ELSEVIER

UNIT ONE Introduction to Maternity & Women's Health Care

- 1 21st Century Maternity and Women's Health Nursing, 1
- 2 Community Care: The Family and Culture, 17
- 3 Nursing and Genomics, 41

UNIT TWO Women's Health

- 4 Assessment and Health Promotion, 59
- 5 Violence Against Women, 97
- 6 Reproductive System Concerns, 120
- 7 Sexually Transmitted and Other Infections, 145
- 8 Contraception and Abortion, 171
- 9 Infertility, 197
- 10 Problems of the Breast, 211
- 11 Structural Disorders and Neoplasms of the Reproductive System, 234

UNIT THREE Pregnancy

- 12 Conception and Fetal Development, 265
- 13 Anatomy and Physiology of Pregnancy, 283
- 14 Nursing Care of the Family During Pregnancy, 301
- 15 Maternal and Fetal Nutrition, 344

UNIT FOUR Childbirth

- 16 Labor and Birth Processes, 367
- 17 Maximizing Comfort for the Laboring Woman, 381
- 18 Fetal Assessment During Labor, 410
- 19 Nursing Care of the Family During Labor and Birth, 430

UNIT FIVE Postpartum

- 20 Postpartum Physiologic Changes, 473
- 21 Nursing Care of the Family During the Postpartum Period, 481
- 22 Transition to Parenthood, 502

UNIT SIX The Newborn

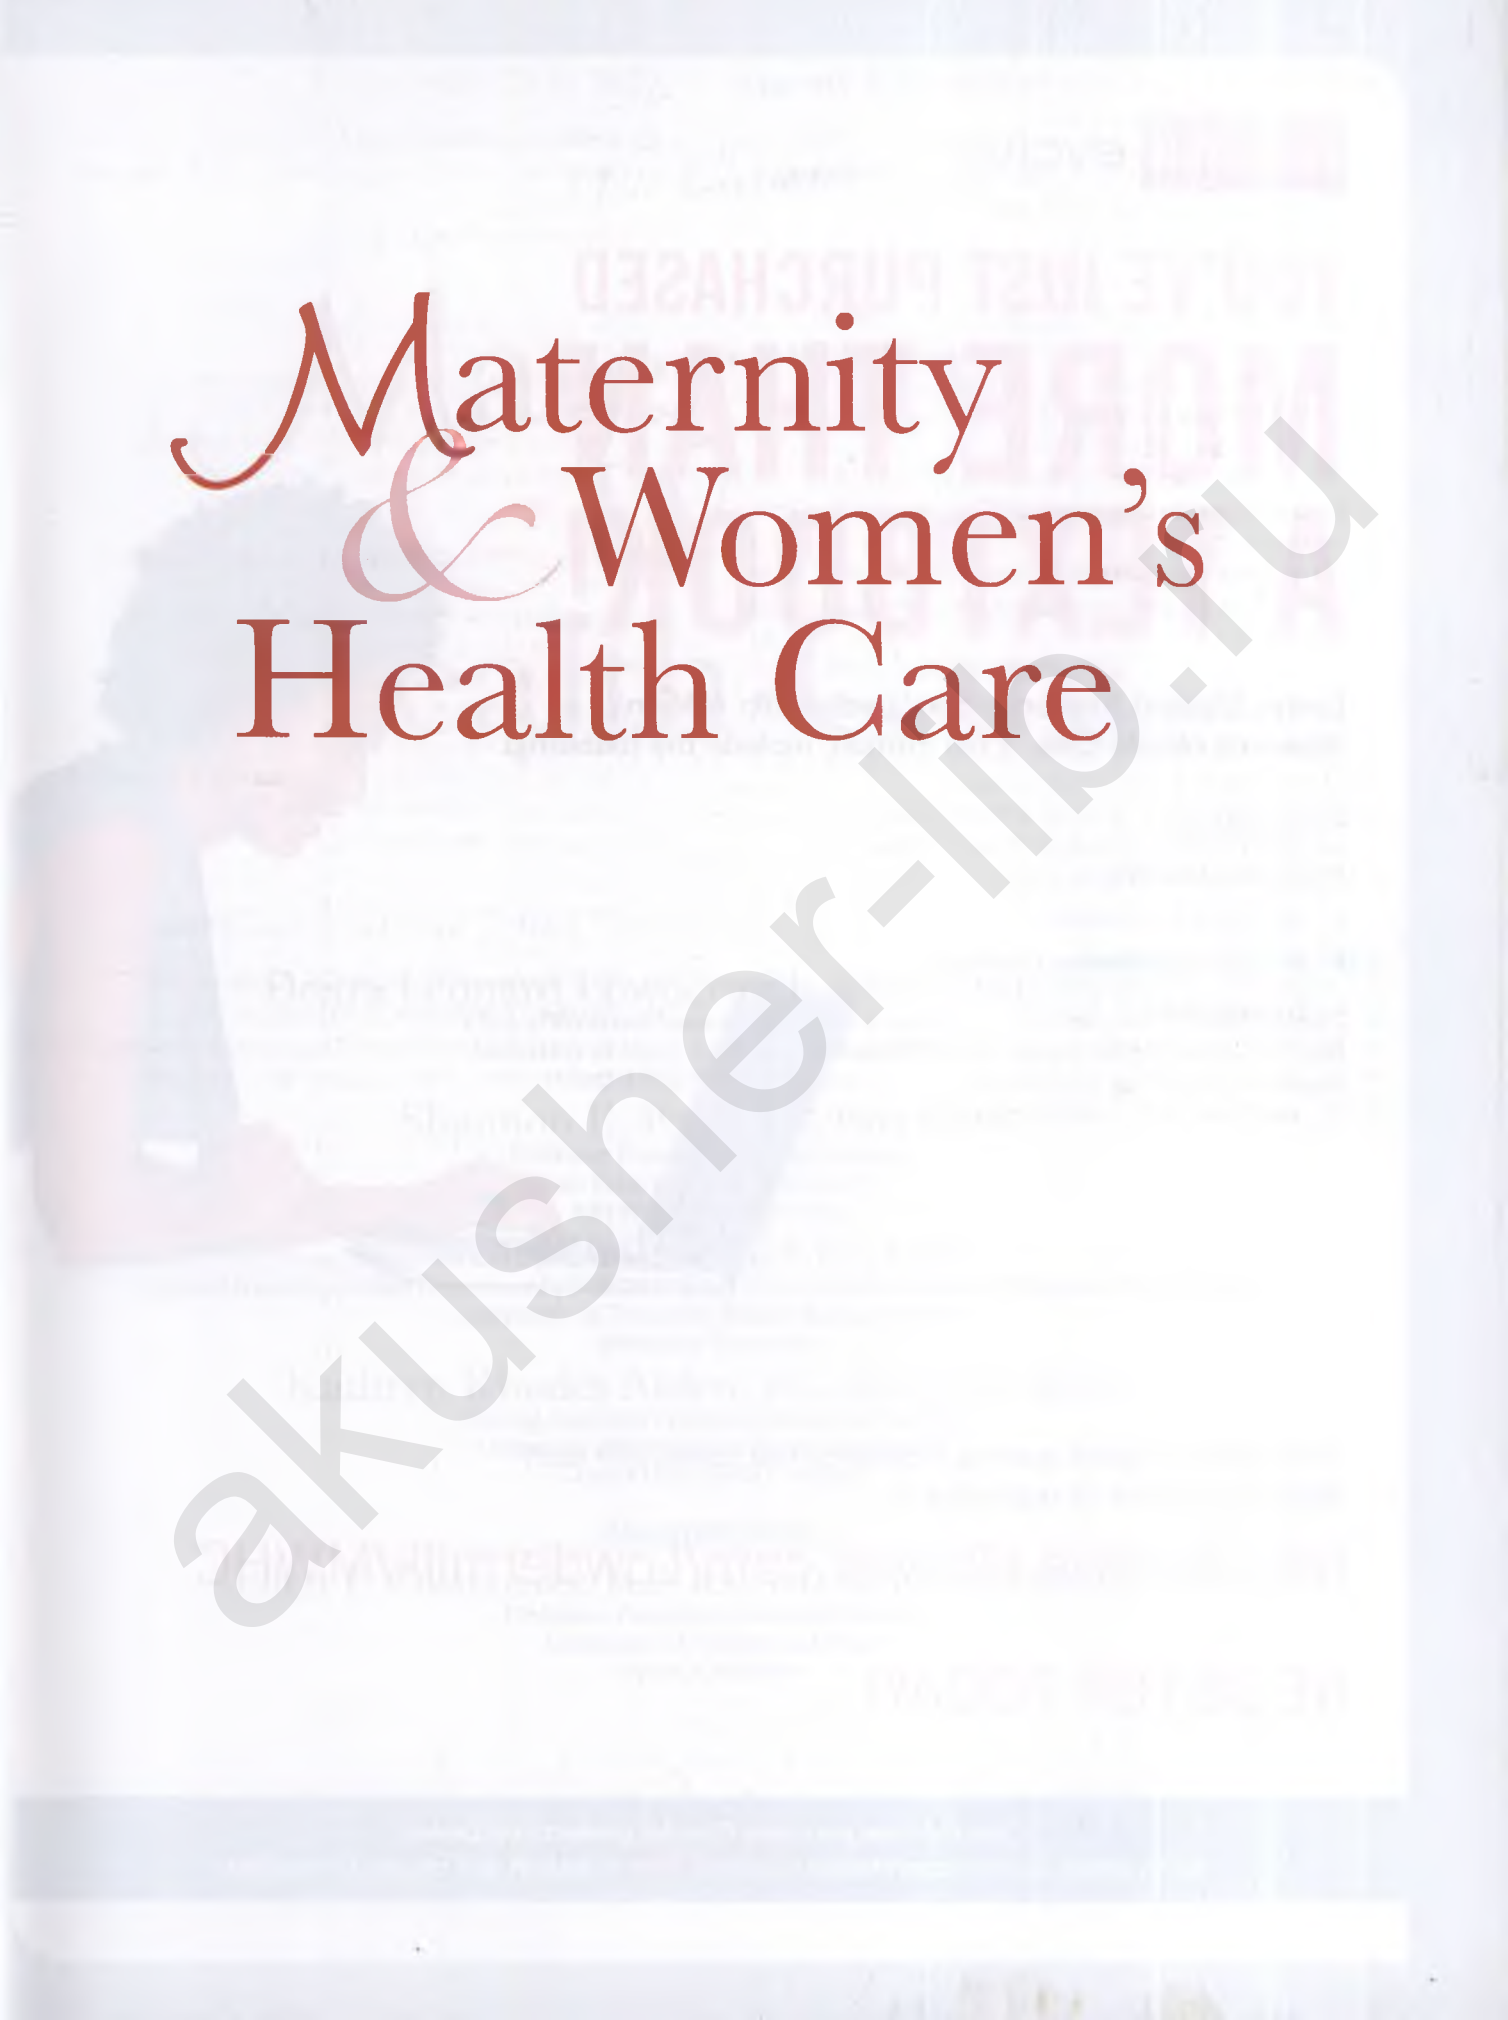

- 23 Physiologic and Behavioral Adaptations of the Newborn, 523
- 24 Nursing Care of the Newborn and Family, 549
- 25 Newborn Nutrition and Feeding, 601

UNIT SEVEN Complications of Pregnancy

- 26 Assessment of High Risk Pregnancy, 633
- 27 Hypertensive Disorders, 653
- 28 Hemorrhagic Disorders, 669
- 29 Endocrine and Metabolic Disorders, 687
- 30 Medical-Surgical Disorders, 710
- 31 Mental Health Disorders and Substance Abuse, 739
- 32 Labor and Birth Complications, 759
- 33 Postpartum Complications, 802

UNIT EIGHT Newborn Complications

- 34 Nursing Care of the High Risk Newborn, 816
- 35 Acquired Problems of the Newborn, 851
- 36 Hemolytic Disorders and Congenital Anomalies, 881
- 37 Perinatal Loss, Bereavement, and Grief, 909

A woman with dark hair, wearing a dark sleeveless top, is sitting at a desk and reading a book. The background is a light-colored wall with some faint text. The overall image is slightly faded and has a watermark.

Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary. Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

ABOUT THE AUTHORS

DEITRA LEONARD LOWDERMILK

Deitra Leonard Lowdermilk is Clinical Professor Emerita, School of Nursing, University of North Carolina at Chapel Hill. She received her BSN from East Carolina University and her MEd and PhD in Education from UNC-CH. She is certified in In-Patient Obstetrics by the National Certification Corporation. She is a fellow in the American Academy of Nursing. In addition to being a nurse educator for more than 34 years, Dr. Lowdermilk has clinical experience as a public health nurse and as a staff nurse in labor and delivery, postpartum, and newborn units, and has worked in gynecologic surgery and cancer care units.

Dr. Lowdermilk has been recognized for her expertise in nursing education. She has repeatedly been selected as Classroom and Clinical Teacher of the Year by graduating seniors. She was a recipient of the Educator of the Year Award from both the District IV Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) and the North Carolina Nurses Association. She also received the 2005 AWHONN Excellence in Education Award.

She is active in AWHONN, having served as chair of the North Carolina Section of AWHONN and has served as chair and member of various committees in AWHONN at the national, district, state, and local levels. She has served as guest editor for the *Journal of Obstetric, Gynecologic and Neonatal Nursing* and served on editorial boards for other publications. Dr. Lowdermilk also is coauthor of

Maternity Nursing (8th edition) and *Maternal Child Nursing Care* (5th edition).

Dr. Lowdermilk's most significant contribution to nursing has been to promote excellence in nursing practice and education in women's health through integration of knowledge into practice. In 2005 she received the first Distinguished Alumni Award from East Carolina University School of Nursing for her exemplary contributions to the nursing profession in the area of maternal-child care and the community. She was also Alumna of the Year for East Carolina University in 2005, and was selected as one of the 100 Incredible ECU Women in 2007 for Outstanding Leadership Among Women in the first 100 years of the university's founding.

In fall 2010, the East Carolina University College of Nursing named the Neonatal Intensive Care and Midwifery Laboratory in honor of Dr. Lowdermilk. In 2011 she was named one of the first 40 nurses inducted into the College of Nursing Hall of Fame.

SHANNON E. PERRY

Shannon E. Perry is Professor Emerita, School of Nursing, San Francisco State University, San Francisco, California. She received her diploma in nursing from St. Joseph Hospital School of Nursing, Bloomington, Illinois; a baccalaureate in Nursing from Marquette University, an MSN from the University of Colorado Medical Center, and a PhD in Educational Psychology with a Specialization in Child Development from Arizona State

University. She completed a 2-year postdoctoral fellowship in perinatal nursing at the University of California, San Francisco, as a Robert Wood Johnson Clinical Nurse Scholar.

Dr. Perry has had clinical experience as a staff nurse, head nurse, and supervisor in surgical nursing, obstetrics, pediatrics, gynecology, and neonatal nursing. She has served as an expert witness and legal consultant. She has taught in schools of nursing in several states for more than 30 years and was interim director and director of the School of Nursing and director of a Child and Adolescent Development baccalaureate program at SFSU. She was Marquette University College of Nursing Alumna of the Year in 1999, and was the University of Colorado School of Nursing Distinguished Alumna of the Year in 2000. She received the San Francisco State University Alumni Association Emeritus Faculty Award in 2005 and the Excellence in Education Award from the Beta Upsilon chapter of Sigma Theta Tau International (STTI) in 2012.

She is coauthor of *Maternity Nursing* (8th edition), *Maternal Child Nursing Care* (5th edition), and *Clinical Companion for Maternity & Newborn Nursing* (2nd edition) and has authored numerous chapters and articles on maternal-newborn topics and the legal aspects of nursing. She is a fellow in the American Academy of Nursing, a member of AWHONN, Arizona Nurses Association (AzNA), and National League for Nursing (NLN), first vice president of the American Association for the History of Nursing (AAHN), and a member of the AAHN Communications Committee and the STTI Foundation Fellows Committee. Dr. Perry's experience in international nursing includes teaching international nursing courses in the United Kingdom, Ireland, Italy, Thailand, Ghana, and China and participating in health missions in Ghana, Kenya, and Honduras. She is participating in establishing a school of nursing in Kenya, has supported the establishment of the library, and has had a wing of a dormitory named after her. For her "exemplary contributions to nursing, public service, and selfless commitment and passion in shaping the future of international health," she received the President's Award from the Global Caring Nurses Foundation, Inc., in 2008. In January 2012, she and 47 other women climbed Mt. Kilimanjaro, the highest mountain in Africa, to raise awareness of human trafficking and to raise funds to support projects to combat human trafficking.

