conditions in the universal screening program (Howell et al., 2012). The Joint Committee on Infant Hearing (2007) recommends routine hearing screening for all newborns before hospital discharge or no later than 1 month of age. The Canadian Paediatric Society recommends hearing screening for all newborns (Patel, Feldman, & Canadian Paediatric Society Community Paediatrics Committee, 2014). Through early hearing detection and intervention (EHDI) programs, the outcome for infants who are deaf or hard of hearing can be maximized.

Using noninvasive technology, newborn hearing screening provides information about the pathways from the external ear to the cerebral cortex. Two tests commonly are used to assess

FIG 24-10 A, Nurse obtaining blood sample from newborn's heel for universal screening. Sample is applied to filter paper. B, All four circles must be filled in completely. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

FIG 24-11 Newborn hearing screening. A, Evoked otoacoustic emissions (EOAE) test. B, Auditory brain response (ABR) test. (A, Courtesy Julie and Darren Nelson, Loveland, CO. B, Courtesy Dee Lowdermilk, Chapel Hill, NC.)

hearing function in the newborn. Initial screening is done with the evoked otoacoustic emissions (EOAE) test. The auditory brainstem response (ABR) test is used as follow-up if the initial screening is abnormal. Neither test is definitive in diagnosing hearing loss; they are used to determine whether further, more accurate hearing testing is needed through audiologic evaluation. For the EOAE test, a soft rubber earpiece that makes a soft clicking noise is placed in the baby's outer ear (Fig. 24-11, A). A healthy ear will "echo" the click sound back to a microphone inside the earpiece. The ABR test is performed by attaching sensors to the baby's forehead and behind each ear. An earphone is placed in the baby's outer ear and sends a series of quiet sounds into the sleeping baby's ear (see Fig. 24-11, B). The sensors measure the responses of the baby's acoustic nerve. The responses are recorded and stored in a computer.

Newborns who do not pass the initial screening test should have the hearing screening test repeated as part of follow-up care. If the infant still does not pass, a comprehensive audiologic evaluation should be done by 3 months of age. Regardless of the outcome of hearing testing, all infants should have regular and ongoing surveillance of developmental, hearing, and speech-language skills through regular well-child visits beginning at the age of 2 months so that any hearing loss can be promptly identified and treated (Joint Committee on Infant Hearing, 2007).

Screening for Critical Congenital Heart Disease (CCHD).

CCHD was added to the uniform screening panel in the United States in 2011 and is endorsed by the AAP (AAP Section on Cardiology and Cardiac Surgery Executive Committee, 2012). The noninvasive screening test is performed using pulse oximetry to measure oxygen saturation for the purpose of detecting hypoxemia. Pulse oximetry testing can detect some critical congenital heart defects that present with hypoxemia in the absence of other physical symptoms. Hypoxemia can be the first sign that a congenital heart defect is present and other symptoms can develop once the newborn has been discharged. Screening is performed at 24 to 48 hours of age. Oxygen saturation is measured in the right hand and one foot. A "passing" result is oxygen saturation of greater than 95% in either extremity, with a less than 3% absolute difference between the upper and lower extremity readings. Immediate evaluation is needed if the

oxygen saturation is less than 90%. The baby is evaluated for hemodynamic stability and hypoxemia; an echocardiogram is usually performed (AAP Section on Cardiology and Cardiac Surgery Executive Committee, 2012).

Collection of Specimens

Ongoing evaluation and screening of a newborn often requires obtaining blood by heelstick or venipuncture or the collection of a urine specimen. Laboratory tests may be ordered routinely (e.g., newborn screening) or for a specific purpose as directed by the health care provider.

Heelstick. Most blood specimens are drawn by laboratory technicians. Nurses, however, may be required to perform heelsticks to obtain blood for glucose monitoring, newborn screening, or other tests.

Blood samples should be collected in a manner that minimizes pain and trauma to the infant and maximizes the accuracy of test results. If a laboratory technician is collecting the specimen, the nurse assists as needed to maximize safety and infant comfort.

It is helpful to warm the heel before the sample is taken; application of heat for 5 to 10 minutes helps dilate the vessels in the area. A cloth soaked with warm water and wrapped loosely around the foot provides effective warming (Fig. 24-12, A). Disposable heel warmers are available from a variety of companies but should be used with care to prevent burns. Nurses should wear gloves when collecting any specimen. The nurse cleanses the area with an appropriate skin antiseptic, restrains the infant's foot with a free hand, and then punctures the site. A spring-loaded automatic puncture device causes less pain and requires fewer punctures than a manual lance blade.

The most serious complication of an infant heelstick is necrotizing osteochondritis resulting from lancet penetration of the bone. To prevent this problem, the puncture is made at the outer aspect of the heel and penetrates no deeper than 2.4 mm. To identify the appropriate puncture site, the nurse draws an imaginary line from between the fourth and fifth toes and parallel to the lateral aspect of the foot to the heel, where the puncture is made; a second line can be drawn from the great toe to the medial aspect of the heel (see Fig. 24-12, B). Repeated trauma

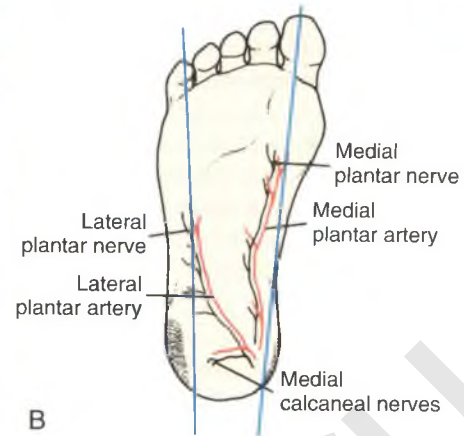

FIG 24-12 Heelstick. **A**, Newborn with foot wrapped for warmth to increase blood flow to extremity before heelstick. **B**, Heelstick sites (*shaded areas*) on infant's foot for obtaining samples of capillary blood. (A, Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

to the walking surface of the heel can cause fibrosis and scarring that can lead to problems with walking later in life.

After the specimen has been collected, gentle pressure is applied with a dry gauze pad. No further skin cleanser should be applied because it will cause the site to continue to bleed. The site is then covered with an adhesive bandage. The nurse safely disposes of equipment used, reviews the laboratory requisition for correct identification, and checks the specimen for accurate labeling and routing.

A heelstick is traumatic for the infant and causes pain. After several heelsticks, infants have been observed to withdraw their feet when they are touched. The nurse can reduce procedural pain using a variety of nonpharmacologic techniques including allowing the mother to hold the neonate skin to skin, using non-nutritive sucking with or without oral sucrose, or swaddling the neonate (see later discussion of neonatal pain) (McNair, Yeo, Johnston, & Taddio, 2013). To reassure the infant and promote feelings of safety, the neonate should be cuddled and comforted when the procedure is complete and appropriate pain management measures taken to minimize the pain.

Venipuncture. Occasionally laboratory tests are ordered that require larger samples of blood than can be collected with a heelstick. Venous blood samples can be drawn from antecubital, saphenous, superficial wrist, and rarely, scalp veins. When venipuncture is required, positioning of the needle is extremely important. A 23- or 25-gauge butterfly needle or hypodermic needle with a syringe is used (Fig. 24-13). Patience is required during the procedure because the blood return in small veins is slow and consequently the small needle must remain in place longer than a larger needle. A tourniquet is optional but can help increase blood flow with venipuncture. The infant is carefully restrained during the procedure to prevent injury. If venipuncture or arterial puncture is performed for blood gas studies, crying, fear, and agitation will affect the values; therefore, every effort must be made to keep the infant quiet during the procedure. Pressure must be maintained over an arterial or femoral vein puncture with a dry gauze square for 3 to 5 minutes to prevent bleeding from the site.

For an hour after any venipuncture, the nurse observes the infant frequently for evidence of bleeding or hematoma

FIG 24-13 Venipuncture using a butterfly needle. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

formation at the puncture site. The infant is cuddled and comforted when the procedure is completed, and appropriate pain management measures are taken. The nurse assesses and documents the infant's tolerance of the procedure.

Urine Specimen. Analysis of urine is a valuable laboratory tool for infant assessment; the way in which the specimen is collected can influence the results. The urine sample should be fresh and analyzed within 1 hour of collection. A urine collection bag is often used to obtain a specimen.

Interventions

Protective Environment

The provision of a protective environment is basic to the care of the newborn. The construction, maintenance, and operation of nurseries in accredited hospitals are monitored by national professional organizations such as the AAP, The Joint Commission (TJC), the Occupational Safety and Health Administration (OSHA), and local or state governing bodies. In addition, hospital personnel develop their own policies and procedures for protecting the newborns under their care. Prescribed standards cover areas such as environmental factors, measures to control infection, and safety factors.

Current health care trends and the focus on nonseparation of mothers and babies (rooming-in) have prompted some

hospitals to abandon having a separate newborn nursery. In the mother/baby model of care, the infant stays in the mother's room, which reduces the need for a separate nursery.

Environmental Factors

Environmental factors include provision of adequate lighting, elimination of potential fire hazards, safety of electrical appliances, adequate ventilation, and controlled temperature and humidity (AAP & ACOG, 2012).

Infection Control Factors

Measures to control infection in newborn nurseries include adequate floor space to permit the positioning of bassinets at least 3 feet apart in all directions, hand hygiene facilities, and areas for cleaning and storing equipment and supplies. Only specified personnel directly involved in the care of mothers and infants are allowed in these areas, thereby reducing the opportunities for the transmission of pathogenic organisms.

FIG 24-14 Mother and infant wear electronic bracelets as part of an infant security system. (Courtesy Shannon Perry, Phoenix, AZ.)

SAFETY ALERT

Proper hand hygiene is essential to prevent the spread of health care–associated infection. Personnel should wash hands with soap and water or use an alcohol-based handrub in accordance with hospital infection control policies. Hand hygiene should be performed before and after touching the infant, before an invasive procedure or medication administration, after contact with potentially contaminated objects (e.g., computer keyboards, telephone, countertop surfaces), and after removing sterile or nonsterile gloves (World Health Organization [WHO], 2009).

Health care workers must wear gloves when handling infants until blood and amniotic fluid have been removed from the skin, when drawing blood (e.g., heelstick), when caring for a fresh wound (e.g., circumcision), and during diaper changes.

Visitors such as siblings and grandparents are expected to perform hand hygiene before having contact with infants or equipment. Individuals with infectious conditions are excluded from contact with newborns or must take special precautions when working with infants. This group includes people with upper respiratory tract infections, gastrointestinal tract infections, and infectious skin conditions.

Preventing Infant Abduction

Nurses discuss infant security precautions with the mother and her family because infant abductions are an ongoing concern. In 1999 The Joint Commission issued a sentinel alert and called for a management plan to address infant security (The Joint Commission, 1999). As a result, many units have special limited-entry systems. Nurses teach mothers and their families to check the identity of any person who comes to remove the baby from their room. Personnel usually wear picture identification badges. On some units all staff members wear matching scrubs or special badges. Other units use closed-circuit television, computer monitoring systems, fingerprint identification pads, or infant bracelet security systems (Fig. 24-14) that alarm if the newborn is separated from the mother or is taken outside the boundaries of the unit. Nurses and new parents must work together to ensure the safety of newborns in the hospital environment (Hiner, Pyka, Burks, et al., 2012).

SAFETY ALERT

Nurses play a critical role in educating parents about measures to prevent infant abduction. Parents should be instructed how to identify legitimate hospital personnel, to never leave the newborn in the hospital room without direct supervision, and to request a second staff member to verify the identity of any questionable person who wants to take the baby from the mother's room. Parents should be instructed to use caution when posting photos of the new baby on the Internet and publishing public notices about the birth (AAP & ACOG, 2012).

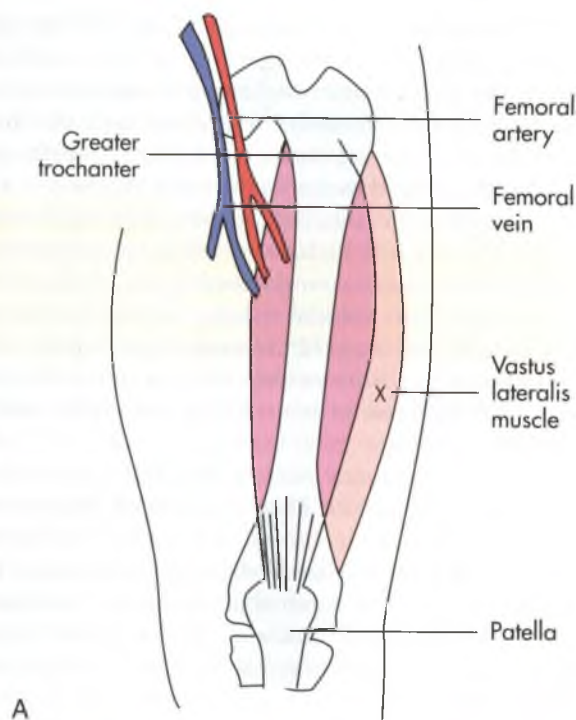

Preventing Newborn Falls

Newborn infants are at risk for injury as a result of falling. Although newborn falls are likely underreported, it is estimated that approximately 600 to 1600 falls occur each year in U.S. hospitals (Helsey, McDonald, & Stewart, 2010). Most falls occur when the mother falls asleep while holding the newborn in her bed or in a reclining chair, although some falls occur at birth or when the infant is transported. Infants who fall, even from low level surfaces such as beds or chairs, are at risk of sustaining head injury that can include skull fracture. Parents may hesitate to report falls due to feelings of guilt and fear of reproach from staff members (Paul, Goodman, Remorino, & Bolger, 2011).

Nurses can help prevent newborn falls by identifying risk factors such as maternal medications (e.g., opioids) that cause drowsiness and can increase the risk of the mother falling asleep while holding the infant. Parents should be instructed to place their newborn in the supine position in the bassinet for sleep. Although bed-sharing is a controversial topic because some believe it promotes bonding, parents need to be aware of potential risks related to this practice. Infants should not be placed on couches or armchairs, whether or not a parent is present (Matteson, Henderson-Williams, & Nelson, 2013). Some hospitals ask parents and staff to sign an infant safety pledge to promote client safety; staff members conduct hourly rounds to monitor for fall risks (Galuska, 2011). Newborns are always transported in their bassinets and are never carried outside the mother's room. Educating parents using a nonjudgmental approach may increase the likelihood that a parent will report a newborn fall (Paul et al., 2011).

Therapeutic and Surgical Procedures

Intramuscular Injection. Newborns routinely receive IM injections before discharge. A single dose of vitamin K is

A

B

FIG 24-15 Intramuscular injection. **A**, Acceptable intramuscular injection site for newborn infant. **X**, injection site. **B**, Infant's leg stabilized for intramuscular injection. Nurse is wearing gloves to give injection. (B, Courtesy Marjorie Pyle, Lifecircle, Costa Mesa, CA.)

administered shortly after birth and hepatitis B (Hep B) vaccine is administered before discharge. Under specific circumstances, other IM injections may be ordered, such as a dose of HepB immune globulin for infants born to mothers who are positive for HepB.

Selection of the appropriate equipment and site for IM injection is important. In most cases a 25-gauge, $\frac{5}{8}$ -inch needle is used. Injections must be given in muscles large enough to accommodate the medication, and major nerves and blood vessels must be avoided. The muscles of newborns may not tolerate more than 0.5 ml per IM injection. The preferred injection site for newborns is the vastus lateralis (Fig. 24-15). The dorsogluteal muscle is very small, poorly developed, and dangerously close to the sciatic nerve, which occupies a proportionately larger area in infants than in older children. Therefore, it is not recommended as an injection site in small children. The

newborn's deltoid muscle has an inadequate amount of muscle for IM administration. A key factor in preventing and minimizing local reaction to IM injections is adequate deposition of the medication deep within the muscle; therefore, muscle size, needle length, and amount of medication injected should be carefully considered.

The nurse wears nonsterile gloves when administering an injection. The neonate's leg should be stabilized. The nurse cleanses the injection site with an appropriate skin antiseptic and then stabilizes the infant's muscle between the thumb and forefinger. The needle is inserted into the vastus lateralis at a 90-degree angle. The medication is injected slowly. After the medication is injected, the nurse withdraws the needle quickly and places a dry gauze pad over the site, applying gentle pressure to minimize pain and bleeding.

The nurse comforts the infant after an injection and discards equipment properly. Needles are never recapped but are properly discarded in an appropriate safety container. The name of the medication, date and time, amount, route, and site of injection are documented in the newborn's record.

MEDICATION GUIDE

Hepatitis B Vaccine (Recombivax HB, Engerix-B)

Action

Hepatitis B (HepB) vaccine induces protective antihepatitis B antibodies in 95% to 99% of healthy infants who receive the recommended three doses. The duration of protection of the vaccine is unknown.

Indication

HepB vaccine is for immunizing against infection caused by all known subtypes of hepatitis B virus (HBV).

Neonatal Dosage

The usual dosage is Recombivax HB 5 mcg/0.5 ml or Engerix-B 10 mcg/0.5 ml intramuscularly at birth, at 1 to 2 months, and at 6-18 months.

Adverse Reactions

Common adverse reactions are rash, fever, erythema, swelling, and pain at the injection site.

Nursing Considerations

- Parental consent must be obtained before administration. Follow proper procedure for administration of intramuscular (IM) injection (see Fig. 24-15). If infant also needs hepatitis B immune globulin (HBIG), use separate sites for the two injections.
- For infants of mothers with negative HepB status, administer HepB vaccine before discharge from birthing facility.
- For infants born to hepatitis B surface antigen (HBsAg)-positive mothers, administer HepB vaccine and HBIG within 12 hours after birth.
- For infants born to mothers whose HepB status is unknown:
 - ≤ 2000 g: administer HepB vaccine and HBIG within 12 hours after birth
 - ≥ 2000 g: administer HepB vaccine within 12 hours; if mother's HepB results are positive, give HBIG by 1 week of age

Data from Centers for Disease Control and Prevention (CDC). (2014). Advisory Committee on Immunization Practices recommended immunization schedule for persons aged 0 through 18 years—United States, 2014. *MMWR Morbidity and Mortality Weekly Report*, 63(5), 108-109.

Immunizations. Hepatitis B (HepB) vaccination is recommended for all infants before discharge (see Medication Guide: Hepatitis B). Prior to administering the vaccine, the nurse obtains parental consent and notes the mother's HepB status. Infants at highest risk for contracting HepB are those born to women who have HepB or whose HepB status is unknown. If the mother is positive for HepB, the infant should receive the HepB vaccine and HepB immune globulin (HBIG) within 12 hours after birth (see Medication Guide: Hepatitis B Immune Globulin (Centers for Disease Control and Prevention [CDC], 2014).

MEDICATION GUIDE

Hepatitis B Immune Globulin

Action

Hepatitis B immune globulin (HBIG) provides a high titer of antibody to hepatitis B surface antigen (HBsAg).

Indication

The HBIG vaccine provides prophylaxis against infection in infants born of HBsAg-positive mothers.

Neonatal Dosage

Administer one 0.5-ml dose intramuscularly within 12 hours of birth.

Adverse Reactions

Hypersensitivity may occur.

Nursing Considerations

The HBIG vaccine must be given within 12 hours of birth. Follow proper procedure for administration of intramuscular injection (see Fig. 24-15). (See guidelines for administration in Medication Guide: Hepatitis B Vaccine.) The HBIG vaccine can be given at the same time as the HepB vaccine but at a different site. Document the date, time, and site of injection, as well as the lot number and expiration date of the vaccine, according to agency policy.

Data from Centers for Disease Control and Prevention (CDC). (2014). Advisory Committee on Immunization Practices recommended immunization schedule for persons aged 0 through 18 years—United States, 2014. *MMWR Morbidity and Mortality Weekly Report*, 63(5), 108-109.

Circumcision

Policies and Recommendations. Circumcision is the removal of all or part of the foreskin (prepuce) of the penis. Usually it is performed during the first few days of life but is sometimes done at a later time for preterm or ill neonates or for religious or cultural reasons.

The CDC reports that rates of newborn circumcision performed in U.S. hospitals peaked at 64.5% in 1981, dropping to a low of 55.4 in 2007. Rates increased slightly to 58.3% in 2010 (Owings, Uddin, & Williams, 2013).

Changes in recommendations from the AAP regarding newborn male circumcision (NMC) have likely influenced U.S. circumcision rates. The AAP policy on circumcision that was issued in 1999 and reaffirmed in 2005 recognized potential benefits of NMC, although the AAP did not deem them sufficient to recommend routine newborn circumcision

(AAP Task Force on Circumcision, 2005). In 2012 the AAP issued a new policy statement regarding newborn male circumcision. The policy states: "Evaluation of current evidence indicates that the health benefits of newborn male circumcision outweigh the risks and that the procedure's benefits justify access to this procedure for families who choose it" (AAP Task Force on Circumcision, 2012, p. 585). The health benefits of NMC cited by AAP include prevention of urinary tract infection in male infants younger than 1 year, reduced risk for penile cancer, and reduced risk for heterosexual acquisition of sexually transmitted infections, particularly HIV (AAP Task Force on Circumcision, 2012). In spite of the new evidence, AAP does not recommend the practice of routine newborn circumcision.

The Canadian Paediatric Society does not support routine newborn circumcision. They recommend that parents should be informed of the current state of medical knowledge about the benefits and harm related to circumcision. The Society acknowledges that parental decisions may "ultimately be based on personal, religious, and cultural factors" (Outerbridge & Canadian Paediatric Society Fetus and Newborn Committee, 1996).

The World Health Organization (WHO) (2012) recognizes male circumcision as an important intervention in reducing the risk for heterosexually acquired HIV in men. The organization recommends early infant circumcision for newborn males weighing more than 2500 grams and without medical contraindication (WHO & Jhpiego, 2010).

Even with the change in AAP policy on NMC, newborn male circumcision remains a controversial topic. Opponents of circumcision feel that the procedure is unnatural and unnecessary and that it violates basic human rights. They cite concerns about acute pain; risks related to acute complications such as hemorrhage, infection, and penile injury (removal of excessive skin, damage to the meatus or glans); and long-term implications such as adverse effects on sexual function and pleasure. Websites such as www.intactamerica.org discourage parents from circumcising their newborn sons.

Parental Decision. Circumcision is a matter of personal parental choice. Parents usually decide to have their newborn circumcised for one or more of the following reasons: hygiene, religious conviction, tradition, culture, or social norms. Cost and insurance coverage are considerations in the parents' decision-making process. Parents need to make an informed choice regarding newborn circumcision based on the most current evidence and recommendations. Health care providers and nurses who care for childbearing families can help parents make an informed choice about newborn circumcision by providing factual, unbiased, evidence-based information. They can provide opportunities for discussion about the benefits and risks of the procedure.

Expectant parents need to begin learning about circumcision during the prenatal period, but circumcision often is not discussed with the parents. In many instances it is only when the mother is being admitted to the hospital or birthing unit that she is first confronted with the decision regarding circumcision. Because the stress of the intrapartum period makes this a difficult time for parental decision making, this is not an ideal time

to broach the topic of circumcision and expect a well-informed decision.

Circumcision requires informed consent. Although the health care provider who will perform the procedure is legally responsible for educating parents about newborn circumcision so they can make an informed decision, nurses are often involved in discussions on this topic and should provide parents with current evidence-based information.

Procedure. Circumcision is not performed immediately after birth because of the danger of cold stress and decreased clotting factors but is usually done in the hospital before discharge. The circumcision of a Jewish male infant is commonly performed on the eighth day after birth at home in a ceremony called a *bris*. This timing is logical from a physiologic standpoint because clotting factors decrease somewhat immediately after birth and do not return to prebirth levels until the end of the first week.

Feedings may be withheld up to 2 to 3 hours before the circumcision to prevent vomiting and aspiration, although in some hospitals, infants are allowed to breastfeed until they are taken to the nursery for the procedure. To prepare the infant for the circumcision, he is positioned on a plastic restraint form (Fig. 24-16) and the penis is cleansed with soap and water or an antiseptic solution such as povidone-iodine. The infant is draped to provide warmth and a sterile field, and the sterile equipment is readied for use.

In the hospital setting newborn circumcision is usually performed using the Gomco (Yellen) or Mogen clamp or the PlastiBell device. The technique is usually based on health care provider training and preference. The procedure takes only a few minutes to perform. Use of the Gomco or Mogen clamp involves surgical removal of the foreskin. The clamp technique minimizes blood loss (Fig. 24-17). After the circumcision is completed, a small petrolatum gauze dressing is applied to the penis for the first 24 hours; thereafter, parents are instructed to apply petrolatum to keep the penis from adhering to the diaper (Association of Women's Health, Obstetric and Neonatal Nurses [AWHONN], 2013).

With the PlastiBell technique, the plastic bell is first fitted over the glans, a suture is tied around the rim of the bell, and

FIG 24-16 Positioning of infant in Circumstraint. (Courtesy Paul Vincent Kuntz, Texas Children's Hospital, Houston, TX.)

excess foreskin is cut away. The plastic rim remains in place for about a week; it falls off after healing has taken place, usually within 5 to 7 days (Fig. 24-18). Petrolatum or dressings are not applied to the penis following circumcision with the PlastiBell (AWHONN, 2013).

Procedural Pain Management. Circumcision is painful. The pain is characterized by both physiologic and behavioral

FIG 24-17 Circumcision with the Gomco (Yellen) clamp. After hemostasis occurs, the foreskin (over the metal dome) is cut away. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

FIG 24-18 The PlastiBell technique. **A**, The PlastiBell is placed over the glans inside the prepuce. **B**, A string is then tied around the prepuce and positioned in the groove of the bell. The excess foreskin is trimmed and the handle is broken off the bell. The foreskin remnant and bell are expected to slough in 1 to 2 weeks. (From Holcomb, G.W., Murphy, J.P., Ostlie D.J. (2014). *Ashcraft's pediatric surgery* [6th ed.]. Philadelphia, Elsevier.)

changes in the infant (see discussion that follows). Four types of anesthesia and analgesia are used for newborn circumcision: ring block, dorsal penile nerve block (DPNB), topical anesthetic such as eutectic mixture of local anesthetic (EMLA) (prilocaine-lidocaine) or LMX4 (4% lidocaine), and concentrated oral sucrose. Nonpharmacologic methods such as nonnutritive sucking and swaddling can be used to enhance pain management.

The Cochrane group exploring pain relief for neonatal circumcision found that DPNB was the most effective intervention for decreasing the pain of circumcision (Brady-Fryer, Wiebe, & Lander, 2004). A DPNB includes subcutaneous injections of buffered lidocaine at the 2 o'clock and 10 o'clock positions at the base of the penis. A ring block is the subcutaneous injection of buffered lidocaine on each side of the penile shaft. The circumcision should not be performed for at least 5 minutes after these injections.

EMLA cream can be applied to the penis at least 1 hour before the circumcision. The area where the prepuce attaches to the glans is well coated with 1 g of the cream and then covered with a transparent occlusive dressing or finger cot. Just before the procedure, the cream is removed. Blanching or redness of the skin can occur.

After the circumcision the infant is comforted until he is quiet. If the parents were not present during the procedure, the infant is returned to them. The infant can be fussy for several hours and can have disturbed sleep-wake states and disorganized feeding behaviors. Some infants will go into a deep sleep after circumcision until they are awakened for feeding. Liquid acetaminophen 10 to 15 mg/kg may be administered orally after the procedure and repeated every 4-6 hours (as ordered by the health care provider) for a maximum of 30 to 45 mg/kg/24 hours (Zeltzer & Krane, 2011).

Care of the Newly Circumcised Infant. Postcircumcision protocols vary. In many settings the circumcision site is assessed for bleeding every 15 to 30 minutes for the first hour and then hourly for the next 4 to 6 hours. The nurse monitors the infant's urinary output, noting the time and amount of the first voiding after the circumcision.

If bleeding occurs from the circumcision site, the nurse applies gentle pressure with a folded sterile gauze pad. A hemostatic agent such as Gelfoam® powder or sponge can be applied to help control bleeding. If bleeding is not easily controlled, a blood vessel may need to be ligated. In this event, one nurse notifies the physician and prepares the necessary equipment (i.e., circumcision tray and suture material) while another nurse maintains intermittent pressure until the physician arrives.

Nurses provide education for parents related to care of the circumcised infant, which includes observing for complications such as bleeding or infection (see Teaching for Self-Management: Care of the Circumcised Newborn at Home). Parents need support and encouragement as they perform post-circumcision care. Newborns typically cry when the diaper is changed and when petrolatum gauze is removed and reapplied. This can make new parents feel anxious because they do not want to inflict pain on the infant. Nurses can inform parents that the discomfort is usually temporary and will soon subside. Additionally, nurses can teach parents a variety of nonpharmacologic comfort measures.

TEACHING FOR SELF-MANAGEMENT

Care of the Circumcised Newborn at Home

- Wash hands before touching the newly circumcised penis.

Check for Bleeding

- Check circumcision site for bleeding with each diaper change.
- If bleeding occurs, apply gentle pressure with a folded sterile gauze square. If bleeding does not stop with pressure, notify primary health care provider.

Observe for Urination

- Check to see that the infant urinates after being circumcised.
- Infant should have a wet diaper 2 to 6 times per 24 hours the first 1 to 2 days after birth and then at least 6 to 8 times per 24 hours after 3 to 4 days.

Keep Area Clean

- Change the diaper and inspect the circumcision at least every 4 hours.
- Wash the penis gently with warm water to remove urine and feces. Apply petrolatum to the glans with each diaper change (omit petrolatum if a PlastiBell was used). Do not use baby wipes because they can contain alcohol.
- Do not wash the penis with soap until the circumcision is healed (5 to 6 days).
- Apply the diaper loosely over the penis to prevent pressure on the circumcised area.

Check for Infection

- The glans penis is dark red after circumcision and then becomes covered with yellow exudate in 24 hours, which is normal and will persist for 2 to 3 days. Do not attempt to remove it.
- Redness, swelling, discharge, or odor indicates infection. Notify the pediatric health care provider if you think the circumcision area is infected.

Provide Comfort

- Circumcision is painful. Handle the area gently.
- Provide comfort measures such as holding the baby skin-to-skin, cuddling, swaddling, or rocking.

Neonatal Pain

Neonatal Responses to Pain

There is clear evidence that neonates can feel pain, despite previous thinking that the immaturity of the nervous system prevented or blunted pain sensation and that neonates were incapable of remembering painful experiences. Pain in the neonate and pain in later life can be qualitatively different, but research has substantiated that newborns do experience pain (Blackburn, 2013).

Pain has physiologic and psychologic components. Its psychologic component and the diffuse total body response to pain exhibited by the neonate led many health care providers in the past to believe that infants, especially preterm infants, do not experience pain. The central nervous system is well developed, however, as early as 24 weeks of gestation. The peripheral and spinal structures that transmit pain information are present and functional between the first and second trimesters. The pituitary-adrenal axis is also well developed at this time, and a fight-or-flight reaction is observed in response to the catecholamines released in response to stress.

The physiologic response to pain in neonates can be life threatening. Pain response can decrease tidal volume, increase demands on the cardiovascular system, increase metabolism, and cause neuroendocrine imbalance. The hormonal-metabolic response to pain in a term infant has greater magnitude and shorter duration than in adults. The newborn's sympathetic response to pain is less mature and therefore less predictable than an adult's.

Pain response is influenced by a variety of factors such as characteristics of the painful stimulus, gestational age, biologic factors, and behavioral state. The source, location, and timing of the pain affect the response; newborns respond differently to acute pain than to prolonged or recurrent pain. Pain perception and stress can be greater in preterm infants, although they often display less vigorous pain responses than term infants (Maxwell, Malavolta, & Fraga, 2013). There can be genetic differences in pain responses related to the amounts and types of neurotransmitters and receptors available to mediate pain. The behavioral state of the neonate also affects the pain response. Those who are more awake tend to have more robust pain responses than those in sleep states (Gardner, Enzman-Hines, & Dickey, 2011).

The most common behavioral sign of pain is a vocalization or crying, ranging from a whimper to a distinctive high-pitched, shrill cry. Facial expressions include grimacing, eye squeeze, brow contraction, deepened nasolabial furrows, a taut and quivering tongue, and an open mouth (Fig. 24-19) (Box 24-4). The infant will flex and adduct the upper body and lower limbs in an attempt to withdraw from the painful stimulus. The preterm infant has a lower than normal threshold for initiation of this response (Gardner et al., 2011).

Pain can result in significant changes in heart rate, blood pressure (increased or decreased), intracranial pressure, vagal tone, respiratory rate, and oxygen saturation. Neonates respond to painful stimuli with release of epinephrine, norepinephrine, glucagon, corticosterone, cortisol, 11-deoxycorticosterone, lactate, pyruvate, and glucose (Blackburn, 2013).

Assessment of Neonatal Pain

In assessing pain the nurse needs to consider the health of the neonate, the type and duration of the painful stimulus,

FIG 24-19 Signs of discomfort: note eye squeeze, brow bulge, nasolabial furrow, and wide-spread mouth. (Courtesy Kathryn Alden, Chapel Hill, NC.)

environmental factors, and the infant's state of alertness. For example, severely compromised neonates may be unable to generate a pain response although they are, in fact, experiencing pain.

Every neonate should have an initial pain assessment as well as a pain management plan. The National Association of Neonatal Nurses (NANN) developed practice guidelines stating that all nurses who care for newborns should have education and competency validation in pain assessment. Pain should be assessed and documented on a regular basis (Walden & Gibbins, 2008).

BOX 24-4 Manifestations of Acute Pain in the Neonate

Physiologic Responses

- Vital signs
 - Increased heart rate
 - Increased blood pressure
 - Rapid, shallow respirations
- Oxygenation
 - Decreased transcutaneous oxygen saturation (tcPo₂)
 - Decreased arterial oxygen saturation (Sao₂)
- Skin
 - Pallor or flushing
 - Diaphoresis
 - Palmar sweating
- Laboratory evidence of metabolic or endocrine changes
 - Hyperglycemia
 - Lowered pH
 - Elevated corticosteroids
- Other observations
 - Increased muscle tone
 - Dilated pupils
 - Decreased vagal nerve tone
 - Increased intracranial pressure

Behavioral Responses

- Vocalizations
 - Crying
 - Whimpering
 - Groaning
- Facial expression
 - Grimaces
 - Brow furrowed
 - Chin quivering
 - Eyes tightly closed
 - Mouth open and squarish
- Body movements and posture
 - Limb withdrawal
 - Thrashing
 - Rigidity
 - Flaccidity
 - Fist clenching
- Changes in state
 - Changes in sleep-wake cycles
 - Changes in feeding behavior
 - Changes in activity level
 - Fussiness, irritability
 - Listlessness

Data from Blackburn, S. (2013). *Maternal, fetal, and neonatal physiology: A clinical perspective* (4th ed.). St. Louis: Mosby; Gardner, S.L., Enzman-Hines, M., & Dickey, L.A. (2011). Pain and pain relief. In S.L. Gardner, B.S. Carter, M. Enzman-Hines, & J.A. Hernandez (Eds.), *Merenstein & Gardner's handbook of neonatal intensive care* (7th ed.). St. Louis: Mosby.

TABLE 24-5 CRIES Neonatal Postoperative Pain Scale*

	0	1	2
Crying	No	High pitched	Inconsolable
Requires oxygen for saturation >95%	No	<30%	>30%
Increased vital signs	Heart rate and blood pressure equal to or less than preoperative state	Heart rate and blood pressure <20% of preoperative state	Heart rate and blood pressure >20% of preoperative state
Expression	None	Grimace	Grimace and grunt
Sleepless	No	Wakes at frequent intervals	Constantly awake
Coding Tips for Using CRIES			
Crying	The characteristic cry of pain is high pitched. If no cry or cry that is not high pitched, score 0. If cry is high pitched but infant is easily consoled, score 1. If cry is high pitched and infant is inconsolable, score 2.		
Requires oxygen for saturation >95%	Look for changes in oxygenation. Infants experiencing pain manifest decreases in oxygenation as measured by total carbon dioxide or oxygen saturation. (Consider other causes of changes in oxygenation, such as atelectasis, pneumothorax, oversedation.) If no oxygen is required, score 0. If <30% oxygen is required, score 1. If >30% oxygen is required, score 2.		
Increased vital signs	Note: Measure blood pressure last because this may wake the infant, causing difficulty with other assessments. Use baseline preoperative parameters from a nonstressed period. Multiply baseline heart rate (HR) \times 0.2; then add this to baseline HR to determine the HR that is 20% over baseline. Do likewise for blood pressure (BP). Use mean BP. If HR and BP are both unchanged or less than baseline, score 0. If HR or BP is increased but increase is <20% of baseline, score 1. If either one is increased >20% over baseline, score 2.		
Expression	The facial expression most often associated with pain is a grimace. This may be characterized by brow lowering, eyes squeezed shut, deepening of the nasolabial furrow, open lips and mouth. If no grimace is present, score 0. If grimace alone is present, score 1. If grimace and noncry vocalization grunt are present, score 2.		
Sleepless	This is scored based on the infant's state during the hour preceding this recorded score. If the child has been continuously asleep, score 0. If he or she has awakened at frequent intervals, score 1. If he or she has been awake constantly, score 2.		

*Neonatal pain assessment tool developed at the University of Missouri—Columbia.

From Krechel, S.W., & Bildner, J. (1995). CRIES: A new neonatal postoperative pain measurement score. Initial testing of validity and reliability. *Paediatric Anaesthesia*, 5(1), 53-61.

Pain assessment tools include:

- Neonatal Infant Pain Scale (NIPS) (Lawrence, Alcock, McGrath, et al., 1993)
- Premature Infant Pain Profile (PIPP) (Stevens, Johnston, Petryshen, & Taddio, 1996)
- Neonatal Pain Agitation and Sedation Scale (NPASS) (Hummel, Puchalski, Creech, & Weiss, 2008)

A pain assessment tool used by nurses in some neonatal intensive care units (NICUs) is CRIES (Krechel & Bildner, 1995) (Table 24-5). This tool was developed for use by nurses who work with preterm and term infants. CRIES is an acronym for the physiologic and behavioral indicators of pain used in the tool: *c*rying, *r*equiring increased oxygen, *i*ncreased vital signs, *e*xpression, and *s*leeplessness. Each indicator is scored from 0 to 2. The total possible pain score, which represents the worst pain, is 10. A pain score greater than 4 should be considered significant. This tool can be used on infants between 32 weeks of gestation and 20 weeks after birth.

Healthy term newborns are exposed to fewer sources of pain than preterm infants in an NICU where painful procedures are inherent to care management. Even in low risk

newborns, nurses need to assess for signs of discomfort as part of routine assessments and especially during and after routine procedures such as heelsticks, injections, and circumcisions (Maxwell et al., 2013).

Management of Neonatal Pain

The goals of the management of neonatal pain are to (1) minimize the intensity, duration, and physiologic cost of the pain and (2) maximize the neonate's ability to cope with and recover from the pain. Nonpharmacologic and pharmacologic strategies are used. It is important to note that despite research evidence, policies, and standards of practice focused on assessing and managing pain in newborns, acute infant pain remains under-managed and, in some cases, unmanaged (Gardner et al., 2011).

Nonpharmacologic Management. A variety of nonpharmacologic pain management techniques are used with neonates. Nurses and parents may combine two or more techniques as they seek to promote infant comfort and reduce pain.

One of the most common measures is swaddling or snugly wrapping the infant with a blanket. Swaddling limits the neonate's boundaries, aids in self-regulation, and reduces

FIG 24-20 A, Newborn is swaddled with arms extended. B, Newborn is swaddled with arms flexed. (A, Courtesy Jennifer and Travis Alderman, Durham, NC. B, Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

physiologic and behavioral stress resulting from acute pain (Riddell, Racine, Turcotte, et al., 2012). Swaddling is popular among nurses and parents as a comfort measure for calming a fussy baby and for promoting sleep. However, it is important that it is done properly. Safe swaddling involves wrapping the infant snugly in a blanket with the arms extended legs flexed, and hips in neutral position without rotation (Fig. 24-20, A) (AAP, 2014). In the early newborn period, nurses often swaddle infants with the arms flexed (Fig. 24-20, B).

SAFETY ALERT

Swaddling an infant tightly with legs extended is associated with increased risk for hip dislocation (developmental dysplasia of the hip [DDH]). The correct way to swaddle an infant is with the hips in slight flexion and abducted and allowing freedom of movement of the knees. It is important that the blanket is not wrapped too tightly as it can cause overheating or respiratory compromise. There should be space for 2 to 3 adult fingers between the infant's chest and the swaddle. A swaddled infant should be lying on his or her back. Swaddling is not recommended after approximately 2 months of age when the infant is capable of rolling over (AAP, 2014).

Other nonpharmacologic pain relief measures are used by nurses and parents. Facilitated tucking, a hand-swaddling technique in which the care provider holds the neonate in a flexed, side-lying position, is effective for reducing pain and distress in preterm infants (Riddell et al., 2012).

Nonnutritive sucking (NNS) on a pacifier is a common comfort measure used with newborns. Oral sucrose in small amounts given with a syringe with or without a pacifier for sucking is safe and effective in reducing neonatal pain during painful procedures such as venipunctures or heelsticks (Cignacco, Sellam, Stoffel, et al. 2012; Kassab, Roydhouse, Fowler, & Foureur, 2012; Riddell et al., 2012; Stevens, Yamada, Lee, & Ohlsson, 2013).

Oral sucrose and NNS used in combination before or during a painful procedure can help reduce discomfort (Liaw, Zeng, Yang, et al., 2011; Naughton, 2013).

Skin-to-skin contact with the mother who holds the infant prone on her chest, also known as *kangaroo care*, during a painful procedure can help reduce pain (Johnston, Campbell-Yeo, Fernandes, et al., 2014; Kostandy, Anderson, & Good, 2013; Riddell et al., 2012). Breastfeeding or breast milk helps reduce pain during heel lancing and blood collection (Academy of Breastfeeding Medicine, 2010; Shah, Herbozo, Aliwalas, & Shah, 2012).

Distraction with visual, oral, auditory, or tactile stimulation can be helpful in term neonates or older infants (see Evidence-Based Practice box). *Sensorial saturation* uses multiple senses to diminish minor pain. This technique involves speaking softly to the infant, massaging the face, and providing oral sucrose solution on the tongue (Bellieni, Tei, Coccina, & Buonocore, 2012).

Other nonpharmacologic measures for reducing pain in newborns include touch, massage, rocking, holding, and environmental modification (e.g., low noise and lighting). Combining two or more nonpharmacologic methods can result in more effective pain reduction (Gabriel, de Mendoza, Figueiroa, et al., 2013).

Pharmacologic Management. Pharmacologic agents are used to alleviate pain associated with procedures. Local anesthesia is routinely used during procedures such as circumcision and chest tube insertion. Topical anesthesia is used for circumcision, lumbar puncture, venipuncture, and heelsticks. Nonopioid analgesia (oral liquid acetaminophen) is effective for mild to moderate pain from inflammatory conditions. Morphine and fentanyl are the most widely used opioid analgesics for pharmacologic management of neonatal pain. Continuous or bolus IV infusion of opioids provides effective and safe pain control. Other methods for managing neonatal pain are epidural infusion, local and

EVIDENCE-BASED PRACTICE

Nonpharmacologic Pain Relief for Newborns

Ask the Question

For term newborns, which complementary or alternative pain relief interventions are effective for minor painful procedures, such as heelstick?

Search for the Evidence

Search Strategies

English language research-based publications on newborn, pain, breastfeeding, heelstick, and sucrose were included.

Databases Used

Cochrane Collaborative Database, National Guideline Clearinghouse (AHRQ), CINAHL, PubMed, and UpToDate

Critical Appraisal of the Evidence

- Pain scores in newborns assess physical changes to determine pain levels. Term newborns have lower pain scores during minor painful procedures when they use sucking-related interventions and are held and rocked. Preterm newborns 30 to 36 weeks benefit from kangaroo care (being held skin-to-skin prone on caregiver's chest), sucking-related interventions, and swaddling (Riddell, Racine, Turcotte, et al., 2012).
- Breastfeeding is the first choice for single painful procedures for the multisensorial and synergistic comfort it brings. It also provides the parents a caregiving role (Academy of Breastfeeding Medicine [ABM] Protocol Committee, 2010).
- Skin-to-skin contact, along with 24% sucrose or 25% to 50% glucose administered via pacifier, dropper, syringe, or finger provide significant pain relief (ABM, 2010; Kassab, Roydhouse, Fowler, & Foureur, 2012).
- Preterm babies are at risk for more painful procedures. If breastfeeding is not possible, sucking-related interventions with sucrose decrease pain scores. However, there is concern that prolonged sucrose exposures in premature infants can lead to delays in motor skills and attention scores (ABM Protocol Committee, 2010).
- For term infants, sensorial saturation uses multiple senses to diminish minor pain. A protocol of simultaneously massaging the infant's face, speaking to the infant, and instilling a sweet solution into the infant's mouth is more effective for relieving pain than the sweet solution alone (Bellieni, Tei, Coccina, & Buonocore, 2012).

Apply the Evidence: Nursing Implications

- Nonpharmacologic pain relief methods for newborns use the gate-control theory to distract the newborn's attention by using strong single or multisensorial stimulation. Warmth, touch, auditory and visual attention, and sucking a sweet solution decrease pain scores.
- Sensorial saturation can be easily accomplished in the nursery. Parents who are taught this technique become active

participants in their newborn's procedural care. However, they need clear education that using sucrose is not an appropriate long-term strategy for use at home.

- Although skin-to-skin contact, breastfeeding, and human milk are not well researched as pain relief interventions for preterm newborns, the ABM recommends that parents be allowed to try these measures (ABM Protocol Committee, 2010).
- Comfort measures usually work best when initiated a few minutes before the procedure to allow the newborn time to relax and reorganize (Kassab et al., 2012).
- Procedures other than single heelsticks or needlestick should be evaluated for pharmacologic analgesia. Sucrose is not sufficient pain relief for circumcisions.

Quality and Safety Competencies: Evidence-Based Practice* Knowledge

Describe how the strength and relevance of available evidence influences the choice of interventions in provision of client-centered care.

Multisensorial stimulation that includes sucrose and sucking works best for pain relief.

Skills

Participate in structuring the work environment to facilitate integration of new evidence into standards of practice.

Parents can learn skills to manage their newborn's pain.

Attitudes

Value the need for continuous improvement in clinical practice based on new knowledge.

Nurses can explain to parents the evidence for pain relief in newborns.

regional nerve blocks, and intradermal or topical anesthetics (Gardner et al., 2011).

Promoting Parent-Infant Interaction

Nurses play an important role in promoting early social interaction between parents and their newborn infant. From birth throughout the hospital stay, nurses assess attachment behaviors (see Chapter 22) and provide support and education to parents as they become acquainted with the neonate.

Nurses working in outpatient settings or home care provide follow-up assessments and care related to parent-child interactions. By teaching parents to recognize infant cues and respond appropriately, the nurse facilitates development of the parents' confidence in meeting the needs of their newborn (see Teaching for Self-Management: Helping Parents Recognize, Interpret, and Respond to Newborn Behaviors).

The sensitivity of the parent to the social responses of the infant is basic to the development of a mutually satisfying

TEACHING FOR SELF-MANAGEMENT

Helping Parents Recognize, Interpret, and Respond to Newborn Behaviors

Learning to read a baby's body language can enable parents to be more effective in preventing and solving problems around the infant's sleeping, eating, and crying and enhances parent-infant interaction. Nurses can teach new parents the following:

1. Identify three newborn "zones," traditionally referred to as *newborn states*.

- "Resting zone": also known as *sleep states*
 - *Still/deep sleep*: Baby is completely still. Breathing is regular. No spontaneous activity. No movement of eyes, and eyelids stay shut. No vocalizing. Muscles are totally relaxed.
 - *Active/light sleep*: Baby may wiggle or vocalize. Eyes may flash open. Baby may make sucking movements—but still be asleep.
- "Ready zone": *alert state*
 - Baby's eyes are bright. Baby can focus on an object or person. Baby reacts to stimulation. Motor activity is minimal.
- "Rebooting zone": *fussy/crying state*
 - Baby's motor activity increases and is jerky. Baby is less responsive and moves from fussing to crying.

2. Identify signs of stress.

- When babies are stressed or overstimulated, they show changes in their body and behavior. These changes are called *SOSs* (Signs of Over-Stimulation), traditionally referred to as a baby's *stress response*.
 - *Body SOSs*: changes in color (becoming more red or pale); changes in breathing (becoming more irregular or choppy); changes in movement (becoming jerky or having more tremors)
 - *Behavioral SOSs*: "spacing out" (going from an alert state to a drowsy state); "switching off" (gaze aversion, or looking away from parent); "shutting down" (going from drowsy to a sleep state)
- When baby shows an SOS, parents should *decrease* stimulation and *increase* support by doing one or several of the following:
 - Quiet one's voice.
 - Glance away from baby.
 - Encourage baby to suck a finger or mother's breast.
 - Swaddle baby.
 - Place baby skin-to-skin.

3. Help baby sleep well.

- Distinguish active/light sleep from still/deep sleep.
- Parent's care:
 - *Prepare baby to sleep*: swaddling may help; feed in quiet, dark room at night and active, light environment during day.
 - *Get baby to sleep*: put baby down for sleep while he or she is still awake.
 - *Help baby stay asleep*: don't pick up during active/light sleep.
 - After breastfeeding is well established, notice when sleeping baby moves into active/light sleep. Wait and see if baby will transition from active/light sleep back to deep/still sleep—and sleep a bit longer.

4. Help baby eat well.

- Recognize early signs of hunger during the first few weeks: wiggling, making sucking movements, bringing hand to mouth.
- Notice if a fragile baby "spaces out" or "shuts down" when trying to eat. Bring this baby skin-to-skin and decrease stimulation before resuming feeding.
- If a parent needs to wake a fragile or small baby to eat, do so from active/light sleep, not from still/deep sleep.

5. Help crying baby: consider what "TO DO."

- **T**: *Talk* quietly to baby in sing-song voice.
- **O**: *Observe* to see if baby takes self-calming actions: brings his or her hand to his or her mouth, making sucking movements, or moves into the fencing reflex position.
- **DO**: *Bring* baby's hands to his or her chest; encourage sucking; make gentle "shooshing" sounds; swaddle baby; and/or bring baby skin-to-skin.

6. Play with baby so he or she can learn and grow.

- Demonstrate baby's ability to look at a parent's face, watch a toy move, or turn to parent's voice.
- Watch for an SOS during play. If an SOS occurs, decrease stimulation and increase support as described previously.
- Observe baby's developing process of interaction: first, getting quiet and still; second, turning toward parent; third, turning toward and looking at parent.
- Reinforce benefits of sensitive, face-to-face parent interaction with baby.

Data from Tedder, J.L. (2008). Give them the HUG: An innovative approach to helping parents understand the language of their newborn. *Journal of Perinatal Education*, 17(2), 14-20; Tedder, J.L. H.U.G.: *Help-understanding-guidance for young families*. Available at www.hugyourbaby.org.

parent-child relationship. Sensitivity increases over time as parents become more aware of their infant's social capabilities. In supporting parents, nurses need to consider cultural beliefs and traditions that influence parenting behaviors and infant care practices (see Cultural Considerations box).

The activities of daily care during the neonatal period are the best times for infant and family interactions. While caring for their newborn, the mother and father (or other family member) can talk to the infant, play baby games, caress and cuddle the baby, and perhaps use infant massage. Feeding is an optimal time for interaction because the infant is usually awake and alert, at least at the beginning of the feeding. **Too much stimulation should be avoided after feeding and before a sleep period.** In Figure 24-21 a great-grandmother and infant are shown engaging in arousal, imitation of facial expression, and smiling. Older children's contact with a newborn is encouraged and supervised based on the developmental level of the child (Fig. 24-22). Parents often keep memento books that record the birth, the hospital stay, and

their infant's progress. Other parents create blogs to share their development as a family.

Discharge Planning and Parent Education

Infant care activities can cause anxiety for new parents. Support from nurses can be an important factor in determining whether new parents seek and accept help in the future. It is best for the nurse to avoid trying to cover all the content about newborn care at one time because the parents can be overwhelmed by too much information and become more anxious. Instead, parent education should occur throughout the hospital stay. However, because hospital stays after birth are relatively short, teaching all the content that is necessary can be a challenge for the nurse. As a result, many institutions have developed home visitation programs that take the necessary teaching to the new parents, although the hospital nurse still provides most of the essential information about newborn care. Printed materials about newborn care are provided to parents. In addition, nurses can direct parents to reliable websites for information on infant care (e.g., www.healthychildren.org).

CULTURAL CONSIDERATIONS

Cultural Beliefs and Practices Related to Infant Care

Nurses working with childbearing families from other cultures and ethnic groups must be aware of cultural beliefs and practices that are important to individual families. People with a strong sense of heritage may hold on to traditional health beliefs long after adopting other U.S. lifestyle practices. These health beliefs can involve practices regarding the newborn. For example, some Asians, Hispanics, Eastern Europeans, and Native Americans delay breastfeeding until the mother's milk is "in" (day 3 or 4) because they believe that colostrum is "bad." Some Hispanics and African-Americans place a belly band over the infant's umbilicus. In some Hispanic cultures, infants wear a special bracelet to help protect them from the evil eye (*mal de ojo*) (see photo). The birth of a male child is generally preferred by Asians and Eastern Indians, and some Asians and Haitians delay naming their infants. Families of Hindu heritage name the baby on the 11th day during a "cradle ceremony." Some women from India keep the cord of a male infant as a good omen that will ward off evil and will bring them more male infants in the future. The practice of skin-to-skin contact after birth may conflict with cultural beliefs about thermoregulation; some women from Africa prefer that the newborn is wrapped prior to being placed on the mother's chest. On the other hand, women from Mexico are wrapped in warm blankets after birth and wrap the newborn inside their blankets. Cultural beliefs influence when the newborn is taken out of the house, such as after the cord falls off, or after the mother's confinement period is over (approximately 30 days after birth). Weighing the infant can raise concerns for some women such as those from rural India, who may believe that frequent weighing will slow the infant's growth.

Newborn wearing "evil eye" bracelet. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

Data from Giger, J. N. (2013). *Transcultural nursing* (6th ed.). St. Louis: Mosby; Purnell, L. D. (2014). *Culturally competent health care* (3rd ed.). Philadelphia: F.A. Davis.

To set priorities for teaching, the nurse follows parental cues. Knowledge deficits or gaps should be identified before beginning to teach. Normal growth and development and the changing needs of the infant (e.g., for personal interaction and stimulation, growth milestones, exercise, injury prevention, and social contacts), as well as the topics that follow, should be included during discharge planning with parents. Safety issues

FIG 24-21 Great-grandmother and infant enjoying social interaction. (Courtesy Freida Belding, Bird City, KS.)

FIG 24-22 Mother supervising contact of older sibling with newborn. (Courtesy Rebekah Vogel, Fort Collins, CO.)

should be addressed (see *Teaching for Self-Management: Infant Safety*).

Temperature

Parents need to understand practical information related to thermoregulation. The nurse discusses the following topics in parent teaching:

- The causes of changes in body temperature (e.g., overwrapping, cold stress with resultant vasoconstriction, or minimal response to infection) and the body's response to extremes in environmental temperature
- Ways to promote normal body temperature, such as dressing the infant appropriately for the environmental air temperature and protecting the infant from exposure to direct sunlight
- Use of warm wraps or extra blankets in cold weather
- Technique for taking the newborn's axillary temperature, and normal values for axillary temperature
- Signs to be reported to the primary health care provider such as high or low temperatures with accompanying fussiness, lethargy, irritability, poor feeding, and excessive crying

TEACHING FOR SELF-MANAGEMENT

Infant Safety

- Always lay the baby flat in bed (in the bassinet or crib) on his or her back for sleep, for naps, and at night. Do not place your infant on the abdomen for sleep.
- Room-sharing, but not bed-sharing, is recommended during the early weeks.
- Never put your baby on a cushion, pillow, beanbag, or water-bed to sleep. Your baby may suffocate.
- There should be no bumper pads, blankets, stuffed toys, or other soft objects in the baby's crib because of the risk for suffocation.
- Do not cover the baby with blankets or quilts; dress the baby in light sleep clothing such as a sleep sack or one-piece sleeper.
- Check your baby's crib for safety. Slats should be no more than 2¼ inches apart. The space between the mattress and sides should be less than 2 fingerwidths. The bedposts should have no decorative knobs.
- The crib mattress should be firm and should fit snugly against the crib rails.
- Do not use a crib with drop rails.
- Never leave your baby alone on a bed, couch, or table. Even newborns can move enough to eventually reach the edge and fall off.
- When using an infant carrier, place the carrier on the floor in a place where you can see the baby. It should never be on a high place, such as a table, sofa, or store counter.
- Infant carriers do not keep your baby safe in a car. Always place your baby in an approved car safety seat when traveling in a motor vehicle (car, truck, bus, or van). Car safety seats are recommended for travel on trains and airplanes as well. Use the car safety seat for every ride. Your baby should be in a rear-facing infant car safety seat from birth until age 2 years or until exceeding the car seat's limits for height and weight. The car safety seat should be in the back seat of the car (see Fig. 24-24). This precaution is especially important in vehicles with front passenger air bags because when air bags inflate, they can be fatal for infants and toddlers. If an infant must ride in the front seat, disable the air bag.
- When bathing your baby, never leave him or her alone. Newborns and infants can drown in 1 to 2 inches of water.
- Be sure that your hot water heater is set at 49° C (120° F) or less. Always check bath water temperature with your elbow before putting your baby in the bath.
- Do not tie anything around your baby's neck. Pacifiers, for example, tied around the neck with a ribbon or string can strangle your baby.
- Keep the crib or playpen away from window blind and drapery cords; your baby could strangle on them.
- Keep the crib and playpen well away from radiators, heat vents, and portable heaters. Linens in the crib or playpen can catch fire if they come into contact with these heat sources.
- Install smoke detectors on every floor of your home. Check them once a month to be sure they are working properly. Change batteries twice a year.
- Avoid exposing your baby to cigarette or cigar smoke in your home or other places. Passive exposure to tobacco smoke greatly increases the likelihood that your infant will have respiratory symptoms and illnesses.
- Be gentle with your baby. Do not pick your baby up or swing your baby by the arms or throw him or her up in the air. Never shake the baby.

Data from American Academy of Pediatrics (AAP) Task Force on Sudden Infant Death Syndrome. (2011). SIDS and other sleep-related infant deaths: Expansion of recommendations for a safe infant sleeping environment. *Pediatrics*, 128(5):e1341-e1367; National Institute of Child Health and Human Development. (2013). *Safe to sleep public education campaign*. Bethesda, MD: Author. National Highway Traffic Safety Administration (NHTSA) Parents Central. (2012). *From car seats to car keys: Keeping kids safe*. Washington, DC: Author.

Respirations

The nurse provides information to parents regarding the normal characteristics of newborn respirations, emergency procedures, and measures to protect the infant. It is helpful to discuss signs of respiratory infection and to offer suggestions related to care of the infant who experiences symptoms. The following points are included in teaching about respirations:

- Normal variations in the rate and rhythm of respirations
- Reflexes such as sneezing to clear the airway
- Use of the bulb syringe
- Steps to take if the infant appears to be choking
- The need to protect the infant from:
 - Exposure to people with upper respiratory tract infections and respiratory syncytial virus
 - Exposure to secondhand tobacco smoke
 - Suffocation from loose bedding, water beds, and beanbag chairs; drowning (in bath water); entrapment under excessive bedding or in soft bedding; anything tied around the infant's neck; poorly constructed playpens, bassinets, or cribs
- Sleep position—on back when put to sleep; room sharing but not bed sharing is recommended during the early weeks

- Avoid the use of baby powder or corn starch; these substances can cause lung irritation
- Notify the health care provider if the infant develops symptoms such as difficulty breathing or swallowing, nasal congestion, excess drainage of mucus, coughing, sneezing, decreased interest in feeding, or fever.
- If the infant has a respiratory illness such as the “common cold,” the following suggestions can be helpful:
 - Feed smaller amounts more often to prevent overtiring the infant.
 - Hold the baby in an upright position to feed.
 - For sleeping, raise the infant's head and chest by raising the mattress 30 degrees (do not use a pillow).
 - Avoid drafts; do not overdress the baby.
 - Use only medications prescribed by a pediatric health care provider. Do not use over-the-counter medications without provider approval.
 - Use nasal saline drops in each nostril and suction well with bulb syringe to decrease and relieve secretions.

Feeding Patterns

Nurses instruct parents about infant feeding and provide assistance based on whether they have chosen breastfeeding or formula feeding. Feeding patterns and practices for newborns are discussed in Chapter 25.

Elimination

Awareness of the normal elimination patterns of newborns helps parents recognize problems related to voiding or stooling. The following points are included in teaching about elimination:

- Color of normal urine and number of voidings to expect each day: at least two to six for the first 1 to 3 days; then a minimum of six to eight voidings per day thereafter. Urine should be pale yellow (like lemonade).
- Changes to be expected in the color and consistency of the stool (i.e., meconium to transitional to soft yellow or golden yellow) and the number of bowel movements, plus the odor of stools for breastfed or bottle-fed infants (see Box 23-1).
- Formula-fed infants may have as few as one stool every other day after the first few weeks of life; stools are pasty to semi-formed.
- Breastfed infants should have at least three stools every 24 hours for the first few weeks. The stools are looser and resemble mustard mixed with cottage cheese; the odor is less offensive than stools of infants who are formula fed.

Safe Sleeping, Positioning, and Holding

The AAP recommends placing the infant in the supine position for sleep during the first year of life to prevent sudden infant death syndrome (SIDS). Infants should lie on a firm surface, specifically on a firm crib mattress covered by a fitted sheet. Soft materials such as bumper pads, comforters, quilts, pillows, sheepskins, or stuffed toys should not be placed in the crib. Room sharing but not bed sharing is recommended during infant sleep; bed sharing can increase the risk of suffocation and falls. Infants may be brought into the parent's bed for comforting or for breastfeeding but should be returned to the crib or bassinet before the parent goes to sleep (AAP Task Force on Sudden Infant Death Syndrome [SIDS], 2011) (see Teaching for Self-Management: Infant Safety).

Parent education prior to hospital discharge should include specific information about safe sleep practices. The Safe to Sleep campaign from the National Institute of Child Health and Human Development (2013) provides materials for health care professionals and parents. The educational resources are designed to reach culturally diverse audiences with messages about promoting a safe sleep environment and preventing SIDS (see www.nichd.nih.gov/sts/Pages/default.aspx).

To help remind parents about safe sleep, some hospitals post a laminated safe sleep card in the newborn's bassinet. Using the mnemonic ABC developed by FirstCandle.com, a nonprofit organization that promotes safe sleeping practices, the message is, "I sleep safest Alone, on my Back, in my Crib" (Hitchcock, 2012).

Anatomically, the infant's shape—a barrel chest and flat, curveless spine—facilitates the infant to roll from the side to the prone position; therefore, the side-lying position for sleep is not recommended. When the infant is awake, "tummy time" can be provided under parental supervision so the infant can begin to develop appropriate muscle tone for eventual crawling; placing the infant prone at intervals when awake aids in preventing a misshapen head (**positional plagiocephaly**).

Care must be taken to prevent the infant from rolling off flat, unguarded surfaces. When an infant is on such a surface, the parent or nurse who must turn away from the infant even for a moment should always keep one hand placed securely on the infant.

The infant is always held securely with the head supported because newborns are unable to maintain an erect head posture for more than a few moments. Figure 24-23 illustrates various positions for holding an infant with adequate support.

CLINICAL REASONING CASE STUDY

Safe Infant Sleep Practices

The mother/baby nurse is teaching the new parents about safe sleep practices for their healthy term newborn son. The grandmother is listening and insists that all her babies slept most soundly when they were on their "tummies." The mother proudly shows the nurse a photo of the baby's nursery at home, including an antique crib with colorful fabric covered bumper pads and a matching fluffy quilt. There are several stuffed animals in the crib. What information should the nurse provide related to safety concerns for the newborn?

1. Evidence—Is there sufficient evidence to draw conclusions about the safety of the sleep environment in terms of preventing sudden infant death syndrome or infant injury?
2. Assumptions—What assumptions can be made about the following factors related to safe infant sleep?
 - a. Infant positioning for sleep
 - b. Risk for suffocation
 - c. Risk for injury
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

Rashes

Diaper Rash. The majority of infants develop a diaper rash at some time. This dermatitis or skin inflammation appears as redness, scaling, blisters, or papules. Various factors contribute to diaper rash including infrequent diaper changes, diarrhea, use of plastic pants to cover the diaper, a change in the infant's diet such as when solid foods are added, or when breastfeeding mothers eat certain foods.

Parents are instructed in measures to help prevent and treat diaper rash. Diapers should be checked often and changed as soon as the infant voids or stools. Plain water with mild soap, if needed, is used to cleanse the diaper area; if baby wipes are used, they should be unscented and contain no alcohol. The infant's skin should be allowed to dry completely before applying another diaper. Exposing the buttocks to air can help dry up diaper rash. Because bacteria thrive in moist, dark areas, exposing the skin to dry air decreases bacterial proliferation. Zinc oxide ointments can be used to protect the infant's skin from moisture and further excoriation (AWHONN, 2013).

Although diaper rash can be alarming to parents and annoying to babies, most cases resolve within a few days with simple home treatments. There are instances when diaper rash is more serious and requires medical treatment.

The warm, moist atmosphere in the diaper area provides an optimal environment for *Candida albicans* growth; dermatitis appears in the perianal area, inguinal folds, and lower abdomen. The affected area is intensely erythematous with a sharply demarcated, scalloped edge, often with numerous satellite lesions that extend beyond the larger lesion (AWHONN, 2013). Therapy consists of applications of an anticandidal ointment,

FIG 24-23 Holding the baby securely with support for head. **A**, Holding infant while moving infant from scale to bassinet. (**A**, Courtesy Kim Molloy, Knoxville, IA. **B**, **C**, and **D**, Courtesy Julie Perry Nelson, Loveland, CO.)

such as clotrimazole or miconazole, with each diaper change. Sometimes the infant is given an oral antifungal preparation such as nystatin or fluconazole to eliminate any gastrointestinal source of infection.

Other Rashes. A rash on the cheeks can result from the infant’s scratching with long unclipped fingernails or from rubbing the face against the crib sheets, particularly if regurgitated stomach contents are not washed off promptly. The newborn’s skin begins a natural process of peeling and sloughing after birth. Dry skin may be treated with an emollient applied once or twice daily (AWHONN, 2013). Newborn rash, erythema toxicum, is a common finding (see Fig. 23-6, *B*) and needs no treatment.

Clothing

Parents commonly ask how warmly they should dress their infant. A simple suggestion is to dress the child for the environment as they dress themselves, adding no more than one layer more than they would be wearing as adults. Overheating should

be avoided (AAP Task Force on Sudden Infant Death Syndrome, 2011). A cap or bonnet is needed to protect the scalp and minimize heat loss if the weather is cool or to protect against sunburn. Wrapping the infant snugly in a blanket maintains body temperature and promotes a feeling of security. Overdressing in warm temperatures can cause discomfort, as can underdressing in cold weather. Parents are encouraged to dress the infant at all times in flame-retardant clothing. The eyes should be shaded if it is sunny and hot. Infant sunglasses are available to protect the infant’s eyes when outdoors (Fig. 24-24).

Car Seat Safety

Infants should travel only in federally approved rear-facing safety seats secured in the rear seat using the vehicle safety belt (Fig. 24-25). To secure the infant in the rear-facing car safety seat, shoulder harnesses are placed in the slots at or below the level of the infant’s shoulders. The harness is snug, and the retainer clip is placed at the level of the infant’s armpits as opposed to on the abdomen or neck area.

FIG 24-24 Sunglasses protect the infant's eyes. (Courtesy Julie Perry Nelson, Loveland, CO.)

FIG 24-25 Rear-facing car seat in rear seat of car. Infant is placed in seat when going home from the hospital. (Courtesy Brian and Mayannyn Sallee, Anchorage, AK.)

⚡ SAFETY ALERT

Infants and toddlers should use a rear-facing car seat until the age of 2 years or for as long as possible up to the weight and height limit for their particular car seat. The safest area of the car is the back seat. A car safety seat that faces the rear gives the best protection for an infant's disproportionately weak neck and heavy head. In this position the force of a frontal crash is spread over the head, neck, and back; the back of the car safety seat supports the spine (AAP, 2012; National Highway Traffic Safety Administration [NHTSA], 2012).

In cars equipped with front air bags, rear-facing infant seats should never be placed in the front seat. Serious injury can occur if the air bag inflates because these types of infant seats fit close to the dashboard. If the infant must ride in the front seat, the air bag must be turned off. For cars with side air bags, parents should read the vehicle owner's manual for information about placement of car seats next to a side air bag (AAP, 2012; NHTSA, 2012).

FIG 24-26 Infant Car Seat Challenge: testing is done before discharge from the birthing facility. Preterm infant is in car seat with pulse oximetry monitoring. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

Infants are positioned at a 45-degree angle in a car seat to prevent slumping and subsequent airway obstruction. Many seats allow for adjustment of the seat angle. For seats that are not adjustable, a tightly rolled newspaper, a solid-core Styrofoam roll, or a firm roll of fabric can be placed under the car safety seat to place the infant at a 45-degree angle (Bull, Engle, & AAP Committee on Injury, Violence, and Poison Prevention & Committee on Fetus and Newborn, 2009).

Before discharge from the birth institution, infants born at less than 37 weeks of gestation should be observed in a car seat (preferably their own) for at least 90 to 120 minutes or a period of time equal to the length of the car ride home. This is known as the Infant Car Seat Challenge. The infant is monitored for apnea, bradycardia, and a decrease in oxygen saturation (Fig. 24-26). If the infant exhibits any of these clinical signs, travel home should be in a Federal Motor Vehicle Safety Standard 213 (FMVSS 213)-approved car bed (Bull et al., 2009).

⚡ SAFETY ALERT

If the parents do not have a car safety seat, arrangements should be made to make an appropriate seat available for purchase, loan, or donation. Parents need to be cautioned about purchasing a secondhand car safety seat without knowing its history. They should never use a car seat that was involved in a moderate to severe crash, is too old, has visible cracks, does not have a label with the model number and manufacture date, does not come with instructions, is missing parts, or was recalled (AAP, 2012).

Nonnutritive Sucking

Sucking is the infant's chief pleasure. However, sucking needs may not be satisfied by breastfeeding or bottle-feeding alone.

In fact, sucking is such a strong need that infants who are deprived of sucking, such as those with a cleft lip, will suck on their tongues. Several benefits of nonnutritive sucking have been demonstrated, such as an increased weight gain in preterm infants, increased ability to maintain an organized state, and decreased crying.

There is compelling evidence that pacifiers help prevent SIDS. The AAP Task Force on Sudden Infant Death Syndrome (2011) suggests that parents consider offering a pacifier for naps and bedtime. The pacifier should be used when the infant is placed supine for sleep, and it should not be reinserted once the infant falls asleep. No infant should be forced to take a pacifier. Pacifiers are to be cleaned often and replaced regularly and should not be coated with any type of sweet solution. Pacifier use for breastfeeding infants should be delayed for 3 to 4 weeks to ensure that breastfeeding is well established.

Problems arise when parents are concerned about the sucking of fingers, thumb, or pacifier and try to restrain this natural tendency. Before giving advice, nurses should investigate the parents' feelings and base the guidance they give on the information solicited. For example, some parents see no problem with the infant sucking on a thumb or finger but find the use of a pacifier objectionable. In general, either practice need not be restrained unless thumb sucking or pacifier use persists past 4 years of age or past the time when the permanent teeth erupt. Parents are advised to consult with their pediatric health care provider or pediatric dentist about this topic.

A parent's excessive use of the pacifier to calm the infant should also be explored, however. Placing a pacifier in the infant's mouth as soon as the infant begins to cry can reinforce a pattern of distress and relief.

SAFETY ALERT

If parents choose to let their infant use a pacifier, they need to be aware of certain safety considerations before purchasing one. A homemade or poorly designed pacifier can be dangerous because the entire object can be aspirated if it is small or a portion can become lodged in the pharynx. Improvised pacifiers, such as those made from a padded nipple, also pose dangers because the nipple can separate from the plastic collar and be aspirated. Safe pacifiers are made of one piece that includes a shield or flange large enough to prevent entry into the mouth and a handle that can be grasped (Fig. 24-27).

Bathing and Umbilical Cord Care

Bathing. Bathing serves several purposes. It provides opportunities for (1) cleansing the skin, (2) observing the infant's condition, (3) promoting comfort, and (4) parent-child-family interaction.

An important consideration in skin cleansing is the preservation of the skin's acid mantle, which is formed from the uppermost horny layer of the epidermis, sweat, superficial fat, metabolic products, and external substances such as amniotic fluid and microorganisms. To protect the newborn's skin it is best to use a cleanser with a neutral pH and preferably without preservatives or with preservatives recognized as safe and well

FIG 24-27 Safe pacifiers for term and preterm infants. Note one-piece construction, easily grasped handle, and large shield with ventilation holes. (Courtesy Julie Perry Nelson, Loveland, CO.)

tolerated in neonates. Antimicrobial cleansers should not be used (AWHONN, 2013).

The latest neonatal skin care guidelines from AWHONN (2013) indicate that bathing should be performed according to agency protocols using sponge bathing, immersion, or *swaddled bathing*. Sponge baths are usually given until the infant's umbilical cord falls off and the umbilicus is healed. However, bathing the newborn by immersion has been found to allow less heat loss and provoke less crying. It has not been shown to increase the risk of bacterial colonization of the cord (AWHONN). *Swaddled bathing* is a type of immersion bathing in which the newborn is swaddled in a blanket or towel and immersed in a tub of warm water. One body part at a time is unwrapped and washed (AWHONN).

Ideally the initial bath is delayed for at least 2 hours after birth until the neonate has reached thermal and cardiorespiratory stability. This bath should be quick (5 to 10 minutes) and can be performed at the mother's bedside or in the nursery. Tap water and a minimal amount of pH neutral or slightly acidic cleanser are recommended. Following the bath the infant should be immediately dried, diapered, and wrapped in warm blankets; a cap is placed on the head. Ten minutes later, the newborn is dressed, wrapped in warm blankets, and the cap is changed (AWHONN, 2013).

A daily bath is not necessary for achieving cleanliness and can do harm by disrupting the integrity of the newborn's skin; cleansing the perineum after a soiled diaper and daily cleansing of the face are usually sufficient. In general, infants should not be bathed more frequently than every other day; the hair should be shampooed once or twice a week (AWHONN, 2013).

The infant bath time provides a wonderful opportunity for parent-infant social interaction (Fig. 24-28). While bathing the baby, parents can talk to the infant, caress and cuddle the infant, and engage in arousal and imitation of facial expressions and smiling. Parents can pick a time for the bath that is easy for them and when the baby is awake, usually before a feeding.

Umbilical Cord Care. The goal of cord care is to prevent or decrease the risk for hemorrhage and infection. The umbilical cord stump is an excellent medium for bacterial growth and can easily become infected. Hospital protocol determines the technique for routine cord care. AWHONN (2013) recommendations for cord care include cleaning the cord with

water (using cleanser sparingly if needed to remove debris) during the initial bath. Evidence does not support the routine use of antiseptic or antimicrobial preparations for cord care (AWHONN; Lund & Durand, 2011).

The plastic cord clamp that was applied at birth is removed once the stump has dried (Fig. 24-29), typically in 24 to 48 hours. The stump and base of the cord should be assessed for edema, redness, and purulent drainage with each diaper change. The area should be kept clean and dry and open to air or loosely covered with clothing. If soiled, the area is cleansed with plain water and dried thoroughly. The diaper is folded down and away from the stump (AWHONN, 2013). The umbilical cord begins to dry, shrivel, and blacken by the second or third day of life. The stump deteriorates through the process of dry gangrene; therefore, odor alone is not a positive indicator of omphalitis (infection of the umbilical stump). Cord separation time is influenced by several factors, including type of cord care, type of birth, and other perinatal events. The average cord separation time is 10 to 14 days, although it can take up to 3 weeks. Some dried blood may be seen in the umbilicus at separation (Fig. 24-30). Parents are instructed in appropriate home cord care (per pediatric health care

practitioner or institution protocol) and the expected time of cord separation.

See Teaching for Self-Management: Home Care for information regarding bathing, skin care, cord care, nail care, and dressing the infant.

Infant Follow-up Care

Follow-up care after hospital discharge usually occurs within 72 hours at the clinic or health care provider's office. This is especially important for breastfed newborns for monitoring their weight and hydration status. When infants are discharged at less than 48 hours of age, home care follow-up is an essential component of care. Home care may be provided either by a nurse as part of the routine follow-up care of infants or through a visiting nurse or community health nurse referral service.

Cardiopulmonary Resuscitation

All personnel working with infants must have current infant cardiopulmonary resuscitation (CPR) certification. Parents should receive instruction in relieving airway obstruction and CPR. Classes are often offered in hospitals and clinics during the prenatal period or to parents of newborns. Such instruction is especially important for parents whose infants were preterm or have a history of cardiac or respiratory problems. Some grandparents take CPR classes. Babysitters should also learn CPR.

Practical Suggestions for the First Weeks at Home

Numerous changes occur during the first weeks of parenthood. Care management should be directed toward helping parents

TEACHING FOR SELF-MANAGEMENT

*Home Care: Bathing, Cord Care, Skin Care, and Nail Care***Timing**

- Newborns do not need a bath every day. Every 2 or 3 days is often enough.
- Fit bath time into the family's schedule.
- Give a bath at any time convenient to you but not immediately after a feeding period because the increased handling can cause regurgitation.

Prevent Heat Loss

- The temperature of the room should be 26°-27° C (79-81° F) and the bathing area should be free of drafts (close the door in the room where the bath is performed).
- The water temperature should be between 38° C and 40° C (100° F to <104° F). A water thermometer is useful for determining appropriate water temperature.
- Control heat loss during the bath to conserve the infant's energy. Bathe the infant quickly; with a sponge bath expose only a portion of the body at a time; and dry thoroughly.

Gather Supplies and Clothing Before Starting

- Tub for water placed in a safe place on a sturdy surface
- Towels for drying the infant and a clean washcloth
- Mild cleanser with a neutral pH and preferably with no preservatives
- Diaper
- Clothing suitable for wearing indoors: shirt; stretch suit or nightgown optional
- Cotton balls
- Receiving blanket

Bathe the Baby

- Take the infant to the bathing area when all supplies are ready.
- Never leave the infant alone on bath table or in the bathwater, not even for a second! If you have to leave, take the infant with you or place the infant back into the crib.
- Test the temperature of the water. Do not hold the infant under running water—the water temperature can change, and the infant can be scalded or chilled rapidly. For immersion bathing (tub bath), carefully lower the infant into the tub; the head and neck should be above the water. The tub should be filled with enough water to keep the baby's shoulders covered; this helps reduce heat loss. First wash the baby's face with a soft washcloth and plain water. Then proceed to wash the rest of the body, going from top to bottom.
- If sponge bathing is to be performed, undress the baby and wrap in a towel with the head exposed. Uncover and gently wash one part of the body at a time, taking care to keep the rest of the baby covered as much as possible to prevent heat loss.
- Begin by washing the baby's face with water; do not use soap on the face. Cleanse the eyes from the inner canthus outward using separate parts of a clean washcloth for each eye. For the first 2 to 3 days, a discharge can result from the reaction of the conjunctiva to the substance (erythromycin) used as a prophylactic measure against infection. Any discharge should be considered abnormal and reported to the pediatric health care provider.
- Cleanse the ears and nose with twists of moistened cotton or a corner of the washcloth. Do not use cotton-tipped swabs because they can cause injury. The areas behind the ears need daily cleansing.
- Wash between the skinfolds. Place your hand under the baby's shoulders and lift gently to expose the neck, lift the chin, and wash the neck, taking care to cleanse between the skinfolds.
- Wash the genital area last.

- If the hair is to be washed, begin by wrapping the infant in a towel with the head exposed. Hold the infant in a football position (under the arm) with one hand, using the other hand to wash the hair. Wash the scalp with water and shampoo that is mild for the eyes and safe for babies. Massage the scalp gently, rinse well, and dry thoroughly. A blow dryer is never used on an infant because the temperature is too hot for a baby's skin.

Wash hair with baby wrapped to limit heat loss. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

Skin Care

- If the skin appears dry or cracking, apply an emollient (lotion) once or twice daily. Check with your pediatric health care provider about the type of emollient to use.
- The fragile skin can be injured by too vigorous cleansing. If stool or other debris has dried and caked on the skin, soak the area to remove it. Do not attempt to rub it off because abrasion can result. Cleanse gently using a mild cleanser and pat dry.
- Babies are very prone to sunburn and should be kept out of direct sunlight. Use of sunscreens should be discussed with the health care provider. For infants younger than 6 months, sunscreen is applied to areas not covered by protective clothing or shade such as the face and backs of the hands.
- Babies often develop rashes that are normal. Neonatal acne resembles pimples and can appear at 2 to 4 weeks of age, resolving without treatment by 6 to 8 months. Heat rash is common in warm weather, which appears as a fine red rash around creases or folds where the baby sweats.

Cord Care

- Cleanse with plain water around base of the cord where it joins the skin. Notify the health care provider of any odor, discharge, or skin inflammation (redness) around the cord. The clamp is removed by the nurse when the cord is dry (approximately 24 to 48 hours after birth). Keep the diaper folded down so that it does not cover the cord. A wet or soiled diaper will slow or prevent drying of the cord and foster infection. When the cord drops off after 10 to 14 days, a few small drops of blood may be seen. If there is active bleeding, notify the pediatric health care provider.

Nail Care

- Do not cut fingernails and toenails immediately after birth. The nails have to grow out far enough from the skin so that the skin is not cut by mistake. If the baby scratches himself or herself, apply loosely fitted mitts over each of the baby's hands.

TEACHING FOR SELF-MANAGEMENT—cont'd

Home Care: Bathing, Cord Care, Skin Care, and Nail Care

Do so as a last resort, however, because it interferes with the baby's ability for self-consolation sucking on thumb or finger. When the nails have grown, the fingernails and toenails can be trimmed with manicure scissors or clippers; nails should be cut straight across. The ideal time to trim the nails is when the infant is sleeping. Soft emery boards may be used to file the nails. Nails should be kept short.

Genital Care

- Cleanse the genitalia of infants daily and after voiding or stooling using disposable diaper wipes or soft cloths and water (with gentle cleanser if needed). For girls, the genitalia are cleansed by gently separating the labia and gently washing from the pubic area to the anus. For uncircumcised boys, wash and rinse the penis with soap and warm water. Do not attempt to retract

the foreskin. The health care provider will inform you when the foreskin can safely be retracted. By age 3 years in the majority of boys, the foreskin can be retracted easily without causing pain or trauma. For others, the foreskin is not retractable until adolescence. As soon as the foreskin is partly retractable and the child is old enough, he can be taught self-care. Once healed, the circumcised penis does not require any special care other than cleansing with diaper changes.

- The infant's skin should be allowed to dry completely before applying another diaper.
- Exposing the buttocks to air can help dry up diaper rash. Because bacteria thrive in moist dark areas, exposing the skin to dry air decreases bacterial proliferation. Zinc oxide ointments can be used to protect the infant's skin from moisture and further excoriation.

cope with infant care, role changes, altered lifestyle, and changes in family structure resulting from the addition of a new baby.

Parents must be helped to anticipate events during the transition from birthing facility to home. This is especially important for first-time parents. Even the simplest strategies can provide enormous support. Printed materials reinforcing education topics are helpful, as is a list of available community resources and websites that provide reliable information about child care. Classes in the prenatal period or during the postpartum stay are helpful. Instructions for the first days at home include relevant topics such as activities of daily living, dealing with visitors, and activity and rest.

Interpretation of Crying and Use of Quieting Techniques.

Crying is an infant's first social communication. Some babies cry more than others, but all babies cry. They cry to communicate that they are hungry, uncomfortable, wet, ill, or bored and sometimes for no apparent reason at all. The longer parents are around their infants, the easier it becomes to interpret the meaning of infant cries and to respond appropriately. Many infants have a fussy period during the day, often in the late afternoon or early evening when everyone is naturally tired. Environmental tension adds to the length and intensity of crying spells. Babies also have periods of vigorous crying when no comforting can help. These periods of crying can last for long stretches until the infants seem to cry themselves to sleep. The nurse informs new parents that time and infant maturation will take care of these types of cries. Many hospitals distribute a DVD on infant crying to new parents. The Period of PURPLE Crying is an example (Box 24-5). It is intended to help parents understand that crying is normal and help them cope with infant crying. If parents have greater understanding of infant crying, they may be less likely to inflict harm such as occurs with shaken-baby syndrome.

Nurses should instruct new parents about strategies to calm a crying or fussy baby. Certain types of sensory stimulation can calm and quiet infants and help them get to sleep. Important characteristics of this sensory stimulation—whether tactile, vestibular, auditory, or visual—appear to be that the

BOX 24-5 The Period of PURPLE Crying

The *Period of PURPLE Crying* is a program to educate new parents about infant crying and the dangers of shaking a baby. Each letter in the acronym *PURPLE* represents key concepts:

P = Peak of crying. Your baby may cry more each week—the most in month 2, then less in months 3 to 5.

U = Unexpected. Crying can come and go and you don't know why.

R = Resists soothing. Your baby may not stop crying no matter what you try.

P = Pain-like face. Crying babies may look like they are in pain, even when they are not.

L = Long lasting. Crying can last as much as 5 hours a day, or more.

E = Evening. Your baby may cry more in the later afternoon and evening.

From Barr, RG and Barr, M: *The period of PURPLE crying*. Available at www.PURPLEcrying.info.

stimulation is mild, slow, rhythmic, and consistently and regularly presented. Tactile stimulation can include skin-to-skin contact, warmth, patting, and back rubbing. Swaddling provides widespread and constant tactile stimulation and a sense of security. Vestibular stimulation is especially effective and can be accomplished by mild rhythmic movement such as rocking or by holding the infant upright, as on the parent's shoulder. Some infants respond to being held in a body carrier. Rhythmic sounds can provide auditory stimulation; parents can use devices that provide white noise or sounds resembling the mother's heartbeat.

Recognizing Signs of Illness. In addition to explaining the need for well-baby follow-up visits, the nurse should discuss with parents the signs of illness in newborns (see Teaching for Self-Management: Signs of Illness). Of particular importance is the parents' assessment of jaundice in newborns discharged early. Parents should be advised to call their pediatric care provider immediately if they notice increasing jaundice or signs of illness.

TEACHING FOR SELF-MANAGEMENT

Signs of Illness

Notify the pediatric health care provider if any of these signs occur:

- Fever: temperature greater than 38° C (100.4° F) axillary; also a continual rise in temperature (Note: Tympanic [ear] thermometers are not recommended for infants younger than 3 months.)
- Hypothermia: temperature less than 36.5° C (97.7° F) axillary
- Poor feeding or little interest in food: refusal to eat for two feedings in a row
- Vomiting: more than one episode of forceful vomiting or frequent vomiting (over a 6-hour period)
- Diarrhea: two consecutive green, watery stools (Note: Stools of breastfed infants are normally looser than stools of formula-fed infants. Diarrhea leaves a water ring around the stool, whereas breastfed stools do not.)
- Decreased bowel movement: in a breastfed infant, fewer than three stools per day; in a formula-fed infant, less than one stool every other day
- Decreased urination: fewer than six to eight wet diapers per day after 3 to 4 days of age
- Breathing difficulties: labored breathing with flared nostrils or absence of breathing for more than 15 seconds (Note: A newborn's breathing is normally irregular and between 30 to 40 breaths/min. Count the breaths for a full minute.)
- Cyanosis (bluish skin color) whether accompanying a feeding or not
- Lethargy: sleepiness, difficulty waking, or periods of sleep longer than 6 hours (most newborns sleep for short periods, usually from 1 to 4 hours, and wake to be fed)
- Inconsolable crying (attempts to quiet not effective) or continuous high-pitched cry
- Bleeding or purulent (yellowish) drainage from umbilical cord or circumcision; foul odor or redness at the site
- Drainage from the eyes

KEY POINTS

- Assessment of the newborn requires data from the prenatal, intrapartal, and postnatal periods.
- The immediate assessment of the newborn includes Apgar scoring and a general evaluation of physical status.
- Knowledge of biologic and behavioral characteristics is essential for guiding assessment and interpreting data.
- Gestational age assessment provides important information for predicting risks and guiding care management.
- Nursing care immediately after birth includes maintaining an open airway, preventing heat loss, and promoting parent-infant interaction.
- Providing a protective environment is a key responsibility of the nurse and includes such measures as careful identification procedures, support of physiologic functions, and ways to prevent infection.
- The newborn has social and physical needs.
- Newborns require careful assessment for physiologic and behavioral manifestations of pain.
- Nonpharmacologic and pharmacologic measures are used to reduce infant pain.
- Before hospital discharge, nurses provide anticipatory guidance for parents regarding feeding and elimination patterns; positioning and holding; comfort measures; car seat safety; bathing, skin care, cord care, and nail care; and signs of illness.
- All parents should have instruction in infant CPR.

Newborn Nutrition and Feeding

Kathryn R. Alden

ⓔ <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Describe current recommendations for infant feeding.
- Explain the nurse's role in helping families choose an infant feeding method.
- Discuss benefits of breastfeeding for infants, mothers, families, and society.
- Describe nutritional needs of infants.
- Describe anatomic and physiologic aspects of breastfeeding.
- Recognize newborn feeding-readiness cues.
- Explain maternal and infant indicators of effective breastfeeding.
- Examine nursing interventions to facilitate and promote successful breastfeeding.
- Analyze common problems associated with breastfeeding and interventions to help resolve them.
- Compare powdered, concentrated, and ready-to-use forms of commercial infant formulas.
- Develop a teaching plan for the formula-feeding family.

Good nutrition in infancy fosters optimal growth and development. Infant feeding is more than providing nutrition; it is an opportunity for social, psychologic, and even educational interaction between parent and infant. It can establish a basis for developing good eating habits that last a lifetime.

Through preconception and prenatal education and counseling nurses play an instrumental role in helping parents make an informed decision about infant feeding. Scientific evidence is clear that human milk provides the best nutrition for infants, and parents should be strongly encouraged to choose breastfeeding (American Academy of Pediatrics [AAP] Section on Breastfeeding, 2012). Although many consider commercial infant formula to be equivalent to breast milk, this belief is erroneous. Human milk is the gold standard for infant nutrition. It is species specific, uniquely designed to meet the needs of human infants. The composition of human milk changes to meet the nutritional needs of growing infants. It is highly complex, with antiinfective and nutritional components combined with growth factors, enzymes that aid in digestion and absorption of nutrients, and fatty acids that promote brain growth and development. Infant formulas are usually adequate in providing nutrition to maintain infant growth and development within normal limits, but they are not equivalent to human milk.

Breastfeeding is defined as the transfer of human milk from the mother to the infant; the infant receives milk directly from the mother's breast. *Exclusive breastfeeding* means that the infant receives no other liquid or solid food (AAP Section on Breastfeeding, 2012). If the infant is fed expressed breast milk from the mother or a donor milk bank, it is called *human milk feeding*.

Whether the parents choose breastfeeding, human milk feeding, or formula feeding, nurses provide support and ongoing education. Parent education and care management are necessarily based on current research findings and standards of practice. Nurses and lactation consultants (who are most often nurses) provide education, assistance, and support for mothers, infants, and families prior to discharge from the birthing facility. After discharge nurses and lactation consultants in primary care and community health settings provide ongoing support and assistance to promote optimal feeding practices and positive health outcomes.

This chapter focuses on meeting nutritional needs for normal growth and development from birth to 6 months, with emphasis on the neonatal period when feeding practices and patterns are established. Breastfeeding and formula feeding are addressed. Information on breastfeeding is focused on the direct transfer of milk from mother to infant.

RECOMMENDED INFANT NUTRITION

The American Academy of Pediatrics (AAP) recommends exclusive breastfeeding for the first 6 months of life and that breastfeeding continues as complementary foods are introduced. Breastfeeding should continue for 1 year and thereafter as desired by the mother and her infant (AAP Section on Breastfeeding, 2012). According to the World Health Organization (WHO, 2013), infants should be exclusively breastfed for 6 months, receive safe and nutritionally adequate complementary foods beginning at 6 months, and continue breastfeeding until age 2 or beyond.

Exclusive breastfeeding for the first 6 months of life is also recommended by other professional health care organizations such as the American Academy of Family Physicians (AAFP, 2012), Academy of Breastfeeding Medicine (ABM Board of Directors, 2008), the American College of Obstetricians and Gynecologists (ACOG Committee on Health Care for Underserved Women and Committee on Obstetric Practice, 2007), and the American Dietetic Association (ADA, 2009). The Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN, 2007) actively supports breastfeeding as the ideal form of infant nutrition and provides guidelines for nurses in promoting breastfeeding and supporting breastfeeding families.

Breastfeeding Rates

Breastfeeding rates in the United States have risen steadily over the past decade. The Centers for Disease Control and Prevention (CDC, 2014) reported that the U.S. breastfeeding initiation rate in 2011 was 79%, which is the highest ever reported. The 6-month breastfeeding rate was 49%, and the 12-month rate was 27%. The rate of exclusive breastfeeding at 3 months was 40.7% and at 6 months, 18.8%. The increase in breastfeeding rates may be related to the increase in the percentage of facilities with at least 90% of mothers and newborns having skin-to-skin contact after birth and in the percentage of facilities with at least 90% of mothers and newborns rooming-in. Early skin-to-skin contact, which places the neonate directly on the mother's chest after birth, fosters the initiation of breastfeeding during the first hour. Rooming-in helps mothers to establish breastfeeding and to learn to recognize infant hunger cues (CDC).

In spite of the increases in breastfeeding rates, the United States continues to fall short of the *Healthy People 2020* goals of 81% of infants ever breastfed, 60.6% breastfeeding at 6 months, and 34.1% at 12 months. Goals for exclusive breastfeeding are 46.2% through 3 months and 25.5% through 6 months (U.S. Department of Health and Human Services [USDHHS], 2010b).

Trends remain unchanged in breastfeeding rates among minority groups in the United States. The lowest breastfeeding rates are among non-Hispanic black women (Allen, Li, Scanlon, et al., 2013; Jensen, 2012), although the overall percentage of

non-Hispanic black women who breastfeed has increased in recent years from 47.4% in 2000 to 58.9% in 2008 (Allen et al.) The minority group most likely to breastfeed is Hispanic women.

Historically, breastfeeding rates have been lower among women participating in the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC). However, that trend appears to be changing as breastfeeding rates in this population of women increased from 63.1% in 2010 to 67.1% in 2012 (Johnson, Thorn, McGill, et al., 2013).

Benefits of Breastfeeding

Extensive evidence exists concerning the health benefits of breastfeeding and human milk for infants, with some of the benefits extending into adulthood (Table 25-1). These benefits are optimized when infants are breastfed exclusively and when the duration of breastfeeding is increased (Mass, 2011). The evidence supporting breastfeeding as the ideal form of infant nutrition is so strong that health care professionals may need to present information about it from two perspectives: benefits of and risks of not breastfeeding (Spatz & Lessen, 2011).

Breastfeeding is associated with health benefits for mothers (see Table 25-1). The benefits are increased with the number of children who were breastfed and the total length of time of lactation.

The psychologic benefits for mothers include enhanced bonding and attachment. For many women breastfeeding is associated with a sense of empowerment in the ability to provide nutrition for the infant.

Breastfeeding is convenient. The milk is ready to feed and at the proper temperature. In most cases there is no need for bottles or other equipment.

The economic benefits of breastfeeding affect families, employers, insurers, and the entire nation. Because infant formula is expensive, breastfeeding represents a significant savings for families. It reduces health care costs and decreases employee absenteeism. It has been estimated that the United States could save \$13 billion per year, and more than 900 infant deaths could be prevented if 90% of infants were breastfed exclusively for 6 months (Bartick & Reinhold, 2010).

TABLE 25-1 Benefits of Breastfeeding

BENEFITS FOR THE INFANT	BENEFITS FOR THE MOTHER	BENEFITS TO FAMILIES AND SOCIETY
<ul style="list-style-type: none"> Reduced risk for: <ul style="list-style-type: none"> Nonspecific gastrointestinal infections Celiac disease Childhood inflammatory bowel disease Necrotizing enterocolitis in preterm infants Clinical asthma, atopic dermatitis, and eczema Lower respiratory tract infection Otitis media SIDS Obesity in adolescence and adulthood Types 1 and 2 diabetes Acute lymphocytic and myeloid leukemia Enhanced neurodevelopmental outcomes, especially in preterm infants 	<ul style="list-style-type: none"> Decreased postpartum bleeding and more rapid uterine involution Reduced risk for: <ul style="list-style-type: none"> Ovarian cancer and breast cancer (primarily premenopausal) Type 2 diabetes Hypertension, hypercholesterolemia, and cardiovascular disease Rheumatoid arthritis Unique bonding experience Increased maternal role attainment 	<ul style="list-style-type: none"> Convenient; ready to feed No bottles or other necessary equipment Less expensive than infant formula Reduced annual health care costs Less parental absence from work because of ill infant Reduced environmental burden related to disposal of formula packaging and equipment

A summary of the Agency for Healthcare Research and Quality's evidence report on breastfeeding in developed countries. *Breastfeeding Medicine*, 4(Suppl 1), S17-S30; Stuebe, A. (2009). The risks of not breastfeeding for mothers and infants. *Reviews in Obstetrics and Gynecology*, 2(4), 222-231.

Breastfeeding has environmental benefits. It reduces the waste that is deposited in landfills, including formula packaging, bottles, nipples, and other equipment. There is no need for fuel to prepare or transport human milk, which saves energy resources (USDHHS, 2011).

CHOOSING AN INFANT FEEDING METHOD

For most women there is a clear choice to either breastfeed or formula feed. In some cases women decide to combine breastfeeding and formula feeding. However, this practice can be associated with a shorter duration of breastfeeding (Holmes, Auinger, & Howard, 2011). Some women want their infants to receive breast milk but prefer not to feed directly from their breasts. These women express their milk and bottle feed it to their infants.

Breastfeeding

Women most often choose to breastfeed because they are aware of the benefits to the infant (Nelson, 2012). This reinforces the importance of prenatal education about the numerous benefits of breastfeeding.

Breastfeeding is a natural extension of pregnancy and childbirth; it is much more than simply a means of supplying nutrition. Many women seek the unique bonding experience between mother and infant that is characteristic of breastfeeding.

Women tend to select the same method of infant feeding for each of their children. If the first child was breastfed, subsequent children will likely also be breastfed.

Partner and family support is a major factor in the mother's decision to breastfeed. Women who perceive their partners to prefer breastfeeding are more likely to breastfeed. Women are more likely to breastfeed successfully when partners and family members are positive about breastfeeding and have the skills to support it.

Cultural factors influence infant feeding decisions. For example, in the Hispanic culture breastfeeding is the norm, whereas formula feeding is more common among African-American families.

The decision to breastfeed exclusively is related to the mother's knowledge about the health benefits to the infant and her comfort level with breastfeeding in social settings (Stuebe & Bonuck, 2011). The likelihood that women will breastfeed exclusively may be greater if they made the decision during pregnancy (Tenfelde, Finnegan, & Hill, 2011).

There appears to be a relationship between maternal weight and infant feeding decisions. Women who are overweight or obese are less likely to breastfeed than women who are underweight or of average weight (Mehta, Siega-Riz, Herring, et al., 2011).

Other factors influence decisions about infant nutrition. Social and systemic factors create obstacles or barriers to breastfeeding among women in the United States. These include a lack of broad social support for breastfeeding and the widespread marketing by infant formula companies. In addition, there is a lack of prenatal breastfeeding education for expectant parents and insufficient training and education of health care professionals about breastfeeding. There is a lack of support for breastfeeding mothers during the first 2 to 3 weeks after birth, when they are most likely to encounter difficulties. In some institutions the policies and practices do not support exclusive breastfeeding (Mass, 2011).

A major obstacle for women is employment and the need to return to work after birth (Mass, 2011). Other common barriers include lack of comfort or uneasiness with breastfeeding, pain, lifestyle incompatibility, discomfort with public breastfeeding, and a lack of formal support (Nelson, 2012).

Formula Feeding

Parents who choose to formula feed often make this decision without complete information and understanding of the benefits of breastfeeding. Even women who are educated about the advantages of breastfeeding may still decide to formula feed. Cultural beliefs and myths and misconceptions about breastfeeding influence women's decision making. Many women see bottle feeding as more convenient or less embarrassing than breastfeeding. Some view formula feeding as a way to ensure that the father, other family members, and daycare providers can feed the baby. Some women lack confidence in their ability to produce breast milk of adequate quantity or quality. Women who have had previous unsuccessful breastfeeding experiences may choose to formula feed subsequent infants. Some women see breastfeeding as incompatible with an active social life, or they think that it will prevent them from going back to work. Modesty issues and societal barriers exist against breastfeeding in public. A major barrier for many women is the influence of family and friends (Nelson, 2012).

Contraindications to Breastfeeding

Breastfeeding is contraindicated in a few circumstances. Newborns who have galactosemia should not receive human milk. Breastfeeding is contraindicated for mothers who are positive for human T-cell lymphotropic virus types I or II and those with untreated brucellosis. Women should not breastfeed if they have active tuberculosis (TB) or if they have active herpes simplex lesions on the breasts. However, neither of these conditions precludes a mother from expressing milk for her infant. Women with active TB can breastfeed when they have been treated for at least 2 weeks and are deemed noninfectious. Varicella that occurs 5 days before or 2 days after birth and acute H1N1 infection require temporary separation of mother and infant. In both instances it is safe for infants to receive expressed milk (AAP Section on Breastfeeding, 2012).

In the United States maternal human immunodeficiency virus (HIV) infection is considered a contraindication for breastfeeding (AAP Section on Breastfeeding, 2012). However, this is not true in other countries. In developing countries where HIV is prevalent, the benefits of breastfeeding for infants outweigh the risk of contracting HIV from infected mothers (WHO, 2013).

CULTURAL INFLUENCES ON INFANT FEEDING

Cultural beliefs and practices are significant influences on infant feeding methods. Although recognized cultural norms exist, one cannot assume that generalized observations about any cultural group hold true for all members of that group. Many regional and ethnic cultures are found within the United States. Dealing effectively with these groups requires that nurses are knowledgeable and sensitive to the cultural factors influencing infant feeding practices.

In general people who have immigrated to the United States from poorer countries often choose to formula feed their infants

because they believe it is a better, more “modern” method or because they want to adapt to U.S. culture and perceive that formula feeding is the custom. Hispanic women who are more acculturated may be less likely to breastfeed and, if they do, tend to breastfeed for a shorter duration (Ahluwalia, D’Angelo, Morrow, & McDonald, 2012).

Breastfeeding beliefs and practices vary across cultures. For example, among the Muslim culture, breastfeeding for 24 months is customary. Before the first feeding rubbing a small piece of softened date on the newborn’s palate is a ritual. Because of the cultural emphasis on privacy and modesty, Muslim women may choose to bottle feed formula or expressed breast milk while in the hospital.

Because of beliefs about the harmful nature or inadequacy of colostrum, some cultures apply restrictions on breastfeeding for a period of days after birth. Such is the case for many cultures in southern Asia, the Pacific Islands, and parts of sub-Saharan Africa. Before the mother’s milk is deemed to be “in,” babies are fed prelacteal food such as honey or clarified butter in the belief that these substances will help clear out meconium. Other cultures begin breastfeeding immediately and offer the breast each time the infant cries.

A common practice among Mexican women is *las dos cosas* (“both things”). This refers to combining breastfeeding and commercial infant formula. It is based on the belief that by combining the two methods, the mother and infant receive the benefits of breastfeeding, and the infant receives the additional vitamins from infant formula (Bartick & Reyes, 2012). This practice can result in problems with milk supply and babies refusing to latch on to the breast, which can lead to early termination of breastfeeding.

Cultural expectations influence breastfeeding patterns and behaviors. In many Western cultures, women are more likely to try to “schedule” feeding sessions. This is in contrast to more frequent breastfeeding in some developing countries where mothers “wear” their babies close against their bodies as they go about daily activities. Those babies have constant or frequent access to the breast to feed on demand (Mohrbacher, 2013).

Some cultures have specific beliefs and practices related to the mother’s intake of foods that foster milk production. Korean mothers often eat seaweed soup and rice to enhance milk production. Among women believe that boiled chicken, rice, and hot water are the only appropriate nourishments during the first postpartum month. The balance between energy forces, hot and cold, or yin and yang is integral to the diet of the lactating mother. Hispanics, Vietnamese, Chinese, East Indians, and Arabs often use this belief in choosing foods. “Hot” foods are considered best for new mothers. This belief does not necessarily relate to the temperature or spiciness of foods. For example, chicken and broccoli are considered “hot,” whereas many fresh fruits and vegetables are considered “cold.” Families often bring desired foods into the health care setting.

NUTRIENT NEEDS

Fluids

During the first 2 days of life the fluid requirement for healthy infants (more than 1500 g) is 60 to 80 ml of water per kilogram of body weight per day. From days 3 to 7 the requirement is

100 to 150 ml/kg/day; from day 8 to day 30 it is 120 to 180 ml/kg/day (Dell, 2011). In general, neither breastfed nor formula-fed infants need to be given water, not even those living in very hot climates. Breast milk contains 87% water, which easily meets fluid requirements. Feeding water to infants can decrease caloric consumption at a time when they are growing rapidly.

Infants have room for little fluctuation in fluid balance and should be monitored closely for fluid intake and water loss. They lose water through excretion of urine and insensibly through respiration. Under normal circumstances they are born with some fluid reserve, and some of the weight loss during the first few days is related to fluid loss. However, in some cases they do not have this fluid reserve, possibly because of inadequate maternal hydration during labor or birth.

Energy

Infants require adequate caloric intake to provide energy for growth, digestion, physical activity, and maintenance of organ metabolic function. Energy needs vary according to age, maturity level, thermal environment, growth rate, health status, and activity level. For the first 3 months the infant needs 110 kcal/kg/day. From 3 months to 6 months the requirement is 100 kcal/kg/day. This level decreases slightly to 95 kcal/kg/day from 6 to 9 months and increases to 100 kcal/kg/day from 9 months to 1 year (AAP Committee on Nutrition, 2009).

Human milk provides an average of 67 kcal/100 ml or 20 kcal/oz. The fat portion of the milk provides the greatest amount of energy. Infant formulas simulate the caloric content of human milk. Usually a standard formula contains 20 kcal/oz, although the composition differs among brands.

Carbohydrate

According to the Institute of Medicine (IOM, 2005), the recommended adequate intake (AI) for carbohydrate in the first 6 months of life is 60 g/day and 95 g/day for the second 6 months. Because newborns have only small hepatic glycogen stores, carbohydrates should provide at least 40% to 50% of the total calories in the diet. Moreover, newborns may have a limited ability to carry out *gluconeogenesis* (the formation of glucose from amino acids and other substrates) and *ketogenesis* (the formation of ketone bodies from fat), the mechanisms that provide alternative sources of energy.

As the primary carbohydrate in human milk and commercially prepared infant formula, lactose is the most abundant carbohydrate in the diet of infants up to age 6 months. Lactose provides calories in an easily available form. Its slow breakdown and absorption also increase calcium absorption. Corn syrup solids or glucose polymers are added to infant formulas to supplement the lactose in the cow’s milk and thereby provide sufficient carbohydrates.

Oligosaccharides, another form of carbohydrate found in breast milk, are critical in the development of microflora in the intestinal tract of the newborn. These prebiotics promote an acidic environment in the intestines, preventing the growth of gram-negative and other pathogenic bacteria, thus increasing the infant’s resistance to gastrointestinal (GI) illness.

Fat

Fats provide a major energy source for infants, supplying as much as 50% of the calories in breast milk and formula. The

recommended AI of fat for infants younger than 6 months is 31 g/day (IOM, 2005). The fat content of human milk is composed of lipids, triglycerides, and cholesterol; cholesterol is an essential element for brain growth. Human milk contains the essential fatty acids (EFAs) linoleic acid and linolenic acid and the long-chain polyunsaturated fatty acids arachidonic acid (ARA) and docosahexaenoic acid (DHA). Fatty acids are important for growth, neurologic development, and visual function. Cow's milk contains fewer of the EFAs and no polyunsaturated fatty acids. Most formula companies add DHA to their products, although there is a lack of evidence supporting the benefit (Lawrence & Lawrence, 2011b). Modified cow's milk is used in most infant formulas, but the milk fat is removed, and another fat source such as corn oil, which the infant can digest and absorb, is added in its place. If whole milk or evaporated milk without added carbohydrate is fed to infants, the resulting fecal loss of fat (and therefore loss of energy) can be excessive because the milk moves through the infant's intestines too quickly for adequate absorption to take place. This can lead to poor weight gain.

Protein

High-quality protein from breast milk, infant formula, or other complementary foods is necessary for infant growth. The protein requirement per unit of body weight is greater in the newborn period than at any other time of life. For infants younger than 6 months the recommended AI for protein is 9.1 g/day (IOM, 2005).

Human milk contains the two proteins whey and casein in a ratio of approximately 70:30 compared with the ratio of 20:80 in most cow's milk-based formulas (Blackburn, 2013). This whey-to-casein ratio in human milk makes it more easily digestible and produces the soft stools seen in breastfed infants. The primary whey protein in human milk is α -lactalbumin; this protein is high in essential amino acids needed for growth. The whey protein lactoferrin in human milk has iron-binding capabilities and bacteriostatic properties, particularly against gram-positive and gram-negative aerobes, anaerobes, and yeasts. The casein in human milk enhances the absorption of iron, thus preventing iron-dependent bacteria from proliferating in the GI tract (Lawrence & Lawrence, 2011a). The amino acid components of human milk are uniquely suited to the newborn's metabolic capabilities. For example, cystine and taurine levels are high, whereas phenylalanine and methionine levels are low.

Vitamins

With the exception of vitamin D, human milk contains all of the vitamins required for infant nutrition, with individual variations based on maternal diet and genetic differences. Vitamins are added to cow's-milk formulas to resemble levels found in breast milk. Although cow's milk contains adequate amounts of vitamins A and B complex, vitamin C (ascorbic acid), vitamin E, and vitamin D must be added.

Vitamin D facilitates intestinal absorption of calcium and phosphorus, bone mineralization, and calcium resorption from bone. According to the AAP, all infants who are breastfed or partially breastfed should receive 400 International Units of vitamin D daily, beginning the first few days of life. Nonbreastfeeding infants and older children who consume less than 1 quart per day of vitamin D-fortified milk should also receive 400 International Units of vitamin D each day (Wagner,

Grier, & AAP Section on Breastfeeding and Committee on Nutrition, 2008).

Vitamin K, required for blood coagulation, is produced by intestinal bacteria. However, the gut is sterile at birth, and a few days are required for intestinal flora to become established and produce vitamin K. To prevent hemorrhagic problems in the newborn an injection of vitamin K is given at birth to all newborns in the United States and Canada, regardless of feeding method (AAP Section on Breastfeeding, 2012; McMillan & Canadian Paediatric Society Fetus and Newborn Committee) (1997, reaffirmed 2014).

The breastfed infant's vitamin B₁₂ intake depends on the mother's dietary intake and stores. Mothers who are on strict vegetarian (vegan) diets and those who consume few dairy products, eggs, or meat are at risk for vitamin B₁₂ deficiency. Mothers who have had bariatric surgery are also at risk for vitamin B₁₂ deficiency. Breastfeeding infants may need vitamin B₁₂ supplements in these instances.

Minerals

The mineral content of commercial infant formula is designed to reflect that of breast milk. Unmodified cow's milk is much higher in mineral content than human milk, which also makes it unsuitable for infants during the first year of life. Minerals are typically highest in human milk during the first few days after birth and decrease slightly throughout lactation.

The ratio of calcium to phosphorus in human milk is 2:1, an optimal proportion for bone mineralization. Although cow's milk is high in calcium, the calcium-to-phosphorus ratio is low, resulting in decreased calcium absorption. Consequently young infants fed unmodified cow's milk are at risk for hypocalcemia, seizures, and tetany. The calcium-to-phosphorus ratio in commercial infant formula is between that of human milk and cow's milk.

Iron levels are low in all types of milk; however, iron from human milk is better absorbed than iron from cow's milk, iron-fortified formula, or infant cereals. Breastfed infants draw on iron reserves deposited in utero and benefit from the high lactose and vitamin C levels in human milk that facilitate iron absorption. Full-term infants have enough iron stores from the mother to last for the first 4 months. After 4 months of age, infants who are exclusively breastfed are at risk for iron deficiency. The AAP recommends giving exclusively breastfed infants an iron supplement (1 mg/kg/day) beginning at 4 months and continuing until the infant is consuming iron-containing complementary foods such as iron-fortified cereals. Infants who are partially breastfed should receive the same iron supplement if more than half of their daily feedings consist of human milk and they are not consuming iron-rich foods. Formula-feeding infants should receive an iron-fortified commercial infant formula until 12 months of age. Infants younger than 1 year should never be fed whole milk (Baker, Greer, & AAP Committee on Nutrition, 2010).

Fluoride levels in human milk and commercial formulas are low. This mineral, which is important in preventing dental caries, can cause spotting of the permanent teeth (fluorosis) in excess amounts. Experts recommend that no fluoride supplements are given to infants younger than 6 months. From 6 months to 3 years, fluoride supplements are based on the concentration of fluoride in the water supply (AAP Section on Breastfeeding, 2012).

ANATOMY AND PHYSIOLOGY OF LACTATION

Anatomy of the Lactating Breast

Each female breast is composed of approximately 15 to 20 segments (lobes) embedded in fat and connective tissues and well supplied with blood vessels, lymphatic vessels, and nerves (Fig. 25-1). Within each lobe is glandular tissue consisting of alveoli, the milk-producing cells, surrounded by myoepithelial cells that contract to send the milk forward to the nipple during milk ejection. Each nipple has multiple pores that transfer milk to the suckling infant. The ratio of glandular to adipose tissue in the lactating breast is approximately 2:1 compared with a 1:1 ratio in the nonlactating breast. Within each breast is a complex, intertwining network of milk ducts that transport milk from the alveoli to the nipple. The milk ducts dilate and expand at milk ejection (Fig. 25-2).

The size and shape of the breast are not accurate indicators of its ability to produce milk. Although nearly every woman can lactate, a small number have insufficient mammary gland development to breastfeed their infants exclusively. Typically these women experience few breast changes during puberty or early pregnancy. In some cases they are still able to produce some breast milk, although the quantity is not likely to be sufficient to meet the nutritional needs of the infant. These mothers can offer supplemental nutrition to support optimal infant growth.

Because of the effects of estrogen, progesterone, human placental lactogen, and other hormones of pregnancy, changes

occur in the breasts in preparation for lactation. Breasts increase in size due to growth of glandular and adipose tissue. Blood flow to the breasts nearly doubles during pregnancy. Sensitivity of the breasts increases, and veins become more prominent. The nipples become more erect, and the areolae darken. Nipples and areolae enlarge. Around week 16 of gestation the alveoli begin producing prepartum milk, or *colostrum*. Montgomery glands on the areola enlarge. The oily substance secreted by these sebaceous glands helps provide protection against the mechanical stress of sucking and invasion by pathogens. The odor of the secretions can be a means of communication with the infant.

Lactogenesis

After the mother gives birth a precipitous fall in progesterone triggers the release of prolactin from the anterior pituitary gland. During pregnancy prolactin prepares the breasts to secrete milk and during lactation to synthesize and secrete milk. Prolactin levels are highest during the first 10 days after birth, gradually declining over time but remaining above baseline levels for the duration of lactation. Prolactin is produced in response to infant suckling and emptying of the breasts (Fig. 25-3, A). Milk production is a **supply-meets-demand system** (i.e., as milk is removed

FIG 25-1 Anatomy of the lactating breast. (Courtesy Medela, Inc., McHenry, IL.)

FIG 25-3 Maternal breastfeeding reflexes. A, Milk production. B, Milk ejection (let-down).

from the breast, more is produced). Incomplete removal of milk from the breasts can lead to decreased milk supply.

Oxytocin is essential to lactation. As the nipple is stimulated by the suckling infant, the posterior pituitary is prompted by the hypothalamus to produce oxytocin. This hormone is responsible for the **milk ejection reflex (MER)**, or **let-down reflex** (see Fig. 25-3, B). The myoepithelial cells surrounding the alveoli respond to oxytocin by contracting and sending the milk forward through the ducts to the nipple. The MER is triggered multiple times during a feeding session. Thoughts, sights, sounds, or odors that the mother associates with her baby (or other babies) such as hearing the baby cry can trigger the MER. Many women report a tingling “pins and needles” sensation in the breasts as milk ejection occurs, although some mothers can detect milk ejection only by observing the sucking and swallowing of the infant. The MER also can occur during sexual activity because oxytocin is released during orgasm. The reflex can be inhibited by fear, stress, and alcohol consumption.

Oxytocin is the same hormone that stimulates uterine contractions during labor. Consequently, the MER can be triggered during labor, as evidenced by leakage of colostrum. This reflex readies the breasts for immediate feeding by the infant after birth. Oxytocin has the important function of contracting the mother’s uterus after birth to control postpartum bleeding and promote uterine involution. Thus mothers who breastfeed are at decreased risk for postpartum hemorrhage. Uterine contractions that occur with breastfeeding are often painful during and after feeding for the first 3 to 5 days. These afterpains are more common in multiparas and tend to resolve completely within 1 week after birth.

Prolactin and oxytocin have been called the “mothering hormones” because they affect the postpartum woman’s emotions and her physical state. Many women report feeling thirsty or very relaxed during breastfeeding, probably as a result of these hormones.

The nipple-erection reflex is an important part of lactation. When the infant cries, suckles, or rubs against the breast, the nipple becomes erect, which aids in the propulsion of milk through the ducts to the nipple pores. Nipple sizes, shapes, and ability to become erect vary with individuals. Some women have flat or inverted nipples that do not become erect with stimulation; these women likely need assistance with effective latch. Their infants should not be offered bottles or pacifiers until breastfeeding is well established.

Uniqueness of Human Milk

Human milk is the ideal food for human infants. It is a dynamic substance with a composition that changes to meet the changing nutritional and immunologic needs of the growing infant. Breast milk is specific to the needs of each infant; for example, the milk produced by mothers of preterm infants differs in composition from that of mothers who give birth at term.

Human milk contains immunologically active components that provide some protection against a broad spectrum of bacterial, viral, and protozoal infections. The major immunoglobulin (Ig) in human milk is secretory IgA; IgG, IgM, IgD, and IgE are also present. Human milk also contains T and B lymphocytes, epidermal growth factor, cytokines, interleukins, bifidus factor, complement (C3 and C4), and lactoferrin, all of which

have a specific role in preventing localized and systemic bacterial and viral infections (Lawrence & Lawrence, 2011a).

Human milk composition and volumes vary according to the stage of lactation. In **lactogenesis stage I**, beginning at approximately 16 to 18 weeks of pregnancy, the breasts prepare for milk production by producing prepartum milk, or colostrum. **Stage II of lactogenesis** begins with birth as progesterone levels drop sharply when the placenta is removed. For the first 2 to 3 days after birth, the baby receives colostrum, a clear, yellowish fluid that is rich in antibodies and higher in protein but lower in fat than mature milk. The high protein level of colostrum facilitates binding of bilirubin, and the laxative action of colostrum promotes early passage of meconium. Colostrum is important in establishing normal *Lactobacillus bifidus* flora in the infant’s digestive tract. It gradually changes to transitional milk. By 3 to 5 days after birth the woman experiences a noticeable increase in milk production. This is often referred to as *the milk coming in*. Breast milk continues to change in composition for approximately 10 days, when the mature milk is established. This is **stage III of lactogenesis** (Lawrence & Lawrence, 2011a).

The composition of human milk changes over time as the infant grows and develops. Fat is the most variable component of human milk with changes in concentration over a feeding, over a 24-hour period, and across time. Variations in fat content exist between breasts and among individuals (Lawrence & Lawrence, 2011a). During each feeding the concentration of fat gradually increases from the lower fat foremilk to the richer hindmilk. The hindmilk contains the denser calories from fat necessary for ensuring optimal growth and contentment between feedings. Because of this changing composition of human milk during each feeding, breastfeeding the infant long enough to supply a balanced feeding is important.

Milk production gradually increases as the baby grows. Infants have fairly predictable **growth spurts** (at approximately 10 days, 3 weeks, 6 weeks, 3 months, and 6 months), when more frequent feedings stimulate increased milk production. These growth spurts usually last 24 to 48 hours, after which the infants resume their usual feeding pattern as the mother’s milk supply increases.

CARE MANAGEMENT

Supporting Breastfeeding Mothers and Infants

The key to encouraging mothers to breastfeed is education and anticipatory guidance, beginning as early as possible during and even before pregnancy. Each encounter with an expectant mother is an opportunity to educate, dispel myths, clarify misinformation, and address concerns. Prenatal education and preparation for breastfeeding influence feeding decisions, breastfeeding success, and the amount of time that women breastfeed. Prenatal preparation ideally includes the father of the baby, partner, or another significant support person and provides information about benefits of breastfeeding and how he or she can participate in infant care and nurturing.

Connecting expectant mothers with women from similar backgrounds who are breastfeeding or have successfully breastfed is often helpful. Nursing mothers’ support groups such as La Leche League provide information about breastfeeding

along with opportunities for breastfeeding mothers to interact with one another and share concerns (Fig. 25-4). Community-based peer counseling programs such as those instituted by the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) are beneficial (Chapman & Perez-Escamilla, 2012 ; Wambach, Aaronson, Breedlove, et al., 2011).

For women with limited access to health care, the postpartum period may provide the first opportunity for education about breastfeeding. Even women who have indicated the desire to formula feed can benefit from information about the benefits of breastfeeding. Offering these women the chance to try breastfeeding with the assistance of a nurse or lactation consultant can influence a change in infant feeding practices.

Promoting feelings of competence and confidence in the breastfeeding mother and reinforcing the unequalled contribution she is making toward the health and well-being of her infant are the responsibility of the nurse and other health care professionals. The first 2 weeks of breastfeeding can be the most challenging as mothers are adjusting to life with a newborn, the baby is learning to latch on and feed effectively, and the mother may be experiencing nipple or breast discomfort. This is a time when support is critical. Primiparous women are most likely to experience early breastfeeding problems, which often result in less exclusive breastfeeding and shorter duration of breastfeeding (Chantry, 2011). Anticipatory guidance during the prenatal period and especially during the hospital stay after birth can provide the mother with information and increase her confidence in her ability to successfully breastfeed her infant. New mothers need access to lactation support following discharge through primary care offices or outpatient lactation services. Peer support is also helpful.

The most common reasons for breastfeeding cessation are insufficient milk supply, painful nipples, and problems getting the infant to feed (Lauwers & Swisher, 2011; Lawrence & Lawrence, 2011a; Wagner, Chantry, Dewey, & Nommsen-Rivers, 2013). Early and ongoing assistance and support from health care professionals to prevent and address problems with breastfeeding can help promote a successful and satisfying breastfeeding experience for mothers and infants. Many health care agencies have certified lactation consultants on staff. These health care

FIG 25-4 Breastfeeding mothers support group with lactation consultant. (Courtesy Shannon Perry, Phoenix, AZ.)

professionals, who are usually nurses, have specialized training and experience in helping breastfeeding mothers and infants.

The U.S. Breastfeeding Committee (USBC, 2010a) has identified key competencies for health care professionals related to breastfeeding care and services. The competencies include knowledge, skills, and attitudes to promote and support breastfeeding. The USBC identifies specific competencies for those who provide more “hands-on” care (e.g., nurses and lactation consultants). The competencies are to “assist in early initiation of breastfeeding, assess the lactating breast, perform an infant feeding observation, recognize normal and abnormal infant feeding patterns, and develop and appropriately communicate a breastfeeding care plan” (USBC, 2010a, p. 5).

All parents are entitled to a birthing environment in which breastfeeding is promoted and supported. The Baby-Friendly Hospital Initiative (BFHI), sponsored by the WHO and UNICEF, was founded in 1991 to encourage institutions to offer optimal levels of care for lactating mothers. When a hospital achieves the “Ten Steps to Successful Breastfeeding for Hospitals,” it is recognized as a Baby-Friendly hospital (Box 25-1). As of December 2013, 172 hospitals and birthing centers in the United States were designated as Baby-Friendly (Baby-Friendly USA, 2013), although many hospitals and birthing facilities are working toward the designation. Approximately 7% of live births in the United States occur at Baby-Friendly facilities (CDC, 2013). More than 20,000 facilities in more than 150 countries have achieved Baby-Friendly status (BFUSA). The Breastfeeding Committee for Canada (2014) reported that 7 hospitals or birthing centers and 17 community health services have achieved Baby-Friendly designation. Women are more likely to achieve their goals for exclusive breastfeeding if they give birth in facilities where all or most of the 10 steps are in place (Perrine, Scanlon, Li, et al., 2012).

The Joint Commission (TJC) issued a set of Perinatal Core Measures that includes exclusive breast milk feeding. In implementing the core measures, hospitals strive to improve their adherence to

BOX 25-1 10 Steps to Successful Breastfeeding for Hospitals

1. Have a written breastfeeding policy that is communicated routinely to all health care staff.
2. Train all health care staff in skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breastfeeding.
4. Help mothers initiate breastfeeding within ½ hour of birth.
5. Show mothers how to breastfeed and maintain lactation, even if they should be separated from their infants.
6. Give newborn infants no food or drink other than breast milk unless medically indicated.
7. Practice rooming-in (i.e., allow mothers and infants to remain together 24 hours a day).
8. Encourage breastfeeding on demand.
9. Give no artificial teats or pacifiers (also called dummies or soothers) to breastfeeding infants.
10. Foster the establishment of breastfeeding support groups and refer mothers to them on discharge from the hospital or clinic.

From Baby-Friendly USA (BFHI USA). (2012). *The ten steps to successful breastfeeding*. Available at www.babyfriendlyusa.org/about-us/baby-friendly-hospital-initiative/the-ten-steps.

evidence-based best practices that can result in increased rates of exclusive breastfeeding (TJC, 2012; USBC, 2010b). Care management of the breastfeeding mother and infant requires that nurses and other health care professionals are knowledgeable about the benefits and basic anatomic and physiologic aspects of breastfeeding. They also need to know how to help the mother with feedings and discuss interventions for common problems. Ongoing support of the mother enhances her self-confidence and promotes a satisfying and successful breastfeeding experience. Mothers should be encouraged to ask for help with breastfeeding, especially while they are in the hospital. Primiparas are likely to need the most assistance and in many facilities are routinely seen by lactation consultants.

The mother needs to understand infant behaviors in relation to breastfeeding and recognize signs that the baby is ready to feed. Infants exhibit **feeding-readiness cues** or early signs of hunger. Instead of waiting to feed until the infant is crying in a distraught manner or withdrawing into sleep, the mother should attempt to breastfeed when the baby exhibits feeding cues (see Evidence-Based Practice box):

- Hand-to-mouth or hand-to-hand movements
- Sucking motions
- Rooting reflex—infant moves toward whatever touches the area around the mouth and attempts to suck
- Mouthing

EVIDENCE-BASED PRACTICE

Maternal Feeding Styles and Childhood Obesity

Ask the Question

Does caregiver responsiveness to infant feeding cues have an effect on obesity in early childhood and beyond?

Search for the Evidence

Critical Appraisal of the Evidence

- Childhood obesity can have its roots in the feeding patterns established in infancy. This research field for primary prevention of obesity is new, and many infant feeding studies are in the pipeline.
- Overfeeding can impair the infant's ability to self-regulate. Infants whose caregivers are responsive to an infant's hunger and satiety (full) cues are significantly less likely to be overweight (DiSantis, Hodges, Johnson, & Fisher, 2011).
- Discordant responsiveness occurs when the caregiver perceives that the infant cannot recognize hunger or satiety. Restrictive feeding style is associated with maternal fear of causing obesity. Pressuring feeding style is associated with caregiver concern that the infant has poor appetite and will be underweight (Gross, Mendelsohn, Fierman, & Messito, 2011).
- Low-income, food-insecure mothers are more likely to be discordant, either restrictive or pressuring, than food-secure mothers (Gross, Mendelsohn, Fierman, et al., 2012). Authoritative parenting style is associated with pressuring to eat (Collins, Duncanson, & Burrows, 2014).

Apply the Evidence: Nursing Implications

- Parental education in infant hunger and satiety cues should ideally begin in prenatal education classes, and be reinforced intensively during the postpartum period. The nurse should point out the infant cues, and praise the parents for appropriate responsiveness.
- Videos and printed material, as well as warm lines, should be made available to new parents. Specific suggestions as to how much formula to feed initially and as the infant grows, and how voiding and stool patterns and weight gain reflect adequate nutrition can provide education guidelines.
- Assessing for familial and cultural beliefs enables the nurse to address parental and extended family concerns. The nurse can address how the new mother might respond to well-meaning but incorrect comments from family and strangers.

- Education regarding the various newborn cries and their possible reasons can reassure parents and their extended families that feeding should not be the first and only option.
- Breastfed infants are less likely to be overfed than infants who are formula fed.
- Nurses can advocate on a local and national level to eliminate food insecurity.

Quality and Safety Competencies: Evidence-Based Practice* Knowledge

Describe EBP to include the components of research evidence, clinical expertise, and client/family values.

Parental education about correctly interpreting infant feeding cues can help to prevent overfeeding and childhood obesity.

Skills

Read original research and evidence reports related to area of practice.

As a new topic this field of research is still developing tools to measure infant feeding cues and caregiver responsiveness, and will soon begin to develop interventions for clinical trials.

Attitudes

Appreciate the importance of regularly reading relevant professional journals.

As further research is published, systematic analyses and clinical guidelines may emerge as to the best interventions for healthy habits in infancy.

Babies normally consume small amounts of milk with feedings during the first 3 days of life. As the baby adjusts to extrauterine life and the digestive tract is cleared of meconium, milk intake increases from 15 to 30 ml per feeding in the first 24 hours to 60 to 90 ml by the end of the first week.

In the postpartum period interventions focus on helping the mother and the newborn initiate successful breastfeeding. An important goal is to build maternal confidence in breastfeeding. Interventions to promote successful breastfeeding include educating and assisting mothers and their partners with basics such as latch and positioning, signs of adequate feeding, and self-care measures such as prevention of engorgement. It is important to provide the parents with a list of resources that they can contact after discharge from the birthing facility.

The ideal time to begin breastfeeding is within the first hour after birth. Newborns without complications should be allowed to remain in direct skin-to-skin contact with the mother until the baby is able to breastfeed for the first time (AAP Section on Breastfeeding, 2012). This is true both for mothers who gave birth by cesarean and for those who gave birth vaginally. Early skin-to-skin contact is associated with higher rates of exclusive breastfeeding and increased duration of breastfeeding (Augustin, Donovan, Lozano, et al., 2013; Moore, Anderson, Bergman, et al., 2012; Suzuki, 2013).

Routine procedures such as vitamin K injection, eye prophylaxis, weighing, and bathing should be delayed until the neonate has completed the first feeding (AAP Section on Breastfeeding, 2012).

Positioning

For the initial feedings it can be advantageous to encourage and assist the mother to breastfeed in a semi-reclining position with the newborn lying prone, skin-to-skin on the mother's bare chest. Her body supports the baby. The mother is more relaxed, nipple pain is reduced or eliminated, and she has more

freedom of movement to use her hands. The baby is able to use inborn reflexes to latch onto the breast and feed effectively. This approach to breastfeeding is based on the concept of "biological nurturing" (Colson, 2010, 2012).

The four traditional positions for breastfeeding are the football or clutch hold (under the arm), modified cradle, cross-cradle or across the lap, cradle, and side-lying (Fig. 25-5). The mother should be encouraged to use the position that most easily facilitates latch while allowing maximal comfort. The football or clutch hold is often recommended for early feedings because the mother can see the baby's mouth easily as she guides the infant onto the nipple.

Mothers who gave birth by cesarean often prefer the football or clutch hold. The modified cradle or across-the-lap hold works well for early feedings, especially with smaller babies. The side-lying position allows the mother to rest while breastfeeding. Women with perineal pain and swelling often prefer this position. Cradling is the most common breastfeeding position for infants who have learned to latch easily and feed effectively. Before discharge from the birth institution the nurse can help the mother try all of the positions so she will be confident in trying these positions at home.

During breastfeeding the mother should be as comfortable as possible. After arranging for privacy, the nurse might suggest that she empty her bladder and attend to other needs before starting a feeding session. The nurse who is assisting with breastfeeding should be at the mother's eye level. The mother holds the infant securely at the level of the breast, supported by firm pillows or folded blankets, facing toward her. The baby's mouth is directly in front of the nipple. The mother should support the baby's neck and shoulders with her hand and not push on the occiput. The baby's body is held in alignment (ears, shoulders, and hips are in a straight line) during latch and feeding.

FIG 25-5 Breastfeeding positions. A, Football or clutch (under the arm) hold. B, Across the lap (modified cradle). C, Cradling. D, Lying down. (A and B, Courtesy Kathryn Alden, Chapel Hill, NC; C and D, courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

Latch

Latch, or latch-on, is defined as placement of the infant's mouth over the nipple, areola, and breast, making a seal between the mouth and breast to create adequate suction for milk removal. In preparation for latch during early feedings the mother should manually express a few drops of colostrum or milk and spread it over the nipple. This action lubricates the nipple and entices the baby to open the mouth as the milk is tasted.

To facilitate latch the mother supports her breast in one hand with the thumb on top and four fingers underneath at the back edge of the areola. The breast is compressed slightly with the fingers parallel to the infant's lips, as one might compress a large

FIG 25-6 Latch. A, Mother tickles baby's lips with nipple until he or she opens wide. B, Once baby's mouth is opened wide, she quickly "hugs" baby to breast. C, Baby should have as much areola (dark area around nipple) in his or her mouth as possible, not just the nipple. (Courtesy Medela, Inc., McHenry, IL.)

sandwich in preparing to take a bite, so an adequate amount of breast tissue is taken into the mouth with latch. Most mothers need to support the breast during feeding for at least the first days until the infant is adept at feeding.

The mother holds the baby close to the breast with the infant's mouth directly in front of the nipple. The infant who is displaying the **rooting reflex** with the mouth opening widely may easily latch on. If the infant is not readily opening the mouth, the mother tickles the baby's lips with her nipple, stimulating the mouth to open. When the mouth is open wide and the tongue is down, the mother quickly "hugs" the baby to the breast, bringing him or her onto the nipple (Fig. 25-6). The amount of areola in the baby's mouth with correct latch depends on the size of the baby's mouth and the size of the areola and nipple. If breastfeeding is painful, the baby likely has not taken enough of the breast into the mouth, and the tongue is pinching the nipple.

Mothers may also use the *asymmetric latch technique*. When the baby's mouth opens widely, the mother moves the baby in toward her body so the chin and lower mandible make contact with the breast first, followed by the top lip. When the baby is latched on, the nose is tilted slightly away from the mother's breast, and the chin is pressed into the underside of the breast. The infant's mouth placement is asymmetric on the areola; the lower part is covered by the baby's mouth, but the top is clearly visible above the top lip.

Once the infant is latched on and sucking, there are signs that the feeding is going well. These include (1) the mother reports a firm tugging sensation on her nipple but feels no pinching or pain; (2) the baby sucks with cheeks rounded, not dimpled; (3) the baby's jaw glides smoothly with sucking; and (4) swallowing is usually audible. Sucking creates a vacuum in the intraoral cavity as the breast is compressed between the tongue and the palate. When the infant is latched on and sucking correctly, breastfeeding is not painful. If she feels pinching or pain after the initial sucks or does not feel a strong tugging sensation on the nipple, the latch and positioning are evaluated. Any time the signs of adequate latch and sucking are not present, the baby should be taken off the breast, and latch attempted again. To prevent nipple trauma as the baby is taken off the breast, the mother is instructed to break the suction by inserting a finger in the side of the baby's mouth between the gums and leaving it there until the nipple is completely out of the mouth (Fig. 25-7) (see Nursing Care Plan).

 **NURSING CARE PLAN**
Breastfeeding and Infant Nutrition

NURSING DIAGNOSIS	EXPECTED OUTCOMES	NURSING INTERVENTIONS	RATIONALES
<i>Ineffective Breastfeeding related to knowledge deficit of the mother as evidenced by ongoing incorrect latch technique</i>	Mother will demonstrate correct latch technique. Infant will latch correctly and suck with gliding jaw movements and audible swallowing. Mother will report "tugging" but no nipple pain with infant suckling. Mother will express increased satisfaction with breastfeeding, and neonate will exhibit satisfaction of hunger and sucking needs.	<p>Assess mother's knowledge and motivation for breastfeeding.</p> <p>Observe breastfeeding session at least once each shift.</p> <p>Describe and demonstrate ways to stimulate sucking reflex, various positions for breastfeeding, use of pillows during session, and how to facilitate a comfortable and effective latch.</p> <p>Monitor position of infant's mouth on areola and position of head and body.</p> <p>Teach mother ways to stimulate neonate to maintain an awake state by diapering, unwrapping, massaging, or burping.</p>	<p>To provide starting point for teaching</p> <p>To provide baseline assessment for positive reinforcement and problem identification</p> <p>To promote maternal and neonatal comfort and effective latch</p> <p>To give positive reinforcement for correct latch position or to correct poor latch position</p> <p>To complete breastfeeding session thoroughly and satisfactorily</p>
<i>Ineffective Infant Feeding Pattern related to inability to coordinate sucking and swallowing</i>	Neonate will coordinate sucking and swallowing to accomplish effective feeding pattern.	<p>Assess for factors that can contribute to ineffective sucking and swallowing.</p> <p>Teach mother to observe feeding-readiness cues.</p> <p>Modify feeding methods as needed.</p> <p>Promote calm, relaxed atmosphere.</p> <p>Refer to lactation consultant.</p>	<p>To provide basis for plan of care</p> <p>To enhance effective feeding</p> <p>To maintain hydration status and nutritional requirements</p> <p>To provide pleasant breastfeeding experience for mother and neonate</p> <p>To provide specialized support</p>
<i>Anxiety related to ineffective infant feeding pattern</i>	Mother will report decrease in anxiety level and express satisfaction with breastfeeding.	<p>Assess mother's feelings and anxieties about breastfeeding.</p> <p>Monitor maternal anxiety level during feeding sessions.</p> <p>Provide education about breastfeeding.</p> <p>Provide positive reinforcement for feeding pattern improvement.</p> <p>Monitor weight, intake, and output of neonate.</p> <p>Enlist assistance of support persons.</p> <p>Provide information for lactation support.</p> <p>Initiate follow-up (telephone calls, follow-up with health care provider, outpatient lactation consultant) as needed.</p>	<p>To identify specific concerns</p> <p>To provide basis for care planning</p> <p>To help mother increase her knowledge about breastfeeding and improve her confidence</p> <p>To decrease anxiety</p> <p>To provide information regarding effective feeding</p> <p>To provide positive feedback for increasing skill</p> <p>To decrease anxiety after discharge</p> <p>To assess progress, detect problems, and provide support</p>

The nurse should observe at least one feeding every 8 to 12 hours while the mother and newborn are in the hospital (Holmes, McLeod, & Bunik, 2013). Using a standard breastfeeding scoring tool such as the LATCH (Jenson, Wallace, & Kelsay, 1994) to document observations provides consistency in assessment criteria. With the LATCH assessment tool, each letter represents a scored item: *L*atch, *A*udible swallowing, *T*ype of nipple, *C*omfort level of the mother, and *H*old (positioning). During the feeding assessment the nurse can provide education about breastfeeding, help with feeding techniques, and offer support. If the mother's partner or other family members are present, the nurse can include them in the teaching and demonstrate how they can help the mother and provide support.

Milk Ejection or Let-down

As the baby begins sucking on the nipple, the milk ejection, or let-down, reflex is stimulated (see Fig. 25-3, B). The following signs indicate that milk ejection has occurred:

- The mother may feel a tingling sensation in the nipples and breasts, although many women never feel when milk ejection (let-down) occurs.
- The baby's suck changes from quick, shallow sucks to a slower, more drawing sucking pattern.
- Audible swallowing is present as the baby sucks.
- In the early days the mother feels uterine cramping and can have increased lochia during and after feedings.
- The mother feels relaxed or drowsy during feedings.
- The opposite breast may leak.

Frequency of Feedings

Feeding patterns vary because every mother-infant dyad is unique. Breastfeeding frequency is influenced by a variety of factors, including the infant's age, weight, maturity level, stomach capacity and gastric emptying time, and the storage capacity of the breast (i.e., the milk available when the breast is full).

Newborns need to breastfeed at least 8 to 12 times in a 24-hour period (AAP Section on Breastfeeding, 2012). Some infants breastfeed every 2 to 3 hours throughout a 24-hour period. Others cluster-feed, breastfeeding every hour or so for three to five feedings and then sleeping for 3 to 4 hours between clusters. During the first 24 to 48 hours after birth most babies do not awaken this often to feed. Parents need to understand that they should awaken the baby to feed at least every 3 hours during the day and at least every 4 hours at night. (Feeding frequency is determined by counting from the beginning of one feeding to the beginning of the next.) Once the infant is feeding well and gaining weight adequately, going to **demand feeding** is appropriate, in which case the infant determines the frequency of feedings. (With demand feeding the infant should still receive at least eight feedings in 24 hours.)

SAFETY ALERT

Nurses should caution parents against attempting to place newborn infants on strict feeding schedules. Strict scheduling of feedings (forcing the baby to wait for a set amount of time before feeding) can result in failure to meet the nutritional needs of infants.

Infants should be fed whenever they exhibit feeding cues. Keeping the baby close is the best way to observe and respond to these cues. Newborns should remain with mothers during the recovery period after birth and room-in during the hospital stay. At home babies should be kept nearby so parents can observe signs that the baby is ready to feed. The mother and breastfeeding infant should sleep in proximity (in the same room but not in the same bed) to promote breastfeeding (AAP Section on Breastfeeding, 2012).

Duration of Feedings. The duration of breastfeeding sessions varies greatly because the timing of milk transfer differs for each mother-baby pair. The average time for early feedings is 30 to 40 minutes or approximately 15 to 20 minutes per breast. As infants grow they become more efficient at breastfeeding, and consequently the length of feedings decreases. The amount of time an infant spends breastfeeding is not a reliable indicator of the amount of milk the infant consumes because some of the time at the breast is spent in nonnutritive sucking.

In the early days after birth the mother may be instructed to feed on the first breast until the neonate falls asleep and try to wake the baby and offer the second breast. Some mothers prefer one-sided nursing, which means that the baby nurses only one breast at each feeding. The first breast offered should be alternated at each feeding to ensure that each breast receives equal stimulation and emptying.

Instead of instructing mothers to feed for a set number of minutes, nurses should teach them to look for signs that the baby has finished feeding (e.g., the baby's sucking and swallowing pattern has slowed, the breast is softened, the baby appears content and may fall asleep or release the nipple).

If a baby seems to be feeding effectively and urine output and bowel movements are adequate but the weight gain is not satisfactory, the mother may be switching to the second breast too soon. Feeding on the first breast until it softens ensures that the baby receives the higher-fat hindmilk, which usually results in increased weight gain.

INDICATORS OF EFFECTIVE BREASTFEEDING

One of the most common concerns of breastfeeding mothers is how to determine if the baby is getting enough milk. In the newborn period, when breastfeeding is becoming established, parents should be taught about the signs that breastfeeding is going well. Awareness of these signs helps them recognize when problems arise so they can seek appropriate assistance (Box 25-2).

During the early days of breastfeeding, keeping a feeding diary can be helpful. This involves recording the time and length of feedings and infant urine output and bowel movements. The data from the diary provide evidence of the effectiveness of breastfeeding and are useful to health care providers in assessing adequacy of feeding. Parents are instructed to take this feeding diary to the follow-up visit with the infant's health care provider.

The infant's output is highly indicative of feeding adequacy. It is important that parents are aware of the expected changes in the characteristics of urine output and bowel movements during the early newborn period. As the volume of breast milk increases, urine becomes more dilute and should be light yellow; dark, concentrated urine can be associated with inadequate intake and possible

BOX 25-2 Signs of Effective Breastfeeding**Mother**

- Onset of copious milk production (milk is “in”) by day 3 or 4
- Firm tugging sensation on nipple as infant sucks but no pain
- Uterine contractions and increased vaginal bleeding while feeding (first week or less)
- Feels relaxed and drowsy while feeding
- Increased thirst
- Breasts soften or feel lighter while feeding
- With milk ejection (let-down), can feel warm rush or tingling in breasts, leaking of milk from opposite breast

Infant

- Latches without difficulty
- Has bursts of 15 to 20 sucks/swallows at a time
- Audible swallowing is present
- Easily releases breast at end of feeding
- Infant appears content after feeding
- Has at least three substantive bowel movements and six to eight wet diapers every 24 hours after day 4

dehydration. (Note: Infants with jaundice often have darker urine as bilirubin is excreted.) Infants should have at least six to eight sufficiently wet diapers (light yellow urine) every 24 hours after day 4. The first 1 to 2 days after birth newborns pass meconium stools, which are greenish black, thick, and sticky. By day 2 or 3 the stools become greener, thinner, and less sticky. If the mother’s milk has come in by day 3 or 4, the stools start to appear greenish yellow and are looser. By the end of the first week breast milk stools are yellow, soft, and seedy (they resemble a mixture of mustard and cottage cheese). If an infant is still passing meconium stool by day 3 or 4, breastfeeding effectiveness and milk transfer should be assessed.

Infants should have at least three stools (quarter-size or larger) per day for the first month. Some babies stool with every feeding. The stooling pattern gradually changes; breastfed infants can continue to stool more than once per day or they may stool only every 2 or 3 days. As long as the baby continues to gain weight and appears healthy, this decrease in the number of bowel movements is normal.

Supplements, Bottles, and Pacifiers

Unless a medical indication exists, no supplements should be given to breastfeeding infants (AAP Section on Breastfeeding, 2012). With sound breastfeeding knowledge and practice, supplements are rarely needed. Early supplementation by hospital staff undermines a new mother’s confidence and models behavior that is counterproductive to establishing breastfeeding.

When supplementation is deemed necessary, giving the baby expressed breast milk is best. If the mother is not able to provide the milk, the recommended alternative is pasteurized donor milk from a milk bank. However, in many cases donor milk is not readily accessible and a commercial infant formula is used. Before supplementation it is important to perform a careful evaluation of the mother-infant dyad.

Possible indications for supplementary feeding include infant factors such as hypoglycemia, dehydration, weight loss of more than 7% associated with delayed lactogenesis, delayed passage of bowel movements or meconium stool continued to day 5, poor milk transfer, or hyperbilirubinemia (ABM Protocol Committee, 2009).

FIG 25-8 Supplemental nursing device. (Courtesy Medela, Inc, McHenry, IL.)

Maternal indications for possible supplementation include delayed lactogenesis and intolerable pain during feedings. Women who have had previous breast surgery such as augmentation or reduction may need to provide supplementary feedings for their infants (ABM Protocol Committee, 2009).

Newborns can become confused going from breast to bottle or bottle to breast when breastfeeding is first being established. Breastfeeding and bottle feeding require different oral motor skills. It is best to avoid bottles until breastfeeding is well established, usually after 3 or 4 weeks.

If supplemental feeding is needed, nurses or lactation consultants can help parents use supplemental nursing devices. This allows the baby to be supplemented with expressed breast milk or infant formula while still breastfeeding (Fig. 25-8). Infants can also be fed with a spoon, dropper, cup, or syringe. If parents choose to use bottles, a slow-flow nipple is recommended. Although some parents combine breastfeeding and bottle feeding, some infants never take a bottle and go directly from the breast to a cup.

Because of the correlation between pacifier use and a decreased risk of sudden infant death syndrome (SIDS), experts recommend pacifier use for healthy term infants at nap or sleep time, but only after breastfeeding is well established at about 3 or 4 weeks of age (AAP Section on Breastfeeding, 2012).

Special Considerations**Sleepy Baby**

Some babies need to be awakened for feedings for the first few days after birth. If the infant is awakened from a sound sleep,

attempts at feeding may be unsuccessful. Babies are more likely to feed if they are awakened from a light or active sleep state. Signs that the infant is in this sleep state are movements of the eyelids, body movements, and making sounds while sleeping. Unwrapping the baby, changing the diaper, sitting the baby upright, talking to him or her with variable pitch, gently massaging his or her chest or back, and stroking the palms or soles may bring the baby to an alert state. It is helpful to place the sleepy baby skin-to-skin with the mother; she can move the infant to the breast when feeding-readiness cues are apparent.

Fussy Baby

Babies sometimes awaken from sleep crying frantically. Although they are hungry, they cannot focus on feeding until they are calmed. Parents can swaddle the baby, hold him or her close, talk soothingly, and allow him or her to suck on a clean finger until calm enough to latch on to the breast. Placing the baby skin-to-skin with the mother can be very effective in calming a fussy infant. Fussiness during feeding can be the result of birth injury such as bruising of the head or fractured clavicle. Changing the feeding position can help alleviate this problem.

Infants who were suctioned extensively or intubated at birth can demonstrate an aversion to oral stimulation. The baby may scream and stiffen if anything approaches the mouth. Parents need to spend time holding and cuddling the baby before attempting to breastfeed.

An infant can become fussy and appear discontented when sucking if the nipple does not extend far enough into the mouth. The feeding can begin with well-organized sucks and swallows, but the infant soon begins to pull off the breast and cry. The mother should support her breast throughout the feeding so the nipple stays in the same position as the feeding proceeds and the breast softens.

Fussiness can be related to GI distress (e.g., cramping, gas pains, gastroesophageal reflux). It can occur in response to an occasional feeding of infant formula, or it can be related to something the mother has ingested, although most women are able to eat a normal diet without causing GI distress to the breastfeeding infant. Persistent crying or refusing to breastfeed can indicate illness. Parents are instructed to notify the health care provider if either circumstance occurs.

Some mothers find that their babies are less fussy when placed in a sling or carrier. Some slings make it easy to breastfeed without removing the baby from the sling (Fig. 25-9).

Slow Weight Gain

Newborn infants typically lose 5% to 6% of body weight after birth before they begin to gain weight. Weight loss of more than 7% in a breastfeeding infant during the first 3 days of life needs to be investigated (Lauwers & Swisher, 2011). After the early milk has transitioned to mature milk, infants should gain approximately 110 to 200 g (3.9 to 7 oz) per week or 20 to 28 g (0.7 to 1 oz) per day for the first 3 months. (Breastfed infants usually do not gain weight as quickly as formula-fed infants.)

Parents are taught the warning signs of ineffective breastfeeding, including inadequate weight gain, minimal output, and feeding constantly. If any of these warning signs is present, the parent should notify the health care provider.

FIG 25-9 Baby breastfeeding while in sling. (Courtesy Julie Perry Nelson, Loveland, CO.)

At times slow weight gain is related to inadequate breastfeeding. Feedings can be short or infrequent, or the infant can be latching incorrectly or sucking ineffectively or inefficiently. Other possibilities are illness or infection; malabsorption; or circumstances that increase the baby's energy needs such as congenital heart disease, cystic fibrosis, or simply being small for gestational age. Slow weight gain must be differentiated from failure to thrive; this can be a serious problem that warrants medical intervention.

Maternal factors can be the cause of slow weight gain. The mother can have a problem with inadequate emptying of the breasts, pain with feeding, or inappropriate timing of feedings. Inadequate glandular breast tissue or previous breast surgery can affect milk supply. Severe intrapartum or postpartum hemorrhage (Sheehan syndrome), illness, or medications can decrease milk supply. Stress and fatigue also negatively affect milk production (Lauwers & Swisher, 2011; Lawrence & Lawrence, 2011a).

In most instances the solution to slow weight gain is to increase feeding frequency and to improve the feeding technique. Positioning and latch are evaluated, and adjustments are made. Adding a feeding or two in a 24-hour period can help. If the problem is a sleepy baby, parents are instructed in waking techniques.

Using alternate breast massage during feedings can help increase the amount of milk going to the infant. With this technique the mother massages her breast from the chest wall to the nipple whenever the baby has sucking pauses. This technique also can increase the fat content of the milk, which aids in weight gain.

When babies are calorie deprived and need supplementation, they can receive expressed breast milk or formula with a supplemental nursing device (see Fig. 25-8), spoon, cup, syringe, or bottle. In most cases supplementation is necessary only for a short time until the baby gains weight and is feeding adequately.

Jaundice

Chapter 23 and Chapter 36 discuss jaundice (hyperbilirubinemia) in the newborn in detail. Breastfeeding infants can develop *early-onset jaundice* or *breastfeeding-associated jaundice*, which is associated with insufficient feeding and infrequent stooling. Colostrum has a natural laxative effect and promotes early passage of meconium. Bilirubin is excreted from the body primarily through the intestines. Infrequent stooling allows bilirubin in the stool to be resorbed into the infant's system, thus increasing bilirubin levels (Blackburn, 2013). To prevent early-onset, breastfeeding-associated jaundice, newborns should be breastfed frequently during the first several days of life. Increased frequency of feedings is associated with decreased bilirubin levels.

To treat early-onset jaundice, breastfeeding is evaluated in terms of frequency and length of feedings, positioning, latch, and milk transfer. Factors such as a sleepy or lethargic infant or maternal breast engorgement can interfere with effective breastfeeding and should be corrected. If the infant's intake of milk needs to be increased, a supplemental feeding device can deliver additional breast milk or formula while the infant is nursing. Bilirubin levels are closely monitored.

Late-onset jaundice or *breast milk jaundice* affects a small number of breastfed infants and develops between 5 and 10 days of age. Affected infants typically thrive, gain weight, and stool normally; all pathologic causes of jaundice have been ruled out. In the presence of other risk factors, hyperbilirubinemia can be severe enough to require phototherapy. In most cases of breast milk jaundice no intervention is necessary. Some health care providers recommend temporary interruption of breastfeeding for 12 to 24 hours to allow bilirubin levels to decrease, although this approach is not preferred (Blackburn, 2013; Lawrence & Lawrence, 2011a).

Any breastfeeding infant who develops jaundice should be evaluated carefully for weight loss greater than 7%, decreased milk intake, infrequent stooling (fewer than three stools per day), and decreased urine output (fewer than four to six wet diapers per day). Bilirubin levels should be assessed by serum testing or transcutaneous monitoring (see Chapter 24).

Preterm Infants

Human milk is the ideal food for preterm infants, with benefits that are unique and in addition to those received by term healthy infants. Breast milk enhances retinal maturation in the preterm infant and improves neurocognitive outcomes; it also decreases the risk of sepsis and necrotizing enterocolitis. Greater physiologic stability occurs with breastfeeding compared to bottle feeding (AAP Section on Breastfeeding, 2012; Lawrence & Lawrence, 2011a).

Initially preterm milk contains higher concentrations of energy, protein, sodium, chloride, potassium, iron, and magnesium than term milk. It is more similar to term milk by approximately 4 to 6 weeks. Depending on gestational age and physical condition, many preterm infants are capable of breastfeeding for at least some feedings each day. Mothers of preterm infants who are not able to breastfeed their infants should begin pumping their breasts as soon as possible after birth with a hospital-grade electric pump (Fig. 25-10). Pumping frequency depends on the mother's breastfeeding goals but may be recommended

FIG 25-10 Hospital-grade electric breast pump. (Courtesy Kathryn Alden, Chapel Hill, NC.)

8 to 10 times every 24 hours to establish the milk supply. These women are taught proper handling and storage of breast milk to minimize bacterial contamination and growth. Kangaroo care (skin-to-skin contact) is encouraged until the baby is able to breastfeed and while breastfeeding is established because it enhances milk production (Lauwers & Swisher, 2011; Meier, Patel, Bigger, et al., 2013).

Mothers of preterm infants often receive specific emotional benefits in breastfeeding or providing breast milk for their babies. They find rewards in knowing that they can provide the healthiest nutrition for the infant and believe that breastfeeding enhances feelings of closeness to the infant.

Late Preterm Infants

Neonates born at 34 0/7 to 36 6/7 weeks of gestation are categorized as *late preterm infants*. These newborns are at risk for feeding difficulties because of their low energy stores and high energy demands. Additionally, they are more prone to hypothermia, hypoglycemia, and hyperbilirubinemia (ABM Protocol Committee, 2011a; Cooper, Holditch-Davis, Verklan, et al., 2012). They tend to be sleepy, with minimal and short wakeful periods. Late preterm infants often tire easily while feeding and have a weak suck and low tone; these factors can contribute to inadequate milk intake resulting in dehydration and poor weight gain (Meier, Patel, Wright, & Engstrom, 2013b). This predisposes mothers to delayed onset of lactogenesis II and inadequate milk supply.

Goals of care are to nourish the infant and protect the mother's milk supply. A lactation consultant should be involved in planning and providing appropriate care that usually includes milk expression with a hospital-grade pump and supplementation of the infant with expressed breast milk or infant formula (Meier et al., 2013).

Early and extended skin-to-skin contact promotes breastfeeding and helps prevent hypothermia. Because these infants are more prone to positional apnea than term infants, mothers are advised to use the clutch (under the arm or football) or cross-cradle hold for feeding, and avoid flexing the head, which can impede breathing. When supplementation is needed, expressed breast milk is the optimal supplement. Due to their weak suck, many infants are fed with a bottle, although in some cases a supplemental feeding device can be used (see Fig. 25-8) (Lanese & Cross, 2013; Meier, Patel, Wright, & Engstrom, 2013).

FIG 25-11 Breastfeeding twins. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

Breastfeeding Multiple Infants

Breastfeeding is especially beneficial to twins, triplets, and other higher-order multiples because of the immunologic and nutritional advantages and the opportunity for the mother to interact with each baby frequently. Most mothers are capable of producing an adequate milk supply for multiple infants. Parenting multiples can be overwhelming; mothers and their husbands or partners need extra support and help to learn how to manage feedings (Fig. 25-11). Parents of multiples can find breastfeeding information and support through groups such as La Leche League International (www.lalecheleague.org/nb/nbmultiples.html).

Expressing and Storing Breast Milk

Breast milk expression is a common practice, typically performed to obtain breast milk for someone other than the mother to feed to the baby. It is most often associated with maternal employment. In some situations expression of breast milk is necessary or desirable such as when engorgement occurs, when the mother's nipples are sore or damaged, when the mother and baby are separated as in the case of a preterm infant who remains in the hospital after the mother is discharged, or when the mother leaves the infant with a caregiver and will not be present for feeding. Some women express milk to have an emergency supply. Some women choose to pump exclusively, providing breast milk for their infants but never allowing the baby to suckle at the breast. Because pumping and hand expression are rarely as efficient as a baby in removing milk from the breast, the milk supply is never judged based solely on the volume expressed. Milk volume can be more accurately assessed using prefeeding and postfeeding infant weights, also known as *test weights* (Lauwers & Swisher, 2011).

Hand Expression

All mothers should be instructed in hand expression. This simple technique can actually be more effective than an electric breast pump for expressing colostrum, which tends to be thicker than mature milk (Flaherman, Gay, Scott, et al., 2012; Morton, Hall, & Pessl, 2013-2014). Hand expression during the first 3 days after birth can have a positive effect on milk production during the early weeks. Morton and colleagues

FIG 25-12 Bilateral breast pumping. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

report that combining hand expression and hands-on pumping (breast massage before and during pumping) with the use of an electric breast pump can increase milk production and enhance fat content and caloric value of milk (Morton, Wong, Hall, et al., 2012). A video of hand expression of breast milk is available at <http://newborns.stanford.edu/Breastfeeding/HandExpression.html>.

Mechanical Milk Expression (Pumping)

For most women recommendations are to initiate pumping only after the milk supply is well established and the infant is latching and breastfeeding well. However, when breastfeeding is delayed after birth such as when babies are ill or preterm, mothers should begin pumping with an electric breast pump as soon as possible and continue to pump regularly until the infant is able to breastfeed effectively. Early pumping may be initiated if the baby is too sleepy to feed effectively or if there are issues with latching or milk transfer. Milk expression is essential to maintaining milk supply if breastfeeding is interrupted. Double pumping (pumping both breasts at the same time) saves time and can stimulate the milk supply more effectively than single pumping (Fig. 25-12).

The amount of milk obtained when pumping depends on the type of pump being used, the time of day, the time since the baby breastfed, the mother's milk supply, how practiced she is at pumping, and her comfort level (pumping is uncomfortable for some women). Breast milk can vary in color and consistency, depending on the time of day, the age of the baby, and foods the mother has eaten.

Types of Pumps. Many types of breast pumps are available, varying in price and effectiveness. Before purchasing or renting a breast pump, the mother will benefit from counseling by a nurse or lactation consultant to determine which pump best suits her needs. The flange (funnel-shaped device that fits over the nipple or areola) should fit the nipple to prevent nipple pain, trauma, and possible reduction in milk supply. Mothers are advised to use the lowest suction setting on electric pumps, increasing gradually if needed. Breast massage before and during pumping can increase the amount of milk obtained (Lauwers & Swisher, 2011).

Manual or hand pumps are the least expensive and can be the most appropriate when portability and quietness of operation are important. These pumps are most often used by mothers who are pumping for an occasional bottle (Fig. 25-13).

FIG 25-13 Manual breast pumps. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

Full-service electric pumps, or hospital-grade pumps (see Figs. 25-10 and 25-12), most closely duplicate the sucking action and pressure of the breastfeeding infant. When breastfeeding is delayed after birth (e.g., preterm or ill newborn) or when the mother and baby are separated for lengthy periods, these pumps are most appropriate. Because hospital-grade breast pumps are very heavy and expensive, portable versions of these pumps are available to rent for home use.

Electric self-cycling double pumps are efficient and easy to use. They are designed for working mothers. Some of these pumps come with carry bags containing coolers to store pumped milk.

Smaller electric or battery-operated pumps are typically used when pumping is performed occasionally, but some models are satisfactory for working mothers or others who pump on a regular basis.

Storage of Breast Milk

Mothers who express and feed breast milk to their infants need to be educated about safe practices for handling, storing, and feeding. Attention to hand hygiene and proper cleaning of equipment can reduce the risk of bacterial contamination. This is especially important when mothers are providing milk for preterm or ill neonates (Labiner-Wolfe & Fein, 2013; Meier, Patel, Bigger, et al., 2013). Guidelines for storing expressed breast milk for a healthy term infant are listed in the Teaching for Self-Management box: Breast Milk Storage Guidelines for Home Use for Term Infants).

The preferred containers for long-term storage of breast milk have hard sides such as hard plastic or glass with an airtight seal. Flexible polyethylene bags are not recommended for long-term milk storage (>72 hours) because there is a greater chance of leakage, puncture, and loss of immune cells (Lauwers & Swisher, 2011).

Maternal Employment

Returning to work after birth is associated with a decrease in the duration of breastfeeding. Women who return to work often face workplace challenges in breastfeeding such as lack of flexibility in work schedules, inadequate breaks to allow time for pumping, lack of privacy, lack of space for pumping, and lack of support from supervisors or coworkers. Mothers in educational

TEACHING FOR SELF-MANAGEMENT

Breast Milk Storage Guidelines for Home Use for Term Infants

- Before expressing or pumping breast milk, wash your hands.
- Containers for storing milk should be washed in hot, soapy water and rinsed thoroughly; they can also be washed in a dishwasher. If the water supply may not be clean, boil containers after washing. Plastic bags designed specifically for breast milk storage can be used for short-term storage (<72 hours).
- Write the date of expression on the container before storing milk. A waterproof label is best.
- Store milk in serving sizes of 2 to 4 ounces to prevent waste.
- Storing breast milk in the refrigerator or freezer with other food items is acceptable.
- You can combine milk from pumping sessions in the same day; cool freshly expressed milk before adding it to the refrigerated container. Do not add warm milk to a container of refrigerated milk.
- When storing milk in a refrigerator or freezer, place containers in the middle or back of the freezer, not on the door.
- When filling a storage container that will be frozen, fill only three quarters full, allowing space at the top of the container for expansion.
- To thaw frozen breast milk, place container in the refrigerator for gradual thawing or under warm, running water for quicker thawing. Never boil or microwave.
- Milk thawed in the refrigerator can be stored for 24 hours.
- Thawed breast milk should never be refrozen.
- Shake milk container before feeding baby and test the temperature of the milk on the inner aspect of your wrist.
- Any unused milk left in the bottle after feeding is discarded.

LOCATION OF STORAGE	TEMPERATURE	RECOMMENDED SAFE DURATION FOR STORAGE
Room temperature	16-29° C (60-85° F)	3-4 hours optimal 6-8 hours acceptable*
Refrigerator	4° C (39° F) or lower	72 hours optimal 5-8 days acceptable*
Freezer	Less than -4° C (24° F)	6 months optimal 12 months acceptable

*Under very clean conditions.

Modified from Academy of Breastfeeding Medicine Protocol Committee. (2010). ABM clinical protocol no. 8: Human milk storage information for home use for full-term infants. *Breastfeeding Medicine*, 5(3), 127-130.

⚡ SAFETY ALERT

Breast milk is never thawed or heated in a microwave oven. Microwaving does not heat evenly and can cause encapsulated boiling bubbles to form in the center of the liquid, which may not be detected when drops of milk are checked for temperature. Babies have sustained severe burns to the mouth, throat, and upper GI tract as a result of microwaved milk. In addition, microwaving significantly decreases the anti-infective properties and vitamin C content. The safety of low-temperature microwaving is questionable (ABM Protocol Committee, 2010; Lawrence & Lawrence, 2011a).

settings face similar challenges. Issues that can affect continued breastfeeding while working include fatigue, child care concerns, competing demands, and household responsibilities.

Employed mothers can continue breastfeeding with appropriate guidance and support. They are encouraged to set realistic goals for employment and breastfeeding, with accurate information regarding the costs, risks, and benefits of available feeding options. Women need information about planning for their return to work; nurses and lactation consultants can provide guidance. Websites such as www.workandpump.com include information about choosing pumps and other supplies, making a plan for breastfeeding and expressing milk, and preparing for their return to work.

Women who are able to breastfeed their infants during the workday tend to breastfeed longer. With increasing numbers of women having the option of working from home, this situation is becoming more common. In some settings mothers are able to breastfeed during the workday, either by going to an on-site daycare center or by having a friend or relative bring the baby to her for some feedings. Many working mothers pump their milk while they are at work and save the milk for later feedings. Working mothers who are unable to pump or breastfeed their infants during the workday have the shortest duration of breastfeeding.

Because women are a significant proportion of the workforce, many companies make provisions for breastfeeding women returning to work. The Affordable Care Act (USDHHS, 2010a) mandates that employers provide accommodations for breastfeeding mothers, specifically reasonable breaks during the workday and a non-bathroom space for milk expression until the child's first birthday. Breastfeeding programs typically include on-site lactation rooms (Fig. 25-14) and education and consulting services. Some employers provide on-site child care and high-quality breast pumps for their employees (Marinelli, Moren, Taylor, & Academy of Breastfeeding Medicine, 2013). Workplace support for breastfeeding mothers has improved significantly in recent years. However, further efforts are needed to educate employers about the importance of supporting their breastfeeding employees. Employers need to realize that breastfeeding programs can provide short- and long-term cost savings with significant health benefits for mothers, infants, and families. The Health Resources and Services Administration offers a free toolkit for employers: the "Business Case for Breastfeeding" outlines steps that employers can take to support breastfeeding employees (www.womenshealth.gov/breastfeeding/programs/business-case/tool-kit.cfm://aks/hrsa/gov).

Weaning

Weaning is initiated when babies are introduced to foods other than breast milk and concludes with the last breastfeeding. Gradual weaning over weeks or months is easier for mothers and infants than abrupt weaning. Abrupt weaning is likely to be distressing for mother and baby and physically uncomfortable for the mother because it can cause engorgement and mastitis (Mohrbacher, 2013).

Weaning is initiated by either the infant or the mother. With infant-led weaning the infant moves at his or her own pace in omitting feedings, which usually facilitates a gradual decrease in the mother's milk supply. Mother-led weaning means that the

FIG 25-14 Lactation room. Note breast pump, rocking chair, nursing foot stool, changing table, books, and supplies. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

mother decides which feedings to drop. This approach is most easily undertaken by omitting the feeding of least interest to the baby or the one through which the infant is most likely to sleep. Every few days thereafter the mother drops another feeding until the infant is gradually weaned from the breast (Lauwers & Swisher, 2011).

Infants can be weaned directly from the breast to a cup. Bottles are usually offered to infants younger than 6 months. If the infant is weaned before 1 year of age, the infant should receive iron-fortified formula instead of cow's milk (AAP Section on Breastfeeding, 2012).

If abrupt weaning is necessary, breast engorgement can occur. To relieve the discomfort the mother can take mild analgesics such as ibuprofen, wear a supportive bra, apply ice packs or cabbage leaves to the breasts, and pump small amounts if needed. When possible it is best to avoid pumping because the breasts should remain full enough to promote a decrease in the milk supply (Lauwers & Swisher, 2011).

Weaning is often a very emotional time for mothers; many believe that it is the end to a special, satisfying relationship with the infant and benefit from time to adapt to the changes. Sudden weaning can evoke feelings of guilt and disappointment. Some women go through a grieving period after weaning. Nurses and others can help the mother by discussing other ways to continue this nurturing relationship with the infant such as skin-to-skin contact while bottle feeding or holding and cuddling the baby. Support from the father or partner and other family members is essential at this time.

Milk Banking

The AAP recommends pasteurized donor milk for preterm infants if the mother's own milk is not available despite substantial lactation support (AAP Section on Breastfeeding, 2012). The value of donor milk is emphasized by the ABM in their recommendation of pasteurized donor milk for the healthy term and preterm infant when the mother's milk is not available (ABM Protocol Committee, 2009).

For infants who cannot be breastfed but who also cannot survive except on human milk, banked donor milk is critically important. Because of the anti-infective and growth-promoting properties of human milk and its superior nutrition, processed

donor milk is used in some neonatal intensive care units, primarily for severely low birth weight infants as well as for other preterm or sick infants when the mother's own milk is not available. Donor milk may be used therapeutically in other situations such as for infants with short gut syndrome, formula intolerance, metabolic disorders, or congenital anomalies. It is also used for infants with IgA deficiency who are not breastfed, and older children or adults with IgA deficiency.

The Human Milk Banking Association of North America (HMBANA) (www.hmbana.org) has established annually reviewed guidelines for the operation of not-for-profit donor human milk banks (HMBANA, 2013). Interestingly, there is no federal oversight or regulation of milk banking in the United States. However, some states have laws and regulations that specify how donor milk is to be procured, processed, and distributed (Landers & Hartmann, 2012). Currently there are 16 HMBANA milk banks in the United States and Canada, with more in various stages of planning and development (Updegrave, 2013). The milk banks collect, screen, process, and distribute the milk donated by lactating mothers. All donors are screened both by interview and serologically for communicable diseases. Donor milk is stored frozen until it is heat processed to kill potential pathogens; it is then refrozen for storage until it is dispensed for use. The heat processing adds a level of protection for the recipient that is not possible with any other donor tissue or organ. Banked milk is dispensed only by prescription. A per-ounce fee is charged by the bank to pay for the processing costs, but the HMBANA guidelines prohibit payment to donors (Landers & Hartmann).

COMMUNITY ACTIVITY

The Human Milk Banking Association of North America is a non-profit organization that provides donor milk that has been safely pasteurized and tested. It is dispensed only by hospital purchase order or health care provider prescription. Go to the website: www.hmbana.org and read about how milk is processed. Also explore how a woman can become a milk donor. Examine websites that offer milk sharing via the Internet: Eats on Feets (www.eatsonfeets.org) and Human Milk for Human Babies (<http://hm4hb.net>). What is the process for procuring human milk? What is the cost? What information is available about potential risks?

Milk Sharing

Some mothers acquire donor milk for their babies through Internet-based milk sharing or community sharing of donor human milk (see Community Activity box). The U.S. Food and Drug Administration (FDA, 2010) issued a warning regarding this practice, recommending that potential users should consult a health care provider before obtaining milk from a source other than the baby's own mother. They warn individuals against feeding donor milk procured directly from individuals or through the Internet, citing safety risks including exposing the infant to infectious diseases or chemical contaminants in donor milk. Samples of milk purchased through the Internet have been shown to have high overall bacterial growth and contamination with pathogenic bacteria; this is likely related to improper techniques for collecting, storing, and shipping the milk (Keim, Hogan, McNamara, et al., 2013).

SAFETY ALERT

Nurses and lactation consultants should be aware of the safety concerns associated with Internet-based or community milk sharing. Parents who indicate an interest in obtaining donor human milk for their infant should be directed to one of the HMBANA milk banks and should be cautioned about the safety risks associated with feeding donor milk from an alternative source.

Care of the Mother

Nutrition. In general the breastfeeding mother should eat a healthy, well-balanced diet. Caloric intake during lactation should be sufficient to achieve the goal of balancing energy intake and expenditure. Most women are able to achieve that balance by adding 450 to 500 calories per day (AAP Section on Breastfeeding, 2012). Even with the increased caloric intake, women who are breastfeeding tend to lose weight more quickly than those who are formula feeding (Lawrence & Lawrence, 2011a).

Medications or diets that promote weight loss are not recommended for breastfeeding mothers. Rapid loss of large amounts of weight can be detrimental, given that fat-soluble contaminants to which the mother has been exposed are stored in body fat reserves and these can be released into the breast milk. Another potential consequence of weight loss is reduced milk production. For most women a weight loss of 1 to 2 kg (2.2 to 4.4 lb) per month is safe; however, if weight loss exceeds this amount, careful evaluation of infant weight and feeding pattern is recommended. The mother's diet is also evaluated.

No specific foods that the breastfeeding mother must consume or avoid have been identified. In most cases the woman can consume a normal diet, according to her personal preferences and cultural practices. Women may be told to continue taking their prenatal vitamins as long as they are breastfeeding.

It is recommended that breastfeeding mothers consume 200 to 300 mg of the omega-3 long-chain polyunsaturated fatty acids (docosahexaenoic acid [DHA]) daily. A DHA supplement and a multivitamin may be needed for women who are undernourished and those on vegan diets (AAP Section on Breastfeeding, 2012).

Mothers are encouraged to drink fluids in response to thirst (women often report feeling thirsty when they are breastfeeding). It can be helpful for the mother to know that if her urine appears light yellow (like lemonade), she is probably consuming adequate fluids. Excessive consumption of water or other fluids by the mother does not increase milk supply, and overhydration can actually decrease milk production.

Rest. The breastfeeding mother should rest as much as possible, especially in the first 1 or 2 weeks after birth. Fatigue, stress, and worry can negatively affect milk production and ejection (let-down). The nurse can encourage the mother to sleep when the baby sleeps. Breastfeeding in a side-lying position promotes rest for the mother. The father or partner, grandparents, other relatives, and friends can help with household chores and caring for other children.

Breast Care. The breastfeeding mother's normal routine bathing is all that is necessary to keep her breasts clean. Soap can have a drying effect on nipples; therefore, the mother should

FIG 25-15 Breast shells.

avoid washing the nipples with soap. Breast creams should not be used routinely because they can block the natural oil secreted by the Montgomery glands on the areola.

The mother with flat or inverted nipples may benefit from wearing breast shells in her bra, although there is a lack of evidence to support the effectiveness of doing so. It is thought that these hard plastic devices exert mild pressure around the base of the nipple to encourage nipple eversion. Breast shells are also useful for sore nipples to keep the mother's bra or clothing from touching the nipples (Fig. 25-15).

If a mother needs breast support, she will likely be uncomfortable unless she wears a bra because otherwise the ligament that supports the breast (Cooper ligament) will stretch and be painful. Bras should fit well and provide nonbinding support. Underwire or improperly fitting bras can cause clogged milk ducts.

If milk leakage between feedings is a problem, mothers can wear breast pads (disposable or washable) inside the bra. Plastic-lined breast pads are not recommended because they trap moisture and can contribute to sore nipples. Pads should be changed when they are damp.

Breastfeeding and Contraception. Although breastfeeding confers a period of infertility, it is not considered an effective method of contraception unless the mother is strictly following guidelines for the lactational amenorrhea method of contraception (see Chapter 8). Breastfeeding delays the return of ovulation and menstruation; however, ovulation can occur before the first menstrual period after birth.

The contraceptives least likely to affect breastfeeding and milk production are the nonhormonal methods such as the lactational amenorrhea method, natural family planning, barrier methods (diaphragm/cap, spermicides, condoms), and intrauterine devices.

Hormonal contraceptives containing estrogen, including combined estrogen-progesterone pills or injectables, are not recommended for breastfeeding mothers because of the potential for reducing milk supply. Progestin-only contraceptives (pill, injection, or implant) are better options for breastfeeding mothers, although their use is not recommended during the first 6 weeks after birth (Lawrence & Lawrence, 2014) (see Chapter 8).

Breastfeeding During Pregnancy. Breastfeeding women who become pregnant can continue to breastfeed if there are no medical contraindications (e.g., risk of preterm labor). For pregnant women who are breastfeeding, adequate nutrition is especially important to promote normal fetal growth.

Nipple tenderness associated with early pregnancy can cause discomfort when breastfeeding the older child. The taste and composition of breast milk are altered during pregnancy, which can prompt some children to self-wean (Lawrence & Lawrence, 2011a).

When the baby is born, colostrum is produced. The practice of breastfeeding a newborn and an older child is called **tandem nursing**. The nurse should remind the mother always to feed the infant first to ensure that he or she is receiving adequate nutrition. The supply-meets-demand principle works in this situation, just as with breastfeeding multiples.

Breastfeeding After Breast Surgery. Previous breast surgery can affect the ability to produce breast milk and transfer it to the infant. Surgical procedures can damage nerves and interrupt milk ducts. Before undergoing breast surgery all women should discuss their lactation potential with their surgeon.

Women who have had augmentation mammoplasty (breast implants) may be able to breastfeed successfully. Many women have breast augmentation surgery purely for cosmetic reasons. However, if the procedure was done because of hypoplastic or asymmetric breasts or for breast reconstruction following cancer surgery, there can be concerns about adequate milk production. Submuscular implants are less likely to cause these problems; implants placed through periareolar incisions are more likely to result in breastfeeding problems. Large implants can impede milk flow by compressing milk ducts. Women who have had hyaluronic acid injections for breast enhancement can safely breastfeed (Smith & Heads, 2013).

Reduction mammoplasty causes problems with milk production and transfer because of interference with milk ducts, removal of glandular tissue, and nerve damage (Newton, 2012). Even so, many women are still able to breastfeed while also supplementing with infant formula or banked donor milk.

! NURSE ALERT

Women may not self-report breast augmentation or reduction mammoplasty. If surgical scars are present on the breast, the nurse should inquire about the type of surgery and the reason it was performed. Mothers with a history of breast surgery should be informed about the risk of interference with milk production and transfer. They are instructed to monitor their infants carefully for signs of adequate feeding.

It is possible for some women with a history of breast cancer to breastfeed. However, treatment for breast cancer (surgery, radiation, chemotherapy) can result in reduced milk supply or absence of lactation in the affected breast.

Breastfeeding and Obesity. Women who are overweight or obese are more likely to experience delayed onset of lactogenesis stage II and reduced milk production compared with women of average weight. There is some evidence that breastfeeding duration may be shorter among this population of mothers (Lepe, Bacardí Gascón, Castañeda-González, et al., 2011; Turcksin, Bel, Galjaard, & Devlieger, 2012; Wojcicki, 2011).

For women who have had bariatric surgery and plan to breastfeed, it is important to know when the surgery was

performed. Nutrient and weight losses tend to stabilize approximately 12 to 18 months following the procedure. If the mother is consuming at least 1800 kcal/day and her weight has stabilized, her milk supply may be adequate. Breastfeeding mothers who have had a malabsorptive procedure such as a Roux-en-Y gastric bypass should take daily dietary supplements, including a prenatal vitamin, vitamin B₁₂, iron with vitamin C (to maximize absorption), and calcium (Lamb, 2011; La Leche League International, 2012). It is important to monitor infant weight gain. Vitamin B₁₂ deficiency or decreased milk production can cause failure to thrive. In addition, vitamin B₁₂ deficiency can result in infant anemia, developmental delays, and neurologic problems (Lamb, 2011).

Medications, Alcohol, Smoking, and Caffeine. Although much concern exists about the compatibility of drugs and breastfeeding, few drugs are absolutely contraindicated during lactation (Sachs & Committee on Drugs, 2013). Considerations in evaluating the safety of a specific medication during breastfeeding include the pharmacokinetics of the drug in the maternal system and the absorption, metabolism, distribution, storage, and excretion in the infant. The gestational and chronologic age of the infant, body weight, and breastfeeding pattern are also considered. In general, any medication that is given to an infant routinely is safe for a mother who is breastfeeding. The benefits of breastfeeding should be weighed against any risks of the medication to the infant (Sachs et al.).

MEDICATION ALERT

Breastfeeding mothers should be cautioned about taking any medications except those that are deemed essential. They are advised to check with their health care provider before taking any medication.

Information about the safety of medications and breastfeeding can be accessed through the Drugs and Lactation Database (LactMed), a website provided by National Library of Medicine: <http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT>. The AAP recommends that providers consult this resource for the most current evidence-based information about specific medications for breastfeeding mothers (Sachs et al., 2013).

Breastfeeding should be discontinued temporarily when the mother undergoes imaging procedures that use radiopharmaceuticals. Mothers are advised to pump and discard milk for a period of time based on the properties of the specific radioactive agent (Sachs et al., 2013).

Drugs that are associated with adverse effects on the breastfeeding infant include antimetabolite and cytotoxic medications and drugs of abuse such as cocaine, heroin, amphetamines, and phencyclidine.

Women who have been stable on a methadone maintenance program should be allowed to breastfeed. Their infants may have decreased severity of neonatal abstinence symptoms when they are receiving breast milk (Lawrence & Lawrence, 2011a).

Pain in postpartum breastfeeding mothers is most safely managed with nonopioid analgesics such as ibuprofen.

When opioid analgesia is used, breastfeeding infants are at risk of sedation and sucking difficulties. Parenteral doses of morphine or butorphanol are preferred over meperidine. Oral hydrocodone is often used; however, frequent administration and doses greater than 10 mg can result in neonatal sedation (Montgomery, Hale, & Academy of Breastfeeding Medicine, 2012). Oxycodone is considered less desirable because relatively high amounts are transferred to the nursing infant and can lead to central nervous system depression (Sachs et al., 2013).

As the use of antidepressant, antianxiety, and mood stabilizing medications rises among childbearing women, there are increasing concerns about the effects of these medications on breastfeeding infants. There is a lack of evidence about the long-term effects on infants and children. Medications that are not recommended while breastfeeding include citalopram, diazepam, escitalopram, fluoxetine, lithium, nortriptyline, sertraline, and venlafaxine because of the high levels excreted in breast milk and potential risks to the infant (Sachs et al., 2013) (see also Chapter 31).

Although there is no standard recommendation about avoiding alcohol use when breastfeeding, it is important for mothers to be aware of potential risks. The AAP Section on Breastfeeding (2012) recommends that alcohol intake by breastfeeding women should be minimal. Intake of alcohol should be limited to occasional consumption of less than 0.5 g/kg of body weight (e.g., 8 oz wine or 2 beers). Alcohol passes freely from the blood into breast milk, with peak levels occurring in 30 to 60 minutes on an empty stomach and 60 to 90 minutes when consumed with food. The MER and milk production can be adversely affected by maternal alcohol intake. If a breastfeeding mother chooses to have one or two drinks, she should not breastfeed for at least 2 hours. Contrary to popular belief, pumping and discarding milk do not accelerate removal of alcohol from the milk (Lawrence & Lawrence, 2011a). Some mothers use test strips for alcohol content of breast milk; however, there is a lack of evidence to support the accuracy or reliability of these strips.

Smoking by breastfeeding mothers should be strongly discouraged (AAP Section on Breastfeeding, 2012). It can impair milk production; it also exposes the infant to the risks of secondhand smoke. Nicotine is transferred to the infant in breast milk, whether the mother smokes or uses a nicotine patch, although the effect on the infant is uncertain. Lactating mothers who continue to smoke should be advised not to smoke within 2 hours before breastfeeding and never to smoke in the same room with the infant.

Moderate intake of caffeine by breastfeeding mothers appears to pose no risk to normal full-term infants. Minimal amounts of caffeine pass through to the infant in the breast milk. However, caffeine accumulates in infants, especially if they are preterm (Lawrence & Lawrence, 2011a).

Herbal Preparations. Herbs and herbal preparations such as teas are often recommended for breastfeeding women, especially when there is a need to increase milk supply. Although these herbal preparations may seem to be effective for some women, the recommendations are based on anecdotal information. There is a lack of evidence related to the prevalence, effectiveness, and safety of herbs during breastfeeding (Budzynska, Gardner, Dugoua, et al., 2012). Herbals are not regulated by the FDA because they are considered dietary supplements. Consequently

there is a lack of quality control; unknown additives in and unknown side effects from herbal preparations can be harmful to the infant. Although some herbs may be considered safe, others contain pharmacologically active compounds that can have unfavorable effects. A thorough maternal history should include the use of any herbal remedies. Each remedy should then be evaluated for its compatibility with breastfeeding. LactMed provides information about the safety of herbal preparations and breastfeeding. Additionally, regional poison control centers can provide information on the active properties of herbs (Lawrence & Lawrence, 2011a; Sachs et al., 2013).

Common Concerns of the Breastfeeding Mother. The breastfeeding mother can experience some common problems. In most cases these complications are preventable if the mother receives appropriate education about breastfeeding. Early recognition and prompt resolution of these problems are important to prevent interruption of breastfeeding and to promote the mother's comfort and sense of well-being. Emotional support provided by the nurse or lactation consultant is essential to help allay the mother's frustration and anxiety and prevent early cessation of breastfeeding.

Engorgement. Engorgement is a common response of the breasts to the sudden change in hormones and the onset of significantly increased milk volume. It usually occurs 3 to 5 days after birth when the milk "comes in." As milk production rapidly increases, the volume can exceed the storage capacity of the alveoli in the breasts. If milk is not removed, the alveoli become distended, causing impairment of capillary blood flow surrounding the alveolar cells. As the blood vessels become more congested, fluid leaks into the surrounding tissue, resulting in edema. The milk ducts can be compressed by the tissue edema so milk cannot flow easily from the breasts. The breasts can become firm, tender, and hot and can appear shiny and taut. The areolae are firm, and the nipples can flatten, making it difficult for the infant to latch on to the breast (see Clinical Reasoning Case Study). Because back pressure on full milk glands inhibits milk production, if milk is not removed from the breasts, the milk supply can diminish.