KITTY CASHION

Kitty Cashion is a Clinical Nurse Specialist in the Maternal-Fetal Medicine Division, College of Medicine, Department of Obstetrics and Gynecology at the University of Tennessee Health Science Center in Memphis. She received her BSN from the University of Tennessee College of Nursing in Memphis and her MSN in Parent-Child Nursing from Vanderbilt University School of Nursing in Nashville, Tennessee. Ms. Cashion is certified as a high risk perinatal nurse through the American Nurses Credentialing Center (ANCC).

Ms. Cashion's job responsibilities at the University of Tennessee include providing education regarding low and high risk obstetrics to staff nurses in West Tennessee community hospitals. For more than 20 years Ms. Cashion has taught obstetric nursing in the clinical setting (mostly in Labor and Delivery) for students at Northwest Mississippi Community College in Senatobia, Mississippi, and Union University in Germantown, Tennessee.

Ms. Cashion has been an active AWHONN member, holding office at both the local and state levels. She also has served as an officer and board member of the Tennessee Perinatal Association and as an active volunteer for the Tennessee chapter, March of Dimes Birth Defects Foundation.

Ms. Cashion has contributed many chapters to maternity nursing textbooks over the years. She also coauthored a series of Virtual Clinical Excursions workbooks to accompany six obstetric nursing textbooks published by Elsevier. More recently she served as one of the authors for *Maternity & Women's Health Care* (10th edition), and *Clinical Companion for Maternity & Newborn Nursing* (2nd edition), and as an associate editor for *Maternal Child Nursing Care* (5th edition).

KATHRYN RHODES ALDEN

Kathryn Rhodes Alden is Clinical Associate Professor, University of North Carolina at Chapel Hill School of Nursing. She received a BSN from the University of North Carolina at Charlotte, an MSN from the University of North Carolina at Chapel Hill, and a doctorate in adult education from North Carolina State University.

Dr. Alden has extensive experience as a nursing educator, having served on the faculty at the University of North Carolina at Charlotte and the University of North Carolina at Chapel Hill. Dr. Alden has clinical experience in pediatrics, pediatric intensive care, and neonatal intensive care. She is also experienced in home health care, having provided nursing care to pediatric and obstetric clients. She has worked as a nursing administrator and coordinator of quality improvement. As a certified lactation consultant, Dr. Alden has provided inpatient and outpatient care for breastfeeding mothers and infants and she has taught prenatal breastfeeding classes to expectant parents. She has taught continuing education courses on breastfeeding throughout North Carolina.

For the past 25 years as an educator for baccalaureate nursing students at UNC-Chapel Hill School of Nursing, Dr. Alden has taught in maternal-newborn nursing courses, providing both classroom and clinical instruction. Dr. Alden coordinates and leads the academic counseling program, providing assistance to students and to faculty. She is actively involved in the leadership of the undergraduate nursing program as member and former chair of the Baccalaureate Executive Committee.

She has received numerous awards for excellence in nursing education at UNC, being recognized for clinical and classroom teaching expertise as well as for academic counseling. Dr. Alden was selected for the Great 100 Nurses in North Carolina in 2008.

Dr. Alden was an early adopter of high-fidelity simulation and has been instrumental in the use of this instructional strategy at UNC-Chapel Hill School of Nursing. She is actively involved in interprofessional collaboration with faculty from the UNC schools of Medicine and Pharmacy to offer obstetric and neonatal simulation learning activities to undergraduate nursing students, pharmacy students, and medical students in obstetrics and pediatrics. She has created numerous simulation scenarios including obstetric simulation cases for Elsevier. She has coauthored chapters on high-fidelity simulation and patient safety in publications by the Agency for Healthcare Research and Quality (AHRQ) and the NLN. Dr. Alden is an active member of AWHONN and the International Nursing Association for Clinical Simulation and Learning (INACSL).

Dr. Alden has authored numerous chapters on a variety of topics in maternity texts for Elsevier. She is associate editor for *Maternal Child Nursing Care* (5th edition) and *Maternity Nursing* (8th edition).

ELLEN F. OLSHANSKY

Ellen F. Olshansky is Professor in the Program in Nursing Science at the University of California, Irvine, and served as its founding director from 2007 to 2014. Under her leadership UC-Irvine initiated the BSN program, followed by the approval and initiation of both the MS and PhD degrees in nursing

science. She is the founder of the UCI Nursing Science Center for the Advancement of Women's Health.

Dr. Olshansky earned a BA in Social Work from the University of California, Berkeley, and a BS, MS, and PhD from the University of California, San Francisco School of Nursing. She was a faculty member at the schools of nursing at the Oregon Health Sciences University, University of Washington, Duquesne University, and the University of Pittsburgh before taking her current position at the UC-Irvine. She is a fellow in the American Academy of Nursing, served as co-chair of its Expert Panel on Women's Health, and is a member of its Board of Directors. She is also a fellow in the Western Academy of Nursing.

Dr. Olshansky also serves as director of the Community Engagement Unit of the

UC-Irvine Institute for Clinical and Translational Science, funded by a National Institutes of Health (NIH) Clinical Translational Science Award. Through this position she engages community members in community-based participatory research, encouraging collaborative research between university faculty and community organizations. She has expertise in qualitative research and community-based participatory research.

Dr. Olshansky is a women's health nurse practitioner, certified through the National Certification Corporation (WHNP-BC). Her research has focused on women's health across the life span, with a focus on reproductive health. Dr. Olshansky recently became a certified Integrative Nurse Wellness Coach, having completed the Integrative Nurse Coach Certification Program through the International Nurse Coach Association and

successfully completing the certification exam through the American Holistic Nurses Credentialing Corporation (NC-BC). She is focused on working with people within their own communities to promote and maintain wellness. She is one of the founders of the Orange County Women's Health Project, which works in collaboration with the UCI Nursing Science Center for the Advancement of Women's Health. The purpose is to promote women's health and wellness in Orange County, California, including holding annual women's health policy summits.

She recently completed a 10-year term as editor of the *Journal of Professional Nursing*, the official journal of the American Association of Colleges of Nursing. She has published extensively in numerous nursing and other health-related journals as well as authored many book chapters and editorials.

PREFACE

Women's health care encompasses reproductive health care and the unique physical, psychologic, and social needs of women throughout their life span. The specialties of women's health and maternity nursing offer challenges and opportunities. Nurses are challenged to assimilate knowledge and develop the technical and critical thinking skills needed to be reflective practitioners. Each woman, with her individual needs that must be identified and met, presents a challenge. However, the opportunities are sufficiently extraordinary to make this one of the most fulfilling specialties of nursing practice.

The goal of nursing education is to prepare today's students to meet the challenges of tomorrow. This preparation must extend beyond mastery of facts and skills. Nurses must be able to provide safe, quality, client-centered care through the combination of clinical reasoning skills, technical competence, and compassionate caring. They must address the physiologic as well as the psychosocial needs of their clients. They must look beyond the condition and see the woman as an individual with distinctive needs. Yet they must consider her needs in the context of family-centered care, realizing and acknowledging the influence and involvement of family members and significant others. Above all, nurses must strive to improve practice on the basis of sound evidence-based information. In a time of dwindling financial resources for health care, nurses can use evidence-based practice to produce measurable outcomes that can validate their unique and necessary role in the health care delivery system.

Maternity & Women's Health Care was designed to provide students with accurate and up-to-date information so that they can develop the knowledge and skills needed to become clinically competent, to think critically, and to attain the necessary sensitivity to become caring nurses. *Maternity & Women's Health Care* has been a leading maternity nursing text since it was first published in 1977. We are proud of the continued support this text has received. With this eleventh edition we have a responsibility to continue this leading tradition.

This edition has been revised and refined in response to comments and suggestions from educators, clinicians, and students. It includes the most accurate, current, and clinically relevant information available. We have had the assistance of expert faculty, nurse clinicians, and specialists from other health disciplines who authored, reviewed, and revised the text. Many exciting updates and additions will be noted throughout the book; they demonstrate the various dimensions of women's health care and areas of rapid and complex changes such as genetics, fetal assessment, and alternative therapies. However, we have retained the underlying philosophy that has been the strength of previous editions: our belief that pregnancy and childbirth and developmental changes in a woman's life are natural processes. We have also retained a base in physiology and a strong, integrated focus on the family and on evidence-based practice.

The text is also used as a reference for the practicing nurse. The most recent recommendations based on evidence from research and clinical experts have been included from

professional organizations such as the Association of Women's Health, Obstetric and Neonatal Nurses; the National Association of Neonatal Nurses; the American College of Obstetricians and Gynecologists; the American Academy of Pediatrics; the American Diabetes Association; the Centers for Disease Control and Prevention; and the U.S. Preventive Health Services Task Force. The text can be used to prepare for certification courses and for review in graduate programs of study. The text and its electronic resources would be an excellent reference on the nursing unit.

Approach

Professional nursing practice continues to evolve and adapt to society's changing health priorities. The ever-changing health care delivery system offers new opportunities for nurses to alter the practice of maternity and women's health nursing and to improve the way care is given. Consumers of maternity and women's health care vary in age, ethnicity, culture, language, social status, marital status, sexual preference, and family configurations. They seek care from obstetricians, gynecologists, family practice physicians, nurse-midwives, nurse practitioners, nurses, and other health care providers in a variety of health care settings, including the home. Increasingly, many are self-treating, accessing web-based information, and using a variety of alternative and complementary therapies.

Nursing education must reflect these changes. Clinical education must be planned to offer students a variety of maternity and women's health care experiences in settings that include hospitals and birth centers, the home health setting, clinics and private physician offices, shelters for the homeless or women in need of protection, in prisons, and in other community-based settings. Advances in nursing education include the increased use of simulation learning activities. Simulation laboratories have emerged in schools of nursing and in health care institutions to provide students and staff with opportunities to engage in care of clients in focused, challenging situations while in the safety of a controlled environment. Simulation experiences offer students in maternity and women's health courses opportunities that are otherwise unavailable due to shrinking opportunities for clinical placements, decreased clinical time, and increased numbers of students in clinical rotations.

Today's nursing students are challenged to learn more than ever and often in less time than their predecessors. Students are diverse. They may be new high school graduates, college students, or older adults with families. They may be male or female. They may have college degrees in other fields and be interested in changing careers. They may represent various cultures; English may not be their first language. Students may be enrolled in associate degree or diploma programs, in baccalaureate or accelerated baccalaureate nursing programs, or in entry level master's programs. This eleventh edition, with its accompanying teaching and learning package, has been revised to meet these changing needs. Each chapter has been reviewed by a

specialist to improve readability and comprehension, especially by a diverse student population. Focused content is presented in a clearly written and easily read manner while retaining the comprehensiveness of previous editions. The text can be used by all levels of nursing education, and in courses of varying lengths.

Health care today emphasizes *wellness* and *health promotion*. This focus is an integral part of our philosophy. Likewise the developmental changes a woman experiences throughout her life are considered natural and normal. In women's health care, the goal is promotion of wellness for the woman through knowledge of her body and its normal functioning throughout her life span, while developing an awareness of conditions that require professional intervention. The unit on women's health care emphasizes the wellness aspect of care but also includes information about common gynecologic problems as well as breast and gynecologic cancers. This unit has been placed before the units on pregnancy because many of the aspects of assessment and care can be applied to later chapters.

Pregnancy and birth are also part of a natural developmental process. We believe that students need to thoroughly understand and recognize the normal processes before they can identify complications and comprehend their implications for care. We present the entire normal childbearing cycle before discussing potential complications.

In this edition of *Maternity & Women's Health Care*, there is expanded and enhanced content related to the risks associated with obesity as it relates to women's health, pregnancy, and neonatal outcomes. In relevant chapters throughout the book, this content is addressed, based on the most current evidence-based information from the medical and nursing literature.

Readers will note that throughout the text, the authors use different terms to describe various racial and ethnic groups. Whenever statistical data are described, the terms in the reference are used, for instance, non-Hispanic black, non-Hispanic white, and Hispanic. When discussing individual clients or population groups and their health beliefs, the more commonly used terms are used, for instance, Latina or Hispanic, Caucasian, African-American, and Asian.

Features

The eleventh edition features a contemporary design and spacious presentation. Students will find that the logical, easy-to-follow headings and attractive full-color design highlight important content and increase visual appeal. More than 450 color photographs (many of them new) and drawings throughout the text illustrate important concepts and techniques to further enhance comprehension. Each chapter begins with a list of *Learning Objectives* designed to focus students' attention on the important content to be mastered. *Key Terms* that alert students to new vocabulary are in blue, defined within the chapter, and included in a glossary at the end of the book. Each chapter ends with *Key Points* that summarize important content. *Community Activity* exercises are included in most chapters to provide opportunities for students to increase their knowledge of community resources. *Clinical Reasoning* case studies are integrated to guide students in applying their knowledge and increasing their ability to think and reflect critically about maternity and women's health care issues.

References have been updated significantly, with most citations being less than 5 years old and all chapters having citations within 1 year of publication. An expanded Table of Contents and Index make it easier for readers to locate exactly the information they are seeking. More of the additional outstanding features follow:

- **Care Management** is used as the consistent framework throughout nursing care chapters to discuss assessment, medical and surgical management, and more specifically, the nursing care related to each topic.
- **Nursing Care Plans** help students apply the nursing process in the clinical setting and use NANDA-approved nursing diagnoses, describe expected outcomes for client care, provide rationales for interventions, and include evaluation of care.
- **Teaching for Self-Management** boxes emphasize guidelines for the client to practice self-care and provide information to help students transfer learning from the hospital to the home setting.
- **Emergency** boxes alert students to the signs and symptoms of various emergency situations and provide interventions for immediate implementation.
- **Signs of Potential Complications** boxes alert students to signs and symptoms of potential problems and are included in chapters that cover uncomplicated pregnancy and birth.
- **Nursing Alert** and **Safety Alert** boxes and new **Medication Alert** boxes highlight critical information.
- **Evidence-Based Practice** is incorporated throughout in new boxes that integrate findings from several studies on selected clinical practices and changing practice; Quality and Safety Education for Nursing (QSEN) competencies are illustrated in these boxes. In addition, research findings summarized in *The Cochrane Pregnancy and Childbirth Database* and other resources for evidence-based practices that confirm effective practices or identify practices that have unknown, ineffective, or harmful effects are integrated throughout the text.
- **Cultural Considerations** boxes describe beliefs and practices about pregnancy, childbirth, parenting, and women's health concerns and the importance of understanding cultural variations when providing care.
- **Legal Tips** are integrated throughout to provide students with relevant information to deal with these important areas in the context of maternity and women's health nursing.
- **Medication Guide** boxes include key information about medications used in maternity and women's health care, including their indications, adverse effects, and nursing considerations.

Organization

The eleventh edition of *Maternity & Women's Health Care* comprises eight units organized to enhance understanding and learning and to facilitate easy retrieval of information.

Unit One, Introduction to Maternity & Women's Health Care, begins with an overview of contemporary issues in maternity and women's health nursing practice. Chapter 1 includes a section on historic milestones in maternity, women's health, and neonatal care and provides an overview of important therapies that can be used instead of or in addition to traditional techniques used in maternity and women's health care. Chapter

2 addresses the community as a unit of care, incorporating family theory, cultural aspects of care, and home care in relation to maternity and women's health nursing. Chapter 3 provides essential discussion about genetics in relation to maternity and women's health care.

Unit Two, Women's Health, is a thoroughly revised unit on women's health. Eight chapters discuss health promotion, screening, and physical assessment, and then present common reproductive concerns. The chapter on assessment and health promotion incorporates normal anatomy and physiology of the female reproductive system and integrates health promotion for common women's health problems. There are separate chapters on reproductive problems and concerns, sexually transmitted infections and other infections, contraception and abortion, infertility, violence, problems of the breast, and structural disorders and neoplasms of the female reproductive system.

Unit Three, Pregnancy, describes nursing care of the woman and her family from conception through preparation for birth. Nursing care during pregnancy includes both physiologic and psychologic aspects of care, as well as information on preparation for birth. A separate chapter on maternal and fetal nutrition emphasizes the important aspects of care, highlights cultural variations in diet, and stresses the importance of early recognition and management of nutritional problems.

Unit Four, Childbirth, focuses on collaborative care among physicians, nurse-midwives, nurses, and women and their families during the processes of labor and birth. Separate chapters deal with the nurse's role in maximizing comfort during labor and birth, and fetal monitoring, both of which have been updated significantly. All four chapters familiarize students with current childbirth practices and focus on evidence-based interventions to support and educate the woman and her family.

Unit Five, Postpartum, deals with a time of profound change for the entire family. Physiologic changes and nursing care based on the changes are addressed. The mother requires both physical and emotional support as she adjusts to her new role. The chapter on transition to parenthood discusses family dynamics in response to the birth of a child and describes ways nurses can facilitate parent-infant adjustment. Anticipatory guidance for the first few weeks at home and home follow-up care are addressed.

Unit Six, The Newborn, has been updated and addresses physiologic adaptations of the newborn and assessment and care of the newborn. Information on the nutritional needs of the newborn and nursing care associated with breastfeeding and formula feeding are highlighted in a separate chapter.

Unit Seven, Complications of Pregnancy, discusses conditions that place the woman, fetus, infant, and family at risk. This unit has been revised and updated and includes a chapter on assessment of the high risk pregnancy and eight other chapters covering specific pregnancy complications including hypertensive disorders, antepartum hemorrhagic disorders, endocrine and metabolic problems, medical-surgical problems, mental health problems and substance abuse, labor and birth complications, and postpartum complications. Care management focuses on achieving the best possible outcomes, as well as supporting the woman and family when expectations are not met.

Unit Eight, Newborn Complications, describes the nursing care for high risk newborns, emphasizing the care of the

preterm infant. There is enhanced content on care of late preterm infants in this edition. It addresses the most common acquired conditions of the neonate as well as hematologic disorders and congenital anomalies. All chapters have been revised and updated. A separate chapter on loss and grief discusses care of the family experiencing a fetal or neonatal loss.

Teaching/Learning Package

Evolve, for Students: Evolve is an innovative website that provides a wealth of content, resources, and state-of-the-art information on maternity nursing. Learning resources for students include Case Studies, Content Updates, Printable Key Points, Nursing Skills, and NCLEX-Style Review Questions.

Simulation Learning System (SLS): The SLS is an online toolkit that helps instructors and facilitators effectively incorporate medium- to high-fidelity simulation into their nursing curriculum. Detailed patient scenarios promote and enhance the clinical decision-making skills of students at all levels. The SLS provides detailed instructions for preparation and implementation of the simulation experience, debriefing questions that encourage critical thinking, and learning resources to reinforce student comprehension. Each scenario in the SLS complements the textbook content and helps bridge the gap between lectures and clinical practice. The SLS provides the perfect environment for students to practice what they are learning in the text for a true-to-life, hands-on learning experience.

Study Guide: This comprehensive and challenging study aid presents a variety of questions to enhance learning of key concepts and content from the text. Multiple-choice and matching questions are included, as well as Critical Thinking Case Studies. Answers for all questions are included at the back of the study guide.

Virtual Clinical Excursions: Virtual Hospital and Workbook Companion: A Virtual Hospital and workbook package has been developed as a clinical experience to expand student opportunities for critical thinking. This package guides the student through a virtual clinical environment and helps the user apply textbook content to virtual clients in that environment. Case studies are presented that allow students to use this textbook as a reference to assess, diagnose, plan, implement, and evaluate "real" clients using clinical scenarios. The state-of-the-art technologies reflected in this virtual hospital demonstrate cutting-edge learning opportunities for students and facilitate knowledge retention of the information found in the textbook. The clinical simulations and workbook represent the next generation of research-based learning tools that promote critical thinking and meaningful learning.

Evolve, for Instructors includes these teaching resources:

- *Test Bank in ExamView format* contains more than 1000 NCLEX-style test items, including alternate format questions. An answer key with page references to the text, rationales, and NCLEX-style coding is included.
- *TEACH for Nurses* includes teaching strategies; in-class case studies; and links to animations, nursing skills, and nursing curriculum standards such as QSEN, concepts, and BSN Essentials.
- *Image Collection*, containing more than 700 full-color illustrations and photographs from the text, helps instructors develop presentations and explain key concepts.

- *PowerPoint slides*, with lecture notes for each chapter of the text, assist in presenting materials in the classroom. *Case Studies* and *Audience Response Questions* for i-clicker are included.
- A *Curriculum Guide* that includes a proposed class schedule and reading assignments for courses of varying lengths is provided. This gives educators suggestions for using the text in the most essential manner or in a more comprehensive way.

ACKNOWLEDGMENTS

The eleventh edition of *Maternity & Women's Health Care* would not have been possible without the contributions of many people. First, we want to thank the many nurse educators, clinicians, and nursing students in the United States, Canada, Australia, and Taiwan whose comments and suggestions about the manuscript led to this collaborative effort by an outstanding group of contributors. A special thanks goes to these people, many of whom are new to this edition, whose names appear in the list of Contributors. Their expertise and knowledge of current clinical practice and research have added to the relevancy and accuracy of the materials presented. We also thank Pat Gingrich for contributing to the Evidence-Based Practice boxes and Ed Lowdermilk for his assistance with Medication Guides and verification of other medication information. We are also appreciative of the critiques given by the reviewers, especially their attention to validating the accuracy of content and their challenge to present content differently and to include new ideas. These combined efforts have resulted in a revision that incorporates the most recent research and current information about the practice of maternity and women's health care.

We offer thanks for shared expertise and photographs to the staff of University of North Carolina Women's Hospital; University of North Carolina School of Nursing; Nurses Certificate Program in Interactive Imagery; and Polly Perez, Cutting Edge Press.

We also would like to thank the following photographers: Cheryl Briggs, RNC, Annapolis, MD; Michael S. Clement, MD, Mesa, AZ; Julie Perry Nelson, Loveland, CO; and Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.

Thanks to the following individuals who allowed us to use their beautiful photos: Jennifer and Travis Alderman, Durham, NC; Freida Belding, Bird City, KS; Jodi Brackett, Phoenix, AZ; David A. Clarke, Philadelphia, PA; Thomas and Christie Coghill, Clayton, NC; Christina and Eva Gardner, Marion, AR; Kara and Casey George, Peoria, AZ; Patricia Hess, San Francisco, CA; Sharon Johnson, Petaluma, CA; Sara Kossuth, Los Angeles, CA; Mahesh Kotwal, MD, Phoenix, AZ; Paul Vincent Kuntz, Houston, TX; Wendy and Marwood Larson-Harris, Roanoke, VA; Lauren and Brian LiVecchi, Raleigh, NC; Ed Lowdermilk, Chapel Hill, NC; Norman L. Meyer, MD, PhD, Memphis, TN; Kim Molloy, Knoxville, IA; Amanda Politte, St. Louis, MO; Chris Rozales, San Francisco, CA; H. Gil Rushton, MD, Washington, DC; Brian and Mayannyn Sallee, Minot, ND; Shari Rivera Sharpe, Chapel Hill, NC; Margaret Spann, New Johnsonville, TN; Edward S. Tank, MD, Portland, OR; Danielle L. Tate, MD, Memphis, TN; Amy and Ken Turner, Cary, NC; Rebekah Vogel, Fort Collins, CO; Roni Wernik, Palo Alto, CA; and Randi and Jacob Wills, Clayton, NC.

Special words of gratitude are extended to Laurie Gower, Content Development Manager; Heather Bays, Senior Content Development Specialist; Jeff Patterson, Publishing Services Manager; Jeanne Genz, Senior Project Manager; and Ashley Miner, Book Designer, for their encouragement, inspiration, and assistance in preparing and producing this text. These talented and hardworking people helped change our manuscript into a beautiful book by editing the manuscript, designing an attractive format for our special features, and overseeing the production of the book from start to finish.

21st Century Maternity and Women's Health Nursing

Shannon E. Perry

ⓔ <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Describe the scope of maternity and women's health nursing.
- Evaluate contemporary issues and trends in maternity and women's health care.
- Examine social concerns in maternity nursing and women's health care.
- Integrate evidenced-based practice into care plans.
- Explain risk management and standards of practice in the delivery of nursing care.
- Discuss legal and ethical issues in perinatal nursing.
- Examine *Healthy People 2020* goals related to maternal and infant care.

Maternity nursing encompasses care of childbearing women and their families through all stages of pregnancy and childbirth and the first 4 weeks after birth. Throughout the prenatal period, nurses, nurse practitioners, and nurse-midwives provide care for women in clinics and physicians' offices and teach classes to help families prepare for childbirth. Nurses care for childbearing families during labor and birth in hospitals, in birthing centers (e.g., www.birthcenters.org), and in the home. Nurses with special training may provide intensive care for high risk neonates in special care units and for high risk mothers in antepartum units, in critical care obstetric units, or in the home. Maternity nurses teach about pregnancy; the process of labor, birth, and recovery; and parenting skills. They provide continuity of care throughout the childbearing cycle.

Women's health care focuses on the physical, psychologic, and social needs of women throughout their lives. In the care of women, their overall experience is emphasized: general physical and psychologic well-being, childbearing functions, and diseases. Women's health nurses specialize in and investigate conditions unique to women (such as reproductive malignancies and menopause) and sociocultural and occupational factors that are related to women's health problems (such as poverty, rape, incest, family violence, and human trafficking). They also provide care for women and their families during the childbearing cycle.

Nurses caring for women have helped make the health care system more responsive to women's needs. They have been critically important in developing strategies to improve the well-being of women and their infants and have led the efforts to implement clinical practice guidelines and to practice using an evidence-based approach. Through professional associations, nurses have a voice in setting standards and in influencing health policy

by actively participating in the education of the public and of state and federal legislators (e.g., www.nursingworld.org; www.can-nurses.ca; www.awhonn.org; www.capwhn.ca; www.nann.org; www.acnm.org). Some nurses hold elective office and influence policy directly. For example, Mary Wakefield, a nurse, is the administrator of the Health Resources and Services Administration (HRSA), the agency that oversees approximately 7000 community clinics that serve low-income and uninsured people.

ADVANCES IN THE CARE OF WOMEN AND INFANTS

Although tremendous advances have taken place in the care of mothers and their infants during the past 150 years (Box 1-1), serious problems exist in the United States related to the health and health care of mothers and infants. Lack of access to pre-pregnancy and pregnancy-related care for all women and the lack of reproductive health services for adolescents are major concerns. Sexually transmitted infections continue to affect reproduction adversely.

Racial and ethnic diversity is increasing within North America. It is estimated that by the year 2050, 46.6% of the population will be European-American, 27% Hispanic, 13% African-American, 7.7% Asian-American, 0.72% American Indians and Alaska Natives, and 0.22% native Hawaiian and other Pacific Islanders (U.S. Census Bureau, 2012). Significant disparity exists in health outcomes among people of various racial and ethnic groups despite the great strides in public health made by the United States.

In addition, people may have lifestyles, health needs, and health care preferences related to their ethnic or cultural backgrounds.

BOX 1-1 Historic Overview of Milestones in the Care of Mothers and Infants in the Western World from 1847

- 1847—James Young Simpson in Edinburgh, Scotland, used ether for an internal podalic version and birth; the first reported use of obstetric anesthesia
- 1861—Ignaz Semmelweis wrote *The Cause, Concept and Prophylaxis of Childbed Fever*
- 1906—First U.S. program for prenatal nursing care established
- 1908—Childbirth classes started by the American Red Cross
- 1908—Archibald Garrod pioneered work on inborn errors of metabolism
- 1909—First White House Conference on Children convened
- 1911—First milk bank in the United States established in Boston
- 1912—U.S. Children's Bureau established
- 1915—Radical mastectomy determined to be effective treatment for breast cancer
- 1916—Margaret Sanger established first American birth control clinic in Brooklyn, New York
- 1918—Condoms became legal in the United States
- 1923—First U.S. hospital center for premature infant care established at Sarah Morris Hospital in Chicago, Illinois
- 1929—The modern tampon (with an applicator) invented and patented
- 1933—Sodium pentothal used as anesthesia for childbirth; *Natural Childbirth* published by Grantly Dick-Read
- 1934—Dionne quintuplets born in Ontario, Canada, and survive partly due to donated breast milk
- 1935—Sulfonamides introduced as cure for puerperal fever
- 1941—Penicillin used as a treatment for infection
- 1941—Papanicolaou (Pap) tests introduced
- 1942—Premarin approved by the U.S. Food and Drug Administration (FDA) as treatment for menopausal symptoms
- 1953—Virginia Apgar, an anesthesiologist, published Apgar scoring system of neonatal assessment
- 1956—Oxygen determined to cause retrolental fibroplasia (now known as retinopathy of prematurity)
- 1958—Edward Hon reported on the recording of the fetal electrocardiogram (ECG) from the maternal abdomen (first commercial electronic fetal monitor produced in the late 1960s)
- 1958—Ian Donald, a Glasgow physician, was first to report clinical use of ultrasound to examine the fetus
- 1959—*Thank You, Dr. Lamaze* published by Marjorie Karmel
- 1959—Cytologic studies demonstrated that Down syndrome is associated with a particular form of nondisjunction now known as trisomy 21
- 1960—American Society for Psychoprophylaxis in Obstetrics (ASPO/Lamaze) formed
- 1960—International Childbirth Education Association founded
- 1960—Birth control pill introduced in the United States
- 1962—Thalidomide found to cause birth defects
- 1963—Title V of the Social Security Act amended to include comprehensive maternity and infant care for women who were low income and high risk
- 1965—Supreme Court ruled that married people have the right to use birth control
- 1967—Rh₀(D) immune globulin produced for treatment of Rh incompatibility
- 1967—Reva Rubin published article on Maternal Role Attainment
- 1968—Rubella vaccine became available
- 1969—Nurses Association of the American College of Obstetricians and Gynecologists (NAACOG) founded; renamed Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) and incorporated as a 501(c)3 organization in 1993
- 1969—Mammogram became available
- 1972—Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) started
- 1973—Abortion legalized in United States
- 1974—First standards for obstetric, gynecologic, and neonatal nursing published by NAACOG
- 1975—The Pregnant Patient's Bill of Rights published by the International Childbirth Education Association
- 1976—First home pregnancy kits approved by FDA
- 1978—Louise Brown, first test-tube baby, born
- 1987—Safe Motherhood initiative launched by World Health Organization and other international agencies
- 1991—Society for Advancement of Women's Health Research founded
- 1992—USPHS recommended that pregnant women take folic acid to prevent neural tube defects
- 1992—Office of Research on Women's Health authorized by U.S. Congress
- 1993—Female condom approved by FDA
- 1993—Human embryos cloned at George Washington University
- 1993—Family and Medical Leave Act enacted
- 1994—DNA sequences of BRCA1 and BRCA2 identified
- 1994—Zidovudine guidelines to reduce mother-to-fetus transmission of HIV published
- 1996—FDA mandated folic acid fortification in all breads and grains sold in United States
- 1998—Newborns' and Mothers' Health Act went into effect
- 1998—COGNN becomes AWHONN Canada
- 1999—First emergency contraception pill for pregnancy prevention (Plan B) in women who had unprotected sex approved by FDA
- 2000—Working draft of sequence and analysis of human genome completed
- 2006—HPV vaccine available
- 2010—Centenary of the death of Florence Nightingale
- 2010—Patient Protection and Affordable Care Act signed into law by President Obama
- 2011—AWHONN Canada becomes the Canadian Association of Perinatal and Women's Health Nurses (CAPWHN)
- 2012—U.S. Supreme Court upheld individual mandate but not the Medicaid expansion provisions of the Patient Protection and Affordable Care Act
- 2012—Scientists reported findings of the ENCODE (Encyclopedia of DNA Elements) project showing that 80% of the human genome is active

HIV, Human immunodeficiency virus; HPV, human papillomavirus.