CLINICAL REASONING CASE STUDY

Breastfeeding: Engorgement

The nurse on the mother/baby unit is caring for Johanna, a 37-year-old primipara who gave birth to a baby girl by emergency cesarean 3 days ago. During the morning assessment the nurse observes that Johanna's breasts are engorged. She sent the baby to the nursery during the night for feeding because she was exhausted. The engorgement seems to have happened overnight while Johanna was sleeping.

1. Evidence—Does the nurse have enough evidence at this time to draw conclusions about the engorgement and feeding issues facing this mother and infant?
2. Assumptions—What assumptions can be made about the following issues?
 - a. The need to relieve the engorgement
 - b. Johanna's understanding of milk production
 - c. The infant's ability to feed effectively
 - d. Johanna's commitment to breastfeeding
3. What implications and priorities for nursing care can be identified at this time?
4. Does the evidence objectively support your conclusion?

When engorgement occurs it is a temporary condition that is usually resolved within 24 hours. The mother is instructed to feed every 2 hours, softening at least one breast and pumping the other breast as needed to soften it. Pumping during engorgement does not cause a problematic increase in milk supply.

A variety of interventions are used to treat engorgement, although there is a lack of research evidence confirming the effectiveness of any specific intervention. Frequently used treatments for engorgement include the use of cold (ice packs, gel packs, cold compresses) after breastfeeding, chilled cabbage leaves, warmth (warm compresses, warm showers) before breastfeeding, antiinflammatory medications, breast massage, and pumping.

To reduce swelling of breast tissue surrounding the milk ducts, ice packs are often recommended in a 15- to 20-minutes-on, 45-minutes-off rotation between feedings. The ice packs should cover both breasts. Large bags of frozen peas make easy packs and can be refrozen between uses.

Fresh, raw cabbage leaves placed over the breasts between feedings can help relieve engorgement. It is thought that the effect of the cabbage leaves is related to the coolness of the leaves and phytoestrogens within them. They are washed, dried, chilled in the refrigerator or freezer, crushed slightly to break up the veins in the leaves, and then placed over the breasts for 15 to 20 minutes (Fig. 25-16). This treatment can be repeated for two or three sessions. Frequent application of cabbage leaves can decrease milk supply. Cabbage leaves should not be used if the mother is allergic to cabbage or develops a skin rash.

Antiinflammatory medications such as ibuprofen can help reduce the pain and swelling associated with engorgement. Ibuprofen also helps reduce fever and aching in the breasts that are often associated with engorgement.

Because heat increases blood flow, its application to an already congested breast is usually counterproductive. However, occasionally standing in a warm shower starts the milk leaking, or the mother may be able to manually express enough milk to soften the areola sufficiently to allow the baby to latch and breastfeed.

As a result of engorgement, excessive intravenous fluids during labor, or oxytocin for labor induction or augmentation, the nipple and areola can become distended, making it difficult for the newborn to latch successfully. A technique called *reverse pressure softening* manually displaces the areolar interstitial fluid

FIG 25-16 Cabbage leaves to treat engorgement. (Courtesy Kathryn Alden, Chapel Hill, NC.)

inward, softening the areola and making it easier for the infant's mouth to grasp the nipple and areola with latch (Lauwers & Swisher, 2011).

Sore Nipples. Mild nipple tenderness during the first few days of breastfeeding is common. Severe soreness or painful, abraded, cracked, or bleeding nipples are not normal and most often result from poor positioning, incorrect latch, improper suck, or infection. Severe nipple pain can be related to vasospasm or Raynaud's phenomenon (Lawrence & Lawrence, 2011a). The key to preventing sore nipples is correct breastfeeding technique. Limiting the time at the breast does not prevent sore nipples. They are often the result of the mother allowing the baby to latch on to the breast before the mouth is open wide.

For the first few days after birth the mother can experience some mild discomfort with the infant's initial sucks. This should quickly dissipate as the milk begins to flow and acts as a lubricant. To make the initial sucks less painful the mother can express a few drops of colostrum or milk to moisten the nipple and areola before latch. If the mother continues to experience nipple pain or discomfort after the first few sucks, the nurse or lactation consultant helps her evaluate the latch and baby's position at the breast. If the nipple pain continues, the mother needs to remove the baby from the breast, breaking suction with her finger in the baby's mouth (see Fig. 25-7). Repositioning the mother or infant can be helpful in resolving the nipple discomfort. The mother then proceeds to attempt latch again, making sure that the baby's mouth is open wide before latching him or her on to the breast (see Fig. 25-6).

The nurse or lactation consultant can assess the infant's suck by inserting a clean, gloved finger into the mouth and stimulating the infant to suck. If the tongue is not extruding over the lower gum and the mother reports pain or pinching with sucking, the baby may have *ankyloglossia*, which is a short or tight frenulum (commonly known as tongue-tie). In some instances this condition is corrected surgically to free the tongue for less painful, more effective breastfeeding (Lawrence & Lawrence, 2011a).

The treatment for sore nipples is first to identify the cause and then attempt to correct the problem. Early assessment and intervention are essential to increase the likelihood that the mother will continue to breastfeed. Once the problem is identified and corrected, sore nipples should heal within a few days, even though the baby continues to breastfeed regularly. When sore nipples occur, the woman is advised to start the feeding on the least sore nipple. It is important to assess the nipples for cracking or other damage to the skin integrity, which increases the risk of infection. If there is any break in the skin, the mother is advised to wipe the nipples with water after feeding to remove the baby's saliva. A thin coating of a topical antibiotic may help reduce the risk of infection and promote healing (the antibiotic cream or ointment should be removed before breastfeeding). Sore nipples should be open to air as much as possible. To promote comfort, breast shells may be worn inside the bra; these devices allow air to circulate while keeping clothing off sore nipples (see Fig. 25-15).

Rapid healing of sore nipples is critical to relieve the mother's discomfort, maintain breastfeeding, and prevent mastitis. Although numerous creams, ointments, gels, and gel pads have been used to treat sore nipples, there is a lack of conclusive evidence related to the effectiveness of any particular method.

However, because they have not been shown to cause harm, many health care professionals recommend their use. Some women report increased comfort for sore nipples with the application of purified lanolin or hydrogel pads. If nipples are extremely sore or damaged and if the mother cannot tolerate breastfeeding, she may need to use an electric breast pump for 24 to 48 hours to allow the nipples to begin healing before resuming breastfeeding. She should use a pump that effectively empties the breasts (see Figs. 25-10 and 25-12).

The mother who has a sudden onset of sore nipples or experiences sore nipples after days or weeks of comfortable breastfeeding likely has some type of nipple infection, most often bacterial or fungal (candidiasis). Other possible causes are skin problems such as psoriasis, allergic reactions, or vasospasm. Careful assessment and referral for treatment are needed.

Insufficient Milk Supply. A major reason that women stop breastfeeding is perceived or actual insufficient milk supply (Brand, Kothari, & Stark, 2011; Lauwers & Swisher, 2011). Careful evaluation of the mother-infant dyad is needed, including assessment of infant weight gain or loss, feeding technique, and milk transfer and consideration of possible medical causes for low supply (e.g., medications, glandular insufficiency, previous breast surgery). Stress and fatigue can cause decreased milk production.

Interventions for increasing milk supply are based on causative factors. In many cases the mother is told to spend time with the baby skin to skin, increase feeding frequency, express milk using an electric pump, rest as much as possible, consume a healthy diet, and reduce stress. If nonpharmacologic measures to increase milk supply are not effective, **galactagogues** (medications or other substances that are believed to increase milk supply) may be recommended. Mothers often use herbal galactagogues such as fenugreek, blessed thistle, goat's rue, and shatavari to increase milk production. However, there is a lack of evidence to support the use of these substances (Sachs & Committee on Drugs, 2013).

Pharmaceutical galactagogues must be prescribed by the health care provider. Metoclopramide and domperidone are the most commonly prescribed medications; both are dopamine antagonists typically used to treat gastroesophageal reflux. It is thought that they increase prolactin levels, which enhances milk production. There is a lack of evidence to support the use of these medications in breastfeeding women (Sachs et al., 2013).

MEDICATION ALERT

Metoclopramide clearance in neonates is prolonged, which increases the risk of conditions resulting from overdose such as methemoglobinemia. Mothers are at risk for adverse reactions to metoclopramide including depression, suicidal ideation, and GI disturbances (Sachs et al., 2013).

Domperidone is often prescribed for lactating women in Canada and other countries (Flanders, Lowe, Kramer, et al., 2012), although it is not available in the United States except through some compounding pharmacies (ABM Protocol Committee, 2011b; Lauwers & Swisher, 2011). The FDA has issued a warning against the use of domperidone, stating that "the importation of this drug presents a public health risk and

violates the Federal Food, Drug, and Cosmetic Act (the Act)” (FDA, 2012).

Plugged Milk Ducts. A milk duct can become plugged or clogged, causing an area of the breast to become swollen and tender. This area typically does not empty or soften with feeding or pumping. A small white pearl may be visible on the tip of the nipple; this pearl is the curd of milk blocking the flow. The mother is afebrile and has no generalized symptoms.

Plugged milk ducts are most often the result of inadequate removal of milk from the breast, which can be caused by clothing that is too tight, a poorly fitting or underwire bra, or always using the same position for feeding. Application of warm compresses to the affected area and to the nipple before feeding helps promote emptying of the breast and release of the plug.

Frequent feeding is recommended, with the baby beginning the feeding on the affected side to foster more complete emptying. The mother is advised to massage the affected area while the infant nurses or while she is pumping. Varying feeding positions and feeding without wearing a bra may be useful in resolving a plugged duct. Plugged milk ducts can increase susceptibility to breast infection. For recurrent plugged ducts, taking lecithin, a fat emulsifier, may be useful (Lawrence & Lawrence, 2011a).

Mastitis. Although the term **mastitis** means inflammation of the breast, it is most often used to refer to infection of the breast. It is characterized by the sudden onset of influenza-like symptoms, including fever, chills, body aches, and headache. The woman usually has localized breast pain and tenderness and a hot, reddened area on the breast. Mastitis most commonly occurs in the upper outer quadrant of the breast; one or both breasts can be affected. Most cases occur during the first 6 weeks of breastfeeding, although mastitis can occur at any time (Lawrence & Lawrence, 2011a).

Certain factors can predispose a woman to mastitis. Inadequate emptying of the breasts is common; this can be related to engorgement, plugged ducts, a sudden decrease in the number of feedings, abrupt weaning, or wearing underwire bras. Sore, cracked nipples can lead to mastitis by providing a portal of entry for causative organisms (*Staphylococcus*, *Streptococcus*, and *Escherichia coli* are most common). Stress, fatigue, maternal illness, ill family members, breast trauma, and poor maternal nutrition also are predisposing factors for mastitis (Lauwers & Swisher, 2011; Lawrence & Lawrence, 2011a). Breastfeeding mothers should be taught the signs of mastitis before they are discharged from the hospital after birth, and they need to know to call the health care provider promptly if the symptoms occur. Treatment includes antibiotics such as cephalexin or dicloxacillin for 10 to 14 days and analgesic and antipyretic medications such as ibuprofen. The mother is advised to rest as much as possible and breastfeed or pump frequently, striving to empty the affected side adequately. Warm compresses to the breast before feeding or pumping can be useful. Adequate fluid intake and a balanced diet are important for the mother with mastitis (Lauwers & Swisher, 2011).

Complications of mastitis include breast abscess, chronic mastitis, and fungal infections of the breast. Most complications can be prevented by early recognition and treatment (see Chapter 34).

Follow-Up After Discharge

Problems with sore nipples, engorgement, and jaundice are likely to occur after discharge from the birth institution. The nurse educates the mother about potential problems she may encounter once she is home. She should be given a list of resources for help with breastfeeding concerns. Community resources for breastfeeding mothers include lactation consultants in hospitals, primary care offices, or private practice; nurses in pediatric or obstetric offices; support groups such as La Leche League; and peer counseling programs (e.g., those offered through WIC). The Internet has many websites containing current and correct information about breastfeeding (e.g., www.breastfeeding.com). The National Breastfeeding Helpline (1-800-994-9662) through the Office of Women’s Health provides breastfeeding information and counseling by English- and Spanish-speaking counselors.

Telephone follow-up by nurses or lactation consultants in hospitals, birth centers, clinics, or offices within the first day or two after discharge can help identify problems and offer needed advice and support. Breastfeeding infants should be seen by a health care provider at 3 to 5 days of age and again at 2 to 3 weeks to assess weight gain and offer encouragement and support to the mother (AAP Section on Breastfeeding, 2012).

FORMULA FEEDING

Parent Education

The majority of infants receives at least some amount of commercial infant formula during their first year of life. Some parents choose formula feeding instead of breastfeeding; others combine the two methods. If the infant is weaned from breastfeeding before the first birthday, iron-fortified infant formula should be given (AAP Section on Breastfeeding, 2012).

It is important for nurses and other health care professionals to be intentional about providing education for parents related to formula preparation, feeding, and common problems they can encounter. Because of the lack of clear information about the practical aspects of formula feeding, parents often rely on advice from friends and family. If that advice is incorrect and the parents use unsafe practices for formula preparation and feeding, the infant is at risk for foodborne illness and burns (see Teaching for Self-Management box: Formula Preparation and Feeding).

Readiness for Feeding

Ideally the first feeding of formula is given after the neonate’s initial transition to extrauterine life. Feeding-readiness cues include stability of vital signs, effective breathing pattern, presence of bowel sounds, an active sucking reflex, and signs described earlier for breastfed infants.

Feeding Patterns

In the first 24 to 48 hours of life a newborn typically consumes 15 to 30 ml of formula at a feeding. Intake gradually increases during the first week of life. Most newborns are drinking 90 to 150 ml at a feeding by the end of the second week or sooner. The newborn infant should be fed at least every 3 to 4 hours, even if it is necessary to wake him or her for the feedings; however, rigid feeding schedules are not recommended. The infant showing an adequate weight gain can be allowed to sleep at night and be fed only on awakening. Most newborns need six to eight feedings in

24 hours; the number of feedings decreases as the infant matures and consumes more at each feeding. By 3 to 4 weeks after birth a fairly predictable feeding pattern has usually developed. Scheduling feedings arbitrarily at predetermined intervals may not meet a newborn's needs, but initiating feedings at convenient times often moves the feedings to times that work for the family.

Mothers usually notice increases in the infant's appetite at the age of approximately 10 days, 3 weeks, 6 weeks, 3 months, and 6 months. These appetite spurts correspond to growth spurts. Mothers should increase the amount of formula per feeding by approximately 30 ml to meet the baby's needs at these times.

Feeding Technique

Infants should be held for all feedings. During feedings parents are encouraged to sit comfortably, holding the infant close in a semi-upright position with good head support. Feedings provide opportunities to bond with the baby through touching, talking, singing, or reading to the infant. Parents should consider feedings a time of peaceful relaxation with the infant. Mothers who bottle feed should be encouraged to spend some time with their newborns in skin-to-skin contact.

SAFETY ALERT

A bottle should never be propped with a pillow or other inanimate object and left with the infant. This practice can result in choking, and it deprives the infant of important interaction during feeding. Moreover, propping the bottle has been implicated in causing nursing-bottle caries or decay of the first teeth resulting from continuous bathing of the teeth with carbohydrate-containing fluid as the infant sporadically sucks the nipple.

Newborns must learn to coordinate sucking, swallowing, and breathing as they feed. The typical fast flow of milk from bottles can create difficulty for an infant trying to learn to feed. A slow-flow nipple is often used for the first few weeks.

Traditionally parents are told to position the infant in a semi-reclining position and to hold the bottle so that fluid fills the nipple and none of the air in the bottle is allowed to enter it (Fig. 25-17, A). A more physiologic approach to bottle feeding is called *paced bottle feeding*. With this method of feeding the bottle is held at more of a horizontal angle; when the baby pauses between bursts of sucking, the parent withdraws the nipple, allowing it to rest on the baby's lip until he or she is ready to resume sucking (Lauwers & Swisher, 2011). This position slows the flow of milk from the bottle so the infant is more in control. Paced bottle feeding works well for infants who are primarily breastfeeding but are occasionally fed from a bottle.

If the infant falls asleep or ceases to suck, it usually indicates that he or she has consumed enough formula to feel satiated. Teach parents to look for these cues and avoid overfeeding, which can contribute to obesity.

Instruct parents to observe the infant for signs of stress during feeding, including turning the head, arching the back, choking, sputtering, changing color, moving the arms, and tensing fists (Lauwers & Swisher, 2011). When these signs occur, the parent should stop feeding and attempt to calm the infant before resuming. The signs can indicate that the infant is finished with the feeding and does not want to drink any more.

FIG 25-17 A, Bottle feeding: traditional technique with infant semi-reclining B, Paced bottle feeding: infant is more upright. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

Most infants swallow air when fed from a bottle and need a chance to burp several times during a feeding. Parents are taught various positions that can be used for burping (Fig. 25-18).

Common Concerns

Parents need to know what to do if the infant spits up. They may need to decrease the amount of feeding or feed smaller amounts more frequently. Burping the infant several times during a feeding such as when the infant's sucking slows down or stops can decrease spitting. Holding the baby upright for 30 minutes after feeding and avoiding bouncing or placing him or her on the abdomen soon after the feeding is finished also can help. Spitting can be a result of overfeeding, or it can be symptomatic of gastroesophageal reflux. Parents should report vomiting one third or more of the feeding at most feeding sessions or projectile vomiting to the health care

TEACHING FOR SELF-MANAGEMENT

Formula Preparation and Feeding

Formula Preparation

- Using warm soapy water, wash your hands, arms, and under your nails; rinse well. Clean and sanitize the surface where you will be preparing the bottles.
- Thoroughly wash bottles, nipples, rings, caps, can opener, and other preparation utensils in hot soapy water and rinse thoroughly. Squeeze water through nipples to make sure that the holes are open.
- Place bottles, nipples, rings, and caps in a pot and cover with water; boil for 5 minutes; remove items from pot with sanitized tongs and allow them to air dry. (Do this before using items the first time; thereafter you can continue to do this or place items in the dishwasher.)
- Note the expiration date on the formula container. It should be used before the expiration date. Any unopened expired formula should be returned to the place of purchase.
- Read the label on the container of formula and mix it exactly according to the directions.
- Mix formula with tap water deemed safe by the local health department. Allow cold water to run for 2 minutes before collecting it. Then bring it to a rolling boil and continue boiling for 1 to 2 minutes. If using bottled water, make sure that it is labeled as "sterile"; unsterile bottled water must be boiled. After boiling allow water to cool before mixing the formula but not for longer than 30 minutes.
- If using a can of ready-to-feed or concentrated formula, wash the top of the can with hot soapy water and rinse well. Shake the can before opening.
- Mixing formula
 - Ready-to-feed: No mixing is needed; do not add water. Pour desired amount of formula into clean bottle; add nipple and ring.
 - Concentrate: Pour desired amount of formula into clean bottle and add equal amount of cooled boiled water. Add nipple and ring and shake well.
 - Powder: When first opening the container of powder, write the date on the lid. Using the scoop from the container, add 1 scoop of powdered formula for each 2 ounces of boiled, cooled water in a clean bottle. For example, if 6 ounces of water is in the bottle, add three scoops of powder. Add nipple and ring and shake well.
- If preparing multiple bottles at the same time, place nipple right side up on each bottle and cover with a clean nipple cap. Use bottles within 48 hours.
- Opened cans of ready-to-feed or concentrated formula should be covered and refrigerated. Any unused portions must be discarded after 48 hours.
- Bottles or cans of unopened formula can be stored at room temperature.
- If the formula is refrigerated, warm it by placing the bottle in a pan of hot water. Never use a microwave to warm any food to be given to a baby. Test the temperature of the formula by letting a few drops fall on the inside of your wrist. If the formula feels comfortably warm to you, the temperature is correct.

Feeding Techniques and Tips

- Newborns should be fed at least every 3 to 4 hours and should never go longer than 4 hours without feeding until a satisfactory

pattern of weight gain is established. This period can be as long as 2 weeks. If a baby cries or fusses between feedings, check to see if the diaper should be changed and if the baby needs to be picked up and cuddled. If the baby continues to cry and acts hungry, feed him or her. Babies do not get hungry on a regular schedule.

- Infants gradually increase the amount of milk they drink with each feeding. The first day or so most newborns consume 15 to 30 ml (0.5 to 1 ounce) with each feeding. This amount increases as the infant grows. If any formula remains in the bottle as the feeding ends, it must be thrown away because saliva from the baby's mouth can cause the formula to spoil.
- Keep a feeding diary, writing down the amount of formula the infant drinks with each feeding for the first week or so. Also record the number of the baby's wet diapers and bowel movements. Take this diary with you to the baby's first follow-up visit with the primary health care provider.
- For feeding hold the infant close in a semi-reclining position. Talk to him or her during the feeding. This time is ideal for social interaction and cuddling.
- Place the nipple in the infant's mouth on the tongue. It should touch the roof of the mouth to stimulate the baby's sucking reflex. Hold the bottle like a pencil. Keep it tipped so the nipple stays filled with milk and the baby does not suck in air.
- Taking a few sucks and then pausing briefly before continuing to suck again is normal for infants. Some infants take longer to feed than others. Be patient. Keep the baby awake; encouraging sucking may be necessary. Moving the nipple gently in the infant's mouth may stimulate sucking.
- Another technique that can be used for bottle feeding is *paced bottle feeding*. The infant is placed in a more upright position, and the bottle is held at a more horizontal angle. When the baby pauses between bursts of sucking, withdraw the nipple and allow it to rest on the baby's lip until he or she is ready to resume sucking. This slows the flow of milk from the bottle so the infant is more in control. Paced bottle feeding works well for infants who are primarily breastfeeding but are occasionally fed from a bottle.
- Newborns are apt to swallow air when sucking. Give the infant opportunities to burp several times during a feeding. As he or she gets older, you will know better when to stop for burping.
- After the first 2 or 3 days the stools of a formula-fed infant are yellow and soft but formed. The infant may have a stool with each feeding in the first 2 weeks, although this amount can decrease to one or two stools each day. It is not abnormal for formula-fed infants to have a stool every other day.

Safety Tips

- Infants should be held and never left alone while feeding. Never prop the bottle. The infant might inhale formula or choke on any that was spit up. Infants who fall asleep with a propped bottle of milk or juice can be prone to cavities when the first teeth come in.
- Know how to use the bulb syringe and help an infant who is choking.

FIG 25-18 Positions for burping an infant. A, Sitting. B, On shoulder. C, Across lap. (Courtesy Julie Perry Nelson, Loveland, CO.)

provider and should be cautioned to refrain from changing the infant's formula without consulting the health care provider.

Bottles and Nipples

Various brands and styles of bottles and nipples are available. Most babies feed well with any bottle and nipple. The bottles, nipples, rings, and caps should be washed in warm soapy water, using a bottle and nipple brush to facilitate thorough cleansing. They should be placed in boiling water for 5 minutes and allowed to air dry; this should be done at least before the first use and thereafter unless they are cleaned in a dishwasher (see Teaching for Self-Management box: Formula Preparation and Feeding). Boiling of feeding equipment is recommended if the infant has oral thrush.

Infant Formulas

Commercial Formulas

Commercial infant formulas are designed to resemble human milk as closely as possible, although none has ever duplicated it. The exact composition of infant formula varies with the manufacturer, but all must meet specific standards.

Infants who are not breastfed should be given commercial iron-fortified formulas. Families with limited income may be eligible for services through the WIC program, which provides iron-fortified infant formula.

The most widely used commercially prepared formulas are cow's milk-based formulas that have been modified to closely resemble the nutritional content of human milk. The caloric content of standard infant formula is 20 kcal/oz. These formulas are altered from cow's milk by removing butterfat, decreasing the protein content, and adding vegetable oil and carbohydrate. Regardless of the commercial brand, the standard cow's milk-based formulas have essentially the same compositions of vitamins, minerals, protein, carbohydrates, and essential amino acids, with minor variations such as the source of carbohydrate; nucleotides to enhance immune function; and long-chain polyunsaturated fatty acids (DHA and ARA), which are thought to improve visual and cognitive function. Furthermore, the FDA regulates the manufacture of infant formula in the United States to ensure product safety. Standard cow's milk-based formulas

are sold as low-iron and iron-fortified formulas; however, only the iron-fortified formulas meet infants' requirements.

Four main categories of commercially prepared infant formulas are available: (1) cow's milk-based formulas; (2) soy-based formulas, commonly used for children who are lactose or cow's milk-protein intolerant; (3) casein- or whey-hydrolysate formulas, used primarily for children who cannot tolerate or digest cow's milk- or soy-based formulas; and (4) amino acid formulas, used for infants with multiple food protein intolerances.

The AAP Committee on Nutrition indicates that few solid indications exist for the use of soy protein-based formulas instead of cow's milk-based formulas (Bhatia, Greer, & AAP Committee on Nutrition, 2008). Soy-based formulas are recommended for infants with galactosemia and congenital lactase deficiency; infants with secondary lactase deficiency may benefit as well. Infants with documented IgE allergies caused by cow's milk should be fed an extensively hydrolyzed protein formula. Soy protein-based formulas have not been proven to be effective against colic or in the prevention of allergy in healthy or high-risk infants.

Alternate milk sources such as goat's milk; skim or low-fat milk; condensed milk; or raw, unpasteurized milk from any animal source should not be fed to infants because they are inadequate to support growth and can contain excess protein or an inadequate calcium-to-phosphorus ratio, which can cause seizures.

⚡ SAFETY ALERT

Because of concerns about potential harmful effects of bisphenol A (BPA), parents should be cautioned about using hard plastic polycarbonate baby bottles or containers. BPA is a chemical that is used to harden plastics, prevent bacterial contamination of foods, and prevent can rusting. It is in many food and liquid containers, including baby bottles. The AAP (2012) recommends avoiding clear plastic bottles or containers imprinted with the recycling number 7 and the letters PC and purchasing bottles that are certified or identified as BPA-free. Glass bottles are an alternative, but parents must be aware of the risk for injury if the bottle is dropped or broken. Because heat can cause the release of BPA from plastic, polycarbonate bottles should never be boiled, heated in the microwave, or washed in a dishwasher (AAP, 2012).

Formula Preparation

Commercial formulas are available in three forms: powder, concentrate, and ready to feed. All forms are equivalent in terms of nutritional content, but they vary considerably in cost.

- Ready-to-feed formula is the most expensive but the easiest to use. The desired amount is poured into the bottle. The opened can is refrigerated safely for 48 hours. This type of formula can be purchased in individual disposable bottles for the most convenient feeding.
- Concentrated formula is less expensive than ready to feed. It is diluted with equal parts of water and can be stored in the refrigerator for 48 hours after opening.
- Powdered formula is the least expensive. It is easily mixed by using one scoop for every 60 ml of water.

The commercial infant formula must include label directions for preparation and use of the formula with pictures and symbols for the benefit of individuals who cannot read. Some manufacturers translate the directions into languages such as Spanish, French, Vietnamese, Chinese, and Arabic to prevent misunderstanding and errors in formula preparation.

SAFETY ALERT

An important aspect to impress on families is that the proportions must not be altered (i.e., neither diluted to extend the amount of formula nor concentrated to provide more calories). The newborn's kidneys are immature; giving the infant overly concentrated formula can provide protein and minerals in amounts that exceed the excretory ability of the kidneys. In contrast, if the formula is diluted too much (sometimes done to save money), the infant does not consume sufficient calories to grow appropriately.

The water used to mix either powdered or concentrated liquid formula need not contain any fluoride, especially in the first 6 months of life. Excess fluoride can permanently stain the teeth once they appear.

Sterilization of formula rarely is recommended when families have access to a safe public water supply. Instead formula is prepared with attention to cleanliness. When water from a private well is used, parents should be advised to contact the health department to have a chemical and bacteriologic analysis of the water performed before using the water in formula preparation. The presence of nitrates, excess fluoride, or bacteria can be harmful to the infant.

It is usually safe to mix infant formula with cold tap water that has been boiled for 1 to 2 minutes and allowed to cool. Bottled water that is labeled as “sterile” is safe for mixing formula. However, nonsterile bottled water should be boiled for 1 to 2 minutes and cooled.

If the conditions in the home appear unsanitary, the nurse should recommend the use of ready-to-feed formula or teach the mother to sterilize the formula. The two traditional methods for sterilization are terminal heating and the aseptic method. In the terminal heating method the prepared formula is placed in the bottles, which are topped with the nipples placed upside down and covered with the caps and sealed loosely with the rings. The bottles are then boiled together in a water bath for 25 minutes. In the aseptic method the bottles, rings, caps, nipples, and any other necessary equipment such as a funnel are boiled separately, after

which the formula is poured into the bottles. Instructions for formula preparation and feeding are provided in the Teaching for Self-Management box: Formula Preparation and Feeding.

Vitamin and Mineral Supplementation

Commercial iron-fortified formula has all of the nutrients that infants need for the first 6 months of life. After 6 months fluoride supplementation is recommended based on levels in the water supply.

Weaning

The bottle-fed infant gradually learns to use a cup, and the parents find that they are preparing fewer bottles. The bottle feeding before bedtime is often the last one to remain. Babies have a strong need to suck, and the baby who has the bottle taken away too early or abruptly compensates with nonnutritive sucking on his or her fingers, thumb, a pacifier, or even the tongue. Therefore, weaning from a bottle should be attempted gradually because the baby has learned to rely on the comfort that sucking provides.

Complementary Feeding: Introducing Solid Foods

Complementary feedings are defined as foods or liquids given to the infant in addition to breast milk or formula. The AAP Committee on Nutrition (2009) recommends introducing solid foods after 4 months of age and preferably after 6 months of age. The AAP Section on Breastfeeding (2012) recommends waiting until 6 months. Traditionally the recommended first foods were single-grain cereals, followed by vegetables and fruits. However, there is a lack of evidence to support any particular order as having advantages for infants. Breastfeeding infants in particular can benefit from a source of iron such as iron-fortified cereal or meat. New foods should be introduced slowly to assess for any allergic reaction or intolerance. It is best to offer no more than three new foods per week. Fruits and vegetables should be offered to infants daily starting at 6 to 8 months. Fruit juices are not recommended before 6 months of age because it is possible that the infant who drinks juice will consume less breast milk or formula. Consumption of low-nutrient foods such as fatty or sugary foods or restaurant foods should be limited.

In spite of the recommendations from the AAP, many parents begin complementary feedings earlier than 4 months. They need to be informed that the infant receives the right balance of nutrients from breast milk or formula during the first 4 to 6 months. The notion that the feeding of solids helps the infant sleep through the night is not true. Parents should not put cereal into the infant's bottle. Introduction of solid foods before the infant is 4 to 6 months of age can result in overfeeding and decreased intake of breast milk or formula.

Cultural beliefs and traditions affect complementary feeding practices. First foods given to infants vary widely. For example, first foods for Egyptian infants include bread soaked in milk and tea or yogurt sweetened with honey. Chinese and Vietnamese infants are sometimes fed prechewed rice paste, rice, or sweetened porridge.

Nurses and other health care professionals educate parents regarding complementary feedings. This most often occurs during well-baby supervision visits with the pediatric health care provider. Early feeding practices have implications for long-term dietary patterns; therefore, it is essential to teach parents about proper nutrition.

KEY POINTS

- Human breast milk is species-specific and is the recommended form of infant nutrition. It provides immunologic protection against many infections and diseases.
- Breast milk changes in composition with each stage of lactogenesis, during each feeding, and as the infant grows.
- During the prenatal period expectant parents should be informed of the benefits of breastfeeding for infants, mothers, families, and society.
- Infants should be breastfed within the first hour after birth and at least 8 to 12 times every 24 hours thereafter.
- Parents should be taught to recognize the signs of effective breastfeeding.
- Breast milk production is based on a supply-meets-demand principle: the more the infant nurses, the greater the milk supply.
- Infants go through predictable growth spurts.
- Sore nipples are most often caused by incorrect latch.
- Commercial infant formulas provide satisfactory nutrition for most infants.
- Infants should be held for feedings.
- Parents should be instructed about the types of infant formulas, proper preparation for feeding, and correct feeding technique.
- Solid (complementary) foods should be introduced at about 6 months of age.
- Unmodified cow's milk is inappropriate for infants less than 1 year of age.
- Nurses must be knowledgeable about feeding methods and provide education and support for families.

Assessment of High Risk Pregnancy

Janet A. Tucker

© <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Explore biophysical, psychosocial, sociodemographic, and environmental influences on high risk pregnancy.
- Examine risk factors identified through history, physical examination, and diagnostic techniques.
- Differentiate among screening and diagnostic techniques, including when they are used in pregnancy and for what purposes.
- Discuss psychologic considerations for the woman and her family experiencing a high risk pregnancy.
- Develop a teaching plan to explain screening and diagnostic techniques and implications of findings to women and their families.

In the most recent year for which figures are available, nearly 4 million births occurred in the United States (Martin, Hamilton, & Osterman, et al., 2013). Many of these were the result of pregnancies considered to be *high risk* because the life or health of the mother, fetus, or newborn was jeopardized by circumstances coincidental with or unique to the pregnancy. Care of these high risk clients requires the combined efforts of medical and nursing personnel. Factors associated with a diagnosis of a high risk pregnancy are identified in this chapter. Diagnostic techniques often used to monitor the maternal-fetal unit at risk also are described.

ASSESSMENT OF RISK FACTORS

Pregnancies can be designated as high risk for any of several undesirable outcomes. In the past risk factors were evaluated only from a medical standpoint. Therefore, only adverse medical, obstetric, or physiologic conditions were considered to place the woman at risk. Today a more comprehensive approach to high risk pregnancy is used, and the factors associated with high risk childbearing are grouped into broad categories based on threats to health and pregnancy outcome. Categories of risk include biophysical, psychosocial, sociodemographic, and environmental (Box 26-1). Risk factors are interrelated and cumulative in their effects.

Biophysical risks include factors that originate within the mother or fetus and affect the development or functioning of either one or both. Examples include genetic disorders, nutritional and general health status, and medical or obstetric-related illnesses. Box 26-2 lists common risk factors for several pregnancy-related problems.

Psychosocial risks consist of maternal behaviors and adverse lifestyles that have a negative effect on the health of the mother or fetus. These risks may include emotional distress, disturbed interpersonal relationships, inadequate social support, and unsafe cultural practices.

Sociodemographic risks arise from the mother and her family. These risks may place the mother and fetus at risk. Examples include lack of prenatal care, low income, marital status, and ethnicity (see Box 26-1).

Environmental factors include hazards in the workplace and the woman's general environment and may include environmental chemicals (e.g., lead, mercury), anesthetic gases, and radiation (Chambers & Scialli, 2014; Cunningham, Leveno, Bloom, et al., 2014).

ANTEPARTUM TESTING

Standard prenatal tests that are done for all pregnant women are discussed in Chapter 14 and listed in Table 14-1. This chapter concentrates on the testing that is done for high risk pregnancies rather than for those considered routine. Antepartum testing has two major goals. The first is to identify fetuses at risk for injury caused by acute or chronic interruption of oxygenation so permanent injury or death might be prevented. The second goal is to identify appropriately oxygenated fetuses so unnecessary intervention can be avoided (Miller, Miller, & Tucker, 2013). In most cases monitoring begins by 32 to 34 weeks of gestation and continues regularly until birth. Assessment tests should be selected on the basis of their effectiveness, and the results must be interpreted in light of the complete clinical

BOX 26-1 Categories of High Risk Factors**Biophysical Factors**

Genetic considerations. Genetic factors may interfere with normal fetal or neonatal development, result in congenital anomalies, or create difficulties for the mother. These factors include defective genes, transmissible inherited disorders and chromosomal anomalies, multiple pregnancy, large fetal size, and ABO incompatibility.

Nutritional status. Adequate nutrition, without which fetal growth and development cannot proceed normally, is one of the most important determinants of pregnancy outcome. Conditions that influence nutritional status include the following: young age; three pregnancies in the previous 2 years; tobacco, alcohol, or drug use; inadequate dietary intake because of chronic illness or food fads; inadequate or excessive weight gain; and hematocrit value less than 33%.

Medical and obstetric disorders. Complications of current and past pregnancies, obstetric-related illnesses, and pregnancy losses put the woman at risk (see Box 26-2).

Psychosocial Factors

Smoking. A strong, consistent, causal relationship has been established between maternal smoking and reduced birth weight. Risks include low-birth-weight infants, higher neonatal mortality rates, increased rates of miscarriage, and increased incidence of premature rupture of membranes. These risks are aggravated by low socioeconomic status, poor nutritional status, and concurrent use of alcohol.

Caffeine. Birth defects in humans have not been related to caffeine consumption. However, pregnant women who consume more than 200 mg of caffeine daily (equivalent to about 12 ounces of coffee per day) may be at increased risk for miscarriage or giving birth to infants with intrauterine growth restriction.

Alcohol. Although the exact effects of alcohol in pregnancy have not been quantified and its mode of action is largely unexplained, it exerts adverse effects on the fetus, resulting in fetal alcohol syndrome, fetal alcohol effects, learning disabilities, and hyperactivity.

Drugs. The developing fetus may be affected adversely by drugs through several mechanisms. They can be teratogenic, cause metabolic disturbances, produce chemical effects, or cause depression or alteration of central nervous system function. This category includes medications prescribed by a health care provider or bought over the counter, and commonly abused drugs such as heroin, cocaine, and marijuana. (See Chapter 31 for more information about drug and alcohol abuse.)

Psychologic status. Childbearing triggers profound and complex physiologic, psychologic, and social changes, with evidence to suggest a relationship between emotional distress and birth complications. This risk factor includes conditions such as specific intrapsychic disturbances and addictive lifestyles; a history of child or spouse abuse; inadequate support systems; family disruption or dissolution; maternal role changes or conflicts; noncompliance with cultural norms; unsafe cultural, ethnic, or religious practices; and situational crises.

Sociodemographic Factors

Low income. Poverty underlies many other risk factors and leads to inadequate financial resources for food and prenatal care, poor general health, increased risk of medical complications of pregnancy, and greater prevalence of adverse environmental influences.

Lack of prenatal care. Failure to diagnose and treat complications early is a major risk factor arising from financial barriers or lack of access to care; depersonalization of the system resulting in long waits, routine visits, variability in health care personnel,

and unpleasant physical surroundings; lack of understanding of the need for early and continued care or cultural beliefs that do not support the need; and fear of the health care system and its providers.

Age. Women at both ends of the childbearing age spectrum have an increased incidence of poor outcomes; however, age may not be a risk factor in all cases. Physiologic and psychologic risks should be evaluated.

Adolescents. More complications are seen in young mothers (younger than 15 years) and in pregnancies occurring less than 6 years after menarche. Complications include anemia, preeclampsia, prolonged labor, and contracted pelvis and cephalopelvic disproportion. The fetus has a greatly increased risk of low birth weight and of dying during the first year of life. Long-term social implications of early motherhood are lower educational attainment, lower income, increased dependence on government support programs, higher divorce rates, and higher parity.

Mature mothers. The risks to older mothers are not from age alone but from other considerations such as number and spacing of previous pregnancies, genetic disposition of the parents, medical history, lifestyle, nutrition, and prenatal care. The increased likelihood of chronic diseases and complications that arise from more invasive medical management of a pregnancy and labor combined with demographic characteristics put an older woman at risk. Conditions more likely to be experienced by mature women include chronic hypertension and preeclampsia, diabetes, prolonged labor, cesarean birth, placenta previa, placental abruption, and death. Her fetus is at greater risk for low birth weight and macrosomia, chromosomal abnormalities, congenital malformations, and neonatal death.

Parity. The number of previous pregnancies is a risk factor associated with age and includes all first pregnancies, especially a first pregnancy at either end of the childbearing age continuum. The incidence of preeclampsia and dystocia is increased with a first birth.

Marital status. The increased mortality and morbidity rates for unmarried women, including an increased risk for preeclampsia, are often related to inadequate prenatal care and a young childbearing age.

Residence. The availability and quality of prenatal care vary widely with geographic residence. Women in metropolitan areas have more prenatal visits than those in rural areas who have fewer opportunities for specialized care and consequently a higher incidence of maternal mortality. Health care in the inner city, where residents are usually poorer and begin childbearing earlier and continue longer, may be of lower quality than in a more affluent neighborhood.

Ethnicity. Although ethnicity by itself is not a major risk, race is associated with some poor pregnancy outcomes. Non-Caucasian women are more than three times as likely as Caucasian women to die of pregnancy-related causes. African-American babies have the highest rates of prematurity and low birth weight, with the infant mortality rate among African-Americans being more than double that among Caucasians.

Environmental Factors

Various environmental substances can affect fertility and fetal development, the chance of a live birth, and the child's subsequent mental and physical development. Environmental influences include infections, radiation, chemicals such as mercury and lead, therapeutic drugs, illicit drugs, industrial pollutants, cigarette smoke, stress, and diet. Paternal exposure to mutagenic agents in the workplace has been associated with an increased risk of miscarriage.

BOX 26-2 Specific Pregnancy Problems and Related Risk Factors

Polyhydramnios

Poorly controlled diabetes mellitus
Fetal congenital anomalies (e.g., gastrointestinal obstruction, twin-twin transfusion syndrome)

Intrauterine Growth Restriction

Maternal Causes

Hypertensive disorders
Diabetes
Chronic renal disease
Collagen vascular disease
Thrombophilia
Cyanotic heart disease
Poor weight gain
Smoking, alcohol use, illicit drug use
Living at a high altitude

Fetoplacental Causes

Chromosomal abnormalities
Congenital malformations
Intrauterine infection
Genetic syndromes (e.g., trisomy 13 and trisomy 18)
Abnormal placental development

Oligohydramnios

Renal agenesis (Potter syndrome)
Premature rupture of membranes
Prolonged pregnancy
Uteroplacental insufficiency
Severe intrauterine growth restriction (IUGR)
Maternal hypertensive disorders

Chromosomal Abnormalities

Advanced maternal age
Parental chromosomal rearrangements
Previous pregnancy with autosomal trisomy
Abnormal ultrasound findings during the current pregnancy (e.g., fetal structural anomalies, IUGR, amniotic fluid volume abnormalities)
Increased risk, as calculated from noninvasive screening results (e.g., nuchal translucency and maternal serum analytes)

picture. Box 26-3 lists common maternal and fetal indications for antepartum testing that are supported by available evidence (Miller et al.).

The remainder of this chapter describes maternal and fetal assessment tests that are often used to monitor high risk pregnancies.

BIOPHYSICAL ASSESSMENT

Daily Fetal Movement Count

Assessment of fetal activity by the mother is a simple yet valuable method for monitoring the fetus's condition. The **daily fetal movement count (DFMC)** (also called *kick count*) can be assessed at home and is noninvasive, inexpensive, and simple to understand and usually does not interfere with a daily routine. It is frequently used to monitor the fetus in pregnancies complicated by conditions that may affect fetal oxygenation (see Box 26-2). The presence of movements is generally a reassuring sign of fetal health. During the third trimester the fetus makes about 30 gross body movements each hour. The mother is able to recognize 70% to 80% of these movements (Greenberg, Druzin, & Gabbe, 2012).

BOX 26-3 Common Maternal and Fetal Indications for Antepartum Testing

Diabetes
Chronic hypertension
Preeclampsia
Fetal growth restriction
Multiple gestation
Oligohydramnios
Preterm premature rupture of membranes
Late term or postterm gestation
Previous stillbirth
Decreased fetal movement
Systemic lupus erythematosus
Renal disease
Cholestasis of pregnancy

From Miller, L., Miller, D., & Tucker, S. (2013). *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* (7th ed.). St. Louis: Mosby.

Several different protocols are used for counting. One recommendation is to count once a day for 60 minutes (Fig. 26-1 is an example of a form used to record fetal kick counts). Other common recommendations are that mothers count fetal activity two or three times daily (e.g., after meals or before bedtime) for 2 hours or until 10 movements are counted or all fetal movements in a 12-hour period each day until a minimum of 10 movements are counted. Except for establishing a very low number of daily fetal movements or a trend toward decreased motion, the clinical value of the absolute number of fetal movements has not been established, other than in the situation in which fetal movements cease entirely for 12 hours (the so-called **fetal alarm signal**). A count of fewer than 3 fetal movements within 1 hour warrants further evaluation by a nonstress test (NST) or a contraction stress test and a complete or modified biophysical profile (see later discussion). Women should be taught the significance of the presence or absence of fetal movements, the procedure for counting, how to record findings on a daily fetal movement record, and when to notify the health care provider.

SAFETY ALERT

In assessing fetal movements it is important to remember that they are usually not present during the fetal sleep cycle; they may be reduced temporarily if the woman is taking depressant medication, drinking alcohol, or smoking a cigarette. They do not decrease as the woman nears term. Obesity decreases perception of fetal movements and consequently the ability of the mother to count them.

Ultrasonography

Diagnostic ultrasonography is an important, safe technique in antepartum fetal surveillance. It is considered by many to be the most valuable diagnostic tool used in obstetrics (Richards, 2012). It provides critical information to health care providers regarding fetal activity and gestational age, normal versus abnormal fetal growth curves, fetal and placental anatomy, fetal well-being, and visual assistance with which invasive tests can be performed more safely (Richards; Simpson, Richards, Otano, & Driscoll, 2012).

Fetal Movement Chart

This chart will help to keep track of your baby's well-being. Carefully count the number of movements your baby makes during the same hour every evening, when babies are typically most active. For example, between 9 and 10 p.m.

If your baby has not moved for 12 hours, please contact 602.406.3521. Be sure to bring this chart with you when visiting your doctor.

Sound is a form of wave energy that causes small particles in a medium to oscillate. The frequency of sound, which refers to the number of peaks or waves that move over a given point per unit of time, is expressed in hertz (Hz). Sound with a frequency of one cycle, or one peak per second, has a frequency of 1 Hz. When directional beams of sound strike an object, an echo is returned. The time delay between the emission of the sound and the return and direction of the echo is noted. From these data the distance and location of an object can be calculated. Ultrasound is sound frequency higher than that detectable by humans (greater than 20,000 Hz). Ultrasound images are a reflection of the strength of the sending beam, the strength of the returning echo, and the density of the medium (e.g., muscle [uterus], bone, tissue [placenta], fluid, or blood) through which the beam is sent and returned.

An ultrasound examination can be performed either abdominally or transvaginally during pregnancy. Ultrasound scans produce a two- or three-dimensional view of the area being

examined and can be used to create pictorial images (Fig. 26-2, A and B). Box 26-4 explains the differences in these scans and the views they produce.

Abdominal ultrasonography is more useful after the first trimester when the pregnant uterus becomes an abdominal organ. During the procedure the woman should have a full bladder to displace the uterus upward to provide a better image of the fetus. Transmission gel or paste is applied to the woman's abdomen to enhance the transmission and reception of the sound waves before a transducer is moved over the skin. She is positioned with small pillows under her head and knees. The display panel is positioned so the woman or her partner (or both) can observe the images on the screen if they desire.

Transvaginal ultrasonography, in which the probe is inserted into the vagina, allows pelvic anatomic features to be evaluated in greater detail and intrauterine pregnancy to be diagnosed earlier. A transvaginal ultrasound examination is well tolerated by most pregnant women because it removes the need

FIG 26-2 Fetus seen on three-dimensional ultrasound. **A**, View of fetus at 15 weeks and 3 days of gestation. **B**, Close-up view of fetal face later in pregnancy. (A, Courtesy Christina and Eva Gardner, Marion, AR; B, courtesy Margaret Spann, New Johnsonville, TN.)

BOX 26-4 Types of Ultrasound Scans

Two-Dimensional (2D)

- Sound waves are sent straight down from the ultrasound transducer.
- The image produced includes only two dimensions (length and width), so it appears flat.
- The image is viewed in black, white, or shades of gray.
- This is the standard medical scan used in pregnancy.

Three-Dimensional (3D)

- Sound waves are sent out at different angles. The returning echoes are processed by a computer program, which adds a third dimension (depth) to the 2D scan, producing a 3D image.
- The image is usually displayed in sepia tones rather than in black and white.
- This scan can be used for diagnostic or management purposes. Viewing certain anomalies using a 3D scan provides further information that assists in planning for care at birth and for the neonate. These images are also often requested by pregnant women and families simply for their own enjoyment.

Four-Dimensional (4D)

- This scan adds a fourth dimension (time) to the 3D scan.
- The images produced are recorded and played back in succession. As the image is continuously updated, the fetus is viewed in real time.

for a full bladder. It is especially useful in obese women whose thick abdominal layers cannot be penetrated adequately with an abdominal approach. A transvaginal ultrasound may be performed with the woman in a lithotomy position or with her pelvis elevated by towels, cushions, or a folded pillow. This pelvic tilt is optimal to image the pelvic structures. A protective cover such as a condom, the finger of a clean surgical glove, or a special probe cover provided by the manufacturer is used to cover the transducer probe. The probe is lubricated with a water-soluble gel and placed in the vagina either by the examiner or by the woman herself. During the examination the position of

the probe or the tilt of the examining table may be changed so the complete pelvis is in view. The procedure is not physically painful, although the woman feels pressure as the probe is moved. Transvaginal ultrasonography is optimally used in the first trimester to detect ectopic pregnancies, monitor the developing embryo, help identify abnormalities, and help establish gestational age. In some instances it may be used along with abdominal scanning to evaluate preterm labor in second- and third-trimester pregnancies.

Levels of Ultrasonography

The American College of Obstetricians and Gynecologists (ACOG, 2009) describes three levels of ultrasonography:

- **Standard** (also called basic) examinations are used most frequently and can be performed by ultrasonographers or other health care professionals, including nurses, who have had special training. Indications for standard ultrasonography are described in detail in the next section. In the second and third trimesters a standard ultrasound examination is used to evaluate fetal presentation, amniotic fluid volume (AFV), cardiac activity, placental position, fetal growth parameters, and number of fetuses. It is also used to perform an anatomic survey of the fetus.
- **Limited** examinations are performed for specific indications such as identifying fetal presentation during labor or estimating AFV. These examinations are usually performed by the woman's physician in the office or the labor and birth unit.
- **Specialized** (also called detailed) or **targeted** examinations are performed if a woman is suspected of carrying an anatomically or physiologically abnormal fetus. Indications for this comprehensive examination include abnormal history or laboratory findings or the results of a previous standard or limited ultrasound examination. Specialized ultrasonography is performed by highly trained and experienced personnel.

Indications for Use

Major indications for obstetric sonography are listed by trimester in Table 26-1. During the first trimester ultrasound examination is performed to obtain information regarding the number, size, and location of gestational sacs; the presence or absence of fetal cardiac and body movements; the presence or absence of uterine abnormalities (e.g., bicornuate uterus or fibroids) or adnexal masses (e.g., ovarian cysts or an ectopic pregnancy); and pregnancy dating.

During the second and third trimesters information regarding the following conditions is sought: fetal viability, number, position, gestational age, growth pattern, and anomalies; amniotic fluid volume; placental location and condition; presence of uterine fibroids or anomalies; presence of adnexal masses; and cervical length.

Ultrasonography provides earlier diagnoses, allowing therapy to be instituted earlier in the pregnancy, thereby decreasing the severity and duration of morbidity, both physical and emotional, for the family. For instance, early diagnosis of a fetal anomaly gives the family choices such as intrauterine surgery or other therapy for the fetus, termination of the pregnancy, or preparation for the care of an infant with a disorder.

TABLE 26-1 Major Uses of Ultrasonography During Pregnancy

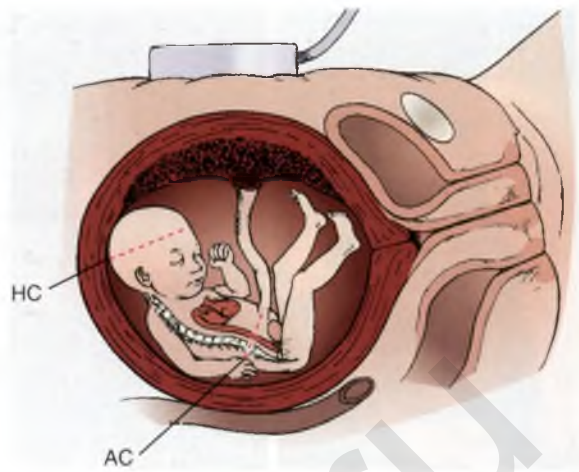

FIRST TRIMESTER	SECOND TRIMESTER	THIRD TRIMESTER
Confirm pregnancy	Establish or confirm dates	Confirm gestational age
Confirm viability	Confirm viability	Confirm viability
Determine gestational age	Detect polyhydramnios, oligohydramnios	Detect macrosomia
Rule out ectopic pregnancy	Detect congenital anomalies	Detect congenital anomalies
Detect multiple gestation	Detect intrauterine growth restriction (IUGR)	Detect IUGR
Determine cause of vaginal bleeding	Assess placental location	Determine fetal position
Use for visualization during chorionic villus sampling	Use for visualization during amniocentesis	Detect placenta previa or placental abruption
Detect maternal abnormalities such as bicornuate uterus, ovarian cysts, fibroids		Use for visualization during amniocentesis, external version
		Biophysical profile
		Amniotic fluid volume assessment
		Doppler flow studies
		Detect placental maturity

Fetal Heart Activity. Fetal heart activity can be demonstrated by about 6 weeks of gestation using transvaginal ultrasound. When the fetus is in a favorable position, good views of the fetal cardiac anatomy are possible in most women at 13 weeks of gestation (Richards, 2012). Fetal death can be confirmed by lack of heart motion along with the presence of fetal scalp edema and maceration and overlap of the cranial bones.

Gestational Age. Gestational dating by ultrasonography is indicated for conditions such as uncertain dates for the last normal menstrual period, recent discontinuation of oral contraceptives, a bleeding episode during the first trimester, uterine size that does not agree with dates, and other high risk conditions. In fact, growing evidence suggests that pregnancies should be dated by an ultrasound performed before 22 weeks of gestation rather than by menstrual dates because the ultrasound dating is more accurate than even “sure” menstrual dates (Richards, 2012). A standard set of measurements has been accepted as being the most useful for determining gestational age: the crown-rump length (after 10 weeks), the biparietal diameter (BPD) (after 12 weeks), the femur length (after 12 weeks), the head circumference, and the abdominal circumference (Fig. 26-3). An ultrasound examination performed for pregnancy dating between 14 and 22 weeks of gestation is comparable to one performed during the first trimester in terms of accuracy. However, after that time ultrasound dating is less reliable because of variability in fetal size (Richards).

Fetal Growth. Fetal growth is determined by both intrinsic growth potential and environmental factors. Conditions that require ultrasound assessment of fetal growth include poor maternal weight gain or pattern of weight gain, previous pregnancy with intrauterine growth restriction (IUGR), chronic infections, ingestion of drugs (tobacco, alcohol, and over-the-counter and street drugs), maternal diabetes, hypertension, multifetal pregnancy, and other medical or surgical complications.

Serial evaluations of BPD, limb length, and abdominal circumference can allow differentiation among size discrepancies

**FIG 26-3** Appropriate planes of sections (dotted lines) for head circumference (HC) and abdominal circumference (AC).

resulting from inaccurate dates, true IUGR, and macrosomia. IUGR may be symmetric (the fetus is small in all parameters) or asymmetric (head and body growth do not match). Symmetric IUGR reflects a chronic or long-standing insult and may be caused by low genetic growth potential, intrauterine infection, chromosomal anomaly, maternal undernutrition, or heavy smoking. Asymmetric growth suggests an acute or late-occurring deprivation such as placental insufficiency resulting from hypertension, renal disease, or cardiovascular disease. Reduced fetal growth is still one of the most frequent conditions associated with stillbirth. Macrosomic infants (those weighing 4000 g or more) are at increased risk for traumatic injury and asphyxia during birth. Macrosomia also may be characterized as symmetric or asymmetric.

Fetal Anatomy. Anatomic structures that can be identified by ultrasonography (depending on the gestational age) include the following: head (including ventricles and blood vessels), neck, spine, heart, stomach, small bowel, liver, kidneys, bladder, and limbs. Ultrasonography permits the confirmation of normal anatomy and detection of major fetal malformations. The presence of an anomaly may influence the location of birth (e.g., a subspecialty center versus a basic care center) and the method of birth (vaginal versus cesarean) to optimize neonatal outcomes. For example, plans are often made for a fetus with a condition that will require immediate surgery to be born in or near a hospital able to provide that care rather than in a small community hospital that is totally unequipped to meet the newborn's needs.

The number of fetuses and their presentations can be assessed by ultrasonography, allowing plans for therapy and mode of birth to be made in advance.

Fetal Genetic Disorders and Physical Anomalies. A prenatal screening technique called *nuchal translucency* (NT) screening uses ultrasound measurement of fluid in the nape of the fetal neck between 10 and 14 weeks of gestation to identify possible fetal abnormalities (Fig. 26-4). A fluid collection greater than 3 mm is considered abnormal. When combined with low maternal serum marker levels, elevated NT indicates a possible increased risk of certain chromosomal abnormalities in the fetus, including trisomies 13, 18, and 21. An elevated NT alone indicates an increased risk of fetal cardiac disease. If the NT is

FIG 26-4 Midsagittal view of a 12-week fetus showing the nuchal translucency (NT) and nasal bone (NB). (From Gabbe, S., Niebyl, J., & Simpson, J. [2012]. *Obstetrics: Normal and problem pregnancies* [6th ed.]. Philadelphia: Saunders.)

abnormal, diagnostic genetic testing is recommended (ACOG, 2009; Gilbert, 2011).

Other ultrasound findings, including the presence or absence (and length, if present) of a nasal bone, short femur or humerus, echogenic intracardiac focus, echogenic bowel, and pyelectasis (enlargement of the renal pelvis, the part of the kidney that collects urine), have been associated with trisomy 21 (Down syndrome) in the fetus. These findings are considered soft markers only; they are not diagnostic for the anomaly. Women in whom these soft markers are found who are at low risk to have a fetus with trisomy 21 should receive expert counseling about the advisability of further diagnostic testing (Simpson et al., 2012).

Placental Position and Function. The pattern of uterine and placental growth and the fullness of the maternal bladder influence the apparent location of the placenta by ultrasonography. During the first trimester differentiation between the endometrium and small placenta is difficult. By 14 to 16 weeks the placenta is clearly defined, but if it is seen to be low lying, its relationship to the internal cervical os can sometimes be altered dramatically by varying the fullness of the maternal bladder. In approximately 4% to 6% of all pregnancies in which ultrasound scanning is performed during the second trimester, the placenta seems to be overlying the os. However, most cases of placenta previa diagnosed during the second trimester resolve by term, primarily because of the elongation of the lower uterine segment as pregnancy advances. Therefore, if placenta previa is diagnosed during the second trimester, repeated ultrasounds should be performed as pregnancy progresses until the placenta moves well away from the cervical os or it becomes clear that the previa will persist (Francois & Foley, 2012; Richards, 2012).

Another use for ultrasonography is grading of placental aging. Calcium and fibrin deposits in an aging placenta result in intervillous hemorrhagic infarcts. Also as blood vessels in the placenta age and thicken, oxygen transport is affected. However, whether these placental changes adversely affect fetal outcomes

in postterm pregnancies is unknown, given that most fetuses continue to grow (Gilbert, 2011).

Adjunct to Other Invasive Tests. The safety of amniocentesis is increased when the positions of the fetus, placenta, and pockets of amniotic fluid can be identified accurately. Ultrasound scanning has reduced risks previously associated with amniocentesis, such as fetomaternal hemorrhage from a pierced placenta. Percutaneous umbilical blood sampling and chorionic villus sampling also are guided by ultrasonography to identify the cord and chorion frondosum accurately.

Fetal Well-being. Physiologic parameters of the fetus that can be assessed with ultrasound scanning include AFV, vascular waveforms from the fetal circulation, heart motion, fetal breathing movements (FBMs), fetal urine production, and fetal limb and head movements. Assessment of these parameters, alone or in combination, yields a fairly reliable picture of fetal well-being. The significance of these findings is discussed in the following sections.

Doppler Blood Flow Analysis. One of the major advances in perinatal medicine is the ability to study blood flow in the fetus and placenta noninvasively using ultrasound. **Doppler blood flow analysis** is a helpful tool in the management of pregnancies at risk because of maternal hypertension and diabetes mellitus, IUGR, multiple fetuses, and preterm labor because it provides an indication of fetal adaptation and reserve.

When a sound wave is reflected from a moving target, a change occurs in the frequency of the reflected wave relative to the transmitted wave, called the *Doppler effect*. An ultrasound beam scattered by a group of red blood cells (RBCs) is an example of this effect. The velocity of the RBCs can be determined by measuring the change in the frequency of the sound wave reflected off the cells (Fig. 26-5).

The shifted frequencies can be displayed as a plot of velocity versus time, and the shape of these waveforms can be analyzed to give information about blood flow and resistance in a given circulation. Velocity waveforms from the umbilical and uterine arteries, reported as systolic/diastolic (S/D) ratios, can be first detected at 15 weeks of pregnancy. Because of the progressive decline in resistance in both the umbilical and uterine arteries, this ratio normally decreases as pregnancy advances. Findings of absent or reversed end-diastolic blood flow and S/D ratios greater than 3 indicate placental vascular disease. IUGR may result from this placental insufficiency. In addition to IUGR, abnormal elevations in the S/D ratio are seen in hypertensive disorders of pregnancy or other causes of uteroplacental insufficiency (Baschat, Galan, & Gabbe, 2012; Gilbert, 2011). In postterm pregnancies evaluated by Doppler umbilical flow studies, an elevated S/D ratio indicates a poorly perfused placenta. Abnormal results also are seen with certain chromosomal abnormalities (trisomy 13 and 18) in the fetus and lupus erythematosus in the mother. Exposure to nicotine from maternal smoking also has been reported to increase the S/D ratio (see Fig. 26-5).

Amniotic Fluid Volume. Abnormalities in AFV are frequently associated with fetal disorders. Subjective determinants of oligohydramnios (decreased fluid) include the absence of fluid pockets in the uterine cavity and the impression of crowding of small fetal parts. An objective criterion of decreased AFV is met if the deepest vertical pocket of fluid measured in two perpendicular planes is less than 2 cm (Kaimal, 2014). Increased amniotic fluid is called **polyhydramnios** or sometimes

FIG 26-5 Color and spectral Doppler evaluation of the umbilical artery. In the left panel the coiling arteries and vein are shown. Red indicates flow toward the transducer, and blue is flow away. The sample gate for the pulse Doppler is superimposed. On the right is the result of the pulse Doppler, depicting a normal flow velocity waveform. (From Gabbe, S., Niebyl, J., & Simpson, J. [2012]. *Obstetrics: Normal and problem pregnancies* [6th ed.]. Philadelphia: Saunders.)

just *hydramnios*. Subjective criteria for polyhydramnios include multiple large pockets of fluid, the impression of a floating fetus, and free movement of fetal limbs. Polyhydramnios is usually objectively defined as pockets of amniotic fluid measuring more than 8 cm (Gilbert, 2012).

The total AFV can be evaluated by a method in which the vertical depths (in centimeters) of the largest pocket of amniotic fluid in all four quadrants surrounding the maternal umbilicus are totaled, providing an **amniotic fluid index (AFI)**. A normal AFI is 10 cm or greater, with the upper range of normal around 25 cm. AFI values between 5 and 10 cm are considered to be low normal, whereas an AFI of less than 5 cm indicates oligohydramnios. With polyhydramnios the AFI is greater than 25 cm (Miller et al., 2013). Oligohydramnios is associated with congenital anomalies (e.g., renal agenesis [Potter syndrome]) and growth restriction. Polyhydramnios is associated with neural tube defects (NTDs), obstruction of the fetal gastrointestinal tract, multiple fetuses, and fetal hydrops.

Biophysical Profile. Real-time ultrasound permits detailed assessment of the physical and physiologic characteristics of the developing fetus and cataloging of normal and abnormal biophysical responses to stimuli. The **biophysical profile (BPP)** is a noninvasive dynamic assessment of a fetus that is based on acute and chronic markers of fetal disease. The BPP includes AFV, FBMs, fetal movements, and fetal tone determined by ultrasound and fetal heart rate (FHR) reactivity determined by means of the NST. Therefore, the BPP can be considered a physical examination of the fetus, including determination of vital signs. FHR reactivity, FBMs, fetal movement, and fetal tone reflect current central nervous system (CNS) status, whereas

TABLE 26-2 Scoring the Biophysical Profile

BIOPHYSICAL VARIABLE	SCORE 2	SCORE 0
Fetal breathing movements	At least one episode of fetal breathing movements of at least 30-second duration in a 30-minute observation	Absent fetal breathing movements or less than 30 seconds of sustained fetal breathing movements in 30 minutes
Fetal movements	At least three trunk/limb movements in 30 minutes	Fewer than three episodes of trunk/limb movements in 30 minutes
Fetal tone	At least one episode of active extension with return to flexion of fetal limb or trunk; opening and closing of hand considered normal tone	Absence of movement or slow extension/flexion
Amniotic fluid index (AFI)	AFI >5 cm or at least one pocket >2 cm	AFI ≤5 cm and no single pocket >2 cm
Nonstress test	Reactive	Nonreactive

From Miller, L., Miller, D., & Tucker, S. (2013). *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* (7th ed.). St. Louis: Mosby.

the AFV demonstrates the adequacy of placental function over a longer period of time (Miller et al., 2013). BPP scoring and management are detailed in Tables 26-2 and 26-3.

The BPP is used frequently in the late second and the third trimester for antepartum fetal testing because it is a reliable predictor of fetal well-being. A BPP of 8 or 10 with a normal AFV is considered normal. Advantages of the test include excellent sensitivity and a low false-negative rate (Miller et al., 2013).

TABLE 26-3 Biophysical Profile Management

SCORE	INTERPRETATION	MANAGEMENT
10	Normal; low risk for chronic asphyxia	Repeat testing at weekly to twice-weekly intervals.
8	Normal; low risk for chronic asphyxia	Repeat testing at weekly to twice-weekly intervals.
6	Suspect chronic asphyxia	If ≥ 36 -37 weeks of gestation or < 36 weeks with positive testing for fetal pulmonary maturity, consider delivery; if < 36 weeks and/or fetal pulmonary maturity testing negative, repeat biophysical profile in 4 to 6 hours; deliver if oligohydramnios is present.
4	Suspect chronic asphyxia	If ≥ 36 weeks of gestation, deliver; if < 32 weeks of gestation, repeat score.
0-2	Strongly suspect chronic asphyxia	Extend testing time to 120 minutes; if persistent score ≤ 4 , deliver, regardless of gestational age.

Modified from Manning, F.A., Harman, C.R., Morrison, I., et al. (1990). Fetal assessment based on fetal biophysical profile scoring. *American Journal of Obstetrics and Gynecology*, 162(3), 703-700. Mannin, F.A. (1992). Biophysical profile scoring. In J. Nijhuis (Ed.), *Fetal behavior*. New York: Oxford University Press.

One limitation of the test is that if the fetus is in a quiet sleep state, the BPP can require a long period of observation. Also unless the ultrasound examination is videotaped, it cannot be reviewed (Greenberg et al., 2012).

Modified Biophysical Profile. The **modified BPP** (mBPP) is being used increasingly as a way to shorten the testing time required for the complete BPP by assessing the components that are most predictive of perinatal outcome. The mBPP combines the NST, which assesses the current fetal condition, with measurement of the quantity of amniotic fluid, an indicator of placental function over a longer period of time. The AFI (rather than the AFV) is often used to measure the amount of amniotic fluid present. Desired test results are a reactive NST and a normal AFI. An AFI greater than 5 is generally considered normal (Greenberg et al., 2012; Miller et al., 2013).

Nursing Role

Although a growing number of nurses perform ultrasound scans and BPPs in certain centers, the main roles of nurses are counseling and educating women about the procedure. Ultrasound is widely used and in fact is considered a standard part of current prenatal care. Unlike many diagnostic tests, most women look forward to and enjoy their prenatal ultrasound. Exposure to diagnostic ultrasonography during pregnancy appears to be safe for the fetus (Richards, 2012).

Nonmedical Ultrasounds

Three- and four-dimensional ultrasonography for nonmedical purposes has become increasingly popular with pregnant women and their families. Although insurance does not cover the cost, women can have ultrasound images made of the fetus, just as professional photographs are often taken of infants and children. Both the American Institute of Ultrasound in Medicine (AIUM) and the ACOG have published statements that strongly discourage this practice. Although ultrasonography is considered safe, exposure of the fetus to high-frequency

soundwaves without a clear medical indication for doing so should be avoided. In addition, casual ultrasonography performed by people who are not qualified health care professionals could give false reassurance to women or result in the discovery of abnormalities in settings that are not conducive to discussion and follow-up of findings (ACOG, 2009; AIUM, 2012; Richards, 2012). Helping the expectant family to understand the role of ultrasound beyond providing a picture of the baby is a component of prenatal education.

CLINICAL REASONING CASE STUDY

Nonmedical Use of Ultrasound

Alicia is a 24-year-old G2 P1 0 0 1 at 19 weeks of gestation. She presents at the maternal-fetal medicine clinic for a targeted ultrasound. Her primary obstetrician suspected a ventricular septal defect in the fetal heart during Alicia's ultrasound in his office last week. As you are taking a history prior to her ultrasound, Alicia says, "There is a new ultrasound business right near my house that advertises walk-in appointments and nice framed 3D pictures. Will I get a 3D picture of her face today? Why couldn't I have just gone to that place?"

1. Evidence—Is there sufficient evidence that Alicia needs a specific type of ultrasound performed by a maternal fetal medicine specialist?
2. Assumptions—Describe an underlying assumption about each of the following types of ultrasound examinations performed during pregnancy.
 - a. Standard or basic examination
 - b. Limited examination
 - c. Specialized or targeted examination
 - d. Nonmedical examination
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a noninvasive radiologic technique used for obstetric and gynecologic diagnosis. Similar to computed tomography (CT), MRI provides excellent pictures of soft tissue. Unlike CT, ionizing radiation is not used. Therefore, vascular structures within the body can be visualized and evaluated without injecting an iodinated contrast medium, thus eliminating any known biologic risk. Similar to sonography, MRI is noninvasive and can provide images in multiple planes, but no interference occurs from skeletal, fatty, or gas-filled structures, and imaging of deep pelvic structures does not require a full bladder.

With MRI the examiner can evaluate fetal structure (CNS, thorax, abdomen, genitourinary tract, musculoskeletal system) and overall growth, the placenta (position, density, and presence of gestational trophoblastic disease), and the quantity of amniotic fluid. Maternal structures (uterus, cervix, adnexa, and pelvis), the biochemical status (pH, adenosine triphosphate content) of tissues and organs, and soft-tissue, metabolic, or functional anomalies can also be evaluated.

The woman is placed on a table in the supine position with one hip elevated if possible and moved into the bore of the main magnet, which is similar in appearance to a CT scanner. Depending on the reason for the study the procedure may take

from 20 to 60 minutes, during which time the woman must be perfectly still except for short breaks. Because of the long time needed to produce MRIs, the fetus will probably move, which will obscure anatomic details. The only way to ensure that this problem does not occur is to administer a sedative to the mother, but this approach should be reserved for selected cases in which visualization of fetal detail is critical.

MRI has little effect on the fetus. Concerns that the FHR or fetal movement will decrease have not been supported.

BIOCHEMICAL ASSESSMENT

Biochemical assessment involves biologic examination (e.g., of chromosomes in exfoliated cells) and chemical determinations (e.g., lecithin/sphingomyelin [L/S] ratio, or phosphatidylglycerol [PG]) (Table 26-4). Procedures used to obtain the needed specimens include amniocentesis, percutaneous umbilical blood sampling, chorionic villus sampling, and maternal sampling (Box 26-5).

TABLE 26-4 Summary of Biochemical Monitoring Techniques

TEST	POSSIBLE FINDINGS	CLINICAL SIGNIFICANCE
Maternal Blood		
Coombs test	Titer of 1:8 and increasing	Significant Rh incompatibility
Cell-free DNA screening	> normal amount of DNA from specific chromosomes	Fetus with trisomy 13, 18, or 21
AFP	See AFP later in table	
Amniotic Fluid Analysis		
Lung profile:		Fetal lung maturity
L/S ratio	2:1	
Phosphatidylglycerol	Present	
LBC	≥50,000/μL	
Creatinine	>2 mg/dl	Gestational age >36 weeks
Lipid cells	>10%	Gestational age >35 weeks
AFP	High levels after 15 weeks of gestation	Open neural tube or other defect

BOX 26-5 Fetal Rights

Amniocentesis, percutaneous umbilical blood sampling (PUBS), and chorionic villus sampling (CVS) are prenatal tests used for diagnosing fetal defects in pregnancy. They are invasive and carry risks to the mother and fetus. A consideration of induced abortion is linked to the performance of these tests because no treatment for genetically affected fetuses has been developed; therefore, the issue of fetal rights is a key ethical concern in prenatal testing for fetal defects.

Amniocentesis

Amniocentesis is performed to obtain amniotic fluid, which contains fetal cells. Under direct ultrasonographic visualization, a needle is inserted transabdominally into the uterus, amniotic fluid is withdrawn into a syringe, and the various assessments are performed (Fig. 26-6). Amniocentesis is possible after week 14 of pregnancy, when the uterus becomes an abdominal organ and sufficient amniotic fluid is available for testing. Indications for the procedure include prenatal diagnosis of genetic disorders or congenital anomalies (NTDs in particular), assessment of pulmonary maturity, and (rarely) diagnosis of fetal hemolytic disease.

Complications in the mother and fetus occur in less than 1% of cases and include the following:

Maternal: leakage of amniotic fluid, hemorrhage, fetomaternal hemorrhage with possible maternal Rh isoimmunization, infection, labor, placental abruption, inadvertent damage to the intestines or bladder, and amniotic fluid embolism (anaphylactoid syndrome of pregnancy)

Fetal: death, hemorrhage, infection (amnionitis), and direct injury from the needle

Many of the complications have been minimized or eliminated by using ultrasonography to direct the procedure.

SAFETY ALERT

Because of the possibility of fetomaternal hemorrhage, administering Rh₀D immune globulin to the woman who is Rh negative is standard practice after an amniocentesis.

Indications for Use

Genetic Concerns. Historically prenatal assessment of genetic disorders focused on women older than 35 years (Box 26-6), women with a previous child with a chromosomal abnormality, or a family history of chromosomal anomalies. Inherited errors of metabolism (such as Tay-Sachs disease), hemophilia, thalassemia, and other disorders for which marker genes are known also can be detected by prenatal screening. Fetal cells can be cultured for karyotyping of chromosomes (see Chapter 3). Karyotyping also permits determination of fetal gender, which is important if an X-linked disorder (occurring almost always in a male fetus) is suspected.

Biochemical analysis of enzymes in amniotic fluid can detect inborn errors of metabolism or fetal structural anomalies. For example, alpha-fetoprotein (AFP) levels in amniotic fluid are assessed as a follow-up for elevated levels in maternal serum. High AFP levels in amniotic fluid help confirm the diagnosis of an NTD such as spina bifida or anencephaly or an abdominal wall defect such as omphalocele. The elevation results from the increased leakage of cerebrospinal or abdominal fluid into the amniotic fluid through the closure defect.

Fetal Maturity. Late in pregnancy accurate assessment of fetal lung maturity is possible by examining amniotic fluid to determine the L/S ratio or for the presence of PG. However, because both of these tests require considerable time, technical expertise, and cost to perform, they are generally used as primary tests only in special clinical circumstances. They may also be used as secondary tests if simpler and less expensive automated tests indicate lung immaturity (Mercer, 2014).

Until recently the TDx FLM assay and a subsequent modification, the TDx FLM II assay, were used as primary tests for fetal lung maturity. These assays determined the surfactant-to-albumin (S/A) ratio. However, they are no longer available for use in the United States. Instead, the lamellar body count (LBC) has become the primary test for determining fetal lung maturity.

Lamellar bodies are surfactant-containing particles secreted by type II pneumocytes. The number of lamellar bodies found in the amniotic fluid increases with the onset of functional fetal pulmonary maturity. The LBC compares favorably with the L/S ratio and the PG test in predicting fetal lung maturity. The automated test is simple to perform, and almost all hospital laboratories have the equipment used to perform it (Mercer, 2014) (see Table 26-4).

Fetal Hemolytic Disease. In the past amniocentesis was used for identification and follow-up of fetal hemolytic disease in cases of isoimmunization. Amniocentesis is now performed for this reason only in rare circumstances because of the availability of noninvasive testing. Doppler velocimetry of the fetal middle cerebral artery has become the method of choice to monitor accurately and noninvasively for fetal anemia in isoimmunized pregnancies (Moise, 2012).

Chorionic Villus Sampling

The combined advantages of earlier diagnosis and rapid results have made **chorionic villus sampling (CVS)** a popular technique for genetic studies in the first trimester. Indications for CVS are similar to those for amniocentesis, although CVS cannot be used for maternal serum marker screening because no fluid is obtained. CVS performed in the second trimester carries no greater risk of pregnancy loss than amniocentesis and is considered equal to amniocentesis in diagnostic accuracy. When performed after the first trimester, the procedure is better known as *late CVS* or *placental biopsy* (Simpson et al., 2012).

CVS can be performed in the first or second trimester, ideally between 10 and 13 weeks of gestation, and involves the removal of a small tissue specimen from the fetal portion of the placenta (Figs. 26-7 and 26-8). Because chorionic villi originate in the zygote, this tissue reflects the genetic makeup of the fetus (Gilbert, 2011).

CVS procedures can be accomplished transcervically or transabdominally. In transcervical sampling a sterile catheter is introduced into the cervix under continuous ultrasonographic guidance, and a small portion of the chorionic villi is aspirated with a syringe. The aspiration cannula and obturator must be placed at a suitable site, and rupture of the amniotic sac must be avoided (see Fig. 26-7). The transcervical procedure is contraindicated if a cervical infection such as chlamydia or herpes is present (Gilbert, 2011).

If the abdominal approach is used, an 18- or 20-gauge spinal needle with stylet is inserted under sterile conditions through the abdominal wall into the chorion frondosum under ultrasound guidance. The stylet is then withdrawn, and the chorionic tissue is aspirated into a syringe (see Fig. 26-8).

BOX 26-6 Elimination of Maternal Age as an Indication for Invasive Prenatal Diagnosis

Maternal age of 35 years and older has been a standard indication for invasive prenatal testing since 1979. However, because most genetically abnormal children are born to parents of varying ages who have no history of abnormality, genetic screening is now recommended for all women, regardless of age (Gilbert, 2011). The American College of Obstetricians and Gynecologists (ACOG) published guidelines in 2007 (and reaffirmed them in 2011) stating that no specific age should be used as a threshold for invasive or noninvasive screening. Furthermore, all women, regardless of age, should have the option of invasive testing without first having screening (ACOG, 2011).

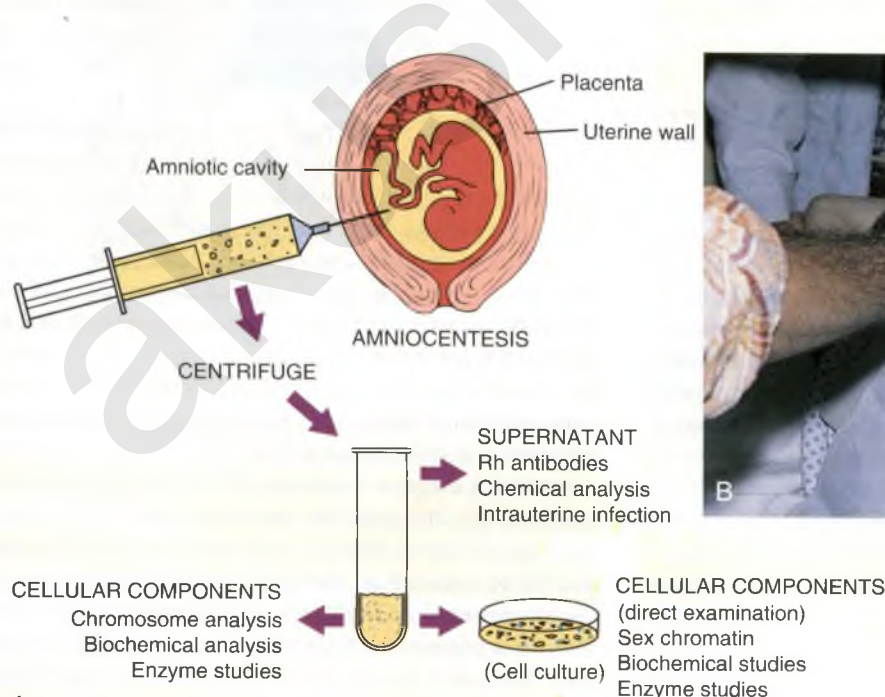

FIG 26-6 A, Amniocentesis and laboratory use of amniotic fluid aspirant. B, Transabdominal amniocentesis. (B, Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

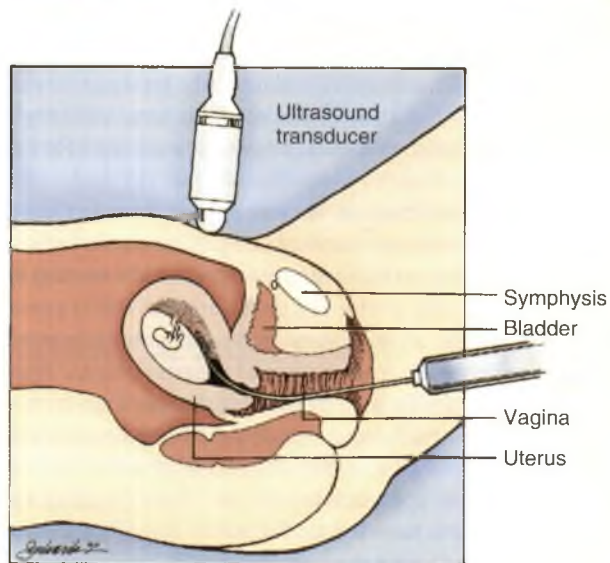

FIG 26-7 Transcervical chorionic villus sampling. (From Gabbe, S., Niebyl, J., & Simpson, J. [2012]. *Obstetrics: Normal and problem pregnancies* [6th ed.]. Philadelphia: Saunders.)

CVS is a relatively safe procedure. The incidence of IUGR, placental abruption, and preterm birth is no higher in women undergoing CVS than would be expected in the general population. In the early 1990s there was controversy concerning an increased risk for fetal limb reduction defects associated with CVS. However, the consensus of further studies is that when CVS is performed after 9 completed weeks of gestation, the risk for limb reduction defects is no higher than it is in the general population (Simpson et al., 2012).

SAFETY ALERT

Because of the possibility of fetomaternal hemorrhage, women who are Rh negative should receive Rh₀D immune globulin after CVS to prevent isoimmunization, regardless of whether the procedure is performed transcervically or transabdominally, unless the fetus is known to be Rh negative (Simpson et al., 2012).

Use of amniocentesis and CVS is declining because of advances in noninvasive screening techniques. These techniques include measurement of NT, maternal serum screening tests in the first and second trimesters, and ultrasonography in the second trimester. A recently available assessment method, cell-free deoxyribonucleic acid (DNA) screening, can be performed as early as 10 weeks of gestation, therefore providing mothers information sooner in the pregnancy to aid in decision making regarding further testing (see later discussion and the Evidence-Based Practice box).

Percutaneous Umbilical Blood Sampling

Direct access to the fetal circulation during the second and third trimesters is possible through **percutaneous umbilical blood sampling (PUBS)** (also called *cordocentesis*). PUBS can be used for fetal blood sampling and transfusion. However, PUBS has been replaced in many centers by placental biopsy because it is a safer, easier, and faster alternative. Improvements in cytogenetic and molecular diagnostic testing have decreased the need for fetal blood samples. Many tests that were once performed

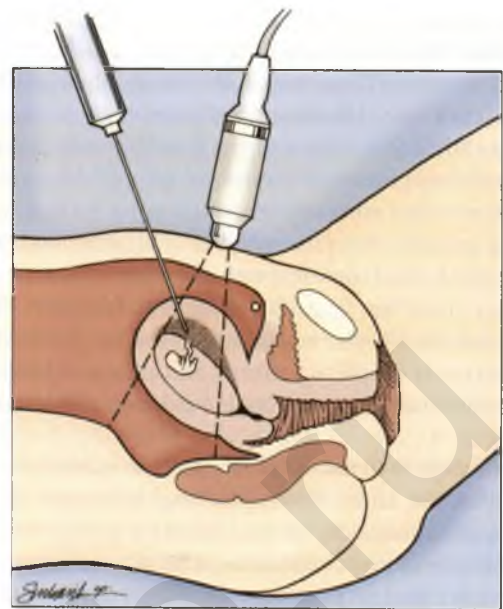

FIG 26-8 Transabdominal chorionic villus sampling. (From Gabbe, S., Niebyl, J., & Simpson, J. [2012]. *Obstetrics: Normal and problem pregnancies* [6th ed.]. Philadelphia: Saunders.)

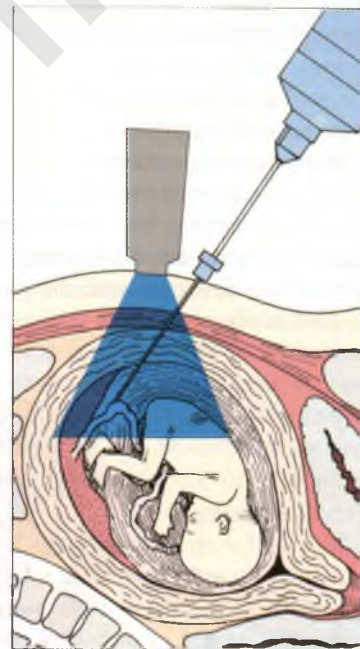

FIG 26-9 Technique for percutaneous umbilical blood sampling guided by ultrasound.

using fetal blood can now be done using DNA-based analysis of chorionic villi (Simpson et al., 2012).

PUBS involves the insertion of a needle directly into a fetal umbilical vessel, preferably the vein, under ultrasound guidance. Ideally the umbilical cord is punctured near its insertion into the placenta (Figs. 26-9 and 26-10). At this point the cord is well anchored and will not move, and the risk of maternal blood contamination (from the placenta) is slight. Generally a small amount of blood is removed and tested immediately by the Kleihauer-Betke procedure (Apt test) to ensure that it is fetal in origin (Simpson et al., 2012). The most common genetic indication for the use of PUBS is evaluation of mosaic results

FIG 26-10 Umbilical cord as seen on ultrasound at 26 weeks of gestation. (Courtesy Advanced Technology Laboratories, Bothell, WA.)

found on amniocentesis or CVS, when a sample of fetal blood is required to determine the specific mutation. PUBS is also used to assess for fetal anemia, infection, and thrombocytopenia (Wapner, 2014). Complications that can occur include loss of the pregnancy, hematomas, bleeding from the puncture site in the umbilical cord, transient fetal bradycardia, and fetomaternal hemorrhage. Maternal complications are rare but include hemorrhage and transplacental hemorrhage (Simpson et al., 2012).

In fetuses at risk for isoimmune hemolytic anemia, PUBS permits precise identification of fetal blood type and RBC count and may prevent the need for further intervention. If the fetus is positive for the presence of maternal antibodies, a direct blood test can confirm the degree of anemia resulting from hemolysis. Intrauterine transfusion of severely anemic fetuses can be performed 4 to 5 weeks earlier than through the intraperitoneal route.

Follow-up includes continuous FHR monitoring for 1 to 2 hours after the procedure. Women should also be taught to count fetal movements at home (Gilbert, 2011) (see previous discussion and Fig. 26-1).

Maternal Assays

Alpha-Fetoprotein

Maternal serum **alpha-fetoprotein (AFP)** levels are used as a screening tool for NTDs in pregnancy. Through this technique approximately 80% to 85% of all open NTDs and open abdominal wall defects can be detected early. Screening is recommended for all pregnant women.

The cause of NTDs is not well understood, but 95% of all affected infants are born to women with no family history of similar anomalies (Wapner, 2014). The defect occurs in approximately 1 in 1000 live births. Risk factors for NTDs include a history of this disorder in a prior pregnancy, folic acid deficiency, pregestational diabetes, and teratogen exposure (e.g., valproic acid [Depakote], carbamazepine [Tegretol]) (Wolf, 2014).

AFP is produced in the fetal gastrointestinal tract and liver, and increasing levels are detectable in the serum of pregnant women from 14 to 34 weeks of gestation. Although amniotic fluid AFP measurement is diagnostic for NTD, maternal serum AFP is a screening tool only. Maternal serum AFP (MSAFP) screening can be performed with reasonable reliability any time between 15 and 20 weeks of gestation (16 to 18 weeks being ideal) (Wapner, 2014).

Once the maternal level of AFP is determined, it is compared with normal values for each week of gestation. Values also should be correlated with maternal age, weight, race, presence of a multifetal pregnancy, and whether the woman has insulin-dependent diabetes. Until recently, an amniocentesis to obtain fluid for determining amniotic fluid AFP and acetylcholinesterase levels was recommended as standard follow-up testing when the AFP level in maternal serum was found to be elevated. A targeted ultrasound performed by an experienced sonographer, however, has since been shown to be as sensitive and specific for identifying NTDs as the amniotic fluid AFP and acetylcholinesterase measurements, which require invasive testing via amniocentesis (Wapner, 2014).

Multiple Marker Screens

Screening to detect fetal chromosomal abnormalities, particularly trisomy 21 (Down syndrome) is available, beginning in the first trimester of pregnancy at 11 to 14 weeks of gestation (Cunningham et al., 2014). This first-trimester screen includes measurement of two maternal biochemical markers, pregnancy-associated placental protein (PAPP-A) and human chorionic gonadotropin (hCG) or the free beta-human chorionic gonadotropin (β -hCG) subunit, and evaluation of fetal nuchal translucency (NT), or a combination of both. In the presence of a fetus with trisomy 21, hCG levels are higher than normal in the first trimester, whereas PAPP-A levels are lower than normal. First-trimester screening using PAPP-A and hCG or β -hCG levels has been shown to be as accurate for detecting fetuses with trisomy 21 as triple screening in the second trimester (Cunningham et al., 2014; Wapner, 2014). Another biochemical marker that can be measured during the first trimester, at 8 to 10 weeks of gestation, is a disintegrin and metalloproteinase 12 (ADAM 12), a glycoprotein that is synthesized by the placenta and secreted throughout pregnancy. Decreased levels of ADAM 12 are found in women carrying a fetus with trisomy 21 (Wapner).

About one third of all fetuses with an increased NT have a chromosomal abnormality; half of these are trisomy 21. Combining the serum marker and NT values results in the detection of Down syndrome in 79% to 87% of cases. These results are comparable to those obtained with quad screening (see discussion following) in the second trimester (Cunningham et al., 2014).

Assessment of the fetal nasal bone by ultrasound during the first trimester provides another way to predict trisomy 21. The nasal bone cannot be identified on ultrasound in about one third to one quarter of fetuses who have trisomy 21 (Wapner, 2014).

In the second trimester triple screening and quad screening are available to screen for fetuses with trisomy 21 and trisomy 18. The triple-marker screen, performed at 16 to 18 weeks of gestation, measures the levels of three maternal serum markers: MSAFP, unconjugated estriol, and hCG. In the presence of a fetus with trisomy 21 the MSAFP and unconjugated estriol levels are low, whereas the hCG level is elevated. Low values in all three markers are associated with trisomy 18 (Cunningham et al., 2014).

The quad screen adds an additional marker, a placental hormone called inhibin A, to increase the accuracy of screening for Down syndrome in women less than 35 years of age.

EVIDENCE-BASED PRACTICE

Cell-Free Fetal DNA Testing for Trisomies

Ask the Question

For women at risk for trisomies or sex chromosome aneuploidies, is there a noninvasive screening test?

Search for the Evidence

Search Strategies English language research-based publications since 2011 on noninvasive prenatal screening, cell-free fetal DNA, trisomy, and aneuploidy were included.

Databases Used Cochrane Collaborative Database, National Guideline Clearinghouse (AHRQ), CINAHL, PubMed, UpToDate, and the professional websites for ACOG and AWHONN

Critical Appraisal of the Evidence

In the past, women at risk for genetic abnormality had the option of screening of maternal blood for serum analytes ("triple screen"), with or without ultrasound for nuchal translucency, an early visible marker for trisomy 21. These combinations had a detection rate ranging from 50% to 95% (Gregg, Gross, Best, et al., 2013). More diagnostic testing, such as chorionic villus sampling and amniocentesis, are definitive but invasive.

- Introduced as a noninvasive pregnancy screening test, cell-free fetal DNA (cffDNA) testing isolates fetal DNA fragments from maternal blood to determine sex and screen for trisomies 21, 18, and 13 with an excellent negative predictive value, high detection rate, and a lower false-positive rate (Mersy, Smits, van Winden, et al., 2013).
- In addition, testing for sex chromosome aneuploidies, such as Turner (45X) and Klinefelter (45XXY), is available at some laboratories (Gregg et al., 2013). Knowing the sex early can also assist in screening for sex chromosome-linked diseases, such as hemophilia and Duchenne muscular dystrophy (Colmant, Morin-Surroca, Fuchs, et al., 2013).
- Offered at 10 to 20 weeks of gestation, cffDNA has limited sensitivity in the presence of a high body mass index. In addition, it may reflect placental DNA, which may have mosaicism and differ from the true fetal karyotype. A "vanishing twin" may confound the results. For these reasons professional recommendations advocate that in the event of abnormal cffDNA results, direct fetal DNA sampling using invasive techniques be used for confirmation (Gregg et al., 2013; Langlois, Brock, Genetics Committee et al., 2013).
- First-trimester ultrasound is still the gold standard for identifying nuchal translucency, multiple fetuses, placental abnormalities, and congenital abnormalities. Maternal blood test for alpha-fetoprotein, although variable in sensitivity, is still recommended at 15 to 20 weeks of gestation as a screening test for open neural tube defects (Gregg et al., 2013).