They may have dietary preferences and health practices that are not understood by caregivers. This presents a challenge for health care providers to provide culturally sensitive care.

The majority of nurses are Caucasian, about 78%, with 10.4% black and 5.1% Hispanic (AFL-CIO Department of Professional Employees, 2012). To meet the health care needs of a culturally diverse society, there must be increasing diversity of the nursing workforce.

EFFORTS TO REDUCE HEALTH DISPARITIES

Significant disparities in morbidity and mortality rates are experienced by African-Americans, Native Americans, Hispanics, Alaska Natives, and Asian/Pacific Islanders compared with Caucasians. Shorter life expectancy, higher infant and maternal mortality rates, more birth defects, and more sexually transmitted infections are found among these ethnic and racial minority

groups. The disparities are thought to result from a complex interaction among biologic factors, environment, and health behaviors. Disparities in education and income are also associated with differences in morbidity and mortality.

The HRSA Health Disparities Collaboratives are part of a national effort with the goal of eliminating disparities and improving delivery systems of health care for everyone in the United States who is cared for in HRSA-supported health centers. More than 900 community health centers have implemented the collaboratives and are successful in improving quality of care (Chin, 2011). The National Institutes of Health has a commitment to improve the health of minorities and provides funding for research and training of minority researchers (www.nih.gov), and the National Institute of Nursing Research includes in its strategic plan support of research that promotes health equity and eliminates health disparities.

The Centers for Disease Control and Prevention (CDC) released the First Periodic Health Disparities and Inequalities Report—United States, 2011 (CDC, 2011). The report includes recent trends and variation in health disparities and inequalities in some social and health indicators and provides data against which to measure progress in eliminating disparities. Topics specific to perinatal nursing that are addressed are infant deaths, preterm births, and adolescent pregnancy and childbirth. Also in 2011 the U.S. Department of Health and Human Services (USDHHS) released the HHS Disparities Action Plan that provides a vision of “a nation free of disparities in health and health care” (USDHHS, 2011). Through this plan HHS promotes evidenced-based programs, integrated approaches, and best practices to reduce disparities. The plan complements the 2011 National Stakeholder Strategy for Achieving Health Equity prepared by the National Partnership for Action. This strategy proposes a comprehensive, community-driven approach to achieve health equity through collaboration and synergy (National Partnership for Action to End Health Disparities, 2011). The Affordable Care Act (ACA) addresses disparities in income. Through these initiatives the United States is making a concerted effort to eliminate health disparities.

This chapter presents a general overview of issues and trends related to the health and health care of women and infants.

CONTEMPORARY ISSUES AND TRENDS

Healthy People 2020 Goals

Healthy People provides science-based 10-year national objectives for improving the health of all Americans. It has four overarching goals: (1) attaining high-quality, longer lives free of preventable disease, disability, injury, and premature death; (2) achieving health equity, eliminating disparities, and improving the health of all groups; (3) creating social and physical environments that promote good health for all; and (4) promoting quality of life, healthy development, and healthy behaviors across all life stages (www.healthypeople.gov/2020/about/default.aspx). The goals of *Healthy People 2020* are based on assessments of major risks to health and wellness, changes in public health priorities, and issues related to the health preparedness and prevention of our nation. Of the approximately 1200 objectives of *Healthy People 2020*, 33 are related to maternal, infant, and child health (Box 1-2). Objectives in this topic

area include to: (1) reduce the rate of fetal and infant deaths, (2) reduce the rate of maternal mortality, (3) reduce preterm births, and (4) reduce cesarean births among low risk women. (See www.healthypeople.gov/2020/topicsobjectives2020/objectiveslist.aspx?topicId+26 for a complete list of objectives.)

Millennium Development Goals

The United Nations Millennium Development Goals (MDGs) are eight goals to be achieved by 2015 that respond to the main development challenges in the world. The MDGs are drawn from the actions and targets contained in the Millennium Declaration that was adopted by 189 nations and signed by 147 heads of state and governments during the United Nations Millennium Summit in September 2000 (www.un.org/millenniumgoals). Goals three through five of the MDGs relate specifically to women and children (Box 1-3).

Interprofessional Education

Interprofessional education consists of faculty and students from two or more health professions who create and foster a collaborative learning environment. The underlying premise of interprofessional collaboration is that client care will improve when health professionals work together. Numerous organizations including the World Health Organization (WHO), the Institute of Medicine (IOM), the National Academies of Practice, and the American Public Health Association, have expressed support of interprofessional education (Buring, Bhushan, Broeseker, et al., 2009). The Interprofessional Education Collaborative published Core Competencies for Interprofessional Collaborative Practice (Interprofessional Education Collaborative Expert Panel, 2011). The interprofessional collaborative practice competency domains include: (1) values/ethics for interprofessional practice, (2) roles/responsibilities, (3) interprofessional communication, and (4) teams and teamwork.

Problems with the U.S. Health Care System

Structure of the Health Care Delivery System

The U.S. health care delivery system is often fragmented and expensive and is inaccessible to many. Opportunities exist for nurses to alter nursing practice and improve the way care is delivered through managed care, integrated delivery systems, and redefined roles. Information about health and health care is readily available on the Internet (e-health). Consumers use this information to participate in their own care and consult health care providers with a knowledge base previously difficult to access.

Reducing Medical Errors

Medical errors are a leading cause of death in the United States and result in as many as 98,000 deaths per year (Pham, Aswani, Rosen, et al., 2012). Since the IOM released its 1999 report, *To Err Is Human: Building a Safer Health System*, a concerted effort has been under way to analyze causes of errors and develop strategies to prevent them. Recognizing the multifaceted causes of medical errors, the Agency for Healthcare Research and Quality (AHRQ, 2000) prepared a fact sheet, “20 Tips to Help Prevent Medical Errors,” for clients and the public. Clients are encouraged to be knowledgeable consumers of health care and to ask questions of providers, including physicians, midwives, nurses, and pharmacists.

BOX 1-2 Healthy People 2020 Maternal, Infant, and Child Health Objectives

- Reduce the rate of fetal and infant deaths.
- Reduce the 1-year mortality rate for infants with Down syndrome.
- Reduce the rate of child deaths.
- Reduce the rate of adolescent and young adult deaths.
- Reduce the rate of maternal mortality.
- Reduce maternal illness and complications caused by pregnancy (complications during hospitalized labor and delivery).
- Reduce cesarean births among low-risk (full-term, singleton, vertex presentation) women.
- Reduce low birth weight (LBW) and very low birth weight (VLBW).
- Reduce preterm births.
- Increase the proportion of pregnant women who receive early and adequate prenatal care.
- Increase abstinence from alcohol, cigarettes, and illicit drugs in pregnant women.
- Increase the proportion of pregnant women who attend a series of prepared childbirth classes.
- Increase the proportion of mothers who achieve a recommended weight gain during their pregnancies.
- Increase the proportion of women of childbearing potential with intake of at least 400 mcg of folic acid from fortified foods or dietary supplements.
- Reduce the proportion of women of childbearing potential who have low red blood cell folate concentrations.
- Increase the proportion of women delivering a live birth; increase those who receive preconception care services and practice key recommended preconception health behaviors.
- Reduce the proportion of people ages 18 to 44 years who have impaired fecundity (i.e., a physical barrier preventing pregnancy or carrying a pregnancy to term).
- Decrease postpartum relapse of smoking in women who quit smoking during pregnancy.
- Increase the proportion of women giving birth who attend a postpartum care visit with a health worker.
- Increase the proportion of infants who are put to sleep on their backs.
- Increase the proportion of infants who are breastfed.
- Increase the proportion of employers who have worksite lactation programs.
- Reduce the proportion of breastfed newborns who receive formula supplementation within the first 2 days of life.
- Increase the proportion of live births that occur in facilities that provide recommended care for lactating mothers and their babies.
- Reduce the occurrence of fetal alcohol syndrome (FAS).
- Reduce the proportion of children diagnosed with a disorder through newborn blood spot screening who experience developmental delay requiring special education services.
- Reduce the proportion of children with cerebral palsy born as LBW infants (less than 2500 g).
- Reduce the occurrence of neural tube defects.
- Increase the proportion of young children with an autism spectrum disorder (ASD) and other developmental delays who are screened, evaluated, and enrolled in early intervention services in a timely manner.
- Increase the proportion of children, including those with special health care needs, who have access to a medical home.
- Increase the proportion of children with special health care needs who receive their care in family-centered, comprehensive, coordinated systems.
- Increase appropriate newborn blood-spot screening and follow-up testing.
- Increase the number of states, including the District of Columbia, that verify through linkage with vital records that all newborns are screened shortly after birth for conditions mandated by their state-sponsored screening program.
- Increase the proportion of screen-positive children who receive follow-up testing within the recommended time period.
- Increase the proportion of children with a diagnosed condition identified through newborn screening who have an annual assessment of services needed and received.
- Increase the proportion of VLBW infants born at level III hospitals or subspecialty perinatal centers.

BOX 1-3 United Nations Millennium Development Goals

1. Eradicate extreme poverty and hunger.
2. Achieve universal primary education.
3. Promote gender equality and empower women.
4. Reduce child mortality.
5. Improve maternal health.
6. Combat HIV/AIDS, malaria, and other diseases.
7. Ensure environmental sustainability.
8. Develop a global partnership for development.

AIDS, Acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.

In 2002 the National Quality Forum (NQF) published a list of Serious Reportable Events in Healthcare. The list was updated in 2006 and again in 2011, resulting in a total of 29 events. Of these 29 events, 3 pertain directly to maternity and newborn care (Box 1-4). The NQF also published *Safe Practices for Better Healthcare* and updated it in 2010 (www.qualityforum.org). The 34 safe practices included should be used in all applicable

BOX 1-4 National Quality Forum Serious Reportable Events Pertaining to Maternal and Child Health

- Maternal death or serious injury associated with labor or birth in a low-risk pregnancy while being cared for in a healthcare setting
- Death or serious injury of a neonate associated with labor or birth in a low-risk pregnancy
- Artificial insemination with the wrong donor sperm or wrong egg
- Abduction of a client/resident of any age

Data from National Quality Forum (NQF). (2011). *Serious reportable events in healthcare—2011 update: A consensus report*. Washington, DC: NQF.

health care settings to reduce the risk of harm that results from processes, systems, and environments of care (NQF, 2010). In August 2007 the Centers for Medicare & Medicaid Services (CMS) issued a rule that became effective October 2008 that denies payment for eight hospital-acquired conditions. Five of the conditions are also on the NQF list. Almost 1300 U.S.

hospitals waive (do not bill for) costs associated with serious reportable events (O'Reilly, 2008).

High Cost of Health Care

Health care is one of the fastest growing sectors of the U.S. economy. Currently, 17.4% of the gross domestic product is spent on health care. Higher spending in the United States compared with 12 other industrialized countries is related to higher prices, readily accessible technology, and greater obesity (Squires, 2012). Most researchers agree that caring for the increased number of low-birth-weight (LBW) infants in neonatal intensive care units contributes significantly to overall health care costs. Nurse-midwifery care has helped contain some health care costs. However, not all insurance carriers reimburse nurse practitioners and clinical nurse specialists as direct care providers, nor do they reimburse for all services provided by nurse-midwives, a situation that continues to be a problem. Only 16 states and the District of Columbia allow nurse practitioners to practice to their fullest potential without physician involvement (American Academy of Nurse Practitioners, 2012). Nurse practitioners are among the health care providers included in the ACA.

Limited Access to Care

Barriers to access must be removed so pregnancy outcomes and care of children can be improved. The most significant barrier to access is the inability to pay. The number of uninsured people in the United States in 2011 was 48.6 million or 15.7% of the population (DeNavas-Walt, Proctor, & Smith, 2012). Lack of transportation and dependent child care are other barriers. In addition to a lack of insurance and high costs, a lack of providers for low-income women exists because many physicians either refuse to take Medicaid clients or take only a few such clients. This presents a serious problem because a significant proportion of births is to mothers who receive Medicaid.

Health Care Reform

In early 2010, President Obama signed into law the Patient Protection and Affordable Care Act (ACA). The act aims to make insurance affordable, contain costs, strengthen and improve Medicare and Medicaid, and reform the insurance market. There are provisions to promote prevention and improve public health; improve the quality of care for all Americans; reduce waste, fraud, and abuse; and reform the health delivery system. There are some immediate benefits, but implementation of the act will occur over the next several years.

The Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) advocated successfully for the inclusion in the ACA of contraceptive methods, services, and counseling, without any out-of-pocket costs to clients; preventive services such as mammograms, well-woman visits, and screening for gestational diabetes; and providing breastfeeding equipment and counseling for pregnant and nursing women in new insurance plans. Work continues on implementation. See Box 1-5 for resources for the ACA.

Accountable Care Organizations

In 2011, the CMS finalized new rules under the ACA to help health care providers and hospitals coordinate care better for

Medicare clients through Accountable Care Organizations (ACOs). An ACO "agrees to be held accountable for improving the health and experience of care for individuals and improving the health of populations while reducing the rate of growth in health care spending" (USDHHS, CMS, 2012). These groups of health care providers and hospitals voluntarily come together to coordinate high-quality care, eliminate duplication of services, and prevent medical errors, which results in savings of health care dollars. As of December 2013, there are more than 360 ACOs (Medicare & Medicaid News, 2013).

Health Literacy

Health literacy involves a spectrum of abilities, ranging from reading an appointment slip to interpreting medication instructions. These skills must be assessed routinely to recognize a problem and accommodate clients with limited literacy skills. Most client education materials are written at too high a level for the average adult; e-health literacy has emerged as a concept. Individuals use the Internet for diagnosis, and more than half of these individuals seek the opinion of a medical professional rather than trying to care for themselves based on the information accessed (Dickens & Piano, 2013).

The CDC health literacy website (www.cdc.gov/healthliteracy) highlights implementation of goals and strategies of the National Action Plan to Improve Health Literacy (USDHHS, 2010b). Health literacy is part of the ACA.

As a result of the increasingly multicultural U.S. population, there is a more urgent need to address health literacy as a component of culturally and linguistically competent care. Older adults, racial or ethnic minorities, and those whose income is at or below the poverty level are most vulnerable. Lower health literacy is associated with adverse health outcomes (Dickens & Piano, 2013).

Health care providers contribute to health literacy by using simple, common words, avoiding jargon, and assessing whether the client understands the discussion. Speaking slowly and clearly and focusing on what is important will increase understanding.

BOX 1-6 Maternal/Infant Biostatistical Terminology

Abortus: An embryo or fetus that is removed or expelled from the uterus at 20 weeks of gestation or less, weighs 500 g or less, or measures 25 cm or less

Birth rate: Number of live births in 1 year per 1000 population

Fertility rate: Number of births per 1000 women between the ages of 15 and 44 years (inclusive), calculated on a yearly basis

Infant mortality rate: Number of deaths of infants younger than 1 year of age per 1000 live births

Maternal mortality rate: Number of maternal deaths from births and complications of pregnancy, childbirth, and puerperium (the first 42 days after end of the pregnancy) per 100,000 live births

Neonatal mortality rate: Number of deaths of infants younger than 28 days of age per 1000 live births

Perinatal mortality rate: Number of stillbirths and the number of neonatal deaths per 1000 live births

Stillbirth: An infant who, at birth, demonstrates no signs of life, such as breathing, heartbeat, or voluntary muscle movements

TRENDS IN FERTILITY AND BIRTH RATE

Fertility trends and birth rates reflect women's needs for health care. Box 1-6 defines biostatistical terminology useful in analyzing maternity health care. In 2012 the **fertility rate**, births per 1000 women from 15 to 44 years of age, was 63.0 (Martin, Hamilton, Osterman, et al., 2013). The highest birth rates occurred among women between 20 and 29 years of age. The **birth rate**, number of live births in 1 year per 1000 population, was 12.6 in 2012; the birth rate for teens 15 to 19 years was 29.4. In 2012 the percentage of births by unmarried women varied widely among racial groups in the United States: Hispanic, 72.6%; black, 62.6%; non-Hispanic white, 32.1%; and Asian or Pacific Islander, 22.9% (Martin et al.).