Apply the Evidence: Nursing Implications

- Earlier screening for trisomies provides pregnant women with either earlier reassurance of a normal fetus or earlier chance to adjust to abnormality. The timing allows for the option for a less risky first trimester termination.
- Pretest counseling recommendations include the benefits and limitations of cffDNA testing. This includes the recommendation for further diagnostic testing using invasive techniques, prior to any irrevocable obstetric decisions (Gregg et al., 2013; Langlois et al., 2013).

- Women and families may need help sorting out the bewildering array of tests available during pregnancy. Tests are only useful if they provide usable information, so health care providers should have knowledge and information ready to assist clients for all possible test result outcomes.
- This test may help women avoid routine invasive procedures, a cost savings. However, cffDNA is expensive, running up to \$2,000 or more. As with all new tests, much research and discussion are needed regarding cost analysis, appropriate population, and economic justice.
- Ethical debates will undoubtedly multiply with the eventual availability of more prenatal genetic testing, including whole-genome sequencing.

Quality and Safety Competencies: Evidence-Based Practice (EBP)*

Knowledge

Describe how the strength and relevance of available evidence influences the choice of interventions in provision of client-centered care.

Health care teams use systematic analysis and professional recommendations to address the meaning of changing prenatal testing options.

Skills

Participate in structuring the work environment to facilitate integration of new evidence into standards of practice.

Pretest counseling provides appropriate and realistic expectations for pregnant women and their families.

Attitudes

Value the concept of EBP as integral to determining best clinical practices.

EBP guides prenatal testing practice so that women get meaningful, actionable, and affordable testing.

DNA, Deoxyribonucleic acid.

DNA, Deoxyribonucleic acid.

Elevated inhibin A levels indicate the possibility of Down syndrome (Cunningham et al., 2014; Wapner, 2014). The addition of inhibin A to the other three markers increases the detection rate for Down syndrome to about 75% in women who are less than 35 years old and to more than 80% in women 35 years of age or older (Simpson et al., 2012). Similar to triple marker screening, the optimal time to perform the quad screen is between 16 and 18 weeks of gestation (Wapner).

The ability of multiple marker tests to detect chromosomal abnormalities depends on the accuracy of gestational age assessment. These tests are screening procedures only and are not diagnostic. A positive screening test result indicates an increased risk but is not diagnostic of trisomy 21 or another chromosome abnormality. Women with positive screening results should be offered diagnostic testing by amniocentesis or CVS for fetal karyotyping (Cunningham et al., 2014).

Coombs' Test

The indirect Coombs' test is a screening tool for Rh incompatibility. If the maternal titer for Rh antibodies is greater than 1:8, amniocentesis for determination of bilirubin in amniotic fluid is indicated to establish the severity of fetal hemolytic anemia. However, middle cerebral artery Doppler studies to determine the degree of fetal hemolysis have almost entirely replaced serial amniocentesis (see earlier discussion) (Moise, 2012). The Coombs' test can also detect other antibodies that may place the fetus at risk for incompatibility with maternal antigens.

Cell-Free DNA Screening in Maternal Blood

A screening method for noninvasive prenatal genetic diagnosis (noninvasive prenatal testing [NIPT]) is now available for use in the clinical setting. Cell-free DNA screening already provides a definitive diagnosis noninvasively for fetal Rh status, fetal gender, and certain paternally transmitted single gene disorders (Cunningham et al., 2014; Simpson et al., 2012).

The method works by amplifying cell-free DNA. If the fetus has a normal karyotype, the amount of DNA is consistent with the known standard for the normal amount. For example, if more than the expected amount of chromosome 21 DNA is detected, it can then be assumed that the fetus is contributing the extra amount and therefore has trisomy 21. The same is true for trisomies 13 and 18. The test cannot actually distinguish fetal from maternal DNA, but it can accurately predict the fetal status by measuring the amount of DNA circulating in maternal blood and comparing it with known standards. The cell-free DNA screen in combination with ultrasound does not provide a definitive diagnosis for all cases of fetal trisomy 21. Women who have a positive cell-free circulating DNA test without confirming ultrasound findings or a negative blood screen with abnormal ultrasound findings require invasive diagnostic testing such as amniocentesis or CVS for a definitive diagnosis (Palomaki, Kloza, Lambert-Messerlian, et al., 2011) (see Evidence-Based Practice box).

Circulating cell-free DNA studies for the detection of fetal chromosomal abnormalities can be performed as early as 10

weeks of gestation. The test is offered to women considered to be at risk for chromosomal abnormalities, including those with advanced maternal age, screen-positive maternal serum screens, or ultrasound abnormalities. Women who have previously given birth to a child with a chromosomal abnormality are also candidates for the screen (Cunningham et al., 2014). It is simple to perform; a sample of maternal blood is obtained by venipuncture and sent to a commercial laboratory. Results are usually available in about 10 business days. The screen has been shown to be 98% effective at detecting trisomy 21 and 99% effective at detecting trisomy 13 or 18. In less than 1% of cases no result is available because not enough DNA was retrieved to perform the screen (Palomaki et al., 2011; Palomaki, Deciu, Kloza, et al., 2012).

FETAL CARE CENTERS

With developing technology, diagnosis and subsequent treatment options exist for some fetal anomalies. Fetal care centers have evolved in response to the need to provide diagnostic and therapeutic options as well as support services for families with a fetal anomaly diagnosis (ACOG, 2011). ACOG and the American Academy of Pediatrics (AAP) recommend that these families have access to support services such as genetic counseling, social work, chaplain services, a palliative care team, and ethics consultation because of the complex emotional stressors they face. Care coordination is critical for the successful management of high risk pregnancies. The majority of fetal care centers has a staff member, often a nurse, who coordinates care and assists the family in navigating multiple appointments with obstetric and pediatric providers.

ANTEPARTUM ASSESSMENT USING ELECTRONIC FETAL MONITORING

Indications

First- and second-trimester antepartum assessment is directed primarily at the diagnosis of fetal anomalies. The goal of third-trimester testing is to determine whether the intrauterine environment continues to support the fetus. The testing is often used to determine the timing of childbirth for women at risk for **uteroplacental insufficiency (UPI)**. Gradual loss of placental function results first in inadequate nutrient delivery to the fetus, leading to IUGR. Subsequently, respiratory function also is compromised, resulting in fetal hypoxia. Evidence-based recommendations for condition-specific testing schemes in cases of identified risk factors have been difficult to develop and often do not exist. There is no ideal single test or testing strategy for all high risk pregnancies (Greenberg et al., 2012).

However, there is evidence to support antepartum assessment using electronic fetal monitoring in pregnancies complicated by the risk factors listed in Box 26-7. Currently the NST and the mBPP are the primary methods used for antepartum fetal evaluation in high risk women at most sites. The complete BPP and the contraction stress test are used for follow-up evaluation in women who have a persistently nonreactive NST or mBPP. Traditionally testing has begun

at 32 to 34 weeks of gestation, with earlier initiation of testing recommended for women with multiple high risk conditions. Testing is usually performed once or twice weekly (Greenberg et al., 2012).

Nonstress Test

The **nonstress test (NST)** is the most widely applied technique for antepartum evaluation of the fetus. The basis for the NST is that the normal fetus produces characteristic heart rate patterns in response to fetal movement, uterine contractions, or stimulation. In the term fetus, accelerations are associated with movement more than 85% of the time (Greenberg et al., 2012). The most common reason for the absence of FHR accelerations is the quiet fetal sleep state. However, medications such as narcotics, barbiturates, and beta-blockers; maternal smoking; and the presence of fetal malformations can also adversely affect the test (Gilbert, 2011; Greenberg et al.). The NST can be performed easily and quickly in an outpatient setting because it is noninvasive, easy to perform and interpret, and relatively inexpensive and has no known contraindications. Disadvantages include the requirement for twice-weekly testing and a high false-positive rate. The test also is slightly less sensitive in detecting fetal compromise than the contraction stress test or the BPP (Greenberg et al.; Miller et al., 2013).

Procedure

The woman is seated in a reclining chair (or in semi-Fowler position) with a slight lateral tilt to optimize uterine perfusion and prevent supine hypotension. The FHR is recorded with a Doppler transducer, and a tocodynamometer is applied to detect uterine contractions or fetal movements. The tracing is observed for signs of fetal activity and a concurrent acceleration of FHR. If evidence of fetal movement is not apparent on the tracing, the woman may be asked to depress a button on a handheld event marker connected to the monitor when she feels fetal movement. The movement is then noted on the tracing. Because almost all accelerations are accompanied by fetal movement, the movements need not be recorded for the test to be considered reactive. The test is usually completed within 20 to 30 minutes, but more time may be required if the fetus must be awakened from a sleep state.

Care providers sometimes suggest that the woman drink orange juice or be given glucose to increase her blood sugar level and thereby stimulate fetal movements. Although this practice is common, there is no evidence that it increases fetal activity (Greenberg et al., 2012).

Vibroacoustic stimulation (see later discussion) is often used to stimulate fetal activity if the initial NST result is nonreactive and thus possibly shortens the time required to complete the test (Greenberg et al., 2012).

Interpretation

NST results are either reactive (Fig. 26-11) or nonreactive (Fig. 26-12). Box 26-8 lists criteria for both results.

A nonreactive test requires further evaluation. The testing period is often extended, usually for an additional 20 minutes, with the expectation that the fetal sleep state will change and the test will become reactive. During this time vibroacoustic stimulation (see later discussion) may be used to stimulate fetal activity. If the test does not meet the criteria after 40 minutes, a BPP usually is performed. Once NST testing is initiated, it is usually repeated once or twice weekly for the remainder of the pregnancy (Greenberg et al., 2012).

Vibroacoustic Stimulation

Vibroacoustic stimulation (also called the *fetal acoustic stimulation test [FAST]*) is another method of testing antepartum FHR response. This test is generally performed in conjunction

BOX 26-7 Indications for Fetal Assessment Using Electronic Fetal Monitoring

- Diabetes
- Hypertension
- Intrauterine growth restriction
- Multiple gestation
- Oligohydramnios
- Intrahepatic cholestasis
- Renal disease
- Decreased fetal movement
- Previous fetal death
- Postterm pregnancy
- Systemic lupus erythematosus

Data from Greenberg, M., Druzin, M., & Gabbe, S. (2012). Antepartum fetal evaluation. In S. Gabbe, J. Niebyl, & J. Simpson (Eds.), *Obstetrics: Normal and problem pregnancies* (6th ed.). Philadelphia: Saunders.

FIG 26-11 Reactive nonstress test. (From Gabbe, S., Niebyl, J., & Simpson, J. [2012]. *Obstetrics: Normal and problem pregnancies* [6th ed.]. Philadelphia: Saunders.)

with the NST and uses a combination of sound and vibration to stimulate the fetus. Whether the acoustic or the vibratory component alters the fetal state is unclear. The fetus is monitored for 5 minutes before stimulation to obtain a baseline FHR. If the fetal baseline pattern is nonreactive, the sound source (usually a laryngeal stimulator) is then activated for 3 seconds on the maternal abdomen over the fetal head. The desired result is a reactive NST, which usually occurs within 3 minutes of stimulation. The accelerations produced may have a significant increase in duration (Fig. 26-13). The test may be repeated at

1-minute intervals up to 3 times when no response is noted. Further evaluation is needed with BPP or contraction stress test if the pattern remains nonreactive (Greenberg et al., 2012).

Contraction Stress Test

The **contraction stress test (CST)** or **oxytocin challenge test (OCT)** was the first widely used electronic fetal assessment test. It was devised as a graded stress test of the fetus, and its purpose was to identify the jeopardized fetus that was stable at rest but showed evidence of compromise after stress. Uterine contractions decrease uterine blood flow and placental perfusion. If this decrease is sufficient to produce hypoxia in the fetus, a deceleration in FHR results.

BOX 26-8 Interpretation of the Nonstress Test

Reactive test: Two accelerations in a 20-minute period, each lasting at least 15 seconds and peaking at least 15 beats/min above the baseline. (Before 32 weeks of gestation, an acceleration is defined as a rise of at least 10 beats/min lasting at least 10 seconds from onset to offset; see Fig. 26-11.)

Nonreactive test: A test that does not demonstrate at least two qualifying accelerations within a 20-minute window (see Fig. 26-12)

! NURSING ALERT

In a healthy fetoplacental unit uterine contractions do not usually produce late decelerations, whereas if underlying UPI exists, contractions produce late decelerations.

The CST provides an earlier warning of fetal compromise than the NST and produces fewer false-positive results. However, the CST is more time consuming and expensive than the

FIG 26-14 Contraction stress test (CST). A, Negative CST. B, Positive CST. (From Tucker, S. [2004]. *Pocket guide to fetal monitoring and assessment* [5th ed.]. St. Louis: Mosby.)

NST. It is also an invasive procedure if oxytocin stimulation is required. In general, the CST cannot be performed on women who should not give birth vaginally at the time the test is done. Absolute contraindications for the CST are the following: preterm labor, placenta previa, vasa previa, reduced cervical competence, multiple gestations, and previous classic incision for cesarean birth (Miller et al., 2013). Because of these disadvantages, the CST is used infrequently.

Procedure

The woman is placed in semi-Fowler position or sits in a reclining chair with a slight lateral tilt to optimize uterine perfusion and avoid supine hypotension. She is monitored electronically with the fetal ultrasound transducer and uterine tocodynamometer. The tracing is observed for 10 to 20 minutes for baseline rate and variability and the possible occurrence of spontaneous contractions. The two methods of CST are the nipple-stimulated contraction test and the more commonly used oxytocin-stimulated contraction test.

Nipple-Stimulated Contraction Test. Several methods of nipple stimulation have been described. In one approach the woman applies warm, moist washcloths to both breasts for several minutes. She is then asked to massage one nipple for 10 minutes. Massaging the nipple causes a release of oxytocin from the posterior pituitary. An alternative approach is for her to massage one nipple through her clothes for 2 minutes, rest for 5 minutes, and repeat the cycles of massage and rest as necessary to achieve adequate uterine activity. When

adequate contractions or hyperstimulation (defined as uterine contractions lasting more than 90 seconds or five or more contractions in 10 minutes) occur, stimulation should be stopped.

Oxytocin-Stimulated Contraction Test. Exogenous oxytocin also can be used to stimulate uterine contractions. An intravenous (IV) infusion is begun, and a dilute solution of oxytocin (e.g., 30 units in 500 ml of fluid) is infused into the tubing of the main IV line through a piggyback port and delivered by an infusion pump to ensure an accurate dose. One method of oxytocin infusion is to begin at 0.5 milliunits/min and double the dose every 20 minutes until three uterine contractions of moderate intensity, each lasting 40 to 60 seconds, are observed within a 10-minute period. These criteria for contractions were selected to approximate the stress experienced by the fetus during the first stage of labor (Greenberg et al., 2012).

Interpretation

CST results are negative, positive, equivocal, suspicious, or unsatisfactory. If no late decelerations are observed with the contractions, the findings are considered negative (Fig. 26-14, A). Repetitive late decelerations render the test results positive (see Fig. 26-14, B). Table 26-5 lists criteria for each possible test result and the clinical significance of each.

The desired CST result is negative because it has consistently been associated with good fetal outcomes. The likelihood of fetal death occurring within 1 week of a negative CST is less than 1 in 1000 (Greenberg et al., 2012). Positive CST results

TABLE 26-5 Interpretation of the Contraction Stress Test

INTERPRETATION	CLINICAL SIGNIFICANCE
Negative At least three uterine contractions in a 10-minute period, with no late or significant variable decelerations	Usually resume routine weekly testing schedule
Positive Late decelerations occur with 50% or more of contractions, even if there are fewer than three contractions in 10 minutes	Usually warrants hospital admission for further evaluation and/or delivery
Suspicious or Equivocal Prolonged, variable, or late decelerations occurring with less than 50% of the contractions	Repeat testing next day
Equivocal-Hyperstimulatory Decelerations that occur in the presence of contractions more frequent than every 2 minutes or lasting longer than 90 seconds	Repeat testing next day
Unsatisfactory Failure to produce three contractions within a 10-minute window or inability to trace the fetal heart rate	Repeat test next day

From Miller, L., Miller, D., & Tucker, S. (2013). *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* (7th ed.). St. Louis: Mosby.

have been associated with intrauterine fetal death, late FHR decelerations in labor, IUGR, and meconium-stained amniotic fluid. A positive CST result usually leads to hospitalization for further close observation or birth. Unsatisfactory, suspicious, and equivocal tests must be repeated within 24 hours (Miller et al., 2013).

PSYCHOLOGIC CONSIDERATIONS RELATED TO HIGH RISK PREGNANCY

Once a pregnancy has been identified as high risk, the pregnant woman and her fetus are monitored carefully throughout the remainder of the pregnancy. All women who undergo antepartum assessments are at risk for real and potential problems and may feel anxious. In most instances the tests are ordered because of suspected fetal compromise, deterioration of a maternal condition, or both. In the third trimester, pregnant women are most concerned about protecting themselves and their fetuses and consider themselves most vulnerable to outside influences. The label of *high risk* often increases this sense of vulnerability.

When a woman is diagnosed with a high risk pregnancy, she and her family will likely experience stress related to the diagnosis. The woman may exhibit various psychologic responses, including anxiety, low self-esteem, guilt, frustration, and inability to function. A high risk pregnancy can also affect parental attachment, accomplishment of the tasks of pregnancy, and family adaptation to the pregnancy. If the woman is fearful for

her well-being, she may continue to feel ambivalent about the pregnancy or may not accept its reality. She may not be able to complete preparations for the baby or go to childbirth classes if she is placed on restricted activity at home or hospitalized. The family may become frustrated because they cannot engage in activities that prepare them for parenthood. The nurse can help the woman and her family regain control and balance in their lives by providing support and encouragement, information about the pregnancy problem and its management, and opportunities to make as many choices as possible about the woman's care.

NURSES' ROLE IN ASSESSMENT AND MANAGEMENT OF THE HIGH RISK PREGNANCY

Nursing interventions for all pregnant women include education, anticipatory planning, counseling for family adaptation, assessment, and planning of appropriate interventions. Providing care to women facing a high risk pregnancy draws on nurses' unique knowledge in understanding the physiologic and psychosocial needs when a pregnancy is complicated by a maternal or fetal issue. Along with receiving a diagnosis of a maternal or fetal health concern, mothers may experience loss and grief, increased stress, uncertainty, information needs, and decision-making dilemmas (Lalor, Begley, & Galavan, 2009).

High risk pregnancies are often accompanied by additional testing and procedures. In these situations the nurse's role is one of educator and supporter as women undergo procedures such as ultrasonography, MRI, CVS, PUBS, and amniocentesis. In some instances the nurse may assist the physician with the test or procedure. When educating the woman and her family, the nurse must explain the purpose of each test, how it is performed, and the difference between screening and diagnostic tests. The nurse must also be aware of potential moral and ethical implications associated with certain tests. For example, women and their families may need to make a decision about pregnancy termination based on test results.

In many settings nurses actually perform tests such as NSTs, CSTs, and BPPs; conduct an initial assessment; and begin necessary interventions for nonreassuring results. Nurses who perform these tests have had additional education and training and function under guidance of established protocols and in collaboration with obstetric providers. Client teaching, which is an integral component of this role, involves preparing the woman for the test, interpreting the findings, and providing psychosocial support when needed.

Women with high risk pregnancies will likely receive many different services from multiple care providers. For all childbearing families effective care management requires that disciplines cooperate, communicate, and collaborate to provide care that promotes the best possible outcomes for mothers and babies. This coordination of care is even more essential in meeting the needs of families who are dealing with the additional stressors associated with a high risk pregnancy (Barron, 2014).

KEY POINTS

- A high risk pregnancy is one in which the life or well-being of the mother or infant is jeopardized by a biophysical or psychosocial disorder coincident with or unique to pregnancy.
- Biophysical, sociodemographic, psychosocial, and environmental factors place the pregnancy and fetus or neonate at risk.
- Biophysical assessment techniques include DFMCs, ultrasonography, and MRI.
- Biochemical monitoring techniques include amniocentesis, PUBS, CVS, MSAFP, multiple marker screens, and cell-free DNA screening in maternal blood.
- Fetal care centers have evolved in response to the need to provide diagnostic and therapeutic options as well as care coordination and other support services for families with a fetal anomaly diagnosis.
- Reactive NSTs and negative CSTs suggest fetal well-being.
- Most assessment tests have some degree of risk for the mother and fetus and usually cause some anxiety for the woman and her family.
- The nurse's roles in assessment and management of the high risk pregnancy are primarily those of educator and support person.

Hypertensive Disorders

Dusty Dix

<http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Differentiate among gestational hypertension, preeclampsia, and chronic hypertension.
- Describe etiologic theories and pathophysiology of preeclampsia.
- Compare care management of women with mild or severe gestational hypertension and preeclampsia with or without severe features.
- Describe appropriate nursing actions during and after an eclamptic seizure.
- Discuss the preconception, antepartum, intrapartum, and postpartum management of the woman with chronic hypertension.

Pregnancy-associated hypertensive disorders develop during pregnancy, labor, or after birth. These disorders include gestational hypertension and preeclampsia–eclampsia. Chronic hypertensive disorders precede pregnancy. Women with chronic hypertension can also develop superimposed preeclampsia. The classification, pathophysiologic changes, assessment, and management of pregnancy-associated hypertensive disorders are discussed in this chapter, with a primary focus on preeclampsia. The care of women with hypertensive disorders during the perinatal period requires a collaborative effort. Care management is directed toward early detection, thorough assessment, and timely intervention.

SIGNIFICANCE AND INCIDENCE

Hypertensive disorders are common medical complications of pregnancy, occurring in approximately 5% to 10% of all pregnancies. The incidence varies among hospitals, regions, and countries (Sibai, 2012). Hypertensive disorders are a major cause of perinatal morbidity and mortality worldwide, primarily related to uteroplacental insufficiency and premature birth (Backes, Markham, Moorehead, et al., 2011; Sibai). Perinatal outcomes are worse in women who have severe essential hypertension, early gestational hypertension, and preeclampsia with severe features (Duley, 2011). Preeclampsia is a significant risk factor for intrauterine growth restriction (IUGR) and fetal demise. The rate of stillbirth in women who have preeclampsia with severe features is 21 per 1000 (Backes et al., 2011).

In the United States and Canada hypertensive disorders are one of the top causes of maternal morbidity and mortality, related to renal failure, coagulopathy, cardiac or liver

failure, placental abruption, seizures, and stroke (Duley, 2011; Harvey & Sibai, 2013). Of maternal deaths worldwide, 10% to 15% can be attributed to preeclampsia and eclampsia (Uzan, Carbonnel, Piconne, et al., 2011). Preeclampsia accounts for more than 50,000 maternal deaths worldwide each year. According to the World Health Organization, approximately one woman dies every 7 minutes from complications related to preeclampsia (Romero-Arauz, Morales-Borrego, García-Espinosa, & Peralta-Pedrero, 2012).

CLASSIFICATION

The classification of hypertensive disorders in pregnancy is confusing because standard definitions are not used consistently by all health care providers. The classification system most commonly used in the United States is based on recommendations from the American College of Obstetricians and Gynecologists (ACOG) (2002) and the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy (Working Group) (2000). More recently, the ACOG convened a task force of experts in the management of hypertension in pregnancy. The Task Force on Hypertension in Pregnancy chose to continue use of this classification system, although it modified some of the system components (ACOG, 2013). The current classification system is summarized in Table 27-1.

Gestational Hypertension

Gestational hypertension is the onset of hypertension without proteinuria or other systemic findings diagnostic for preeclampsia after week 20 of pregnancy (ACOG, 2013). Hypertension is defined as a systolic blood pressure (BP) greater than

TABLE 27-1 Classification of Hypertensive States of Pregnancy

TYPE	DESCRIPTION
Gestational Hypertensive Disorders	
Gestational hypertension	Development of hypertension after week 20 of pregnancy in a previously normotensive woman without proteinuria or other systemic findings (see description of Preeclampsia below)
Preeclampsia	Development of hypertension and proteinuria in a previously normotensive woman after 20 weeks of gestation or in the early postpartum period. In the absence of proteinuria, the development of new-onset hypertension with the new onset of any of the following: thrombocytopenia, renal insufficiency, impaired liver function, pulmonary edema, or cerebral or visual symptoms
Eclampsia	Development of convulsions or coma not attributable to other causes in a preeclamptic woman
Chronic Hypertensive Disorders	
Chronic hypertension	Hypertension in pregnant woman present before pregnancy
Superimposed preeclampsia	Chronic hypertension in association with preeclampsia

Data from American College of Obstetricians and Gynecologists (ACOG). (2013). Executive summary: Hypertension in pregnancy. *Obstetrics and Gynecology*, 122(5), 1122-1131.

140 mm Hg or a diastolic BP greater than 90 mm Hg. The hypertension should be recorded on two occasions at least 4 hours apart after 20 weeks of gestation in a woman with a previously normal blood pressure (ACOG, 2013). Only one pressure (either systolic or diastolic) needs to be elevated to meet the definition of hypertension (Harvey & Sibai).

The definitions of gestational hypertension are the same as the definitions for blood pressure readings for preeclampsia (Table 27-2). Gestational hypertension does not persist longer than 12 weeks postpartum and usually resolves during the first postpartum week (Harvey & Sibai, 2013). Some women who are initially thought to have gestational hypertension are eventually diagnosed with chronic hypertension instead. Others go on to develop proteinuria or other systemic findings, thereby changing their diagnosis to preeclampsia.

Preeclampsia

Preeclampsia is a pregnancy-specific condition in which, traditionally, hypertension and proteinuria develop after 20 weeks of gestation in a woman who previously had neither condition. The signs and symptoms of preeclampsia also can develop for the first time during the postpartum period. The recent ACOG Task Force on Hypertension in Pregnancy eliminated proteinuria as a requirement for the diagnosis of preeclampsia (see Evidence-Based Practice box). Although proteinuria may still be used to diagnose preeclampsia, it is often difficult to collect a 24-hour urine sample for accurate measurement in a timely manner. In the absence of proteinuria preeclampsia may be defined as hypertension along with either thrombocytopenia, impaired liver function, the new development of renal insufficiency, pulmonary edema, or new-onset cerebral or visual disturbances (see Table 27-2) (ACOG, 2013). Table 27-3 lists common laboratory changes that occur in preeclampsia.

TABLE 27-2 Diagnostic Criteria for Preeclampsia and Preeclampsia with Severe Features

	PREECLAMPSIA	SEVERE FEATURES OF PREECLAMPSIA
Component		
Hypertension	Blood pressure (BP) reading $\geq 140/90$ mm Hg $\times 2$, at least 4 hours apart after 20 weeks of gestation in a previously normotensive woman	BP reading $\geq 160/110$ mm Hg $\times 2$, at least 4 hours apart while the client is on bed rest (unless antihypertensive therapy has already been initiated)
Proteinuria	Proteinuria of ≥ 300 mg in a 24-hr specimen Protein/creatinine ratio ≥ 0.3 (with each measured as mg/dl) $\geq 1+$ on dipstick (used only if quantitative methods are not available)	Massive proteinuria (>5 g in a 24-hr specimen) is no longer used as a diagnostic criterion
Thrombocytopenia	Platelet count $<100,000/\mu\text{L}$	Platelet count $<100,000/\mu\text{L}$
Impaired liver function	Elevated blood levels of liver transaminases to twice the normal concentration	Abnormally elevated blood concentrations of liver enzymes to twice the normal concentration; severe persistent epigastric or right upper quadrant pain unresponsive to medication and not accounted for by alternative diagnoses, or both
Renal insufficiency	New development of serum creatinine >1.1 mg/dl or a doubling of the serum creatinine concentration in the absence of other renal disease	Progressive renal insufficiency (serum creatinine concentration >1.1 mg/dl or a doubling of the serum creatinine concentration in the absence of other renal disease)
Pulmonary edema		Present
Cerebral or visual disturbances		New onset

Modified from American College of Obstetricians and Gynecologists (ACOG). (2013). Executive summary: Hypertension in pregnancy. *Obstetrics and Gynecology*, 122(5), 1122-1131.

Eclampsia

Eclampsia is the onset of seizure activity or coma in a woman with preeclampsia who has no history of preexisting pathology that can result in seizure activity (Harvey & Sibai, 2013; Markham & Funai, 2014). In developed countries eclampsia occurs in approximately 1 of 2000 births (Duley, 2011). Although eclamptic seizures can occur before, during, or after birth, approximately 50% of cases occur during the antepartum period (Poole, 2014).

Chronic Hypertension

Chronic hypertension is defined as hypertension that is present before the pregnancy (ACOG, 2013). Hypertension initially diagnosed during pregnancy that persists longer than 12 weeks postpartum is also classified as chronic hypertension (Harvey & Sibai, 2013).

TABLE 27-3 Common Laboratory Changes in Preeclampsia

	NORMAL	NONPREGNANT PREECLAMPSIA	HELLP
Hemoglobin, hematocrit	12-16 g/dl, 37%-47%	May ↑	↓
Platelets (cells/mm ³)	150,000-400,000/mm ³	<100,000/mm ³	<100,000/mm ³
Prothrombin time (PT), partial thromboplastin time (PTT)	12-14 sec, 60-70 sec	Unchanged	Unchanged
Fibrinogen	200-400 mg/dl	300-600 mg/dl	↓
Fibrin split products (FSPs)	Absent	Absent or present	Present
Blood urea nitrogen (BUN)	10-20 mg/dl	↑	↑
Creatinine	0.5-1.1 mg/dl	>1.1 mg/dl	↑
Lactate dehydrogenase (LDH)*	45-90 units/l	↑	↑ (>600 units/L)
Aspartate aminotransferase (AST)	4-20 units/l	Elevated	↑ (>70 units/L)
Alanine aminotransferase (ALT)	3-21 units/l	Elevated	↑
Creatinine clearance	80-125 ml/min	130-180 ml/min	↓
Burr cells or schistocytes	Absent	Absent	Present
Uric acid	2-6.6 mg/dl	>5.9 mg/dl	>10 mg/dl
Bilirubin (total)	0.1-1 mg/dl	Unchanged or ↑	↑ (>1.2 mg/dl)

*LDH values differ according to the test or assays being performed.

Chronic Hypertension with Superimposed Preeclampsia

Women with chronic hypertension may develop superimposed preeclampsia. This condition, which is associated with adverse maternal or fetal outcomes, can be difficult to diagnose (ACOG, 2013).

PREECLAMPSIA

Etiology

Preeclampsia is a condition unique to human pregnancy. It occurs in approximately 2% to 7% of healthy nulliparous pregnant women and much more frequently in women with multifetal gestation, a history of preeclampsia, chronic hypertension, and preexisting diabetes (Sibai, 2012).

Common risk factors associated with the development of preeclampsia are listed in Box 27-1. The strongest risk factors are a first pregnancy when the woman is younger than 19 or older than 40 years of age, a first pregnancy with a new partner,

BOX 27-1 Common Risk Factors for Preeclampsia

- Primigravida younger than 19 or older than 40 years
- Preeclampsia with severe features in a previous pregnancy
- Family history (mother or sister) of preeclampsia
- Paternal history (partner previously fathered a preeclamptic pregnancy in another woman)
- African descent
- Multifetal gestation
- Maternal infection/inflammation in current pregnancy (i.e., urinary tract infection, periodontal disease)
- Preexisting medical or genetic conditions
 - Chronic hypertension
 - Renal disease
 - Pregestational diabetes mellitus
 - Connective tissue disease (i.e., systemic lupus erythematosus, rheumatoid arthritis)
 - Thrombophilia (i.e., antiphospholipid antibody syndrome, protein C or S deficiency, factor V Leiden mutation)
 - Obesity

From Gilbert, E.S. (2011). *Manual of high risk pregnancy and delivery* (ed. 5). St. Louis: Mosby; Harvey, C., & Sibai, B. (2013). Hypertension in pregnancy. In N. Troiano, C. Harvey, & B. Chez (Eds.), *AWHONN's high risk and critical care obstetrics* (3rd ed.). Philadelphia: Lippincott Williams & Wilkins.

and a history of preeclampsia with severe features (Gilbert, 2011). Pregnancy-onset snoring may also be a risk factor for gestational hypertension and preeclampsia (O'Brien, Bullough, Owusu, et al., 2012).

The cause of preeclampsia is unknown. Many theories have been suggested to explain its etiology. Theories include abnormal trophoblast invasion, immunologic response to partially foreign genetic placental and fetal tissue, stimulation of the inflammatory system by cardiovascular changes of pregnancy, various dietary deficiencies, and genetic abnormalities (Harvey & Sibai, 2013).

Pathophysiology

Preeclampsia is a progressive disorder, with the placenta as the root cause. Therefore, the disease begins to resolve after the placenta has been expelled. Current thought is that the pathologic changes that occur in the woman with preeclampsia are caused by disruptions in placental perfusion and endothelial cell dysfunction (ACOG, 2013; Gilbert, 2011; Harvey & Sibai, 2013; Sibai, 2012). These changes develop early in pregnancy, long before the signs and symptoms of preeclampsia become evident (Eiland, Nzerue, & Faulkner, 2012; Markham & Funai, 2014). Normally in pregnancy the spiral arteries in the uterus widen from thick-walled muscular vessels to thinner, saclike vessels with much larger diameters. This change increases the capacity of the vessels, allowing them to handle the increased blood volume of pregnancy. Because this vascular remodeling does not occur or only partially develops in women with preeclampsia, decreased placental perfusion and hypoxia result (Harvey & Sibai).

Placental ischemia is thought to cause endothelial cell dysfunction by stimulating the release of a substance that is toxic to endothelial cells. This anomaly causes generalized vasospasm, which results in poor tissue perfusion in all organ systems, increased peripheral resistance and BP, and increased endothelial cell permeability, leading to intravascular protein and fluid loss and ultimately to less plasma volume. The main pathogenic factor is not an increase in BP but poor perfusion as a result

EVIDENCE-BASED PRACTICE

What's Up with Preeclampsia?**Ask the Question**

For pregnant women what are the new best practices for identifying and treating preeclampsia?

Search for the Evidence

Search Strategies English language research-based publications since 2012 on preeclampsia and gestational hypertension were included.

Databases Used Cochrane Collaborative Database, National Guideline Clearinghouse (AHRQ), CINAHL, PubMed, UpToDate, and the professional websites for ACOG and AWHONN

Critical Appraisal of the Evidence

Risk factors for preeclampsia include young or old age, nulliparity, smoking, unmarried status, African-American, multiple fetuses, chronic hypertension, diabetes, and history of preeclampsia.

Recent research has also found the following to be risk factors for preeclampsia:

- For women with normal prepregnancy weight, excessive (>10) increase in body mass index (BMI) during pregnancy is associated with increased risk for preeclampsia. For overweight and obese women, even moderate BMI increase (5-10) can increase risk (Swank, Caughey, Farinelli, et al., 2014).
- Higher levels of C-reactive protein, an indicator of general inflammation, are associated with an increased risk for preeclampsia, especially with elevated BMI (Rebelo, Schlusssel, Vaz, et al., 2013).
- Low levels of placental growth factor, an angiogenic factor, when detected before 35 weeks of gestation, is a secondary marker for placental dysfunction and is highly sensitive for preeclampsia (Chappell, Duckworth, Seed, et al., 2013).
- Psychosocial stress and chronic hypertension each increase risk for preeclampsia. When paired, their additive effect can increase the risk up to 20-fold (Yu, Zhang, Wang, et al., 2013).
- Preeclampsia is more likely to occur when birth occurs during the colder months of the year (Beltran, Wu, & Laurent, 2013).

The American College of Obstetricians and Gynecologists (ACOG) Task Force on Hypertension in Pregnancy (2013) has issued the following guideline changes for diagnosis and treatment of preeclampsia:

- Although proteinuria may still be used for diagnosis, a massive amount (greater than 5 g in a 24-hour urine collection) is no longer considered to be a severe feature of preeclampsia. Routine screening, beyond an appropriate medical history, is not recommended.
- Vitamins C and E to prevent preeclampsia do not prevent preeclampsia.
- Daily low-dose aspirin can help high risk women.
- Antihypertensives (labetalol or hydralazine) are useful for severe hypertension.
- Magnesium sulfate is used for seizure prevention but not as an antihypertensive agent.

Apply the Evidence: Nursing Implications

- Preconception counseling for modifiable risk factors, such as smoking and weight gain, can decrease preeclampsia risk. When possible, planning a pregnancy to give birth during warm months may be preferable.
- Physical activity has a protective effect against preeclampsia (Kasawar, do Nascimento, Costa, et al., 2012).
- Teaching stress management techniques for lifelong and pregnancy stress is important, especially in the presence of chronic hypertension.

- In addition to assessing blood pressure, alert nurses are often the first to note subtle clinical changes indicating preeclampsia, such as sudden weight gain, edema, headache, oliguria, right-sided pain, and fetal distress.
- In the event of emergent hypertensive crisis, nurses must be familiar and proficient with assessments, including reflexes and fetal monitoring; must understand medications; and must be proactive in environmental alteration, such as limiting visitors and lowering lights and sound in the room.

Quality and Safety Competencies: Evidence-Based Practice (EBP)***Knowledge**

Describe reliable sources for locating evidence reports and clinical practice guidelines.

Use of high-level evidence guides the comprehensive prepregnancy and prenatal care of women at risk for preeclampsia.

Skills

Locate evidence reports related to clinical practice topics and guidelines.

Relevant systematic reviews and professional guidelines provide recommendations for improving outcomes by identifying women at risk for preeclampsia and educating clients about prevention and treatment.

Attitudes

Value the concept of EBP as integral to determining best clinical practices.

An evidence base guides practice and fosters client confidence and efficacy.

of vasospasm and reduced plasma volume (Fig. 27-1) (Gilbert 2011; Markham & Funai, 2014). Figure 27-2 demonstrates how endothelial cell dysfunction causes many of the common signs and symptoms of preeclampsia.

Reduced kidney perfusion decreases the glomerular filtration rate and can lead to degenerative glomerular changes and oliguria. Pathologic changes in the endothelial cells of the glomeruli (glomerular endotheliosis) are uniquely characteristic of preeclampsia. Protein, primarily albumin, is lost in the urine. Uric acid clearance is decreased, but serum uric acid levels increase. Sodium and water are retained. Acute tubular necrosis and renal failure may occur (Gilbert, 2011; Poole, 2014).

Plasma colloid osmotic pressure decreases as serum albumin levels decrease. Intravascular volume is reduced as fluid moves out of the intravascular compartment, resulting in hemoconcentration, increased blood viscosity, and tissue edema. The hematocrit value increases as fluid leaves the intravascular space. Arteriolar vasospasm can lead to endothelial damage and increased capillary permeability, predisposing the woman to pulmonary edema (see Fig. 27-2) (Gilbert, 2011; Poole, 2014).

Decreased liver perfusion can lead to impaired liver function and elevated liver enzyme levels. If hepatic edema and subcapsular hemorrhage develop, the woman may complain of epigastric or right upper quadrant pain. Hemorrhagic necrosis in the liver can result in a subcapsular hematoma, which is a rare occurrence (Gilbert, 2011; Poole, 2014). Rupture of a subcapsular hematoma is a life-threatening complication and a surgical emergency (see Fig. 27-2).

Neurologic complications associated with preeclampsia include cerebral edema and hemorrhage and increased central nervous system (CNS) irritability. CNS irritability manifests as headaches, hyperreflexia, positive ankle clonus, and seizures. Arteriolar vasospasms and decreased blood flow to the retina

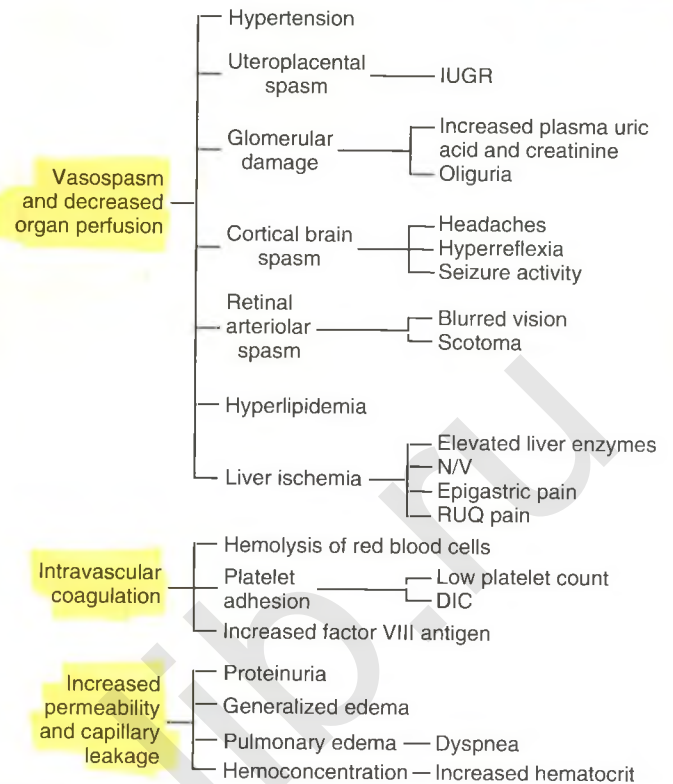

FIG 27-2 Consequences of endothelial cell dysfunction. *DIC*, Disseminated vascular coagulation; *IUGR*, intrauterine growth restriction; *N/V*, nausea/vomiting; *RUQ*, right upper quadrant. (From Gilbert, E. [2011]. *Manual of high risk pregnancy & delivery* [5th ed.]. St. Louis: Mosby.)

can lead to visual disturbances such as scotoma (dim vision or blind or dark spots in the visual field) and blurred or double vision (Gilbert, 2011; Poole, 2014).

Traditionally preeclampsia was considered to primarily affect the woman, causing hypertension, proteinuria, and perhaps associated multisystem dysfunction. However, it is now recognized that preeclampsia can also greatly affect the fetus, resulting in fetal growth restriction, decreased amniotic fluid volume, abnormal fetal oxygenation, low birth weight, and preterm birth (Sibai, 2012).

HELLP Syndrome

HELLP syndrome is a laboratory diagnosis for a variant of severe preeclampsia that involves hepatic dysfunction, characterized by hemolysis (*H*), elevated liver enzymes (*EL*), and low platelet (*LP*) count. It is not a separate illness. Specific laboratory findings are needed to diagnose HELLP syndrome and distinguish it from other serious diseases that share the same signs and symptoms. HELLP syndrome occurs in 0.5% to 0.9% of all pregnancies—10% to 20% of women with preeclampsia with severe features develop it (Harvey & Sibai, 2013). Table 27-3 lists laboratory changes that occur in HELLP syndrome. Traditionally it was not diagnosed unless all three laboratory abnormalities were present. Currently, however, women who develop only one or two of the diagnostic laboratory values are being diagnosed with incomplete HELLP, partial HELLP, or the ELLP syndrome (Harvey & Sibai).

The pathophysiologic changes of HELLP syndrome occur as a result of arteriolar vasospasm, endothelial cell dysfunction with

fibrin deposits, and adherence of platelets in blood vessels. Red blood cells are damaged as they pass through narrowed blood vessels and become hemolyzed, resulting in a decreased red blood cell and platelet count, as well as hyperbilirubinemia. Endothelial damage and fibrin deposits in the liver lead to impaired liver function and can cause hemorrhagic necrosis. Liver enzymes are elevated when hepatic tissue is damaged (Gilbert, 2011).

HELLP syndrome usually develops during the antepartum period. The clinical presentation is often nonspecific. Most women with the disorder report a history of malaise, influenza-like symptoms, and epigastric or right upper quadrant abdominal pain. Symptoms tend to worsen at night and improve during the daytime. HELLP syndrome can progress rapidly (Harvey & Sibai, 2013).

! NURSING ALERT

An extremely important point to understand is that many women with HELLP syndrome may not have signs or symptoms of severe features of preeclampsia. For example, although most women have hypertension, BP may be only mildly elevated in 15% to 50% of cases. Proteinuria may be absent. As a result, women with HELLP syndrome are often misdiagnosed with a variety of other medical or surgical disorders (Sibai, 2012).

HELLP syndrome occurs more often in Caucasian women than in women of other races. A diagnosis of HELLP syndrome is associated with an increased risk for maternal death and adverse perinatal outcomes, including pulmonary edema, acute renal failure, disseminated intravascular coagulopathy (DIC), placental abruption, liver hemorrhage or failure, acute respiratory distress syndrome (ARDS), sepsis, and stroke. The reported perinatal mortality rate ranges from 7.4% to 34%, with a maternal mortality rate of approximately 1% (Sibai, 2012). The rate of preterm birth in women with HELLP syndrome is approximately 70%, with 15% occurring before 28 weeks of gestation. Most of the perinatal deaths occur before 28 weeks of gestation in association with placental abruption or severe fetal growth restriction (Sibai).

CARE MANAGEMENT

Identifying and Preventing Preeclampsia

Numerous clinical trials have examined various interventions to prevent preeclampsia, including protein or salt restriction; zinc, magnesium, fish oil, or vitamins C and E supplementation; use of diuretics or other antihypertensive medications or heparin; and bed rest. All of these interventions demonstrated minimal to no benefit in preventing or reducing the severity of preeclampsia (Sibai, 2012). However, low-dose aspirin (60 to 80 mg) has been found to reduce preeclampsia and adverse outcomes in selected high risk women. It is recommended that daily low-dose aspirin therapy be initiated late in the first trimester for women who have a history of early-onset preeclampsia and subsequent preterm birth at less than 34 weeks of gestation or a history of preeclampsia in more than one previous pregnancy (ACOG, 2013).

No reliable test that can be used as a routine screening tool for predicting preeclampsia has yet been developed. However, the search for biomarkers that can identify individual women who will develop hypertension during pregnancy is ongoing

(Harvey & Sibai, 2013). For example, the tyrosine kinase (sFlt) and serum placental growth factor (PlGF) ratio at 22 to 26 weeks of gestation was shown in one study to be highly predictive of early-onset preeclampsia. An abnormal uterine artery Doppler velocimetry in the first or second trimester of pregnancy has also been suggested as a good screening test to predict preeclampsia (Gilbert, 2011).

Although research offers future promise, much work remains before a screening test for preeclampsia is available for widespread clinical use. Nurses should be aware of what strategies are being studied and use the most valid results so they can counsel pregnant women about evidence-based interventions. Meanwhile, early prenatal care to identify women at risk and early detection of the disease are the best ways to care for women who have or may develop preeclampsia.

Assessment and Nursing Diagnoses

Accurate measurement of BP is essential for the early detection of hypertensive disorders. Personnel caring for pregnant women need to be consistent in taking and recording BP measurements in a standardized manner. Both the National High Blood Pressure Education Program and the American Heart Association (AHA) have published extensive recommendations for accurately measuring BP (National High Blood Pressure Education Program, 2000; Pickering, Hall, Appel, et al., 2005). Box 27-2 provides detailed instructions for measurement.

Assessment for edema is another component of the physical examination, although the presence of edema is no longer included in the definition of preeclampsia. Edema is assessed for distribution, degree, and pitting. Dependent edema is edema of the lowest or most dependent parts of the body, where hydrostatic pressure is greatest. If a pregnant woman is ambulatory, the edema may first be evident in the feet and ankles. If she is confined to bed, it is more likely to occur in the sacral region. Pitting edema leaves a small

BOX 27-2 Blood Pressure Measurement

- Measure blood pressure with the woman seated (ambulatory) or in the lateral recumbent position with the arm at heart level. Neither the woman nor the health care provider should talk while the blood pressure is being measured.
- After positioning, allow the woman at least 10 minutes of quiet rest before the blood pressure measurement to encourage relaxation.
- Instruct the woman to refrain from tobacco or caffeine use 30 minutes before the blood pressure measurement.
- Use the right arm each time.
- Support the arm in a horizontal position at heart level.
- Use the proper-size cuff (cuff should cover approximately 80% of the upper arm or be 1½ times the length of the upper arm).
- Maintain a slow, steady deflation rate.
- Take the average of two readings at least 6 hours apart to minimize recorded blood pressure variations across time.
- Use the Korotkoff phase V (disappearance of sound) for recording the diastolic value.
- Use accurate equipment. The mercury sphygmomanometer is the most accurate device.
- If interchanging manual and electronic devices, use caution in interpreting different blood pressure values.

Data from Peters, R. (2008). High blood pressure in pregnancy. *Nursing for Women's Health*, 12(5), 412-421.

depression or pit after finger pressure is applied to the swollen area (Fig. 27-3). The pit, which is caused by movement of fluid to adjacent tissue away from the point of pressure, normally disappears within 10 to 30 seconds. Although the amount of edema is difficult to quantify, the method shown in Figure 27-4 may be used to record relative degrees of edema formation.

Deep tendon reflexes (DTRs) reflect the balance between the cerebral cortex and spinal cord. They are evaluated as a baseline

FIG 27-3 Pitting edema. (Courtesy Shannon Perry, Phoenix, AZ.)

FIG 27-4 Assessment of pitting edema of lower extremities. A, +1; B, +2; C, +3; D, +4.

and to detect any changes. The biceps and patellar reflexes are assessed and the findings recorded (Fig. 27-5 and Table 27-4). To elicit the biceps reflex, the examiner strikes a downward blow over the thumb, which is situated over the biceps tendon (see Fig. 27-5, A). Normal response is flexion of the arm at the elbow, described as a 2+ response. The patellar reflex is elicited with the woman's legs hanging freely over the end of the examining table or with the woman lying on her side with the knee slightly flexed (see Fig. 27-5, D). The patellar tendon (inferior to the patella) is tapped with a percussion hammer. Normal response is the extension or kicking out of the leg.

To assess for **clonus** (hyperactive reflexes) at the ankle joint, the examiner supports the leg with the knee flexed (see Fig. 27-5, F). With one hand the examiner sharply dorsiflexes the foot, maintains the position for a moment, and then releases the foot. Normal (negative clonus) response is elicited when no rhythmic oscillations (jerks) are felt while the foot is held in dorsiflexion. When the foot is released, no oscillations are seen as the foot drops to the plantar-flexed position. Abnormal (positive clonus) response is recognized by rhythmic oscillations of one or more "beats" felt when the foot is in dorsiflexion and seen as the foot drops to the plantar-flexed position.

The presence of proteinuria is ideally determined by evaluation of a 24-hour urine collection. In a 24-hour specimen, proteinuria is defined as a concentration at or greater than 300 mg. Although proteinuria may still be used to define preeclampsia, studies have shown little relationship between the degree of proteinuria in women with preeclampsia and pregnancy outcome. Therefore, massive proteinuria (greater than 5 g) is not considered to be a severe feature of preeclampsia. Because a 24-hour collection to measure the quantity of protein and creatinine clearance is more reflective of true renal status, it is preferred over dipstick testing, which should not be used for diagnosis of preeclampsia if at all possible (ACOG, 2013). Alkaline, concentrated, or dilute urine can yield a false reading.

FIG 27-5 Location of tendons for evaluation of deep tendon reflexes. A, Biceps. B, Brachioradial. C, Triceps. D, Patellar. E, Achilles. F, Evaluation of ankle clonus. (From Seidel, H., Ball, J., Dains, J., et al. [2011]. *Mosby's guide to physical examination* [7th ed.]. St. Louis: Mosby.)

TABLE 27-4 Assessing Deep Tendon Reflexes

GRADE	DEEP TENDON REFLEX RESPONSE
0	No response
1+	Sluggish or diminished
2+	Active or expected response
3+	More brisk than expected, slightly hyperactive
4+	Brisk, hyperactive, with intermittent or transient clonus

From Seidel, H., Ball, J., Dains, J., et al. (2011). *Mosby's guide to physical examination* (7th ed.). St. Louis: Mosby.

Urine contaminated with bacteria, blood, and amniotic fluid also can yield a false positive for proteinuria. Therefore, to ensure accurate results, proteinuria should be determined using only a urine specimen that has been collected by either a thorough clean-catch midstream technique or catheterization (Gilbert, 2011).

During the examination the woman is evaluated for signs and symptoms considered to be severe features of preeclampsia such as severe headaches (usually frontal), epigastric pain (heartburn), right upper quadrant abdominal pain, or visual disturbances such as scotoma, photophobia, or double vision.

Nursing diagnoses for the woman with preeclampsia may include the following:

- *Anxiety* related to
 - Preeclampsia and its effects on woman and infant
- *Deficient Knowledge* related to
 - Management of preeclampsia (diet, medications, activity restriction, plans for labor and birth)
- *Disabled Family Coping* related to
 - Restricted activity and concern over a high risk pregnancy
 - Financial concerns
- *Powerlessness* related to
 - Inability to prevent or control condition and outcomes
- *Risk for Injury* to mother related to
 - Hypertension
 - Central nervous system (CNS) irritability secondary to cerebral edema
 - Vasospasm
 - Decreased renal perfusion
- *Risk for Injury* to fetus related to
 - Disruption of oxygen transfer from environment to fetus
 - Intrauterine growth restriction (IUGR)
 - Placental abruption
 - Preterm birth

Interventions

Mild Gestational Hypertension and Preeclampsia Without Severe Features

In the past, both gestational hypertension and preeclampsia were usually described as either “mild” or “severe.” Because preeclampsia is a dynamic disease process, this practice is no longer recommended. A diagnosis of “mild preeclampsia” applies only at the time it is made. Women must be evaluated frequently to determine if the disease has progressed to the point that severe features are present (see Table 27-2) (ACOG, 2013).

The goals of therapy for women with mild gestational hypertension and preeclampsia without severe features are to ensure maternal safety and to deliver a healthy newborn as close to

term as possible. Prior to 37 gestational weeks, care management is expectant with close monitoring of the maternal and fetal status. Women with mild gestational hypertension or preeclampsia can be safely managed at home, provided they have frequent maternal and fetal evaluation (Gilbert, 2011; Sibai, 2012). Vaginal birth by induction of labor, preceded by cervical ripening (if necessary), is recommended at 37 gestational weeks. At this gestational age the risks to the fetus outweigh any potential benefits of continuing the pregnancy (ACOG, 2013; Backes et al., 2011; Sibai, 2012).

Criteria for home management include BP less than 150/100 mm Hg and no increase in proteinuria if they have no symptoms, a normal platelet count, and normal liver enzymes (Sibai, 2012). Successful home care requires the woman to be well educated about preeclampsia and highly motivated to follow the plan of care (see Teaching for Self-Management: Assessing and Reporting Clinical Signs of Preeclampsia). All teaching should include the woman and her family, and time must be allowed for them to absorb information, ask questions, and voice concerns. Methods for enhancing learning include visual aids, DVDs or Internet videos, handouts, and demonstrations with return demonstrations. Furthermore, the effects of illness, language, age, cultural beliefs, and support systems must be considered.

TEACHING FOR SELF-MANAGEMENT

Assessing and Reporting Clinical Signs of Preeclampsia

- Take your blood pressure as directed. Always sit to take your blood pressure and use your right arm each time for consistent and accurate readings. Support your arm on a table in a horizontal position at heart level.
- Report to your health care provider immediately any increase in your blood pressure.
- Dipstick test your clean-catch urine sample as directed to assess proteinuria.
- Report to your health care provider if proteinuria is 1+ or more or if you have a decrease in urine output.
- Assess your baby's activity daily. Decreased activity (four or fewer movements per hour) may indicate fetal compromise and should be reported.
- Be sure to keep your scheduled prenatal appointments so that any changes in your or your baby's condition can be detected.
- Keep a daily log or diary of your assessments for your home health care nurse, or take it with you to your next prenatal visit.
- Report to your health care provider immediately any headache, dizziness, or blurred vision.

Maternal and Fetal Assessment

Initial maternal laboratory evaluation for women with preeclampsia without severe features includes measurement of serum creatinine, platelet count, liver enzymes, and a 24-hour urine protein assessment. Thereafter, the platelet count and liver enzymes should be assessed weekly. Women are also evaluated for signs or symptoms of severe features such as severe headaches, blurred or double vision, mental confusion, right upper quadrant or epigastric pain, nausea or vomiting, shortness of breath, and decreased urinary output (ACOG, 2013; Sibai, 2012). BP should be monitored twice weekly and proteinuria assessed weekly (ACOG).

Fetal evaluation generally includes daily fetal movement counts and nonstress testing or a biophysical profile once or twice weekly until birth. (See Chapter 26 for more information on fetal assessment tests.) Ultrasound evaluation of amniotic fluid status and determination of estimated fetal weight are performed at the time preeclampsia is diagnosed and serially thereafter, depending on findings (Sibai, 2012).

Activity Restriction. Complete or partial bed rest for the duration of the pregnancy is still recommended frequently by health care providers. However, no evidence has been found that this practice improves pregnancy outcome. Moreover, prolonged bed rest is known to increase the risk of thrombophlebitis (Sibai, 2012). Other adverse physiologic outcomes related to complete bed rest include cardiovascular deconditioning; diuresis with accompanying fluid, electrolyte, and weight loss; muscle atrophy; and psychological stress. These changes begin on the first day of bed rest and continue for the duration of therapy. Therefore, restricted activity rather than complete bed rest is recommended (ACOG, 2013; Sibai).

Women with preeclampsia generally feel reasonably well; therefore, boredom from activity restriction is common. Diversionary activities, including television and computer or smart phone use, visits from friends, and a comfortable and convenient

environment are ways to cope with the boredom. Participation in online prenatal classes also may be possible. Gentle exercise (e.g., range-of-motion exercises, stretching, Kegel exercises, pelvic tilts) is important in maintaining muscle tone, blood flow, regular bowel function, and a sense of well-being (see Teaching for Self-Management: Coping with Activity Restriction).

A high risk pregnancy can be very stressful for a woman and her family. Family stressors include separation from family members when hospitalized, need for activity restriction, financial concerns, ability to manage the household, family activities, and child care. The family needs to use coping mechanisms and support systems to help them through this crisis. An excellent web-based support group for pregnant women on restricted activity is Sidelines (www.sidelines.org) (Gilbert, 2011). Relaxation techniques also may help reduce stress and prepare the woman for labor and birth.

Diet. Women with preeclampsia can have a regular diet with adequate protein (60 to 70 g), calcium (1200 mg), 600 mcg of folic acid, and adequate zinc (11 to 12 mg) and sodium (1.5 g). Adequate fluid intake (six to eight 8-ounce glasses of water per day) is encouraged to enhance renal perfusion and bowel function (Gilbert, 2011; Otten, Helwig, & Meyers, 2006) (see Teaching for Self-Management: Diet for Preeclampsia).

TEACHING FOR SELF-MANAGEMENT

Coping with Activity Restriction

At Home

- Clarify with your health care provider: What is bed rest? Question your activity level, positioning, bathroom privileges, children's visits, activities, personal hygiene, mobility, diet, and visitors.
- Have your computer, tablet, or smart phone available at your bedside. These devices can be used to communicate with friends, conduct business, and shop as necessary. Also use your computer or smart phone to communicate with Internet support groups and obtain information.
- Have a television and DVD player to watch television programs or movies (can also watch on computer or tablet) and a radio, CD player, or MP3 player to listen to music.
- Delegate responsibilities to family members or friends as much as possible (i.e., attend to the laundry, pick up groceries, drop off and pick up dry cleaning, meet repair people, attend to child care, organize meals).
- Have these available for use on your bed or couch:
 - Eggcrate mattress
 - Pillows and more pillows (body pillow)
- Keep a big trash basket near your bed and daytime resting place.
- Place a box or crate near the bed/sofa to store items such as:
 - Post-it Notes
 - Cups with lids and flexible straws
 - Paper plates
 - Plastic forks, spoons, and knives
 - Baby monitor or walkie-talkies
 - Wet wipes
 - Notebook to record questions for providers, telephone numbers, to-do lists
 - Envelopes and stationery
 - Take-out menus
 - Reading materials
 - Books
 - Audio books
 - Magazines

- Stock a mini-refrigerator or cooler with water or other beverages or healthy snacks.
- Plan for family time—visits and interaction, particularly with small children (see the Teaching for Self-Management box: Activities for Children of Women on Activity Restriction in Chapter 32).
- Explore your interest in a new hobby.
 - Work crossword or jigsaw puzzles.
 - Learn to embroider, smock, crochet, or knit.
 - Do mending or sewing.
- Do craft projects; make something for the baby.
- Identify relaxation exercises and activities (music) and implement.
- Arrange to have a facial, manicure/pedicure, neck massage, or other special treat when you need a lift.

In the Hospital

- Clarify with your health care provider: What is bed rest? Question your activity level, positioning, bathroom privileges, children's visits, activities, personal hygiene, mobility, diet, and visitors.
- In addition to survival tips for the home, the following may be useful in the hospital setting:
 - Bring your own pillow, shampoo, and conditioner.
 - Have a wheelchair for outside visits or visiting other antepartal women if allowed.
 - If possible bring a laptop computer or a tablet so you can watch movies or television programs if Internet access is available.
 - Ask friends to bring healthy food and snacks rather than flowers when visiting.
 - Explore your interest in handheld games.
 - Work with staff regarding scheduling (e.g., obstetrics provider examinations, vital signs, nursing assessments).
 - Bring earplugs to block the hospital noise.
 - Ask for a room with a view.
 - Have a large calendar and clock for easy viewing. Record significant events on the calendar.

TEACHING FOR SELF-MANAGEMENT

Diet for Preeclampsia

- Eat a nutritious, balanced diet (60 to 70 g protein, 1200 mg calcium, 600 mcg folic acid, 11 to 12 mg zinc, and 1.5 g sodium). Consult with registered dietitian on the diet best suited for you.
- Salt foods to taste. Limiting excessively salty foods (luncheon meats, pretzels, chips, pickles, and sauerkraut) will likely be necessary to meet the recommended sodium intake of 1.5 g/day.
- Eat foods with roughage (whole grains, raw fruits, and vegetables).
- Drink six to eight 8-ounce glasses of water per day.
- Avoid alcohol and tobacco and limit caffeine intake.

Severe Gestational Hypertension and Preeclampsia with Severe Features

Women with severe gestational hypertension are at greater risk for pregnancy complications than are women who have preeclampsia without severe features. Therefore, these women should be managed as if they have preeclampsia with severe features. Women diagnosed with severe gestational hypertension or preeclampsia with severe features should be hospitalized immediately for a thorough evaluation of maternal-fetal status (Sibai, 2012). These women are placed on magnesium sulfate to prevent eclamptic seizures. Maternal assessments include monitoring BP, urine output, and cerebral status as well as for the presence of epigastric pain, tenderness, labor, or vaginal bleeding (Sibai). Laboratory evaluation includes a platelet count, liver enzymes, and serum creatinine (see Table 27-3). Fetal assessment includes continuous electronic fetal heart rate monitoring, a biophysical profile, and ultrasound evaluation of fetal growth and amniotic fluid (Sibai). If evidence of fetal growth restriction is found, umbilical artery Doppler velocimetry is recommended (ACOG, 2013; Sibai).

After this initial assessment period a multidisciplinary plan of care is developed with the woman and her family. The goals of care management are to ensure maternal safety, assess the degree of maternal and fetal risk, formulate a plan for giving birth, and prevent eclampsia and other serious complications such as placental abruption, HELLP syndrome, fetal growth restriction, and fetal demise. If the pregnancy has reached 34 weeks of gestation or more, it is recommended that birth be expedited soon after maternal stabilization has been achieved (ACOG, 2013). At or beyond 34 weeks of gestation, the risks of continuing the pregnancy are considered greater than the risks of preterm birth (Backes et al., 2011; Sibai, 2012).

Expectant Management. Women who are less than 34 0/7 weeks of gestation and have no indication for giving birth immediately may be candidates for expectant management. These women should be hospitalized at a tertiary care facility that is able to provide both maternal and neonatal intensive care. Care management decisions should be made in consultation with a **perinatologist** (a maternal fetal medicine specialist), and client and family counseling by a neonatologist should be provided (ACOG, 2013; Sibai, 2012).

Expectant management includes the use of oral antihypertensive medications to maintain a BP less than 160/110 mm Hg. Management also includes ongoing maternal and fetal assessment for indicators of worsening condition. Corticosteroids

(betamethasone) are ordered to enhance fetal lung maturation for gestations less than 34 weeks. The dose is 12.5 mg intramuscularly, repeated in 24 hours. Optimal benefit begins 24 hours after the first dose is administered and lasts for 7 days (see Medication Guide: Antenatal Glucocorticoid Therapy with Betamethasone or Dexamethasone in Chapter 32) (ACOG, 2013; Gilbert, 2011; Sibai, 2012). Most women managed expectantly develop a maternal or fetal indication for giving birth within 2 weeks, although some are able to continue their pregnancies safely for several more weeks. Immediate birth is indicated if any of the following complications are present: uncontrollable severe hypertension, eclampsia, pulmonary edema, placental abruption, DIC, evidence of nonreassuring fetal status, or intrapartum fetal demise (ACOG; Sibai).

CLINICAL REASONING CASE STUDY

Severe Preeclampsia

Karen is a 30-year-old G1 P0 who is currently 32 weeks of gestation. At 28 weeks of gestation Karen developed preeclampsia. Since then Karen has been home on modified bed rest. A home health nurse visits her twice a week and calls her daily.

Today when the home health nurse visits, Karen tells her, "I have a terrible headache and hardly slept at all last night." When asked about other symptoms Karen replies, "My vision is blurry, I'm seeing spots, and my stomach hurts." Karen's blood pressure is 154/100, she has pitting edema in her legs, and her first voided urine this morning tested 3+ for protein. The nurse calls Karen's physician, who decides to admit her to the labor and birth unit immediately. At the hospital Karen continues to complain of a severe headache and seeing spots. Physical assessment reveals a blood pressure of 160/110 and 4+ deep tendon reflexes with 3 beats of ankle clonus. The electronic fetal monitor reveals minimal variability and late decelerations.

1. Evidence—Is there sufficient evidence to draw conclusions about Karen's diagnosis?
2. Assumptions—Describe the rationale for each of the following:
 - a. Karen's probable diagnosis
 - b. Signs and symptoms associated with this diagnosis
 - c. Laboratory values associated with this diagnosis
 - d. Risks associated with the diagnosis
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

Intrapartum Care. Intrapartum nursing care is directed toward the early identification of fetal heart rate (FHR) abnormalities and the prevention of maternal complications. Continuous FHR and uterine contraction monitoring are initiated and the woman is assessed for signs of placental abruption such as a tense, tender uterus. Maternal evaluation also includes assessment of the central nervous, cardiovascular, pulmonary, hepatic, and renal systems. Vital signs and assessments are performed as ordered and per hospital policy. Client and family education and supportive measures are also initiated (Gilbert, 2011; Poole, 2014) (see Nursing Care Plan).

The woman with preeclampsia with severe features is maintained on bed rest with the side rails up in a quiet, darkened environment. Emergency drugs, oxygen, and suction equipment should be checked and readily available (Box 27-3). To reduce the risk of pulmonary edema, total

 **NURSING CARE PLAN**
Preeclampsia with Severe Features

NURSING DIAGNOSIS	EXPECTED OUTCOME	INTERVENTIONS	RATIONALES
<i>Risk for Injury to woman and fetus related to CNS irritability (seizures)</i>	Woman will show diminished signs of CNS irritability (e.g., DTRs $\leq 2+$, absence of clonus) and have no seizure activity.	Establish baseline data (e.g., DTRs, clonus). Administer IV magnesium sulfate per physician's orders. Monitor maternal vital signs, level of consciousness, FHR, urine output, DTRs, IV flow rate, and serum levels of magnesium sulfate. Have calcium gluconate or calcium chloride on the unit. Maintain a quiet, darkened environment. Administer IV magnesium sulfate per physician order. Place woman on bed rest in side-lying position. Monitor FHR tracing for rate, baseline variability, and absence of late decelerations.	To use as basis for evaluating effectiveness of treatment To decrease hyperreflexia and minimize risk of seizure activity To assess for and prevent magnesium sulfate toxicity (e.g., drowsiness, lethargy, slurred speech, loss of DTRs, depressed respirations, cardiac arrest) To be available if needed as an antidote for magnesium sulfate toxicity To avoid stimuli that may precipitate seizure activity To relax vasospasms and increase renal perfusion To maximize uteroplacental blood flow, reduce blood pressure, and promote diuresis To assess for evidence of adequate uteroplacental oxygenation
<i>Ineffective Peripheral Tissue Perfusion related to preeclampsia secondary to arteriolar vasospasm</i>	Woman will exhibit signs of adequate tissue perfusion (i.e., adequate urine output and normal FHR tracing).	Administer IV magnesium sulfate per physician order. Place woman on bed rest in side-lying position. Monitor FHR tracing for rate, baseline variability, and absence of late decelerations.	To relax vasospasms and increase renal perfusion To maximize uteroplacental blood flow, reduce blood pressure, and promote diuresis To assess for evidence of adequate uteroplacental oxygenation
Other Possible Nursing Diagnoses			
<i>Risk for Excess Fluid Volume related to increased sodium retention secondary to administration of magnesium sulfate</i>	Woman will exhibit signs of normal fluid volume (i.e., balanced intake and output, normal serum creatinine levels, normal breath sounds), adequate oxygenation (i.e., normal respirations; full orientation to person, time, and place), normal range of cardiac output (i.e., normal pulse rate and rhythm), and fetal well-being (i.e., adequate fetal movement, normal FHR and pattern).	Monitor woman for signs of fluid volume excess (increased edema, decreased urine output, elevated serum creatinine level, weight gain, dyspnea, crackles). Monitor woman for signs of impaired gas exchange (increased respirations, dyspnea, altered blood gases, hypoxemia). Monitor woman for signs of decreased cardiac output (altered pulse rate and rhythm). Monitor fetus for abnormal signs (decreased fetal activity, abnormal FHR or pattern). Record findings and report signs of increasing problems to physician.	To detect potential complications To detect potential complications To detect potential complications To prevent complications To enable timely interventions
<i>Risk for Impaired Gas Exchange related to pulmonary edema secondary to increased vascular resistance</i>			
<i>Risk for Decreased Cardiac Output related to use of antihypertensive drugs</i>			
<i>Risk for Injury to Fetus related to uteroplacental insufficiency secondary to use of antihypertensive medications</i>			

CNS, Central nervous system; DTR, deep tendon reflex; FHR, fetal heart rate; IV, intravenous.

intravenous (IV) and oral fluids should not exceed 125 ml/hr. Intensive hemodynamic monitoring with a pulmonary artery (Swan-Ganz) catheter to evaluate central venous and pulmonary artery pressures is not a routine standard of care. It is indicated only in selected women, such as those with oliguria unresponsive to a fluid challenge (Markham & Funai, 2014; Poole, 2014).

Magnesium Sulfate. Magnesium sulfate is the drug of choice for preventing and treating seizure activity (eclampsia). It is almost always administered intravenously as a secondary infusion (piggyback) by a volumetric infusion pump. Per protocol or health care provider's order, an initial

loading dose of 4 to 6 g of magnesium sulfate is infused over 15 to 30 minutes. This dose is followed by a maintenance dose of magnesium sulfate that is diluted in an IV solution (e.g., 40 g of magnesium sulfate in 1000 ml of lactated Ringer's solution [1 g = 25 ml]) and administered by an infusion pump at 2 to 3 g/hr. This dose should maintain a therapeutic serum magnesium level of 4 to 7 mEq/L. Contrary to popular belief, magnesium sulfate has little effect on maternal BP when administered in this fashion (Markham & Funai, 2014; Poole, 2014).

Magnesium sulfate is rarely given intramuscularly because the absorption rate cannot be controlled, injections are painful,

and tissue necrosis may occur. However, the intramuscular (IM) route may be used in low-resource settings or with some women who are being transported to a tertiary care center. The IM dose is a 10-g loading dose (administered as two separate injections of 5 g in each buttock). The maintenance dosage is 5 g administered every 4 hours in alternating buttocks (Harvey & Sibai, 2013). Local anesthetic can be added to the solution to reduce injection pain. The Z-track technique should be used for the deep IM injection, followed by gentle massage at the site.

BOX 27-3 Hospital Precautionary Measures

- Environment
 - Quiet
 - Nonstimulating
 - Lighting subdued
- Seizure precautions
 - Suction equipment tested and ready to use
 - Oxygen administration equipment tested and ready to use
 - Call button within easy reach
- Emergency medications available on the unit
 - Hydralazine
 - Labetalol
 - Nifedipine
 - Magnesium sulfate
 - Calcium gluconate or calcium chloride
- Emergency birth pack easily accessible

It is unclear how magnesium sulfate works to prevent and treat eclamptic seizures. It may cause vasodilation in the peripheral and cerebral circulation, prevent or decrease cerebral edema, or function as a central anticonvulsant (Harvey & Sibai, 2013). Because magnesium is excreted in the urine, accurate recordings of maternal urine output must be obtained. If renal function declines, not all of the magnesium sulfate will be excreted adequately, resulting in magnesium toxicity. Common side effects of magnesium sulfate are a feeling of warmth, flushing, diaphoresis, and burning at the IV site. Symptoms of magnesium toxicity include absent deep tendon reflexes, respiratory depression, blurred vision, slurred speech, severe muscle weakness, and cardiac arrest (Harvey & Sibai). Blood can be drawn to determine the serum magnesium level if toxicity is suspected (Box 27-4).

MEDICATION ALERT

High serum levels of magnesium can cause relaxation of smooth muscle, such as the uterus. However, when administered as a 4- to 6-g loading dose followed by a 1- to 2-g/hr maintenance dose, magnesium sulfate has not been shown to significantly affect the need for oxytocin (Pitocin) stimulation of labor. Other than a brief period of uterine muscle relaxation during and immediately after administration of the loading dose, no evidence of decreased uterine contractility has been observed (Cunningham, Leveno, Bloom, et al., 2014).

BOX 27-4 Care of the Woman with Preeclampsia Receiving Magnesium Sulfate

Client and Family Teaching

- Explain technique, rationale, and reactions to expect
 - Route and rate
 - Purpose of “piggyback” infusion
- Reasons for use
 - Tailor information to woman’s readiness to learn
 - Explain that magnesium sulfate is used to prevent disease progression.
 - Explain that magnesium sulfate is used to prevent seizures, *not* to decrease blood pressure.
- Reactions to expect from medication
 - Initially the woman appears flushed and feels hot, sedated, and nauseated. She may experience burning at the IV site, especially during the bolus.
 - Sedation continues.
- Monitoring to anticipate
 - *Maternal*: blood pressure, pulse, respiratory rate, DTRs, level of consciousness, urine output (indwelling catheter), presence of headache, visual disturbances, epigastric pain
 - *Fetal*: FHR and activity

Administration

- Verify physician’s order.
- Position woman in side-lying position.
- Prepare solution and administer with an infusion control device (pump).
- Piggyback a solution of 40 g of magnesium sulfate in 1000 ml lactated Ringer’s solution using an infusion control device at the ordered rate: loading dose—initial bolus of 4 to 6 g over 15 to 30 min; maintenance dose—2 g/hr, according to unit protocol or specific physician’s order

Maternal and Fetal Assessments

Vital signs and assessments are performed as ordered by the health care provider and per hospital protocol.

- Monitor blood pressure, pulse, and respiratory rate every 15 to 30 minutes, depending on the woman’s condition.
- Monitor FHR and contractions continually.
- Monitor intake and output, DTRs, presence of headache, visual disturbances, level of consciousness, and epigastric pain at least hourly.
- Restrict hourly fluid intake to a total of no more than 125 ml/hr; urinary output should be at least 25 to 30 ml/hr.

Reportable Conditions

- Blood pressure: systolic ≥ 160 mm Hg or diastolic ≥ 110 mm Hg
- Respiratory rate: < 12 breaths/min
- Urinary output < 25 to 30 ml/hr
- Presence of headache, visual disturbances, decrease in level of consciousness, or epigastric pain
- Increasing severity or loss of DTRs, increasing edema
- Any abnormal laboratory values (magnesium level; platelet count; creatinine clearance; levels of uric acid, AST, ALT, prothrombin time, partial thromboplastin time, fibrinogen, fibrin split products)
- Any other significant change in maternal or fetal status

Emergency Measures

- Keep emergency drugs and intubation equipment immediately available.
- Keep the side rails up.
- Keep the lights dimmed, and maintain a quiet environment.

Documentation

- All of the above

MEDICATION ALERT

If magnesium toxicity is suspected, prompt actions are needed to prevent respiratory or cardiac arrest. The magnesium infusion should be discontinued immediately. Calcium gluconate or calcium chloride (antidotes for magnesium sulfate) can be given intravenously (Cunningham et al., 2014).

The effect of magnesium sulfate on FHR baseline variability is controversial. Because fetal levels of magnesium approximate those of the mother, fetal sedation is possible. However, absent or minimal baseline variability should not be assumed to be the result of magnesium sulfate therapy until other causes of fetal hypoxemia have been ruled out (Poole, 2014). Neonatal serum magnesium levels are almost identical to those of the mother (Markham & Funai, 2014).

SAFETY ALERT

Magnesium sulfate is considered a high-alert medication because it can cause client harm when administered incorrectly. Measures to improve the safe use of this medication include developing detailed policies, procedures, protocols, and standing orders as well as thorough client assessment and documentation. *Never* abbreviate magnesium sulfate as $MgSO_4$ anywhere in the medical record (Institute for Safe Medication Practices [ISMP], 2012).

Control of Blood Pressure. Antihypertensive medications are indicated when the systolic BP exceeds 160 mm Hg or the diastolic BP exceeds 110 mm Hg. Maternal risks associated with severe hypertension include left ventricular failure, cerebral hemorrhage, and placental abruption. To maintain uteroplacental perfusion, antihypertensive therapy must not decrease the arterial pressure too much or too rapidly. Hydralazine (Apresoline), labetalol (Trandate), and nifedipine (Procardia) are effective drugs for treating hypertension intrapartum. They may also be used during pregnancy or in the postpartum period for BP control (ACOG, 2013; Gilbert, 2011; Harvey & Sibai, 2013). Table 27-5 compares antihypertensive agents commonly used to treat hypertension in pregnancy.

Postpartum Care. Throughout the postpartum period the woman needs careful assessment of her vital signs, intake and output, DTRs, and level of consciousness. The magnesium sulfate infusion is continued after birth for seizure prophylaxis as ordered, usually for 12 to 24 hours. Assessments for effects and side effects continue until the medication is discontinued. Given that magnesium sulfate potentiates the action of narcotics, CNS depressants, and calcium channel blockers, these medications must be administered with caution. The signs and symptoms of preeclampsia usually resolve within 48 hours after birth. Clinical signs that demonstrate resolution of preeclampsia include diuresis and decreased edema (Gilbert, 2011).

TABLE 27-5 Pharmacologic Control of Hypertension in Pregnancy

ACTION	TARGET TISSUE	MATERNAL EFFECTS	FETAL EFFECTS	NURSING ACTIONS
Hydralazine (Apresoline, Neopresol)				
Arteriolar vasodilator	Peripheral arterioles: to decrease muscle tone, decrease peripheral resistance; hypothalamus and medullary vasomotor center for minor decrease in sympathetic tone	Headache, flushing, palpitations, tachycardia, some decrease in uteroplacental blood flow, increase in heart rate and cardiac output, increase in oxygen consumption, nausea and vomiting	Tachycardia; late decelerations and bradycardia if maternal diastolic pressure <90 mm Hg	Assess for effects of medication; alert woman (family) to expected effects of medication; assess blood pressure frequently because precipitous drop can lead to shock and perhaps placental abruption; if giving multiple doses, wait at least 20 minutes after the first dose is given to administer an additional dose to allow time to assess the effects of the initial dose; assess urinary output; maintain bed rest in lateral position with side rails up; use with caution in presence of maternal tachycardia
Labetalol Hydrochloride (Normodyne, Trandate)				
Combined alpha- and beta-blocking agent causing vasodilation without significant change in cardiac output	Peripheral arterioles (see <i>Hydralazine</i>)	Minimal: flushing, tremulousness, orthostatic hypotension; minimal change in pulse rate	Minimal, if any	See <i>Hydralazine</i> ; less likely to cause excessive hypotension and tachycardia; less rebound hypertension than hydralazine. Do not use in women with asthma or heart failure. Do not exceed 80 mg in a single dose.
Methyldopa (Aldomet)				
Maintenance therapy if needed: 250-500 mg orally every 8 hr (α_2 -receptor agonist)	Postganglionic nerve endings: interferes with chemical neurotransmission to reduce peripheral vascular resistance; causes CNS sedation	Sleepiness, postural hypotension, constipation; rare: drug-induced fever in 1% of women and positive Coombs' test result in 20% of women	After 4 months of maternal therapy, positive Coombs' test result in infant	See <i>Hydralazine</i>
Nifedipine (Adalat, Procardia)				
Calcium channel blocker	Arterioles; to reduce systemic vascular resistance by relaxation of arterial smooth muscle	Headache, flushing; may interfere with labor	Minimal	See <i>Hydralazine</i> . Avoid concurrent use with magnesium sulfate because skeletal muscle blockade can result. Do not administer sublingually.

CNS, Central nervous system.

The nurse should assess the postpartum woman regularly for any symptoms of preeclampsia such as headaches, visual disturbances, or epigastric pain. Some women develop signs and symptoms of preeclampsia for the first time after giving birth. Women who develop hypertension and severe features of preeclampsia such as headaches or blurred vision or severe hypertension should be placed on IV magnesium sulfate for seizure prophylaxis. Nonsteroidal antiinflammatory pain medications should be used with caution when hypertension persists for more than 1 day after birth because these agents can contribute to an increase in BP. Women should be taught to contact their health care provider or return to the hospital immediately if they develop headaches, visual disturbances, or epigastric pain after discharge (ACOG, 2013; Sibai, 2012).

Because preeclampsia is a major cause of intrauterine growth restriction and preterm birth, the baby may be cared for in a neonatal intensive care unit (NICU) (Backes et al., 2011; Uzan et al., 2011). Nursing care that facilitates bonding and attachment while the infant is in the NICU includes providing the family with photographs of the infant, keeping the family informed of the infant's status, encouraging the father to visit the NICU, and taking the woman to the NICU by wheelchair after her condition has stabilized (Poole, 2014).

Most women with gestational hypertension become normotensive during the first week after giving birth. On the other hand, hypertension may take longer to resolve in women with preeclampsia. For women with gestational hypertension, preeclampsia, or superimposed preeclampsia, it is recommended that BP be monitored in the hospital or that equivalent outpatient surveillance be performed for at least 72 hours after birth. The BP should then be rechecked at 7 to 10 days postpartum, or earlier in women who are symptomatic. Women with a BP of 150/100 mm Hg or higher (on two occasions that are 4 to 6 hours apart) should be placed on an antihypertensive medication, often labetalol or nifedipine (ACOG, 2013). If this is the case, the BP needs to be checked frequently either at home or at the health care provider's office. Within a few weeks after birth antihypertensive medications often can be discontinued.

Future Health Care

Women with preeclampsia with severe features have a significantly increased risk of developing preeclampsia in a future pregnancy, especially those who had early-onset (diagnosed during the second trimester) preeclampsia. Even if these women remain normotensive in a subsequent pregnancy, they may have a greater likelihood of an adverse pregnancy outcome such as preterm birth, small for gestational age infant, and perinatal death (Sibai, 2012).

Ideally, women who have had preeclampsia in a previous pregnancy should receive counseling during a preconception visit before the next planned pregnancy. At this visit the previous pregnancy history should be reviewed and the prognosis for the upcoming pregnancy discussed. Potential lifestyle modifications such as weight loss and increased physical activity should be encouraged. The current status of any chronic medical conditions, such as diabetes or chronic hypertension, should be assessed, so that they are brought into the best control possible before the upcoming pregnancy. Current medications should be reviewed and their administration modified if

necessary for the upcoming pregnancy. If the woman has given birth to a preterm infant during a preeclamptic pregnancy or has had preeclampsia in more than one prior pregnancy, the use of low-dose aspirin during the upcoming pregnancy should be suggested (ACOG, 2013).

Women with preeclampsia (especially early-onset and preeclampsia with severe features) also have an increased risk of developing chronic hypertension and cardiovascular disease later in life. It is believed that preeclampsia does not cause cardiovascular disease but rather that preeclampsia and cardiovascular disease share common risk factors. Further research is needed to determine how to take advantage of this information relating preeclampsia to cardiovascular disease later in life. For now, women should be educated about lifestyle changes (maintaining a healthy weight, increasing physical activity, and avoiding smoking) that may decrease the risk for developing future health problems (ACOG, 2013; Sibai, 2012).

Eclampsia

Eclampsia is usually preceded by premonitory signs and symptoms, including persistent headache, blurred vision, severe epigastric or right upper quadrant abdominal pain, and altered mental status. However, convulsions can appear suddenly and without warning in a seemingly stable woman with only minimal BP elevations (Sibai, 2012). The convulsions that occur in eclampsia are frightening to observe. Tonic contraction of all body muscles (seen as arms flexed, hands clenched, legs inverted) precedes the tonic-clonic convulsion. During this stage muscles alternately relax and contract. Respirations are halted and then begin again with long, deep, stertorous inhalations. Hypotension follows, and muscular twitching, disorientation, and amnesia persist for a while after the convulsion. The woman may also vomit or be incontinent of urine or stool.

Immediate Care. Nursing actions during a convulsion are directed toward ensuring a patent airway and client safety (see Emergency box).

It is important to note the time of onset and duration of the seizure. Call for help but do not leave the bedside. Make certain that the side rails on the bed are raised; pad them with a folded blanket or pillow if possible. Women with eclampsia have been known to sustain fractures from falling out of bed during the seizure. Immediately after the convulsion, lower the head of the bed and turn the woman onto her side. This helps prevent aspiration of vomitus (Gilbert, 2011).

Nursing actions after a convulsion are directed toward maternal stabilization. First assess the status of the woman's airway, breathing, and pulse. Suction secretions from her glottis to clear the airway, insert an oral airway, and administer oxygen at 10 L/min by face mask. If an IV infusion is not in place, start one with an 18-gauge needle. If an IV line was in place before the seizure, it may have infiltrated and will need to be restarted immediately. As soon as IV access is obtained, administer magnesium sulfate as ordered (Gilbert, 2011).

If eclampsia develops after initiating magnesium sulfate therapy, additional magnesium sulfate should be administered. Magnesium sulfate is the drug of choice for treating eclamptic seizures and preventing repeated seizures. One of its advantages over other antiseizure medications such as diazepam (Valium)

EMERGENCY**Eclampsia****Tonic-Clonic Convulsion Signs**

- Stage of invasion: 2-3 seconds, eyes fixed, twitching of facial muscles
- Stage of contraction: 15-20 seconds, eyes protrude and are bloodshot, all body muscles in tonic contraction
- Stage of convulsion: muscles relax and contract alternately (clonic), respirations halted; then begin again with long, deep, stertorous inhalation; coma ensues

Intervention

- Keep airway patent: turn head to one side, place pillow under one shoulder or back if possible.
- Call for assistance. Do not leave the bedside.
- Raise side rails and pad them with a folded blanket or pillow if possible.
- Observe and record convulsion activity.

After Convulsion

- Do not leave the woman unattended until fully alert.
- Observe for postconvulsion confusion, coma, and incontinence.
- Use suction as needed.
- Apply a pulse oximetry monitor.
- Administer oxygen via nonrebreather face mask at 10 L/min.
- Start intravenous fluids and monitor for potential fluid overload.
- Give magnesium sulfate or other anticonvulsant drug as ordered.
- Insert an indwelling urinary catheter.
- Monitor blood pressure, pulse, and respirations frequently until stabilized.
- Monitor fetal and uterine status.
- Expedite laboratory work as ordered to monitor kidney and liver function, coagulation system, and drug levels.
- Provide hygiene and a quiet environment.
- Support the woman and her family and keep them informed.
- Be prepared to assist with birth when the woman is in stable condition.

is that it reduces the risk of aspiration because it does not depress the gag reflex (Harvey & Sibai, 2013).

After the woman is stabilized, assess uterine activity, cervical status, and fetal status. During a convulsion the uterus becomes hypercontractile and hypertonic. As a result, the membranes may have ruptured or the cervix may have dilated rapidly, and birth may be imminent (Poole, 2014). The FHR tracing may demonstrate bradycardia, late decelerations, minimal baseline variability, or any combination. These findings usually resolve soon after the convulsion ends and the woman's hypoxia is corrected (Sibai, 2012).

SAFETY ALERT

Immediately after a seizure a woman may be very confused and combative. Restraints may be necessary temporarily. Several hours may be needed for the woman to regain her usual level of mental functioning.

After stabilizing the woman and fetus, a decision is made regarding the timing and method of birth. Eclampsia alone is not an indication for immediate cesarean birth. The route of birth (induction of labor versus cesarean birth) depends on

maternal and fetal condition, fetal gestational age, presence of labor, and the cervical Bishop score (ACOG, 2013; Sibai, 2012).

Regional anesthesia is not recommended for eclamptic women with coagulopathy or a platelet count less than 50,000/mm³ (Sibai, 2012).

Chronic Hypertension

An increasing number of women who give birth have chronic hypertension, which affects approximately 4% to 5% of all pregnancies (Gilbert, 2011). Non-Hispanic black women are much more likely to have a pregnancy complicated by chronic hypertension than are women of other races or ethnicities (Martin, Hamilton, Sutton, et al., 2012). In addition to race, other risk factors for chronic hypertension in pregnancy are older age and obesity. As more women delay childbearing and are obese, the number of pregnancies complicated by chronic hypertension can be expected to increase (Sibai, 2012).

More than 90% of women with chronic hypertension have primary or essential hypertension. In the remaining 10% the hypertension is secondary to a medical condition such as renal or collagen disease (Harvey & Sibai, 2013). Chronic hypertension in pregnancy is associated with maternal complications such as superimposed preeclampsia, stroke, acute kidney injury, heart failure, placental abruption, and death. Fetal risks include IUGR, death, and preterm birth (Cunningham et al., 2014; Sibai, 2012).

Ideally the management of chronic hypertension in pregnancy begins before conception. An evaluation of the cause and severity of the hypertension and the presence of any target organ damage (e.g., heart, eye, and kidney) is performed. Moreover, the woman should be encouraged to make lifestyle changes prior to conception such as smoking and alcohol cessation, participating in aerobic exercise, and losing weight if indicated. A diet that includes a maximum of 2.4 g sodium per day is recommended (Gilbert, 2011). These lifestyle modifications should continue throughout the pregnancy.

Based on the BP and presence of target organ damage, women with chronic hypertension are classified as either low or high risk for pregnancy complications. Antihypertensive medications are frequently discontinued before pregnancy in women with low risk chronic hypertension. This decreases the risk of fetal exposure to some medications (e.g., angiotensin-converting enzyme [ACE] inhibitors) that can be teratogenic (Harvey & Sibai, 2013). For women who persistently have BP readings of 160/105 mm Hg or higher, antihypertensive therapy is suggested. Labetalol (Trandate), nifedipine (Procardia), or methyldopa (Aldomet) are the medications most commonly recommended (see Table 27-5). If antihypertensive therapy is necessary, the BP should be maintained between 120 and 160 mm Hg systolic and 80 to 105 mm Hg diastolic (ACOG, 2013).

Women with chronic hypertension who are considered high risk are monitored closely, and the route and timing of birth depend on the maternal and fetal status. After giving birth the woman should be monitored closely for complications such as pulmonary edema, hypertensive encephalopathy, and renal failure. Women with chronic hypertension can breastfeed if they desire. All antihypertensive medications are present to some degree in breast milk. Levels of methyldopa in breast milk

appear to be low and are considered safe. Labetalol also has a low concentration in breast milk. Little is known about the transfer of calcium channel blockers such as nifedipine in breast milk, but no apparent side effects have been noted in infants (Sibai, 2012).

COMMUNITY ACTIVITY

- Visit the National Women's Health Resource Center website at www.healthywomen.org. Select health topics, and under Health Center click on Heart Health. Review any featured articles about hypertension. Go to the Related Conditions link and click on High Blood Pressure. Review client information about definition of high blood pressure, diagnosis, treatment, prevention, facts to know, questions to ask, key Q&A, organizations, and support. Read any related article about pregnancy and high blood pressure.
- Visit the Sister to Sister/The Women's Heart Health Foundation website at www.sistertosister.org. Select Heart Facts and click on Pregnancy Complications. Review client information about preeclampsia. Select Healthy Living, Health Tools, and My Heart Health links and review the information. Evaluate the information you located on these websites for use with various client populations.

KEY POINTS

- Hypertensive disorders during pregnancy are a leading cause of maternal and perinatal morbidity and mortality worldwide.
- The cause of preeclampsia is unknown, and there are no known reliable tests for predicting women at risk for developing preeclampsia.
- Preeclampsia is a multisystem disease, and the pathologic changes are present long before clinical manifestations such as hypertension become evident.
- HELLP syndrome, which is usually diagnosed during the third trimester, is a variant of preeclampsia, not a separate illness.
- Magnesium sulfate, the anticonvulsant of choice for preventing or controlling eclamptic seizures, requires careful monitoring of reflexes, respirations, and renal function.
- Women with preeclampsia (especially early-onset and preeclampsia with severe features) have an increased risk of developing chronic hypertension and cardiovascular disease later in life.
- The intent of emergency interventions for eclampsia is to prevent self-injury, enhance oxygenation, reduce aspiration risk, and establish control with magnesium sulfate.