Low Birth Weight and Preterm Birth

The risks of morbidity and mortality increase for newborns weighing less than 2500 g (5 lb, 8 oz)—**low-birth-weight (LBW)** infants. In the United States in 2012, the LBW rate was 7.99 per 1000. Multiple births contribute to the incidence of LBW. The twin birth rate was 33.1 per 1000 in 2012. The downward trend in the birth rate of higher-order multiples (triplet, quadruplet, and greater) continued in 2012, with a rate of 124.4 per 100,000 (Martin et al., 2013).

Non-Hispanic black infants are almost twice as likely as non-Hispanic white infants to be of LBW and to die in the first year of life. For non-Hispanic black births, the incidence of LBW was 13.18%, whereas the rate was 6.97% for non-Hispanic white births and 6.96% for Hispanic births (Martin et al., 2013). Cigarette smoking is associated with LBW, prematurity, and intrauterine growth restriction. In 2010, 12.3% of pregnant women smoked, including 14.3% of non-Hispanic white women, 8.9% non-Hispanic black women, 3.4% of Hispanic women, 26% of American Indian/Alaska Native women, and 2.1% of Asian/Pacific Islander women (Tong et al., 2013).

The percentage of infants born preterm (i.e., born before 38 weeks of gestation) was 11.55% in 2012. There was variation in the percentage according to race and Hispanic origin: 18.46% for non-Hispanic black births, 11.58% for Hispanic births, and 10.29% for non-Hispanic white births (Martin et al., 2013). Multiple births accounted for 3.4% of births in 2012; most of the increase is associated with increased use of fertility drugs and older age at childbearing.

Infant Mortality in the United States

A common indicator of the adequacy of prenatal care and the health of a nation as a whole is the **infant mortality rate**. The U.S. infant mortality rate for 2010 was 6.14 (Mathews & MacDorman, 2013). The **disparity** in infant mortality rate between African-American infants and Caucasian infants has increased over time. The infant mortality rate continues to be higher for non-Hispanic black babies (11.46 per 1000) than for non-Hispanic whites (5.18 per 1000) and Hispanic (5.25 per 1000) babies (Mathews & MacDorman). Limited maternal education, young maternal age, unmarried status, poverty, lack of prenatal care, and smoking appear to be associated with higher infant mortality rates. Poor nutrition, alcohol use, and maternal conditions such as poor health or hypertension also are important contributors to infant mortality. To address the factors associated with infant mortality, a shift from the current emphasis on high-technology medical interventions to a focus on improving access to preventive care for low-income families must occur.

The leading cause of death in the neonatal period is congenital anomalies. Other causes of **neonatal death** include disorders related to short gestation and LBW, sudden infant death, respiratory distress syndrome, and the effects of maternal complications. Racial differences in the infant mortality rates continue to challenge public health experts. Increased rates of survival during the neonatal period have resulted largely from high-quality prenatal care and the improvement in perinatal services, including technologic advances in neonatal intensive care and obstetrics.

Commitment at national, state, and local levels is required to reduce the infant mortality rate. More research is needed to identify the extent to which financial, educational, sociocultural, and behavioral factors individually and collectively affect perinatal morbidity and mortality. Barriers to care must be removed and perinatal services modified to meet contemporary health care needs.

International Infant Mortality Trends

In 2008, the infant mortality rate of Canada (5.7/1000) ranked twenty-ninth, and that of the United States (6.6/1000) ranked thirty-first, when compared with those of other industrialized nations (Heisler, 2012). Decreases in the infant mortality rate in the United States do not keep pace with the rates of other industrialized countries. One reason for this is the high rate of LBW infants in the United States in contrast with the rates in other countries.

Maternal Mortality Trends

The United Nations estimated that 358,000 women died of problems related to pregnancy or childbirth in 2008, a decline

difference, imbalance

anomalies

from approximately 546,000 in 1990 (Wilmoth, Mizoguchi, Oestergaard, et al., 2012). In the United States in 2010, the annual **maternal mortality rate** (number of maternal deaths per 100,000 live births) was 21 (WHO, 2013). The CDC began working with national and international groups in 2001 to develop and implement programs to promote safe motherhood (Jones, 2008). Although the overall number of maternal deaths in the United States is small (548 in 2007), maternal mortality remains a significant problem because a high proportion of deaths are preventable, primarily through improving the access to and use of prenatal care services. In the United States, there is significant racial disparity in the rates of maternal death: non-Hispanic black women (28.4), non-Hispanic white women (10.5), and Hispanic women (8.9) (USDHHS, 2010a). The leading causes of maternal death attributable to pregnancy differ over the world. In general, three major causes have persisted for the past 50 years: hypertensive disorders, infection, and hemorrhage. The three leading causes of maternal mortality in the United States today are cardiovascular disease, infection/sepsis, and noncardiovascular diseases (CDC, 2013). Factors that are strongly related to maternal death include age (younger than 20 years and 35 years or older), lack of prenatal care, low educational attainment, unmarried status, and non-Caucasian race. The *Healthy People 2010* goal of 3.3 maternal deaths per 100,000 posed a significant challenge and was not achieved. Worldwide strategies to reduce maternal mortality rates include improving access to skilled attendants at birth, providing postabortion care, improving family planning services, and providing adolescents with better reproductive health services.

Maternal Morbidity

Although mortality is the traditional measure of maternal health and maternal health is often measured by neonatal outcomes, pregnancy complications are important. Currently no surveillance method is available to measure the incidence of maternal **morbidity**. It includes such conditions as acute renal failure, amniotic fluid embolism, cerebrovascular accident, eclampsia, pulmonary embolism, liver failure, obstetric shock, respiratory failure, septicemia, and complications of anesthesia (pulmonary, cardiac, central nervous system) (Berg, Mackay, Qin, et al., 2009). Maternal morbidity results in a high risk pregnancy. The diagnosis of high risk imposes a situational crisis on the family. The combined efforts of medical and nursing personnel are required to care for these clients, who often need the expertise of physicians and nurses trained in both critical care obstetrics and intensive care medicine or nursing.

Obesity

More than one third (36.2%) of women in the United States are obese (body mass index of 30 or greater); in Canada less than one fourth (23.9%) of women are obese. Obesity in women demonstrates significant racial disparities: in the United States 49.6% of non-Hispanic black women, 45.1% of Mexican-American women, and 33% of non-Hispanic white women ages 20 years and older are obese (Flegal, Carroll, Ogden, et al., 2010; Shields, Carroll, & Ogden, 2011). Approximately 20% of women who give birth in the United States are

obese. The two most frequently reported maternal medical risk factors are hypertension associated with pregnancy and diabetes, both of which are associated with obesity. Decreased fertility, congenital anomalies, miscarriage, and fetal death are associated with obesity. Obesity in pregnancy is associated with the use of increased health care services and longer hospital stays.

REGIONALIZATION OF PERINATAL HEALTH CARE SERVICES

Not all facilities can develop and maintain the full spectrum of services required for high risk perinatal clients. A regionalized system focusing on integrated delivery of graded levels of hospital-based perinatal health care services is effective and results in improved outcomes for mothers and their newborns. This system of coordinated care can be extended to preconception and ambulatory prenatal care services. New guidelines for regionalization of maternal care are in preparation.

Ambulatory Prenatal Care

Guidelines have been established regarding the level of care that can be expected at any given facility. In ambulatory settings, providers must distinguish themselves by the level of care they provide. *Basic care* is provided by obstetricians, family physicians, certified nurse-midwives, and other advanced practice clinicians approved by local governance. Routine risk-oriented prenatal care, education, and support are provided. Providers offering *specialty care* are obstetricians who must provide fetal diagnostic testing and management of obstetric and medical complications in addition to basic care. *Subspecialty care* is provided by maternal-fetal medicine specialists and reproductive geneticists and includes the aforementioned in addition to genetic testing, advanced fetal therapies, and management of severe maternal and fetal complications. Collaboration among providers to meet the woman's needs is the key to reducing perinatal morbidity and mortality (American Academy of Pediatrics [AAP] & American College of Obstetricians and Gynecologists [ACOG], 2012).

HIGH-TECHNOLOGY CARE

Advances in scientific knowledge and the large number of high risk pregnancies have contributed to a health care system that emphasizes high-technology care. Maternity care has extended to preconception counseling, more and better scientific techniques to monitor the mother and fetus, more definitive tests for hypoxia and acidosis, and neonatal intensive care units. The labors of virtually all women who give birth in hospitals are monitored electronically despite the lack of evidence of efficacy of such monitoring. The numbers of assisted labors and births are increasing. Internet-based information is available to the public that enhances interactions among health care providers, families, and community providers. Point-of-care testing is available. Personal data assistants are used to enhance comprehensive care; the medical record is increasingly in electronic form.

Strides are being made in identifying genetic codes, and genetic engineering is taking place. Women's health has expanded to

BOX 1-7 Principles for Social Networking and the Nurse

- Nurses must not transmit or place online individually identifiable client information.
- Nurses must observe ethically prescribed professional client-nurse boundaries.
- Nurses should understand that clients, colleagues, institutions, and employers may view postings.
- Nurses should take advantage of privacy settings and seek to separate personal and professional information online.
- Nurses should bring content that could harm a client's privacy, rights, or welfare to the attention of appropriate authorities.
- Nurses should participate in developing institutional policies governing online contact.

From American Nurses Association. (2011). *Principles for social networking and the nurse: Guidance for the registered nurse*. Washington, DC: Author.

emphasize care of older women, new cancer-screening techniques, advances in the diagnosis and treatment of breast cancer, and work on an AIDS vaccine. In general, high-technology care has flourished, whereas “health” care has become relatively neglected. Nurses must use caution and prospective planning and assess the effect of the emerging technology.

Social Media

Social media uses Internet-based technologies to allow users to create their own content and participate in dialogue. The most common social media platforms are Facebook, Twitter, and LinkedIn (Duffy, 2011). Through use of these technologies, nurses can link with nurses with similar interests, share insights about client care, and advocate for clients (Saver, 2010). However, there are pitfalls for nurses using this technology. Client privacy and confidentiality can be violated, and institutions and colleagues can be cast in unfavorable lights with negative consequences for those posting the information. Nursing students have been expelled from school, and nurses have been fired or reprimanded by a board of nursing for injudicious posts. To help make nurses aware of their responsibilities when using social media, the American Nurses Association (ANA) published six principles for social networking and the nurse (Box 1-7). In addition, the National Council of State Boards of Nursing (NCSBN) issued *White Paper: A Nurse's Guide to the Use of Social Media* (NCSBN, 2011). The paper details issues of confidentiality and privacy, possible consequences of inappropriate use of social media, common myths and misunderstandings of social media, and tips on how to avoid problems.

COMMUNITY-BASED CARE

A shift in settings, from acute care institutions to ambulatory settings including the home, has occurred (see Chapter 2). Even childbearing women at high risk are cared for on an outpatient basis or in the home. Technology previously available only in the hospital is now found in the home. This has affected the organizational structure of care, the skills required in providing such care, and the costs to consumers. Nursing education curricula are increasingly community based.

CHILDBIRTH PRACTICES

Prenatal care can promote better pregnancy outcomes by providing early risk assessment and promoting healthy behaviors such as improved nutrition and smoking cessation. Prenatal care ideally begins before pregnancy because early decisions lay the foundation for the entire perinatal year. If at all possible, education continues in each trimester of pregnancy and extends through the early postpartum weeks. Some health care providers promote preconception care as an important component of perinatal services. Preconception or early pregnancy classes also emphasize health-promoting behavior as well as choices of care.

In the United States in 2012, 74.1% of all women received care in the first trimester. There is disparity in receiving prenatal care by race and ethnicity: 10% of non-Hispanic blacks, 7.5% of Hispanic women, and 4.3% of non-Hispanic whites received late or no prenatal care (CDC, 2012). In spite of these statistics, substantial gains have been made in the use of prenatal care since the early 1990s, which are attributed to the expansion in the 1980s of Medicaid coverage for pregnant women.

Women can choose physicians or nurse-midwives as primary care providers. In 2012, physicians attended 92% of all births and certified nurse-midwives attended 7.6% (Martin et al., 2013). Women who choose nurse-midwives as their primary providers participate more actively in childbirth decisions, receive fewer interventions during labor, and are less likely to give birth prematurely (Sandall, Soltani, Gates, et al., 2013). The rate of vaginal births after cesarean (VBACs) (10.2%) declined, whereas the cesarean birth rate of 32.8% of live births in the United States was unchanged in 2012 (Martin et al.; National Center for Health Statistics, 2012).

CLINICAL REASONING CASE STUDY**Safety and Efficacy of Midwifery Care**

A group of nurse-midwives is setting up practice in your hometown. They are to collaborate with one of the groups of obstetricians in the same city. A letter to the editor appeared in the local newspaper stating that the presence of midwives will jeopardize the care of pregnant women in the community because midwives usually care for the poor and indigent, deliver babies at home, and therefore do not have the skills to work in hospitals and care for middle-class women who have insurance. The letter writer urged the community to boycott the midwives to ensure safe childbirth for women in the community.

1. Evidence—Is there sufficient evidence to document the qualifications of nurse-midwives and their safety record to write a response to this letter?
2. Assumptions—What assumptions can be made about midwifery care and the knowledge base of the public regarding that care?
3. What implications and priorities for nursing can be made at this time?
4. Does the evidence objectively support your conclusion?

With family-centered care, fathers, partners, grandparents, siblings, and friends may be present for labor and birth. Fathers or partners may be present for cesarean births and may participate in vaginal births by “catching the baby” or cutting the umbilical cord or both (Fig. 1-1). Doulas (i.e., trained and experienced female labor attendants) may be present to provide a

FIG 1-1 Father “catching” newborn daughter who cried before her lower body emerged following an unmedicated birth. (Courtesy Darren and Julie Nelson, Loveland, CO.)

continuous, one-on-one caring presence throughout the labor and birth. Ideally, newborns are placed skin-to-skin with the mother immediately after birth and are encouraged to breast-feed as soon as possible. Neonates often remain in the room with their parents and may never transfer to a newborn nursery. Parents actively participate in newborn care on mother/baby units, in nurseries, and in neonatal intensive care units.

Discharge of a mother and baby within 24 hours of birth has created a growing need for follow-up or home care. In some settings, discharge may occur as early as 6 hours after birth. Legislation has been enacted to ensure that mothers and babies are permitted to stay in the hospital for at least 48 hours after vaginal birth and 96 hours after cesarean birth, although they may choose to leave earlier. Focused and efficient teaching is necessary to enable the parents and infant to make the transition safely from the hospital to the home.

INVOLVING CONSUMERS AND PROMOTING SELF-MANAGEMENT

Self-management is appealing to clients as well as the health care system because of its potential to reduce health care costs. Maternity care is especially suited to self-management because childbearing is primarily health focused, women are usually well when they enter the system, and visits to health care providers can present the opportunity for health and illness interventions. Measures to improve health and reduce risks associated with poor pregnancy outcomes and illness can be addressed. Topics such as nutrition education, stress management, smoking cessation, alcohol and drug treatment, violence prevention, social support improvement, and parenting education are appropriate for such encounters.

INTERNATIONAL CONCERNS

Access to prenatal care and family planning education, care for women experiencing postpartum hemorrhage, obstructed labors with no access to hospital care or operative birth, fistulas

due to obstructed labors, and HIV-positive parents are major international concerns. The high maternal and infant mortality in developing countries is a serious problem with limited resources to address the problems. Two concerns that nurses in the United States and Canada might encounter are female genital mutilation and human trafficking.