Hemorrhagic Disorders

Kitty Cashion

<http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Differentiate among causes of early pregnancy bleeding, including miscarriage, ectopic pregnancy, cervical insufficiency, and hydatidiform mole.
- Discuss signs and symptoms, possible complications, and management of miscarriage, ectopic pregnancy, cervical insufficiency, and hydatidiform mole.
- Compare and contrast placenta previa and placental abruption in relation to signs and symptoms, complications, and management.
- Discuss the diagnosis and management of disseminated intravascular coagulation.

Bleeding in pregnancy may jeopardize maternal and fetal well-being. Maternal blood loss decreases oxygen-carrying capacity, which places the woman at increased risk for hypovolemia, anemia, infection, and preterm labor and adversely affects oxygen delivery to the fetus. Fetal risks from maternal hemorrhage include blood loss or anemia, hypoxemia, hypoxia, anoxia, and preterm birth. Hemorrhagic disorders in pregnancy are medical emergencies. The incidence and type of bleeding vary by trimester. Ruptured ectopic pregnancy and abruptio placentae (placental abruption) have the highest incidence of maternal mortality. Prompt assessment and intervention by the health care team are essential to save the lives of both the woman and her fetus.

EARLY PREGNANCY BLEEDING

Bleeding during early pregnancy is alarming to the woman and of concern to health care providers. The common bleeding disorders of early pregnancy include miscarriage (spontaneous abortion), cervical insufficiency, ectopic pregnancy, and hydatidiform mole (molar pregnancy).

Miscarriage (Spontaneous Abortion)

A pregnancy that ends as a result of natural causes before 20 weeks of gestation is defined as a **miscarriage (spontaneous abortion)**. This 20-week marker has traditionally been considered to be the point of viability, when a fetus may survive in an extrauterine environment. A fetal weight less than 500 g also may be used to define an abortion (Cunningham, Leveno, Bloom, et al., 2014). The term *miscarriage* rather than *abortion* is used throughout this discussion because it is more appropriate to use with clients. Abortion may be perceived as an insensitive term by families who are grieving a pregnancy loss. Therapeutic or elective induced abortion is discussed in Chapter 8.

Incidence and Etiology

Approximately 10% to 15% of all clinically recognized pregnancies end in miscarriage (Simpson & Jauniaux, 2012). The majority—greater than 80% of miscarriages—are early pregnancy losses, occurring before 12 weeks of gestation (Cunningham et al., 2014). Of all clinically recognized first-trimester losses, 25% result from chromosomal abnormalities (Cunningham et al.). Other possible causes of early miscarriage include endocrine imbalance (as in women who have luteal phase defects, hypothyroidism, or insulin-dependent diabetes mellitus with high blood glucose levels in the first trimester), immunologic factors (e.g., antiphospholipid antibodies), systemic disorders (e.g., lupus erythematosus), and genetic factors. Infections are not a common cause of early miscarriage (Cunningham et al.), but there is an increased risk for a spontaneous abortion with varicella infection in the first trimester (Gilbert, 2011).

A late miscarriage, sometimes called a second-trimester loss, occurs between 12 and 20 weeks of gestation. Risk factors for a second-trimester loss include race, ethnicity, poor outcomes in previous pregnancies, and extremes of maternal age. Other factors associated with an increased risk for miscarriage are severe dietary deficiencies, morbid obesity, regular or heavy alcohol use, and excessive (about 500 mg daily) caffeine intake. Bleeding during the first trimester is also a significant risk factor (Cunningham et al., 2014). Some of these risk factors cannot be modified, but correction of maternal disorders, a healthy lifestyle, adequate early prenatal care, and treatment of pregnancy complications can do much to prevent other causes of miscarriage.

Types

The types of miscarriages include threatened, inevitable, incomplete, complete, and missed. All types of miscarriage can recur

in subsequent pregnancies. All types except the threatened miscarriage can lead to infection (Fig. 28-1).

Clinical Manifestations

Signs and symptoms of miscarriage depend on the duration of pregnancy. The presence of uterine bleeding, uterine contractions, or abdominal pain is an ominous sign during early pregnancy and must be considered a threatened miscarriage until proven otherwise.

If miscarriage occurs before the sixth week of pregnancy, the woman may report what she believes is a heavy menstrual flow. Miscarriage that occurs between weeks 6 and 12 of pregnancy causes moderate discomfort and blood loss. After week 12, miscarriage is typified by severe pain, similar to that of labor, because the fetus must be expelled. Diagnosis of the type of miscarriage is based on the signs and symptoms present (Table 28-1).

Symptoms of a *threatened* miscarriage (see Fig. 28-1, A) include spotting of blood but with the cervical os closed. Mild uterine cramping may be present.

Inevitable (see Fig. 28-1, B) and *incomplete* (see Fig. 28-1, C) miscarriages involve a moderate to heavy amount of bleeding with an open cervical os. Tissue may be present with the bleeding. Mild to severe uterine cramping may be present. An inevitable miscarriage is often accompanied by rupture of membranes (ROM) and cervical dilation. Passage of the products

of conception occurs. An incomplete miscarriage involves the expulsion of the fetus with retention of the placenta.

In a *complete* miscarriage (see Fig. 28-1, D), the cervix has already closed after all fetal tissue was expelled. Slight bleeding may occur and mild uterine cramping may be present, as well.

The term *missed* miscarriage (see Fig. 28-1, E) refers to a pregnancy in which the fetus has died but the products of conception are retained in utero for up to several weeks. It may be diagnosed by ultrasonic examination after the uterus stops increasing in size or even decreases in size. There may be no bleeding or cramping, and the cervical os remains closed.

Recurrent (habitual) early miscarriage is three or more spontaneous pregnancy losses before 20 weeks of gestation. The most widely accepted causes of recurrent miscarriage are parental chromosomal abnormalities, antiphospholipid antibody syndrome, and certain uterine abnormalities (Cunningham et al., 2014).

The evaluation of couples experiencing recurrent pregnancy loss usually includes karyotyping of both partners and miscarriage specimens and assessment of the placenta; evaluating the woman's uterine cavity; and testing the woman for antiphospholipid antibody syndrome and thyroid disease. Evaluation should also address the psychological response to this diagnosis because women and their partners often report feelings of guilt, anxiety, and depression. Thus couples experiencing recurrent pregnancy loss should be screened for depression and post-traumatic stress disorder (Rink & Lockwood, 2014).

FIG 28-1 Miscarriage. A, Threatened. B, Inevitable. C, Incomplete. D, Complete. E, Missed.

Miscarriages can become septic, although this is uncommon. Symptoms of a septic miscarriage include fever and abdominal tenderness. Vaginal bleeding, which may be slight to heavy, is usually malodorous.

CARE MANAGEMENT

Assessment and Nursing Diagnoses

Whenever a woman has vaginal bleeding early in pregnancy, a thorough assessment should be performed. The data to be collected include pregnancy history, vital signs, type and location of pain, quantity and nature of bleeding, and emotional status. Laboratory tests may include evaluation of human chorionic gonadotropin (β -hCG) - (pregnancy), hemoglobin level (anemia), and white blood cell count (infection).

The following nursing diagnoses are appropriate for the woman experiencing a miscarriage:

- *Anxiety* related to
 - unknown outcome and unfamiliarity with medical procedures
- *Deficient Fluid Volume* related to
 - excessive bleeding secondary to miscarriage
- *Acute Pain* related to
 - uterine contractions
- *Situational Low Self-Esteem* related to
 - inability to carry a pregnancy successfully to term gestation
- *Risk for Infection* related to
 - surgical treatment
 - dilated cervix

Initial Care. Management depends on the classification of the miscarriage and on signs and symptoms (see Table 28-1). Traditionally, threatened miscarriages have been managed

TABLE 28-1 Assessing Miscarriage and the Usual Management

TYPE OF MISCARRIAGE	AMOUNT OF BLEEDING	UTERINE CRAMPING	PASSAGE OF TISSUE	CERVICAL DILATION	MANAGEMENT
Threatened	Slight, spotting	Mild	No	No	Bed rest is often ordered but has not proven to be effective in preventing progression to actual miscarriage. Repetitive transvaginal ultrasounds and assessment of human chorionic gonadotropin (hCG) and progesterone levels may be done to determine if the fetus is still alive and in the uterus. Further treatment depends on whether progression to actual miscarriage occurs.
Inevitable	Moderate	Mild to severe	No	Yes	Bed rest if no pain, bleeding, or infection. If rupture of membranes (ROM), pain, bleeding, or infection is present, then prompt termination of pregnancy is accomplished usually by dilation and curettage.
Incomplete	Heavy, profuse	Severe	Yes	Yes, with tissue in cervix	May or may not require additional cervical dilation before curettage. Suction curettage may be performed.
Complete	Slight	Mild	Yes	No (cervix has already closed after tissue passed)	No further intervention may be needed if uterine contractions are adequate to prevent hemorrhage and no infection is present. Suction curettage may be performed to ensure no retained fetal or maternal tissue.
Missed	None, spotting	None	No	No	If spontaneous evacuation of the uterus does not occur within 1 month, pregnancy is terminated by method appropriate to duration of pregnancy. Blood clotting factors are monitored until uterus is empty. Disseminated intravascular coagulation (DIC) and incoagulability of blood with uncontrolled hemorrhage may develop in cases of fetal death after the twelfth week, if products of conception are retained for longer than 5 weeks. May be treated with dilation and curettage or misoprostol (Cytotec) given orally or vaginally.
Septic	Varies, usually malodorous	Varies	Varies	Yes, usually	Immediate termination of pregnancy by method appropriate to duration of pregnancy. Cervical culture and sensitivity studies are performed, and broad-spectrum antibiotic therapy (e.g., ampicillin) is started. Treatment for septic shock is initiated if necessary.
Recurrent (generally defined as three or more consecutive miscarriages)	Varies	Varies	Yes	Yes, usually	Varies; depends on type. Prophylactic cerclage may be performed if cervical insufficiency is the cause. Tests of value include karyotyping of both partners and miscarriage specimens and assessment of the placenta; evaluating the woman's uterine cavity; and testing the woman for antiphospholipid antibody syndrome and thyroid disease.

Data from Cunningham, F., Leveno, K., Bloom, S., et al. (2014). *William's obstetrics* (24th ed.). New York: McGraw-Hill Medical; Gilbert, E. (2011). *Manual of high risk pregnancy & delivery* (5th ed.). St. Louis: Mosby; Rink, B.D., & Lockwood, C.J. (2014). Recurrent pregnancy loss. In R.K. Creasy, R. Resnik, J.D. Iams, et al. (Eds.), *Creasy and Resnik's maternal-fetal medicine: Principles and practice* (7th ed.). Philadelphia: Saunders.

expectantly with supportive care. However, there are no proven effective therapies for this condition. Bed rest, although often prescribed, does not prevent progression to actual miscarriage. Repetitive transvaginal ultrasounds and measurement of human chorionic gonadotropin (hCG) and progesterone levels may be performed to determine if the fetus is alive and within the uterus (Cunningham et al., 2014).

Follow-up treatment depends on whether the threatened miscarriage progresses to actual miscarriage or symptoms subside and the pregnancy remains intact. If bleeding and infection do not occur, expectant management is a reasonable option. In approximately half of all threatened miscarriages managed in this way, the pregnancy continues (Cunningham et al., 2014).

Once the cervix begins to dilate, the pregnancy cannot continue and miscarriage becomes inevitable. If all the products of conception are passed, no surgical intervention is necessary. If heavy bleeding, excessive cramping, or infection is present, however, the remaining embryonic, fetal, or placental tissue must be removed from the uterus, usually by suction curettage. In women who are clinically stable, expectant management to allow spontaneous resolution of an incomplete miscarriage is another treatment option (Cunningham et al., 2014; Gilbert, 2011).

Most missed miscarriages eventually end spontaneously. Women may be offered expectant management at the time the pregnancy loss is diagnosed. Expectant management results in eventual spontaneous miscarriage in 16% to 76% of cases (Gilbert, 2011).

Medical management is another treatment option if bleeding and infection are not present. Prostaglandin medications (e.g., misoprostol [Cytotec]) may be given and are usually effective in completing the miscarriage within 7 days (Cunningham et al., 2014). If medical management is chosen, nursing care is similar to the care for any woman whose labor is induced (see Chapter 32). Special care may be needed for management of side effects of prostaglandin, such as nausea, vomiting, and diarrhea. If the products of conception are not passed completely, the woman may be prepared for manual or surgical evacuation of the uterus.

A third management option, and one that is often chosen, is **dilation and curettage (D&C)**, a surgical procedure in which the cervix is dilated if necessary and a curette is inserted to scrape the uterine walls and remove uterine contents. Uterine contents may also be removed by suction curettage, using a catheter attached to an electric-powered vacuum source (Cunningham et al., 2014). Pain relief during a D&C is usually achieved by administering analgesics or sedatives intravenously or orally (conscious sedation). A paracervical block using a local anesthetic may also be administered (Cunningham et al.). Before a surgical procedure is performed, a full history should be obtained and general and pelvic examinations conducted. General preoperative and postoperative care is appropriate for the woman requiring surgical intervention for miscarriage. The nurse reinforces explanations, answers any questions or concerns, and prepares the woman for surgery.

After evacuation of the uterus, oxytocin is often given to prevent hemorrhage. For excessive bleeding after the miscarriage, ergot products such as ergonovine (Methergine) or a prostaglandin derivative such as methylcarboprost tromethamine (Hemabate) may be given to contract the uterus. (See the Medication

Guide: Drugs Used to Manage Postpartum Hemorrhage in Chapter 33). Antibiotics are given as necessary. Analgesics, such as antiprostaglandin agents (e.g., nonsteroidal antiinflammatory drugs [NSAIDs]), may decrease discomfort from cramping. Transfusion therapy may be required for shock or anemia. The woman who is Rh negative and is not isoimmunized is given Rh₀(D) immune globulin (Cunningham et al., 2014).

Psychosocial aspects of care focus on what the pregnancy loss means to the woman and her family. Grief from perinatal loss is complex and unique to each individual. Explanations are provided regarding the nature of the miscarriage, expected procedures, and possible future implications for childbearing.

As with other fetal or neonatal losses, the woman should be offered the option of seeing the products of conception. She may also want to know what the hospital does with the products of conception or whether she needs to make a decision about final disposition of fetal remains.

Follow-up Care. The woman will likely be discharged home within a few hours after a D&C or as soon as her vital signs are stable, vaginal bleeding remains minimal, and she has recovered from anesthesia. Discharge teaching emphasizes the need for rest. If significant blood loss has occurred, iron supplementation may be ordered. Teaching includes information about normal physical findings, such as cramping, type and amount of bleeding, resumption of sexual activity, and family planning (see Teaching for Self-Management: Discharge Teaching for the Woman After Early Miscarriage).

TEACHING FOR SELF-MANAGEMENT

Discharge Teaching for the Woman After Early Miscarriage

- Clean the perineum after each voiding or bowel movement and change perineal pads often.
- Shower (avoid tub baths) for 2 weeks.
- Avoid tampon use, douching, and vaginal intercourse for 2 weeks.
- Notify your physician if an elevated temperature or a foul-smelling vaginal discharge develops.
- Eat foods high in iron and protein to promote tissue repair and red blood cell replacement.
- Seek assistance from support groups, clergy, or professional counseling as needed.
- Allow yourself (and your partner) to grieve the loss before becoming pregnant again.

Frequently the woman and her partner want to know when she should attempt to become pregnant again. Discuss with them the importance of completely resolving the loss before attempting another pregnancy (Gilbert, 2011). Follow-up care should assess the woman's emotional as well as physical recovery. Referrals to local support groups are provided as needed. Share Pregnancy and Infant Loss Support, Inc. (www.nationalshare.org) is an excellent online resource for families who have experienced an early pregnancy loss.

Follow-up telephone calls after a loss are important. The woman may appreciate a telephone call on what would have been her due date. These calls provide opportunities for the woman to ask questions, seek advice, and receive information to help process her grief.

Cervical Insufficiency

One cause of late miscarriage is **cervical insufficiency**, which has traditionally been defined as passive and painless dilation of the cervix leading to recurrent preterm births during the second trimester in the absence of other causes. It was believed that these criteria defined women whose early births were caused solely by structural weakness of cervical tissue that could be corrected surgically by cerclage placement. Measurement of cervical length has been used as a way to diagnose cervical insufficiency.

However, it is now known that an abnormally short cervix identified during the second trimester can also represent an early step in the process of preterm labor (see Evidence-Based Practice). Therefore, the challenge is to identify women who have cervical changes because of impaired cervical strength before conception or in early pregnancy rather than when they are beginning the process of preterm labor. However, **assessment of cervical function to diagnose or rule out cervical insufficiency can be done only during pregnancy** (Berghella & Iams, 2014).

EVIDENCE-BASED PRACTICE

Interventions for Short Cervix

Ask the Question

For pregnant women in the second trimester with short cervix and previous preterm birth, what interventions can protect against preterm birth?

Search for the Evidence

Search Strategies English language research-based publications since 2011 on antenatal, short cervix, preterm, cerclage, pessary, and progesterone were included.

Databases Used Cochrane Collaborative Database, National Guideline Clearinghouse (AHRQ), CINAHL, PubMed, UpToDate, and the professional websites for ACOG and AWHONN

Critical Appraisal of the Evidence

Normally the cervix remains thick until the end of pregnancy. If the cervix is short (less than 25 mm), there is a risk for premature cervical opening. Sometimes called "cervical insufficiency," often the first symptom is pregnancy loss in the second trimester. Women with a history of second-trimester loss and preterm birth should have their cervix measured via ultrasound. To prevent preterm birth, three options provide additional mechanical support.

- **Cerclage:** First used in 1902, a cervical suture is placed surgically to tie the cervix closed and clipped at term. Metaanalysis of 12 trials found that compared with no treatment, cerclage decreased preterm births. However, there were no differences in perinatal morbidity or mortality. Cesarean births were more likely in the cerclage group (Alfirevic, Stampalija, Roberts, & Jorgensen, 2012).
- **Pessaries:** Used for centuries to support a prolapsed uterus, pessaries are rings inserted into the vagina that distribute the weight of the uterus away from the cervix and obstruct the internal cervical os. When women with short cervixes began using pessaries midpregnancy, they experienced significantly less preterm birth, less use of tocolytic medications, and fewer neonatal intensive care admissions (Abdel-Aleem, Shaaban, & Abdel-Aleem, 2013).
- **Progesterone:** This essential hormone of pregnancy maintenance can be given by oral, vaginal, or intramuscular route. Metaanalysis of trials for women with a short cervix showed that those who received progesterone vaginally had significantly less incidence of preterm birth. Their babies had less morbidity and mortality, respiratory distress syndrome, neonatal intensive care admissions, and need for mechanical ventilation compared with women who were treated with a placebo (Romero, Nicolaides, Conde-Aquedo, et al., 2012).
- **Comparisons:** A systematic analysis found no difference between cerclage and progesterone in preventing preterm birth in women with short cervix, previous preterm birth, and singleton pregnancy (Conde-Aquedo et al., 2013). A comparison of 142 women with short cervix, history of previous preterm birth

and single pregnancy who were treated with either cerclage (U.S.), vaginal progesterone (UK), and cervical pessary (Spain) found no differences in preterm births, perinatal losses, or neonatal morbidity (Alfirevic, Owen, Carreras Moratonas, et al., 2013). Client preferences may guide available method selection.

Apply the Evidence: Nursing Implications

Cerclage is a surgical procedure, requiring skill, sterile technique, and fetal monitoring. Anesthesia is usually spinal, epidural, or general. For this reason it is usually day surgery, done in proximity to a hospital setting. Clients may be NPO prior to surgery and need rest afterward. Surgery can be stressful, invasive, and expensive.

Vaginal progesterone may cause minor irritation and must be administered every day. Oral progesterone may have side effects of sleepiness, headache, and fatigue. Intramuscular progesterone is given weekly.

Pessaries can increase vaginal discharge and may need to be repositioned for comfort. Despite these side effects, most women were satisfied with this method (Abdel-Aleem et al., 2013).

The risk of very preterm birth and perinatal loss is frightening, and much clinical decision making is based on client history of prior pregnancy loss. Clients frequently carry guilt or anxiety about something they did or didn't do into the current pregnancy. The nurse can explore their understanding and feelings about prior losses and their current pregnancy.

Because the cervix provides protection against pathogens, couples may be instructed to avoid intercourse until 1 week after a cerclage placement and to use condoms thereafter. Clients and partners need pictures, literature, websites, and warm lines to call with questions.

Quality and Safety Competencies: Evidence-Based Practice* Knowledge

Describe how the strength and relevance of available evidence influences the choice of interventions in provision of client-centered care.

The nurse should be able to explain the pathophysiology of short cervix and treatments for prevention of preterm birth to the client and partner.

Skills

Participate in structuring the work environment to facilitate integration of new evidence into standards of practice.

Client-centered care includes providing a team approach to treatment of short cervix, including psychosocial counseling for anxiety and previous perinatal loss.

Attitudes

Value the need for continual improvement in clinical practice based on new knowledge.

EVIDENCE-BASED PRACTICE—cont'd

Interventions for Short Cervix

Creating an accepting and caring environment enables honest communication between the client and the health care team about intensely personal reproductive and sexual issues.

Etiology

Cervical insufficiency may be either acquired or congenital. Congenital risk factors for cervical insufficiency include collagen disorders, uterine anomalies, and ingestion of diethylstilbestrol (DES) by the woman's mother while pregnant with the woman. Because DES has not been used since the early 1970s, however, it is now rare to encounter women who have this risk factor (Berghella & Iams, 2014). A risk factor for acquired cervical insufficiency is a history of previous cervical trauma resulting from lacerations during childbirth or mechanical dilation of the cervix during gynecologic procedures. Women who have had prior cervical surgery such as a biopsy in which a large cone specimen was removed or destroyed are also at risk for cervical insufficiency (Berghella & Iams; Ludmir & Owen, 2012).

Diagnosis

Cervical insufficiency is a clinical diagnosis, made by a thorough obstetric history along with speculum and digital pelvic examinations and a transvaginal ultrasound examination. Speculum and digital examinations allow identification of an opening at the internal cervical os, prolapsed fetal membranes, or both. A vaginal ultrasound examination will reveal an abnormally short (<25 mm) cervix. Often the short cervix is accompanied by *cervical funneling* (beaking), effacement of the internal cervical os, although the external cervical os remains closed (Berghella & Iams, 2014; Cunningham et al., 2014; Ludmir & Owen, 2012).

CARE MANAGEMENT

Cervical **cerclage** placement has been the treatment of choice for women with cervical insufficiency due to cervical weakness. Indications for cerclage placement are a poor obstetric history (three or more previous early preterm births or second-trimester losses), a short (<25 mm) cervical length identified on transvaginal ultrasound, and an open cervix found on digital or speculum examination (Berghella & Iams, 2014). The McDonald technique is often the procedure of choice because of its proven effectiveness and ease of placement and removal. In this procedure a suture is placed around the

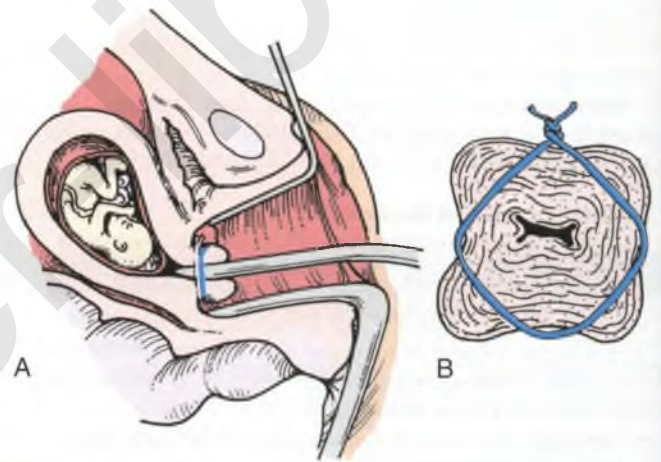

FIG 28-2 A, Cerclage correction of premature dilation of the cervical os. B, Cross-sectional view of closed internal os.

cervix beneath the mucosa to constrict the internal os of the cervix (Fig. 28-2) (Cunningham et al., 2014).

A cerclage may be placed either prophylactically or as a therapeutic or rescue procedure after cervical change has been identified (Berghella & Iams, 2014; Cunningham et al., 2014). A prophylactic, or history-indicated, cerclage is usually placed at 12 to 14 weeks of gestation. An ultrasound-indicated cerclage may be placed therapeutically at 14 to 23 weeks of gestation in women with a singleton pregnancy and a history of a prior preterm birth if a short (<25 mm) cervix is identified on vaginal ultrasound. Finally, a rescue cerclage may be placed between 16 and 23 weeks of gestation in women who are found to have cervical change (>1 cm dilated or prolapsed membranes) on physical examination. The cerclage is removed if preterm premature rupture of membranes or advanced preterm labor that puts pressure on the stitch occurs. If the pregnancy progresses without further complications, the cerclage is removed when the woman reaches 36 weeks of gestation (Berghella & Iams).

In women with an extremely short cervix such as those who were exposed prenatally to DES, who have a history of a large cone biopsy, or who have had a failed vaginal cerclage, an

FIG 28-3 Abdominal cerclage. Surgical placement of circumferential Mersilene tape around uterine isthmus and median to uterine vessel. Knot is tied anteriorly. (From: S. Gabbe, J. Niebyl, & J. Simpson [Eds.]. (2012). *Obstetrics: Normal and problem pregnancies* [6th ed.]. Philadelphia: Saunders.)

abdominal cerclage may be performed instead. This procedure is usually done at 11 to 13 weeks of gestation by means of a laparotomy. Suture (Mersilene tape) is placed at the junction of the lower uterine segment and the cervix (Fig. 28-3). Cesarean birth is necessary following an abdominal cerclage, and the suture is left in place if future pregnancies are desired. Although the procedure is usually done during pregnancy, it has been performed between pregnancies with subsequent positive pregnancy outcomes (Ludmir & Owen, 2012).

The nurse assesses the woman's feelings about her pregnancy and her understanding of cervical insufficiency. Evaluating the woman's support systems is also important. Because the diagnosis of cervical insufficiency is usually not made until the woman has lost one or more pregnancies, she may feel guilty or to blame for this impending loss. Assessing for previous reactions to stresses and appropriateness of coping responses is therefore important. The woman needs the support of both her health care providers and her family.

Follow-up Care

The woman will likely be on bed rest for at least a few days immediately following cerclage placement. She will also probably be advised to avoid sexual intercourse, at least until after a postoperative check. Thereafter, decisions about physical activity and lifestyle changes are individualized, based on the status of the woman's cervix, as determined by digital and ultrasound examination (Ludmir & Owen, 2012). The woman must understand the need for close observation and supervision for the remainder of the pregnancy. Additional instruction includes the need to watch for and report signs of preterm labor, rupture of membranes, and infection. Finally, the woman should know the signs that would warrant an immediate return to the hospital, including strong contractions less than 5 minutes apart,

FIG 28-4 Sites of implantation of ectopic pregnancies. Order of frequency of occurrence is ampulla, isthmus, interstitium, fimbria, tuboovarian ligament, ovary, abdominal cavity, and cervix (external os).

preterm premature rupture of membranes, severe perineal pressure, and an urge to push. If management is unsuccessful and the fetus is born before viability, appropriate grief support should be provided. If the fetus is born prematurely, appropriate anticipatory guidance and support will be necessary. (See Chapter 34 for information on high risk newborns and Chapter 37 for information on perinatal loss and grief.)

Ectopic Pregnancy

Incidence and Etiology

An **ectopic pregnancy** is one in which the fertilized ovum is implanted outside the uterine cavity (Fig. 28-4). One to two percent of all first-trimester pregnancies in the United States are ectopic, and these account for 6% of all pregnancy-related maternal deaths. Women are less likely to have a successful subsequent pregnancy after an ectopic pregnancy (Cunningham et al., 2014). Ectopic pregnancy is also a leading cause of infertility.

FIG 28-5 Ectopic pregnancy, abdominal, diagnosed on a routine ultrasound at 25 weeks of gestation. Note that the gestational sac is clearly outside the uterus. The placenta was attached to the right uterine tube and right ovary. (Courtesy Danielle L. Tate, MD, Memphis, TN.)

Ectopic pregnancies are often called *tubal pregnancies* because at least 90% are located in the uterine tube (American Society for Reproductive Medicine [ASRM], 2013). Although they are much less common, ectopic pregnancies can also occur in the abdominal cavity, on an ovary, or on the cervix. Of all tubal ectopic pregnancies, approximately 80% are located in the ampulla, or largest portion of the tube (ASRM).

More than 100,000 ectopic pregnancies are reported each year in the United States. The actual number is certainly much larger, however, because only surgically managed cases are reported (ASRM, 2013). Some of the increased incidence is likely because of improved diagnostic techniques, such as more sensitive β -hCG measurement and transvaginal ultrasound, resulting in the identification of more cases. Other causes for the rise include an increased incidence of sexually transmitted infections, tubal infection and damage, popularity of contraceptive methods that predispose failures to be ectopic (e.g., the intrauterine device [IUD]), use of tubal sterilization methods that increase the chance of ectopic pregnancy, increased use of assisted reproductive techniques, and increased use of tubal surgery (Cunningham et al., 2014; Gilbert, 2011).

Ectopic pregnancy is classified according to site of implantation (e.g., tubal, ovarian, or abdominal). The uterus is the only organ capable of containing and sustaining a term pregnancy. Only approximately 5% of abdominal pregnancies reach viability. Surgery to remove the embryo or fetus is usually performed as soon as an abdominal pregnancy is identified, however, because of the high risk for hemorrhage at any time during the pregnancy (Fig. 28-5) (Cunningham et al., 2014; Gilbert, 2011). The chance of fetal survival in an abdominal pregnancy depends on gestational age at birth. The risk for fetal deformity in an abdominal pregnancy is high as a result of pressure deformities caused by oligohydramnios. The most common problems include facial or cranial asymmetry, various joint deformities, limb deficiency, and central nervous system anomalies (Cunningham et al.; Gilbert).

Clinical Manifestations

Most cases of ectopic (tubal) pregnancy are diagnosed before rupture based on the three most classic symptoms: (1) abdominal pain, (2) delayed menses, and (3) abnormal vaginal bleeding (spotting) that occurs approximately 6 to 8 weeks after the last normal menstrual period (Gilbert, 2011). Abdominal pain occurs in almost every case. It usually begins as a dull, lower quadrant pain on one side. The discomfort can progress from a dull pain to a colicky pain when the tube stretches, to sharp, stabbing pain (Cunningham et al., 2014; Gilbert). It progresses to a diffuse, constant, severe pain that is generalized throughout the lower abdomen (Gilbert). Up to 90% of women with an ectopic pregnancy report a period that is delayed 1 to 2 weeks or is lighter than usual, or an irregular period. Mild to moderate dark red or brown intermittent vaginal bleeding occurs in up to 80% of women (Gilbert).

If the ectopic pregnancy is not diagnosed until after rupture has occurred, referred shoulder pain may be present in addition to generalized, one-sided, or deep lower quadrant acute abdominal pain. Referred shoulder pain results from diaphragmatic irritation caused by blood in the peritoneal cavity. The woman may exhibit signs of shock, such as faintness and dizziness, related to the amount of bleeding in the abdominal cavity and not necessarily related to obvious vaginal bleeding. An ecchymotic blueness around the umbilicus (Cullen sign), indicating hemoperitoneum, may also develop in an undiagnosed, ruptured intraabdominal ectopic pregnancy.

Diagnosis

The differential diagnosis of ectopic pregnancy involves consideration of numerous disorders that share many signs and symptoms. Many of these women go to the emergency department experiencing first-trimester bleeding or pain. Miscarriage, ruptured corpus luteum cyst, appendicitis, salpingitis, ovarian cysts, torsion of the ovary, and urinary tract infection are possible diagnoses. The key to early detection of ectopic pregnancy is having a high index of suspicion for this condition. *Every woman*

with abdominal pain, vaginal spotting or bleeding, and a positive pregnancy test should undergo screening for ectopic pregnancy.

The most important screening tools for ectopic pregnancy are quantitative β -hCG levels and transvaginal ultrasound examination. When β -hCG levels are greater than 1500 to 2000 milli-International Units/ml, a normal intrauterine pregnancy should be visible on transvaginal ultrasound. Therefore, if β -hCG levels are greater than 1500 milli-International Units/ml but no intrauterine pregnancy is seen on transvaginal ultrasound, an ectopic pregnancy is very likely. β -hCG levels will probably be redrawn every 48 hours to determine if the pregnancy is viable. A transvaginal ultrasound may also be repeated to determine if the pregnancy is inside the uterus. Sometimes the location of an ectopic pregnancy will be visible on transvaginal ultrasound (Cunningham et al., 2014; Gilbert, 2011).

Another laboratory test that can be ordered to determine if the pregnancy is developing normally is a progesterone level. A progesterone level greater than 25 ng/ml almost always rules out the presence of an ectopic pregnancy. However, a progesterone level less than 5 ng/ml suggests either an ectopic pregnancy or an abnormal intrauterine pregnancy (Cunningham et al., 2014).

The woman should also be assessed for the presence of active bleeding, which is associated with tubal rupture. If internal bleeding is present, assessment may reveal vertigo, shoulder pain, hypotension, and tachycardia. A vaginal examination should be performed only once, and then with great caution. Approximately 20% of women with a tubal pregnancy have a palpable mass on examination. Rupturing the mass is possible during a bimanual examination; thus a gentle touch is critical.

CARE MANAGEMENT

Medical Management

Approximately 40% of women diagnosed with ectopic pregnancy are appropriate candidates for medical management, which involves giving methotrexate to dissolve the tubal pregnancy (ASRM, 2013). Methotrexate is an antimetabolite and folic acid antagonist that destroys rapidly dividing cells. It is classified as a hazardous drug and can cause serious toxic side effects even when given in low doses. These side effects can cause safety risks for health care providers if the drug is not handled appropriately. Additionally, the Institute for Safe Medication Practices considers methotrexate to be a high-alert drug (Box 28-1) (National Institute for Occupational Safety and Health, 2012; Shastay & Paparella, 2010).

Methotrexate therapy avoids surgery and is a safe, effective, and cost-effective way of managing many cases of tubal pregnancy. The woman must be hemodynamically stable and have normal liver and kidney function to be eligible for methotrexate therapy. The best results following methotrexate therapy are usually obtained if the mass is unruptured and measures less than 3.5 cm in diameter by ultrasound, if no fetal cardiac activity is noted on ultrasound, and if the initial serum β -hCG level is less than 1000 milli-International Units/L (Cunningham et al., 2014). The woman must also be willing to comply with posttreatment lifestyle restrictions and monitoring. She is informed of how the medication works, possible side effects, general self-care guidelines, and the importance of follow-up care (see Teaching for Self-Management: Teaching for Women Receiving Methotrexate Therapy).

BOX 28-1 Methotrexate Administration

- Obtain the woman's height and weight. These measurements are used to calculate her body surface area in order to determine the correct dose of methotrexate, so they must be accurate.
- The standard dose of methotrexate used to treat ectopic pregnancy is 50 mg/m² given intramuscularly, although it may also be ordered as 1 mg/kg.
- The dose of methotrexate should be prepared in the hospital pharmacy under a biologic safety cabinet. Syringe(s) containing the methotrexate should be dispensed from the pharmacy no more than three quarters full without a needle attached in a sealed plastic bag.
- Don two pairs of gloves before removing the syringe(s) from the sealed plastic bag.
- Remove the syringe cap and replace with an appropriate needle for intramuscular injection.
- Do not expel air from the syringe or prime the needle because these actions could aerosolize the methotrexate.
- Check the client's identity and the medication and dosage before injecting the methotrexate. Another nurse should also perform an independent check before the injection is given.
- Dispose of any items worn or used to prepare, dispense, or administer the methotrexate injection in a waste container designated specifically for hazardous drugs.
- Wash your hands thoroughly after removing gloves.

Data from Shastay, A., & Paparella, S. (2010). Ectopic pregnancies and methotrexate: Are you prepared to manage this hazardous drug? *Journal of Emergency Nursing*, 36(1), 57-59.

TEACHING FOR SELF-MANAGEMENT

Teaching for Women Receiving Methotrexate Therapy

- Explain that methotrexate dissolves ectopic (tubal) pregnancies by destroying rapidly dividing cells.
- Explain that urine contains levels of drug metabolite that could be considered toxic for approximately 72 hours after receiving methotrexate. The levels are highest during the first 8 hours after treatment. Teach the woman to avoid getting urine on the toilet seat and to double flush the toilet (with the lid down) after urinating. Also explain that her stools may contain residual drug for up to 7 days.
- Inform the woman of possible side effects. Gastric distress, nausea and vomiting, stomatitis, and dizziness are common. Rare side effects include severe neutropenia, reversible hair loss, and pneumonitis.
- Advise the woman to:
 - Avoid foods and vitamins containing folic acid.
 - Avoid "gas-forming" foods.
 - Avoid sun exposure.
 - Avoid sexual intercourse until the beta-human chorionic gonadotropin (β -hCG) level is undetectable.
 - Keep all scheduled follow-up appointments.
 - Contact her health care provider immediately if she has severe abdominal pain, which may be a sign of impending or actual tubal rupture.

Data from American Society for Reproductive Medicine (ASRM). (2013). Medical treatment of ectopic pregnancy: A committee opinion. *Fertility and Sterility*, 100(3), 638-644; Shastay, A., & Paparella, S. (2010). Ectopic pregnancies and methotrexate: Are you prepared to manage this hazardous drug? *Journal of Emergency Nursing*, 36(1), 57-59.

⚡ SAFETY ALERT

Women receiving methotrexate to treat an ectopic pregnancy should not take any analgesic stronger than acetaminophen. Stronger analgesics can mask symptoms of tubal rupture.

Surgical Management

Surgical management depends on the location and cause of the ectopic pregnancy, the extent of tissue involvement, and the woman's desires regarding future fertility. One option is removal of the entire tube (salpingectomy). If the tube has not ruptured and the woman desires future fertility, salpingostomy may be performed instead. In this procedure an incision is made over the pregnancy site in the tube and the products of conception are gently and very carefully removed. The incision is not sutured but left to close by secondary intention instead, given that this method results in less scarring.

If surgery is planned, general preoperative and postoperative care is appropriate for the woman with an ectopic pregnancy. Before surgery, vital signs (pulse, respirations, and blood pressure [BP]) are assessed every 15 minutes or as needed, according to the severity of the bleeding and the woman's condition. Preoperative laboratory tests include determination of blood type and Rh factor, complete blood cell count, and serum quantitative β -hCG level. Ultrasonography is used to confirm an extrauterine pregnancy. Blood replacement may be necessary. The nurse verifies the woman's Rh and antibody status and administers Rh₀(D) immune globulin postoperatively if appropriate.

Follow-Up Care

Women who have received methotrexate therapy have their β -hCG level measured weekly to make certain that it continues to drop steadily until it becomes undetectable. Complete resolution of an ectopic pregnancy usually occurs in 2 to 3 weeks but can require as long as 6 to 8 weeks (ASRM, 2013).

Whether treated medically or surgically, the woman and her family should be encouraged to share their feelings and concerns related to the loss. Future fertility should be discussed. A contraceptive method should be used for at least three menstrual cycles to allow time for the woman's body to heal (Gilbert, 2011). Every woman who has been diagnosed with an ectopic pregnancy should be instructed to contact her health care provider as soon as she suspects that she might be pregnant because of the increased risk for recurrent ectopic pregnancy. These women may need referral to grief or infertility support groups. In addition to the loss of the current pregnancy, they are faced with the possibility of future pregnancy losses or infertility. (See Chapter 37 for information on perinatal loss and grief.)

Hydatidiform Mole (Molar Pregnancy)

Hydatidiform mole (molar pregnancy) is a benign proliferative growth of the placental trophoblast in which the chorionic villi develop into edematous, cystic, avascular transparent vesicles that hang in a grapelike cluster. Hydatidiform mole is a gestational trophoblastic disease (GTD). GTD is a group of pregnancy-related trophoblastic proliferative disorders without a viable fetus that are caused by abnormal fertilization. In addition to hydatidiform mole, GTD includes invasive mole and choriocarcinoma (DiGiulio, Wiedaseck, & Monchek, 2012).

FIG 28-6 Gross specimen in a woman treated for complete hydatidiform mole with primary hysterectomy. (Courtesy John Soper, MD.) (From DiSaia, P., & Creasman, W. [2007]: *Clinical gynecologic oncology* [7th ed.]. Philadelphia: Mosby.)

Incidence and Etiology

Hydatidiform mole occurs in 1 in 1000 pregnancies in the United States (Cohn, Ramaswamy, & Blum, 2014). The cause is unknown, although it may be related to an ovular defect or a nutritional deficiency. Women at increased risk for hydatidiform mole formation are those who have had a prior molar pregnancy and those who are in their early teens or older than 40 years of age (DiGiulio et al., 2012).

Types

A hydatidiform mole may be further categorized as a complete or partial mole. The complete mole results from fertilization of an egg in which the nucleus has been lost or inactivated. The nucleus of a sperm (23,X or 23,Y) duplicates itself (resulting in the diploid number 46,XX or 46,XY) because the ovum has no genetic material or the material is inactive. It is also possible for an "empty" egg to be fertilized by two normal sperm, thereby producing either a 46,XX or 46,XY genotype (Moore, 2014). The mole resembles a bunch of white grapes. The hydropic (fluid-filled) vesicles grow rapidly, causing the uterus to be larger than expected for the duration of the pregnancy. The complete mole contains no fetus, placenta, amniotic membranes, or fluid (Fig. 28-6). Maternal blood has no placenta to receive it; therefore, hemorrhage into the uterine cavity and

FIG 28-7 Partial hydatidiform mole. (Courtesy Norman L. Meyer, MD, PhD, Memphis, TN.)

vaginal bleeding occur. Approximately 15% to 20% of women with a complete mole have evidence of persistent GTD (Cunningham et al., 2014).

In a partial mole one apparently normal ovum is fertilized by two or more sperm. Triploidy (69XXY) or quadraploidy (92XXXYY) genotypes then result (Moore, 2014). Partial moles often have embryonic or fetal parts and an amniotic sac (Fig. 28-7). Congenital anomalies are usually present. The risk of persistent GTD is much less than with a complete mole. If persistent GTD does occur, it is usually not a choriocarcinoma (Cunningham et al., 2014).

Clinical Manifestations

In the early stages the clinical manifestations of a complete hydatidiform mole cannot be distinguished from those of normal pregnancy. Later, vaginal bleeding occurs in almost 95% of cases. The vaginal discharge may be dark brown (resembling prune juice) or bright red and either scant or profuse. It may continue for only a few days or intermittently for weeks. Early in pregnancy the uterus in approximately one half of affected women is significantly larger than expected from menstrual dates. The percentage of women with an excessively enlarged uterus increases as length of time since the last menstrual period increases. Approximately 25% of affected women have a uterus smaller than would be expected from menstrual dates.

Anemia from blood loss, excessive nausea and vomiting (hyperemesis gravidarum), and abdominal cramps caused by uterine distention are relatively common findings. Women may also pass vesicles, which are frequently avascular edematous villi, from the uterus. Preeclampsia occurs in approximately 70% of women with large, rapidly growing hydatidiform moles and occurs earlier than usual in the pregnancy. If preeclampsia is diagnosed before 24 weeks of gestation, hydatidiform mole should be suspected and ruled out. Hyperthyroidism is another serious complication of hydatidiform mole. Usually treatment of the hydatidiform mole restores thyroid function to normal. Partial moles cause few of these symptoms and may be mistaken for an incomplete or missed miscarriage (DiGiulio et al., 2012; Markham & Funai, 2014; Moore, 2014; Nader, 2014).

Diagnosis

Transvaginal ultrasound and serum hCG levels are used for diagnosis. Transvaginal ultrasound is the most accurate tool for diagnosing a hydatidiform mole. A characteristic pattern of multiple diffuse intrauterine masses, often called a *snowstorm pattern*, is seen in place of, or along with, an embryo or a fetus. The trophoblastic tissue secretes the hCG hormone. In a molar pregnancy, hCG levels are persistently high or rising beyond 10 to 12 weeks of gestation, the time they would begin to decline in a normal pregnancy (Cohn et al., 2014; Gilbert, 2011; Moore, 2014).

CARE MANAGEMENT

Surgical Management

Although most moles abort spontaneously, suction curettage offers a safe, rapid, and effective method of evacuating a hydatidiform mole if necessary (Cunningham et al., 2014; Gilbert, 2011). Induction of labor with oxytocic agents or prostaglandin is not recommended because of the increased risk of embolization of trophoblastic tissue. Postevacuation administration of Rh₀(D) immune globulin to women who are Rh negative is necessary to prevent isoimmunization (Gilbert).

Nursing Interventions

The nurse provides the woman and her family with information about the disease process, the necessity for a long course of follow-up, and the possible consequences of the disease. The nurse also helps the woman and her family cope with the pregnancy loss and recognize that the pregnancy was not normal. In addition, the woman and her family are encouraged to express their feelings, and information is provided about local support groups or counseling resources as needed. Internet resources such as Share: Pregnancy and Infant Loss Support, Inc., at www.nationalshare.org and the International Society for the Study of Trophoblastic Disease at www.isstd.org may also be useful. Explanations about the importance of postponing a subsequent pregnancy and contraceptive counseling are provided to emphasize the need for consistent and reliable use of the method chosen.

NURSING ALERT

To avoid confusion in regard to rising levels of hCG that are normal in pregnancy but could indicate GTD, pregnancy should be avoided during the follow-up assessment period. Any contraceptive method except an intrauterine device (IUD) is acceptable. Oral contraceptives are preferred because they are highly effective. Injectable medroxyprogesterone acetate is a practical option for women who have difficulty complying with the daily dosing required for oral contraceptive use.

Follow-Up Care

Follow-up care includes frequent physical and pelvic examinations along with weekly measurements of the β -hCG level until the level decreases to normal and remains normal for 3 consecutive weeks. Monthly measurements are then taken for 6 months. The follow-up assessment period usually continues for a year. During that time a rising β -hCG level and an enlarging uterus may indicate GTD (see Chapter 11 for further discussion) (DiGiulio et al., 2012; Gilbert, 2011).

COMMUNITY ACTIVITY

Talk with someone who has experienced an early pregnancy loss, either a miscarriage, an ectopic pregnancy, or a hydatidiform mole. What helpful things did her health care providers say or do at the time of the loss? What things did they say or do that were not helpful? Are there things that she wishes had been done or said differently? Which of her suggestions do you think would be helpful to people experiencing a different kind of loss?

LATE PREGNANCY BLEEDING

The major causes of bleeding in late pregnancy are placenta previa and premature separation of the placenta (abruptio placentae, or placental abruption). Rapid assessment for and diagnosis of the cause of bleeding are essential to reduce maternal and perinatal morbidity and mortality (Table 28-2).

Placenta Previa

Because of advances in ultrasonography, especially transvaginal ultrasound, and an increased understanding of the changing relationship between the placenta and the internal cervical os as pregnancy progresses, definitions and classifications of placenta previa have changed. In **placenta previa** the placenta is implanted in the lower uterine segment such that it completely or partially covers the cervix or is close enough to the cervix to cause bleeding when the cervix dilates or the lower uterine segment effaces (Fig. 28-8) (Hull & Resnik, 2014). When transvaginal ultrasound is used, the placenta is classified as a **complete placenta previa** if it totally covers the internal cervical os. In a **marginal placenta previa** the edge of the placenta is seen on transvaginal ultrasound to be 2.5 cm or closer to the internal cervical os. When the exact relationship of the placenta to the internal cervical os has not been determined or in the case of apparent placenta previa in the second trimester, the term **low-lying placenta** is used (Hull & Resnik).

TABLE 28-2 Summary of Findings: Placental Abruption and Placenta Previa

FINDINGS	PLACENTAL ABRUPTION			PLACENTA PREVIA
	GRADE 1 MILD SEPARATION (10%-20%)	GRADE 2 MODERATE SEPARATION (20%-50%)	GRADE 3 SEVERE SEPARATION (>50%)	
Physical and Laboratory Findings				
Bleeding, external, vaginal	Minimal	Absent to moderate	Absent to moderate	Minimal to severe and life threatening
Total amount of blood loss	<500 ml	1000-1500 ml	>1500 ml	Varies
Color of blood	Dark red	Dark red	Dark red	Bright red
Shock	Rare; none	Mild shock	Common, often sudden, profound	Uncommon
Coagulopathy	Rare, none	Occasional DIC	Frequent DIC	None
Uterine tonicity	Normal	Increased, may be localized to one region or diffuse over uterus, uterus fails to relax between contractions	Tetanic, persistent uterine contractions, boardlike uterus	Normal
Tenderness (pain)	Usually absent	Present	Agonizing, unremitting uterine pain	Absent
Ultrasonographic Findings				
Location of placenta	Normal, upper uterine segment	Normal, upper uterine segment	Normal, upper uterine segment	Abnormal, lower uterine segment
Station of presenting part	Variable to engaged	Variable to engaged	Variable to engaged	High, not engaged
Fetal position	Usual distribution*	Usual distribution*	Usual distribution*	Commonly transverse, breech, or oblique
Gestational or chronic hypertension	Usual distribution*	Commonly present	Commonly present	Usual distribution*
Fetal effects	Normal fetal heart rate and pattern	Abnormal fetal heart rate and pattern	Abnormal fetal heart rate and pattern; fetal death can occur	Normal fetal heart rate and pattern

DIC, Disseminated intravascular coagulation.

*Usual distribution refers to the expected variations of incidence seen when there is no concurrent problem.

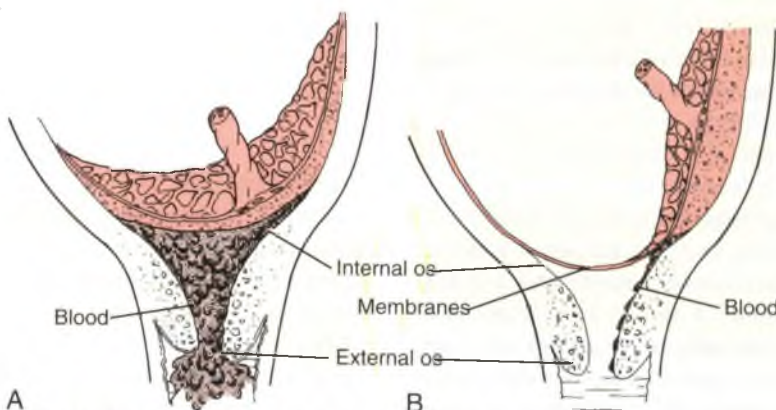

FIG 28-8 Types of placenta previa. A, Complete. B, Marginal.

Incidence and Etiology

Placenta previa affects approximately 1 in 200 pregnancies at term. Some evidence suggests that the incidence of placenta previa is increasing, perhaps as a result of more cesarean births. In addition to a history of previous cesarean birth, other risk factors for placenta previa include advanced maternal age (more than 35 to 40 years of age), multiparity, history of prior suction curettage, and smoking (Hull & Resnik, 2014). Living at a higher altitude is also a risk factor for placenta previa. Like cigarette smoking, a higher altitude causes a decrease in utero-placental oxygenation and thus a need for increased placental surface area. Placenta previa also occurs more frequently in women carrying male fetuses. A possible explanation for this is that placental sizes are larger in pregnancies involving male fetuses (Francois & Foley, 2012). Multiple gestation is also a risk factor for placenta previa because of the larger placental area in these pregnancies (Cunningham et al., 2014). Women who had placenta previa in a previous pregnancy are more likely than others to develop the problem in a subsequent pregnancy, perhaps as a result of a genetic predisposition. Previous cesarean birth and curettage in the past for miscarriage or induced abortion are risk factors for placenta previa because both result in endometrial damage and uterine scarring (Francois & Foley; Hull & Resnik).

Clinical Manifestations

Placenta previa is typically characterized by painless bright red vaginal bleeding during the second or third trimester. In the past, placenta previa was usually diagnosed after an episode of bleeding. Currently, however, most cases are diagnosed by ultrasound before significant vaginal bleeding occurs. This bleeding is associated with the disruption of placental blood vessels that occurs with stretching and thinning of the lower uterine segment (Francois & Foley, 2012). The initial bleeding is usually a small amount and stops as clots form. It can recur, however, at any time (Gilbert, 2011).

Vital signs may be normal, even with heavy blood loss, because a pregnant woman can lose up to 40% of her blood volume without showing signs of shock. Clinical presentation and decreasing urinary output may be better indicators of acute blood loss than vital signs alone. The fetal heart rate (FHR) is normal unless a major detachment of the placenta occurs.

Abdominal examination usually reveals a soft, relaxed, nontender uterus with normal tone. The presenting part of the fetus usually remains high because the placenta occupies the lower uterine segment. Thus the fundal height is often greater than expected for gestational age. Because of the abnormally located placenta, fetal malpresentation (breech and transverse or oblique lie) is common.

Maternal and Fetal Outcomes

The major maternal complication associated with placenta previa is hemorrhage. Another serious complication is development of an abnormal placental attachment (e.g., *placenta accreta*, *increta*, or *percreta*) (see Chapter 33). If excessive bleeding cannot be controlled, hysterectomy may be necessary (Cunningham et al., 2014; Hull & Resnik, 2014). Because most women with placenta previa give birth by cesarean, surgery-related trauma to structures adjacent to the uterus and anesthesia

complications are also possible. In addition, blood transfusion reactions, anemia, thrombophlebitis, and infection may occur.

The greatest risk of fetal death is caused by preterm birth. Other fetal risks include stillbirth, malpresentation, and fetal anemia. Intrauterine growth restriction (IUGR) has also been associated with placenta previa. This association can be related to poor placental exchange (Gilbert, 2011). The incidence of fetal anomalies is increased in pregnancies complicated by placenta previa (Cunningham et al., 2014).

Diagnosis

All women with painless vaginal bleeding after 20 weeks of gestation should be assumed to have a placenta previa until proven otherwise. A transabdominal ultrasound examination should be performed initially followed by a transvaginal scan, unless the transabdominal ultrasound clearly shows that the placenta is not located in the lower uterine segment. A transvaginal ultrasound is better than a transabdominal scan for accurately determining placental location (Hull & Resnik, 2014). If ultrasonographic scanning reveals a normally implanted placenta, a speculum examination may be performed to rule out local causes of bleeding (e.g., cervicitis, polyps, carcinoma of the cervix), and a coagulation profile is obtained to rule out other causes of bleeding.

CARE MANAGEMENT

Once placenta previa has been diagnosed, a management plan is developed. The woman will be managed either expectantly or actively, depending on the gestational age, amount of bleeding, and fetal condition.

Potential nursing diagnoses include:

- *Decreased Cardiac Output* related to:
 - excessive blood loss secondary to placenta previa
- *Deficient Fluid Volume* related to:
 - excessive blood loss secondary to placenta previa
- *Ineffective Peripheral Tissue Perfusion* related to:
 - hypovolemia and shunting of blood to central circulation
- *Anxiety* related to:
 - maternal condition and pregnancy outcome
- *Grieving* related to:
 - actual or perceived threat to self, pregnancy, or infant

Expectant Management. Expectant management (observation and bed rest) is implemented if the fetus is at less than 36 weeks of gestation and has a normal FHR tracing, the bleeding is mild (<250 ml) and stops, and the woman is not in labor. The purpose of expectant management is to allow the fetus time to mature (Gilbert, 2011). The woman will initially be hospitalized in a labor and birth unit for continuous FHR and contraction monitoring. Large-bore intravenous (IV) access should be initiated immediately. Initial laboratory tests include hemoglobin, hematocrit, platelet count, and coagulation studies. A “type and screen” blood sample should be maintained at all times in the hospital’s transfusion services department to allow for immediate crossmatch of blood component therapy if necessary. If the woman is at less than 34 weeks of gestation, antenatal corticosteroids should be administered (Francois & Foley, 2012; Gilbert).

If the bleeding stops, the woman will most likely be placed on bed rest with bathroom privileges and limited activity (e.g., able to use the bathroom, shower, and move around her hospital

room for 15 to 30 minutes at a time, four times a day). No vaginal or rectal examinations are performed, and the woman is placed on “pelvic rest” (nothing in the vagina). Ultrasound examinations may be performed every 2 to 3 weeks. Fetal surveillance may include a nonstress test (NST) or biophysical profile (BPP) once or twice weekly. Bleeding is assessed by checking the amount of blood on perineal pads, bed pads, and linens. Serial laboratory values are evaluated for decreasing hemoglobin and hematocrit levels and changes in coagulation values. The woman should also be monitored for signs of preterm labor. Magnesium sulfate can be given for tocolysis if uterine contractions are identified (Francois & Foley, 2012; Gilbert, 2011).

The woman with placenta previa should always be considered a potential emergency because massive blood loss with resulting hypovolemic shock can occur quickly if bleeding resumes. The possibility always exists that she will require an emergency cesarean for birth. Placenta previa in a preterm gestation may be an indication for transfer to a tertiary-care perinatal center, given that a neonatal intensive care unit may be necessary for care of the preterm infant. Also because many community hospitals are not prepared to perform emergency surgery 24 hours per day, 7 days per week, transfer to a tertiary-care center may be necessary to ensure constant access to cesarean birth.

Home Care. Sometimes women with placenta previa are discharged from the hospital before giving birth to be managed at home. The woman’s condition should be stable, and she should have experienced no vaginal bleeding for at least 48 hours before discharge (Hull & Resnik, 2014). A candidate for home care must meet other strict criteria as well. She should be willing and able to comply with activity restrictions (bed rest with bathroom privileges and pelvic rest), live within 20 minutes of the hospital, and have access to a telephone, close supervision by family or friends in the home, and constant access to transportation (Francois & Foley, 2012). If bleeding resumes, she needs to return to the hospital immediately. She must also be able to keep all appointments for fetal testing, laboratory assessments, and prenatal care. Visits by a perinatal home care nurse may be arranged.

If hospitalization or home care with activity restriction is prolonged, the woman can have concerns about her work- or family-related responsibilities or become bored with inactivity. She should be encouraged to participate in her own care and decisions about care as much as possible. Providing diversionary activities or encouraging her to participate in activities she enjoys and can perform during bed rest are necessary. Participating in a support group made up of other women on bed rest while hospitalized or online if at home may be a helpful coping mechanism (see Teaching for Self-Management: Coping with Activity Restriction in Chapter 27).

Active Management. If the woman definitely has placenta previa and she is at or beyond 36 weeks of gestation, birth is appropriate. If bleeding is excessive or continues or there are concerns about the condition of the fetus, immediate birth is indicated, regardless of gestational age (Hull & Resnik, 2014). All women whose placenta lies within 2 cm of the cervix, as documented by a transvaginal ultrasound performed late in the third trimester, should give birth by cesarean. However, an asymptomatic woman whose placenta clearly lies more than

2 cm from the cervical os can safely be allowed to labor (Francois & Foley, 2012; Hull and Resnik).

If cesarean birth is planned, the nurse continually assesses maternal and fetal status while preparing the woman for surgery. Maternal vital signs are assessed frequently for decreasing BP, increasing pulse rate, changes in level of consciousness, and oliguria. Fetal assessment is maintained by continuous electronic fetal monitoring (EFM) to assess for signs of hypoxia.

Blood loss may not stop with the birth of the infant. The large vascular channels in the lower uterine segment may continue to bleed because of that segment’s diminished muscle content. The natural mechanism to control bleeding so characteristic of the upper part of the uterus—the interlacing muscle bundles, the “living ligature” contracting around open vessels—is absent in the lower part of the uterus. Postpartum hemorrhage may therefore occur even if the fundus is contracted firmly (see Chapter 33).

Emotional support for the woman and her family is extremely important. The actively bleeding woman is concerned not only for her own well-being but also for that of her fetus. All procedures should be explained, and a support person should be present. The woman should be encouraged to express her concerns and feelings. If the woman and her support person or family desire pastoral support, the nurse can notify the hospital chaplain service or provide information about other supportive resources.

CLINICAL REASONING CASE STUDY

Third-Trimester Vaginal Bleeding

Crystal is a 41-year-old G5 P2 1 1 4 (one set of twins) who presents to the emergency department with heavy vaginal bleeding. She has had no prenatal care but is approximately 33 weeks of gestation by her LMP. Crystal said, “I was fine when I went to bed last night. In the middle of the night I woke up and found a huge puddle of blood in my bed. I called the ambulance right away and they brought me here.” During her medical screening exam you learn that Crystal has had one cesarean birth (with her twins) and a D&C after a miscarriage 5 years ago. She also smokes 1 pack of cigarettes per day.

1. Evidence—Is there sufficient evidence to determine the cause of Crystal’s bleeding?
2. Assumptions—Describe an underlying assumption about each of the following issues:
 - a. Possible diagnoses for Crystal
 - b. Diagnostic tests necessary to determine the cause of Crystal’s bleeding
 - c. Inpatient and outpatient management options for Crystal
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

D&C, Dilation and curettage; LMP, last menstrual period.

Premature Separation of the Placenta (Abruptio Placentae [Placental Abruptio])

Premature separation of the placenta, or **abruptio placentae**, is the detachment of part or all of a normally implanted placenta from the uterus (Fig. 28-9). Separation occurs in the area of the decidua basalis after 20 weeks of gestation and before the birth of the infant.

FIG 28-9 Placental abruption. Premature separation of normally implanted placenta. A large retroplacental clot is present. (From Creasy, R., Resnik, R., Iams, J., et al. [2009]. *Creasy & Resnik's maternal-fetal medicine: Principles and practice* [6th ed.]. Philadelphia: Saunders.)

Incidence and Etiology

Placental abruption is a serious complication that accounts for significant maternal and fetal morbidity and mortality. Approximately 1 in 75 to 1 in 226 pregnancies is complicated by placental abruption. The range in incidence likely reflects both variable criteria for diagnosis and an increased recognition of milder forms of abruption. Approximately one third of all antepartum bleeding is caused by placental abruption (Francois & Foley, 2012).

Maternal hypertension, whether chronic or pregnancy related, is the most consistently identified risk factor for abruption. Cocaine use is also a risk factor because it causes vascular disruption in the placental bed. Blunt external abdominal trauma, most often the result of motor vehicle accidents (MVAs) or maternal battering, is another frequent cause of placental abruption (Cunningham et al., 2014; Francois & Foley, 2012). Other risk factors include cigarette smoking, a history of abruption in a previous pregnancy, and preterm premature rupture of membranes (preterm PROM). There has been great interest in a possible association between thrombophilic disorders and abruption. However, both retrospective and prospective studies of women with the factor V Leiden mutation have shown no increase in risk for abruption (Hull & Resnik, 2014). Abruption is more likely to occur in twin gestations than in singletons (Francois & Foley). Women who have had two previous abruptions have a recurrence risk of 25% in the next pregnancy (Hull & Resnik).

Classification

The most common classification of placental abruption is according to type and severity. This classification system is summarized in Table 28-2.

Clinical Manifestations

The separation may be partial or complete, or only the margin of the placenta may be involved. Bleeding from the placental site may dissect (separate) the membranes from the decidua basalis and flow out through the vagina (70% to 80%), it may remain concealed (retroplacental hemorrhage) (10% to 20%), or both (Fig. 28-10) (Francois & Foley, 2012; Gilbert, 2011). Clinical symptoms vary with degree of separation (see Table

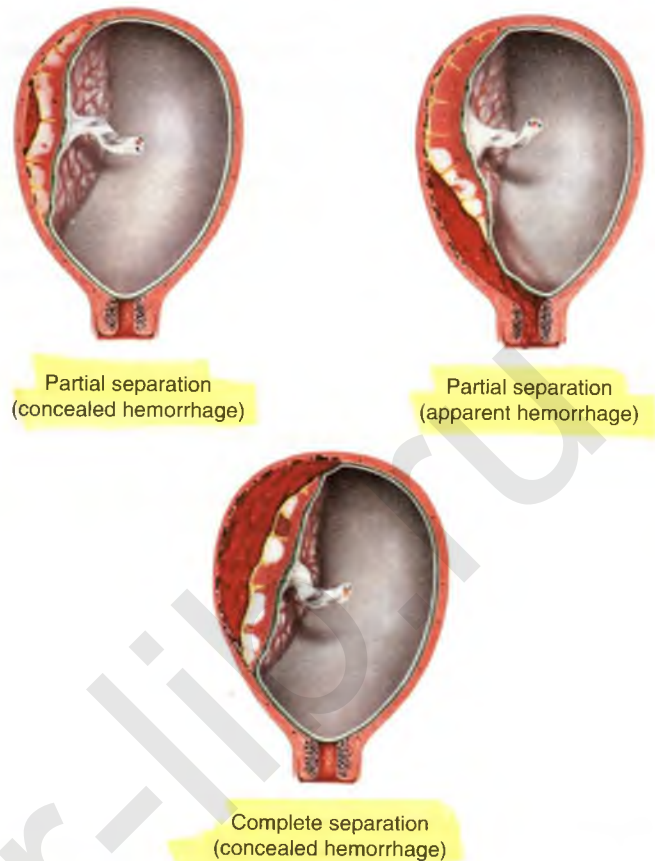

FIG 28-10 Placental abruption, showing partial and complete placental separation.

28-2). If cesarean birth is performed, blood clots may be noted on entry into the uterus. A blood clot often will be attached to the posterior surface of the placenta (referred to as a retroplacental clot) (see Fig. 28-9).

Classic symptoms of placental abruption include vaginal bleeding, abdominal pain, and uterine tenderness and contractions (Cunningham et al., 2014; Hull & Resnik, 2014). Bleeding may result in maternal hypovolemia (i.e., shock, oliguria, anuria) and coagulopathy. Mild to severe uterine hypertonicity is present. Pain is mild to severe and localized over one region of the uterus or diffuse over the uterus with a boardlike abdomen.

Extensive myometrial bleeding damages the uterine muscle. If blood accumulates between the separated placenta and the uterine wall, it may produce a **couvelaire uterus**. The uterus appears purple or blue, rather than its usual “bubblegum pink” color, and contractility is lost. Shock may occur and is out of proportion to blood loss. Laboratory findings include a positive Apt test result (blood in the amniotic fluid); a decrease in hemoglobin and hematocrit levels, which may appear later; and a decrease in coagulation factor levels. Clotting defects (e.g., disseminated intravascular coagulation [DIC]) may be present when more than 50% of the placental surface area abrupts (Francois and Foley, 2012). A Kleihauer-Betke (KB) test may be ordered to determine the presence of fetal-to-maternal bleeding (transplacental hemorrhage), although it is of no diagnostic value. The KB test may be useful, however, to guide Rh₀(D) immune globulin therapy in Rh-negative women who have had an abruption (Hull & Resnik, 2014).

Maternal and Fetal Outcomes

The mother's prognosis depends on the extent of placental detachment, overall blood loss, degree of coagulopathy present, and the time that passes between placental detachment and birth. Maternal complications are associated with the abruption or its treatment. Hemorrhage, hypovolemic shock, hypofibrinogenemia, and thrombocytopenia are associated with severe abruption. Renal failure and pituitary necrosis may result from ischemia. In rare cases, women who are Rh negative can become sensitized if fetal-to-maternal hemorrhage occurs and the fetal blood type is Rh positive.

Fetal complications, which include IUGR and preterm birth, are related to the severity and timing of the hemorrhage. The size of the hemorrhage is related to fetal survival. Large (>60 ml) hemorrhages are associated with 50% or higher fetal mortality (Francois & Foley, 2012). Risks for neurologic defects, cerebral palsy, and death from sudden infant death syndrome are greater in newborns following placental abruption (Cunningham et al., 2014; Francois & Foley).

Diagnosis

Placental abruption is primarily a clinical diagnosis. Although ultrasound can be used to rule out placenta previa, it cannot detect all cases of abruption. A retroplacental mass may be detected with ultrasonographic examination, but negative findings do not rule out a life-threatening abruption. In fact, at least 50% of abruptions cannot be identified on ultrasound (Hull & Resnik, 2014). Hypofibrinogenemia and evidence of DIC support the diagnosis, but many women with placental abruption do not develop coagulopathy. The diagnosis of abruption is confirmed after birth by visual inspection of the placenta. Adherent clot on the maternal surface of the placenta and depression of the underlying placental surface are usually present (see Fig. 28-9) (Francois & Foley, 2012; Gilbert, 2011).

Placental abruption should be highly suspected in the woman who experiences a sudden onset of intense, usually localized, uterine pain, with or without vaginal bleeding. Initial assessment is much the same as for placenta previa. Physical examination usually reveals abdominal pain, uterine tenderness, and contractions. The fundal height may be measured over time because an increasing fundal height indicates concealed bleeding. Approximately 60% of live fetuses exhibit abnormal FHR patterns, and elevated uterine resting tone may also be noted on the monitor tracing (Francois & Foley, 2012). Coagulopathy, as evidenced by abnormal clotting studies (fibrinogen, platelet count, partial thromboplastin time [PTT], fibrin split products), may be present if a large or complete abruption has occurred.

CARE MANAGEMENT

Expectant Management. Management depends on the severity of blood loss and fetal maturity and status. If the fetus is between 20 and 34 weeks of gestation and both the woman and fetus are stable, expectant management can be implemented. The woman is monitored closely because the abruption may extend at any time. The fetus is assessed regularly for evidence of appropriate growth because there is risk for IUGR. In addition, assessments of fetal well-being (e.g., NST and BPP)

are performed regularly. See Chapter 26 for further discussion of these tests. Corticosteroids are given to accelerate fetal lung maturity (Hull & Resnik, 2014).

Active Management. Immediate birth is the management of choice if the fetus is at term gestation or if the bleeding is moderate to severe and the mother or fetus is in jeopardy. At least one large-bore (16- to 18-gauge) IV line should be started. Maternal vital signs are monitored frequently to observe for signs of declining hemodynamic status, such as increasing pulse rate and decreasing BP. Serial laboratory studies include hematocrit or hemoglobin determinations and clotting studies. Continuous EFM is mandatory. An indwelling catheter is inserted for continuous assessment of urine output, an excellent indirect measure of maternal organ perfusion. Blood and fluid volume replacement may be necessary, along with administering blood products to correct any coagulation defects.

Although vaginal birth is usually preferable, cesarean birth may become necessary. Cesarean birth should not be attempted when a woman has severe and uncorrected coagulopathy because it can result in uncontrollable bleeding (Francois & Foley, 2012).

Nursing care of women experiencing moderate to severe abruption is demanding because it requires constant close monitoring of the maternal and fetal condition. Information about placental abruption, including the cause, treatment, and expected outcome, is given to the woman and her family. Emotional support is also extremely important because the woman and her family may be experiencing fetal loss in addition to the woman's critical illness.

Cord Insertion and Placental Variations

When fetal vessels lie over the cervical os, the condition is termed **vasa previa**. In vasa previa the vessels are implanted into the fetal membranes rather than into the placenta. Usually these vessels are protected only by the membranes (not by Wharton's jelly); thus they are at risk for rupture or compression. Vasa previa is rare, affecting between 1 in 1275 and 1 in 8333 pregnancies (Hull & Resnik, 2014). There are two variations of vasa previa. In both situations artificial or spontaneous rupture of the membranes or traction on the cord may rupture one or more of the fetal vessels. As a result the fetus may rapidly bleed to death (Francois & Foley, 2012; Sosa, 2014). Risk factors for vasa previa include low-lying placentas, pregnancies resulting from assisted reproductive technology, and multiple gestations (Francois & Foley).

One variation of vasa previa, *velamentous insertion of the cord*, occurs when the cord vessels begin to branch at the membranes and then course onto the placenta (Fig. 28-11). The other variant of vasa previa occurs when the placenta has divided into two or more lobes rather than remaining as a single mass. This is known as a *succenturiate placenta* (Fig. 28-12). Fetal vessels then run between the lobes of the placenta. The vessels collect at the periphery, and the main trunks eventually unite to form the vessels of the cord. During the third stage of labor one or more of the separate lobes may remain attached to the decidua basalis, preventing uterine contraction and increasing the risk of postpartum hemorrhage.

Another placental variation is *Battledore* (marginal) insertion of the cord (Fig. 28-13). This variation also increases the

blow's inability to clot - immature

FIG 28-11 Vasa previa (velamentous insertion of cord). Arrow shows velamentous cord insertion in the placenta. (From Creasy, R., Resnik, R., Iams, J., et al. [2009]. *Creasy & Resnik's maternal-fetal medicine: Principles and practice* [6th ed.]. Philadelphia: Saunders.)

risk of fetal hemorrhage, especially after marginal separation of the placenta.

Clotting Disorders in Pregnancy

Normal Clotting

Normally a delicate balance (homeostasis) exists between the opposing hemostatic and fibrinolytic systems. The hemostatic system stops the flow of blood from injured vessels, first by a platelet plug, which is followed by the formation of a fibrin clot. The coagulation process involves an interaction of the coagulation factors that constantly circulate in the bloodstream in which each factor sequentially activates the factor next in line, the “cascade effect” sequence. The fibrinolytic system is the process through which the fibrin clot is split into fibrinolytic degradation products and circulation is restored.

Clotting Problems

Disseminated Intravascular Coagulation. Disseminated intravascular coagulation (DIC), or consumptive coagulopathy, is a pathologic form of clotting that is diffuse and consumes large

BOX 28-2 Clinical Manifestations and Laboratory Screening Results for Women with Disseminated Intravascular Coagulation

Possible Physical Examination Findings

- Spontaneous bleeding from gums, nose
- Oozing, excessive bleeding from venipuncture site, intravenous access site, or site of insertion of urinary catheter
- Petechiae (e.g., on the arm where blood pressure cuff was placed)
- Other signs of bruising
- Hematuria
- Gastrointestinal bleeding
- Tachycardia
- Diaphoresis

Laboratory Coagulation Screening Test Results

- Platelets—decreased
- Fibrinogen—decreased
- Factor V (proaccelerin)—decreased
- Factor VIII (antihemolytic factor)—decreased
- Prothrombin time—prolonged
- Activated partial thromboplastin time—prolonged
- Fibrin degradation products—increased
- D-dimer test (specific fibrin degradation fragment)—increased
- Red blood smear—fragmented red blood cells

Data from Cunningham, F., Leveno, K., Bloom, S., et al. (2014). *Williams obstetrics* (24th ed.). New York: McGraw-Hill Education. Labelle, C., & Kitchens, C. (2005). amounts of clotting factors, causing widespread external bleeding, internal bleeding, or both and clotting (Cunningham et al., 2014). DIC is never a primary diagnosis. Instead it results from some event that triggered the clotting cascade, either extrinsically, by the release of large amounts of tissue thromboplastin, or intrinsically, by widespread damage to vascular integrity.

In the obstetric population, DIC is most often triggered by the release of large amounts of tissue thromboplastin, which occurs in placental abruption (the most common cause of severe consumptive coagulopathy in obstetrics) and in the retained dead fetus syndrome and amniotic fluid embolus (anaphylactoid syndrome of pregnancy). Severe preeclampsia, HELLP (Hemolysis, Elevated Liver enzymes, and Low Platelet count) syndrome, and gram-negative sepsis are examples of conditions that can trigger DIC because of widespread damage to vascular integrity (Cunningham et al., 2014; Gilbert, 2011). DIC is an overactivation of the clotting cascade and the fibrinolytic system, resulting in depletion of platelets and clotting factors, which causes the formation of multiple fibrin clots throughout the body's vasculature, even in the microcirculation. Blood cells are destroyed as they pass through these fibrin-choked vessels. Thus DIC results in a clinical picture of clotting, bleeding, and ischemia (Cunningham et al.). Clinical manifestations and laboratory test results are summarized in Box 28-2.

CARE MANAGEMENT

Medical management in all cases of DIC involves correction of the underlying cause (e.g., removal of the dead fetus, treatment of existing infection or of preeclampsia or eclampsia, or removal of an abrupted placenta). Volume expansion, rapid replacement

of blood products and clotting factors, optimization of oxygenation, achievement of normal body temperature, and continued reassessment of laboratory parameters are the usual forms of treatment. Vitamin K administration, recombinant activated factor VIIa, fibrinogen concentrate, and hemostatic agents should be considered as additional therapies (Francois & Foley, 2012).

Nursing Interventions

Nursing interventions include assessment for signs of bleeding (see Box 28-2) and complications from the administration of blood and blood products, administering fluid or blood replacement as ordered, cardiac and hemodynamic monitoring, and protecting the woman from injury. Because renal failure is one

consequence of DIC, urinary output is closely monitored by using an indwelling catheter. Urinary output must be maintained at more than 30 ml/hr (Gilbert, 2011). Vital signs are assessed frequently. If DIC develops before birth, continuous electronic fetal monitoring is necessary. The woman should be maintained in a side-lying tilt to maximize blood flow to the uterus. Oxygen may be administered through a nonrebreather face mask at 10 L/min or per hospital protocol or physician order. DIC usually is “cured” with the birth and as coagulation abnormalities resolve.

The woman and her family will be anxious and concerned about her condition and prognosis. The nurse offers explanations about care and provides emotional support to the woman and her family through this critical time.

KEY POINTS

- Blood loss during pregnancy should always be regarded as a warning sign until the cause is determined.
- Some miscarriages occur for unknown reasons, but fetal or placental maldevelopment and maternal factors account for many others.
- The type of miscarriage and signs and symptoms direct care management.
- Cervical insufficiency may be treated with a cerclage placed cervically or abdominally; the woman is instructed on recognizing the warning signs of preterm labor, preterm premature rupture of membranes, and infection.
- Ectopic pregnancy is a significant cause of maternal morbidity and mortality.
- Hydatidiform mole is a gestational trophoblastic disease (GTD). GTD is a group of pregnancy-related trophoblastic proliferative disorders without a viable fetus that are caused by abnormal fertilization.
- Placenta previa and placental abruption are differentiated by type of bleeding, uterine tonicity, and presence or absence of pain.
- Management of late-pregnancy bleeding requires immediate evaluation; care is based on gestational age, amount of bleeding, and fetal condition.
- DIC is a pathologic form of clotting that causes widespread bleeding and clotting. It is never a primary diagnosis but always results from some event that triggered the clotting cascade.

Endocrine and Metabolic Disorders

Jo M. Kendrick

e <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Differentiate the types of diabetes mellitus and their respective risk factors in pregnancy.
- Compare insulin requirements during pregnancy, postpartum, and with lactation.
- Identify maternal and fetal risks or complications associated with diabetes in pregnancy.
- Develop a plan of care for the pregnant woman with pregestational or gestational diabetes.
- Explain the effects of hyperemesis gravidarum on maternal and fetal well-being.
- Discuss management of the woman with hyperemesis gravidarum.
- Explain the effects of thyroid disorders on pregnancy.
- Compare the management of a pregnant woman with hyperthyroidism with one who has hypothyroidism.
- Discuss care management for the woman with phenylketonuria during the perinatal period.
- Examine the effects of maternal phenylketonuria on pregnancy outcome.

This chapter discusses the care of women for whom pregnancy represents a significant risk because it is superimposed on an endocrine or metabolic disorder. Specific disorders covered include diabetes mellitus, hyperemesis gravidarum, hyper- and hypothyroidism, and phenylketonuria. Providing safe and effective care for women with these disorders and their fetuses is a challenge. Although unique needs related to the specific endocrine or metabolic condition are present, these women also experience the feelings, needs, and concerns associated with a normal pregnancy. The primary objective of nursing care is to achieve optimal outcomes for both the pregnant woman and the fetus. With the active participation of well-motivated women in the treatment plan and careful management from a multidisciplinary health care team, positive outcomes are often possible.

DIABETES MELLITUS

Worldwide, the incidence of diabetes mellitus is growing at a rapid rate, mostly because of increases in overweight, obesity, and physical inactivity. An estimated 347 million people are now diabetic, and the disease is expected to become the seventh leading cause of death worldwide by 2030 (World Health Organization [WHO], 2013). In 2012 an estimated 29.1 million people in the United States (9.3% of the total population) had

diabetes. Of these, 8.1 million were undiagnosed (Centers for Disease Control and Prevention [CDC], 2014). If this trend continues, it is predicted that by 2050 as many as 1 in 3 adults in the United States will have diabetes. The prevalence of diabetes among women of childbearing age is increasing in the United States, which will greatly affect the care of mothers and children for years to come (Moore, Hauguel-DeMouzon, & Catalano, 2014).

Diabetes mellitus is the most common endocrine disorder associated with pregnancy, occurring in approximately 4% to 14% of pregnant women (Gilbert, 2011). The perinatal mortality rate for well-managed pregnancies complicated by diabetes, excluding major congenital malformations, is approximately the same as for any other pregnancy (Landon, Catalano, & Gabbe, 2012). The key to an optimal pregnancy outcome is strict maternal glucose control before conception and throughout the gestational period. Consequently, for women with diabetes, much emphasis is placed on preconception counseling.

Pregnancy complicated by diabetes is still considered high risk. It is most successfully managed by a multidisciplinary approach involving the obstetrician, perinatologist, internist or endocrinologist, ophthalmologist, nephrologist, neonatologist, nurse, nutritionist or dietitian, and social worker. A favorable outcome also requires commitment and active participation by the pregnant woman and her family.

Pathogenesis

Diabetes mellitus refers to a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both (American Diabetes Association [ADA], 2013a). Insulin, produced by the beta cells in the islets of Langerhans in the pancreas, regulates blood glucose levels by enabling glucose to enter adipose and muscle cells, where it is used for energy. When insulin is insufficient or ineffective in promoting glucose uptake by the muscle and adipose cells, glucose accumulates in the bloodstream, and hyperglycemia results. Hyperglycemia causes hyperosmolarity of the blood, which attracts intracellular fluid into the vascular system, resulting in cellular dehydration and expanded blood volume. Consequently, the kidneys function to excrete large volumes of urine (polyuria) in an attempt to regulate excess vascular volume and to excrete the unusable glucose (glycosuria). Polyuria, along with cellular dehydration, causes excessive thirst (polydipsia).

The body compensates for its inability to convert carbohydrate (glucose) into energy by burning proteins (muscle) and fats. However, the end products of this metabolism are ketones and fatty acids, which, in excess quantities, produce ketoacidosis and acetonuria. Weight loss occurs as a result of the breakdown of fat and muscle tissue. This tissue breakdown causes a state of starvation that compels the individual to eat excessive amounts of food (polyphagia).

Over time, diabetes causes significant changes in the microvascular and macrovascular circulations. These structural changes affect a variety of organ systems, particularly the heart, the eyes, the kidneys, and the nerves. Complications resulting from diabetes include premature atherosclerosis, retinopathy, nephropathy, and neuropathy.

Diabetes may be caused either by impaired insulin secretion, when the beta cells of the pancreas are destroyed by an autoimmune process, or by inadequate insulin action in target tissues at one or more points along the metabolic pathway. Both of these conditions are commonly present in the same person, and determining which, if either, abnormality is the primary cause of the disease is difficult (ADA, 2013a). For additional information on diabetes, visit the American Diabetes Association (ADA)'s website at www.diabetes.org.

Classification

The current classification system includes four groups: type 1 diabetes, type 2 diabetes, other specific types (e.g., diabetes caused by genetic defects in beta cell function or insulin action, disease or injury of the pancreas, or drug-induced diabetes), and gestational diabetes mellitus (GDM) (ADA, 2013b; Moore et al., 2014).

Type 1 diabetes includes cases that are caused primarily by pancreatic islet beta cell destruction and that are prone to ketoacidosis. People with type 1 diabetes usually have an abrupt onset of illness at a young age and an absolute insulin deficiency. Type 1 diabetes includes cases thought to be caused by an autoimmune process and those for which the cause is unknown (ADA, 2013b; Landon et al., 2012).

Type 2 diabetes is the most prevalent form of the disease and includes individuals who have insulin resistance and usually relative (rather than absolute) insulin deficiency. Although type 2

diabetes was once believed to affect mostly older individuals, increasing numbers of children and adolescents have been diagnosed with the disorder since the early 1990s (Moore et al., 2014). Specific causes of type 2 diabetes are unknown at this time. It often goes undiagnosed for years because hyperglycemia develops gradually and is often not severe enough for the person to recognize the classic signs of polyuria, polydipsia, and polyphagia. Most people who develop type 2 diabetes are obese or have an increased amount of body fat distributed primarily in the abdominal area. Other risk factors for the development of type 2 diabetes include aging, a sedentary lifestyle, family history and genetics, puberty, hypertension, and prior gestational diabetes. Type 2 diabetes often has a strong genetic predisposition (ADA, 2013b; Moore et al.).

Pregestational diabetes mellitus is the label sometimes given to type 1 or type 2 diabetes that existed before pregnancy.

The traditional definition of GDM is carbohydrate intolerance with the onset or first recognition occurring during pregnancy (American College of Obstetricians and Gynecologists [ACOG], 2013). This definition is appropriate whether or not management includes medication in addition to dietary changes or the diabetes persists after pregnancy. It does not exclude the possibility that the glucose intolerance preceded the pregnancy or that medication might be required for optimal glucose control (Landon et al., 2012). The ADA has adopted a new definition for gestational diabetes that excludes women with overt diabetes (type 1 or type 2) that is diagnosed during pregnancy. This definition for GDM is simply diabetes diagnosed during pregnancy that is clearly not overt (preexisting) diabetes (ADA, 2013a).

Classification of Diabetes in Pregnancy

Dr. Priscilla White, a physician who worked with pregnant women with diabetes during the 1940s, developed a system specifically to further classify diabetes in this group of women (Table 29-1). White's system was based on age at diagnosis, duration of illness, and presence of end-organ, especially eye and kidney, involvement (Landon et al., 2012; Moore et al., 2014). Her classification system has been modified through the years, changing her original definitions and adding increasing complexity, which has resulted in confusion (Sacks & Metzger, 2013). It is still frequently used, however, to assess maternal and fetal risk.

A new system has since been developed by the ADA that further classifies type 1 and type 2 diabetes as (a) without vascular complications and (b) with vascular complications that are specified. This distinction is important, because perinatal risk increases with vascular complications regardless of the duration of illness. Only women whose glucose intolerance was diagnosed during pregnancy but who do not meet the criteria defining type 1 or type 2 diabetes are included in the gestational diabetes category. It has been suggested that White's modified classification system be replaced by the new ADA system in clinical practice (Sacks & Metzger, 2013).

Metabolic Changes Associated with Pregnancy

Normal pregnancy is characterized by complex alterations in maternal glucose metabolism, insulin production, and metabolic homeostasis. During normal pregnancy adjustments in maternal metabolism allow for adequate nutrition for the mother and the developing fetus. Glucose, the primary fuel used by the

fetus, is transported across the placenta through the process of carrier-mediated facilitated diffusion, meaning that the glucose levels in the fetus are directly proportional to maternal levels. Although glucose crosses the placenta, insulin does not. Around the tenth week of gestation the fetus begins to secrete its own insulin at levels adequate to use the glucose obtained from the mother. Therefore, as maternal glucose levels rise, fetal glucose levels are increased, resulting in increased fetal insulin secretion.

During the first trimester of pregnancy the pregnant woman's metabolic status is significantly influenced by the rising

levels of estrogen and progesterone. These hormones stimulate the beta cells in the pancreas to increase insulin production, which promotes increased peripheral use of glucose and decreased blood glucose, with fasting levels being reduced by approximately 10% (Fig. 29-1, A). At the same time, an increase in tissue glycogen stores and a decrease in hepatic glucose production occur, which further encourage lower fasting glucose levels. As a result of these normal metabolic changes of pregnancy, women with insulin-dependent diabetes are prone to hypoglycemia during the first trimester.

During the second and third trimesters, pregnancy exerts a "diabetogenic" effect on the maternal metabolic status. Because of the major hormonal changes, decreased tolerance to glucose, increased insulin resistance, decreased hepatic glycogen stores, and increased hepatic production of glucose occur. Rising levels of human chorionic somatomammotropin, estrogen, progesterone, prolactin, cortisol, and insulinase increase insulin resistance through their actions as insulin antagonists. Insulin resistance is a glucose-sparing mechanism that ensures an abundant supply of glucose for the fetus. Maternal insulin requirements gradually increase from approximately 18 to 24 weeks of gestation to approximately 36 weeks of gestation. Maternal insulin requirements may double or quadruple by the end of the pregnancy (see Fig. 29-1, B and C).

At birth, expulsion of the placenta prompts an abrupt drop in levels of circulating placental hormones, cortisol, and insulinase (see Fig. 29-1, D). Maternal tissues quickly regain their prepregnancy sensitivity to insulin. For the nonbreastfeeding mother the prepregnancy insulin-carbohydrate balance usually returns in approximately 7 to 10 days (see Fig. 29-1, E). Lactation uses maternal glucose; therefore, the breastfeeding mother's insulin requirements remain lower during lactation. On completion of weaning the mother's prepregnancy insulin requirement is reestablished (see Fig. 29-1, F).

TABLE 29-1 White's Classification of Diabetes in Pregnancy (Modified)

Gestational Diabetes	
Class A ₁	Woman has two or more abnormal values on OGTT with normal fasting blood sugar. Blood glucose levels are diet controlled.
Class A ₂	Woman was not known to have diabetes before pregnancy but requires medication for blood glucose control.
Pregestational Diabetes	
Class B	Onset of disease occurs after age 20 and duration of illness <10 years.
Class C	Onset of disease occurs between 10 and 19 years of age or duration of illness for 10 to 19 years or both.
Class D	Onset of disease occurs at <10 years of age or duration of illness >20 years or both.
Class F	Client has developed diabetic nephropathy.
Class R	Client has developed retinitis proliferans.
Class T	Client has had a renal transplant.

OGTT, Oral glucose tolerance test.

Data from Landon, M., Catalano, P., & Gabbe, S. (2012). Diabetes mellitus complicating pregnancy. In S. Gabbe, J. Niebyl, & J. Simpson (Eds.), *Obstetrics: Normal and problem pregnancies* (6th ed.). Philadelphia: Saunders; Moore, T.R., Hauguel-deMouzon, S., & Catalano, P. (2014). Diabetes in pregnancy. In R.K. Creasy, R. Resnik, J.D. Iams, et al., (Eds.), *Creasy and Resnik's maternal-fetal medicine: Principles and practice* (7th ed.). Philadelphia: Saunders.

FIG 29-1 Changing insulin needs during pregnancy. *A*, First trimester: Insulin need is reduced because of increased insulin production by pancreas and increased peripheral sensitivity to insulin; nausea, vomiting, and decreased food intake by mother and glucose transfer to embryo or fetus contribute to hypoglycemia. *B*, Second trimester: Insulin needs begin to increase as placental hormones, cortisol, and insulinase act as insulin antagonists, decreasing insulin's effectiveness. *C*, Third trimester: Insulin needs may double or even quadruple but usually level off after 36 weeks of gestation. *D*, Day of birth: Maternal insulin requirements decrease dramatically to approach prepregnancy levels. *E*, Breastfeeding mother maintains lower insulin requirements, as much as 25% less than those of prepregnancy; insulin needs of nonbreastfeeding mother return to prepregnancy levels in 7 to 10 days. *F*, Weaning of breastfeeding infant causes mother's insulin needs to return to prepregnancy levels.

PREGESTATIONAL DIABETES MELLITUS

Only about 10% of pregnancies complicated by diabetes occur in women who have preexisting disease (Landon et al., 2012). Women who have **pregestational diabetes mellitus** can have either type 1 or 2 diabetes, which may be complicated by vascular disease, retinopathy, nephropathy, or other diabetic complications. Type 2 is a more common diagnosis than type 1. **Almost all women with pregestational diabetes are insulin dependent during pregnancy.** According to White's classification system, these women fall into classes B through T (see Table 29-1).

The diabetogenic state of pregnancy imposed on the compromised metabolic system of the woman with pregestational diabetes has significant implications. The normal hormonal adaptations of pregnancy affect glycemic control, and pregnancy may accelerate the progress of vascular complications.

During the first trimester, when maternal blood glucose levels are normally reduced and the insulin response to glucose is enhanced, glycemic control may be improved. **The insulin dose for the woman with well-controlled diabetes may have to be reduced to prevent hypoglycemia.** Nausea, vomiting, and cravings typical of early pregnancy result in dietary fluctuations that influence maternal glucose levels and may necessitate a reduction in the insulin dose.

Because insulin requirements steadily increase after the first trimester, the insulin dose must be adjusted accordingly to prevent hyperglycemia. Insulin resistance begins as early as 14 to 16 weeks of gestation and continues to rise until it stabilizes during the last few weeks of pregnancy.

COMMUNITY ACTIVITY

Visit the March of Dimes website at www.marchofdimes.com. Review the information specifically intended for women with gestational diabetes and preexisting diabetes. Read the section on preconception, "Baby makes three. Are you ready?" Determine the helpfulness of this information for your clients. Develop a teaching plan for a woman with pregestational diabetes based on the information you decided would be useful.

Preconception Counseling

Preconception counseling is recommended for all women of reproductive age who have diabetes because it is associated with less perinatal mortality and fewer preterm births and congenital anomalies (Moore et al., 2014). Under ideal circumstances, women with pregestational diabetes are counseled before conception to plan the optimal time for pregnancy, establish glycemic control before conception, and diagnose any vascular complications of diabetes. However, estimates indicate that less than 20% of women with diabetes in the United States participate in preconception counseling (Landon et al., 2012).