Female genital mutilation, infibulation (surgical closure of the labia majora), and circumcision are terms used to describe procedures in which part or all of the female external genitalia is removed for cultural or nontherapeutic reasons (WHO, 2013). Worldwide, many women undergo such procedures. The International Council of Nurses and other health professionals have spoken out against procedures that result in mutilation as harmful to women's health. In the United States, performing female genital mutilation on a person younger than 18 years is a crime (Sandy, 2011) (see Cultural Considerations: Female Genital Mutilation box in Chapter 4).

Human trafficking is a \$32 billion business that exists in the United States and internationally (Dovydaitis, 2010). Trafficked individuals, mostly women and children, are forced into hard labor, sex work, and even organ donation (Budiani-Saberi, Raja, Findley, et al., 2014; Macy & Graham, 2012). Health care professionals may interact with victims who are in captivity. This provides an opportunity to identify victims, intervene to help them obtain necessary health services, and provide information about ways to escape from their situation (Fig. 1-2) (see Chapter 5). The National Human Trafficking Resource Center (1-888-373-7888) can provide assistance.

WOMEN'S HEALTH

Heart disease is the leading cause of death of women followed closely by malignant neoplasms including breast cancer. Symptoms of a heart attack in women are different from symptoms in men. Nurses providing care for women have opportunities for client education to ensure that their clients are aware of these differences (Longley, 2013). Early detection of breast cancer through mammography can reduce the mortality rate resulting from this type of cancer. However, because of lack of information or lack of insurance and access, many women never have mammograms. Wide disparity exists between Caucasian women and women of other races and between older and younger women in their rates of mammography, detection, and treatment of breast cancer, and in their survival rates (see Chapter 10). Cancer genetic predisposition testing is increasingly available. Women may approach providers of women's health services to request such testing (Mahon & Crecelius, 2013).

Various factors and conditions affect women's health. Race is a major factor: Caucasian women born in 2015 have a life expectancy at birth of 81.8 years, in contrast with 78.2 years for African-American women (Murphy, Xu, & Kochanek, 2012). The population has grown older: approximately 50 million women are older than 50 years of age; 51 is the median age for menopause. Hormone replacement therapy for menopausal women has been used for many years and has both benefits and risks (see Chapter 6).

Violence is a major factor affecting women (see Chapter 5). Violence includes battery, rape or other sexual assaults, and attacks with various weapons. Rates of reported intimate partner

FIG 1-2 In January 2012, a group of 48 women participated in the Freedom Climb of Mt. Kilimanjaro, the tallest mountain in Africa. The women climbed to call attention to human trafficking and to raise funds to support projects to combat trafficking. The group raised more than \$350,000, which went for projects such as prenatal care, education, safe houses, and micro loans for victims of trafficking in many countries served by Operation Mobilization (www.om.org). (Courtesy Shannon Perry, Phoenix, AZ.)

violence have increased, possibly because of better assessment and reporting mechanisms. Approximately 4% to 8% of pregnant women are battered; the incidence of battering increases during pregnancy. Violence is associated with complications of pregnancy such as bleeding. Alcoholism and substance abuse by the woman and her abuser are associated with violence and homelessness, which affect a growing number of women and children and place them at risk for a variety of health problems.

THE FUTURE OF NURSING

In 2008 the Robert Wood Johnson Foundation and the IOM initiated a 2-year process to meet the need to assess and transform the nursing profession. The IOM appointed a committee that developed four key messages: (1) nurses should practice to the full extent of their education and training; (2) nurses should achieve higher levels of education and training through an improved education system that promotes seamless academic progression; (3) nurses should be full partners with physicians and other health care professionals in redesigning health care in the United States; and (4) effective workforce planning and policymaking require better data collection and an improved information infrastructure (IOM, 2010). Throughout the United States individual states and nursing organizations are making concerted efforts to implement the recommendations of the report.

TRENDS IN NURSING PRACTICE

The increasing complexity of care for maternity and women's health clients has contributed to specialization of nurses working with these clients. This specialized knowledge is gained through experience, advanced degrees, and certification programs. Nurses in advanced practice (e.g., nurse practitioners and nurse-midwives) may provide primary care throughout a

woman's life, including during the pregnancy cycle. In some settings the clinical nurse specialist and nurse practitioner roles are blended, and nurses deliver high-quality, comprehensive, and cost-effective care in a variety of settings. Lactation consultants provide services in the hospital setting, in clinics and physician offices, and during home visits.

Nursing Interventions Classification

When the IOM proposed that all client records be computerized by the year 2000, a need for a common language to describe the contributions of nurses to client care became evident. Nurses from the University of Iowa developed a comprehensive standardized language that describes interventions that are performed by generalist or specialist nurses. This language is included in the Nursing Interventions Classification (NIC) (Bulachek, Butcher, Dochterman, & Wagner, 2013). Examples of interventions for childbearing care to assist in the preparation for childbirth before, during, and after include breastfeeding assistance, childbirth preparation, circumcision care, electronic fetal monitoring, family planning, and kangaroo care.

Evidence-Based Practice

Evidence-based practice—providing care based on evidence gained through research and clinical trials—is increasingly emphasized. Although not all practice can be evidence based, practitioners must use the best available information on which to base their interventions. The AWHONN *Standards and Guidelines for Professional Nursing Practice in the Care of Women and Newborns* (AWHONN, 2009a) and the *Standards for Professional Perinatal Nursing Practice and Certification in Canada* (AWHONN, 2009b) include an evidence-based approach to practice. Discussion of nursing care and evidence-based practice boxes throughout this text provide examples of evidence-based practice in perinatal and women's health nursing (see Evidence-Based Practice box).

EVIDENCE-BASED PRACTICE

Seeking and Evaluating Evidence: A Necessary Competency for Quality and Safety

Throughout this text you will see Evidence-Based Practice boxes. These boxes provide examples of how a nurse might conduct an inquiry into an identified practice question. Curiosity and access to a virtual or real library are all the nurse needs to be confident that his or her practice has a sound foundation of evidence.

A literature search may reveal up to three levels of evidence. The first level consists of primary studies. The strongest of these are randomized controlled trials. Well-designed studies, even small ones, add another piece to the puzzle.

These primary studies may be combined into the second level of evidence. In systematic analyses such as those in the Cochrane Database, the researcher uses a methodology to identify all studies relevant to a particular question. If the data are similar enough, they can be pooled into a metaanalysis. If the evidence is strong, some analyses will form the basis for recommendations for practice and to guide further inquiry.

At the tertiary level professional organizations such as the Agency for Healthcare Research and Quality (AHRQ) (www.ahrq.gov) or the National Guidelines Clearinghouse (NGC) (guideline.gov) may decide to address a broad practice question by sorting through all the available primary and secondary evidence and consulting experienced clinicians. After thoughtful review, the committee of experts in the organization crafts its consensus statement. These recommendations for best practice stand on the shoulders of the systematic analysts, who stand on the many shoulders of the primary researchers.

Provided that the professional organization is well respected and the process is rigorous, these guidelines in the consensus

statement carry enormous authority. Individuals and institutions may choose to adopt them with confidence. An example of this is the Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) (www.awhonn.org) Late Preterm Infant Initiative. This initiative began in 2005 in response to the confusion that surrounded the care of infants who do not qualify for neonatal intensive care unit (NICU) admission yet require extra vigilance. Nurseries can adapt these recommendations to their specific institutions, enabling nurses to become more effective at caring for the unique problems of this population of neonates. Like AWHONN, most of the professional organizations make their guidelines available free of charge on their websites.

To develop common language and goals for nursing education, the Quality and Safety Education for Nurses (QSEN) (www.qsen.org) project expert panel identified six competencies necessary to enable the new nurse to continually improve the health care system: client-centered care, teamwork and collaboration, evidence-based practice, quality improvement, safety, and informatics. Most nursing challenges require a combination of these competencies. Each competency is further defined as having targets for knowledge, skills, and attitude. The Evidence-Based Practice boxes in this textbook include examples that illustrate each of these targets specific to that competency. A mastery of QSEN competencies greatly enriches a nurse's ability to identify and improve client and health care-system problems and communicate within the interdisciplinary team.

Pat Mahaffee Gingrich

Cochrane Pregnancy and Childbirth Database

The **Cochrane Pregnancy and Childbirth Database** was first planned in 1976 with a small grant from the WHO to Dr. Iain Chalmers and colleagues at Oxford. In 1993, the Cochrane Collaboration was formed, and the Oxford Database of Perinatal Trials became known as the Cochrane Pregnancy and Childbirth Database. The Cochrane Collaboration oversees up-to-date, systematic reviews of randomized controlled trials of health care and disseminates these reviews. The premise of the project is that these types of studies provide the most reliable evidence about the effects of care.

The evidence from these studies should encourage practitioners to implement useful measures and to abandon those that are useless or harmless. Studies are ranked in six categories:

1. Beneficial forms of care
2. Forms of care that are likely to be beneficial
3. Forms of care with a trade-off between beneficial and adverse effects
4. Forms of care with unknown effectiveness
5. Forms of care that are unlikely to be beneficial
6. Forms of care that are likely to be ineffective or harmful

Joanna Briggs Institute

Established in 1996 as an initiative of the Royal Adelaide Hospital and the University of Adelaide in Australia, the Joanna Briggs Institute (JBI) uses a collaborative approach for evaluating evidence from a range of sources (www.joannabriggs.edu.au). The JBI has formed collaborations with a variety of universities and hospitals around the world including in the United States and

Canada. The JBI uses the following grades of recommendation for evidence of feasibility, appropriateness, meaningfulness, and effectiveness: *A*, strong support that merits application; *B*, moderate support that warrants consideration of application; and *C*, not supported (JBI, 2013). The JBI provides another source for perinatal nurses to access information to support evidence-based practice.

Outcomes-Oriented Practice

Outcomes of care (that is, the effectiveness of interventions and quality of care) are receiving increased emphasis. **Outcomes-oriented care** measures effectiveness of care against benchmarks or standards. It is a measure of the value of nursing using quality indicators and answers the question, "Did the client benefit or not benefit from the care provided?" (Moorhead, Johnson, Maas, & Swanson, 2012). The Outcome and Assessment Information Set (OASIS) is an example of an outcomes system important for nursing. Its use is required by the CMS in all home health organizations that are Medicare accredited. The Nursing Outcomes Classification (NOC) is an effort to identify outcomes and related measures that can be used for evaluation of care of individuals, families, and communities across the care continuum (Moorhead et al.); for example, the scale for *Breastfeeding Establishment: Infant* ranges from Not Adequate to Totally Adequate. Indicators include proper alignment and latching, proper areolar grasp and compression, correct suck and tongue placement, and audible swallowing. Through this assessment, the nurse can determine whether the infant met the desired outcome of ingesting adequate nutrition.

A Global Perspective

Advances in medicine and nursing have resulted in increased knowledge and understanding in the care of mothers and infants and reduced perinatal morbidity and mortality rates. However, these advances have affected predominantly industrialized nations. For example, the majority of the 3.2 million children living with human immunodeficiency virus (HIV) or AIDS acquired the infection through perinatal transmission

FIG 1-3 Nurse interviewing a young girl accompanied by her mother in a clinic in rural Kenya. (Courtesy Shannon Perry, Phoenix, AZ.)

and live in sub-Saharan Africa. The State of the World's Mothers annual report from Save the Children is available at www.savethechildren.org/mothers.

As the world becomes smaller because of travel and communication technologies, nurses and other health care providers are gaining a global perspective and participating in activities to improve the health and health care of people worldwide. Nurses participate in medical outreach, providing obstetric, surgical, ophthalmologic, orthopedic, or other services (Fig. 1-3); attend international meetings; conduct research; and provide international consultation. International student and faculty exchanges occur. More articles about health and health care in various countries are appearing in nursing journals. Several schools of nursing in the United States are World Health Organization Collaborating Centers.

STANDARDS OF PRACTICE AND LEGAL ISSUES IN PROVISION OF CARE

Nursing standards of practice in perinatal and women's health nursing have been described by several organizations, including the ANA, which publishes standards for maternal-child health nursing; AWHONN, which publishes standards of practice and education for perinatal nurses (Box 1-8); ACNM, which publishes standards of practice for midwives; and the National Association of Neonatal Nurses (NANN), which

BOX 1-8 Standards of Care for Women and Newborns

Standards of Practice

Assessment

- Collects health data of the woman or newborn

Diagnosis

- Analyses data to determine nursing diagnosis

Outcome Identification

- Identifies expected outcomes that are individualized

Planning

- Develops a plan of care

Implementation

- Performs interventions for the plan of care
 - (a) *Coordination of Care.* Coordinated care delivery within her/his scope of practice
 - (b) *Health Teaching and Health Promotion.* Employs teaching strategies to promote, maintain, or restore health

Evaluation

- Evaluates effectiveness of interventions in relation to expected outcomes

Standards of Professional Performance

Quality of Practice

- Systematically evaluates and implements measures to improve quality, safety, and effectiveness of nursing practice

Education

- Acquires and maintains knowledge and competencies that reflect current evidence-based practice

Professional Practice Evaluation

- Evaluates own practice in relation to current evidence-based information, standards and guidelines, statutes, rules and regulations

Ethics

- Decisions and actions determined in an ethical manner and guided by a sound ethical decision-making process

Collegiality

- Interacts with and contributes to professional development of peers, colleagues, and other health care providers

Collaboration and Communication

- Collaborates and communicates with women, families, health care providers, and the community in the providing safe and effective care

Research

- Generates and/or integrates evidence to identify, examine, validate, and evaluate knowledge, theories, and approaches in providing care to clients

Resources and Technology

- Considers factors related to safety, effectiveness, technological advances, and costs in planning and delivering client care

Leadership

- Within appropriate roles, seeks to serve as a role model, change agent, consultant, and mentor to clients and other health care professionals

publishes standards of practice for neonatal nurses. These standards reflect current knowledge, represent levels of practice agreed on by leaders in the specialty, and can be used for clinical benchmarking.

In addition to these more formalized standards, agencies have their own policy and procedure books that outline standards to be followed in that setting. In legal terms, the **standard of care** is that level of practice that a reasonably prudent nurse would provide in the same or similar circumstances. In determining legal negligence, the care given is compared with the standard of care. If the standard was not met and harm resulted, negligence occurred. The number of legal suits in the perinatal area typically has been high. As a consequence, malpractice insurance costs are high for physicians, nurse-midwives, and nurses who work in labor and birth settings.

LEGAL TIP: Standard of Care

When you are uncertain about how to perform a procedure, consult the agency procedure book guidelines printed therein. These guidelines are the standard of care for that agency.

Risk Management

Risk management is an evolving process that identifies risks, establishes preventive practices, develops reporting mechanisms, and delineates procedures for managing lawsuits. Nurses should be familiar with concepts of risk management and their implications for nursing practice. These concepts can be viewed as systems of checks and balances that ensure high-quality client care from preconception until after birth. Effective risk management minimizes the risk of injury to clients and the number of lawsuits against nurses, doctors, and hospitals. Each facility or site develops site-specific risk management procedures based on accepted standards and guidelines. The procedures and guidelines must be reviewed periodically.

To decrease risk of errors in the administration of medications, The Joint Commission (TJC) (2009) developed a list of abbreviations, acronyms, and symbols *not* to use. In addition, each agency must develop its own list.

Sentinel Events

TJC describes a **sentinel event** as “an unexpected occurrence involving death or serious physical or psychological injury, or the risk thereof. Serious injury specifically includes loss of limb or function.” These events are called *sentinel* because they signal a need for an immediate investigation and response. Reportable sentinel events in perinatal nursing include any maternal death related to the process of birth, any perinatal death unrelated to a congenital condition in an infant having a birth weight greater than 2500 g, severe neonatal hyperbilirubinemia (bilirubin greater than 30 mg/dl), and infant discharge to the wrong family (TJC, 2013). Other sentinel events that may occur in perinatal nursing include hemolytic transfusion reaction involving major blood group incompatibilities, leaving a foreign body (e.g., sponge or forceps) in a client after surgery, and falls that result in death or major permanent loss of function that is a direct result of the injuries caused by the fall. When a sentinel event occurs, there must be a root cause analysis and an action

plan formulated that identifies strategies to reduce the risk of future similar events.