The woman's partner should be included in the counseling to assess the couple's level of understanding related to the effects of pregnancy on the diabetic condition and of the potential complications of pregnancy as a result of diabetes. The couple should also be informed of the anticipated alterations in management of diabetes during pregnancy and the need for a multidisciplinary team approach to health care. Financial implications of diabetic pregnancy and other demands related

to frequent maternal and fetal surveillance should be discussed. In addition, medications the woman is currently taking must be assessed for safety during pregnancy. Medications that carry risk for adverse maternal or fetal outcomes should be changed to ones that are safer but equally effective. Preconception counseling should also include discussion of microvascular and macrovascular complications that carry significant risk for maternal morbidity and mortality during pregnancy such as coronary artery disease and renal insufficiency. Renal transplantation may be necessary prior to conception. Contraception is another important aspect of preconception counseling to assist the couple in planning effectively for pregnancy. They should be encouraged to use reliable contraception until glycemic control is optimal.

Maternal Risks and Complications

Although maternal morbidity and mortality rates have improved significantly, the pregnant woman with diabetes remains at risk for the development of complications during pregnancy. **Poor glycemic control around the time of conception and in the early weeks of pregnancy is associated with an increased incidence of miscarriage.** Women with good glycemic control before conception and in the first trimester are no more likely to miscarry than women who do not have diabetes (Moore et al., 2014).

Poor glycemic control later in pregnancy, particularly in women without vascular disease, increases the rate of fetal macrosomia. **Macrosomia** has been defined as a birth weight more than 4000 to 4500 g or greater than the 90th percentile. It occurs in approximately 40% of pregestational diabetic pregnancies and up to 50% of pregnancies complicated by GDM (Landon et al., 2012). Infants born to women with diabetes tend to have a disproportionate increase in shoulder, trunk, and chest size. **Because of this tendency the risk for shoulder dystocia is greater in these babies than in other macrosomic infants.** Therefore, women with diabetes face an increased likelihood of cesarean birth because of failure of fetal descent or labor progress or of operative vaginal birth (birth involving the use of episiotomy, forceps, or vacuum extractor) (Moore et al., 2014).

Women with preexisting diabetes are at risk for several obstetric and medical complications, including hypertension, preeclampsia, cesarean birth, preterm birth, and maternal mortality. In general, the risk of developing these complications increases with the duration and severity of the woman's diabetes. For example, more than one third of women who have had diabetes for more than 20 years develop preeclampsia. Women with nephropathy and hypertension in addition to diabetes are also increasingly likely to develop preeclampsia. **Poor glycemic control at the beginning of pregnancy is also related to the development of preeclampsia.** The rate of hypertensive disorders in all types of pregnancies complicated by diabetes is 15% to 30%. Chronic hypertension occurs in 10% to 20% of all pregnant women with diabetes and in up to 40% of women who have preexisting renal or retinal vascular disease (Moore et al., 2014).

Hydramnios (polyhydramnios) frequently develops during the third trimester of pregnancy in women with diabetes. Its cause is unknown. One theory is that hydramnios in women with diabetes is caused by an increased glucose concentration in amniotic fluid resulting from maternal and fetal hyperglycemia,

which induces fetal polyuria. The complications most frequently associated with hydramnios (usually defined as an amniotic fluid index [AFI] greater than 25 cm) are placental abruption, uterine dysfunction, and postpartum hemorrhage (Cunningham, Leveno, Bloom, et al., 2014).

Infections are more common and more serious in pregnant women with diabetes than in those without the disease. Disorders of carbohydrate metabolism alter the normal resistance of the body to infection. The inflammatory response, leukocyte function, and vaginal pH are all affected. Vaginal infections, particularly monilial vaginitis, are more common. Urinary tract infections (UTIs) are also more prevalent. Infection is serious because it causes increased insulin resistance and may result in ketoacidosis.

Ketoacidosis (accumulation of ketones in the blood resulting from hyperglycemia and leading to metabolic acidosis) occurs most often during the second and third trimesters, when the diabetogenic effect of pregnancy is greatest. When the maternal metabolism is stressed by illness or infection, the woman is at increased risk for diabetic ketoacidosis (DKA). DKA can also be caused by poor compliance with treatment or the onset of previously undiagnosed diabetes (Moore et al., 2014). The use of beta-mimetic drugs such as terbutaline (Brethine) for tocolysis to treat preterm labor or corticosteroids given to enhance fetal lung maturation may also contribute to

the risk for hyperglycemia and subsequent DKA (Mercer, 2014; Simhan, Berghella, & Iams, 2014).

DKA may occur with blood glucose levels barely exceeding 200 mg/dl, compared with 300 to 350 mg/dl in the nonpregnant state. In response to stress factors such as infection or illness, **hyperglycemia** occurs as a result of increased hepatic glucose production and decreased peripheral glucose use. Stress hormones, which act to impair insulin action and further contribute to insulin deficiency, are released. Fatty acids are mobilized from fat stores to enter the circulation. As they are oxidized, ketone bodies are released into the peripheral circulation. The woman's buffering system is unable to compensate, and metabolic acidosis develops. The excessive blood glucose and ketone bodies result in osmotic diuresis with subsequent loss of fluid and electrolytes, volume depletion, and cellular dehydration. DKA is a medical emergency. Prompt treatment is necessary to prevent maternal coma or death. Ketoacidosis occurring at any time during pregnancy can lead to intrauterine fetal death. The incidence of DKA has decreased in recent years because of advances in clinical management and blood glucose monitoring (Inturrisi, Lintner, & Sorem, 2013). Currently it affects only about 1% to 2% of pregnant women with diabetes. The rate of intrauterine fetal demise (IUFD) with DKA, formerly approximately 35%, is now 10% or less (Moore et al., 2014) (Table 29-2).

TABLE 29-2 Differentiation of Hypoglycemia (Insulin Shock) and Hyperglycemia (Diabetic Ketoacidosis)

CAUSES	ONSET	SYMPTOMS	INTERVENTIONS
Hypoglycemia (insulin shock) Excess insulin Insufficient food (delayed or missed meals) Excessive exercise or work Indigestion, diarrhea, vomiting	Rapid (regular insulin) Gradual (modified insulin or oral hypoglycemic agents)	Irritability Hunger Sweating Nervousness Personality change Weakness Fatigue Blurred or double vision Dizziness Headache Pallor; clammy skin Shallow respirations Rapid pulse Laboratory values Urine: Negative for sugar and acetone Blood glucose: less than 70 mg/dl	Check blood glucose level when symptoms first appear. If blood glucose is less than 70 mg/dl, eat 2-4 glucose tablets or gel (8-16 g carbohydrate) immediately. Recheck blood glucose level in 15 minutes. If glucose level is still less than 70 mg/dl, eat 2-4 additional glucose tablets. Recheck blood glucose level in 15 minutes. If glucose level is still less than 70 mg/dl, notify health care provider immediately. If woman is unconscious, administer 50% dextrose IV push, 5% to 10% dextrose in water IV drip, or 1 mg glucagon intramuscularly. Obtain blood and urine specimens for laboratory testing.
Hyperglycemia (DKA) Insufficient insulin Excess or wrong kind of food Infection, injuries, illness Emotional stress Insufficient exercise	Slow (hours to days)	Thirst Nausea or vomiting Abdominal pain Constipation Drowsiness Dim vision Increased urination Headache Flushed, dry skin Rapid breathing Weak, rapid pulse Acetone (fruity) breath odor Laboratory values Urine: Positive for sugar and acetone Blood glucose: greater than 200 mg/dl	Notify primary health care provider. Administer insulin in accordance with blood glucose levels. Give IV fluids such as normal saline solution or one-half normal saline solution; potassium when urinary output is adequate; bicarbonate for pH <7. Monitor laboratory testing of blood and urine.

DKA, Diabetic ketoacidosis; IV, intravenous.

The risk of **hypoglycemia** (a less than normal amount of glucose in the blood) is also increased during pregnancy. Early in pregnancy, when hepatic production of glucose is diminished and peripheral use of glucose is enhanced, hypoglycemia occurs frequently, often during sleep. Later in pregnancy it may also result as insulin doses are adjusted to maintain **euglycemia** (a normal blood glucose level). Women with a prepregnancy history of severe hypoglycemia are at increased risk for severe hypoglycemia during gestation. Hypoglycemic episodes do not appear to have significant damaging effects on fetal well-being (see Table 29-2).

Fetal and Neonatal Risks and Complications

From the moment of conception the infant of a woman with diabetes faces an increased risk of complications that may occur during the antepartum, intrapartum, or neonatal periods. Infant morbidity and mortality rates associated with diabetic pregnancy are significantly reduced with strict control of maternal glucose levels before and during pregnancy.

Despite improvements in the care of pregnant women with diabetes, the perinatal mortality rate is three times higher for women with diabetes than for women who do not have this disease. Major causes of perinatal mortality are congenital malformations, respiratory distress syndrome, and extreme prematurity. IUFD (sometimes called *stillbirth*) remains a major concern. Approximately 4% of all stillbirths occur in women whose pregnancies are complicated by preexisting diabetes. Poor glycemic control is the most consistent finding in women who had a stillbirth. In addition to hyperglycemia, other causes of stillbirth include congenital abnormalities, placental insufficiency or fetal growth restriction, macrosomia or polyhydramnios, or obstructed labor (intrapartum stillbirth) (Reddy & Spong, 2014).

Hyperglycemia during the first trimester of pregnancy, when organs and organ systems are forming, is the main cause of diabetes-associated birth defects. Anomalies commonly seen in infants born to women with diabetes affect primarily the cardiovascular system and the central nervous system (CNS) (Moore et al., 2014) (see Chapter 35).

The fetal pancreas begins to secrete insulin at 10 to 14 weeks of gestation. The fetus responds to maternal hyperglycemia by secreting large amounts of insulin (hyperinsulinism). Insulin acts as a growth hormone, causing the fetus to produce excess stores of glycogen, protein, and adipose tissue and leading to increased fetal size, or macrosomia. Birth injuries are more common in infants born to mothers with diabetes compared

with mothers who do not have diabetes, and macrosomic fetuses have the highest risk for this complication. Common birth injuries associated with diabetic pregnancies include brachial plexus palsy, facial nerve injury, humerus or clavicle fracture, and cephalhematoma. Most of these injuries are associated with difficult vaginal birth and shoulder dystocia (Moore et al., 2014).

Hypoglycemia at birth is also a risk for infants born to mothers with diabetes (for further discussion of neonatal complications related to maternal diabetes, see Chapter 35).

CARE MANAGEMENT

Assessment and Nursing Diagnoses

When a pregnant woman with diabetes initiates prenatal care, a thorough evaluation of her health status is completed. At the initial visit a complete physical examination is performed to assess the woman's health status. In addition to the routine prenatal examination, specific efforts are made to assess the effects of the diabetes, especially retinopathy, nephropathy, peripheral and autonomic neuropathy, peripheral vascular and cardiac involvement (Gilbert, 2011).

Routine prenatal laboratory tests are performed, and baseline renal function may be assessed with a 24-hour urine collection for total protein excretion and creatinine clearance. Urinalysis and culture are performed to assess for the presence of a UTI, which is common in diabetic pregnancy. Because of the risk of coexisting thyroid disease, thyroid function tests may also be performed (see later discussion of thyroid disorders). The **glycosylated hemoglobin A_{1c}** level may be measured to assess recent glycemic control. With prolonged hyperglycemia some of the hemoglobin remains saturated with glucose for the life of the red blood cell (RBC). Therefore, a test for glycosylated hemoglobin provides a "diabetic report card," an evaluation of glycemic control over the previous 4 to 6 weeks. Hemoglobin A_{1c} levels greater than 6 indicate elevated glucose levels during the previous 4 to 6 weeks (Gilbert, 2011). Fasting blood glucose or random (1 to 2 hours after eating) glucose levels may be assessed during antepartum visits (Fig. 29-2).

Self-monitoring blood glucose records should be reviewed at every prenatal visit. Accuracy of reporting should be reviewed periodically by accessing the meter memory and addressed if falsification of blood glucose results is detected. Most meters can be downloaded using manufacturer software but this cannot replace logging, which affords more information for both the health care provider and the woman.

FIG 29-2 A, Clinic nurse collects blood to determine glucose level. B, Nurse interprets glucose value displayed by monitor. (Courtesy Dee Lowdermilk, UNC Ambulatory Care Clinics, Chapel Hill, NC.)

Potential nursing diagnoses for the woman with pregestational diabetes include the following:

- *Deficient Knowledge* related to
 - diabetic pregnancy, management, and potential effects on pregnant woman and fetus
 - insulin administration and its effects
 - hypoglycemia and hyperglycemia
 - diabetic diet
- *Anxiety, Grieving, Powerlessness, Disturbed Body Image, Situational Low Self-Esteem, Spiritual Distress, Ineffective Role Performance, Interrupted Family Processes* related to
 - stigma of being labeled “diabetic”
 - effects of diabetes and its potential sequelae on the pregnant woman and the fetus
- *Risk for Injury* to fetus related to
 - disruption of oxygen transfer from environment to fetus
 - birth trauma
- *Risk for Injury* to mother related to
 - improper insulin administration
 - hypoglycemia and hyperglycemia
 - cesarean or operative vaginal birth
 - postpartum infection

Interventions

Antepartum

Because of her high risk status, a woman with pregestational diabetes is monitored much more frequently and thoroughly than other pregnant women. During the first and second trimesters of pregnancy, her routine prenatal care visits are scheduled every 1 to 2 weeks. In the last trimester she will likely be seen 1 or 2 times each week. In the past, routine hospitalization for management of the diabetes, such as for insulin dose changes, was common. With the availability of improved home glucose monitoring and the growing reluctance of third-party payers to reimburse for hospitalization, pregnant women with diabetes generally now are managed as outpatients. Some client and family education and maternal and fetal assessment may be performed in the home, depending on the woman’s insurance coverage and care provider preference.

Achieving and maintaining constant euglycemia is the primary goal of medical therapy. Blood glucose levels should be in the range of 60 to 99 mg/dl before meals and 100 to 129 mg/dl when measured 1 hour after a meal (ADA, 2013a). Postmeal glucose levels at 2 hours should be no higher than 120 mg/dl (Landon et al., 2012) (Table 29-3). (Euglycemia is achieved

through a combination of diet, insulin, and exercise. Providing the woman with the knowledge, skill, and motivation she needs to achieve and maintain excellent blood glucose control is the primary nursing goal.

Achieving euglycemia requires commitment on the part of the woman and her family to make the necessary lifestyle changes, which can sometimes seem overwhelming. Maintaining tight blood glucose control necessitates that the woman follow a consistent daily schedule. She must get up and go to bed, eat, exercise, and take insulin at the same time each day. Blood glucose measurements are taken frequently to determine how well the major components of therapy (diet, insulin, and exercise) are working together to control blood glucose levels. The pregnant woman with diabetes should wear a medical identification bracelet at all times and carry insulin, syringes or pens, blood glucose meter, and glucose tablets with her whenever she is away from home.

Because the woman with pregestational diabetes is at increased risk for infections, eye problems, and neurologic changes, foot and general skin care are important. A daily bath that includes thorough perineal and foot care is important. For dry skin, lotions, creams, or oils can be applied. Tight clothing should be avoided. Shoes or slippers that fit properly should be worn at all times and are best worn with socks or stockings. Feet should be inspected regularly; toenails should be cut straight across, and professional help should be sought for any foot problems. Extremes of temperature should be avoided.

Diet. The woman with pregestational diabetes has usually had nutrition counseling regarding managing her diabetes. However, because pregnancy produces special nutritional concerns and needs, the woman must be educated to incorporate these changes into dietary planning. The woman who has “controlled” her diabetes for several years may find it difficult to adjust to the changes in her insulin and dietary needs mandated by pregnancy. Nutritional counseling is usually provided by a registered dietitian. Counseling should address general nutrition principles appropriate for all pregnant women as well as diabetes-specific nutritional needs.

Dietary management during diabetic pregnancy must be based on blood glucose levels. The diet is individualized to allow for increased fetal and metabolic requirements, with consideration of such factors as prepregnancy weight and dietary habits, overall health, ethnic background, lifestyle, stage of pregnancy, knowledge of nutrition, and insulin therapy. The dietary goals are to provide weight gain consistent with a normal pregnancy, prevent ketoacidosis, and minimize wide fluctuation of blood glucose levels.

For women with a BMI of 22 to 27, dietary counseling includes advice to consume about 35 kcal/kg of ideal body weight per day (Landon et al., 2012). In contrast, for obese women with a BMI of 30 or greater, experts recommend that the caloric intake total 25 kcal/kg of actual weight per day or less (Moore et al., 2014). The average diet includes 2200 calories (first trimester) to 2500 calories (second and third trimesters). Total calories may be distributed among three meals and one evening snack or, more commonly, three meals and two or three snacks. Meals should be eaten on time and never skipped. Going more than 4 hours without food intake increases the risk for episodes of hypoglycemia. Snacks must be planned carefully

TABLE 29-3 Target Blood Glucose Levels During Pregnancy

TIME OF DAY	TARGET PLASMA GLUCOSE LEVEL (mg/dl)
Premeal or fasting	60-99
Postmeal (1 hr)	100-129
Postmeal (2 hr)	≤120

Data from American Diabetes Association (ADA). (2013). Standards of medical care in diabetes—2013. *Diabetes Care*, 36(Suppl 1), S11-S65; Landon, M., Catalano, P., & Gabbe, S. (2012). Diabetes mellitus complicating pregnancy. In S. Gabbe, J. Niebyl, & J. Simpson (Eds.), *Obstetrics: Normal and problem pregnancies* (6th ed.). Philadelphia: Saunders.

in accordance with insulin therapy to prevent fluctuations in blood glucose levels. A large bedtime snack of at least 25 g of complex carbohydrate with some protein or fat is recommended to help prevent hypoglycemia and starvation ketosis during the night (Moore et al.).

The ideal diet is composed of 55% carbohydrate, 20% protein, and 25% fat, with less than 10% as saturated fat (Cunningham, et al., 2014) (see Teaching for Self-Management: Dietary Management for Pregnant Women with Diabetes). Simple carbohydrates are limited. Complex carbohydrates that are high in fiber content are recommended because the starch and protein in such foods help regulate the blood glucose level by more sustained glucose release (Gilbert, 2011; Moore et al., 2014).

TEACHING FOR SELF-MANAGEMENT

Dietary Management for Pregnant Women with Diabetes

- Follow the prescribed diet plan.
- Eat a well-balanced diet, including daily food requirements for a normal pregnancy.
- Divide daily food intake among three meals and two or three snacks, depending on individual needs.
- Eat a substantial bedtime snack to prevent a severe drop in blood glucose level during the night.
- Take daily vitamins and iron as prescribed by the health care provider.
- Avoid foods high in refined sugar.
- Eat consistently each day; never skip meals or snacks.
- Eat foods high in dietary fiber.
- Avoid alcohol and nicotine; limit caffeine.
- Avoid excessive use of nonnutritive sweeteners.

Exercise. Although studies have shown that exercise enhances the use of glucose and decreases insulin need in women without diabetes, data regarding exercise in women with pregestational diabetes are limited. Any prescription of exercise during pregnancy for women with diabetes should be given by the primary health care provider and monitored closely to prevent complications. Regular exercise may be contraindicated in women with diabetes who also have uncontrolled hypertension, advanced retinopathy, or severe autonomic or peripheral neuropathy (Gilbert, 2011).

When exercise is prescribed by the health care provider as part of the treatment plan, specific instructions are given to the woman. Aerobic exercise with resistance training for at least 30 minutes most days of the week is the best type of exercise (Gilbert, 2011). Other exercises that may be recommended are non-weight-bearing activities such as arm exercises or use of a recumbent bicycle. The best time for exercise is after meals, when the blood glucose level is rising. To monitor the effect of insulin on blood glucose levels the woman can measure her blood glucose before, during, and after exercise. The onset of hypoglycemia may be delayed in women with pregestational diabetes, so blood glucose should be monitored for several hours after exercising. Exercising with another person is prudent for safety reasons. Women should be advised to avoid exercise if they have positive urine ketones or a blood glucose greater than 250 mg/dl because hyperglycemia and ketosis can worsen with physical activity.

⚡ SAFETY ALERT

Uterine contractions may occur during exercise. The woman should be advised to stop exercising immediately if they are detected, drink two to three glasses of water, and lie down on her side for an hour. If the contractions continue, she should contact her health care provider.

Insulin Therapy. Adequate insulin is the primary factor in the maintenance of euglycemia during pregnancy, thus ensuring proper glucose metabolism of the woman and fetus. Insulin requirements during pregnancy change dramatically as the pregnancy progresses, necessitating frequent adjustments in the dose. In the first trimester, from weeks 3 to 7 of gestation, insulin requirements are increased, followed by a decrease between weeks 7 and 15 of gestation. The commonly prescribed insulin dose is 0.7 units/kg in the first trimester for women with type 1 diabetes. During the second and third trimesters, because of insulin resistance, the dose must be increased significantly to maintain target glucose levels. Insulin requirements normally peak at 36 weeks of gestation and drop significantly after that (Moore et al., 2014).

For the woman with type 1 pregestational diabetes who has typically been accustomed to one injection per day of intermediate-acting insulin, multiple daily injections of mixed insulin are a new experience. The woman with type 2 diabetes previously treated with oral hypoglycemics is faced with the task of learning to self-administer injections of insulin. The nurse is instrumental in educating and supporting women with pregestational diabetes in regard to insulin administration and adjustment of the insulin dose to maintain euglycemia (see Teaching for Self-Management: Self-Administration of Insulin and Box 29-1).

TEACHING FOR SELF-MANAGEMENT

Self-Administration of Insulin

Procedure for Mixing NPH (Intermediate-Acting) and Rapid-Acting Insulin

- Wash hands thoroughly and gather supplies. Be sure the insulin syringe corresponds to the concentration of insulin you are using.
- Check the insulin bottle to be certain it is the appropriate type, and check the expiration date.
- Gently rotate (do not shake) the insulin vial to mix the insulin.
- Wipe off the rubber stopper of each vial with alcohol.
- Draw into syringe the amount of air equal to total dose.
- Inject air equal to NPH dose into NPH vial. Remove syringe from vial.
- Inject air equal to rapid-acting insulin dose into vial and leave syringe in the vial.
- Invert insulin bottle and withdraw insulin dose.
- Without adding more air to NPH vial, carefully withdraw NPH dose.

Procedure for Self-Injection of Insulin

- Select proper injection site.
- Injection site should be clean. No need to use alcohol. If alcohol is used, let it dry before injecting.
- Puncture the skin at a 90-degree angle.
- Slowly inject the insulin.
- As you withdraw the needle, cover the injection site with sterile gauze and apply gentle pressure to prevent bleeding.
- Record insulin dose and time of injection.

Since 1982 most insulin preparations have been produced by inserting portions of deoxyribonucleic acid (DNA) (“recombinant DNA”) into special laboratory-cultivated bacteria or yeast cells. The cells then produce synthetic human insulin (Humulin), which is less likely to cause antibody formation than animal-derived (beef or pork) insulin. More recently insulin products called *insulin analogues*, in which the structure differs slightly from human insulin, have been produced. This small alteration in insulin structure results in changes in the onset and peak of action of the medication. The most commonly used insulin preparations include rapid acting, short acting, intermediate acting, and long acting (Landon et al., 2012) (Table 29-4). Mixtures of short- and intermediate-acting insulins in several proportions are also available but usually are not in the correct percentages to be effective in pregnancy. Therefore, they are rarely used.

BOX 29-1 Helpful Hints for Using Insulin

- The most common type of insulin used during pregnancy is a biosynthetic human insulin (Humulin) made by programming *Escherichia coli* bacteria to produce insulin.
- Insulin is classified either as rapid acting, short acting, intermediate acting, or long acting (see Table 29-4).
- Unused vials of insulin should be stored in the refrigerator until reaching their expiration date. Insulin should not be frozen. Vials currently in use can be stored at room temperature for up to a month. They should not be left in a car or exposed to extreme heat as in the sun.
- Regular insulin can be mixed with NPH insulin in the same syringe. Lispro insulin can also be mixed in a syringe with NPH insulin. Once mixed, the syringe can be used immediately or stored for future use. If it is used later, the syringe should be rotated 20 times before injection.
- Glargine insulin is usually administered at bedtime. It cannot be mixed with any other insulin in the same syringe. Prepared syringes are stable for 2 weeks in the refrigerator.
- Insulin may be administered by pen injector, jet injector, or insulin pump, in addition to syringe.
- The abdomen is the preferred injection site because insulin is best absorbed there. Other possible injection sites are the upper outer arm (not the deltoid area), the thighs, and the buttocks.
- Each injection should be given 2 inches from the previous injection in one quadrant before moving to another quadrant.

Lispro (Humalog) and aspart (NovoLog) are commonly prescribed rapid-acting insulins with a shorter duration of action than regular insulin. They are preferred for use during pregnancy (Landon et al., 2012). Advantages of rapid-acting insulins include convenience because they are injected immediately before mealtime, produce less hyperglycemia after meals, and cause fewer hypoglycemic episodes in some people. Because their effects last only 3 to 5 hours, most clients require a longer-acting insulin in addition to the rapid-acting insulin to maintain optimal blood glucose levels (Gilbert, 2011; Landon et al.) (see Table 29-4).

Glargine (Lantus) is long-acting insulin lasting approximately 24 hours. Small amounts of glargine insulin are released slowly, with no pronounced peak. This preparation is most often used with women who have insulin-resistant diabetes (type 2) requiring high doses of long-acting insulin. Glargine insulin is combined with rapid-acting insulin to prevent hypoglycemia. Glargine insulin is not approved for use in pregnancy but appears to be safe. When it is administered with rapid- or short-acting insulin, unpredictable spikes in insulin levels and resulting hypoglycemia appear to occur less often (Landon et al., 2012) (see Table 29-4).

Most women with insulin-dependent diabetes are managed with three or four injections per day (Landon et al., 2012). An insulin regimen that works well for pregnancy is to administer short-acting insulin before each meal and longer-acting insulin at bedtime. This regimen, referred to as *basal/bolus insulin*, provides a more physiologic profile (Gilbert, 2011; Landon et al.). Basal, or long-acting insulin, provides glucose control between meals and reduces hepatic glucose production. Bolus, or prandial insulin (rapid or short acting), provides coverage for glucose with meals (Gilbert). The ratio of basal to bolus is usually 50/50 or 40/60 in pregnancy (Landon et al.).

Continuous subcutaneous insulin infusion (CSII) systems are used increasingly during pregnancy. The insulin pump is designed to mimic more closely the function of the pancreas in secreting insulin (Fig. 29-3). This portable battery-powered device is worn similar to a pager during most daily activities. The pump infuses rapid-acting insulin (usually lispro or aspart) (Landon et al., 2012) at a set basal rate. It has the capacity to deliver up to 24 different basal rates in 24 hours although only three or four rates are necessary to provide individualized

TABLE 29-4 Common Insulin Preparations

TYPE OF INSULIN	EXAMPLES			
	GENERIC (TRADE) NAME	ONSET OF ACTION	PEAK OF ACTION	DURATION OF ACTION
Rapid acting	Lispro (Humalog)	15 min	30-90 min	4-5 hr
	Aspart (NovoLog)	15 min	1-3 hr	3-5 hr
Short acting	Humulin R	30 min	2-4 hr	5-7 hr
	Novolin R	30 min	2.5-5 hr	6-8 hr
Intermediate acting	Humulin NPH	1-2 hr	6-12 hr	18-24 hr
	Novolin N	1.5 hr	4-20 hr	24 hr
	Humulin Lente	1-3 hr	6-12 hr	18-24 hr
	Novolin L	2.5 hr	7-15 hr	22 hr

FIG 29-3 Insulin pump shows basal rate for pregnant women with diabetes. (Courtesy MiniMed, Inc., Sylmar, CA.)

glycemic control. The pump also delivers bolus doses of insulin before meals to control postprandial blood glucose levels or to correct elevations in blood glucose. A fine-gauge plastic catheter is inserted into subcutaneous tissue, usually in the abdomen, and attached to the pump syringe by connecting tubing. The subcutaneous catheter and connecting tubing are changed every 2 to 3 days. Although the insulin pump is convenient and generally provides good glycemic control, complications such as pump failure, precipitation of insulin inside the pump mechanism, abscess formation, and poor uptake from the infusion site still can occur. To safely use the pump during pregnancy, the woman must monitor her blood glucose levels frequently and be able to count carbohydrates appropriately. Therefore, use of the insulin pump requires a knowledgeable, motivated woman; skilled health care providers; and prompt 24-hour availability of emergency assistance (Gilbert, 2011).

Self-Monitoring of Blood Glucose (SMBG). Blood glucose testing at home using a glucose meter is considered the standard of care for monitoring blood glucose levels during pregnancy. It provides the most important tool available to the woman to assess her degree of glycemic control. The newer meters are calibrated to provide plasma (rather than whole blood) glucose values. The nurse must be knowledgeable about the specific glucose meter that the woman uses in order to troubleshoot problems, assess accuracy of technique, and determine accuracy of reported results. To perform blood glucose monitoring a drop of blood is obtained and placed on a test strip. Most glucose meters allow the user to obtain the blood sample from the forearm or palm rather than a finger. Fingersticks are recommended during pregnancy, however, because use of other sites can affect the accuracy of results. After a specified amount of time the glucose level is displayed by the meter (see Teaching for Self-Management: Self-Monitoring of Blood Glucose). Blood glucose levels are routinely measured at various times throughout the day such as before breakfast, lunch, and dinner; 1 to 2 hours after each meal; at bedtime; and in the middle of the night if nighttime insulin is being adjusted. When any adjustment in the insulin dose or diet is made, more frequent measurement of blood glucose is warranted. If nausea, vomiting, or diarrhea occurs or if infection is present, the woman is asked to monitor her blood glucose levels more closely than usual.

TEACHING FOR SELF-MANAGEMENT

Self-Monitoring of Blood Glucose (SMBG)

- Gather supplies, check expiration date, and read instructions on testing materials. Prepare glucose meter for use according to the manufacturer's directions.
- Wash hands in warm water (warmth increases circulation).
- Select site on side of any finger (all fingers should be used in rotation).
- Pierce site with lancet (may use automatic spring-loaded, puncturing device). Cleaning the site with alcohol is not necessary.
- Drop hand down to side; with other hand gently squeeze finger from hand to fingertip.
- Allow blood to be drawn into glucose test strip.
- Record results displayed.
- Repeat as instructed by the health care provider and as needed for signs of hypoglycemia or hyperglycemia.

Target levels of blood glucose during pregnancy are lower than nonpregnant values (see Table 29-3). Acceptable fasting levels are generally between 60 and 99 mg/dl, and peak (1 hour) postmeal levels should be between 100 and 129 mg/dl (ADA, 2013a). Two-hour postmeal levels should be 120 mg/dl or less (Landon et al., 2012). The woman should be told to report recurrent episodes of hypoglycemia (less than 70 mg/dl) and hyperglycemia (more than 200 mg/dl) to her health care provider so adjustments in diet or insulin therapy can be made.

Pregnant women with diabetes are much more likely to develop hypoglycemia than hyperglycemia. Most episodes of mild or moderate hypoglycemia can be treated with oral intake of 15 g of carbohydrate, preferably in the form of commercial glucose tablets (Gilbert, 2011) (see Teaching for Self-Management: Treatment for Hypoglycemia). If severe hypoglycemia occurs and the woman experiences a decrease in or loss of consciousness or an inability to swallow, she will require a parenteral injection of glucagon or intravenous (IV) glucose. Because hypoglycemia can develop rapidly and impaired judgment can be associated with even moderate episodes, family members, friends, and work colleagues must be able to recognize signs and symptoms quickly and initiate proper treatment if necessary.

Some women with long-term pregestational diabetes develop hypoglycemia unawareness, a condition in which early symptoms of hypoglycemia are not recognized. Women with hypoglycemia unawareness should test their blood glucose levels more frequently, especially during the night, in order to detect hypoglycemia earlier. Glycemic thresholds in women with hypoglycemia unawareness should be higher than for other women with diabetes in order to avoid dangerous hypoglycemia. The threshold for recognition of hypoglycemia should be determined at the first prenatal visit so that individual guidelines for hypoglycemia can be determined and the woman and her family educated.

Hyperglycemia is less likely than hypoglycemia to occur, although it can rapidly progress to DKA, which is associated with an increased risk of fetal death (Landon et al., 2012). Women and family members should be particularly alert for signs and symptoms of hyperglycemia when infections or other illnesses occur (see Teaching for Self-Management: What to Do When Illness Occurs).

TEACHING FOR SELF-MANAGEMENT

Treatment for Hypoglycemia

- Be familiar with signs and symptoms of hypoglycemia (nervousness, headache, fatigue, shaking, irritability, tachycardia, hunger, blurred vision, sweaty skin, tingling of mouth or extremities).
- Check blood glucose level immediately when hypoglycemic symptoms occur.
- If blood glucose is less than 70 mg/dl, immediately eat 2 to 4 glucose tablets or gel (8-16 g carbohydrate). If glucose tablets or gel are not available, then other simple carbohydrates (15 g) can be eaten instead. Examples are:
 - ½ cup (4 oz) unsweetened orange juice
 - ½ cup (4 oz) regular (not diet) soda
 - 5 or 6 hard candies
 - 1 cup (8 oz) skim milk
- Rest for 15 minutes, and then recheck blood glucose.
- If glucose level is greater than 70 mg/dl, eat a meal to stabilize the sugar level.
- If glucose level is still less than 70 mg/dl, eat 2 to 4 additional glucose tablets.
- Wait 15 minutes, and then recheck blood glucose. If the level is still less than 70 mg/dl, notify your health care provider immediately.
- If nausea related to hypoglycemia prevents ingestion of carbohydrate, inject 0.15 mg glucagon intramuscularly. This will elevate the blood glucose enough to allow eating.

TEACHING FOR SELF-MANAGEMENT

What to Do When Illness Occurs

- Be sure to take insulin even if unable to eat or appetite is less than normal. (Insulin needs are increased with illness or infection.)
- Call the health care provider and relay the following information:
 - Symptoms of illness (e.g., nausea, vomiting, diarrhea)
 - Elevated temperature
 - Most recent blood glucose level
 - Urine ketones
 - Time and amount of last insulin dose
- Increase oral intake of fluids to prevent dehydration.
- Rest as much as possible.
- If you are unable to reach your health care provider and blood glucose exceeds 200 mg/dl with moderate urine ketones present, seek emergency treatment at the nearest health care facility. Do not attempt to self-treat for this condition.

Urine Testing. Urine testing for glucose is not beneficial during pregnancy. Because of the lowered renal threshold for glucose, the degree of glycosuria does not accurately reflect the blood glucose level. However, urine testing for ketones continues to have a place in diabetes management. Monitoring for urine ketones may detect inadequate caloric or carbohydrate intake or skipped meals or snacks. Testing may also be performed when illness occurs or when the blood glucose level is greater than 200 mg/dl (Gilbert, 2011).

Complications Requiring Hospitalization. Occasionally hospitalization is necessary to regulate insulin therapy and stabilize glucose levels. Infection, which can lead to hyperglycemia and DKA, is an indication for hospitalization, regardless

of gestational age. Hospitalization during the third trimester for close maternal and fetal observation may be indicated for women whose diabetes is poorly controlled. In addition, women with diabetes are more likely than women who do not have diabetes to also have preexisting hypertension or develop preeclampsia, which may necessitate hospitalization (Gilbert, 2011).

Fetal Surveillance. Diagnostic techniques for fetal surveillance are often performed to assess fetal growth and well-being. The goals of fetal surveillance are to detect fetal compromise as early as possible and prevent IUFD or unnecessary preterm birth.

Early in pregnancy the estimated date of birth is determined. A baseline sonogram is obtained during the first trimester to assess gestational age. Follow-up ultrasound examinations are usually performed during the pregnancy (as often as every 3 to 4 weeks) to monitor fetal growth; estimate fetal weight; and detect hydramnios, macrosomia, and congenital anomalies.

Because the fetus of a woman with diabetes is at increased risk for neural tube defects such as spina bifida, anencephaly, or microcephaly, measurement of maternal serum alpha-fetoprotein is performed between 15 and 20 weeks of gestation (ideally between 16 and 18 weeks of gestation) (Wapner, 2014). In addition, a detailed ultrasound study to examine the fetus for neural tube defects and other anomalies should be performed between 18 and 20 weeks of gestation (Moore et al., 2014).

Ultrasound measurement of the fetal nuchal translucency (NT) in conjunction with maternal serum screening late in the first trimester (between 11 and 14 weeks of gestation) has been found to increase the detection of heart defects and other anomalies in women with pregestational diabetes (Miller, de Veciana, Turan, et al., 2013). Fetal echocardiography may be performed between 20 and 22 weeks of gestation to detect cardiac anomalies, especially in women who had less than desirable glucose control early in pregnancy, as demonstrated by a hemoglobin A_{1c} level greater than 6% at the first prenatal visit (Gilbert, 2011; Moore et al., 2014). Some practitioners repeat this fetal surveillance test at 34 weeks of gestation. Doppler studies of the umbilical artery may be performed in women with vascular disease to detect placental compromise.

Most fetal surveillance measures are concentrated in the third trimester, when the risk of fetal compromise is greatest. The goals of antepartum testing during the third trimester are to monitor fetal growth and ensure fetal well-being. Pregnant women should be taught how to make daily fetal movement counts, beginning at 28 weeks of gestation (see Chapter 26) (Moore et al., 2014).

The nonstress test (NST) is the preferred primary method to evaluate fetal well-being. It is usually begun by 32 weeks of gestation and performed at least twice weekly. If the NST is nonreactive, a biophysical profile or contraction stress test will be performed. Testing often begins earlier, between 28 and 32 weeks of gestation, in women who have vascular disease or poor glucose control (Landon et al., 2012) (see Chapter 26).

Determination of Birth Date and Mode of Birth. The optimal time for birth is between 39 and 40 weeks of gestation, as long as good metabolic control is maintained and parameters of antepartum fetal surveillance remain within normal limits. Reasons to proceed with birth before term include poor

metabolic control, coexisting hypertension, and nonreassuring responses to fetal testing (Moore et al., 2014).

Many practitioners plan for elective labor induction between 38 and 40 weeks of gestation.

To confirm fetal lung maturity an amniocentesis should be performed when birth will occur before 38 weeks of gestation. For the pregnancy complicated by diabetes, fetal lung maturation is best predicted by the amniotic fluid phosphatidylglycerol (greater than 3%). If the fetal lungs are still immature, birth should be postponed until 40 weeks of gestation as long as fetal assessment test results remain reassuring. After that time, however, the benefits of conservative management are outweighed by the increasing risk of fetal compromise if the pregnancy is allowed to continue. Birth, despite poor fetal lung maturity, may be necessary when testing suggests fetal compromise or worsening maternal condition, such as deteriorating renal function or severe preeclampsia (Moore et al., 2014).

Although vaginal birth is expected for most women with pregestational diabetes, the cesarean rate for these women is as high as 80% (Cunningham et al., 2014). The American College of Obstetricians and Gynecologists (ACOG) recommends that cesarean birth be considered when the estimated fetal weight is expected to be greater than 4500 g in an attempt to reduce the risk of shoulder dystocia. This recommendation may reduce the risk of shoulder dystocia to some degree for an individual woman, but the benefit to a larger group of women is unclear (Moore et al., 2014). Fetal distress and induction failures before term also contribute to the high rate of cesarean birth in these women (Gilbert, 2011).

Intrapartum

During the intrapartum period the woman with pregestational diabetes must be monitored closely to prevent complications related to dehydration, hypoglycemia, and hyperglycemia. An IV line is inserted for infusion of a maintenance fluid. Initially this infusion will be either normal saline or lactated Ringer's solution. Once active labor begins or glucose levels fall below 70 mg/dl, a piggybacked pump-controlled infusion of a solution containing 5% dextrose should be added. The dextrose provides the energy (calories) necessary for the woman to accomplish the work and manage the stress of labor and birth. Most commonly, insulin is administered by continuous infusion, piggybacked into the main IV line. Only rapid- or short-acting insulin can be administered intravenously. Insulin may also be given intermittently by subcutaneous injection as needed to maintain glucose levels within the target range. Determinations of blood glucose levels are made every hour, and fluids and insulin are adjusted to maintain the blood glucose level between 90 and 110 mg/dl (Moore et al., 2014). Maintaining this target glucose level is essential because hyperglycemia during labor can cause metabolic problems in the neonate, particularly hypoglycemia (Landon et al., 2012).

During labor continuous fetal heart monitoring is necessary. The woman should assume an upright or side-lying position during labor to prevent supine hypotension caused by a large fetus or polyhydramnios. Labor, whether spontaneous or induced, is allowed to progress as long as expected rates of cervical dilation and fetal descent are maintained, and fetal well-being is evident. Failure to progress in labor may indicate

a macrosomic infant and cephalopelvic disproportion, necessitating a cesarean birth. The woman is observed and treated during labor for complications of diabetes such as hyperglycemia, ketosis, and ketoacidosis. During second-stage labor, shoulder dystocia may occur with the birth of a macrosomic infant (see Chapter 35). A neonatologist, pediatrician, or neonatal nurse practitioner will likely be present at the birth to initiate assessment and neonatal care.

If a cesarean birth is planned, it should be scheduled in the early morning to facilitate glycemic control. Women should take their full dose of insulin the night before surgery. No morning insulin is given on the day of surgery, and the woman is given nothing by mouth. Epidural anesthesia is recommended because hypoglycemia can be detected earlier if the woman is awake. After surgery, glucose levels should be monitored carefully.

Postpartum

During the first 24 hours postpartum, insulin requirements decrease substantially because the major source of insulin resistance, the placenta, has been removed. Women with type 1 diabetes usually only require 50% to 60% of their pregnancy insulin dose on the first postpartum day, provided they are eating a full diet (Gilbert, 2011). Women who give birth by cesarean may need an IV infusion of glucose and insulin until they resume a regular diet (Moore et al., 2014). A subcutaneous dose of insulin should be given at least an hour before discontinuing IV insulin.

After birth, several days may be required to reestablish carbohydrate homeostasis (see Fig. 29-1, *D* and *E*). Blood glucose levels are carefully monitored in the postpartum period and the insulin dose is adjusted appropriately. The woman who has insulin-dependent diabetes must realize the importance of eating on time even if the baby needs feeding or other pressing demands exist. Women with type 2 diabetes may resume taking their prepregnancy oral hypoglycemics if these medications are compatible with breastfeeding and provide adequate glycemic control.

Possible postpartum complications include preeclampsia or eclampsia, hemorrhage, and infection. Hemorrhage is a possibility if the mother's uterus was overdistended (hydramnios, macrosomic fetus) or overstimulated (oxytocin induction). Postpartum infections such as endometritis are more likely to occur in women with diabetes than in women who do not have diabetes.

Mothers are encouraged to breastfeed. In addition to the advantages of maternal satisfaction and pleasure, breastfeeding has an antidiabetogenic effect for the children of women with diabetes and for women with gestational diabetes. Breastfed infants of women with diabetes are also less likely to become obese (Moore et al., 2014). These benefits are important because a child born to a mother with type 2 diabetes has a 70% chance of also developing type 2 diabetes later in life (Gilbert, 2011).

Insulin requirements in breastfeeding women may be one half of prepregnancy levels because of the carbohydrate used in human milk production. Because glucose levels are lower than normal, breastfeeding women are at increased risk for hypoglycemia, especially in the early postpartum period and after breastfeeding sessions, particularly after late-night

nursing (Gilbert, 2011; Moore et al., 2014). Breastfeeding mothers with diabetes may be at increased risk for mastitis and yeast infections of the breast. The insulin dose, which is decreased during lactation, must be recalculated at weaning (see Fig. 29-1, F).

The mother may have early breastfeeding difficulties. Poor metabolic control may delay lactogenesis and contribute to decreased milk production (Moore et al., 2014). Initial contact with and opportunity to breastfeed the infant may be delayed for mothers who gave birth by cesarean or if infants are placed in neonatal intensive care units or special care nurseries for observation during the first few hours after birth. Support and assistance from nursing staff and lactation specialists can facilitate the mother's early experience with breastfeeding and encourage her to continue.

The new mother needs information about family planning and contraception. Although family planning is important for all women, it is essential for the woman with diabetes in order to safeguard her own health and promote optimal outcomes in future pregnancies. The risks and benefits of contraceptive methods should be discussed with the mother and her partner before discharge from the hospital. Barrier methods are often recommended as safe, inexpensive options that have no inherent risks for women with diabetes. An intrauterine device (IUD) may also be used without concerns about an increased risk of infection (Landon et al., 2012).

Use of oral contraceptives by women with diabetes is controversial because of the possible increased risk of thromboembolic and vascular complications and the effect on carbohydrate metabolism (Landon et al., 2012). In nonsmoking women who are less than 35 years old and do not have vascular disease, combination low-dose oral contraceptives may be prescribed. Progestin-only oral contraceptives also may be used because they do not significantly affect glucose levels (Cunningham et al., 2014). Close monitoring of blood pressure and lipid levels is necessary to detect complications (Landon et al., 2012).

Opinion is divided about the use of long-acting parenteral progestins, such as Depo-Provera. Some health care providers recommend their use, particularly in women who are noncompliant with daily dosing oral contraceptives. In contrast, other health care providers believe this method may adversely affect glycemic control. In addition, although Depo-Provera may lower serum triglyceride and high-density lipoprotein (HDL) cholesterol levels, it does not lower total cholesterol or low-density lipoprotein (LDL) levels. For this reason it is not recommended as a first-choice method for contraception for women with diabetes (Landon et al., 2012). Implants that contain only progesterone (e.g., Implanon, Nexplanon) can be used by many women with diabetes because they do not significantly affect glucose levels (Cunningham et al., 2014).

Transdermal (patch) and transvaginal (vaginal ring) are newer contraceptive options, particularly effective in women who prefer weekly or every-third-week dosing, respectively. For women weighing more than 90 kg (198 lb) the contraceptive failure rate with transdermal administration is higher than in normal-weight women. Therefore, this method is contraindicated in obese women. In addition, women who choose the patch as their contraceptive method may be at risk for developing thromboembolic disease (Cunningham et al., 2014).

The risks associated with pregnancy increase with the duration and severity of diabetes. In addition, pregnancy may contribute to the vascular changes associated with diabetes. This information needs to be thoroughly discussed with the woman and her partner. Sterilization is often recommended for the woman who has completed her family, who has poor metabolic control, or who has significant vascular problems. Vasectomy for the partner is very effective and is safer than surgical sterilization in the woman with diabetes.

GESTATIONAL DIABETES MELLITUS

Gestational diabetes mellitus (GDM) complicates approximately 7% of all pregnancies (a range of 1% to 14%, depending on the population and the type of diagnostic test used) and accounts for 200,000 cases per year (ADA, 2013b). It occurs more often now worldwide than in the past, probably because of increasing rates of overweight and obesity (ACOG, 2013). According to White's classification system, women with GDM fall into classes A₁ and A₂ (see Table 29-1). It is more likely to occur among Hispanic, African-American, Native-American, Asian, and Pacific Islander women than Caucasians and is likely to recur in future pregnancies; the risk for development of overt diabetes later in life is also increased (ACOG). This tendency is especially true of women whose GDM is diagnosed early in pregnancy (Landon et al., 2012). Classic risk factors for GDM include a family history of diabetes and a previous pregnancy that resulted in an unexplained stillbirth or the birth of a malformed or macrosomic fetus. Other risk factors for GDM include obesity, hypertension, glycosuria, and maternal age older than 25 years. However, more than half of all women diagnosed with GDM do not have these risk factors (Landon et al.).

Although most women are screened for GDM between 24 and 28 weeks of gestation, those with strong risk factors should be screened earlier in pregnancy. Women with morbid obesity, a strong family history of diabetes, a history of GDM in a previous pregnancy, or a history of giving birth to a macrosomic stillborn infant or an infant weighing more than 4500 g are candidates for early screening. If the early screening results are normal, they should be rescreened at 24 to 28 weeks of gestation (Landon et al., 2012).

GDM is usually diagnosed during the second half of pregnancy. As fetal nutrient demands rise during the late second and the third trimesters, maternal nutrient ingestion induces greater and more sustained levels of blood glucose. At the same time maternal insulin resistance is also increasing because of the insulin-antagonistic effects of the placental hormones, cortisol, and insulinase. Consequently maternal insulin demands rise as much as threefold. Most pregnant women are capable of increasing insulin production to compensate for insulin resistance and maintain euglycemia. However, when the pancreas is unable to produce sufficient insulin or the insulin is not used effectively, GDM can result.

Fetal Risks

No increase in the incidence of birth defects has been found among infants of women who develop GDM after the first trimester because the critical period of organ formation has already passed by that time (Moore et al., 2014). Obesity

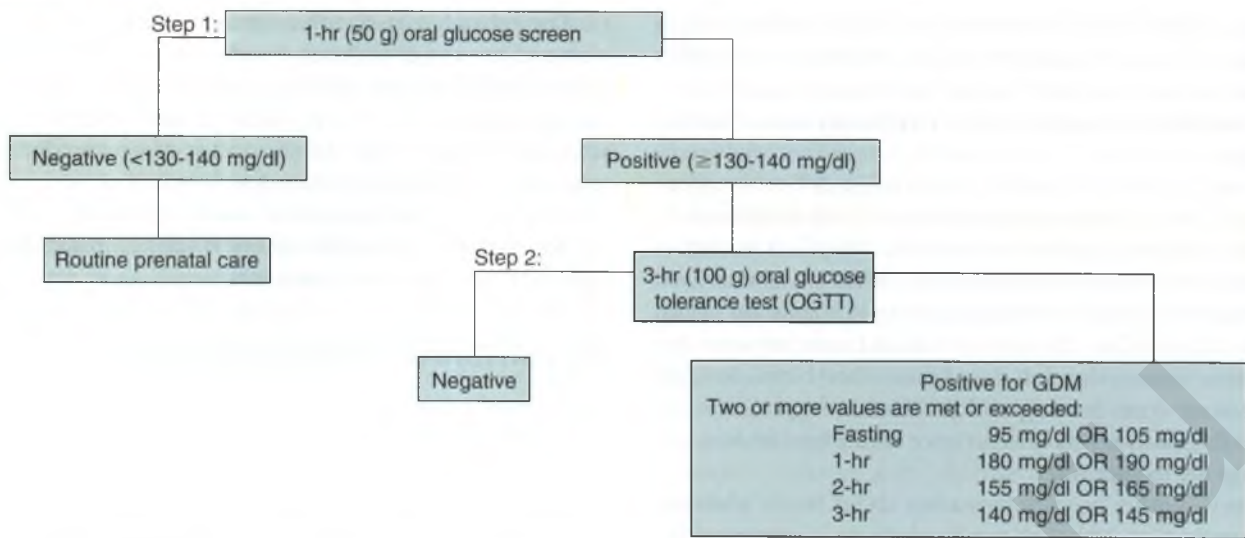

FIG 29-4 Two-step method for diagnosing gestational diabetes mellitus (GDM), recommended by the American College of Obstetricians and Gynecologists (ACOG). Data from American College of Obstetricians and Gynecologists (ACOG). (2013). *Gestational diabetes mellitus*. ACOG practice bulletin no. 137. Washington, DC: ACOG.

(BMI >30) also contributes to congenital defects even in the absence of GDM. As with pregestational diabetes, infants born to women with GDM are at risk for macrosomia and associated risks for birth trauma and electrolyte imbalances including neonatal hypoglycemia

CARE MANAGEMENT

Screening for Gestational Diabetes Mellitus

All pregnant women not known to have pregestational diabetes should be screened for GDM by history, clinical risk factors, or laboratory screening of blood glucose levels (ACOG, 2013). Based on history and clinical risk factors, some women are at low risk for developing GDM; therefore, glucose testing for this population may not be cost-effective. This group includes normal-weight women younger than 25 years of age who have no family history of diabetes, are not members of an ethnic or a racial group known to have a high prevalence of the disease, and have no history of abnormal glucose tolerance or adverse obstetric outcomes usually associated with GDM. However, only 10% of pregnant women meet all of these criteria (ACOG).

Two different blood glucose screening methods for GDM are used in the United States. The ACOG still recommends the two-step screening method that has been used for many years. The first step is a screen consisting of a 50-g oral glucose load followed by a plasma glucose measurement 1 hour later. The woman need not be fasting when the screen is done. A glucose value of 130 to 140 mg/dl is considered a positive screen. An initial positive screening result is followed by step 2, a 3-hour (100-g) oral glucose tolerance test (OGTT) on another day. The ACOG recommends use of the two-step screening procedure because there is no evidence that the one-step method leads to clinically significant improvement in maternal or newborn outcomes. Use of the one-step method does, however, significantly increase health care costs because more women will be diagnosed with GDM and thus will require more visits, tests, and procedures than pregnant women who do not have this disease (ACOG, 2013).

The OGTT is administered after an overnight fast and at least 3 days of unrestricted diet (at least 150 g of carbohydrate) and physical activity. The woman is instructed to avoid caffeine because it increases glucose levels and to abstain from smoking for 12 hours before the test. The 3-hour OGTT requires a fasting blood glucose level, which is drawn before giving a 100-g glucose load. Blood glucose levels are then drawn 1, 2, and 3 hours later. The woman is diagnosed with GDM if two or more values are met or exceeded (ACOG, 2013). Two different sets of glucose values are commonly used to diagnose GDM following the 100-g OGTT (Fig. 29-4). At this time, use of one set of glucose values cannot be clearly recommended over the other. Therefore, providers are urged to select one set of blood glucose values and use it consistently in their practice (ACOG).

An international consensus group, the International Association of Diabetes and Pregnancy Study Groups (IADPSG),

CLINICAL REASONING CASE STUDY

Screening for Gestational Diabetes Mellitus (GDM)

Kelly is a 30-year-old G1 P0 African-American woman who is obese. Both her mother and maternal grandmother have been diagnosed with type 2 diabetes. Kelly failed her 50-g oral glucose screen, which was performed at 26 weeks of gestation, with a value of 160 mg/dl. She reported to her health care provider's office one week later to have a 3-hour OGTT done. Kelly's test results from the 3-hour OGTT were fasting blood glucose (FBS), 96 mg/dl; 1 hour, 182 mg/dl; 2 hour, 161 mg/dl; 3 hour, 138 mg/dl.

- Evidence—Is there sufficient evidence at this time to determine if Kelly has gestational diabetes (GDM)?
- Assumptions—Describe an underlying assumption regarding the following interventions for the management of GDM:
 - Medical nutrition therapy (diet)
 - Insulin
 - Oral hypoglycemic agents
- What implications and priorities for nursing care can be drawn at this time?
- Does the evidence objectively support your conclusion?

consisting of representatives from multiple obstetric and diabetic organizations including the ADA, recommends a different (one-step) method of screening and diagnosis. Increasing rates of obesity and diabetes have resulted in more women of childbearing age with type 2 diabetes, many of whom are undiagnosed when they become pregnant. The IADPSG recommends that high risk women be tested for overt diabetes at their initial prenatal visit using standard criteria for diagnosis (ADA, 2013b). If the tests done early in pregnancy for overt diabetes are normal, a 75-g OGTT diagnostic test is administered

between 24 and 28 weeks of gestation. The 75-g OGTT requires a fasting blood glucose level, which is drawn before giving the glucose load. Blood glucose levels are then drawn 1 and 2 hours later. A diagnosis of GDM is made if only one glucose value is exceeded (Fig. 29-5). The one-step method of screening and diagnosis significantly increases the incidence of GDM. The ACOG does not recommend this method (ACOG, 2013; ADA 2013b). However, some practitioners in the United States are using the IADPSG recommendations for screening and diagnosing GDM (ADA, 2013b) (see Evidence-Based Practice box).

EVIDENCE-BASED PRACTICE

Debating Gestational Diabetes Diagnosis

Ask the Question

For pregnant women with hyperglycemia, at what level do diagnosis and treatment for gestational diabetes become most beneficial for the baby?

Search for the Evidence

Search Strategies English language research-based publications since 2011 on gestational diabetes screening or diagnosis, hyperglycemia, ADA, ACOG, and NIH were included.

Databases Used Cochrane Collaborative Database, National Guideline Clearinghouse (AHRQ), CINAHL, PubMed, UpToDate, and the professional websites for ACOG, ADA, and AWHONN

Toward a Diagnosis of Gestational Diabetes Mellitus

Background:

- High serum glucose in pregnancy is associated with complications such as preeclampsia, macrosomia, operative vaginal birth, shoulder dystocia, birth injury, cesarean birth, neonatal hypoglycemia, need for neonatal intensive care, respiratory distress, and jaundice. A commonly accepted method of diagnosing gestational diabetes mellitus (GDM) has been a nonfasting glucose challenge at 24-28 weeks of gestation (Moyer, 2014). For a 50-g glucose challenge test, the most common cutoff was 140 mg/dl, a level that was associated with macrosomia and gestational hypertension (Prutsky, Domecq, Sunderesh, et al., 2013). An elevated result triggered a fasting 2- or 3-hour oral glucose tolerance test (OGTT). A second abnormal result resulted in diagnosis of GDM. Using this approach, about 5% to 6% of pregnant women received treatment, including diet, exercise, glucose monitoring, and possibly metformin.

Conflicting Guidelines:

- **ACOG:** In 2006 at least nine different criteria were used to identify gestational diabetes, using 50-100 g of glucose as the challenge. The American College of Obstetrics and Gynecology (ACOG) approach used two-step screening, clinical criteria, and history. Critics of this approach questioned its reliance on maternal, rather than newborn, outcomes; its acceptance of clinical criteria or history alone for diagnosis; and its ambiguous screening cutoffs (Ryan, 2013).
- **ADA:** In 2008 the International Association of Diabetes in Pregnancy Study Group (IADPSG) set out to identify levels at which treatment would benefit the baby. They proposed a one-step approach, consisting of a 75-g OGTT. Abnormal levels were set based on their association with macrosomia and cord blood C-peptide, a marker for fetal insulin levels. One abnormal result was enough to trigger diagnosis of GDM. This approach is estimated to identify GDM in nearly 18% of all pregnant women. The American Diabetes Association (ADA) endorsed this approach (Ryan, 2013).

NIH Consensus Conference:

- Criticism of the one-step approach includes reliance on just one abnormal result and the unintended consequences of

labeling women with GDM: increase in cesarean birth and possibly labor induction, additional fetal assessments, more intensive newborn assessments, significantly increased client costs, life disruptions, and psychologic stress. To resolve the differences between the ACOG and ADA approaches, the National Institutes of Health (NIH) convened a Consensus Conference. The NIH statement found some advantages for convenience of diagnosis within the context of one visit; however, there was insufficient evidence of clear improvement in client outcomes to recommend the one-step approach. Therefore, the NIH group recommended continuing the current two-step approach and called for further targeted research (Vandorsten, Dodson, Espeland, et al., 2013).

Quality and Safety Competencies: Evidence-Based Practice (EBP)*

Knowledge

Describe reliable sources for locating evidence reports and clinical practice guidelines.

The nurse working with pregnant women needs to understand evolving professional recommendations.

Skills

Locate evidence reports related to clinical practice topics and guidelines.

Relevant systematic reviews and professional guidelines provide recommendations for improving perinatal outcomes.

Attitudes

Value the concept of EBP as integral to determining best clinical practices.

EBP represents the best practice and its use fosters client confidence and efficacy.

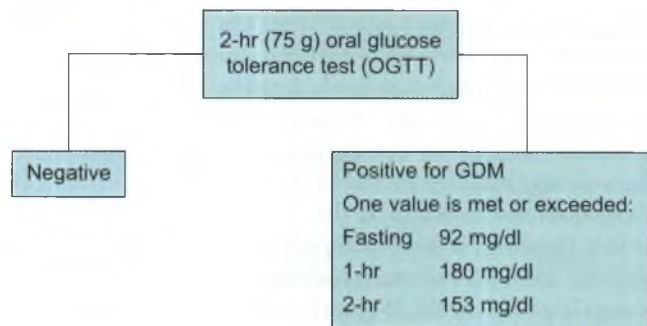

FIG 29-5 One-step method for diagnosing gestational diabetes mellitus (GDM), recommended by the International Association of Diabetes in Pregnancy Study Groups (IADPSG). Data from American Diabetes Association (ADA) (2013). Position statement: Diagnosis and classification of diabetes mellitus. *Diabetes Care*, 36(Suppl 1), S67-S74.

Nursing diagnoses and expected outcomes of care for women with GDM are basically the same as those for women with pre-gestational diabetes except that the time frame for planning may be shortened with GDM because the diagnosis is usually made later in pregnancy (see Nursing Care Plan).

Interventions

Antepartum

When the diagnosis of GDM is made, treatment begins immediately, allowing little or no time for the woman and her family to adjust to the diagnosis before they are expected to participate in the treatment plan. With each step of the treatment plan the nurse and other health care providers should educate the woman and her family, providing detailed and comprehensive explanations to ensure understanding, participation, and

NURSING CARE PLAN

The Pregnant Woman with Gestational Diabetes

NURSING DIAGNOSIS	EXPECTED OUTCOME	INTERVENTIONS	RATIONALES
<i>Deficient Knowledge related to gestational diabetes as evidenced by the woman's questions and concerns</i>	The woman will be able to verbalize important information regarding gestational diabetes, its management, and potential effects on the pregnancy and fetus.	<ul style="list-style-type: none"> Assess woman's current knowledge base regarding the disease process, management, effects on pregnancy and fetus, and potential complications. Explain pathophysiologic aspects of diabetes, its effects on pregnancy and fetus, and potential complications. Explain principles of diabetic diet and have woman plan her meals for 1 day following these principles. Demonstrate procedure for blood glucose monitoring and obtain return demonstration. Demonstrate procedure for insulin administration, should this become necessary, and obtain return demonstration. Explain importance of correctly taking oral hypoglycemic medication (right dose, right time), should this become necessary. Review signs and symptoms of hypoglycemia and hyperglycemia and appropriate interventions for both. Provide contact numbers for health care team for prompt interventions and answers to questions on ongoing basis. Review expected plan of care. 	<ul style="list-style-type: none"> To provide database for further teaching To promote compliance with treatment plan To promote self-management and compliance with treatment plan To establish woman's comfort and competence with procedure To establish woman's comfort and competence with procedure To promote self-management and compliance with treatment plan To promote prompt recognition of complications and self-management To promote comfort
<i>Risk for Fetal Injury related to elevated maternal glucose levels</i>	The fetus will remain free of injury and be born at term in a healthy state.	<ul style="list-style-type: none"> Assess woman's current diabetic control. Monitor fundal height during each prenatal visit. Assess fetal movement and heart rate during each prenatal visit and perform fetal assessment tests as ordered during the third trimester. 	<ul style="list-style-type: none"> To allay anxiety and enlist cooperation of woman in her care To identify risk for fetal macrosomia To identify appropriate fetal growth To assess fetal well-being
<i>Anxiety related to threat to maternal and fetal well-being as evidenced by the woman's verbal expressions of concern</i>	The woman will identify sources of anxiety and report feeling less anxious.	<ul style="list-style-type: none"> Through therapeutic communication promote open relationship with woman. Listen to woman's feelings and concerns. Review potential dangers by providing factual information. Encourage woman to share concerns with her health care team. 	<ul style="list-style-type: none"> To promote trust To assess for any misconception or misinformation that may be contributing to anxiety To correct any misconceptions or misinformation To promote collaboration in her care

adherence to the necessary interventions. Potential complications should be discussed, and the need for maintaining euglycemia throughout the remainder of the pregnancy reinforced. Knowing that GDM typically disappears when the pregnancy is over may be reassuring for the woman and her family.

As with pregestational diabetes, the aim of therapy in women with GDM is strict blood glucose control. Fasting blood glucose levels should range from 60 to 99 mg/dl, and 1-hour postprandial values between 100 and 129 mg/dl (ADA, 2013a). Postmeal glucose levels at 2 hours should be no higher than 120 mg/dl (Landon et al., 2012) (see Table 29-3).

Diet. Dietary modification is the mainstay of treatment for GDM. The woman with GDM is placed on a standard diet for women with diabetes. The usual prescription is 30 kcal/kg/day based on a normal preconception weight. For obese women the usual prescription is up to 25 kcal/kg/day, which translates into 1500 to 2000 kcal/day. Carbohydrate intake is restricted to approximately 50% of caloric intake (Moore et al., 2014). Dietary counseling by a registered dietitian is recommended.

Exercise. There are few published studies on the benefits of exercise in women with GDM. In adults who are not pregnant, exercise increases lean muscle mass and improves sensitivity to insulin. Therefore, a moderate exercise program is recommended for overweight or obese women with GDM in order to improve blood sugar control and facilitate weight loss (ACOG, 2013).

Self-Monitoring of Blood Glucose. Blood glucose monitoring is necessary to determine whether euglycemia can be maintained by diet and exercise. Women are instructed to monitor their blood sugar daily. The frequency and timing of blood glucose monitoring should be individualized for each woman. A typical schedule for monitoring blood glucose is on rising in the morning, 1 or 2 hours after breakfast, before and after lunch, before dinner, and at bedtime (Moore et al., 2014). Women with GDM usually perform self-monitoring at home with a review of their results at prenatal visits to determine the effectiveness of diet and exercise. If glycemic thresholds are not met, then pharmacologic intervention is indicated.

Pharmacologic Therapy. Approximately 25% of women with GDM require insulin during the pregnancy to maintain satisfactory blood glucose levels, despite compliance with the prescribed diet (Landon et al., 2012). In contrast to women with insulin-dependent diabetes, women with GDM are managed initially with diet and exercise alone. If fasting plasma glucose levels are persistently greater than 95 mg/dl, 1-hour postmeal levels are persistently greater than 140 mg/dl, or 2-hour postmeal levels are persistently greater than 120 mg/dl, insulin therapy is begun (ACOG, 2013).

For the past several years oral hypoglycemic therapy has been used as an alternative to insulin in women with GDM who require medication in addition to diet for blood glucose control. Women who are unable or unwilling to take insulin by injection or are cognitively impaired also may be candidates for oral hypoglycemic medication.

Glyburide is the oral agent most frequently prescribed. The fact that only minimal amounts of glyburide cross the placenta to the fetus makes it a good drug for use during pregnancy (Moore et al., 2014). Several studies have shown that glyburide

controls blood glucose levels as well as insulin does in women with GDM. Furthermore, research revealed no increase in hypoglycemia or macrosomia in neonates whose mothers took glyburide. However, in one study neonates born to women taking glyburide were found to be more likely to experience birth injury or require phototherapy. Glyburide may not work as well in women who are obese or who experienced higher levels of hyperglycemia early in pregnancy (Landon et al., 2012). Studies have shown that glyburide should be taken at least 30 minutes (preferably 1 hour) before a meal so its peak effect covers the 2-hour postmeal blood glucose level. Because episodes of hypoglycemia can occur between meals, women taking glyburide should always carry their glucose meter with them, along with glucose tablets or gel (Moore et al.).

Metformin is another oral hypoglycemic agent sometimes used in the management of GDM. Although metformin crosses the placenta, it does not appear to be teratogenic. However, glyburide may be better than metformin at controlling blood glucose levels in women with GDM because glyburide causes the maternal pancreas to produce more insulin, whereas metformin decreases hepatic glucose production and increases peripheral sensitivity to insulin (Landon et al., 2012).

Fetal Surveillance. Women with GDM whose blood glucose levels are well controlled by diet are at low risk for an IUFD. Therefore, antepartum fetal testing is not performed routinely in these women unless they also have hypertension, a history of a prior stillbirth, or suspected macrosomia. Women with these complications or those who require insulin for blood glucose control may have twice-weekly NSTs beginning at 32 weeks of gestation. Women with uncomplicated GDM begin fetal testing at 40 weeks of gestation. In general, women with well-controlled GDM can continue pregnancy until 40 weeks of gestation and the spontaneous onset of labor. However, fetal growth should be monitored carefully because the risk for macrosomia as the pregnancy approaches 40 weeks of gestation is apparently increased (Landon et al., 2012).

Intrapartum

During the labor and birth process blood glucose levels are monitored hourly to maintain levels at 80 to 110 mg/dl. Levels within this range decrease the incidence of neonatal hypoglycemia. Infusing rapid-acting insulin intravenously may be necessary during labor to maintain the desired blood glucose levels. However, it is usually possible to maintain excellent glucose control in women with GDM during labor by avoiding the use of IV fluids containing dextrose (Moore et al., 2014). If glucose-containing solutions are given, they should be administered by an infusion device so that inadvertent boluses are avoided. Although GDM is not an indication for cesarean birth, this procedure may be necessary in the presence of preeclampsia or macrosomia.

Postpartum

Although most women with GDM return to normal glucose levels after childbirth, up to one third will be found to have diabetes or impaired glucose metabolism when they are screened postpartum. It is estimated that 15% to 50% of women who have had GDM will develop type 2 diabetes later in life (ACOG, 2013).

The ACOG recommends assessing all women who had GDM for carbohydrate intolerance with a 75-g, 2-hr OGTT or a fasting plasma glucose level at 6 to 12 weeks postpartum. The optimal frequency of subsequent testing has not been established. However, the ADA recommends repeat testing at least every 3 years for women with a history of GDM and normal postpartum glucose testing results (Landon et al., 2012). Obesity is a major risk factor for the later development of diabetes. Women with a history of GDM, particularly those who are overweight, should be encouraged to make lifestyle changes that include weight loss and exercise to reduce this risk (Gilbert, 2011). Children born to women with GDM are also at risk for becoming obese in childhood or adolescence (Landon et al., 2012).

Low-dose oral contraceptives may be safely used by women with a history of GDM. The rate of subsequent diabetes in these women is no different from that in women without a history of GDM who use low-dose oral contraceptives. Women who are also obese or have hypertension or high lipid levels in addition to a history of GDM should use a contraceptive method without the potential for causing cardiovascular side effects. For these women, the intrauterine device is a good option (Cunningham et al., 2014).

HYPEREMESIS GRAVIDARUM

Nausea and vomiting complicate 50% to 80% of all pregnancies, typically beginning at 4 to 10 weeks of gestation. These symptoms are usually confined to the first 20 weeks of gestation (Kelly & Savides, 2014). Although nausea and vomiting are distressing, they are typically benign, with no significant metabolic alterations or risks to the mother or fetus.

The cause of nausea and vomiting in pregnancy is not well understood, although it may involve relaxation of the smooth muscle of the stomach and increasing levels of estrogen and human chorionic gonadotropin (hCG). Gastric dysrhythmias, reduced gastric motility, and gastroesophageal reflux may also contribute to nausea and vomiting during pregnancy. Some authorities have suggested that nausea and vomiting are evolutionary adaptations that occur during pregnancy in order to protect the woman and fetus from potentially harmful foods. Pregnancies complicated by nausea and vomiting generally have a more favorable outcome than those without these symptoms (Gordon, 2012; Kelly & Savides, 2014).

When vomiting during pregnancy becomes excessive enough to cause weight loss, electrolyte imbalance, nutritional deficiencies, and ketonuria, the disorder is termed **hyperemesis gravidarum**. This disorder occurs in approximately 0.5% of all live births. Hyperemesis gravidarum usually begins during the first trimester, but approximately 10% of women with the disorder continue to have symptoms throughout the pregnancy (Kelly & Savides, 2014). Hyperemesis gravidarum is the second most common reason for hospitalization during pregnancy in the United States (Summers, 2012).

Risk factors for hyperemesis include clinical hyperthyroid disorders, prepregnancy psychiatric diagnosis, previous pregnancy complicated by hyperemesis gravidarum, molar pregnancy, multiple gestation with a male and female fetus, diabetes, and gastrointestinal disorders (Cappell, 2012). For unknown reasons

women carrying a female fetus are more likely than those carrying a male fetus to develop hyperemesis (Kelly & Savides, 2014). A family history of hyperemesis may also be present (Gilbert, 2011). Women 30 years of age and older and women who smoke have a lower risk for hyperemesis (Tamay & Kuscu, 2011).

Severe but rare maternal complications of hyperemesis gravidarum include esophageal rupture, pneumomediastinum, and deficiencies of vitamin K and thiamine with resulting Wernicke encephalopathy (CNS involvement) (Kelly & Savides, 2014).

Infants born to women who had poor pregnancy weight gain because of hyperemesis may be small for gestational age, have a low birth weight, or be born prematurely. They may also have 5-minute Apgar scores less than 7 (Kelly & Savides, 2014).

Etiology

Psychosocial, cultural, and psychogenic, as well as physiologic, factors may play a part in the development of hyperemesis gravidarum for some women (Tamay & Kuscu, 2011). Conflicting feelings regarding prospective motherhood, body changes, and lifestyle alterations may contribute to episodes of vomiting, particularly if these feelings are excessive or unresolved. Women with associated psychosocial factors usually improve dramatically while in the hospital but may resume vomiting after discharge.

Clinical Manifestations

The woman with hyperemesis gravidarum usually has significant weight loss and dehydration. She may have dry mucous membranes, decreased BP, increased pulse rate, and poor skin turgor. Frequently she is unable to keep down even clear liquids taken by mouth. Laboratory tests may reveal electrolyte imbalances.

CARE MANAGEMENT

Assessment

Whenever a pregnant woman has nausea and vomiting, the first priority is a thorough assessment to determine the severity of the problem. In most cases the woman should be told to come immediately to the health care provider's office or the emergency department because the severity of the illness is often difficult to determine by telephone conversation.

The assessment should include frequency, severity, and duration of episodes of nausea and vomiting. If the woman reports vomiting, the assessment should also include the approximate amount and color of the vomitus. Other symptoms such as diarrhea, indigestion, and abdominal pain or distention also are identified. The woman is asked to report any precipitating factors relating to the onset of her symptoms. Any pharmacologic or nonpharmacologic treatment measures used should be recorded. Prepregnancy weight and documented weight gain or loss during pregnancy are important to note.

The woman's weight and vital signs are measured, and a complete physical examination is performed, with attention to signs of fluid and electrolyte imbalance and nutritional status. The most important initial laboratory test to be obtained is a determination of ketonuria. Other laboratory tests that may be ordered are a urinalysis, a complete blood cell count, electrolytes, liver enzymes, and bilirubin levels. These tests help rule

out underlying diseases such as gastroenteritis, pyelonephritis, pancreatitis, cholecystitis, peptic ulcer, and hepatitis (Cunningham et al., 2014). Because of the recognized association between hyperemesis gravidarum and hyperthyroidism, thyroid levels may also be measured (Nader, 2014).

Psychosocial assessment includes asking the woman about anxiety, fears, and concerns related to her own health and the effects on pregnancy outcome. Family members should be assessed both for anxiety and their role in providing support for the woman.

Potential nursing diagnoses for women experiencing hyperemesis gravidarum include:

- *Deficient Fluid Volume* related to excessive vomiting as evidenced by fluid and electrolyte imbalance
- *Imbalanced Nutrition: Less Than Body Requirements*, related to nausea and persistent vomiting as evidenced by weight decrease as compared with prepregnant weight
- *Anxiety* related to effects of hyperemesis on fetal well-being as evidenced by woman's statements of concern

Interventions

Initial Care

Initially the woman who is unable to keep down clear liquids by mouth requires IV therapy for correction of fluid and electrolyte imbalances. In the past women requiring IV therapy were admitted to the hospital. However, today they may be and often are successfully managed at home, even if on enteral therapy. Medications may be used if nausea and vomiting are uncontrolled. The ACOG recommends the use of pyridoxine (vitamin B₆), either alone or in combination with doxylamine (Unisom) as initial medical management because these medications are considered to be both safe and effective (Gordon, 2012).

Other frequently prescribed drugs include promethazine (Phenergan), chlorpromazine (Thorazine), prochlorperazine (Compazine), and trimethobenzamide (Tigan). These medications demonstrated benefit clinically, but their safety in pregnancy has not been proven. Metoclopramide (Reglan) accelerates gastric emptying and corrects gastric dysrhythmias. It has been demonstrated in some small studies to be both safe and effective. Ondansetron (Zofran) and droperidol (Inapsine) have been used to treat postoperative nausea and vomiting but their use in pregnancy has not been well studied (Kelly & Savides, 2014).

Corticosteroids (methylprednisolone [Medrol] or hydrocortisone) may be prescribed for women who do not respond well to the medications previously discussed. These medications have not been proven to treat hyperemesis effectively in all women, however. Because exposure to corticosteroids may increase the risk of facial clefting, they should be used with caution and avoided if possible during the first trimester, when organs and organ systems are developing (Kelly & Savides, 2014).

Finally, enteral or parenteral nutrition may be used as a last resort in women who are nonresponsive to other medical therapies (Kelly & Savides, 2014). Because of potential risks, parenteral therapy should only be used after multiple medical management and enteral tube feeding attempts have been unsuccessful (Gordon, 2012).

Nursing Interventions. Nursing care of the woman with hyperemesis gravidarum involves implementing the medical plan of care, whether it is given in the hospital or home setting.

Interventions may include initiating and monitoring IV therapy, administering drugs and nutritional supplements, and monitoring the woman's response to interventions. The nurse observes her for any signs of complications such as metabolic acidosis (secondary to starvation), jaundice, or hemorrhage and alerts the health care provider should these occur. Monitoring includes assessing the woman's nausea, retching without vomiting, and vomiting, given that these symptoms, although related, are separate. Intake and output, including the amount of emesis, should be measured accurately and recorded. Oral hygiene while the woman is receiving nothing by mouth and after episodes of vomiting helps lessen associated discomforts. Assistance with positioning and providing a quiet, restful environment that is free from odors may increase her comfort.

Once the vomiting has stopped, feedings are started in small amounts at frequent intervals. In the beginning limited amounts of oral fluids and bland foods such as crackers, toast, or baked chicken are offered. The diet progresses slowly as tolerated until the woman is able to consume a nutritionally sound diet. Because sleep disturbances may accompany hyperemesis gravidarum, promoting adequate rest is important. The nurse can help coordinate treatment measures and periods of visitation to provide opportunity for rest periods.

Follow-Up Care

Most women are able to take nourishment by mouth after several days of treatment. They should be encouraged to eat small, frequent meals and foods that sound appealing (e.g., nongreasy, dry, sweet, and salty foods). In many instances women discover that foods they normally like have no appeal at all during this time. (See Teaching for Self-Management: Diet for Hyperemesis for more suggestions.) Many pregnant women find exposure to cooking odors nauseating. Having other family members cook may lessen the woman's nausea and vomiting, even if only

TEACHING FOR SELF-MANAGEMENT

Diet for Hyperemesis

- Avoid an empty stomach. Eat frequently, at least every 2 to 3 hours. Separate liquids from solids and alternate every 2 to 3 hours.
- Eat a high-protein snack at bedtime.
- Eat dry, bland, low-fat, and high-protein foods. Cold foods may be better tolerated than those served at a warm temperature.
- In general, eat what sounds good to you rather than trying to balance your meals.
- Follow the salty and sweet approach; even so-called junk foods are okay.
- Eat protein after sweets.
- Dairy products may stay down more easily than other foods.
- If you vomit even when your stomach is empty, try sucking on a Popsicle.
- Try ginger tea. Peel and finely dice a knuckle-sized piece of ginger and place it in a mug of boiling water. Steep for 5 to 8 minutes and add brown sugar to taste.
- Try warm ginger ale (with sugar, not artificial sweetener) or water with a slice of lemon.
- Drink liquids from a cup with a lid.

temporarily. The woman is counseled to contact her health care provider immediately if the nausea and vomiting recur.

The woman with hyperemesis gravidarum needs calm, compassionate, and sympathetic care, with recognition that the manifestations of hyperemesis can be physically and emotionally debilitating to her and stressful for her family. Irritability, tearfulness, and mood changes are often consistent with this disorder. Fetal well-being is the woman's primary concern. The nurse can provide an environment conducive to discussion of concerns and help the woman identify and mobilize sources of support. The family should be included in the plan of care whenever possible. Their participation may help alleviate some of the emotional stress associated with this disorder.

THYROID DISORDERS

Hyperthyroidism

Hyperthyroidism in pregnancy is rare. The incidence varies, occurring in approximately 2 to 17 of every 1000 births (Cunningham et al., 2014). In 90% to 95% of pregnant women it is caused by Graves' disease (Nader, 2014). Clinical manifestations of hyperthyroidism include heat intolerance, diaphoresis, fatigue, anxiety, emotional lability, and tachycardia. Many of these symptoms also occur with pregnancy; thus the disorder can be difficult to diagnose. Signs that may help differentiate hyperthyroidism from normal pregnancy changes include weight loss, goiter, and a pulse rate greater than 100 beats/minute (Nader). Laboratory findings typically include elevated free thyroxine (T_4) and triiodothyronine (T_3) levels and greatly suppressed thyroid-stimulating hormone (TSH) levels (Nader). Moderate and severe hyperthyroidism must be treated during pregnancy. Untreated or inadequately treated women have an increased risk of miscarriage, preterm birth, and giving birth to stillborn infants or infants with goiter, hyperthyroidism, or hypothyroidism. However, most neonates born to women with hyperthyroidism have normal thyroid function. Women with hyperthyroidism are at increased risk for developing severe preeclampsia and heart failure (Cunningham et al.; Nader).

The primary treatment of hyperthyroidism during pregnancy is drug therapy. The medications most often prescribed in the United States are propylthiouracil (PTU) or methimazole (MM). Both drugs are effective at controlling symptoms, but both have potentially dangerous maternal and fetal side effects. PTU can cause hepatic toxicity serious enough to require liver transplantation. When taken during the first trimester of pregnancy, MM can cause choanal atresia or esophageal atresia, facial anomalies, and developmental delay in exposed fetuses. Although the likelihood of maternal and fetal side effects from both drugs is low, a panel convened by the U.S. Food and Drug Administration (FDA) and the American Thyroid Association recommended that PTU be used only in the first trimester of pregnancy or by women who are intolerant of or allergic to MM. Women requiring drug therapy for hyperthyroidism should be switched to MM for the remainder of pregnancy (Mestman, 2012; Nader, 2014).

The usual starting dose of PTU is 100 to 150 mg three times a day. For MM the initial dose is generally 20 mg/day. Women usually show clinical improvement (weight gain and

less tachycardia) within 2 to 6 weeks after beginning therapy. Once clinical improvement occurs, the dose of PTU or MM may be cut in half. If symptoms worsen, the medication dosage is doubled (Mestman, 2012). During therapy thyroid test results are used to taper the drug to the smallest effective dose to prevent development of unnecessary fetal or neonatal hypothyroidism. In many women the medication can be discontinued by 32 to 36 weeks of gestation. PTU readily crosses the placenta and may cause fetal hypothyroidism, which is characterized by goiter, bradycardia, and intrauterine growth restriction (IUGR) (Nader, 2014).

Both medications work well in and are well tolerated by most women. The most common maternal side effects of both PTU and MM are pruritus and skin rash. Other possible side effects include drug-related fever, bronchospasm, migratory polyarthritis, a lupus-like syndrome, and cholestatic jaundice (Mestman, 2012; Nader, 2014). The most severe side effect is agranulocytosis, which occurs rarely and usually develops only in older women and in those taking high doses of the drug. Symptoms of agranulocytosis are fever and unexpected sore throat, which should be reported immediately to the health care provider; also the woman should stop taking the medication (Mestman; Nader). Beta-adrenergic blockers such as propranolol (Inderal) may be used in severe hyperthyroidism to control maternal symptoms, especially elevated heart rate. However, long-term use of these medications is not recommended because of the potential for IUGR, bradycardia, and hypoglycemia (Nader).

! NURSING ALERT

A serious but uncommon complication of undiagnosed or partially treated hyperthyroidism is thyroid storm, which can occur in response to stress such as labor and vaginal birth, infection, preeclampsia, or surgery. A woman with this emergency disorder may have fever, restlessness, tachycardia, vomiting, hypotension, or stupor. Prompt treatment is essential. IV fluids and oxygen are administered, along with high doses of PTU. After administration of PTU, iodide is given. Other medications include antipyretics, dexamethasone, and beta-blockers (Cunningham et al., 2014; Nader, 2014).

After birth, women taking either PTU or MM who choose to breastfeed should be informed that the medications do appear in small amounts in breastmilk (Lawrence & Lawrence, 2011). However, they do not appear to adversely affect the neonate's thyroid function. The woman should take her antithyroid medication just after breastfeeding, thus allowing a 3- to 4-hour period before nursing again (Mestman, 2012; Nader, 2014).

Radioactive iodine must not be used in diagnosis or treatment of hyperthyroidism in pregnancy because therapeutic doses given to treat maternal thyroid disease may also destroy the fetal thyroid (Cunningham et al., 2014).

In severe cases surgical treatment of hyperthyroidism, subtotal thyroidectomy, can be performed during pregnancy. Surgery is best performed during the early second trimester of pregnancy when the risk for teratogenesis and preterm labor is lower, although it can be done during the first or third trimester if necessary. Surgery is usually reserved for women with severe

disease, those for whom drug therapy proves toxic, and those who are unable to follow the prescribed medical regimen. Risks associated with the surgery are hypoparathyroidism, recurrent laryngeal nerve paralysis, and anesthesia-related complications (Nader, 2014).

Hypothyroidism

Hypothyroidism occurs in two to three pregnancies per 1000. Because severe hypothyroidism is often associated with infertility and an increased risk of miscarriage, it is not often seen during pregnancy (Cunningham et al., 2014). Although iodine deficiency is rare in the United States, it is a common cause of maternal, fetal, and neonatal hypothyroidism in the rest of the world (Nader, 2014). Adult hypothyroidism is usually caused by glandular destruction by autoantibodies, most commonly because of Hashimoto's thyroiditis. Characteristic symptoms of hypothyroidism include weight gain, lethargy, decrease in exercise capacity, and cold intolerance. Women who are moderately symptomatic can also develop constipation, hoarseness, hair loss, brittle nails, and dry skin. Laboratory values in pregnancy include elevated levels of TSH, with or without low T_4 levels (Nader).

Pregnant women with untreated hypothyroidism are at increased risk for miscarriage, preeclampsia, gestational hypertension, placental abruption, preterm birth, and stillbirth. Infants born to mothers with hypothyroidism may also be of low birth weight (Cunningham et al., 2014; Nader, 2014). These outcomes can be improved with early treatment (Nader).

Thyroid hormone supplements are used to treat hypothyroidism. Levothyroxine (e.g., T_4 [Synthroid]) is most often prescribed during pregnancy. The usual beginning dosage is 0.1 to 0.15 mg/day, with adjustment by 25 to 50 mcg every 4 to 6 weeks as necessary based on the maternal TSH level (Cunningham et al., 2014; Nader, 2014). The aim of drug therapy is to maintain the TSH level at the lower end of the normal range for pregnant women. Women with little or no functioning thyroid tissue require higher doses of levothyroxine. In addition, as pregnancy progresses, increased doses of thyroid hormone are usually required. This increased demand during pregnancy is probably related to increased estrogen levels (Cunningham et al.; Nader).

MEDICATION ALERT

If taking iron supplementation, pregnant women should be told to take levothyroxine at a different time of day, at least 4 hours apart, from their iron tablets because ferrous sulfate decreases absorption of T_4 (Nader, 2014).

The fetus depends on maternal thyroid hormones until approximately 18 weeks of gestation, when fetal production begins. Normal maternal T_4 levels early in pregnancy are important for proper fetal brain development. Studies have shown that even mild maternal hypothyroidism during the first trimester has been associated with long-term neuropsychologic damage in their children. More research needs to be conducted on this topic (Mestman, 2012).

Nursing Interventions

Education of the pregnant woman with thyroid dysfunction is essential to promote compliance with the plan of treatment.

Important points to discuss with the woman and her family include the disorder and its potential effect on her, her family, and her fetus; the medication regimen and possible side effects; the need for continuing medical supervision; and the importance of adherence.

The woman often needs the nurse's help to cope with the discomforts and frustrations associated with symptoms of the disorder. For example, a woman with hyperthyroidism who has nervousness and hyperactivity along with weakness and fatigue can benefit from suggestions to channel excess energies into quiet diversional activities such as reading or crafts. Discomfort associated with hypersensitivity to heat (hyperthyroidism) or cold intolerance (hypothyroidism) can be minimized by appropriate clothing and regulation of environmental temperatures and by avoiding temperature extremes.

Nutrition counseling with a registered dietitian may provide guidance in selecting a well-balanced diet. The woman with hyperthyroidism who has increased appetite and poor weight gain and the hypothyroid woman who has anorexia and lethargy need counseling to ensure adequate intake of nutritionally sound foods to meet both maternal and fetal needs.

MATERNAL PHENYLKETONURIA

Phenylketonuria (PKU), a recognized cause of cognitive impairment, is an inborn error of metabolism caused by an autosomal recessive trait that creates a deficiency in the enzyme phenylalanine hydrolase. Absence of this enzyme impairs the body's ability to metabolize the amino acid phenylalanine found in all protein foods. Consequently, toxic accumulation of phenylalanine in the blood occurs, which interferes with brain development and function. Individuals with this disorder also have hypopigmentation of hair, eyes, and skin because phenylalanine inhibits melanin production. PKU affects 1 in every 10,000 to 15,000 Caucasian newborns (Cunningham et al., 2014).

PKU was the first inborn error of metabolism to be universally screened in the United States. Since 1961 all newborns have been tested soon after birth for this disorder. Prompt diagnosis and therapy with a phenylalanine-restricted diet significantly decrease the incidence of cognitive impairment (Aminoff & Douglas, 2014). The special diet should be followed indefinitely because individuals who do not continue phenylalanine restriction have been reported to have significantly lower IQs (Cunningham et al., 2014).

The keys to the prevention of fetal anomalies caused by maternal PKU are the identification of women in their reproductive years with the disorder and dietary compliance for women who are diagnosed. Screening for undiagnosed homozygous maternal PKU at the first prenatal visit may be warranted, especially in individuals with a family history of the disorder, with low intelligence of uncertain origin, or who have given birth to microcephalic infants. Ideally women with PKU begin dietary phenylalanine restriction before conception and continue it throughout pregnancy (Aminoff & Douglas, 2014). The dietary modification normally excludes all high-protein foods such as meat, milk, eggs, and nuts and wheat products, making it very similar to a vegan diet (Feillet & Agostoni, 2010; Gilbert, 2011). Phenylalanine levels are monitored at least once and preferably twice a week throughout pregnancy (Gilbert). Experts recommend that maternal phenylalanine levels be less than 6 mg/dl for at least 3 months before

conception and range between 2 and 6 mg/dl throughout pregnancy. These levels are associated with a decrease in fetal sequelae (Cunningham et al., 2014; Gilbert). High maternal phenylalanine levels are associated with microcephaly, cognitive impairment, and congenital heart defects in their children (Aminoff & Douglas; Cunningham et al.). Ultrasound examinations are used for fetal surveillance beginning in the first trimester. A spontaneous vaginal birth is anticipated.

Women with PKU should be advised against breastfeeding because their milk contains a high concentration of

phenylalanine (Aminoff & Douglas, 2014). If these women choose to breastfeed despite the risk, their phenylalanine blood levels must be monitored closely. Infants diagnosed with PKU can usually be breastfed safely if the mother does not also have PKU because human breast milk is a relatively low-phenylalanine food (Pollard, 2012). If infants with PKU are breastfed, the amount of human breast milk ingested daily may be monitored so phenylalanine levels do not get too high. Another strategy is to alternate human breast milk feedings with products that contain little or no phenylalanine (Pollard).

KEY POINTS

- In pregnant women with pregestational diabetes, lack of glycemic control before conception and in the first trimester of pregnancy may be responsible for fetal congenital malformations.
- For pregnant women who have diabetes and are insulin dependent, insulin requirements increase as the pregnancy progresses and may quadruple by term as a result of insulin resistance created by placental hormones, insulinase, and cortisol. After birth, levels decrease dramatically; breastfeeding affects insulin needs.
- Poor glycemic control before and during pregnancy in women who have diabetes can lead to maternal complications such as miscarriage, infection, and dystocia (difficult labor) caused by fetal macrosomia.
- Careful glucose monitoring, insulin administration when necessary, and dietary counseling are used to create a normal intrauterine environment for fetal growth and development in the pregnancy complicated by diabetes mellitus.
- Because GDM is asymptomatic in most cases, all women who are not known to have pregestational diabetes undergo routine screening by history, clinical risk factors, or laboratory assessment of blood glucose levels during pregnancy. Two different methods for diagnosing GDM are currently used.
- The woman with hyperemesis gravidarum may have significant weight loss and dehydration. Management focuses on restoring fluid and electrolyte balance and preventing recurrence of nausea and vomiting.
- Thyroid dysfunction, hyperthyroidism or hypothyroidism, during pregnancy requires close monitoring of thyroid hormone levels to regulate therapy and prevent fetal insult.
- High levels of phenylalanine in the maternal bloodstream cross the placenta and are teratogenic to the developing fetus. Damage can be prevented or minimized by dietary restriction of phenylalanine before and during pregnancy.

LEARNING OBJECTIVES

- Describe the management of selected cardiovascular disorders in pregnant women.
- Identify nursing interventions for a pregnant woman with a cardiovascular disorder.
- Discuss anemia during pregnancy.
- Explain the care of pregnant women with pulmonary disorders.
- Examine the effect of a gastrointestinal disorder on gastrointestinal function during pregnancy.
- Identify the effects of neurologic disorders on pregnancy.
- Describe the care of women whose pregnancies are complicated by autoimmune disorders.
- Differentiate signs and symptoms and management during pregnancy of urinary tract infections.
- Explain the basic principles of care for a pregnant woman who is having surgery.
- Discuss the implications of trauma in regard to mother and fetus.
- Identify priorities in assessment and stabilization measures for the pregnant trauma victim.