Failure to Rescue

Failure to rescue, that is, the failure to recognize or act on early signs of distress, was introduced in the 1990s in relation to the care of adult postsurgical clients (Beaulieu, 2009; Simpson, 2005). Mothers and babies are generally healthy, and complications leading to death in obstetrics are comparatively rare. When applying the concept of failure to rescue to the perinatal setting, Simpson proposed evaluating the ability of the perinatal team to decrease the risk of adverse outcomes by measuring processes involved in common complications and emergencies in obstetrics (Simpson, 2005, 2006). Key components of failure to rescue are (1) careful surveillance and identification of complications, and (2) quick action to initiate appropriate interventions and activate a team response. For the perinatal nurse, this involves careful surveillance, timely identification of complications, appropriate interventions, and activation of a team response to minimize client harm. The Fetal Safety Failure to Rescue Process Tool as adapted by Simpson from the AHRQ (2004) client safety indicators can be used for this purpose (Beaulieu). Maternal complications that are appropriate for process measurement are placental abruption, postpartum hemorrhage, uterine rupture, eclampsia, and amniotic fluid embolism (Simpson, 2005, 2006; Simpson, Knox, Martin, et al., 2011). Fetal complications include nonreassuring fetal heart rate and pattern, prolapsed umbilical cord, shoulder dystocia, and uterine hyperstimulation (Simpson, 2005, 2006; Simpson et al.). Perinatal nurses can use these complications to develop a list of expectations for monitoring, timely identification, interventions, and roles of team members. The list can be used to evaluate the perinatal team's response. Practicing emergency interventions as a team using simulation is important. Promoting a culture of safety, effective communication, and team building are important in providing safe care during labor and birth (Simpson et al.).

Quality and Safety Education for Nurses

Quality and Safety Education for Nurses (QSEN) is an effort to provide nurses with the competencies to improve the quality and safety of the systems of health care in which they practice (Cronenwett, Sherwood, Barnsteiner, et al., 2007). The competencies for nursing delineated by the IOM (2003) (Box 1-9) were adapted by QSEN faculty members and defined by describing essential features of a competent and respected nurse. They

BOX 1-9 Institute of Medicine QSEN Competencies for Nursing

- Client-centered care
- Teamwork
- Collaboration
- Evidence-based practice
- Quality improvement
- Safety
- Informatics

Data from Institute of Medicine. (2003). *Health professions education: A bridge to quality*. Washington, DC: National Academies Press.

then developed knowledge, skills, and attitudes (KSAs) for each competency. Incorporation of these KSAs into prelicensure education for nurses helps faculty to plan learning experiences to prepare respected and qualified nurses. In this text, QSEN competencies are incorporated into the evidence-based practice boxes.

Teamwork and Communication

Situation, Background, Assessment, Recommendation

The situation, background, assessment, recommendation (SBAR) technique gives a specific framework for communication among health care providers about a client's condition. SBAR is an easy to remember, useful, concrete mechanism for communicating important information that requires a clinician's immediate attention (Kaiser Permanente of Colorado, 2014 (Table 1-1)). Failure to communicate is one of the major reasons for errors in health care. The SBAR technique has the potential to serve as a means to reduce errors.

TeamSTEPPS

TeamSTEPPS (Team Strategies to Enhance Performance and Patient Safety) was developed by the Department of Defense's Patient Safety Program in collaboration with the AHRQ as a teamwork system for health professionals to provide higher quality, safer client care (AHRQ, n.d.). It provides an evidence base to improve communication and teamwork skills. Through this system medical teams use information, people, and resources to achieve the best possible clinical outcomes, increase team awareness and clarify roles and responsibilities of team members, resolve conflicts and improve sharing of information, and eliminate barriers to quality and safety.

The three phases of the TeamSTEPPS delivery system are to: (1) assess the need, (2) plan, train, and implement the TeamSTEPPS initiative, and (3) sustain the improvements in

performance, processes, and outcomes that result from the initiative. Teams of trainers should include physicians, nurses, and support staff. Evaluation and revision of the plan as the needs change are built in to the system (AHRQ).

ETHICAL ISSUES IN PERINATAL NURSING AND WOMEN'S HEALTH CARE

Ethical concerns and debates have multiplied with the increased use of technology and with scientific advances. For example, with reproductive technology, pregnancy is now possible in women who thought they would never bear children, including some who are menopausal or postmenopausal. Should scarce resources be devoted to achieving pregnancies in older women? Is giving birth to a child at an older age worth the risks involved? Should older parents be encouraged to conceive a baby when they may not live to see the child reach adulthood? Should a woman who is HIV positive have access to assisted reproduction services? Should third-party payers assume the costs of reproductive technology such as the use of induced ovulation and in vitro fertilizations? With induced ovulation and in vitro fertilization, multiple pregnancies occur, and multifetal pregnancy reduction (selectively terminating one or more fetuses) may be considered.

Questions about informed consent and allocation of resources must be addressed with innovations such as intrauterine fetal surgery, fetoscopy, therapeutic insemination, genetic engineering, stem cell research, surrogate childbearing, surgery for infertility, "test tube" babies, fetal research, and treatment of very LBW (VLBW) babies.

The introduction of long-acting contraceptives has created moral choices and policy dilemmas for health care providers and legislators; that is, should some women (substance abusers, women with low incomes, or women who are HIV positive) be required to take these contraceptives? With the potential for great good that can come from fetal tissue transplantation, what research is ethical? What are the rights of the embryo? Should cloning of humans be permitted? Discussion and debate about these issues will continue for many years. Nurses and clients as well as scientists, physicians, attorneys, lawmakers, ethicists, and clergy must be involved in the discussions.

RESEARCH IN PERINATAL NURSING AND WOMEN'S HEALTH CARE

Research plays a vital role in establishing maternity and women's health science. It can validate that nursing care makes a difference. For example, although prenatal care is clearly associated with healthier infants, no one knows exactly which nursing interventions produce this outcome. The research into women's health must increase. In the past, medical researchers rarely included women in their studies, so more research in this area is crucial. Many possible areas of research exist in maternity and women's health care. The clinician can identify problems in the health and health care of women and infants. Through research, nurses can make a difference for these clients. Nurses should promote research funding and conduct research on maternity and women's health, especially concerning the effectiveness of nursing strategies for these clients.

TABLE 1-1 Sample SBAR Report to Physician or Midwife about A Critical Situation

S	Situation I am calling about Mary Smith. I have just assessed her and she saturated a peripad in the last hour. Her blood pressure is 112/62, pulse 86, and respirations 18. I think she is bleeding excessively.
B	Background Mrs. Smith is 12 hours postpartum after giving birth vaginally to a 9 lb, 12 oz term infant after an uncomplicated pregnancy. She had a rapid labor, just over 4 hours, and had no analgesia. She plans to bottle-feed this baby. She had an IV with 10 units of Pitocin but it was completed and discontinued about 2 hours ago. This is her sixth birth. All were uncomplicated and she had an uneventful recovery from them.
A	Assessment Her fundus becomes firm after massage but relaxes again. She has voided and her bladder feels empty. I think she might have retained placenta and she needs to be examined.
R	Recommendation I would like you to come and examine her immediately. Do you want her IV restarted? Do you want her to have an Hb and HCT?

Hb, Hemoglobin; HCT, hematocrit; IV, intravenous.

The SBAR tool was developed by Kaiser Permanente. This example was prepared by Shannon Perry.

Ethical Guidelines for Nursing Research

Research with perinatal clients may create ethical dilemmas for the nurse. For example, participating in research may cause additional stress to a woman concerned about outcomes of genetic testing or one who is waiting for an invasive procedure. Obtaining amniotic fluid samples or performing cordocentesis poses risks to the fetus. Nurses must protect the rights of human subjects (i.e., clients) in all of their research. For example, nurses

can collect data on or care for clients who are participating in clinical trials. The nurse ensures that the participants are fully informed and aware of their rights as subjects. The nurse can be involved in determining whether the benefits of research outweigh the risks to the mother and the fetus. Following the ANA ethical guidelines in the conduct, dissemination, and implementation of nursing research helps nurses ensure that research is conducted ethically.

KEY POINTS

- Maternity nursing focuses on women and their infants and families during the childbearing cycle.
- Women's health nursing focuses on the special physical, psychologic, and social needs of women throughout their life spans.
- *Healthy People 2020* provides an update on goals for maternal and infant health.
- Nurses caring for women can play an active role in shaping health care systems to be responsive to the needs of contemporary women.
- Childbirth practices have changed to become more focused on the family and allow alternatives in care.
- A variety of factors, including race, age, violence, and human trafficking affect women's health.
- Canada ranks twenty-ninth and the United States ranks thirty-first among industrialized nations in infant mortality rates.
- Evidence-based practice and outcomes orientation are emphasized in current practice.
- Risk management and learning from sentinel events can improve quality of care.
- Research plays a vital role in establishing a scientific base for the care of women and infants.
- Ethical concerns have multiplied with the increasing use of technology and scientific advances.

Community Care: The Family and Culture

Raquel Martinez-Campos

© <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Describe the main characteristics of contemporary family forms.
- Identify key factors influencing family health.
- Compare theoretic approaches for working with childbearing families.
- Relate the impact of culture on childbearing families.
- Discuss cultural competence in relation to one's own nursing practice.
- Identify key components of the community assessment process.
- List indicators of community health status and their relevance to perinatal health.
- Describe data sources and methods for obtaining information about community health status.
- Identify predisposing factors and characteristics of vulnerable populations.
- List the potential advantages and disadvantages of home visits.
- Explore telephonic nursing care options in perinatal nursing.
- Describe how home care fits into the maternity continuum of care.
- Describe the nurse's role in perinatal home care.

INTRODUCTION TO FAMILY, CULTURE, COMMUNITY, AND HOME CARE

The composition, structure, and function of the American family have changed dramatically in recent years, largely in response to economic, demographic, sociocultural, and technologic trends that influence family life and health. Despite current efforts to improve the overall health of the nation, there is widespread concern about family health and well-being as a reflection of individual, community, and national health status. Recent economic changes have further reduced the ability to access health care. The Patient Protection and Affordable Care Act (ACA) signed into law in 2010 aims to make insurance affordable, contain costs, strengthen and improve Medicare and Medicaid, and reform the insurance market. In addition to facing significant barriers in accessing needed services, women and families are faced with the challenge of overcoming discrimination in health care practices. It is critical to consider racial and ethnic differences and sexual orientation when addressing the health status of women. American women with a minority racial or ethnic affiliation share poorer outcomes in a wide variety of conditions. Lesbian women may conceal sexual orientation for fear of discrimination. As cultural diversity increases and demographics change, nurses must become culturally competent in order

to recognize and reduce or eliminate health disparities (Freund, 2012).

Trends in maternal and infant health in the United States reveal that progress has been made in relation to reduced infant and fetal deaths and use of prenatal care (see Chapter 1). Although progress has been made, low-birth-weight, preterm birth, and infant mortality rates fell short of the *Healthy People 2010* target goals, therefore remaining as high priority areas for *Healthy People 2020*. Among the nation's most pressing challenges are reducing the rate of preterm births and reducing the infant death rate, which in 2011 remained higher than the infant death rate in 46 other countries (U.S. Department of Health and Human Services [HHS], 2013). Because many of these outcomes are preventable through access to prenatal care, the use of preventive health practices clearly demonstrates the need for comprehensive community-based care for mothers, infants, and families. As perinatal health trends emerge, nurses are assuming greater roles in assessing family health status and providing care across the perinatal continuum. This continuum begins with family planning and continues with the following categories of care: preconception (before pregnancy), prenatal, intrapartum, postpartum, newborn, interconception (between pregnancies), and the child from infancy to 1 year of age. In the community, health care ranges from individual care to

group and community services and from primary prevention to tertiary care experiences and home health. Depending on the needs of the individual family unit, independent self-management, outpatient care, home care, low risk hospitalization, or specialized intensive care may be appropriate at different points along this continuum.

In community-based health care, both the population (group of people who may or may not interact with each other) and the aggregate (group of people within the larger population who possess some common characteristics) become the focus of intervention. Health professionals are required not only to determine health priorities but also develop successful plans of care to be delivered in the health clinic, the community health center, or the client's home (see Community Activity). This home- and community-based delivery system presents unique challenges for perinatal and maternity nurses.

COMMUNITY ACTIVITY

- Visit the Health Resources and Services Administration (HRSA) website at www.communityhealth.hrsa.gov. What is the definition of a health center by the HRSA? What populations do they serve? What are the different types of health centers?
- Locate a health center in your community at the HRSA website. What types of services do they provide? Do they provide primary and preventive maternal and women's health services? Is care provided regardless of a client's ability to pay?
- Visit your state center for health statistics (SCHS) website. Evaluate the health status of women and infants in your county. Vital statistics include live births, physician versus midwife attended births, out of wedlock births, cesarean births, low birth weight, maternal smoking, and fetal/infant mortality.

THE FAMILY IN CULTURAL AND COMMUNITY CONTEXT

The family and its cultural context play an important role in defining the work of maternity nurses. Despite modern stresses and strains, the family forms a social network that acts as a potent support system for its members. Family health-seeking behavior and relationships with providers are greatly influenced by culturally related health beliefs and values. Ultimately all of these factors have the power to affect maternal and child health outcomes. **The current emphasis in working with families is on wellness and empowerment for families to achieve control over their lives. It is therefore essential that nurses become culturally competent in order to provide the most appropriate care possible.**

Defining Family

The family has traditionally been viewed as the primary unit of socialization—the basic structural unit within a community. Being the oldest and most persistent of all social institutions, the family plays a pivotal role in health care, representing the primary target of health care delivery for maternal and newborn nurses. As one of society's most important institutions, the family represents a primary social group that influences and is influenced by other people and institutions. A variety of family

FIG 2-1 Nuclear family. (Courtesy Makeba Felton, Wake Forest, NC.)

configurations exist. Each of these is characterized by certain structural features.

Family Organization and Structure

The **nuclear family** has long represented the traditional American family in which husband, wife, and their children (either biologic or adopted) live as an independent unit, sharing roles, responsibilities, and economic resources (Fig. 2-1). Today the number of families living in a nuclear family structure is steadily decreasing in response to societal changes. By race and Hispanic origin, this family structure is represented as follows (Lofquist, Lugaila, O'Connell, M. & Feliz, 2012):

- Caucasian: 51.1%
- Hispanic: 50.1%
- African-American: 28.5%
- Asian: 59.7%
- American Indian and Alaska Native: 40.1%
- Native Hawaiian and Pacific Islander: 51.3%

According to the 2010 U.S. Vital and Health Statistics, 48.4% of children younger than the age of 18 live in a nuclear family. The percent distribution for non-Hispanic black children was 20.5%, 41% for Hispanic children, and 57.3% for non-Hispanic white children (Blackwell, 2010).

Many nuclear families have other relatives living in the same household. These extended family members include grandparents, aunts, uncles, or other people related by blood. Members of extended families can also live in close proximity to the nuclear family (Fig. 2-2). Due to societal changes, internet access, increased mobility, these families may also be a long-distance unit. **For some groups, such as African-American and Hispanic-American, extended family is an important resource in terms of preventive health behavior. The extended family is becoming more common as American society ages.** The extended family provides social, emotional, and financial support to one another. It is therefore important for nurses to recognize the desire for people of many cultures to include their family in making important decisions. This has implications for privacy and sharing individual health information under Health Insurance Portability and Accountability Act (HIPAA) rules.

FIG 2-2 Extended family. (Courtesy Raquel Martinez-Campos, Lake Forest, CA.)

Multigenerational families consisting of three or more generations of relatives (grandparents, children, and grandchildren) are becoming increasingly common. In 2010 they made up 4.4% of all households (Lofquist et al., 2012). This type of arrangement can create stress for some because children must care for their parents as well as their own children. Other types of multigenerational families consist of grandparents supporting the children and grandchildren or as sole caregivers for the grandchildren.