For most women, pregnancy represents a normal part of life. This chapter discusses the care of women for whom pregnancy represents a significant risk because it is superimposed on a preexisting medical condition. Care of women with normal pregnancies who develop medical or surgical problems that could happen to anyone at any time of life but occur during pregnancy is also discussed. With the active participation of well-motivated women in the treatment plan and careful management from a multidisciplinary health care team, positive pregnancy outcomes are often possible in both of these situations.

This chapter focuses on cardiovascular disorders, along with selected hematologic, respiratory, integumentary, neurologic, autoimmune, gastrointestinal, and urinary tract diseases. Care of the pregnant woman undergoing surgery or experiencing trauma also is discussed.

CARDIOVASCULAR DISORDERS

During a normal pregnancy the maternal cardiovascular system undergoes many changes that place a physiologic strain on the heart (see Chapter 13). The major cardiovascular changes that occur during a normal pregnancy and affect the woman with cardiac disease are increased intravascular volume, decreased systemic vascular resistance, cardiac output changes occurring during labor and birth, and the intravascular volume changes that occur just after childbirth. These

physiologic changes are present during pregnancy and continue for a few weeks after birth. The normal heart can compensate for the increased workload so that pregnancy, labor, and birth are generally well tolerated, but the diseased heart is hemodynamically challenged.

If the cardiovascular changes are not well tolerated, cardiac failure can develop during pregnancy, labor, or the postpartum period. In addition, if myocardial disease develops, valvular disease exists, or a congenital heart defect is present, *cardiac decompensation* (inability of the heart to maintain a sufficient cardiac output) may occur.

About 1% of pregnancies are complicated by serious heart disease. The risk of maternal morbidity and mortality ranges from low to high, depending on the cardiac defect (Roos-Hesselink, Ruys, & Johnson, 2013). The rates of congenital heart disease and mitral valve disease are increasing in women of childbearing age, whereas the incidence of rheumatic fever has diminished. The presence of a maternal congenital cardiac defect increases the risk to the fetus for a congenital heart defect from 1% to about 4% to 6% (Roos-Hesselink et al.). A perinatal mortality of up to 50% is anticipated with persistent cardiac decompensation. Box 30-1 lists maternal cardiac disease risk groups.

The degree of disability experienced by the woman with cardiac disease is often more important in the treatment and prognosis of cardiac disease complicating pregnancy than is the diagnosis of cardiovascular disease. The New York Heart

BOX 30-1 Maternal Cardiac Disease Risk Groups**Group I (Mortality Rate <1%)**

Atrial septal defect
 Ventricular septal defect (uncomplicated)
 Patent ductus arteriosus
 Pulmonic and tricuspid disease
 Biosynthetic valve prosthesis (porcine and human allograft)
 Tetralogy of Fallot (corrected)
 Mitral stenosis (New York Heart Association [NYHA] classes I and II)

Group II (Mortality Rate 5%-15%)

Mitral stenosis (NYHA classes III and IV or with atrial fibrillation)
 Aortic stenosis
 Coarctation of aorta (uncomplicated)
 Uncorrected tetralogy of Fallot
 Previous myocardial infarction
 Marfan syndrome with normal aorta
 Artificial heart valve

Group III (Mortality Rate 25%-50%)

Pulmonary hypertension
 Coarctation of the aorta (complicated)
 Endocarditis
 Marfan syndrome with aortic involvement
 Eisenmenger syndrome

Data from Gaddipati, S., & Troiano, N.H. (2013). Cardiac disorders in pregnancy. In N.H. Troiano, C.J. Harvey, & B.F. Chez (Eds.), *AWHONN's high risk and critical care obstetrics* (3rd ed.). Philadelphia: Lippincott Williams & Wilkins.

Association's (NYHA) functional classification of organic heart disease is a widely accepted standard:

- Class I: asymptomatic without limitation of physical activity
- Class II: symptomatic with slight limitation of activity
- Class III: symptomatic with marked limitation of activity
- Class IV: symptomatic with inability to carry on any physical activity without discomfort

No classification of heart disease can be considered rigid or absolute, but the NYHA classification offers a basic practical guide for treatment, assuming that frequent prenatal visits, good client cooperation, and appropriate obstetric care occur. The functional classification may change for the pregnant woman because of the hemodynamic changes that occur in the cardiovascular system during pregnancy. A 30% to 45% increase in cardiac output occurs compared with nonpregnancy resting values, with most of the increase in the first trimester and the peak at 20 to 26 weeks of gestation (Blanchard & Daniels, 2014). The functional classification of the disease is determined at 3 months and again at 7 or 8 months of gestation. Pregnant women may progress from class I or II to III or IV during the pregnancy as cardiac output increases and more stress is placed on the heart. Women with cyanotic congenital heart disease do not fit into the NYHA classification because their exercise-induced symptoms have causes unrelated to heart failure.

A diagnosis of cardiac disease depends on the history, physical examination, radiographic and electrocardiographic findings, Holter monitoring, and, if indicated, ultrasonographic results. Most diagnostic studies are noninvasive and can be safely performed during pregnancy. The differential diagnosis

of heart disease also involves ruling out respiratory problems and other potential causes of chest pain.

The maternal mortality rate in women with cardiac events is higher than that for abortion, genital tract sepsis, and hemorrhage (Easterling & Stout, 2012). The highest risk of complications or death occurs in women with pulmonary hypertension, complicated coarctation of the aorta, and Marfan syndrome with aortic involvement (Roos-Hesselink et al., 2013).

Cardiac diseases vary in their effect on pregnancy depending on whether they are acute or chronic conditions. The following discussion focuses on selected congenital and acquired cardiac conditions and other cardiac disorders. A review of the care of the pregnant woman who has had a heart transplant concludes this section.

Congenital Cardiac Disease**Septal Defects**

Atrial Septal Defect. Atrial septal defect (ASD) (an abnormal opening between the atria), one of the causes of a left-to-right shunt, is one of the most common congenital defects seen during pregnancy. This defect may go undetected because the woman usually is asymptomatic. The pregnant woman with an ASD will most likely have an uncomplicated pregnancy. Some women may have right-sided heart failure or arrhythmias as the pregnancy progresses as a result of increased plasma volume (Gaddipati & Troiano, 2013). The risk for congenital heart disease to the fetus of a woman with ASD is 4% to 10% (Tomlinson, 2011).

Ventricular Septal Defect. Ventricular septal defect (VSD) (an abnormal opening between the right and left ventricles), another cause of a left-to-right shunt, is usually diagnosed and corrected early in life. As a result, a VSD is not very common in pregnancy. Women with small, uncomplicated VSDs usually do not have pregnancy complications. For women with a large VSD, there is a higher risk for arrhythmias, heart failure, and pulmonary hypertension. Medical management includes rest and decreased physical activity, as well as administration of anticoagulants, if indicated (Gaddipati & Troiano, 2013). The risk for a congenital heart defect to the fetus of a woman with VSD is 6% to 10% (Tomlinson, 2011).

Patent Ductus Arteriosus. Patent ductus arteriosus (PDA) is another cause of a left-to-right shunt that is usually diagnosed and corrected during infancy. Possible complications of a PDA include those of VSD as well as endocarditis and pulmonary emboli. Medical management is the same as for VSD (Blanchard & Daniels, 2014).

Cyanotic Lesions

Coarctation of the Aorta. Coarctation of the aorta (localized narrowing of the aorta near the insertion of the ductus) is an example of an acyanotic congenital heart lesion. If at all possible the lesion should be corrected surgically before pregnancy (Blanchard & Daniels, 2014; Roos-Hesselink et al., 2013). However, pregnancy is usually relatively safe for the woman with uncomplicated, uncorrected coarctation. Maternal mortality is about 3% for uncorrected defects (Blanchard & Daniels). Complications include hypertension, congestive heart failure, infective endocarditis, cerebrovascular accident

(stroke), aortic dissection, aneurysm, and rupture (Blanchard & Daniels; Easterling & Stout, 2012). The mainstays of treatment for uncorrected coarctation of the aorta during pregnancy are rest and antihypertensive medications, preferably beta-adrenergic blocking agents. Vaginal birth is preferable, with epidural anesthesia and shortening of the second stage with vacuum extraction or use of forceps, if necessary. Beta-blockers should be continued throughout labor. Because of the risk of endocarditis, antibiotic prophylaxis is recommended at birth (see later discussion).

Cyanotic Lesions

Tetralogy of Fallot. Tetralogy of Fallot is by far the most common cyanotic heart disease observed during pregnancy (Roos-Hesselink et al., 2013). Components of tetralogy of Fallot include a VSD, pulmonary stenosis, overriding aorta, and right ventricular hypertrophy, leading to a right-to-left shunt. Women with tetralogy of Fallot are encouraged to have surgical repair before conception because pregnancy does not pose a significant risk once the VSD and pulmonary stenosis have been repaired. Women with uncorrected tetralogy of Fallot, however, experience more right-to-left shunting during pregnancy, resulting in reduced blood flow through the pulmonary circulation and increasing hypoxemia, which can cause syncope or death (Gaddipati & Troiano, 2013). Maintenance of venous return in women with uncorrected tetralogy of Fallot is critical. Therefore, the most dangerous time for these women is the late third trimester of pregnancy and the early postpartum period, when venous return is reduced by the large pregnant uterus and by peripheral venous pooling after birth. Use of pressure-graded support hose is recommended. Blood loss during birth may also adversely affect venous return; thus blood volume must be adequately maintained. Prophylactic antibiotics should be given during the intrapartum period (Blanchard & Daniels, 2014).

Acquired Cardiac Disease

Mitral Valve Stenosis

Mitral valve stenosis (narrowing of the opening of the mitral valve caused by stiffening of valve leaflets, which obstructs blood flow from the left atrium to the left ventricle) is the characteristic lesion resulting from rheumatic heart disease (RHD) (Tomlinson, 2011). As the mitral valve narrows, dyspnea worsens, occurring first on exertion and eventually at rest. A tight stenosis plus the increase in blood volume and cardiac output of normal pregnancy may cause pulmonary edema, atrial fibrillation, right-sided heart failure, infective endocarditis, pulmonary embolism, and massive hemoptysis (Blanchard & Daniels, 2014; Cunningham, Leveno, Bloom, et al., 2014). Maternal mortality is related to functional capacity. Almost all maternal deaths related to mitral stenosis occur in women who are classified as NYHA class III or class IV (Cunningham et al.).

Pharmacologic treatment for women with a history of rheumatic heart disease may include diuretics such as furosemide (Lasix) to prevent pulmonary edema and beta-blockers or calcium channel blockers to prevent tachycardia (Easterling & Stout, 2012). A combination of drugs will most likely be needed. Cardioversion may be needed for new-onset atrial fibrillation. Women who have chronic atrial fibrillation may require digoxin

and beta-blockers or calcium channel blockers to control the heart rate. In addition, anticoagulant therapy may be needed to prevent embolism (Blanchard & Daniels, 2014). About 25% of women with mitral valve stenosis experience cardiac failure for the first time during pregnancy (Cunningham et al., 2014).

Care of the woman with mitral stenosis typically is managed by reducing her activity, restricting dietary sodium, and monitoring weight. The pregnant woman with mitral stenosis should be assessed clinically for symptoms and with echocardiograms to monitor the atrial and ventricular size, as well as heart valve function. Prophylaxis for intrapartum endocarditis and pulmonary infections may be provided for women at high risk (Blanchard & Daniels, 2014; Easterling & Stout, 2012) (Box 30-2).

During labor adequate pain control is required to prevent tachycardia. Epidural analgesia for labor is preferred (Tomlinson, 2011). Laboring and birthing in the lateral decubitus position are desirable. The lithotomy position, with the woman supine and her feet in stirrups, is an invitation to pulmonary edema (Blanchard & Daniels, 2014). Shortening the second stage of labor by vacuum- or forceps-assisted birth is also important to decrease the cardiac workload. Even with close monitoring, the woman with moderate to severe mitral stenosis is at risk for pulmonary edema, right-sided heart failure, and hypotension. Central hemodynamic monitoring may be necessary for some women during labor, birth, and the postpartum period because fluid shifts can place the woman at risk for pulmonary edema.

For women with NYHA class III or IV cardiac disease, percutaneous balloon mitral valvuloplasty can be performed, but this procedure should be considered only when symptoms cannot be controlled by standard means. Mitral balloon valvuloplasty is optimally performed after the first trimester to decrease radiation risks to the fetus. This relatively safe nonsurgical procedure is now performed more frequently during pregnancy than surgical valvotomy (Blanchard & Daniels, 2014). The balloon procedure is just as successful as surgical repair and is associated with less maternal and fetal morbidity and mortality (Cunningham et al., 2014).

BOX 30-2 Prophylaxis for Bacterial Endocarditis During Labor and Birth

High Risk Clients

In active labor: ampicillin 2 g IV or IM plus gentamicin 1.5 mg/kg (not to exceed 120 mg)
6 hours later: ampicillin 1 g IV or IM or amoxicillin 1 g PO

Penicillin-Allergic Clients

In active labor: vancomycin 1 g IV over 1-2 hr plus gentamicin as above

Moderate Risk Clients

In active labor: amoxicillin 2 g PO or ampicillin 2 g IV or IM

Penicillin-Allergic Clients

In active labor: vancomycin 1 g IV over 1-2 hr

IM, Intramuscular; IV, intravenous; PO, by mouth.

Data from Dajani, D.A., Taubert, K.A., Wilson, W., Bolger, A.F., Bayer, A., et al. (1997). Prevention of bacterial endocarditis: Recommendations by the American Heart Association. *JAMA* 96, 358-366.

Mitral Valve Prolapse

Mitral valve prolapse (MVP) is a fairly common, usually benign, condition. More specific echocardiographic diagnostic criteria have resulted in significantly reduced prevalence estimates for MVP (perhaps 1% of the female population) than previously thought (Blanchard & Daniels, 2014). The mitral valve leaflets prolapse into the left atrium during ventricular systole, allowing some backflow of blood. Midsystolic click and late systolic murmur are hallmarks of this syndrome. Most cases are asymptomatic. A few women have atypical chest pain (sharp and located in the left side of the chest) that occurs at rest and does not respond to nitrates. They may also have anxiety, palpitations, dyspnea on exertion, and syncope. If women are symptomatic, beta-blocking drugs are given to relieve chest pain and palpitations and reduce the risk of life-threatening arrhythmias (Cunningham et al., 2014). If symptoms are unusually severe, thyroid function should also be checked (Blanchard & Daniels, 2014). Pregnancy and its associated hemodynamic changes may alter or alleviate the murmur and click of MVP, as well as symptoms (Cunningham et al.; Easterling & Stout, 2012). Antibiotic prophylaxis for bacterial endocarditis is no longer recommended for women with uncomplicated mitral valve prolapse. Pregnancy, labor, and birth are usually safe and well tolerated (Blanchard & Daniels; Cunningham et al.).

Aortic Stenosis

Aortic stenosis (narrowing of the opening of the aortic valve leading to an obstruction to left ventricular ejection) is rarely encountered as a complication of pregnancy because most women who develop this condition do so after their childbearing years are over. In the past, the maternal mortality rate was reported to be as high as 17%, but it has decreased over the past several decades (Easterling & Stout, 2012). Medical management is similar to that for mitral stenosis.

Ischemic Heart Disease

Myocardial Infarction

Myocardial infarction (MI) (an acute ischemic event) is a rare event in women of childbearing age, usually occurring in the third trimester, with a maternal mortality rate of 5% to 8% (Tomlinson, 2011). When MI occurs *peripartum* (period of time that extends from the last month of pregnancy through the first few months postpartum), the mortality approaches 20%. MI is estimated to occur in only 1 in 10,000 women during pregnancy and usually in women more than 33 years of age (Blanchard & Daniels, 2014). Increasing age, chronic hypertension, diabetes, hypertensive disorders of pregnancy, thrombophilias, and postpartum infection are risk factors. Many of these factors are related to obesity so it is anticipated that the incidence of MI will rise because increasing numbers of women are obese (Tomlinson). Women with an MI intrapartum are likely to also have preeclampsia with severe features or eclampsia. Antepartum or postpartum MIs are most likely related to diabetes, coronary artery disease, and lipid disorders (Martin, Hill, & Foley, 2012). Women who have MIs during pregnancy or the postpartum period should be assessed for thrombophilias (deficiency of proteins involved in coagulation inhibition), such as antiphospholipid antibody.

Medical management for pregnant women after MI is the same as for nonpregnant women and includes the administration

of oxygen, aspirin, beta-blockers, nitrates, and heparin. Women who have had symptomatic cardiac disease during the pregnancy should continue cardiac medications and receive oxygen during labor. Because pain can lead to tachycardia and increased cardiac demand, pain control during labor is crucial (Martin et al., 2012). The side-lying position is preferred to avoid pressure on the vena cava. Vaginal birth is preferable, with avoidance of maternal pushing and a vacuum- or forceps-assisted birth (Easterling & Stout, 2012).

Other Cardiac Diseases and Conditions

Primary Pulmonary Hypertension

Women with primary pulmonary hypertension (PPH) have constriction of the arteriolar vessels in the lungs, leading to an increase in the pulmonary artery pressure. As a result of this pathology, there is right ventricular hypertension, right ventricular hypertrophy and dilation, and right ventricular failure with tricuspid regurgitation and systemic congestion. The major physiologic difficulty in PPH is maintaining blood flow to the lungs. Any event that significantly decreases venous return to the heart, such as hypotension, impairs the ability of the right ventricle to pump blood through the pulmonary vessels with their high, fixed vascular resistance. Because hypotension can occur quickly and is often unresponsive to medical therapy, it must be avoided at all costs (Blanchard & Daniels, 2014).

Symptoms may be nonspecific, such as fatigue and shortness of breath. Dyspnea on exertion is the most common symptom (Cunningham et al., 2014).

PPH is diagnosed by electrocardiography. Although cardiac catheterization remains the standard procedure for measuring pulmonary artery pressures, noninvasive echocardiography is often used to provide an estimate of these pressures (Cunningham et al., 2014). Mortality rates reported during pregnancy are as high as 50%, so pregnancy is not advised in women with this condition (Blanchard & Daniels, 2014). The most dangerous times for women with this condition are the intrapartum and early postpartum periods because of increases in cardiac output and fluid shifts (Roos-Hesselink et al., 2013).

Medical management of women with PPH during pregnancy includes limiting activity and avoiding supine positioning (Roos-Hesselink et al., 2013). Diuretics, supplemental oxygen, and vasodilator medications also will be ordered. During labor and birth hypotension must be avoided by carefully establishing epidural analgesia and preventing blood loss (Cunningham et al., 2014).

Marfan Syndrome

Marfan syndrome is an autosomal dominant genetic disorder characterized by generalized weakness of the connective tissue, resulting in joint deformities, ocular lens dislocation, and weakness of the aortic wall and root. Associated cardiovascular changes include mitral valve prolapse, mitral regurgitation, aortic regurgitation, aortic root dilation, and possible dissection or rupture of the aortic root (Roos-Hesselink et al., 2013).

The majority of deaths from Marfan syndrome are caused by aortic dissection and rupture. Excruciating chest pain is the most common symptom of aortic dissection. Aortic dissection most often occurs in the third trimester or postpartum. Overall the maternal mortality rate associated with Marfan syndrome

is greater than 50%. However, it is significantly increased if the aortic root diameter measures more than 4 cm (Easterling & Stout, 2012). Preconception genetic counseling is recommended to make women aware of the risks of pregnancy with this condition. Because the condition is inherited, each child born to a woman with Marfan syndrome has a 50% chance of having the disorder (Blanchard & Daniels, 2014; National Marfan Association, 2013). Baseline data should be gathered about the aortic root before pregnancy or at the first prenatal visit by noninvasive imaging with transesophageal echocardiography, computed tomography (CT), or magnetic resonance imaging (MRI).

Management during pregnancy includes restricted activity and use of beta-blockers; surgery may be indicated in some women (Roos-Hesselink et al., 2013). Vaginal birth is considered safe for women with aortic root diameters less than 4 cm. Some authorities, however, recommend that women with larger aortic root diameters give birth by elective cesarean because of concerns about increased pressure in the aorta during labor (Roos-Hesselink et al.).

Infective Endocarditis

Infective endocarditis is inflammation of the innermost lining—the endocardium—of the heart, caused by invasion of microorganisms. In the United States, women at greatest risk to develop infective endocarditis are those who have congenital heart lesions, degenerative valve disease, or intracardiac devices or who use drugs intravenously (Cunningham et al., 2014). Bacterial endocarditis, leading to incompetence of heart valves and thus congestive heart failure and cerebral emboli, can result in death. Treatment is with antibiotics. Prophylactic treatment with antibiotics is used only for women at highest risk for this condition.

Eisenmenger Syndrome

Eisenmenger syndrome is a right-to-left or bidirectional shunting that can occur either at the atrial or the ventricular level of the heart and is combined with elevated pulmonary vascular resistance (Roos-Hesselink et al., 2013). The syndrome is associated with high mortality (50% in mothers and 50% in fetuses). Because of the risk for poor pregnancy outcomes, pregnancy should be avoided by women with Eisenmenger syndrome (Gaddipati & Troiano, 2013).

In women who become pregnant despite the risks, physical activity is strictly limited. Hospitalization may be necessary to provide optimal care, which includes oxygen administration, rest, and fetal monitoring. During labor and birth, intrathecal or epidural morphine sulfate is recommended to maintain hemodynamic stability. Hypotension must be avoided at all costs because it results in more right-to-left shunting (Blanchard & Daniels, 2014; Easterling & Stout, 2012). Pulse oximetry is a useful assessment tool to guide the treatment plan during labor and birth. Cesarean birth should be performed only for obstetric indications and avoided whenever possible (Roos-Hesselink et al., 2013).

Peripartum Cardiomyopathy

Peripartum cardiomyopathy (PCM) is congestive heart failure with cardiomyopathy. The classic criteria for the

diagnosis of PCM include development of congestive heart failure in the last month of pregnancy or within the first 5 postpartum months, absence of heart disease before the last month of pregnancy, a left ventricular ejection fraction (EF) of less than 45%, and, most important, lack of another cause for heart failure. The cause of the disease is unknown. The U.S. incidence is 1 in 3000 to 4000 live births (Blanchard & Daniels, 2014).

Associated risk factors for PCM include maternal age older than 35 years, multifetal gestation, preeclampsia, gestational hypertension, multiparity, African descent, and prolonged tocolytic therapy. Maternal mortality has been reported with rates as high as 56%, but more recent data have indicated a lower rate, more likely around 9% (Martin et al., 2012). Clinical findings are those of congestive heart failure (left ventricular failure). Clinical manifestations include dyspnea, fatigue, and edema, as well as radiologic findings of cardiomegaly.

Medical management of PCM includes a regimen used for congestive heart failure: diuretics, sodium and fluid restriction, afterload-reducing agents, and digoxin. Anticoagulation may be necessary if the cardiac chambers are significantly dilated and contract poorly because of the increased risk for clot formation. During labor epidural anesthesia is often used for pain control to decrease the cardiac workload and reduce tachycardia. Cesarean birth should be performed only for obstetric indications (Easterling & Stout, 2012).

In half of all women with PCM, left ventricular dysfunction resolves within 6 months. These women generally do well. If left ventricular dysfunction does not resolve within 6 months, however, approximately 85% of women with PCM will die in the next 4 to 5 years. Death is usually the result of progressive congestive heart failure, arrhythmia, or thromboembolism (Easterling & Stout, 2012). The recurrence rate for cardiomyopathy in a subsequent pregnancy is high—anywhere from 20% to 50%. The risk of recurrence is increased in women who did not have complete recovery of left ventricular function after the initial episode of PCM (Blanchard & Daniels, 2014).

Valve Replacement

Pregnant women with mechanical or bioprosthetic heart valves require specialized care for this high risk situation. The primary medical management, anticoagulation, is both controversial and complicated. A high risk for thromboembolism exists because of the hypercoagulability of pregnancy. At the same time, the use of anticoagulants during pregnancy presents the possibility of maternal and fetal hemorrhage. Some oral anticoagulants pose a significant risk to the fetus for abnormalities and intracranial hemorrhage. Prosthetic heart valve thrombosis is a life-threatening emergency during pregnancy and requires clot removal surgery, which carries a high mortality rate (Roos-Hesselink et al., 2013).

Women with bioprosthetic heart valves usually do not require anticoagulation during pregnancy. This type of valve is an ideal replacement for women of childbearing age. A disadvantage of this valve, however, is premature failure, which may occur within 10 to 15 years of placement. Premature valve failure may be exacerbated by pregnancy (Tomlinson, 2011).

The recommendations for pregnant women with mechanical prosthetic valves who need anticoagulation therapy include several different treatment regimens. Because the most effective and safest management has not been determined through controlled trials, the decision regarding choice of therapy should be made between the physician and the woman, who should be fully informed about the potential risks of the various options to her and her unborn child. One option is to use subcutaneous heparin for the first 12 weeks of gestation. Warfarin (Coumadin) then is used until week 35 of gestation, followed by a return to heparin (intravenous) until after the birth. If prothrombin time (PT) results are reported in international normalized ratio (INR) values, then the desired range is between 2.5 and 3.5 (Tomlinson, 2011). A second option is to use warfarin for the entire pregnancy up to 35 weeks of gestation followed by intravenous heparin until labor begins. Data are inconclusive regarding the use of low-molecular-weight heparin (Lovenox). Anticoagulation therapy should be discontinued during active labor and resumed in the postpartum period. Warfarin does not adversely affect breastfeeding.

Heart Transplantation

Increasing numbers of heart recipients are successfully completing pregnancies. It is recommended that pregnancy be avoided for at least 1 year after the transplant (Blanchard & Daniels, 2014). Before conception the woman should be assessed for quality of ventricular function and potential rejection of the transplant. She also should be considered to be stabilized on her immunosuppressant regimen. Women who have no evidence of rejection and have normal cardiac function at the beginning of the pregnancy appear to do well during pregnancy, labor, and birth. Risks to the woman include hypertension, preeclampsia, preterm birth, and mild rejection episodes (Martin et al., 2012).

CARE MANAGEMENT

The presence of cardiac disease is a significant influencing factor in the decision-making process for or against becoming pregnant. Couples planning a pregnancy must understand the risks involved in their situation. If the pregnancy is unplanned, the nurse should explore the couple's desire to continue the pregnancy in light of the risks involved. Pregnancy termination is one option, depending on the severity of the cardiac defect. The family may need further information to make an informed decision regarding the future of the pregnancy.

Assessment and Nursing Diagnoses

The pregnant woman with a cardiac disorder is in a high risk situation. She requires detailed assessment throughout the peripartum period to determine the potential for optimal maternal health and a viable fetus. Her care will be provided by a multidisciplinary team, including a cardiologist, obstetrician, perinatologist, and registered nurse experienced in the care of women with high risk pregnancies. If she chooses to continue the pregnancy, the woman's condition may be assessed as often as weekly. For additional information on

cardiac disease, visit the American Heart Association's website at www.americanheart.org.

Potential nursing diagnoses include:

- *Fear* related to
 - increased peripartum risk
- *Risk for Ineffective Coping/Compromised Family Coping* related to
 - woman's cardiac condition
 - changes in role performance
- *Ineffective Peripheral Tissue Perfusion* related to
 - hypotensive syndrome
- *Activity Intolerance* related to
 - cardiac condition
- *Deficient Knowledge* related to
 - cardiac condition
 - pregnancy and how it affects cardiac condition
 - medication: dosages and possible side effects
 - requirements to alter self-care activities
- *Self-Care Deficit* (Bathing, Dressing, Toileting) related to
 - fatigue or activity intolerance
 - need for bed rest
- *Impaired Home Maintenance* related to
 - woman's confinement to bed and/or limited activity level

COMMUNITY ACTIVITY

- Identify a major medical center near where you live. Check to see if they offer maternity services. If they do, see if they have information related to high risk pregnancies and the staff available to care for them. Maternal-fetal medicine physicians (perinatologists) are physicians who specialize in high risk maternal care. Determine how many providers are at the facility and what types of resources they offer online for women with a high risk pregnancy. Also find out if the hospital offers high risk neonatal care. Many infants born to women with medical complications need to be cared for in a neonatal intensive care unit (NICU). Review the website for information on what the NICU is like and resources to support the family with an infant in the NICU.
- Review the local newspaper or community websites to determine if there are support groups in your area for women with high risk pregnancies. Also check online sites because many women connect with online communities when they are pregnant.

Interventions

Antepartum

Therapy for the pregnant woman with heart disease is focused on minimizing stress on the heart, which intensifies as cardiac output increases. Cardiac output begins to rise significantly early in pregnancy and probably peaks somewhere between 25 and 30 weeks of gestation (Gordon, 2012). Factors that increase the risk of cardiac decompensation are avoided. The workload of the cardiovascular system is reduced by appropriate treatment of any coexisting emotional stress, hypertension, anemia, hyperthyroidism, or obesity.

Signs and symptoms of cardiac decompensation are taught at the first prenatal visit and reviewed at each subsequent visit (see the Signs of Potential Complications box).

SIGNIS OF POTENTIAL COMPLICATIONS

Cardiac Decompensation

Pregnant Woman: Subjective Symptoms

- Increasing fatigue or difficulty breathing, or both, with her usual activities
- Feeling of smothering
- Frequent cough
- Palpitations; feeling that her heart is “racing”
- Generalized edema: swelling of face, feet, legs, fingers (e.g., rings do not fit anymore)

Nurse: Objective Signs

- Irregular, weak, rapid pulse (≥ 100 beats/min)
- Progressive, generalized edema
- Crackles at base of lungs after two inspirations and exhalations that do not clear after coughing
- Orthopnea; increasing dyspnea
- Rapid respirations (≥ 25 breaths/min)
- Moist, frequent cough
- Cyanosis of lips and nailbeds

Infections are treated promptly because respiratory, urinary, or gastrointestinal (GI) tract infections can complicate the condition by accelerating the heart rate and by direct spread of organisms (e.g., streptococci) to the heart structures. The woman should notify her physician at the first sign of infection or exposure to an infection. Vaccination against influenza and pneumococci can be given (Easterling & Stout, 2012).

Nutrition counseling is necessary, optimally with the woman's family present. The pregnant woman needs a well-balanced diet

with iron and folic acid supplementation, high protein levels, and adequate calories to gain weight. Iron supplements tend to cause constipation, so the woman should increase her intake of fluids and fiber. A stool softener may also be prescribed. It is important that the woman with a cardiac disorder avoid straining during defecation, thus causing the Valsalva maneuver (forced expiration against a closed airway, which when released, causes blood to rush to the heart and overload the cardiac system). Sodium restriction may be necessary. The woman's intake of potassium may be monitored to prevent hypokalemia, especially if she is taking diuretics. Depending on the specific cardiac condition, some women may be limited in their total daily fluid intake. A referral to a registered dietitian may be necessary for a nutritional plan of care.

Cardiac medications are prescribed as needed, with attention to fetal well-being. The hemodynamic changes that occur during pregnancy, such as increased plasma volume and increased renal clearance of drugs, can alter the amount of medication needed to establish and maintain a therapeutic drug level. Therefore, monitoring drug levels during pregnancy is crucial to maintain effective therapy for the woman while minimizing risk to the fetus. Table 30-1 lists information on medications that are often used to treat cardiac disorders during pregnancy.

Anticoagulant therapy may be prescribed during pregnancy for several conditions, such as recurrent venous thrombosis, pulmonary embolus, rheumatic heart disease, prosthetic valves, or cyanotic congenital heart defects. If anticoagulant therapy is required during pregnancy a number of various regimens may be recommended (see the section on valve disorders for more discussion of anticoagulant therapy). The nurse should be aware of the goals of therapy and monitor

TABLE 30-1 Selected Drugs Used in Treatment of Cardiac Disorders in the Pregnant Woman

GENERIC (TRADE) NAME	USE IN PREGNANCY	POTENTIAL SIDE EFFECTS
Digoxin (Lanoxin)	Maternal and fetal arrhythmias, heart failure	No evidence for unfavorable side effects on the fetus
Procainamide (Procanbid, Pronestyl)	Maternal and fetal arrhythmias	Limited data; no fetal side effects reported
Verapamil (Calan, Isoptin)	Maternal and fetal arrhythmias	Limited data; other than one case of fetal death of uncertain cause, no adverse fetal or newborn effects reported
B-Blockers (a class of drugs)	Hypertension, maternal arrhythmias, myocardial ischemia, mitral stenosis, hypertrophic cardiomyopathy, hyperthyroidism, Marfan syndrome	Fetal bradycardia, low placental weight, possible IUGR, hypoglycemia; no information on carvedilol
Heparin	Anticoagulation	None reported
Warfarin (Coumadin)	Anticoagulation	Crosses placenta; fetal hemorrhage, embryopathy, CNS abnormalities
Diuretics (a class of drugs)	Hypertension, congestive heart failure	Hypovolemia leads to reduced uteroplacental perfusion, fetal hypoglycemia, thrombocytopenia, hyponatremia, hypokalemia; thiazide diuretics can inhibit labor and suppress lactation
Lidocaine (Xylocaine)	Local anesthesia, maternal arrhythmias	No evidence for unfavorable fetal effects; high serum levels may cause CNS depression at birth
Quinidine (Quinidex)	Maternal and fetal arrhythmias	Minimal oxytocic effect, high dosages may cause premature labor or miscarriage; transient neonatal thrombocytopenia and damage to eighth cranial nerve reported
Nifedipine (Procardia, Adalat)	Hypertension, tocolysis	Fetal distress related to maternal hypotension reported
ACE inhibitors (a class of drugs)	Hypertension	Oligohydramnios, IUGR, prematurity, neonatal hypotension, renal failure, anemia, death, skull ossification defect, limb contractures, patent ductus arteriosus
Sodium nitroprusside	Hypertension, aortic dissection	Limited data; potential thiocyanate fetal toxicity, fetal mortality reported in animals

ACE, Angiotensin-converting enzyme; CNS, central nervous system; IUGR, intrauterine growth restriction.

From Blanchard, D.G., & Daniels, L.B. (2014). Cardiac diseases. In R.K. Creasy, R. Resnik, J.D. Iams, et al. (Eds.), *Creasy and Resnik's maternal-fetal medicine: Principles and practice* (7th ed.). Philadelphia: Saunders.

the PT and INR accordingly. The woman may need to learn to self-administer injectable agents such as heparin or low-molecular-weight heparin. A woman taking warfarin (Coumadin) requires specific nutritional teaching to avoid foods high in vitamin K, such as raw, dark green leafy vegetables, which counteract the effects of warfarin. In addition, she will require a folic acid supplement.

Tests for fetal maturity and well-being and placental sufficiency may be necessary. Other therapy is directly related to the functional classification of heart disease. The nurse must reinforce the need for close medical supervision (see the Nursing Care Plan).

Heart Surgery During Pregnancy. Ideally surgery to correct a cardiac lesion should be performed prior to pregnancy. In some women, however, cardiac disease is diagnosed for the first time during pregnancy. The maternal mortality risk does not increase, but there is a fetal mortality risk of 10% to 15% if heart surgery is performed, especially if cardiopulmonary bypass is used. If possible, surgery should be postponed until the third trimester of pregnancy, when the risk to the fetus is considerably decreased (Blanchard & Daniels, 2014).

Intrapartum

For all pregnant women the intrapartum period is the one that causes the most apprehension in clients and caregivers. The woman with impaired cardiac function has additional reasons to be anxious because labor and giving birth place an additional burden on her already compromised cardiovascular system.

Assessments include the routine assessments for all laboring women, as well as for cardiac decompensation. In addition, arterial blood gases (ABGs) may be needed to assess for adequate oxygenation. A pulmonary artery catheter may be inserted to monitor hemodynamic status accurately during labor and birth. Electrocardiographic monitoring and continuous monitoring of blood pressure and oxygen saturation (pulse oximetry) are usually instituted for the woman, and continuous fetal heart rate monitoring is used to monitor the fetus.

Nursing care during labor and birth focuses on promoting cardiac function. Minimize anxiety by maintaining a calm atmosphere in the labor and birth rooms. Provide anticipatory guidance by keeping the woman and her family informed of labor progress and events that can occur, as well as answering any questions. Support the woman's childbirth preparation method to the degree it is feasible for her cardiac condition. Nursing techniques that promote comfort, such as back massage, also are used.

Cardiac function is supported by keeping the woman's head and shoulders elevated and body parts resting on pillows. The

side-lying position usually facilitates positive hemodynamics during labor. Discomfort is relieved with medication and supportive care. Physiologically the ideal labor for a woman with heart disease is one that is short and pain free. Therefore, use of epidural anesthesia is encouraged, although care must be taken to avoid hypotension, a common side effect of regional anesthesia (Easterling & Stout, 2012; Gaddipati & Troiano, 2013).

LEGAL TIP: Cardiac and Metabolic Emergencies

The management of emergencies such as maternal cardiopulmonary distress or arrest or maternal metabolic crisis should be documented in policies, procedures, and protocols. Any independent nursing actions appropriate to the emergency should be clearly identified.

Beta-adrenergic agents such as terbutaline (Brethine) are associated with various side effects, including tachycardia, irregular pulse, myocardial ischemia, and pulmonary edema. Therefore, these medications should not be used in women with known or suspected heart disease (Gilbert, 2011; Simhan, Berghella, & Iams, 2014; Simhan, Iams, & Romero, 2012). A synthetic oxytocin (Syntocinon) can be used to induce labor. This drug does not appear to cause significant coronary artery constriction in doses prescribed for labor induction or control of postpartum uterine atony. Cervical ripening agents containing prostaglandin are usually tolerated well but should be used cautiously.

If there are no obstetric problems, vaginal birth is recommended and may be accomplished with the woman in the side-lying position to facilitate uterine perfusion. If the supine position is used, position a pad under one hip to displace the uterus laterally and minimize the danger of supine hypotension. Have the woman flex her knees and place her feet flat on the bed. To prevent compression of popliteal veins and an increase in blood volume in the chest and trunk as a result of the effects of gravity, do not use stirrups. Open-glottis pushing is recommended. The woman should avoid the Valsalva maneuver when pushing in the second stage of labor because it reduces diastolic ventricular filling and obstructs left ventricular outflow. Mask oxygen is important. Episiotomy and vacuum extraction or outlet forceps can be used to decrease the length of the second stage of labor and decrease the heart's workload during that time. Cesarean birth is not routinely recommended for women who have cardiovascular disease because of the risks of dramatic fluid shifts, sustained hemodynamic changes, and increased blood loss.

According to the American Heart Association, prophylactic antibiotics to prevent infective endocarditis are recommended only for those women considered to be at the highest risk. Women who should receive prophylactic antibiotics include those with a prosthetic heart valve, a history of infective endocarditis, unrepaired congenital heart disease or a congenital heart defect repaired with prosthetic material or with residual defects at or adjacent to the repair site, or cardiac transplant recipients who develop cardiac valvulopathy (Blanchard & Daniels, 2014) (see Box 30-2). Oxytocin is usually given immediately after birth to prevent hemorrhage. Ergot products (e.g.,

NURSING ALERT

A pulse rate of 100 beats/minute or greater or a respiratory rate of 25 breaths/minute or greater is a concern. Check the respiratory status frequently for developing dyspnea, coughing, or crackles at the base of the lungs. Note the color and temperature of the skin as well. Pale, cool, clammy skin may indicate cardiac shock.

methylergonovine [Methergine]) should not be used because they increase blood pressure. Fluid balance should be maintained and blood loss replaced. If tubal sterilization after vaginal birth is desired, surgery can be delayed for several days if necessary, until the woman is hemodynamically near normal, afebrile, nonanemic, and able to ambulate normally (Cunningham et al., 2014).

Postpartum

Monitoring for cardiac decompensation in the postpartum period is essential. The first 24 to 48 hours after birth are the most hemodynamically difficult for the woman. Hemorrhage or infection, or both, may worsen the cardiac condition. The woman with a cardiac disorder may continue to require a pulmonary artery catheter and ABG monitoring.

NURSING CARE PLAN

The Pregnant Woman with Heart Disease

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Activity Intolerance related to effects of pregnancy on the woman with rheumatic heart disease with mitral valve stenosis</i>	Woman will verbalize a plan to change lifestyle throughout pregnancy so as to reduce the risk of cardiac decompensation.	Assist the woman in identifying factors that decrease activity tolerance and explore extent of limitations.	To establish a baseline for evaluation
		Help the woman develop an individualized program of activity and rest, taking into account the living and working environment, as well as support of family and friends.	To maintain sufficient cardiac output
		Teach the woman to monitor physiologic responses to activity (e.g., pulse rate, respiratory rate) and reduce activity that causes fatigue or pain.	To maintain sufficient cardiac output and prevent potential injury to the fetus
		Enlist the woman's family and friends to assist her in pacing activities and to provide support in performing role functions and self-management activities that are too strenuous.	To increase the chances of compliance with activity restrictions
		Suggest that the woman maintain an activity log that records activities, time, duration, intensity, and physiologic response.	To evaluate effectiveness of and adherence to the activity program
		Discuss various quiet diversional activities that the woman can or may perform.	To decrease the potential for boredom during rest periods
<i>Risk for Ineffective Therapeutic Regimen Management related to the woman's first pregnancy and perceived sense of wellness</i>	Woman will participate in an effective therapeutic regimen for pregnancy complicated by heart disease.	Identify factors such as insufficient knowledge about the effect of cardiac disease on pregnancy that might inhibit the woman from participating in a therapeutic regimen.	To promote early interventions, such as teaching about the importance of rest
		Teach the woman and her family about factors such as lack of rest or not taking prescribed medications that might adversely affect the pregnancy.	To provide information and promote empowerment over the situation
		Encourage expression of feelings about the disease and its potential effect on the pregnancy.	To promote a sense of trust
		Identify resources in the community.	To provide a shared sense of common experiences and sources of assistance if needed to fulfill personal, family, and home responsibilities
		Encourage the woman to verbalize her plan for carrying out the regimen of care.	To evaluate the effects of teaching

 **NURSING CARE PLAN—cont'd**
The Pregnant Woman with Heart Disease

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Decreased Cardiac Output related to increased circulatory volume secondary to pregnancy and cardiac disease</i>	Woman will exhibit signs of adequate cardiac output (i.e., normal pulse and blood pressure; normal heart and breath sounds; normal skin color, tone, and turgor; normal capillary refill; normal urine output; no evidence of edema).	<p>Reinforce the importance of activity and rest cycles.</p> <p>Reinforce the importance of the frequent visit schedule to the caregiver.</p> <p>Teach the woman and her family members the signs of cardiac decompensation.</p> <p>Teach the woman to lie on her side.</p> <p>Teach the woman to elevate her legs while sitting.</p> <p>Monitor intake and output and check for edema.</p> <p>Monitor the fetal heart rate and fetal activity and perform a non-stress test as indicated.</p>	<p>To prevent cardiac complications</p> <p>To provide adequate surveillance of the high risk pregnancy</p> <p>To provide information about when to contact the health care provider</p> <p>To increase uteroplacental blood flow</p> <p>To promote venous return</p> <p>To assess for renal complications or venous return problems</p> <p>To assess fetal status and detect uteroplacental insufficiency</p>

 **SAFETY ALERT**

The immediate postbirth period is hazardous for a woman whose heart function is compromised. Cardiac output increases rapidly as extravascular fluid is remobilized into the vascular compartment. At the moment of birth, intraabdominal pressure is reduced dramatically; pressure on veins is removed, the splanchnic vessels engorge, and blood flow to the heart is increased.

Care in the postpartum period is tailored to the woman's functional capacity. Postpartum assessment of the woman with cardiac disease includes vital signs, oxygen saturation levels, lung and heart auscultation, presence and degree of edema, amount and character of bleeding, uterine tone and fundal height, urinary output, pain (especially chest pain), the activity-rest pattern, dietary intake, mother-infant interactions, and emotional state. The head of the bed is elevated, and the woman is encouraged to lie on her side. Bed rest may be ordered, with or without bathroom privileges. Progressive ambulation may be permitted as tolerated. The nurse may help the woman meet her grooming and hygiene needs and other activities. Bowel movements without stress or strain are promoted with stool softeners, diet, and fluids.

The woman may need a family member to help care for the infant. Breastfeeding is not contraindicated, but some women with heart disease (particularly those with life-threatening disease) may be unable to breastfeed. The woman who chooses to breastfeed will need the support of her family and the nursing staff to be successful. For example, she may need assistance in positioning herself or the infant for feeding. To further conserve the woman's energy, the infant can be given to the mother and taken from her after the feeding. Most medications used to manage cardiac disorders are compatible with breastfeeding. Thiazide diuretics, however, may suppress lactation (Blanchard & Daniels, 2014). Because diuretics can cause neonatal diuresis

that can lead to dehydration, lactating women must be monitored closely to determine if medication doses can be reduced and still be effective.

If the woman is unable to breastfeed and her energies do not allow her to bottle feed the infant, the baby can be kept at the bedside so she can look at and touch her baby to establish an emotional bond with a low expenditure of energy. The infant should be held at the mother's eye level and near her lips and brought to her fingers. At the same time, involving the mother passively in her infant's care helps the mother feel vitally important—as she is—to the infant's well-being (e.g., “You can offer something no one else can: you can provide your baby with your sounds, touch, and rhythms that are so comforting”). Perhaps the woman can be encouraged to make a tape recording of her talking, singing, or whispering, which can be played for the baby in the nursery to help the infant feel her presence and be in contact with her voice. This also enhances maternal-infant bonding.

Preparation for discharge is carefully planned with the woman and family. Provision of help for the woman in the home by relatives, friends, and others must be addressed. If necessary, the nurse refers the family to community resources (e.g., for assistance with household activities). Rest and sleep periods, activity, and diet must be planned. The couple may need information about reestablishing sexual relations and contraception or sterilization.

Women with congenital heart disease should be offered contraceptive counseling. In general, the complications associated with pregnancy are usually greater than the risks associated with any form of contraception (Easterling & Stout, 2012). Women at particular risk for thromboembolism should avoid combined estrogen-progestin oral contraceptives, but progestin-only pills may be used. Parenteral progestins (e.g., medroxyprogesterone [Depo-Provera]) are safe and effective. However, they cause irregular bleeding, which may be problematic for women on

anticoagulant therapy. An intrauterine device (IUD) may be used by some women with congenital heart lesions. Although a theoretic risk exists for developing endocarditis, the actual risk for women using an IUD is probably very minimal (Easterling & Stout).

Monitoring for cardiac decompensation continues through the first few weeks after birth because of hormonal shifts that affect hemodynamics. Maternal cardiac output is usually stabilized by 2 weeks postpartum (Easterling & Stout, 2012).

Men and women with congenital heart disease are at increased risk for having children who also have congenital heart disease. The risk for affected mothers is greater, approximately two to more than three times that of affected fathers. Children born with congenital heart disease to parents with congenital heart defects appear to inherit the risk for a defect in general rather than for a specific defect (Easterling & Stout, 2012). Therefore, preconception counseling and genetic counseling before a subsequent pregnancy are essential.

OTHER MEDICAL DISORDERS IN PREGNANCY

Anemia

Anemia is a common medical disorder of pregnancy, affecting from 20% to 52% of women (Kilpatrick, 2014). Anemia results in a reduction of the oxygen-carrying capacity of the blood. Because the oxygen-carrying capacity of the blood is decreased, the heart tries to compensate by increasing the cardiac output. This effort increases the workload of the heart and stresses ventricular function. Therefore, anemia that occurs with any other complication (e.g., preeclampsia) may result in congestive heart failure.

An indirect index of the oxygen-carrying capacity is the packed red blood cell (RBC) volume, or hematocrit level. The normal hematocrit range in nonpregnant women is 37% to 47%. However, normal values for pregnant women with adequate iron stores may be as low as 33%. According to the Centers for Disease Control and Prevention (CDC), anemia in pregnancy is defined as hemoglobin less than 11 g/dl in the first and third trimesters and less than 10.5 g/dl in the second trimester (Kilpatrick, 2014). A hemoglobin level less than 6 to 8 mg/dl is considered severe anemia (Blackburn, 2013).

When a woman has anemia during pregnancy, the loss of blood at birth, even if minimal, is not well tolerated. She is at an increased risk for requiring blood transfusions. Women with anemia have a higher incidence of puerperal complications, such as infection, than postpartum women with normal hematologic values.

Care of the anemic pregnant woman requires that the health care provider distinguish between the normal physiologic anemia of pregnancy and disease states. The majority of cases of anemia in pregnancy are caused by iron deficiency. The other types include a considerable variety of acquired and hereditary anemias, such as folic acid deficiency, sickle cell anemia, and thalassemia.

Iron Deficiency Anemia

Iron deficiency anemia is the most common anemia of pregnancy. It is diagnosed by checking the woman's serum ferritin level in addition to her hemoglobin and hematocrit levels.

The serum ferritin level reflects iron reserves (Samuels, 2012). A serum ferritin value less than 12 mcg/l in the presence of a low hemoglobin value indicates iron deficiency anemia (Blackburn, 2013). There appears to be an association between maternal iron deficiency anemia, especially severe anemia, and preterm birth and low-birth-weight infants, although whether these poor pregnancy outcomes are caused by iron deficiency anemia is uncertain (Samuels). Usually even the fetus of an anemic woman will receive adequate iron stores from the mother, at the cost of further depleting the mother's iron level (Blackburn).

Generally iron deficiency anemia is preventable or easily treated with iron supplements. Because of the increased amounts of iron needed for fetal development and maternal stores, pregnant women are often encouraged to take prophylactic iron supplementation (Blackburn, 2013; Gilbert, 2011). Most women with iron deficiency anemia can absorb as much iron as they need by taking one 325-mg tablet of ferrous sulfate twice each day (Samuels, 2012). Some pregnant women cannot tolerate the prescribed oral iron because of nausea and vomiting associated with the pregnancy and as a side effect of iron therapy. In such cases they may be given parenteral iron therapy by intramuscular or intravascular injection. Women who are severely anemic may require blood transfusions (Samuels).

Teach the importance of iron supplements for preventing or treating iron deficiency anemia. In addition, teach dietary ways to decrease the GI side effects of iron therapy (see Teaching for Self-Management: Iron Supplementation in Chapter 15).

Folate Deficiency Anemia

Folate is a water-soluble vitamin found naturally in dark green leafy vegetables, citrus fruits, eggs, legumes, and whole grains. Even in well-nourished women, folate deficiency is common. Poor diet, cooking with large volumes of water, and increased alcohol use may contribute to folate deficiency. During pregnancy the need for folate increases, both because of fetal demands and because it is less well absorbed from the GI tract during gestation.

Folic acid is the form of the vitamin used in vitamin supplements. The recommended daily intake of folic acid for nonpregnant women is 400 mcg. Pregnant women need 50% more, or 600 mcg/day (Otten, Helwig, & Meyers, 2006). Since 1998 the U.S. Food and Drug Administration (FDA) has required the addition of folic acid to cereals, pasta, breads, and other foods that are labeled "enriched." However, the amount added is small, and most pregnant women need a supplement. Both prescription and nonprescription prenatal vitamins contain more than this amount of folic acid and should be sufficient to prevent and treat folate deficiency. Women at particular risk for folate deficiency include those who have significant hemoglobinopathies, take an anticonvulsant medication, or are pregnant with a multifetal gestation. These women require larger doses of folic acid (Samuels, 2012).

Folate deficiency is the most common cause of megaloblastic anemia during pregnancy, but a vitamin B₁₂ deficiency must also be considered. Vitamin B₁₂ deficiency in pregnant women is seen much more often than in the past because of the increasing number of women who become pregnant after undergoing

bariatric surgery. Megaloblastic anemia rarely occurs before the third trimester of pregnancy (Kilpatrick, 2014; Samuels, 2012). Women with megaloblastic anemia caused by folic acid deficiency have the usual presenting symptoms and signs of anemia: pallor, fatigue, and lethargy, as well as glossitis and skin roughness, which are associated specifically with megaloblastic anemia (Kilpatrick). Folate deficiency usually improves rapidly with folic acid therapy. It rarely occurs in the fetus and is not a significant cause of perinatal morbidity. Iron deficiency often occurs along with folate deficiency (Samuels).

Sickle Cell Hemoglobinopathy

Sickle cell hemoglobinopathy is a disease caused by the presence of abnormal hemoglobin in the blood. Sickle cell trait (SA hemoglobin pattern) is sickling of the RBCs but with a normal RBC life span. Most people with sickle cell trait are asymptomatic. Approximately 1 in 12 African-American adults in the United States has sickle cell trait (Samuels, 2012). Women with sickle cell trait require genetic counseling and partner testing to determine their risk of producing children with sickle cell trait or disease.

Women with sickle cell trait usually do well in pregnancy. However, they are at increased risk for preeclampsia, intrauterine fetal death, preterm birth and low-birth-weight infants, and postpartum endometritis. They are also at increased risk for urinary tract infections (UTIs) and may be deficient in iron (Kilpatrick, 2014; Samuels, 2012).

Sickle cell anemia (sickle cell disease) is a recessive, hereditary, familial hemolytic anemia that affects people of African or Mediterranean ancestry. These individuals usually have abnormal hemoglobin types (SS or SC). The average life span of RBCs in a person with sickle cell anemia is only 5 to 10 days, in comparison to the 120-day life span of a normal RBC. Sickle cell anemia occurs in 1 in 708 African-Americans in the United States (Samuels, 2012). People with sickle cell anemia have recurrent attacks (crises) of fever and pain, most often in the abdomen, joints, or extremities, although virtually all organ systems can be affected. These attacks are attributed to vascular occlusion when RBCs assume a characteristic sickled shape. Crises are usually triggered by dehydration, hypoxia, or acidosis (Samuels).

Women with sickle cell anemia require genetic counseling before pregnancy. All children born to a woman with sickle cell anemia will be affected in some way by the disease. The woman's partner must be tested to determine the couple's risk of producing children with sickle cell disease rather than sickle cell trait. Women with sickle cell anemia are at risk for poor pregnancy outcomes, including miscarriage, IUGR, and stillbirth. Although maternal mortality is rare, maternal morbidity is significant and includes an increased risk for preeclampsia and infection, particularly in the urinary tract and in the lungs. The frequency of painful crises also appears to be increased during pregnancy (Samuels, 2012).

The woman is monitored carefully during pregnancy for the development of a UTI or preeclampsia. In addition, she will have serial ultrasound examinations to monitor fetal growth and will likely have antepartum fetal testing performed regularly during the third trimester. Infections are treated aggressively with antibiotics. If crises occur they are managed with analgesia, oxygen, and hydration.

If no complications occur, pregnancy can continue until term. Intrapartum, women with sickle cell disease should be encouraged to labor in a side-lying position. They may require supplemental oxygen. Adequate hydration should be maintained while preventing fluid overload. Conduction anesthesia (e.g., epidural or combined spinal epidural anesthesia) is recommended because it provides excellent pain relief. Vaginal birth is preferred. Cesarean birth should be performed only for obstetric indications (Samuels, 2012).

⚡ SAFETY ALERT

Women with sickle cell anemia are not iron deficient. Therefore, routine iron supplementation, even that found in prenatal vitamins, should be avoided because these women can develop iron overload (Samuels, 2012).

Thalassemia

Thalassemia is a relatively common anemia in which an insufficient amount of hemoglobin is produced to fill the RBCs. Thalassemia is a hereditary disorder that involves the abnormal synthesis of the alpha or beta chains of hemoglobin. Beta thalassemia is the more common variety in the United States and usually occurs in people of Mediterranean, North African, Middle Eastern, and Asian descent (Kilpatrick, 2014).

Beta thalassemia minor is the heterozygous form of this disorder. People with heterozygous beta thalassemia are carriers of the disorder and are usually asymptomatic (Samuels, 2012). They may be mildly anemic but are usually healthy otherwise. Women whose pregnancies are complicated by beta thalassemia minor generally do not experience associated maternal or infant complications if their condition is stable (Blackburn, 2013) and do not require antepartum fetal testing. Iron therapy should only be prescribed for women who are iron deficient, although folic acid supplementation is recommended for all women with beta thalassemia minor (Samuels).

The homozygous form of beta thalassemia is known as thalassemia major, or Cooley's anemia. Persons with this form of the disease usually have hepatosplenomegaly and bone deformities caused by massive marrow tissue expansion. These individuals usually die of infection or cardiovascular complications fairly early in life. If women live to reach childbearing age, infertility is common. If women with this disorder do become pregnant, they usually experience severe anemia and congestive heart failure, although successful full-term pregnancies have been reported. Women with beta thalassemia major are managed much like those with sickle cell anemia during pregnancy (Samuels, 2012).

Pulmonary Disorders

As pregnancy advances and the uterus presses on the thoracic cavity, a woman may have increased respiratory difficulty. This difficulty is compounded by pulmonary disease.

Asthma

Asthma is a chronic inflammatory disorder involving the tracheobronchial airways, with increased airway responsiveness to a variety of stimuli. It is characterized by periods of exacerbations

and remissions. Exacerbations are usually triggered by stimuli such as allergens, upper respiratory infection, medications (i.e., aspirin, beta-blockers), environmental pollutants, occupational exposures, exercise, cold air, or emotional stress (Gibson & Powrie, 2011). In many cases the actual cause may be unknown, although a family history of allergy is common in people with asthma. In response to stimuli, there is widespread but reversible narrowing of the hyperreactive airways, making it difficult to breathe. The clinical manifestations are expiratory wheezing, productive cough, thick sputum, dyspnea, or any combination.

Asthma may be the most common potentially serious medical condition to complicate pregnancy. It affects approximately 4% to 8% of all pregnancies. The prevalence and morbidity rates are increasing, although the asthma-related mortality has dropped in recent years (Whitty & Dombrowski, 2014).

The effect of pregnancy on asthma is unpredictable. In one large study 23% of women with asthma improved during pregnancy, whereas 30% became worse (Whitty & Dombrowski, 2014). If asthma worsens, the more severe symptoms usually occur between 17 and 24 weeks of gestation (Gilbert, 2011). Asthma appears to be associated with preterm birth, preeclampsia, small for gestational age fetuses, IUGR, and an increased rate of cesarean birth (Whitty & Dombrowski, 2014).

The ultimate goal of asthma therapy in pregnancy is maintaining adequate oxygenation of the fetus by preventing hypoxic episodes in the mother. Achieving this goal requires monitoring lung function objectively (e.g., peak expiratory flow rate and forced expiratory volume in 1 second), avoiding or controlling asthma triggers (e.g., dust mites, animal dander, pollen, wood smoke), educating clients about the importance of controlling asthma during pregnancy, and drug therapy. Current drug therapy for asthma emphasizes treatment of airway inflammation to decrease airway hyperresponsiveness and prevent asthma symptoms. Decreasing airway inflammation with inhaled corticosteroids is the preferred treatment for managing persistent asthma during pregnancy (Whitty & Dombrowski, 2014).

During pregnancy women with poorly controlled asthma may benefit from ultrasound examinations and antenatal testing. Because asthma has been associated with IUGR and preterm birth, accurate pregnancy dating should be established by a first-trimester ultrasound if possible. Evaluation of fetal activity and growth by serial ultrasound examinations may be considered for women who have suboptimally controlled asthma or moderate to severe asthma (beginning at 32 weeks of gestation) and after recovery from a severe asthma exacerbation. All women with asthma should be encouraged to attend to fetal activity (see Chapter 26 for information on daily fetal movement counts) (Whitty & Dombrowski, 2014). Acute exacerbations may require albuterol, steroids, aminophylline, beta-adrenergic agents, and oxygen. Women with severe exacerbations unresponsive to treatment may require intubation and mechanical ventilation (Whitty & Dombrowski, 2012).

Although asthma exacerbations during labor are very rare, medications for asthma are continued during labor and the postpartum period. Women who have received systemic corticosteroids during the previous 4 weeks should be given stress doses of corticosteroids during labor and for the first 24 hours after birth (Whitty & Dombrowski, 2012). Pulse oximetry should be instituted during labor. Epidurals are recommended for

pain relief. Morphine and meperidine are histamine-releasing narcotics and should be avoided. Fentanyl may be used as an alternative for pain relief because it is less likely to cause histamine release (Gibson & Powrie, 2011).

During the postpartum period women who have asthma are at increased risk for hemorrhage. If excessive bleeding occurs, prostaglandin (PG)_{E₁} or E₂ can be given, although the woman's respiratory status should be monitored (Whitty & Dombrowski, 2012). Because carboprost (15-methyl PGF_{2α} [Hemabate]) and ergonovine and methylergonovine can cause bronchospasm, their use should be avoided (Cunningham et al., 2014). In general, only small amounts of asthma medications enter breast milk; therefore, their use is not considered a contraindication to breastfeeding. However, in sensitive individuals theophylline in breast milk can cause vomiting, feeding difficulties, jitteriness, and cardiac arrhythmias in neonates (Whitty & Dombrowski, 2012). The woman usually returns to her prepregnancy asthma status within 3 months after giving birth.

Cystic Fibrosis

Cystic fibrosis is a common autosomal recessive genetic disorder in which the exocrine glands produce excessive viscous secretions, which causes problems with both respiratory and digestive functions. Most people with cystic fibrosis have chronic obstructive pulmonary disease, pancreatic exocrine insufficiency, and elevated levels of sweat electrolytes. Morbidity and mortality are usually caused by progressive chronic bronchial pulmonary disease (Whitty & Dombrowski, 2014).

Because the gene for cystic fibrosis was identified in 1989, data can be collected for the purpose of genetic counseling for couples regarding carrier status. In the United States, approximately 4% of the Caucasian population are carriers of the cystic fibrosis gene. Cystic fibrosis occurs in 1 in 3200 Caucasian live births (Whitty & Dombrowski, 2014). People with cystic fibrosis live longer than in the past because of earlier diagnosis and advances in antibiotic therapy and nutritional support. More than 40% of all individuals in the United States with cystic fibrosis are more than 18 years old (Whitty & Dombrowski, 2014). Men tend to live a little longer (median age of survival is 29.6 years) compared with women, whose median age of survival is 27.3 years. Although most men with cystic fibrosis are infertile, women with the disease are often fertile and thus able to become pregnant (Whitty & Dombrowski, 2012).

In women with good nutrition, mild obstructive lung disease, and minimal lung impairment, pregnancy is tolerated well (Whitty & Dombrowski, 2012). In women with severe disease the pregnancy is often complicated by chronic hypoxemia and frequent pulmonary infections. Risk factors that may predict a poor pregnancy outcome are poor prepregnancy nutritional status, significant pulmonary disease with hypoxemia, pulmonary hypertension, liver disease, and diabetes mellitus. The incidence of preterm birth, IUGR, and uteroplacental insufficiency is increased (Whitty & Dombrowski, 2014).

Care of the pregnant woman with cystic fibrosis requires a team effort. Ideally the woman should lose or gain weight to reach 90% of her ideal body weight before becoming pregnant. A weight gain of 11 to 12 kg (24 to 26 lb) is recommended during pregnancy. Women who are unable to achieve the recommended weight gain through oral supplements may require

nasogastric tube feedings at night. Pancreatic insufficiency may put the woman at risk for malnutrition because she cannot meet the increased nutritional requirements of pregnancy. If malnutrition is severe, parenteral hyperalimentation may be necessary. Fat-soluble vitamins may not be well absorbed, resulting in deficiency in those nutrients. Throughout pregnancy frequent monitoring of the woman's weight, blood glucose, hemoglobin, total protein, serum albumin, prothrombin time, and fat-soluble vitamins A and E is suggested. Pancreatic enzymes should be adjusted as necessary (Whitty & Dombrowski, 2014).

Women with cystic fibrosis are followed closely with serial pulmonary function testing. Test results are used both to guide management and to predict pregnancy outcome. Inhaled recombinant human deoxyribonuclease I may be given to improve lung function by decreasing sputum viscosity. Inhaled 7% saline also produces both short- and long-term benefits (Cunningham et al., 2014). Early detection and treatment of infection are critical. Management of infection includes IV antibiotics along with chest physical therapy and bronchial drainage (Whitty & Dombrowski, 2012).

Fetal assessment is essential, given that the fetus is at risk for uteroplacental insufficiency, which can result in IUGR. Maternal nutritional status and weight gain during pregnancy significantly affect fetal growth. Fundal height should be measured routinely, and ultrasound examinations performed to evaluate fetal growth and amniotic fluid volume. Fetal movement counts are often recommended, starting at 28 weeks of gestation. Nonstress tests (NSTs) should be initiated at 32 weeks of gestation or sooner if evidence of fetal compromise exists (see Chapter 26 for more information on fetal assessment tests) (Whitty & Dombrowski, 2012).

During labor increased cardiac output stresses the cardiovascular system and can lead to cardiopulmonary failure in the woman with pulmonary hypertension or cor pulmonale. These women are also more likely to develop right-sided heart failure. Epidural or local analgesia is the preferred analgesic for birth, with vaginal birth recommended. Cesarean birth should be reserved for obstetric indications. If general anesthesia is needed for cesarean birth, anticholinergic medications should not be given before surgery because they tend to promote airway drying (Whitty & Dombrowski, 2014).

Breastfeeding appears to be safe as long as the sodium content of the milk is not abnormal (Lawrence & Lawrence, 2011). Pumping and discarding the milk are continued until the sodium content has been determined. Milk samples should be tested periodically for sodium, chloride, and total fat, and the infant's growth pattern should be monitored.

Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS), or shock lung, occurs when the lungs are unable to maintain levels of oxygen and carbon dioxide within normal limits. Severe hypoxemia, in spite of high levels of inspired oxygen, is accompanied by an increase in pulmonary capillary permeability, a decrease in lung volume, and shunting of blood.

ARDS is not specific to pregnancy; it can also result from trauma, pneumonia, sepsis, aspiration of gastric contents, fat emboli, acute pancreatitis, and drug overdose. When ARDS is associated with pregnancy, the precipitating factors can also be amniotic fluid embolism, air embolism, tocolytic therapy, asthma,

thromboembolism, disseminated intravascular coagulopathy, pyelonephritis, preeclampsia, eclampsia, severe hemorrhage, blood transfusion reactions, or peripartum cardiomyopathy (Gibson & Powrie, 2011).

An initial intervention is to find and correct the underlying cause, if possible. To provide the best fetal environment, early intubation and mechanical ventilation are recommended. With severe lung injury, positive end-expiratory pressure (PEEP) may be necessary. Sedatives may be prescribed for intubation and ventilation. The administration of vasoactive agents, inotropic agents, and corticosteroids may be necessary. Maintaining fluid balance is a challenge and a key component of management. For the woman who is hypovolemic, administration of blood may help increase cardiac output. For the woman who is hypervolemic, diuretics may be necessary to maintain adequate cardiac output. Whether birth of the fetus improves maternal oxygenation remains controversial (Cunningham et al., 2014).

The postpartum incidence of ARDS is affected not by the method of birth but by the amount of trauma occurring during pregnancy and birth. ARDS can also occur after miscarriage or therapeutic abortion.

Laboratory results are important in identifying the origin of acute pulmonary problems. Chest radiographs can indicate the presence of infiltrates in the lungs, and ABGs identify the status of acid-base balance. The priority assessments are vital signs, oxygen saturation levels, and signs and symptoms of thrombophlebitis and hemorrhage. During the postpartum period, apprehension, distended neck veins, cyanosis, diaphoresis, or pallor may indicate hypoxemia. Mental confusion or disorientation also may be noted.

The pulse rate increases to compensate for respiratory insufficiency of any origin. The severity of the pulmonary problem increases as the pulse rate increases. An initial increase in blood pressure occurs as cardiac output increases in an attempt to supply the tissue with oxygen. When lung damage is severe, blood pressure decreases.

Respiratory changes are the most important indicators of ARDS. The rate and depth of respirations, respiratory pattern, symmetry of chest movement, and use of accessory muscles should be noted; therefore, observation of respiratory characteristics after activity is important.

! NURSE ALERT

If there is any indication of abnormality, respirations are counted for a full minute; an error in rate of plus or minus four respirations per minute may be highly significant.

On auscultation, crackles, rhonchi, wheezes, or a pleural friction rub should be reported, especially when they are present after an earlier assessment with normal findings. The pregnant woman should be positioned for breathing comfort. Oxygen and emergency equipment should be available. The woman should be reassured and coached in relaxation techniques to lessen her anxiety.

Although they are usually younger and healthier than most adults who develop ARDS, pregnant women with this condition still experience mortality rates of 25% to 40%. With pulmonary injury, the clinical condition is determined by the degree of damage, the ability to compensate for it, and the stage

of the disease. Ideally, lung injury will be detected at an early stage and the underlying disease process promptly identified and treated. At present, there are no long term follow-up studies on pregnant women who recovered from respiratory distress syndrome. Nonpregnant clients have been reported to require several years to recover normal lung function (Cunningham et al., 2014).

Integumentary Disorders

Dermatologic disorders induced by pregnancy include melasma (chloasma), vascular “spiders,” palmar erythema, and striae gravidarum (see Chapter 13). A number of chronic skin disorders may complicate pregnancy. These disorders may be present prior to pregnancy or appear for the first time during pregnancy. The course of these disorders varies during pregnancy. Acne, for example, may improve. Psoriasis is unpredictable during pregnancy, but postpartum flares are common. Lesions from neurofibromatosis may increase in size and number during pregnancy (Cunningham et al., 2014). Explanation, reassurance, and commonsense measures should suffice for normal skin changes. In contrast, disease processes during and soon after pregnancy may be extremely difficult to diagnose and treat.

FIG 30-1 Pruritic urticarial papules and plaques of pregnancy (PUPPP). Lesions commonly begin in the abdominal striae. Confluent, erythematous urticarial papules and plaques are seen on the thighs in this woman. (From R.K. Creasy, R. Resnik, J.D. Iams, et al. [Eds.]. [2014]. *Creasy and Resnik's maternal-fetal medicine: Principles and practice* [7th ed.]. Philadelphia: Saunders.)

It rarely persists or begins after birth. PUPPP does not usually recur in subsequent pregnancies (Kroumpouzou, 2012; Rapini, 2014).

Intrahepatic cholestasis of pregnancy (ICP) is a liver disorder unique to pregnancy that is characterized by generalized pruritus. The itching commonly affects the palms and soles but can occur on any part of the body and is usually worse at night. No skin lesions are present. Women with ICP have elevated serum bile acids and elevated liver function tests. Jaundice may be present. Up to one half of women with ICP develop dark urine and light-colored stools. The cause of ICP is unknown, but approximately half of women have a family history of the disorder. ICP occurs more frequently during the winter months. A geographic variance in the prevalence of the disease also exists. ICP occurs most often in Southeast Asia, Chile, Bolivia, and Scandinavia, although it is seen less frequently now in Chile and in Scandinavia than in the past (Cappell, 2012; Williamson, Mackillop, & Heneghan, 2014).

The major fetal complications associated with ICP are asphyxial events, meconium staining, stillbirth, and preterm birth. The cause of these complications is likely related to increased levels of fetal serum bile acids. Treatment consists of giving ursodeoxycholic acid, which effectively controls the pruritus and laboratory abnormalities associated with ICP, and continued monitoring of liver function tests and bile acid levels (Cappell, 2012; Williamson et al., 2014). Antepartum fetal testing is essential. If liver function tests do not improve, induction of labor is considered at 36 to 37 weeks of gestation if the fetal lungs are mature. Symptoms usually disappear and laboratory abnormalities resolve within 2 to 4 weeks postpartum. ICP can recur in subsequent pregnancies, however, or with oral contraceptive use (Cappell).

Neurologic Disorders

The pregnant woman with a neurologic disorder must deal with potential teratogenic effects of prescribed medications, changes of mobility during pregnancy, and impaired ability to care for the baby. The nurse should be aware of all medications

SAFETY ALERT

Isotretinoin (Accutane), commonly prescribed for cystic acne, is highly teratogenic. There is a risk for craniofacial, cardiac, and central nervous system (CNS) malformations in exposed fetuses. This drug should not be taken during pregnancy.

Pruritus is a major symptom in several pregnancy-related skin diseases. *Pruritus gravidarum*, generalized itching without the presence of a rash, develops in up to 14% of pregnant women. It is often limited to the abdomen and is usually caused by skin distention and development of striae. *Pruritus gravidarum* is associated with twin gestation, fertility treatment, diabetes, and nulliparity. It is not associated with poor perinatal outcomes. It is treated symptomatically with skin lubrication, topical antipruritics, and oral antihistamines. Ultraviolet light and careful exposure to sunlight decrease itching. *Pruritus gravidarum* usually disappears shortly after birth but can recur in approximately half of all subsequent pregnancies (Rapini, 2014).

Another common pregnancy-specific cause of pruritus is **pruritic urticarial papules and plaques of pregnancy (PUPPP)** (Fig. 30-1), also known as polymorphic eruption of pregnancy. PUPPP classically appears in primigravidas during the third trimester. The lesions usually appear first on the abdomen but can spread to the arms, thighs, back, and buttocks. PUPPP almost always causes pruritus, and the itching is severe in 80% of cases. It is associated with increased maternal weight gain, an increased rate of twin gestation, hypertension, and induction of labor. It is not, however, associated with poor maternal or fetal outcomes. Therefore, the goal of therapy is simply to relieve maternal discomfort. Antipruritic topical medications, topical steroids, and oral antihistamines usually provide relief. Women with severe symptoms may require oral prednisone. PUPPP usually resolves before birth or within several weeks after birth.

the woman is taking and the associated potential for producing congenital anomalies. As the pregnancy progresses, the woman's center of gravity shifts and causes balance and gait changes. The nurse should advise the woman of these expected changes and suggest safety measures as appropriate. Family and community resources may be needed to assist in providing infant care for the neurologically impaired woman.

Epilepsy

Epilepsy (often called *seizure disorder*) is a disorder of the brain that causes recurrent seizures and is the most common major neurologic disorder accompanying pregnancy. Less than 1% of all pregnant women have a seizure disorder (Aminoff & Douglas, 2014). Seizure disorders are either acquired (less than 15% of all cases) or idiopathic (more than 85% of all cases), which means that a specific cause for the seizures cannot be identified. The majority of women with a seizure disorder who become pregnant have an uneventful pregnancy with an excellent outcome (Samuels & Niebyl, 2012).

Women with epilepsy should receive preconception counseling if at all possible. A detailed history of medication use and seizure frequency should be obtained. If the woman has frequent seizures before conception, she is likely to continue this pattern during pregnancy; therefore, achieving effective seizure control is extremely important before conception, even if changing medications is required (Samuels & Niebyl, 2012).

Infants born to women taking anticonvulsant medications have an increased incidence of congenital anomalies, including cleft lip and palate, congenital heart disease, and neural tube defects (NTDs). These anomalies are often related to the dose, type, and number of anticonvulsant medications taken (Aminoff & Douglas, 2014; Samuels & Niebyl, 2012). However, epilepsy itself can be associated with an increased risk of fetal malformations (Aminoff & Douglas).

SAFETY ALERT

Carbamazepine (Tegretol) and valproate (Depakote) should be avoided if possible during pregnancy because their use is associated with NTDs in the fetus.

Several anticonvulsant medications have been developed for use during the 2000s. More information is needed regarding the fetal effects of these medications. Any anticonvulsant medication required to achieve good seizure control in a woman with epilepsy should be used, however, regardless of the increased risk of fetal anomalies because the most important goal during pregnancy is to prevent seizures (Samuels & Niebyl, 2012).

Pregnant women with epilepsy are advised to take a folic acid supplement of 4 mg daily, which may decrease the incidence of NTDs. They are also encouraged to take a prenatal vitamin containing vitamin D daily because anticonvulsant medications can interfere with production of the active form of this vitamin (Samuels & Niebyl, 2012).

During pregnancy only one anticonvulsant medication—at the lowest dose level that is effective at keeping the woman seizure free—should be prescribed. The increase in plasma volume that is a normal pregnancy change can affect drug metabolism and distribution. Therefore, blood levels of anticonvulsant

medications should be checked and drug dosages adjusted as necessary (Aminoff & Douglas, 2014; Samuels & Niebyl, 2012). With client cooperation and close monitoring, most women with epilepsy should experience no change or even have fewer seizures during pregnancy. An increase in seizure frequency is usually related either to noncompliance with taking prescribed anticonvulsant medications or to sleep deprivation (Samuels & Niebyl).

In addition to congenital anomalies, the fetus of a woman with epilepsy is also at risk for IUGR. Determining an accurate gestational age as early as possible is important. This information decreases any confusion later in pregnancy in regard to fetal growth issues. Maternal serum screening around 16 weeks of gestation and ultrasound examination at 18 to 22 weeks of gestation should be performed to assess for the presence of an NTD or other fetal anomalies. Nonstress testing later in pregnancy is not necessary, unless the woman has other medical or obstetric factors that increase the risk for stillbirth (Samuels & Niebyl, 2012).

Managing anticonvulsant therapy during prolonged labor is challenging. During labor, absorption of medications given orally is unpredictable, especially if vomiting occurs. Women who are maintained on phenytoin (Dilantin) or phenobarbital may be given these medications parenterally during labor. No parenteral form of carbamazepine has been developed. Oral administration of carbamazepine may be attempted, but if the woman experiences a seizure or a pre seizure aura, she may be given phenytoin intravenously instead to carry her through labor. Vaginal birth is preferred (Samuels & Niebyl, 2012).

After birth the levels of anticonvulsant medications must be monitored frequently for the first few weeks because they can rise rapidly. If medication dose levels were increased during pregnancy, they will need to be decreased quickly to prepregnancy levels. All of the major anticonvulsant medications are found in breast milk, but the use of these medications is not a contraindication to breastfeeding. However, topiramate has been associated with neonatal weight loss; thus it probably should not be prescribed if the woman is breastfeeding (Aminoff & Douglas, 2014; Samuels & Niebyl, 2012). Neonatal sedation may be a side effect of carbamazepine, primidone (Mysoline), and phenobarbital (Samuels & Niebyl).

During the neonatal period infants can have a hemorrhagic disorder associated with exposure to anticonvulsant medications in utero, which causes vitamin K deficiency. Some authorities recommend giving vitamin K daily during the last few weeks of pregnancy to women taking anticonvulsant medications, but this practice is not considered the standard of care (Samuels & Niebyl, 2012).

All methods of contraception can be used by women with an idiopathic seizure disorder. However, commonly prescribed anticonvulsant medications such as carbamazepine, primidone, phenobarbital, and phenytoin reduce the effectiveness of oral contraceptives. Therefore, use of other contraceptive methods, such as the intrauterine device or hormonal implants, should be considered (Cunningham et al., 2014). Valproic acid and the newer anticonvulsant medications have not been reported to cause oral contraceptive failure (Aminoff & Douglas, 2014). In planning for future childbearing, couples should be informed that children born to women with a seizure disorder of unknown

cause have a four times greater chance of developing an idiopathic seizure disorder compared with the general population. Epilepsy in the father does not appear to increase a child's risk for developing a seizure disorder (Samuels & Niebyl, 2012).

Multiple Sclerosis

Multiple sclerosis (MS), a patchy demyelination of the spinal cord and CNS, may be a viral disorder. It occurs equally in men and women. Onset of symptoms, which include weakness of one or both lower extremities, visual complaints, and loss of coordination, is subtle and usually occurs between the ages of 20 and 40 years. The disease is characterized by exacerbations and remissions. Pregnancy does not seem to worsen the disease (Samuels & Niebyl, 2012).

Remissions during pregnancy are common. If an exacerbation occurs, it is more likely to do so during the third trimester of pregnancy or postpartum. Treatment may include corticosteroids and immunosuppressive agents. Several drugs and biopharmaceuticals are available for treating MS. Their use in pregnancy has been limited; thus few data and no controlled studies are available. However, many consist of molecules that are too large to cross the placenta. Therefore, they may be acceptable for use during pregnancy. They do not appear to be associated with anomalies (Samuels & Niebyl, 2012). Interferon is also sometimes used to treat MS relapses during pregnancy and postpartum. Its safety for use during pregnancy has not been established, although in theory it should not cross the placenta because of its large molecular size (Stuart & Bergstrom, 2011).

Women who have become paraplegic with MS are more likely to develop UTIs during pregnancy but may feel no symptoms. Therefore, they should be screened routinely. Women who have become paraplegic or have lumbosacral lesions as a result of MS may have little pain during labor. Determining when labor begins may be difficult for them. Uterine contractions occur normally, but these women may have difficulty pushing effectively during the second stage of labor. Therefore, vacuum- or forceps-assisted birth may be necessary (Samuels & Niebyl, 2012). Epidural anesthesia can be used during labor (Stuart & Bergstrom, 2011).

Depression is common among women with MS; thus they should be assessed frequently for evidence of postpartum depression. Breastfeeding is encouraged, although medications that are Lactation Risk Category L5 should not be prescribed. Intravenous immunoglobulin (IVIG) is considered safe for use during lactation; no adverse effects in infants have been reported. All hormonal contraceptives may be used by women with MS (Stuart & Bergstrom, 2011).

Bell Palsy

Bell palsy is an acute idiopathic facial paralysis. The cause is unknown, but it may be related to the reactivation of herpes simplex virus infection or acute human immunodeficiency virus type 1 (HIV-1) retroviral infection. Bell palsy occurs fairly often, especially in women of reproductive age. An association between Bell palsy and pregnancy was first cited by Bell in 1830. Pregnant women are affected four times more often than nonpregnant women. Women who develop Bell palsy during pregnancy have an increased risk for gestational hypertension or preeclampsia as well (Cunningham et al., 2014).

The clinical manifestations of Bell palsy include the sudden development of a unilateral facial weakness, with maximal weakness within 48 hours after onset, pain surrounding the ear, difficulty closing the eye on the affected side, hyperacusis (abnormal acuteness of the sense of hearing), and occasionally a loss of taste (Aminoff & Douglas, 2014; Cunningham et al., 2014).

No effects of maternal Bell palsy have been observed in infants. Maternal outcome is generally good unless a complete block in nerve conduction occurs. Steroid therapy is the only medical treatment that has been shown to influence the outcome of Bell palsy. To be effective, treatment should begin within the first 3 to 5 days after the paralysis develops (Aminoff & Douglas, 2014). Supportive care includes prevention of injury to the constantly exposed cornea, facial muscle massage, careful chewing and manual removal of food from inside the affected cheek, and reassurance. Although 80% of affected men and nonpregnant women recover to a satisfactory level within a year, only approximately half of women who develop the disorder during pregnancy do so (Cunningham et al., 2014).

Autoimmune Disorders

Autoimmune disorders make up a large group of diseases that disrupt the function of the immune system of the body. In these types of disorders the body's immune system is unable to distinguish "self" from "nonself." As a result, antibodies develop that attack its normally present antigens, causing tissue damage. Autoimmune disorders can occur during pregnancy because a large percentage of women with an autoimmune disease are women of childbearing age (Gilbert, 2011). Common autoimmune diseases include systemic lupus erythematosus, myasthenia gravis, antiphospholipid syndrome, rheumatoid arthritis, and systemic sclerosis (Chin & Branch, 2012; Cunningham et al., 2014).

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a chronic, multisystem inflammatory disease that affects the skin, joints, kidneys, lungs, nervous system, liver, and other body organs. The exact cause is unknown but probably involves the interaction of immunologic, environmental, hormonal, and genetic factors. SLE is the most common serious autoimmune disease affecting women of reproductive age. It occurs two to four times more often in African-American and Hispanic women than in Caucasian women and is nine times more common in women than in men. Most cases of SLE occur in adolescence or young adulthood (Chin & Branch, 2012; Lockshin, Salmon, & Erkan, 2014).

Common symptoms, including myalgias, fatigue, weight change, and fevers, occur in nearly all women with SLE at some time during the course of the disease. Although a diagnosis of SLE is suspected based on clinical signs and symptoms, it is confirmed by laboratory testing that demonstrates the presence of circulating autoantibodies. As is the case with other autoimmune diseases, SLE is characterized by a series of exacerbations (flares) and remissions (Chin & Branch, 2012; Lockshin et al., 2014).

Pregnancy probably does not increase the likelihood of serious SLE flares (Lockshin et al., 2014). However, it appears that disease activity at the beginning of pregnancy is an important predictor of exacerbations during pregnancy. Therefore,

women are advised to wait until they have been in remission for at least 6 months before attempting to become pregnant (Chin & Branch, 2012; Gilbert, 2011). In addition to exacerbations, other maternal risks include an increased rate of miscarriage, nephritis, preeclampsia, possible need to give birth at a preterm gestation, and an increased risk of cesarean birth. Fetal risks include stillbirth, IUGR, and preterm birth (Chin & Branch).

Medical therapy during pregnancy is kept to a minimum in women who are in remission or who have a mild form of SLE. Occasional doses of nonsteroidal antiinflammatory drugs (NSAIDs) can be given to treat arthralgia. Low-dose aspirin can be used throughout pregnancy (Cunningham et al., 2014). Glucocorticoids such as prednisone are often used to treat SLE during pregnancy, either as maintenance therapy or short-term treatment for flares. There is a small risk of fetal cleft lip and palate if glucocorticoids are used during early pregnancy. Prolonged use of this group of medications also increases the risks for bone demineralization, gestational diabetes, preeclampsia, premature rupture of membranes, and IUGR. Given the significant risks associated with long-term glucocorticoid use, hydroxychloroquine, an antimalarial drug, may be the best medication for maintenance SLE therapy during pregnancy. It significantly reduces SLE disease activity but appears to cause no adverse effects on the fetus (Chin & Branch, 2012).

Prenatal care otherwise focuses on close monitoring to detect common pregnancy complications such as hypertension, proteinuria, and IUGR. Ultrasound examinations are performed frequently to monitor fetal growth. Fetal assessment tests, including daily fetal movement counts and weekly or twice-weekly NSTs and amniotic fluid volume assessments or biophysical profiles, likely begin at 30 to 32 weeks of gestation (see Chapter 26). More frequent ultrasound examinations and fetal testing are necessary if the woman develops an SLE flare, antiphospholipid syndrome, hypertension, proteinuria, or evidence of IUGR (Chin & Branch, 2012).

Women with SLE can develop an exacerbation during labor. Any maintenance medications should be continued throughout the intrapartum period or resumed immediately postpartum at the last pregnancy dose. Even if a flare does not occur, all women who have received chronic glucocorticoid therapy (20 mg or more of prednisone daily for at least 3 weeks) need larger (stress) doses of steroids during labor (Chin & Branch, 2012). Vaginal birth is preferred, but cesarean birth is common because of maternal and fetal complications.

Close monitoring of all women with SLE should continue after birth. Women who have more severe SLE manifestations or who had an SLE exacerbation during pregnancy are at greatest risk to experience a postpartum flare (Chin & Branch, 2012).

Women with SLE and chronic vascular or renal disease should limit their number of pregnancies because of maternal complications associated with the illness and increased adverse perinatal outcomes. If desired, the safest time for tubal sterilization is during the postpartum period or when the disease is in remission (Cunningham et al., 2014). Estrogen-containing oral contraceptives may increase the risk of thromboembolism (Gilbert, 2011). Progestin-only implants and injections provide effective contraception with no known effects on lupus flares (Cunningham et al.). Barrier methods, in addition to progestin-only contraceptive options, are the least risky forms

of contraception for women with SLE (Gilbert). Evidence does not support concerns regarding an increased risk of infection when IUDs are prescribed for women receiving immunosuppressive therapy (Cunningham et al.).

Myasthenia Gravis

Myasthenia gravis (MG), an autoimmune motor (muscle) end-plate disorder that involves acetylcholine use, affects the motor function at the myoneural junction. Muscle weakness results, particularly of the eyes, face, tongue, neck, limbs, and respiratory muscles. In addition, women may experience ptosis, diplopia, and dysphagia. Women are affected twice as often as men, and the incidence peaks between the ages of 20 and 30 years (Denney, Porter, & Branch, 2011). Because the greatest period of risk is during the first year after diagnosis, pregnancy should probably be avoided until symptomatic improvement occurs (Cunningham et al., 2014). The response of women with MG to pregnancy is unpredictable; remission, exacerbation, or continued stability during pregnancy can occur.

Pregnancy does not appear to affect the overall course of MG, but as the uterus enlarges respirations may be compromised. Also the normal fatigue experienced by many pregnant women may be tolerated poorly by those with MG (Cunningham et al., 2014). Treatment during pregnancy is the same as for nonpregnant women. Usual medications include glucocorticoids and acetylcholinesterase inhibitors. Monitoring blood glucose values is important because hyperglycemia may result from corticosteroid therapy. Thymectomy may result in remission of the disease but is best performed before or after pregnancy, if at all possible. For severe weakness, plasmapheresis or IVIG therapy may be needed (Aminoff & Douglas, 2014).

Because MG does not affect smooth muscle, most women usually tolerate labor well. Vaginal birth is desired, but vacuum or forceps assistance may be required because of muscle weakness. Oxytocin may be given, but all medications that cause muscular relaxation should be avoided if at all possible. Narcotics must be used cautiously because they may cause respiratory depression, and women with MG are already at risk for respiratory muscle weakness. Regional analgesia is preferred (Aminoff & Douglas, 2014; Cunningham et al., 2014). After birth, women must be carefully supervised because relapses often occur during the puerperium.

SAFETY ALERT

Magnesium sulfate must not be administered to women with MG because it inhibits the release of acetylcholine and can trigger myasthenic crisis.

Approximately 10% to 15% of neonates born to women with MG develop neonatal myasthenia. This transient disorder results from the transfer of maternal antibody against acetylcholine receptors across the placenta. Symptoms, including a poor cry, respiratory difficulties, weakness in suckling, a weak Moro reflex, and feeble limb movements, usually appear within the first 72 hours after birth. Neonatal myasthenia can be treated with anticholinesterase medications and usually resolves by 6 weeks after birth (Aminoff & Douglas, 2014).

Gastrointestinal Disorders

Compromise of GI function during pregnancy is a concern. Obvious physiologic alterations, such as the greatly enlarged uterus, and less apparent changes, such as hormonal differences and hypochlorhydria (deficiency of hydrochloric acid in the stomach's gastric juice), require understanding for proper diagnosis and treatment. Gallbladder disease and inflammatory bowel disease are examples of GI disorders that may occur during pregnancy.

Cholelithiasis and Cholecystitis

Cholelithiasis (the presence of gallstones in the gallbladder) occurs more often in women than in men. Its incidence increases during pregnancy, probably because of increased hormone levels and pressure from the enlarged uterus that interferes with the normal circulation and drainage of the gallbladder. Most gallstones are asymptomatic during pregnancy. Usually the first symptom of cholelithiasis is biliary colic, epigastric or right upper quadrant pain that can radiate to the back or shoulders (Cappell, 2012; Williamson et al., 2014). Pain may occur spontaneously or after eating a high-fat meal. Approximately two thirds of clients with biliary colic have recurrent attacks (Cappell). Multiparity and prepregnancy obesity are risk factors for cholelithiasis (Williamson et al.).

Cholecystitis (inflammation of the gallbladder) is usually caused when a gallstone obstructs a cystic duct. As in biliary colic that occurs with cholelithiasis, epigastric or right upper quadrant pain is present, but the pain is usually more severe and prolonged. Nausea, vomiting, and fever may also be present. Acute cholecystitis is the third most common indication for nonobstetric surgical intervention in pregnancy, occurring in about 4 cases per 10,000 pregnancies (Cappell, 2012).

Often gallbladder surgery is postponed until the puerperium. The woman can usually be managed conservatively for the remainder of the pregnancy (see Teaching for Self-Management: Nutritional Counseling for the Pregnant Woman with Cholelithiasis or Cholecystitis). However, women with recurrent biliary colic or acute cholecystitis generally require immediate cholecystectomy. Although the second trimester has traditionally been considered the safest time for this surgery, it is increasingly performed at any time during pregnancy because of improved surgical techniques and outcomes. Both laparoscopic and open cholecystectomy procedures are acceptable during pregnancy (Cappell, 2012; Cunningham et al., 2014). Preoperative care includes IV fluids, discontinuing oral intake, analgesia, and usually antibiotics (Cappell).

TEACHING FOR SELF-MANAGEMENT

Nutritional Counseling for the Pregnant Woman with Cholelithiasis or Cholecystitis

- Assess your diet for foods that cause discomfort and flatulence, and omit foods that trigger episodes.
- Reduce dietary fat intake to 40 to 50 g/day.
- Limit protein to 10% to 12% of total calories.
- Choose foods so that most of the calories come from carbohydrates.
- Prepare food without adding fats or oils as much as possible.
- Avoid fried foods.

Inflammatory Bowel Disease

Inflammatory bowel disease refers to ulcerative colitis and Crohn disease. It is relatively common in young women, so these disorders are seen during pregnancy. The incidence of an inflammatory bowel disease flare is not increased in pregnancy and no evidence suggests that pregnancy significantly affects either ulcerative colitis or Crohn disease (Cunningham et al., 2014; Kelly & Savides, 2014). In general, infants born to mothers with inflammatory bowel disease have a higher risk for preterm birth, low birth weight, and being small for gestational age. However, these infants do not have an increased risk for congenital anomalies (Kelly & Savides). Active disease early in pregnancy increases the risk for a poor pregnancy outcome (Cunningham et al.).

Treatment of inflammatory bowel disease is usually the same for the pregnant woman as it is for the nonpregnant woman. Discontinuing her prepregnancy medications can cause the woman to have a relapse or disease flare. The medications 5-aminosalicylates, prednisone, and 6-mercaptopurine or azathioprine are often prescribed for treatment of inflammatory bowel disease. Occasionally biologic agents such as infliximab also are ordered. Antibiotics such as metronidazole and ciprofloxacin may also be necessary from time to time. These drugs appear to be safe for use during pregnancy (Kelly & Savides, 2014). Folic acid supplementation is especially important because of problems with intestinal malabsorption. Calcium supplementation is also necessary because osteoporosis is common. Some women may require parenteral nutrition (Cunningham et al., 2014). Surgery during pregnancy is done for emergencies such as intestinal obstruction, perforation, abscess, or fulminant colitis. In these situations, surgery is required for the mother's health (Kelly & Savides).

Urinary Tract Infections

UTIs are a common medical complication of pregnancy, occurring in approximately 20% of all pregnancies. They are also responsible for 10% of all hospitalizations during pregnancy (Duff, 2014). UTIs include asymptomatic bacteriuria, cystitis, and pyelonephritis. They are usually caused by coliform organisms that are a normal part of the perineal flora. By far the most common cause is *Escherichia coli*, a gram-negative bacterium responsible for 85% of cases. Another gram-negative bacterium that causes UTIs is *Klebsiella pneumoniae*. The gram-positive organisms group B streptococci, enterococci, and staphylococci account for approximately 3% to 7% of all infections (Gilbert, 2011).

Asymptomatic Bacteriuria

Asymptomatic bacteriuria refers to the persistent presence of bacteria within the urinary tract of women who have no symptoms. A clean-voided urine specimen containing more than 100,000 organisms per milliliter is diagnostic. If asymptomatic bacteriuria is not treated, up to 40% of infected women will subsequently develop symptomatic infection during the pregnancy. Therefore, the American College of Obstetricians and Gynecologists (ACOG) recommends that all women be screened for asymptomatic bacteriuria at their first prenatal visit (Colombo, 2012). Asymptomatic bacteriuria has been associated with preterm birth and low-birth-weight infants, (American Academy of Pediatrics [AAP] & ACOG, 2012; Cunningham et al., 2014).

Asymptomatic bacteriuria should be treated with an antibiotic. Antibiotics that are often prescribed include amoxicillin, ampicillin, cephalexin (Keflex), ciprofloxacin (Cipro), levofloxacin (Levaquin), nitrofurantoin (Macrochantin), and trimethoprim-sulfamethoxazole (Bactrim DS). Several different regimens, including single-dose or 3-, 7-, and 10-day treatment may be used (Cunningham et al., 2014). A repeat urine culture is usually ordered 1 to 2 weeks after completing therapy because approximately 15% of women do not respond to therapy or have a reinfection (Colombo, 2012). Women who have persistent or frequent recurrences of bacteriuria may be placed on suppressive therapy, often nitrofurantoin each night at bedtime, for the remainder of the pregnancy (Cunningham et al.).

Cystitis

Cystitis (bladder infection) is characterized by dysuria, urgency, and frequency, along with lower abdominal or suprapubic pain. Usually white blood cells, as well as bacteria, are found in the urine. Microscopic or gross hematuria also may be present. Typically, symptoms are confined to the bladder rather than becoming systemic. Cystitis is usually uncomplicated but it may lead to ascending UTI if untreated. Approximately 40% of pregnant women with pyelonephritis experienced symptoms of bladder infection before developing pyelonephritis (Cunningham et al., 2014).

Cystitis is often treated with a 3-day course of antibiotic therapy, which is usually 90% effective in curing the infection. Antibiotics often prescribed include amoxicillin, ampicillin, cephalexin (Keflex), ciprofloxacin (Cipro), levofloxacin (Levaquin), nitrofurantoin (Macrochantin), and trimethoprim-sulfamethoxazole (Bactrim DS) (Cunningham et al., 2014). Phenazopyridine (Pyridium), a urinary analgesic, is often prescribed along with an antibiotic for relief of symptoms caused by irritation of the urinary tract. Although phenazopyridine is effective at relieving dysuria, urgency, and frequency, women should be taught that the medication colors urine and tears orange. Therefore, they should be instructed to avoid wearing contact lenses while taking this medication and warned that it will stain underwear.

Pyelonephritis

Renal infection (pyelonephritis) is the most common serious medical complication of pregnancy and the leading cause of septic shock during pregnancy (Cunningham et al., 2014). The most common maternal complications associated with pyelonephritis include anemia, septicemia, transient renal dysfunction, and pulmonary insufficiency. Women with pyelonephritis can develop urosepsis, sepsis syndrome, and renal dysfunction. In addition, pulmonary injury resembling ARDS can occur in pregnant women with acute pyelonephritis, most likely the result of damage to alveolar tissue caused by the release of endotoxins from gram-negative bacteria (Colombo, 2012; Cunningham et al.). Recurrent pyelonephritis is thought to cause fetal death and IUGR. Acute pyelonephritis is associated with preterm labor (Colombo).

Pyelonephritis develops most often during the second trimester of pregnancy and is usually caused by the *E. coli* organism. Infection develops only in the right kidney in at least half of all cases. The onset of pyelonephritis is often abrupt, with fever, shaking chills, and aching in the lumbar area of the back. Anorexia and nausea and vomiting also can be present. Usually one or both costovertebral angles are tender to palpation (Duff, 2014).

Women diagnosed with pyelonephritis are usually admitted to the hospital immediately. Treatment with IV antibiotics is started as soon as urine and blood samples for culture and sensitivity have been collected (Cunningham et al., 2014). Given the high resistance of *E. coli* to ampicillin, cephalexin (Keflex), and cefazolin (Ancef), these medications are not recommended. Ceftriaxone (Rocephin) is often prescribed because it provides excellent coverage against many of the organisms that commonly cause pyelonephritis (Duff, 2014). The woman must be monitored closely for the possible development of sepsis (Cunningham et al., 2014). A woman with mild to moderate disease (low-grade fever, normal or slightly elevated white blood cell count, and no nausea or vomiting) may be treated with oral antibiotics as an outpatient (Duff, 2014).

Clinical symptoms generally resolve within a couple of days after antibiotic therapy is begun. The antibiotic may need to be changed based on the results of the initial culture and sensitivity testing, or if the woman has not responded to therapy within 48 hours (Gilbert, 2011). Most women become afebrile within 72 hours. If no clinical improvement is seen within 48 to 72 hours, an ultrasound should be performed to assess for a urinary tract obstruction. Once the woman is afebrile, she will be changed from IV to oral antibiotics (Cunningham et al., 2014).

Usually antibiotic therapy is continued for 7 to 14 days after the woman is discharged from the hospital. A urine culture will likely be repeated 1 to 2 weeks after antibiotic therapy has been completed. Recurrent infection develops in 30% to 40% of women after completion of treatment for pyelonephritis. Therefore, urine cultures should be obtained each trimester for the remainder of the pregnancy. Many women are maintained on a prophylactic antibiotic (often nitrofurantoin once or twice daily) for the remainder of the pregnancy (Colombo, 2012; Cunningham et al., 2014).

Nursing Interventions

Nurses are often responsible for teaching pregnant women about taking medications safely and effectively. This education

CLINICAL REASONING CASE STUDY

Urinary Tract Infection

Emily is a 23-year-old G1 P0 who has her initial prenatal visit at 8 weeks of gestation. She is complaining of urinary frequency and burning with urination. During the visit a routine urine sample is collected and sent to the lab. Emily declines antibiotics because she wants to be sure she really has an infection, choosing to wait on the lab results. Two days later Emily receives a call at work from her health care provider, telling her that she needs to pick up a prescription for an antibiotic because her lab results indicated that she has a urinary tract infection (UTI). Emily asks, "Is the antibiotic okay for the baby? I thought medications should be avoided in the first trimester."

1. Evidence—Is there sufficient evidence to determine the type of UTI that Emily has?
2. What assumptions can be made about the following issues:
 - a. Risks associated with UTI during pregnancy
 - b. Management plan for treating UTI during pregnancy
3. What are the priorities for nursing care at this time?
4. Does the evidence objectively support your conclusion?

is especially important in regard to antibiotics because this type of medication is so often misused by the general public. The woman should be instructed to finish the entire course of prescribed antibiotic therapy rather than stopping the medication as soon as she feels better. Failure to do so can lead to the creation of additional drug-resistant organisms. Antibiotics should be taken on time and around the clock so that medication levels in the body remain constant. Finally, many women will develop a yeast infection while taking antibiotics because the medication kills normal flora in the genitourinary tract as well as pathologic organisms. Therefore, they should be encouraged to include yogurt, cheese, or milk containing active acidophilus cultures in their diet while on antibiotics.

Women should also be taught simple ways to prevent UTIs. See *Teaching for Self-Management: Prevention of Genital Tract Infections* in Chapter 7 for several suggestions.

SURGERY DURING PREGNANCY

The need for abdominal surgery occurs as frequently among pregnant women as among nonpregnant women of comparable age. However, pregnancy may make the diagnosis more difficult. An enlarged uterus and displaced internal organs may make abdominal palpation more difficult, alter the position of an affected organ, or change the usual signs and symptoms associated with a particular disorder. The most common surgical emergency during pregnancy is appendicitis (Cappell, 2012).

Appendicitis

Appendicitis occurs approximately once in 1000 pregnancies. The incidence is 30%, 45%, and 25% in the first, second, and third trimesters, respectively (Mahomed, 2011). The diagnosis of appendicitis is often delayed because the usual signs and symptoms mimic some normal changes of pregnancy such as nausea and vomiting and increased white blood cell (WBC) count. As pregnancy progresses, the appendix is pushed upward and to the right from its usual anatomic location (see Fig. 13-14) (Cunningham et al., 2014). Because of these changes, rupture of the appendix and the subsequent development of peritonitis occur in up to 25% of pregnant women with appendicitis (Cappell, 2012).

The most common symptom of appendicitis in pregnant women is right lower quadrant abdominal pain, regardless of gestational age. Nausea and vomiting are often present, but loss of appetite is not a reliable indicator of appendicitis. Fever, tachycardia, a dry tongue, and localized abdominal tenderness are commonly found in nonpregnant people with appendicitis, but they are less likely indicators for the disorder in pregnant women. Because of the physiologic increase in WBCs that occurs in pregnancy, this test is not helpful in making the diagnosis. A urinalysis and a chest x-ray should be performed to rule out UTI and right lower lobe pneumonia, given that both of these conditions can cause lower abdominal pain (Kelly & Savides, 2014). Appendicitis can also be confused with other disorders such as cholecystitis, preterm labor, pyelonephritis, or placental abruption (abruptio placentae) (Cunningham et al., 2014).

Radiologic imaging is necessary if appendicitis is suspected after history, physical examination, and laboratory studies have

been completed. Although CT is the imaging test of choice in nonpregnant clients because it is highly accurate, the use of ultrasound during pregnancy is preferred to avoid fetal exposure to radiation from CT (Cappell, 2012). MRI may be used if appendicitis has not been confirmed by other imaging techniques (Cappell; Kelly & Savides, 2014).

Prompt surgical intervention to remove the appendix is still the standard treatment (Kelly & Savides, 2014). Laparoscopic surgery may be performed during the first and second trimesters of pregnancy if the appendix has not ruptured or the diagnosis is uncertain. Antibiotics are often administered for uncomplicated appendicitis and are definitely necessary if rupture, abscess, or peritonitis has occurred. Clindamycin and gentamicin are often prescribed because they are considered both effective and safe. The maternal mortality rate from ruptured appendix is about 4%. The fetal mortality rate from ruptured appendix is much higher, more than 30% (Cappell, 2012).

CARE MANAGEMENT

Initial assessment of the pregnant woman requiring surgery focuses on her presenting signs and symptoms. A thorough history and physical examination are performed. Laboratory testing includes, at a minimum, a complete blood count with differential and a urinalysis. Additional laboratory and other diagnostic tests may be necessary to reach a diagnosis. In addition, fetal heart rate (FHR) and activity, along with uterine activity, should be monitored, and constant vigilance for symptoms of impending obstetric complications maintained. The extent of presurgery assessment is determined by the immediacy of surgical intervention and the specific disorder that requires surgery.

Hospital Care

When surgery becomes necessary during pregnancy, the woman and her family are concerned about the effects of the procedure and medication on fetal well-being and the course of pregnancy. An important aspect of preoperative nursing care is encouraging the woman to express her fears, concerns, and questions.

Preoperative care for a pregnant woman differs from that for a nonpregnant woman in one significant aspect: the presence of at least one other person, the fetus. Continuous FHR and uterine contraction monitoring should be performed if the fetus is considered viable. Procedures such as preparation of the operative site and time of insertion of IV lines and urinary retention catheters vary with the physician and the facility. However, in every instance there is a total restriction of solid foods and liquids or a clear specification of the type, amount, and time at which clear liquids may be taken before surgery. Some bowel preparation such as clear liquids and laxatives may be required before surgery. Food by mouth is restricted for several hours before a scheduled procedure. Even if she has had nothing by mouth—but more important, if surgery is unexpected—the woman is in danger of vomiting and aspirating, and special precautions are taken before anesthetic is administered (e.g., administering an antacid).

Intraoperatively perinatal nurses may collaborate with the surgical staff to increase their knowledge about the special

needs of pregnant women undergoing surgery. One intervention to improve fetal oxygenation is positioning the woman on the operating table with a lateral tilt to avoid compression of the maternal vena cava. Continuous FHR and uterine contraction monitoring during surgery may be performed if the fetus is considered viable. Monitoring may be accomplished by using sterile Aquasonic gel and a sterile sleeve for the transducer. During abdominal surgery uterine contractions may be palpated manually. However, many practitioners simply monitor for the FHR and presence of uterine contractions before and after the procedure.

In the immediate recovery period general observations and care pertinent to postoperative recovery are initiated. Frequent assessments are carried out for several hours after surgery. Whether the woman is cared for in the surgical postanesthesia recovery area or in a labor and birth unit, continuous fetal and uterine monitoring will likely be initiated or resumed because of the potential risk for preterm labor. Tocolysis may be necessary if preterm labor occurs (see Chapter 32).

Home Care

Plans for the woman's return home and for convalescent care should be completed as early as possible before discharge. Depending on her insurance coverage, nursing care may be provided through a home health agency. If not, the woman and other support individuals must be taught necessary skills and procedures, such as wound care. Ideally the woman and other caregivers should have opportunities for supervised practice before discharge so that they can feel comfortable with their knowledge and ability before being totally responsible for providing care. Box 30-3 lists information that should be included in discharge teaching for the postoperative client. The woman also may need referrals to various community agencies for evaluation of the home situation, child care, home health care, and financial or other assistance.

TRAUMA DURING PREGNANCY

Trauma remains a common complication during pregnancy because most pregnant women in the United States continue their usual activities. Approximately 30,000 pregnant women in the United States experience treatable injuries each year because of trauma (Mozurkewich & Pearlman, 2012).

BOX 30-3 Discharge Teaching for Home Care After Surgery

- Care of incision site
 - Diet and elimination related to gastrointestinal (GI) function
 - Signs and symptoms of developing complications: wound infection, thrombophlebitis, pneumonia
 - Equipment needed and technique for assessing temperature
 - Recommended schedule for resumption of activities of daily living
 - Treatments and medications ordered
 - List of resource individuals and their telephone numbers
 - Schedule of follow-up visits
- If birth has not occurred:
- Assessment of fetal activity (kick counts)
 - Signs of preterm labor

Significance

Approximately 1 in 12 pregnancies are complicated by physical trauma (Mendez-Figueroa, Dahike, Vrees, & Rouse, 2013). As pregnancy progresses the risk of trauma increases because more cases of trauma are reported in the third trimester than earlier in gestation. Most maternal injuries are a result of motor vehicle accidents (MVAs) and falls (Robbins, Martin, & Wilson, 2014), and most maternal deaths are caused by MVAs (Ruth & Miller, 2013). Serious injuries are more likely to occur in an MVA if the woman is not wearing a seat belt with a shoulder harness and is ejected from the vehicle. Therefore, to improve chances of survival for mother and fetus, pregnant women should wear properly positioned restraints at all times when in a motor vehicle (see Fig. 14-17). However, approximately one third of pregnant women do not wear seat belts because of discomfort, inconvenience, or fears of hurting the baby. Other sources of trauma include intimate partner violence, assaults, and suicide attempts (Robbins et al.).

Trauma is the leading cause of death among women of child-bearing age. It is also the leading cause of nonobstetric maternal death in the United States (Mendez-Figueroa et al., 2013; Ruth & Miller, 2013). Fetal morbidity and mortality are also significantly affected by maternal trauma. In fact, trauma causes fetal death more often than maternal death (Gilbert, 2011). Fetal death rates related to maternal trauma are reported to be as high as 65% (Ruth & Miller), and this information is probably underreported (Mozurkewich & Pearlman, 2012). Fortunately most trauma injuries during pregnancy are minor and have no effect on pregnancy outcome. However, each case must be evaluated carefully because pregnancy can mask signs of severe injury.

The effect of trauma on pregnancy is influenced by the length of gestation, type and severity of the trauma, and degree of disruption of uterine and fetal physiologic features. Trauma increases the incidence of preterm labor and birth, placental abruption, and fetal or neonatal death (Robbins et al., 2014). Other common fetal effects of trauma include premature rupture of membranes (PROM), fetomaternal transfusion, skull injuries, and hypoxia because of maternal respiratory compromise (Gilbert, 2011).

Special considerations for mother and fetus are necessary when trauma occurs during pregnancy because of the physiologic alterations that accompany pregnancy and because of the presence of the fetus.

Maternal Physiologic Characteristics

Optimal care for the pregnant woman after trauma depends on understanding the physiologic state of pregnancy and its effects on trauma. The pregnant woman's body exhibits responses different from those of a nonpregnant person to the same traumatic insults. Because of this, management strategies must be adapted for appropriate resuscitation, fluid therapy, positioning, assessments, and most other interventions. Significant maternal adaptations and the relation to trauma are summarized in Table 30-2.

The uterus and bladder are confined to the bony pelvis during the first trimester of pregnancy and are at reduced risk for injury in cases of abdominal trauma. After pregnancy progresses beyond the fourteenth week, the uterus becomes an abdominal organ, and the risk for injury in cases of abdominal trauma increases. During the second and third trimesters, the distended bladder becomes an abdominal organ and is at

TABLE 30-2 Maternal Adaptations During Pregnancy and Relation to Trauma

SYSTEM	ALTERATION	CLINICAL RESPONSES
Respiratory	↑ Oxygen consumption	↑ Risk of acidosis
	↑ Tidal volume	↑ Risk of respiratory mismanagement
	↓ Functional residual capacity	
	Chronic compensated alkalosis ↓ PaCO ₂ ↓ Serum bicarbonate	↓ Blood-buffering capacity
Cardiovascular	↑ Circulating volume, 1600 ml	Can lose 1000 ml blood
	↑ CO	No signs of shock until blood loss >30% total blood volume
	↑ Heart rate	
	↓ SVR	↓ Placental perfusion in supine position
	↓ Arterial blood pressure Heart displaced upward to left	Point of maximal impulse, fourth intercostal space
Renal	↑ Renal plasma flow	
	Dilation of ureters and urethra Bladder displaced forward	↑ Risk of stasis, infection ↑ Risk of bladder trauma
Gastrointestinal	↓ Gastric motility	↑ Risk of aspiration
	↑ Hydrochloric acid production	
	↓ Competency of gastroesophageal sphincter	Passive regurgitation of stomach acid if head lower than stomach
Reproductive	↑ Blood flow to organs	Source of ↑ blood loss
	Uterine enlargement	Vena caval compression in supine position
Musculoskeletal	Displacement of abdominal viscera	↑ Risk of injury, altered rebound response
	Pelvic venous congestion	Altered pain referral
	Cartilage softened	↑ Risk of pelvic fracture Center of gravity changed
	Fetal head in pelvis	↑ Risk of fetal injury
Hematologic	↑ Clotting factors	↑ Risk of thrombus formation
	↓ Fibrinolytic activity	

CO, Cardiac output; PaCO₂, arterial partial pressure of carbon dioxide; SVR, systemic vascular resistance.

increased risk for injury and rupture. Bowel injuries occur less often during pregnancy because of the protection provided by the enlarged uterus.

The elevated levels of progesterone that accompany pregnancy relax smooth muscle and profoundly affect the GI tract. GI motility decreases, with a resultant increased time required for gastric emptying, whereas the production of hydrochloric acid increases in the last trimester, and the gastroesophageal sphincter relaxes (Ruth & Miller, 2013). Because of these changes, airway management of the unconscious pregnant woman is critical.

! NURSING ALERT

The unconscious pregnant woman is at increased risk for regurgitation of gastric contents and aspiration whenever her head is positioned lower than her stomach or if abdominal pressure is applied.

A pregnant woman has decreased tolerance for hypoxia and apnea because of her decreased functional residual capacity and increased renal loss of bicarbonate. Acidosis develops more quickly in the pregnant than in the nonpregnant state.

Cardiac output increases 30% to 50% over prepregnancy values and is position dependent in the third trimester. Because of compression of the inferior vena cava and descending aorta by the pregnant uterus, cardiac output decreases dramatically if the woman is placed in the supine position. Therefore, the supine position must be avoided, even in women with cervical spine injuries. It is a primary priority that lateral uterine displacement be accomplished without any head movement. As soon as the neck is immobilized, the stretcher should be tilted laterally (Mozurkewich & Pearlman, 2012; Ruth & Miller, 2013).

Circulating blood volume increases 40% to 50% during gestation. As a result, significant intraabdominal or intrauterine blood loss can occur with only minimal changes in vital signs (Robbins et al., 2014). By the time maternal tachycardia and hypotension, which are considered hallmark symptoms of blood loss, are evident, massive hemorrhage has likely already occurred (Ruth & Miller, 2013).

Fetal Physiologic Characteristics

Perfusion of the uterine arteries, which provide the primary blood supply to the uteroplacental unit, depends on adequate maternal arterial pressure because these vessels lack autoregulation. Therefore, maternal hypotension decreases uterine and fetal perfusion. Maternal shock results in splanchnic and uterine artery vasoconstriction, which decreases blood flow and oxygen transport to the fetus. Electronic fetal monitoring (EFM) tracings can assist in evaluating maternal status after trauma. They reflect fetal cardiac responses to hypoxia and hypoperfusion, including tachycardia or bradycardia, minimal or absent baseline variability, and late decelerations.

Careful monitoring of fetal status assists greatly in maternal assessment because the fetal monitor tracing serves as an “oximeter” of internal maternal well-being. Hypoperfusion may be present in the pregnant woman before the onset of clinical signs of shock. The EFM tracings show the first signs of maternal compromise, such as when maternal heart rate, blood pressure (BP), and color appear normal, yet the EFM printout shows signs of fetal hypoxia (Miller, Miller, & Tucker, 2013).

Mechanisms of Trauma

Blunt Abdominal Trauma

Blunt abdominal trauma is most commonly the result of MVAs but also may be the result of battering or falls. Maternal and fetal mortality and morbidity rates are directly correlated with whether the mother remains inside the vehicle or is ejected. Maternal death is usually the result of a head injury or exsanguination from a major vessel rupture. Serious retroperitoneal hemorrhage after lower abdominal and pelvic trauma is reported more frequently during pregnancy. Serious maternal abdominal injuries are usually the result of splenic rupture or liver or renal injury.

When the mother survives, placental abruption is the most common cause of fetal death (Gilbert, 2011). Placental separation is thought to be a result of deformation of the

elastic myometrium around the relatively inelastic placenta. Shearing of the placental edge from the underlying decidua basalis results and is worsened by the increased intrauterine pressure resulting from the impact. It is critical that all pregnant victims be carefully evaluated for signs and symptoms of placental abruption after even minor blunt abdominal trauma.

NURSING ALERT

Signs and symptoms of placental abruption include uterine tenderness or pain, uterine irritability, uterine contractions, vaginal bleeding, leaking of amniotic fluid, or a change in FHR characteristics.

Pelvic fracture may result from severe injury and may produce bladder trauma or retroperitoneal bleeding with the two-point displacement of pelvic bones that usually occurs. One point of displacement is commonly at the symphysis pubis, and the second point is posterior because of the structure of the pelvis. Careful evaluation for clinical signs of internal hemorrhage is indicated.

Direct fetal injury as a complication of trauma during pregnancy most often involves the fetal skull and brain. Most commonly this injury accompanies maternal pelvic fracture in late gestation, after the fetal head becomes engaged. When the force of the impact is great enough to fracture the maternal pelvis, the fetus often sustains a skull fracture. Evaluation for fetal skull fracture or intracranial hemorrhage is indicated.

Uterine rupture as a result of trauma is rare, occurring in less than 1% of severe cases. Rupture is more likely to occur in a previously scarred uterus. When uterine rupture occurs it is usually associated with a direct blow delivered with substantial force (Cunningham et al., 2014). Traumatic uterine rupture almost always results in fetal death. Maternal death occurs less frequently, in about 30% of cases (Ruth & Miller, 2013).

Penetrating Abdominal Trauma

Bullet and stab wounds are the most frequent causes of penetrating abdominal trauma in pregnant women. When the uterus sustains penetrating wounds, the fetus is more likely than the mother to be seriously injured. The enlarged uterus may protect other maternal organs, particularly the bowel, but the fetus is more vulnerable (Robbins et al., 2014).

Numerous factors determine the extent and severity of maternal and fetal injury from a bullet wound, including size and velocity of the bullet, anatomic region penetrated, angle of entry, path of the bullet, organs damaged, gestational age, and exit wound. Once the bullet enters the body, it may ricochet several times as it encounters organs or bone, or it may sever a large blood vessel. During the second half of pregnancy the fetus usually sustains a direct injury from the bullet. Gunshot wounds require surgical exploration to determine the extent of injury and repair damage as needed.

Stab wounds are limited by the length and width of the penetrating object and are usually confined to the pathway of the weapon. Maternal and fetal injury is less if the stab wound

is located in the upper abdomen and from movement of the penetrating object from above the head downward toward the abdomen than from movement of the penetrating object from the ground upward toward the lower abdomen. Stab wounds usually require surgical exploration to clean out debris, determine extent of injury, and repair damage.

Thoracic Trauma

Thoracic trauma is reported to produce 25% of all trauma deaths. Pulmonary contusion results from nearly 75% of blunt thoracic trauma and is a potentially life-threatening condition. Pulmonary contusion can be difficult to recognize, especially if flail chest also is present or if there is no evidence of thoracic injury. Pulmonary contusion should be suspected in cases of thoracic injury, especially after blunt acceleration or deceleration trauma, such as that occurring when a rapidly moving vehicle crashes into an immovable object.

Penetrating wounds into the chest can result in pneumothorax or hemothorax. This type of injury is usually caused by an MVA that results in impalement by the steering column or a loose article in the vehicle that became a projectile with the force of impact. Stab wounds into the chest also may occur as a result of violence.

CARE MANAGEMENT

Immediate Stabilization

Immediate priorities for stabilization of the pregnant woman after trauma should be identical to those of the nonpregnant trauma client. Pregnancy should not result in any restriction of the usual diagnostic, pharmacologic, or resuscitative procedures or maneuvers (AAP & ACOG, 2012). The initial response of many trauma team members when caring for the pregnant woman is to assess fetal status first because of the concern for a healthy neonate. Instead the trauma team should follow a methodic evaluation of maternal status to ensure complete assessment and stabilization of the mother. Fetal survival depends on maternal survival, and stabilizing the mother improves the chance of fetal survival.

SAFETY ALERT

Priorities of care for the pregnant woman after trauma must be to resuscitate the woman and stabilize her condition first and then to consider fetal needs.

Primary Survey

The systematic evaluation begins with a primary survey and the initial CABDs of resuscitation: compressions, airway, breathing, and defibrillation. Increased oxygen needs during gestation necessitate a rapid response. The presence of a cervical spine injury is always assumed.

SAFETY ALERT

Hyperextension of the neck is avoided; instead jaw thrust is used to establish an airway for the trauma victim.

Once an airway is established, assessment should focus on adequacy of oxygenation. The chest wall is observed for movement. If breathing is absent, ventilations and endotracheal intubation are initiated. Supplemental oxygen should be administered with a tight-fitting, nonrebreathing face mask at 10 to 12 L/min to maintain adequate oxygen availability to the fetus. The chest wall is assessed for penetrating chest wound or flail chest. Breathing with a flail chest is rapid and labored; chest wall movements are uncoordinated and asymmetric; crepitus from bony fragments may be palpated.

Rapid placement of two large-bore (14- to 16-gauge) IV lines is necessary in the majority of seriously injured women. It is important to place the lines while veins are still distended. Cardiac arrest during the immediate stabilization period is usually the result of profound hypovolemia, necessitating massive fluid resuscitation. Infusion of crystalloids such as Ringer's solution or normal saline solution should be given as a 3:1 ratio; that is, 3 ml of crystalloid replacement to 1 ml of the estimated blood loss is given over the first 30 to 60 minutes of acute resuscitation. Because of the 50% increase in blood volume during pregnancy, published formulas for nonpregnant adults used for estimating crystalloid and blood replacement to counter blood loss must be adjusted upward for pregnancy. When severe hemorrhage exists, transfusion with fresh frozen plasma, platelets, and packed red blood cells at a 1:1:1 ratio lowers the rate of coagulopathy and may improve survival (Mendez-Figueroa et al., 2013).

Replacement of red blood cells and other blood components is anticipated, and blood is drawn for type, crossmatch, complete blood cell count, and platelet count. Infusion of type-specific whole blood or packed red blood cells is usually necessary to improve fetal oxygenation status and replace blood loss. During an extreme emergency, type O Rh-negative blood may be administered without matching.

Administering vasopressor drugs to treat maternal hypotension should be avoided if possible. These medications may significantly reduce uterine blood flow and thus decrease oxygen delivery to the fetus. In addition, their use does not address the cause of the hypovolemia (Ruth & Miller, 2013).

After 20 weeks of gestation venous return to the heart is best accomplished by positioning the uterus to one side to eliminate the weight of the uterus compressing the inferior vena cava or the descending aorta. This facilitates efforts to establish the forward flow of blood through resuscitation and stabilization. If a lateral position is not possible because of resuscitative efforts or cervical spine immobilization, the uterus can be manually deflected, or a wedge should be inserted underneath one side of the backboard or stretcher.

Cardiopulmonary Resuscitation of the Pregnant Woman

Trauma, cardiac abnormalities, embolism, magnesium overdose, sepsis, intracranial hemorrhage, anesthetic complications, eclampsia, and uterine rupture are the most common causes of cardiac arrest in a pregnant woman (Robbins et al., 2014). Special modifications are necessary when cardiopulmonary resuscitation (CPR) is performed during the second half of pregnancy. In nonpregnant women chest compressions produce a cardiac output of only about 30% of normal. Cardiac output in pregnant

women may be even less as a result of aortocaval compression caused by the gravid uterus. Therefore, uterine displacement during resuscitation efforts is critical (Cunningham et al., 2014). The uterus may be displaced laterally either manually or by placing a wedge, rolled blanket, or towel under one of the woman's hips. If defibrillation is needed, the paddles must be placed one rib interspace higher than usual because the heart is displaced slightly by the enlarged uterus (see the Emergency box).

EMERGENCY

Cardiopulmonary Resuscitation for the Pregnant Woman

Assessment

- Determine unresponsiveness and no breathing or no normal breathing.
- Activate emergency medical system and get AED if available.
- Return to victim and check for pulse.
- Begin chest compressions if no pulse is felt.

Compressions

- Position the woman on a flat, firm surface with her uterus displaced to the left with a wedge (e.g., a rolled towel placed under her hip) or manually or place her in a left lateral position.
- Begin chest compressions at a rate of 100/minute. Push hard and push fast! At the end of each compression allow the chest to recoil (reexpand) completely.
- Chest compressions may be performed slightly higher on the sternum if the uterus is enlarged enough to displace the diaphragm into a higher position.
- After five cycles of 30 compressions and two breaths (or approximately 2 minutes), check for a pulse. If no pulse is present, continue CPR.

Airway

- Open airway using head tilt-chin lift maneuver.

Breathing

- Deliver breaths using a face mask or bag-mask device if possible.
- Deliver each breath over 1 second, watching for chest rise.
- Deliver breaths using a ratio of 30 chest compressions to 2 breaths.

Defibrillation

- Use an AED according to standard protocol to analyze heart rhythm and deliver shock if indicated.

AED, Automated external defibrillator; *CPR*, cardiopulmonary resuscitation
Data from Vanden Hoek, T.L., Morrison, L.J., Shuster, M., et al. (2010). Part 12: Cardiac arrest in special situations: 2010 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care science. *Circulation*, 122(Suppl 3), S829-S861.

Complications, including laceration of the liver, rupture of the spleen or uterus, hemothorax, hemopericardium, or fracture of ribs or sternum may be associated with CPR on a pregnant woman. Fetal complications, including cardiac arrhythmia or asystole related to maternal defibrillation and medications and CNS depression related to antiarrhythmic drugs and inadequate uteroplacental perfusion, with possible fetal hypoxemia and acidemia, also may occur.

If the resuscitation is successful, the woman must be monitored carefully afterward. She remains at increased risk for recurrent cardiac arrest and arrhythmias (e.g., ventricular tachycardia, supraventricular tachycardia, bradycardia). Therefore,

her cardiovascular, pulmonary, and neurologic status should be assessed continually. If the pregnancy remains intact, uterine activity and resting tone must be monitored. Fetal status and gestational age should also be determined and used in decision making regarding continuation of the pregnancy or the timing and route of birth.

Another common reason for performing CPR on a pregnant woman is airway obstruction caused by choking. Clearing an airway obstruction is usually accomplished by performing abdominal thrusts. However, during the second and third trimesters, chest thrusts rather than abdominal thrusts should be used (see the Emergency box and Fig. 30-2).

EMERGENCY

Relief of Foreign Body Airway Obstruction

If the pregnant woman is unable to speak or cough, perform chest thrusts. Stand behind her and place your arms under her armpits to encircle her chest. Press backward with quick thrusts until the foreign body is expelled (see Fig. 30-2). If the woman becomes unconscious, carefully support her to the ground, immediately activate EMS, and begin CPR.

EMS, Emergency medical services; CPR, cardiopulmonary resuscitation. Data from Berg, R.A., Hemphill, R., Abella, B.S., et al. (2010). Part 5: Adult basic life support: 2010 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care science. *Circulation*, 122(Suppl 3), S685-S705.

Secondary Survey

After immediate resuscitation and successful stabilization measures, a more detailed *secondary survey* of the mother and fetus should be accomplished. A complete physical assessment including all body systems is performed.

The maternal abdomen should be evaluated carefully because a large percentage of serious injuries involve the uterus, intraperitoneal structures, and the retroperitoneum. The greatest clinical concern after severe abdominal trauma is placental abruption because as many as 40% of these women have an abruption. If placental abruption occurs, the associated fetal mortality rate can be as high as 50% to 80% (Mozurkewich & Pearlman, 2012). Assessments should focus on recognition of this complication, with careful evaluation of fetal monitor tracings, uterine tenderness, labor, or vaginal bleeding. Ultrasound examination may be performed to determine gestational age, viability of the fetus, and placental location. However, ultrasound studies cannot exclude placental abruption. Most cases of abruption that occur as a result of trauma are associated with relatively minor injuries (Robbins et al., 2014).

If trauma is the result of a penetrating wound, the woman should be completely undressed and carefully examined for all entrance and exit wounds. Focused abdominal ultrasound for trauma (FAST) and CT are commonly used to assess the likelihood of intraabdominal bleeding. Peritoneal lavage is less frequently used because of the availability of FAST, but it can be performed on hemodynamically unstable women to rule out bleeding or gross visceral perforation. Under direct visualization the peritoneum is incised, and a peritoneal dialysis catheter is positioned. If aspiration yields free-flowing blood, the test is considered positive. If not, 1 L of saline is infused into the peritoneal cavity. The recovered lavage fluid is

FIG 30-2 Clearing airway obstruction in woman in late stage of pregnancy. **A**, Standing behind victim, place your arms under woman's armpits and across chest. Place thumb side of your clenched fist against middle of sternum, and place other hand over fist. **B**, Perform backward chest thrusts until foreign body is expelled or woman becomes unconscious (see Emergency box: Relief of Foreign Body Airway Obstruction). (Data from Berg, R.A., Hemphill, R., Abella, B.S., et al. (2010). Part 5: Adult basic life support: 2010 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care science. *Circulation*, 122(Suppl 3), S685-S705.)

then examined for evidence of blood, bile, or bowel contents. Exploratory laparotomy is recommended if active hemorrhage or bowel perforation is suspected (Robbins et al., 2014).

Exploratory laparotomy is necessary after a gunshot wound to explore the abdominal cavity for organ damage and to repair any damage, with careful examination of all organs, the entire bowel, and posterior vessels. If uterine injury is found, a careful evaluation of the risks and benefits of cesarean birth is quickly accomplished. A cesarean birth is desirable if the fetus is alive and near term and may be necessary for the preterm fetus because of the high incidence of fetal injury in these cases. The fetus usually tolerates surgery and anesthesia if adequate uterine perfusion and oxygenation are maintained. Tetanus prophylaxis guidelines are not changed by pregnancy.

Trauma may affect numerous systems in the maternal body and may affect more than the pregnancy. External signs of maternal trauma should suggest the possibility of internal trauma. Back and neck pain suggest spine injury, abrasions on the chest suggest

chest injury, and limb pain and malposition suggest limb fractures. If head injury results in nonresponsiveness, suspect spinal, thoracic, and abdominal injuries. Hypovolemic shock can occur with internal hemorrhage, fracture of long bones, ruptured liver or spleen, hemothorax, or arterial dissection.

All female trauma victims of childbearing age should be considered pregnant until proven otherwise. Determination of the health history and a history of the events preceding the trauma are important components of care. If the pregnant woman was involved in an MVA, it should be determined whether she was the driver or a passenger and if she was ejected from the vehicle or used a restraining device and remained within the vehicle.

Electronic Fetal Monitoring. External FHR and contraction monitoring is recommended after blunt trauma in a viable gestation for a minimum of 4 hours, regardless of injury severity. Fetal monitoring should be initiated soon after the woman is stable (Cunningham et al., 2014; Robbins et al., 2014). Continuous EFM may show early signs of placental abruption, including a change in baseline rate, loss of accelerations, or the presence of late decelerations, especially when accompanied by absent or minimal variability. The external device to monitor uterine activity, the tocodynamometer, is unable to measure pressures, so the pattern made with this device shows the frequency and duration of contractions only. Palpation is required to evaluate the intensity of contractions and the uterine resting tone. It is important to palpate between contractions to verify that the uterus is well relaxed. If the uterus does not relax between contractions, placental abruption could be present.

The exact duration of FHR and contraction monitoring required after blunt abdominal trauma are not known. Monitoring should be continued indefinitely if uterine contractions, abnormal FHR characteristics, vaginal bleeding, uterine tenderness or irritability, serious maternal injury, or ruptured membranes are present (Cunningham et al., 2014). Most physicians recommend continuous monitoring for at least 24 hours because most serious complications appear to develop soon after the traumatic event (Robbins et al., 2014).

LEGAL TIP: Care of the Pregnant Woman Involved in a Minor Trauma Situation

After minor trauma the pregnant woman may be discharged after an adequate period of EFM that demonstrates a normal (category I) tracing (see Chapter 18) and absence of uterine contractions. However, clear instructions must be given for immediate return if vaginal bleeding, leaking of amniotic fluid, decreased fetal movement, or severe abdominal pain occurs.

Fetomaternal Hemorrhage. The potential for fetomaternal hemorrhage exists after trauma. Hemorrhage can lead to fetal anemia, distress, or even death. If the pregnant trauma victim is Rh negative, fetomaternal hemorrhage can result in sensitization and hemolytic disease of the neonate. The Kleihauer-Betke assay is often performed in women following blunt abdominal trauma to estimate the amount of fetal blood within the maternal circulation. Because most cases have less than 30 ml of hemorrhage, however, Kleihauer-Betke test results seldom alter management (Cunningham et al., 2014; Robbins et al., 2014). Usually the routine administration of 300 mcg of Rh₀(D) immune globulin is sufficient to protect almost all Rh-negative pregnant trauma clients from isoimmunization (Mozurkewich & Pearlman, 2012).

Ultrasound. Ultrasonography after trauma is not as sensitive as EFM for diagnosing placental abruption. Ultrasound may be useful to help establish gestational age, locate the placenta, evaluate cardiac activity (to determine whether the fetus is alive), and determine amniotic fluid volume. It also may be used to evaluate the presence of intraabdominal fluid that would suggest the presence of intraabdominal hemorrhage.

Radiation Exposure. If the pregnant woman has sustained serious injuries, any necessary radiographic examination should be performed, regardless of fetal exposure. If radiographic examination would be performed for the nonpregnant trauma victim, it also should be performed for the pregnant woman. Abdominal or pelvic CT scanning can be used to visualize extraperitoneal and retroperitoneal structures and the genitourinary tract. Radiation exposure of less than 5 rads has not been associated with fetal abnormalities or pregnancy loss, and the radiation level associated with abdominal or pelvic CT scans is far below this amount (Robbins et al., 2014). Blunt head trauma and loss of consciousness necessitate skull films and CT assessment with neurosurgical consultation. MRI also can safely be used to assess injuries because it does not produce ionizing radiation (Robbins et al.).

Perimortem Cesarean Birth. In the presence of multisystem trauma, perimortem cesarean birth may be indicated. Removal of the stressor of pregnancy early in the process of resuscitation may increase the chance for an intact neonatal outcome and also improve maternal resuscitative efforts (Robbins et al., 2014). Therefore, a cesarean birth should be performed after 4 minutes of resuscitative efforts if there is no spontaneous return of circulation (Mozurkewich & Pearlman, 2012; Robbins et al., 2014; Ruth & Miller, 2013). It should be emphasized that perimortem cesarean birth is rarely successful, especially when the maternal arrest is related to trauma (Ruth & Miller).

KEY POINTS

- The normal hemodynamic values are significantly altered as a result of pregnancy.
- The stress of the normal maternal adaptations to pregnancy on a heart whose function is already taxed may cause cardiac decompensation.
- Maternal morbidity and mortality are significant risks in a pregnancy complicated by mitral stenosis.
- Anemia, a common medical disorder of pregnancy, affects at least 20% of pregnant women.
- Asthma is a common medical condition to complicate pregnancy, and the prevalence and morbidity from this disorder are increasing.
- Pruritus is a common symptom in pregnancy-specific inflammatory skin diseases.

- A pregnant woman with epilepsy should take only one anti-convulsant medication at the lowest dose level that is effective at keeping her seizure free.
- Autoimmune disorders can occur during pregnancy because a large percentage of people with an autoimmune disorder are women of childbearing age. Common autoimmune diseases include SLE and MG.
- Cholecystitis and cholelithiasis are common GI problems in pregnancy.
- UTIs are a common medical complication of pregnancy.
- Pyelonephritis is the most common serious medical complication of pregnancy and the leading cause of septic shock during pregnancy.
- In the pregnant woman, an enlarged uterus, displaced internal organs, and altered laboratory values may confuse the diagnosis when the need for immediate abdominal surgery occurs.
- Perioperative care for a pregnant woman differs from that for a nonpregnant woman in one significant aspect: the presence of at least one other person, the fetus.
- The active roles assumed by most pregnant women today place them at risk for vehicular crashes, falls, violence, and other injuries.
- Pregnancy does not limit or restrict resuscitative, diagnostic, or pharmacologic treatment after trauma.
- Fetal survival depends on maternal survival. After trauma the first priority, before consideration of fetal concerns, is to resuscitate and stabilize the mother.
- Optimal care for the pregnant victim of trauma depends on knowledge of the physiologic state of pregnancy.
- Minor trauma can be associated with major complications for the pregnancy, including placental abruption, fetomaternal hemorrhage, preterm labor and birth, and fetal death.
- Trauma from accidents is the most common cause of death in women of childbearing age.
- In the case of a cardiac arrest in a pregnant woman, the standard advanced cardiac life support guidelines should be implemented with a few slight modifications: the uterus must be displaced to the left, and the defibrillation paddles should be placed one rib interspace higher.

Mental Health Disorders and Substance Abuse

Jan Sherman

<http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Describe mental health disorders occurring in the perinatal period, including mood disorders, anxiety disorders, post-traumatic stress disorder, and bipolar disorder.
- Compare postpartum blues, postpartum depression, and postpartum psychosis including risk factors, assessment, and management.
- Evaluate the role of the nurse in caring for women with mental health disorders during pregnancy and the postpartum period.
- Examine substance abuse during pregnancy, including prevalence, barriers to treatment, legal considerations, and commonly abused drugs.
- Discuss the care of pregnant women who use, abuse, or are dependent on alcohol or illicit or prescription drugs.

This chapter covers the most common maternal mental health disorders: perinatal mood disorders, anxiety disorders, postpartum depression, and postpartum psychosis, which usually manifests as bipolar disorder. Issues related to substance abuse during pregnancy also are discussed.

MENTAL HEALTH DISORDERS DURING PREGNANCY

Management of mental health disorders takes place primarily in community settings. Compared with births in the general non-mentally ill population, women with mental illness who give birth have a higher risk of obstetric complications (Thornton, Guendelman, & Hosang, 2009). However, mentally ill women who are treated are at lower risk than women who are not treated.

Perinatal mental illness has been recognized and discussed throughout history. In the 19th century, medical interest in perinatal mental illness accelerated, along with more general interest in severe mental illness (O'Hara & Wisner, 2014).

Women are at the greatest risk for developing a psychiatric disorder between the ages of 18 and 45 years—the childbearing years. Women who have serious mental disorders may be engaging in sexual activities that can result in pregnancy. The pregnant woman may have a history of disorder in mood, anxiety, substance use, schizophrenia, personality, or development. Assessment throughout pregnancy and the postpartum period is critical to the mother's and the baby's health. With a history or current symptoms of mental illness, referral to a mental health care provider for evaluation is recommended. Mental

health disorders have implications for the pregnant woman, the fetus, the newborn, and the entire family.

Perinatal Mood Disorders

Although the general public commonly uses the term *depression*, the term connotes a range of disorders that are collectively termed mood disorders (Yonkers, Vigod, & Ross, 2011). **Perinatal mood disorders (PMDs)** are a set of disorders that can occur any time during pregnancy as well as in the first year postpartum and can include depression, anxiety, obsessive-compulsive disorder, post-traumatic stress disorder (PTSD), and postpartum psychosis.

Depression *during* pregnancy is a major risk factor for postpartum depression (PPD). Postpartum depression has been associated with negative effects on child development, including a difficult infant and childhood temperament, attachment insecurity, and increased risk of developmental delay and lower IQ scores. A substantial rate of suicide occurs postpartum, because maternal suicide accounts for up to 20% of postpartum deaths in depressed women (Wisner, Sit, Altemus, et al., 2012).

Prevalence

Perinatal mental health problems are common worldwide. Clinical depression is common among reproductive-age women and is a leading cause of disability in U.S. women each year. Between 14% and 23% of pregnant women will experience depression symptoms during pregnancy. An estimated 5% to 25% of women will have PPD. In high-income countries, about 10% of pregnant women and 13% of women who have just given birth experience a mental disorder, primarily depression or anxiety. Depression accounts

for \$30 to \$50 billion in lost productivity and direct medical costs in the United States each year. Higher rates of common perinatal mental disorders have also been seen among women from low- and lower-middle-income countries (American Academy of Pediatrics [AAP] & American College of Obstetricians and Gynecologists [ACOG], 2012; Rahman, Fisher, Bower, et al., 2013).

Studies have shown that untreated maternal depression can negatively affect an infant's cognitive, neurologic, and motor skill development. A mother's untreated depression can also negatively affect older children's mental health and behavior. During pregnancy depression can lead to preeclampsia, preterm birth, and low birth weight (AAP & ACOG, 2012; ACOG, 2010; Mikacich, 2014).

Diagnosis

A mood disorder that emerges during childbearing requires a thorough medical and family history, review of systems, and complete physical examination. The use of prescribed and over-the-counter medications as well as commonly abused substances must be assessed. Thyroid abnormalities and anemia, which are common in childbearing women, should be ruled out (AAP & ACOG, 2012; Yonkers et al., 2011).

To be diagnosed with major depression, at least five of the following signs or symptoms must be present nearly every day: depressed mood, often with spontaneous crying; markedly diminished interest in all activities; insomnia or hypersomnia; weight changes (increases or decreases); psychomotor retardation or agitation; fatigue or loss of energy; feelings of worthlessness or inappropriate guilt; diminished ability to concentrate; and suicidal ideation with or without a suicidal plan (American Psychiatric Association [APA], 2013). The 10-item Edinburgh Postnatal Depression Scale (see later discussion) accurately identifies depression in pregnant and postpartum women (Sadock, Sadock, & Ruiz, 2009).

! NURSING ALERT

Diagnostic assessment for depression in pregnant women is difficult because many of the symptoms of pregnancy mimic depression. Critical cues are the presence of psychologic symptoms, a suicide plan, and major disruptions in sleep pattern. Risk factors for developing depression in pregnancy include a prior history in self or family, a lack of social support, stressful life events, partner discord, and history of premenstrual syndrome (PMS).

CARE MANAGEMENT

Medical management of depression is usually a combination of antidepressants and cognitive-behavioral therapy (CBT) or interpersonal psychotherapy (IPT). For mild cases of depression in pregnant women, psychotherapy is the treatment of choice as the initial intervention. Both IPT and CBT are time-limited treatments (usually 10 to 12 sessions) that focus on present problems and encourage the woman to regain control over her mood and functioning. Short-term therapies, such as CBT, may be delivered by psychiatrists and non-physician professionals such as psychologists, psychiatric nurse clinical specialists or practitioners, or licensed clinical social workers (Guille, Newman, Fryml, et al., 2013; Wisner et al., 2012).

Self-help strategies such as exercise, respite from caregiving, self-help groups, and making time for one's self can be helpful.

Antidepressant Medications. It is estimated that more than 6% of women are prescribed an antidepressant at some point during pregnancy (Ray & Stowe, 2014). No consensus exists regarding safety in the use of antidepressant medications by pregnant women. To date, the U.S. Food and Drug Administration (FDA) has not approved any psychotropic medication for use during pregnancy. None of these medications is rated as an FDA Category A drug (controlled studies show no risk to the fetus) (see Box 31-1 for FDA pregnancy risk categories of most common antidepressant medications). The commonly used antidepressant drugs are often divided into four groups: selective serotonin reuptake inhibitors (SSRIs), serotonin/norepinephrine reuptake inhibitors (SNRIs), tricyclic antidepressants (TCAs), and monoamine oxidase inhibitors (MAOIs). The most common antidepressants are listed in Table 31-1.

Because the majority of women are not aware of their pregnancy until at least 6 weeks of gestation, psychotropic medications may not be discontinued until after the period of greatest potential risk to the fetus has passed. Risk-benefit analyses of depression treatment options should consider the potential risks that can accrue if depressive episodes go untreated in the pregnant woman. Risks include severe psychologic distress, suicide, financial hardships, and inability to plan for transition to parenthood. Most women who discontinue antidepressant medications relapse during pregnancy. The majority of relapses occurs in the first trimester, and relapse is more prevalent in women with

BOX 31-1 FDA Pregnancy Risk Categories

Category A

Adequate and well-controlled studies have failed to demonstrate a risk to the fetus in the first trimester of pregnancy (and there is no evidence of risk in later trimesters).

Category B

Animal reproduction studies have failed to demonstrate a risk to the fetus and there are no adequate and well-controlled studies in pregnant women.

Category C

Animal reproduction studies have shown an adverse effect on the fetus and there are no adequate and well-controlled studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.

Category D

There is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.

Category X

Studies in animals or humans have demonstrated fetal abnormalities and/or there is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience, and the risks involved in use of the drug in pregnant women clearly outweigh potential benefits.

Category N

FDA has not classified drug

FDA, U.S. Food and Drug Administration.

From www.drugs.com. (2014). FDA categories A, B, C, D, X, N explained. Available at www.drugs.com/pregnancy-categories.html.

histories of chronic depression. Because randomized clinical trial data regarding the relative safety of available psychotropic medications are unavailable, clinical decision making is complicated.

Concerns regarding the safety of antidepressant medications are common (Ray & Stowe, 2014). However, untreated depression can also cause adverse effects on the developing fetus and neonate, such as preterm birth, small head circumference, and low Apgar scores. For women with a diagnosis of major depression, treatment with antidepressants is appropriate. Use of antidepressants, including SSRIs, is indicated for vegetative

signs accompanying a **major depressive episode (MDE)** that do not resolve with supportive interventions. There is a lack of definitive evidence to demonstrate a statistically significant association between fetal exposure to anti-depressant medications and congenital abnormalities, although isolated cases have been reported (Box 31-2). Reports have linked third-trimester

TABLE 31-1 Antidepressant Medications

	PREGNANCY RISK CATEGORY*	LACTATION RISK CATEGORY*
Selective Serotonin Reuptake Inhibitors (SSRIs)		
Citalopram (Celexa)	C	L3

Fluoxetine (Prozac)	C	L2 in older infants; L3 in neonates
Fluvoxamine (Luvox)	C	L2
Paroxetine (Paxil)	D	L2
Sertraline (Zoloft)	C	L2
Serotonin/Norepinephrine Reuptake Inhibitors (SNRIs)		
Bupropion (Wellbutrin) IR & SR	B	L3
Maprotiline (Ludiomil)	B	L3
Mirtazapine (Remeron)	C	L3
Trazodone (Desyrel)	C	L2
Venlafaxine (Effexor)	C	L3
Tricyclic Antidepressants (TCAs)		
Amitriptyline (Elavil)	D	L2
Amoxapine (Asendin)	C	L2
Clomipramine (Anafranil)	C	L2
Desipramine (Norpramin)	C	L2
Doxepin (Sinequan)	C	L5
Imipramine (Tofranil)	D	L2
Nortriptyline (Pamelor)	D	L2
Monoamine Oxidase Inhibitors (MAOIs)		
Phenelzine (Nardil)	C	Unknown
Tranylcypromine (Parnate)	C	Unknown

B = Animal studies have not shown fetal risk, but no controlled studies in pregnant women or animal studies showed adverse effect that was not confirmed in controlled studies in women in first trimester—no risk in later trimesters.

C = Animal studies show adverse effects on fetus, but no controlled studies in pregnant women or no studies available.

D = Positive evidence of human fetal risk.

L2 = Drug studied in limited number of breastfeeding women without an increase in adverse effects in infant or risk is remote.

L3 = No controlled studies in breastfeeding women or studies show minimal nonthreatening adverse effects.

L5 = Contraindicated because studies have shown significant and documented risk to infant.

IR, Intermediate release; SR, sustained release.

BOX 31-2 SSRIs: Effects on Pregnancy and Birth Defects

Intrauterine Fetal Demise and Miscarriage

Studies to support an association between miscarriage rates and antidepressant use have inadequate control for confounding variables related to the depressive disorder. There is no evidence that the rate of stillbirths is increased during antidepressant treatment (Wisner, Sit, Altemus, et al., 2012).

Physical Malformations

The majority of studies does not demonstrate an association between tricyclic antidepressants (TCAs) and birth defects. Similarly, studies of first-trimester selective serotonin reuptake inhibitor (SSRI) exposure do not demonstrate consistent data to support a risk for structural malformations (Wisner et al., 2012).

Persistent Pulmonary Hypertension of the Newborn (PPHN)

Grigoriadis, VonderPorten, and Ross (2014) found that the risk of PPHN seems to be increased for infants exposed to SSRIs in late pregnancy. A significant relation for exposure to SSRIs in early pregnancy was not evident.

Poor Neonatal Adaptation Syndrome

Infants who are exposed in late pregnancy to SSRI or serotonin/norepinephrine reuptake inhibitors (SNRIs) have a 10% to 30% rate of poor neonatal adaptation syndrome, which often is proven to be associated with low systemic levels of the antidepressants. Although most signs of this neonatal syndrome resemble neonatal withdrawal from opioids, benzodiazepines, and ethanol, in some cases SSRI withdrawal is associated with respiratory failure that necessitates short-term respiratory support, which is unique to the SSRIs and SNRIs (Ornoy & Koren, 2013).

Neonatal Seizures

Hayes, Wu, Shelton, et al. (2013) found that third-trimester SSRI use is associated with infant convulsions within the first 14 days of life.

Cardiac Defects

The association of SSRI use and neonatal cardiac defects, in particular septal defects, has been of concern. However, Margulis, Abou-Ali, Strazzeri, et al. (2013) found no association between maternal use of SSRIs in early pregnancy and cardiac malformations or septal defects.

use of SSRIs by pregnant women to a constellation of neonatal signs that include continuous crying, irritability, jitteriness, and restlessness; shivering; fever; tremors; hypertonia or rigidity; tachypnea or respiratory distress; feeding difficulty; sleep disturbance; hypoglycemia; and seizures. The onset of these signs ranged from several hours to several days after birth and usually resolved within 1 to 2 weeks (Hudak, Tan, & AAP, 2012). Paroxetine has been associated with ventricular septal defects for first-trimester exposure; venlafaxine has been associated with a poor neonatal adaptation syndrome and mirtazapine with greater risk of preterm birth (Sadock et al., 2009).

Although less information is known regarding the use of SSRIs during pregnancy compared with the use of TCAs, this class of drugs is emerging as first-line agents in treatment (Ray & Stowe, 2014). They are relatively safe and carry fewer side effects than the TCAs. However, if an SSRI is taken with dextromethorphan, an agent found in cough syrup, the combination could trigger the serotonin syndrome (e.g., mental status changes, agitation, hyperreflexia, shivering, and diarrhea). The most frequent side effects with the SSRIs are gastrointestinal (GI) disturbances (e.g., nausea and diarrhea), headache, and insomnia. SSRIs also can inhibit specific P-450 isoenzymes, resulting in a marked elevation in drug concentration and a reduction in drug clearance.

The TCAs cause many central nervous system (CNS) and peripheral nervous system side effects. In overdose, these medications can cause death. A common CNS effect is sedation. Other side effects include weight gain, tremors, grand mal seizures, nightmares, agitation or mania, and extrapyramidal side effects. Anticholinergic side effects include dry mouth, blurred vision (usually temporary), difficulty voiding, constipation, sweating, and difficulty with orgasm.

The use of MAOIs during pregnancy is contraindicated because of the risk for fetal growth restriction. In animals hypertension with subsequent placental hypoperfusion and complications with anesthesia during labor have been reported (Sadock et al., 2009).

Nursing Interventions

Nursing strategies include educating the woman about depression as an illness and the plan of care, including medications. For the woman who refuses medications during pregnancy, the nurse should discuss alternative treatments and respect her choice. The nurse also can be effective by maintaining a caring relationship, which includes being hopeful. The nurse can ask about a time when the woman was coping well and how she was able to combat the depression then.

ANXIETY DISORDERS

Anxiety disorders are the most common psychiatric disorders, and some (e.g., panic disorder, generalized anxiety disorder, PTSD, agoraphobia) are twice as likely to be diagnosed in women compared with men. Anxiety and stress during pregnancy are associated with miscarriage, preterm birth, and birth complications, although a direct causal relationship has not been established (Glover, 2014).

Anxiety disorders are characterized by prominent symptoms of anxiety that impair functioning. Examples are obsessive-compulsive disorder (OCD), PTSD, generalized

anxiety disorder, panic disorder, agoraphobia, and other phobias (Wisner et al., 2012).

Diagnosis

Panic attacks are characterized by brief (5 to 15 minutes), intense episodes of fear or discomfort. Panic attacks occur in a variety of anxiety disorders, as well as in healthy individuals exposed to acute stress. Symptoms include palpitations, sweating, shortness of breath, choking, nausea, abdominal discomfort, dizziness, unsteadiness, numbness or tingling, chills, hot flashes, or a fear of dying or losing control (Wisner et al., 2012).

Panic disorder is diagnosed if panic attacks are recurrent or associated with a continuing fear of future attacks, which results in anxiety between attacks. The most disabling consequence of panic disorder, agoraphobia, occurs in 30% to 40% of women with untreated panic disorder. Individuals with agoraphobia restrict their activities outside the home or insist on being accompanied by another individual due to fear of having a panic attack where help is unavailable (Wisner et al., 2012).

Generalized anxiety disorder is characterized by excessive worrying about multiple problems. The issues of concern to people with generalized anxiety disorder are realistic but the level of worry is much more intense than appropriate. For example, a woman might worry for hours about whether a friend received a thank-you note for a baby shower gift (Wisner et al., 2012). The pregnant woman also may have persistent thoughts that something is wrong with the fetus.

Individuals with generalized anxiety disorder often have physical symptoms associated with worrying, such as muscle tension, fatigue, headache, nausea, diarrhea, or abdominal pain. To meet criteria for the disorder, individuals must have significant impairment of functioning and anxiety for at least 6 months (Wisner et al., 2012).

PTSD can occur as a result of rape or intimate partner violence (see Chapter 5). Symptoms include reexperiencing the traumatic event, persistent avoidance of stimuli, and numbing, as well as difficulty sleeping, irritability or angry outbursts, difficulty concentrating, hypervigilance, and exaggerated startle response. Nurses can support the healing process of individuals with PTSD by being alert to what the woman is experiencing during pregnancy and labor.

If the current pregnancy is a result of rape, the woman may be extremely ambivalent about the baby. If the rape occurred some time ago, the whole experience of pregnancy with prenatal visits and physical examinations can trigger memories of the original trauma. She may avoid prenatal care because of the anxiety triggered by bodily touch and vaginal examinations. Some pregnant women with PTSD may feel more comfortable with a female nurse-midwife or a female physician. Giving birth can trigger memories of being out of control, and she may lose contact with reality. The nurse can verbalize understanding of the anxiety and orient the woman to current reality by saying, "You're having an examination to make sure the baby is okay," or, "You're in labor preparing to give birth to your baby. I am your nurse. You're in the hospital. I will check on you frequently. You are safe here." Treatment usually includes psychotherapy and referral to support groups.

→ fear of physical stimuli that might cause you helplessness, embarrassment

CARE MANAGEMENT

When anxiety substantially impairs work, family, or social adjustment, mental health evaluation is indicated and treatment is appropriate. Generalized anxiety disorder responds to a variety of antidepressant medications as well as cognitive therapy (Wisner et al., 2012). Cognitive therapy, a time-limited, structured psychotherapy, also is for panic disorder. Panic disorder responds to most antidepressant medications, which are first-line therapies for this disorder (Wisner et al., 2012). Benzodiazepines are also effective but can be associated with abuse and physical dependence in some women. Prenatal benzodiazepine exposure increases the risk of oral cleft. Maternal benzodiazepine use shortly before birth is associated with floppy infant syndrome (ACOG, 2008).

Note that most of the anti-anxiety medications are FDA Category D (evidence of human fetal risk) or Category X (demonstrated fetal abnormalities and use is contraindicated) (Table 31-2). However, benzodiazepines should not be abruptly discontinued during pregnancy, and they should be tapered sufficiently before the birth to limit neonatal withdrawal syndrome.

OCD is effectively treated with SSRIs. A behavioral therapy technique, exposure and response prevention, is also effective for OCD (Wisner et al., 2012). PTSD is partially responsive to antidepressant medication, but cognitive therapy with exposure is more effective. The first-line medication treatment for social phobia is SSRIs; cognitive therapy also can be very helpful. Specific phobias are most effectively treated with focused desensitization psychotherapy rather than medication (Wisner et al., 2012).

A risk-to-benefit evaluation for treatments during pregnancy must be individualized for the pregnant woman with

anxiety disorder, which, like an MDE, can have a negative effect on pregnancy outcome. If psychotherapy treatment is refused, not available, or ineffective, pharmacologic treatment should be considered (Wisner et al., 2012).

Nursing Interventions

Nursing strategies to reduce anxiety include empowerment through education; sensory interventions such as music therapy and aromatherapy; medication (see Table 31-2); behavioral interventions such as breathing exercises, progressive muscle relaxation, and guided imagery; and cognitive strategies such as encouraging positive self-talk and questioning negative thinking.

Nurses should educate women about the dangers of benzodiazepines during pregnancy, assess for use during pregnancy, and help pregnant women find other ways to handle their anxiety and insomnia, or refer them to a psychiatrist who specializes in psychiatric disorders in pregnancy.

Special Considerations for Medications During Pregnancy

Even though the basic rule is to avoid administering any medication to a pregnant woman, particularly during the first trimester, decisions about the use of medications during pregnancy should be made jointly by the woman, her partner, and her health care providers. If the woman is stable and appears likely to remain well while not taking medication, then discontinuation before pregnancy is a viable option. For those women with a history of relapse after medication discontinuation, remaining on the drug during pregnancy is advised. There is a lack of conclusive evidence that antipsychotic medications (either typical or atypical) are teratogenic (Sadock et al., 2009).

Although a pregnant woman should be receiving the lowest therapeutic dose, psychotropic medications may have to be increased over the course of pregnancy to maintain adequate therapeutic serum concentrations and response (Sadock et al., 2009). Administering psychotherapeutic medications at or near birth can cause a baby to be overly sedated at birth and require ventilatory support or to be physically dependent on the drug and require detoxification and treatment of a withdrawal syndrome (see Chapter 35).

If a woman becomes psychotic during pregnancy, it is usually either because she has stopped taking mood stabilizers or antipsychotics or because she has a history of schizophrenia. Psychosis is a medical emergency. To treat a psychotic state, antipsychotic medication or electroconvulsive therapy (ECT) can be used (Sadock et al., 2009). Lithium is currently considered the first-line medication for the treatment of psychosis during pregnancy (Roy & Payne, 2009).

Most of the mood-stabilizing medications such as lithium carbonate, carbamazepine (Tegretol), gabapentin (Neurontin), lamotrigine (Lamictal), and valproic acid (Depakote) are Category D (see Table 31-3 for FDA categories of mood stabilizers). In women with preexisting illness, there is a high recurrence of mania during pregnancy that can present as psychosis; thus maintenance on lithium is important to deter the development of adverse effects in the mother and infant. Mood stabilizers are often taken over the life span by women with bipolar disorder. Women with this disorder should receive preconception counseling. Those who have experienced a single manic episode

may elect to have the medication tapered gradually and make an attempt to have a lithium-free pregnancy or, if indicated, reinstitute the lithium after the first trimester.

If the pregnant woman is receiving pharmacologic treatment, the nurse must make sure that she is being treated by a psychiatrist or an advanced practice psychiatric nurse. No woman should withdraw abruptly from any psychotropic medication because of the risk of withdrawal symptoms.

POSTPARTUM MOOD DISORDERS

The weeks after birth are a time of vulnerability to psychologic complications for many women, causing significant distress for the mother, disrupting family life, and, if prolonged, negatively affecting the child's emotional and social development. Preexisting mood and anxiety disorders are particularly likely to recur or worsen during these weeks. Such conditions can interfere with attachment to the newborn and family integration, and some may threaten the safety and well-being of the mother, the newborn, and other children. Because birth is usually thought to be a happy event, a new mother's emotional distress can puzzle and immobilize family and friends. When she most needs the caring attention of loved ones, they may either criticize or withdraw because of their anxiety. Nurses can offer anticipatory guidance, assess the mental health of new mothers, offer therapeutic interventions, and make referrals when necessary. Failure to do so can result in tragic consequences. In the rarest of cases, a disturbed mother may kill her infant, other family members, or herself.

Mood disorders are the predominant mental health disorder in the postpartum period (APA, 2013). Up to 85% of women experience a mild depression or "baby blues" after the birth of a child; however, the woman's functioning is usually not impaired. Baby blues are characterized by mood swings, feelings

of sadness and anxiety, crying, difficulty sleeping, and loss of appetite. The symptoms resolve within a few days, and treatment is not needed (Paschetta, Berrisford, Coccia, et al., 2014).

Postpartum Depression

Serious depression, experienced by 10% to 15% of postpartum women, can eventually incapacitate them to the point of being unable to care for themselves or their babies (Sadock et al., 2009). **Postpartum depression** affects women from all cultures, although the manifestations vary.

The *Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-V)* contains the official guidelines for the assessment and diagnosis of psychiatric illness (APA, 2013). However, specific criteria for PPD are not listed. Instead, women must meet the criteria for an MDE and the criteria for the *peripartum-onset* specifier. The diagnosis of PPD is therefore an MDE with an onset in pregnancy or within 4 weeks of childbirth (APA). The following discussion focuses on the postpartum onset.

The cause of PPD can be biologic, psychologic, situational, or multifactorial. Estrogen fluctuations and postpartum hypogonadism (the change from the high levels of estrogen and progesterone at the end of pregnancy to the much lower levels of both hormones that are present after birth) are important etiologic factors. Women at greatest risk for PPD are those with a history of anxiety or depression and especially those who had a previous episode of major depressive disorder (MDD) in the past, including during or after pregnancy (Cunningham, Leveno, Bloom, et al., 2014; Davey, Tough, Adair, & Benzie, 2011). Other risk factors include younger age, unintended pregnancy, personal history of severe premenstrual dysphoria, family history of mood disorder, unmarried status, marital discord, lack of social support, socioeconomic deprivation, lower education, substance abuse, and stressful life events in the previous year (Cunningham et al.; Le Strat, Dubertret, & Le Foll, 2011). Women facing multiple or severe psychosocial problems or chronic interpersonal difficulties are at increased risk for an MDE.

Poor nutrition may also contribute to the pathogenesis of an MDE. Folate and vitamin B₁₂ are needed for the synthesis of serotonin and other neurotransmitters. Marginal or low folate also increases the likelihood of a poor response to antidepressant medication as well as the potential for relapse in people who initially responded well to pharmacologic therapy (Wisner et al., 2012).

Complications of pregnancy and birth increase the risk for PPD (Blom, Jansen, Verhulst, et al., 2010). Having a preterm, low-birth-weight, and ill neonate is associated with higher rates of PPD (Vigod, Villegas, Dennis, & Ross, 2010). Women who are victims of intimate partner violence are at increased risk for PPD (Beydoun, Beydoun, Kaufman, et al., 2012; Cerulli, Talbot, Tang, & Chaudron, 2011; Woolhouse, Gartland, Hegarty, et al., 2012). Cultural practices can positively or negatively affect the development of PPD. Common risk factors for PPD are listed in Box 31-3.

Paternal Postpartum Depression

Often women are not alone in their experience of PPD; new fathers may have PPD as well. The incidence is unclear, with reports varying from 10% to more than 50% (Letourneau,

BOX 31-3 Risk Factors for Postpartum Depression

- Prenatal anxiety or depression
- History of major depressive episode
- History of postpartum depression
- Life stress
- Major life event (e.g., moving, job loss)
- Lack of social support
- Unmarried
- Marital relationship problems
- Intimate partner violence
- Thyroid imbalance
- Diabetes: type 1, type 2, or gestational
- Mothers who have undergone infertility treatment
- Complicated pregnancy or birth
- Complications of breastfeeding
- Preterm or ill infant
- Mothers of multiples
- Postpartum blues
- Low socioeconomic status
- Unintended pregnancy

Data from Beck, C. (2002). Revision of the postpartum depression predictors inventory. *Journal of Obstetric, Gynecologic, and Neonatal Nursing*, 31(4), 394-402; Beck, C. (2001). Predictors of postpartum depression: An update. *Nurse Researcher*, 50(5), 275-282; Postpartum Support International. (2014). Depression during pregnancy and postpartum. Available at www.postpartum.net/get-the-facts/depression-during-pregnancy-postpartum.aspx.

Tryphonopoulos, Duffett-Leger, et al., 2012; Paulson & Bazemore, 2010). The best predictor of paternal depression is having a partner with PPD. Men may not exhibit classic symptoms of PPD but are likely to display fatigue, frustration, anger, irritability, indecisiveness, and withdrawal from social situations (Paulson & Bazemore).

Postpartum Depression Without Psychotic Features

PPD is an intense and pervasive sadness with severe and labile mood swings; it is more serious and persistent than postpartum blues. Intense fears, anger, anxiety, and despondency that persist past the baby's first few weeks are not a normal part of postpartum blues. These symptoms rarely disappear without outside help (Sadock et al., 2009). Most of these mothers seek help only after reaching a "crisis point."

The symptoms of postpartum major depression do not differ from those of nonpostpartum mood disorders except that the mother's ruminations of guilt and inadequacy feed her worries about being an incompetent and inadequate parent. In PPD there can be loss of appetite or odd food cravings (often sweet desserts) and binges with abnormal appetite and weight gain. New mothers report an increased yearning for sleep, sleeping heavily but awakening instantly with any infant noise, and an inability to go back to sleep after infant feedings. Determining difficulty falling asleep is a relevant screening question to ascertain risk for PPD.

A distinguishing feature of PPD is irritability. These episodes of irritability can flare up with little provocation, and they sometimes escalate to violent outbursts or dissolve into uncontrollable sobbing. Many of these outbursts are directed against significant others (e.g., "He never helps me") or the baby (e.g., "She cries all the time, and I feel like hitting her"). Women with postpartum MDEs often have severe anxiety,

panic attacks, and spontaneous crying long after the usual duration of baby blues.

Many women feel especially guilty about having depressive feelings at a time when they believe they should be happy. They can be reluctant to discuss their symptoms or their negative feelings toward the infant. A prominent feature of PPD is rejection of the infant, often caused by abnormal jealousy. The mother can be obsessed by the notion that the baby will take her place in her partner's affections. Attitudes toward the infant can include disinterest, annoyance with care demands, and blaming because of her lack of maternal feeling. When observed, she can appear awkward in her responses to the baby. Obsessive thoughts about harming the infant are very frightening to her. Often she does not share these thoughts because of embarrassment; when she does, other family members become very frightened.

Medical Management. The natural course is one of gradual improvement over the 6 months after birth. However, supportive treatment alone is not effective for major PPD. Antidepressant medication along with some form of psychotherapy is used to treat severe depression during or after pregnancy. Often an SSRI is prescribed initially. If symptoms improve during a 6-week trial period, the medication should be continued for at least 6 months to prevent relapse. If response to the medication is less than optimal, another SSRI can be prescribed instead (Cunningham et al., 2014) (see Tables 31-1, 31-2, and 31-3). Alternative therapies such as herbs, dietary supplements, massage, aromatherapy, and acupuncture may be helpful. Psychotherapy focuses on the woman's fears and concerns regarding her new responsibilities and roles and monitoring for suicidal or homicidal thoughts. Support groups and marital counseling can be helpful. For some women, hospitalization is necessary.

Postpartum Depression with Psychotic Features

The most severe of the perinatal mood disorders, **postpartum psychosis**, is rare, affecting approximately 0.1% to 0.2% of postpartum women (Sadock et al., 2009).

Episodes of postpartum psychosis are typified by auditory or visual hallucinations, paranoid or grandiose delusions, elements of delirium or disorientation, and extreme deficits in judgment accompanied by high levels of impulsivity that can contribute to increased risks of suicide or infanticide (in 5% of psychotic women) (Sadock et al., 2009). Characteristically, the woman begins to complain of fatigue, insomnia, and restlessness and can have episodes of tearfulness and emotional lability. Complaints regarding the inability to move, stand, or work also are common. Later, suspiciousness, confusion, incoherence, irrational statements, and obsessive concerns about the baby's health and welfare can be present. Delusions are present in 50% of women with postpartum psychosis, and hallucinations occur in approximately 25% of women with this disorder. Auditory hallucinations that command the mother to kill the infant can occur in severe cases. When delusions are present, they are often related to the infant. The mother may think the infant is possessed by the devil, has special powers, or is destined for a terrible fate. Grossly disorganized behavior can be manifested as a disinterest in the infant or an inability to provide care. Some women will insist that something is wrong with

the baby or accuse nurses or family members of hurting or poisoning their child.

! NURSING ALERT

Nurses are advised to be alert for mothers who are agitated, overactive, confused, complaining, or suspicious.

Postpartum psychosis is most commonly associated with the diagnosis of **bipolar disorder** (or manic-depressive disorder). Rates of postpartum relapse in women with bipolar disorder range from 32% to 67%. Perinatal episodes of the disorder tend to be depressive and are more likely to recur in subsequent pregnancies. Postpartum psychosis tends to show onset within 2 weeks postpartum; however, it can present later in the course of the illness as a depression (Sadock et al., 2009).

Postpartum psychosis is defined by the presence of one or more episodes of abnormally elevated energy levels, cognition, and mood and one or more depressive episodes. The elevated moods are clinically referred to as *mania*. Clinical manifestations of a manic episode include at least three of the following: grandiosity, decreased need for sleep, pressured speech, flight of ideas, distractibility, psychomotor agitation, and excessive involvement in pleasurable activities without regard for negative consequences (APA, 2013). While in a manic state mothers need constant supervision when caring for their infant. Usually, however, they are too preoccupied to provide child care. Individuals who experience manic episodes also commonly experience depressive episodes or symptoms or mixed episodes, in which features of both mania and depression are present at the same time. These episodes are usually separated by periods of “normal” mood, but in some individuals, depression and mania may rapidly alternate. These rapid changes in mood are known as *rapid cycling*.

Medical Management. Postpartum psychosis carries a relatively good prognosis with early detection and aggressive treatment; however, if left untreated, it can progress to the second postpartum year and become more refractory to treatment (Sadock et al., 2009). Postpartum psychosis is a psychiatric emergency, and the mother will probably need inpatient psychiatric care. Antipsychotics (Table 31-4) and mood stabilizers (see Table 31-3) such as lithium are the treatments of choice. Antidepressants should be used very cautiously in treating postpartum psychosis, even when depressive symptoms are present, because of the risk for precipitating rapid cycling. Because of potential risks to the breastfeeding infant, informed consent regarding the risks and benefits of exposing the newborn to a psychotropic agent and maternal mental illness must be discussed and documented (see additional discussion of lactation and psychotropic medications later in this chapter). ECT, especially when bilaterally administered, has also been shown to be highly effective in the treatment of postpartum psychosis. It is usually advantageous for the mother to have contact with her baby if she so desires, but visits must be closely supervised. Psychotherapy is indicated after the period of acute psychosis has passed.

Even though the prevalence of PPD is fairly well established, some women are unlikely to seek help from a mental health

TABLE 31-4 Antipsychotic Medications

ANTIPSYCHOTIC MEDICATIONS	PREGNANCY RISK CATEGORY*	LACTATION RISK CATEGORY*
Traditional Antipsychotics		
Chlorpromazine (Thorazine)	C	L3
Fluphenazine (Prolixin)	C	L3
Haloperidol (Haldol)	C	L2
Perphenazine (Trilafon)	C	L3
Thioridazine (Mellaril)	C	L4
Thiothixene (Navane)	C	L4
Trifluoperazine (Stelazine)	Unknown	Unknown
Atypical Antipsychotics		
Aripiprazole (Abilify)	C	L3
Clozapine (Clozaril)	C	L3
Loxapine (Loxitane)	C	L4
Olanzapine (Zyprexa)	C	L2
Quetiapine (Seroquel)	C	L4
Risperidone (Risperdal)	C	L3
Ziprasidone (Geodon)	C	L4

C = Animal studies show adverse effects on fetus, but no controlled studies in pregnant women *or* no studies available.

L2 = Drug studied in limited number of breastfeeding women without an increase in adverse effects in infant *or* risk is remote.

L3 = No controlled studies in breastfeeding women *or* studies show minimal nonthreatening adverse effects.

L4 = Possibly hazardous.

care provider. This can be related to social stigma of mental illness, cultural beliefs, lack of knowledge, or fear of child custody implications (Yonkers et al., 2011).

CARE MANAGEMENT

Primary health care providers usually recognize severe PPD or postpartum psychosis but may miss milder forms. Even if it is recognized, the woman may be treated inappropriately or subtherapeutically. Identification and treatment of maternal depression must be continued beyond the immediate postpartum period to prevent negative effects of maternal depression on the children of these mothers. To recognize symptoms of PPD as early as possible, the nurse should be an active listener and demonstrate a caring attitude. Nurses cannot depend on women to volunteer unsolicited information about their depression or ask for help. Examples of ways to initiate conversation include the following: “Now that you’ve had your baby, how are things going for you? Have you had to change many things in your life since having the baby?” and “How much time do you spend crying?” If the nurse assesses that the new mother is depressed, she or he must ask if the mother has thought about hurting herself or the baby. The woman may be more willing to answer honestly if the nurse says, “Many women feel depressed after having a baby, and some feel so badly that they think about hurting themselves or the baby. Have you had these thoughts?” (see Nursing Care Plan).

 **NURSING CARE PLAN**
Postpartum Depression

NURSING DIAGNOSIS	EXPECTED OUTCOME	INTERVENTIONS	RATIONALES
<i>Risk for Injury to the woman and/or newborn related to woman's emotional state and/or treatment</i>	The mother and newborn will remain free of injury. The woman's family will verbalize understanding of the need for maternal and infant supervision and have a plan to provide that supervision.	<p>Assess the postpartum woman for risk factors for depression (before discharge).</p> <p>Provide information about signs of postpartum depression (PPD) to woman and family.</p> <p>Observe maternal-infant interactions before discharge.</p> <p>Maintain frequent contact with woman by telephone calls and home visits after discharge.</p> <p>Counsel woman and family to contact health care provider if behaviors indicating depression, such as crying, increase.</p> <p>Provide opportunities for woman and family to verbalize feelings and concerns in a nonjudgmental setting.</p> <p>Assess woman for any suicidal thoughts or plans.</p> <p>Assist family to develop a plan for maternal and infant supervision.</p> <p>Provide information about community resources for assistance.</p> <p>Reinforce teaching or refer breastfeeding mother to lactation consultant.</p>	<p>To determine if she is at risk and in need of prompt interventions or referral</p> <p>To promote prompt recognition of problems</p> <p>To determine appropriateness</p> <p>To determine if further interventions are necessary</p> <p>To provide prompt care and referral if necessary and avoid injury to newborn and mother</p> <p>To promote a trusting relationship</p> <p>To provide for safety of woman and infant</p> <p>To provide for safety of woman and infant</p> <p>To ensure care if woman is unable to care for herself or infant</p> <p>To obtain information regarding effects of antidepressant and antipsychotic medications</p> <p>To establish a trusting relationship</p>
<i>Disabled Family Coping related to postpartum maternal depression as evidenced by family members' denial of woman's illness</i>	Family will identify positive coping mechanisms and initiate a plan to cope with the woman's depression.	<p>Provide opportunity for family and significant others to verbalize feelings and concerns.</p> <p>Give information regarding postpartum depression to the family.</p> <p>Assist family to identify positive coping mechanisms that have been effective during past crises.</p> <p>Assist family to identify community sources of support.</p> <p>Refer family to mental health care provider as needed.</p>	<p>To clarify any misconceptions or misinformation</p> <p>To promote active participation in care</p> <p>To provide additional resources as needed</p> <p>To provide further expertise from a mental health professional</p>
<i>Risk for Impaired Parenting related to inability of mother to attach to infant</i>	Woman demonstrates appropriate attachment behaviors in infant interactions. Woman expresses satisfaction with infant.	<p>Observe maternal-infant interactions.</p> <p>Encourage the woman to express her anxiety, fears, or other feelings.</p> <p>Encourage the woman to have as much contact with the infant as possible.</p> <p>Encourage family participation in care of infant.</p> <p>Demonstrate infant care and explain infant behaviors.</p> <p>Make referrals as needed to community resources.</p>	<p>To assess quality of interactions and to determine need for interventions</p> <p>To allow woman to ventilate her concerns and have them accepted</p> <p>To minimize separation and to promote attachment</p> <p>To promote attachment</p> <p>To enhance mother's care abilities and understanding of infant's abilities</p> <p>To assist the woman in developing parenting skills or promoting confidence in infant care</p>

! NURSING ALERT

Because mothers with PPD with psychotic features can harm their infants, extra caution is needed in assessment and intervention. The nurse needs to ask specifically if the mother has had thoughts about harming her baby.

Screening for Postpartum Depression

When PPD is identified early it is highly treatable. Screening for depression during pregnancy and the postpartum period aids in prevention and early intervention for depressive symptoms. There are no national guidelines for depression screening during pregnancy and after birth. The American College of Obstetricians and Gynecologists (ACOG) Committee on Obstetric Practice (2010) and the Agency for Healthcare Research and Quality (AHRQ, 2013) cite a lack of sufficient evidence to warrant firm recommendations for universal screening of postpartum women, although they recognize there are benefits to screening. The U.S. Preventive Services Task Force (USPSTF, 2009) recommends screening of adults for depression, including during pregnancy and the postpartum period.

Postpartum nurses can screen for PPD before women are discharged from the birth setting. Although this identifies some who are at risk, it is important that follow-up screening is also done. PPD is most likely to occur around 4 weeks after birth. Follow-up assessments for risks and signs of PPD can be done by primary care providers during pediatric care visits for the infant and during postpartum follow-up visits for the mother. The American Academy of Pediatrics (AAP) recommends maternal depression screening at the infant's 1-, 2-, and 4-month visits (Earls & AAP Committee on Psychosocial Aspects of Child and Family Health, 2010). Women with a positive screen should be referred appropriately for evaluation and treatment.

In perinatal populations the most widely used and validated tools are the Edinburgh Postnatal Depression Scale (EPDS) and the Postpartum Depression Screening Scale (PDSS). Both are brief, self-report questionnaires specifically developed for use with perinatal women, which take between 5 and 10 minutes to complete (Milgrom & Gemmill, 2014).

The EPDS tool asks the woman to respond to 10 statements about the common symptoms of depression. The woman is asked to choose the response that is closest to describing how she has felt for the past week. A maximum score on the EPDS is 30; women with scores of 12 or higher may possibly have depression and need further assessment. One item on the tool addresses suicidal thoughts; responses to this item should be carefully examined (Cox, Holden, & Sagovsky, 1987).

The PDSS is a 35-item Likert response scale that assesses for seven dimensions of depression: sleeping or eating disturbances, anxiety or insecurity, emotional lability, mental confusion, loss of self, guilt or shame, and suicidal thoughts (Beck, 2008a, 2008b; Myers, Aubuchon-Endsley, & Bastian, 2013). Both published tools are designed to be used by nurses and other health care professionals to elicit information from the woman during an interview to assess risk. Areas assessed include the predictors of depression as listed in Box 31-3.

In addition, a simple two-item tool has been shown to be effective in identifying women at risk for PPD. If the woman

answers yes to either of the two questions, the screen is considered to be positive. The questions are as follows: "Over the past 2 weeks have you ever felt down, depressed, or hopeless?" and "Over the past 2 weeks have you felt little interest or pleasure in doing things?" (Earls & AAP Committee on Psychosocial Aspects of Child and Family Health, 2010).

If PPD screening results are positive or if the woman's self-report shows signs that she might be depressed, a formal screening is needed to determine the urgency of the referral and the type of provider. Also important is the need to assess the woman's family because they may be able to offer valuable information, as well as need to express how they have been affected by the woman's emotional disorder.

Interventions**Nursing Care on the Postpartum Unit**

The postpartum nurse observes the new mother carefully for any signs of tearfulness and conducts further assessments as necessary. Nurses must discuss PPD to prepare new parents for potential problems in the postpartum period and discuss ways to help prevent PPD (see Teaching for Self-Management: Preventing Postpartum Depression and Chapters 21 and 22). The family must be able to recognize the symptoms and know where to go for help. Printed materials that explain what the woman can do to prevent depression can be used as part of discharge education (Logsdon, Tomasulo, Eckert, et al., 2012).

TEACHING FOR SELF-MANAGEMENT**Preventing Postpartum Depression**

- Share knowledge about postpartum emotional problems with close family and friends.
- At least once each day or every other day, purposely relax for 15 minutes: deep breathing, meditating, taking a hot bath.
- Take care of yourself: eat a balanced diet.
- Exercise on a regular basis, at least 30 minutes a day.
- Sleep as much as possible; make a promise to yourself to try to sleep when the baby sleeps.
- Get out of the house: try to leave home for 30 minutes a day; take a walk outdoors or walk at the mall.
- Share your feelings with someone close to you; don't isolate yourself at home with the TV.
- Don't overcommit yourself or feel like you need to be a superwoman. Ask for help from family and friends.
- Don't place unrealistic expectations on yourself; no mother is perfect!
- Be flexible with your daily activities.
- Go to a new mothers' support group: for example, take a postpartum exercise class or attend a breastfeeding support group.
- Don't be ashamed of having emotional problems after your baby is born. It happens to approximately 15% of women.

Women are often discharged before the blues or depression occurs. If the postpartum nurse is concerned about the mother, a mental health consult should be requested before the mother leaves the hospital. Routine instructions regarding PPD should be given to the person who comes to take the woman home; for example, "If you notice that your wife [or partner] is upset or crying a lot, please call the postpartum care provider

immediately—don't wait for the routine postpartum appointment.” (See Teaching for Self-Management: Signs of Postpartum Blues, Depression, and Psychosis.)

TEACHING FOR SELF-MANAGEMENT

Signs of Postpartum Blues, Depression, and Psychosis

- Baby blues (these should go away in a few days or a week):
 - Sad, anxious, or overwhelmed feelings
 - Crying spells
 - Loss of appetite
 - Difficulty sleeping
- Postpartum depression (can begin any time in the first year):
 - Same signs as baby blues, but they last longer and are more severe
 - Thoughts of harming yourself or your baby
 - Not having any interest in the baby
- Postpartum psychosis:
 - Seeing or hearing things that are not there
 - Feelings of confusion
 - Rapid mood swings
 - Trying to hurt yourself or your baby
- When to call your health care provider:
 - The baby blues continue for more than 2 weeks
 - Symptoms of depression get worse
 - Difficulty performing tasks at home or at work
 - Inability to care for yourself or your baby
 - Thoughts of harming yourself or your baby

Data from U.S. Department of Health and Human Services Office of Women's Health. (2009). *Depression during and after pregnancy*. Available at www.womenshealth.gov/publications/our-publications/fact-sheet/depression-pregnancy.pdf.

Nursing Care in the Home and Community

Postpartum home visits can reduce the incidence of or complications from depression. A brief home visit or phone call at least once a week until the new mother returns for her postpartum visit may save the life of a mother and her infant; however, home visits may not be feasible or available. Supervision of the mother with emotional complications can become a prime concern. Because depression can greatly interfere with her mothering functions, family and friends may need to participate in the infant's care. This is a time for the extended family and friends to determine what they can do to help; the nurse can work with them to ensure adequate supervision and their understanding of the woman's mental illness.

When the woman has PPD, a partner often reacts with confusion, shock, denial, and anger and feels neglected and blamed. The nurse can provide nonjudgmental opportunities for the partner to verbalize feelings and concerns, help the partner identify positive coping strategies, and be a source of encouragement for the partner to continue supporting the woman. Suggestions for partners of women with PPD include helping around the house, setting limits with family and friends, going with her to appointments with the health care provider, educating himself or herself, writing down concerns and questions to take to the primary care provider or therapist, and just being with her—sitting quietly, hugging her, and demonstrating concern and compassion. Both the woman and her partner need an opportunity to express their needs, fears, thoughts, and feelings in a nonjudgmental environment.

Even if the woman is severely depressed, hospitalization can be avoided if adequate resources can be mobilized to ensure

safety for mother and infant. The nurse in home health care needs to make frequent phone calls or home visits for assessment and counseling. Community resources that may be helpful are temporary child care or foster care, homemaker service, Meals on Wheels, parenting guidance centers, mother's-day-out programs, and telephone support groups such as Postpartum Support International (<http://postpartum.net>) and Depression After Delivery (www.depressionafterdelivery.com).

Referral

Women with moderate to severe cases of PPD should be referred to a mental health professional such as a psychiatric nurse practitioner or psychiatrist for evaluation and therapy. Inpatient psychiatric hospitalization may be necessary. This decision is made when the safety of the mother or children is threatened.

Providing Safety

If delusional thinking about the baby is suspected, the nurse asks, “Have you thought about hurting your baby?” When depression is suspected, the nurse asks, “Have you thought about hurting yourself?” Four criteria can be used to measure the seriousness of a suicidal plan: method, availability, specificity, and lethality. Has the woman specified a method? Is the method of choice available? How specific is the plan? If the method is concrete and detailed, with access to carry it out at hand, the suicide risk increases. How lethal is the method? The most lethal method is shooting, with hanging a close second. The least lethal is slashing one's wrists.

! NURSING ALERT

Suicidal thoughts or attempts are among the most serious symptoms of PPD and require immediate assessment and intervention.

Psychiatric Hospitalization

Women with postpartum psychosis have a psychiatric emergency and must be referred immediately to a psychiatric health care provider who is experienced in working with women with PPD, can prescribe medication and other forms of therapy, and can assess the need for hospitalization.

LEGAL TIP: Commitment for Psychiatric Care

If a woman with PPD is experiencing active suicidal ideation or harmful delusions about the baby and is unwilling to seek treatment, legal intervention may be necessary to commit the woman to an inpatient setting for treatment.

If allowed within the inpatient psychiatric setting, the reintroduction of the baby to the mother can occur at the mother's own pace. A schedule is set for increasing the number of hours the mother cares for the baby over several days, culminating in the infant's staying overnight in the mother's room. This method allows the mother to experience meeting the infant's needs and giving up sleep for the baby, a situation difficult for new mothers even under ideal conditions. The mother's readiness for discharge and caring for the baby is assessed. Her

interactions with her baby are carefully supervised and guided. A postpartum nurse is often asked to assist the psychiatric nursing staff in assessment of the mother–infant interactions.

Nurses should observe the mother for signs of bonding with the baby. Attachment behaviors are defined as eye-to-eye contact; physical contact that involves holding, touching, cuddling, and talking to the baby and calling the baby by name; and the initiation of appropriate care. A staff member is assigned to observe the baby at all times. Praise and encouragement are used to bolster the mother’s self-esteem and self-confidence.

Psychotropic Medications

If the woman with PPD is not breastfeeding, in most cases antidepressants can be prescribed without special precautions. A variety of medications can be prescribed for these women, including TCAs, SSRIs, SNRIs, MAOIs, mood stabilizers, and antipsychotic medications.