No-parent families are those in which children live independently in foster or kinship care such as living with a grandparent. An estimated 5.4 million children in the United States live with a grandparent. Of these grandparents, 2.7 million are responsible for most of the basic needs (i.e., food, shelter, and clothing) of one or more grandchildren (U.S. Census Bureau, 2011a).

Married-blended families, those formed as a result of divorce and remarriage, consist of unrelated family members (stepparents, stepchildren, and stepsiblings) who join to create a new household. These family groups frequently involve a biologic or adoptive parent whose spouse may or may not have adopted the child.

Cohabiting-parent families are those in which children live with two unmarried biologic parents or two adoptive parents. Hispanic children are more than twice as likely as African-American children to live in cohabiting-parent families and about four times as likely as Caucasian children to live in this kind of family arrangement (Lofquist et al., 2012).

Single-parent families comprise an unmarried biologic or adoptive parent who may or may not be living with other adults. The single-parent family may result from the loss of a spouse by death, divorce, separation, or desertion; from either an unplanned or planned pregnancy; or from the adoption of a child by an unmarried woman or man. This family structure is continually on the rise. In 2012 according to the U.S. Census Bureau, 24% of children lived with only their mothers, 4% lived with only their fathers, and 4% lived with neither of their parents (America's Children, 2013).

The single-parent family tends to be vulnerable economically and socially, which can create an unstable and deprived environment for the growth of children. This in turn affects health status, school achievement, and high risk behaviors for

these children (Scharte & Bolte, 2012). Alternatively some families become more stable with the absence of drugs, alcohol, and/or physical/emotional abuse.

Homosexual families (lesbian, gay, bisexual, and transgender [LGBT]) may live together with or without children. Usually formed by same-sex couples, they can also consist of single LGBT parents or multiple parenting figures. Children in LGBT families may be the offspring of previous heterosexual unions, conceived by one member of a lesbian couple through natural or therapeutic insemination, conceived by a gay couple using a surrogate, or adopted. Approximately 594,000 same-sex couple households lived in the United States in 2010, raising about 115,000 children ages less than 18 years. When these children are combined with LGBT parents who are raising children, almost 2 million children are being raised by LGBT parents in the United States (Siegel & Perrin, 2013).

The Family in Society

The social context for the family can be viewed in relation to social and demographic trends that define the population as a whole. Racial and ethnic diversity of the population has grown dramatically, necessitating consideration of such diversity in provision of health care. According to the 2010 U.S. Census, approximately 36.3% of the population belongs to a racial or ethnic minority group (Centers for Disease Control and Prevention [CDC], 2013a).

THEORETIC APPROACHES TO UNDERSTANDING FAMILIES

Family Nursing

Family plays a pivotal role in health care, representing the primary target of health care delivery for maternal and newborn nurses. It is crucial that nurses assist families as they incorporate new additions to their family (see Nursing Care Plan). When treating the woman and family with respect and dignity, health care providers listen to and honor perspectives and choices of the woman and family. They share information with families in ways that are positive, useful, timely, complete, and accurate. The family is supported in participating in the care and decision making at the level of their choice.

Because so many variables affect ways of relating, the nurse must be aware that family members may interact and communicate with each other in ways that are distinct from those of the nurse's own family of origin. Most families will hold some beliefs about health that are different from those of the nurse. Their beliefs can conflict with principles of health care management predominant in the Western health care system.

Family Theories

A family theory can be used to describe families and how the family unit responds to events both within and outside the family. Each family theory makes certain assumptions about the family and has inherent strengths and limitations. Most nurses use a combination of theories in their work with families. A brief synopsis of several theories useful in working with families is included in Table 2-1. Application of these concepts can guide assessment and interventions for the family.

NURSING CARE PLAN

Incorporating the Infant into the Family

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<p><i>Readiness for Enhanced Family Coping related to adaptation of family to new infant</i></p>	<p>Family members will verbalize that individual and family goals are met during a smooth transition of new family member into the home.</p>	<p>Assess type and amount of support available to family on daily basis during postpartum period.</p> <p>Encourage family to use past successful coping mechanisms.</p> <p>Encourage mother to use family and other support or services.</p> <p>Suggest that woman take time to rest when infant sleeps.</p> <p>Assess family structure and relationships, including culture.</p> <p>Teach family about sensory needs and capabilities of infant.</p> <p>Refer to parent support group or community agencies, as needed.</p>	<p>To facilitate adaptation of family to situation of a new member</p> <p>To enhance ability to cope with new situation and promote self-esteem</p> <p>To carry out daily household tasks to permit her to focus on herself and infant</p> <p>To conserve energy for healing and limit responsibility to herself and infant</p> <p>To evaluate if longer period of adjustment may be expected</p> <p>To motivate family to meet infant's needs and set realistic expectations for infant's capabilities</p> <p>To facilitate and validate ongoing positive adjustment of family to new family member</p>
<p><i>Ineffective Role Performance related to developmental challenge of addition of new family member</i></p>	<p>Each family member will verbalize realistic expectations regarding his or her role in the family and formulate a plan to incorporate the role into overall family goals.</p>	<p>Assess family structure, roles, and each member's perception of his or her role in family.</p> <p>Evaluate individual's perception of goals and new roles during this transition.</p> <p>Encourage discussion of family members' thoughts and feelings regarding this transition.</p> <p>Provide positive reinforcement for family members' actions that promote positive environment for infant.</p> <p>Refer to community support groups.</p> <p>Give information about sibling and grandparent classes and support groups as available.</p>	<p>To evaluate impact of new member on structure and roles of family as perceived by members</p> <p>To promote early intervention and correct any misinterpretation</p> <p>To promote open communication and trust</p> <p>To increase self-esteem and provide encouragement</p> <p>To provide group reinforcement and further assistance</p> <p>To promote empowerment and self-esteem for significant others in family</p>

Family Assessment

When selecting a family assessment framework, an appropriate model for a perinatal nurse is one that is a health-promoting rather than an illness-care model. The low risk family can be assisted in promoting a healthy pregnancy, childbirth, and integration of the newborn into the family. The high risk perinatal family has illness-care needs, and the nurse can help to meet those needs while also promoting the health of the childbearing family.

A family assessment tool such as the Calgary Family Assessment Model (CFAM) (Box 2-1) can be used as a guide for assessing aspects of the family. Such an assessment is based on "the nurse's personal and professional life experiences, beliefs, and relationships with those being interviewed" (Wright & Leahey, 2012) and is not "the truth" about the family but, rather, one perspective at one point in time.

The CFAM comprises three major categories: structural, developmental, and functional. Several subcategories are within

each category. The three assessment categories and the many subcategories can be conceptualized as a branching diagram (Fig. 2-3). The categories and subcategories can be used to guide the assessment that will provide data to help the nurse better understand the family and formulate a nursing care plan. The nurse asks questions of family members about themselves to gain understanding of the structure, development, and function of the family at this point in time. Not all questions within the subcategories should be asked at the first interview, and some questions may not be appropriate for all families. Although individuals are the ones interviewed, the focus of the assessment is on interaction of individuals within the family.

Graphic Representations of Families

A family *genogram* (family tree format depicting relationships of family members over at least three generations) (Fig. 2-4) provides valuable information about a family and can be placed

TABLE 2-1 Theories and Models Relevant to Family Nursing Practice

THEORY	SYNOPSIS OF THEORY
Family Systems Theory (Wright & Leahey, 2012)	The family is viewed as a unit, and interactions among family members are studied rather than studying individuals. A family system is part of a larger suprasystem and is composed of many subsystems. The family as a whole is greater than the sum of its individual members. A change in one family member affects all family members. The family is able to create a balance between change and stability. Family members' behaviors are best understood from a view of circular rather than linear causality.
Family Life Cycle (Developmental) Theory (Carter & McGoldrick, 1999)	Families move through stages. The family life cycle is the context in which to examine the identity and development of the individual. Relationships among family members go through transitions. Although families have roles and functions, a family's main value is in relationships that are irreplaceable. The family involves different structures and cultures organized in various ways. Developmental stresses may disrupt the life cycle process.
Family Stress Theory (Boss, 1996)	How families react to stressful events is the focus. Family stress can be studied within the internal and external contexts in which the family is living. The internal context involves elements that a family can change or control, such as family structure, psychological defenses, and philosophic values and beliefs. The external context consists of the time and place in which a particular family finds itself and over which the family has no control, such as the culture of the larger society, the time in history, the economic state of society, maturity of the individuals involved, success of the family in coping with stressors, and genetic inheritance.
McGill Model of Nursing (Allen, 1997; Gottlieb & Gottlieb, 2007)	Strength-based approach in clinical practice with families, as opposed to a deficit approach, is the focus. Identification of family strengths and resources, provision of feedback about strengths, and assistance given to family to develop and elicit strengths and use resources are key interventions.
Health Belief Model (Becker, 1974; Janz & Becker, 1984)	The goal of the model is to reduce cultural and environmental barriers that interfere with access to health care. Key elements of the Health Belief Model include the following: perceived susceptibility, perceived severity, perceived benefits, perceived barriers, cues to action, and confidence.
Human Developmental Ecology (Bronfenbrenner, 1979; 1989)	Behavior is a function of interaction of traits and abilities with the environment. Major concepts include ecosystem, niches (social roles), adaptive range, and ontogenetic development. Individuals are "embedded in a microsystem [role and relations], a mesosystem [inter-relations between two or more settings], an exosystem [external settings that do not include the person], and a macrosystem [culture]" (Klein & White, 1996). Change over time is incorporated in the chronosystem.

BOX 2-1 Calgary Family Assessment Model

There are three major categories of the Calgary Family Assessment Model (CFAM): structural, developmental, and functional. Each category has several subcategories. In this box only the major categories are listed. A few sample questions are included.

Structural Assessment

Determine the members of the family, relationship among family members, and context of family.

Genograms and ecomaps (see Figs. 2-4; 2-5) are useful in outlining the internal and external structures of a family.

Sample Questions

- Who are the members of your family?
- Has anyone moved in or out lately?
- Are there any family members who don't live with you?

Developmental Assessment

Describe the life cycle—that is, the typical trajectory that most families experience.

Sample questions

- Is your family the size you wanted?
- When you think back, what do you most enjoy about your life?
- What do you regret about your life?
- Have you made plans for your care as your health declines?

Functional Assessment

Evaluate the way in which individuals behave in relation to each other in instrumental and expressive aspects. (Instrumental aspects are activities of daily living; expressive aspects include communication, problem solving, roles, etc.)

Sample questions

- Which one of the family is responsible for helping with the children while the mother is caring for the newborn?
- Whose turn is it to do the shopping and fix dinner for the family?
- How can we get more family involvement in care of the household?

Data from Wright, L.M., & Leahey, M. (2012). *Nurses and families: A guide to family assessment and intervention* (6th ed.). Philadelphia: F.A. Davis.

in the nursing care plan for easy access by care providers. An *ecomap*, a graphic portrayal of social relationships of the women and family, may also help the nurse understand the social environment of the family and identify support systems available to them (Fig. 2-5). Software is available to generate genograms and ecomaps (www.interpersonaluniverse.net).

THE FAMILY IN A CULTURAL CONTEXT

Cultural Factors Related to Family Health

The culture of an individual and a group is influenced by religion, environment, and historic events and plays a powerful role in the individual's and group's behavior and patterns of

human interaction. Culture is not static; it is an ongoing process that influences a woman throughout her entire life, from birth to death. Culture is an essential element of what defines us as people.

Cultural knowledge includes beliefs and values about each facet of life and is passed from one generation to the next. Cultural beliefs and traditions relate to food, language, religion, art, health and healing practices, kinship relationships, and all other aspects of community, family, and individual life. Culture has also been shown to have a direct effect on health behaviors. Values, attitudes, and beliefs that are culturally acquired may influence perceptions of illness, as well as health care-seeking behavior and response to treatment. The political, social, and

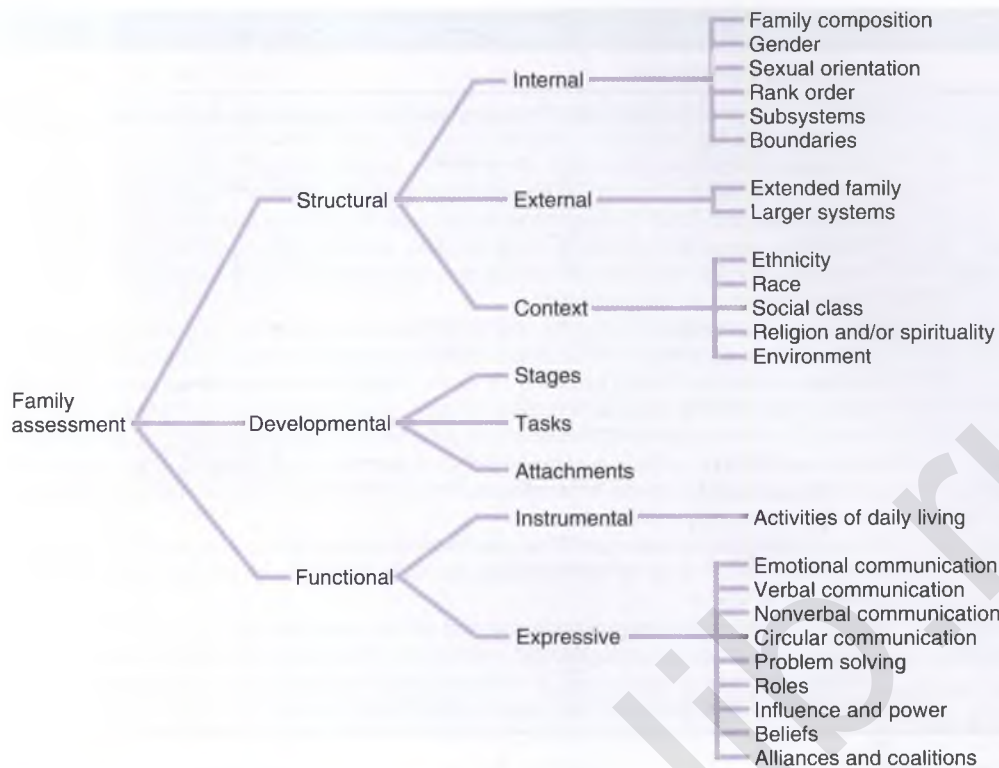

FIG 2-3 Branching diagram of Calgary Family Assessment Model (CFAM). (From Wright, L.M., & Leahey, M. [2012]. *Nurses and families: a guide to family assessment and intervention* [6th ed.]. Philadelphia: FA Davis).

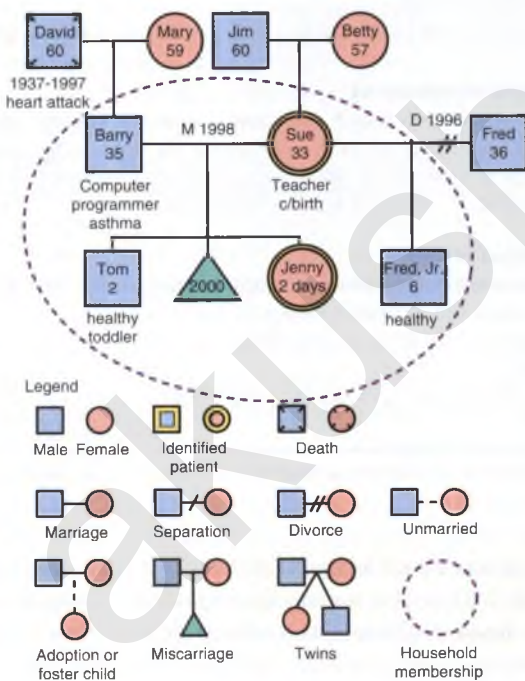

FIG 2-4 Example of a family genogram.

procedures, as well as patterns of human interaction and expressions of emotion. The effect of these influences must be assessed by health care professionals in providing health care and developing effective intervention strategies.

Many subcultures may be found within each culture. **Subculture** refers to a group existing within a larger cultural system that retains its own characteristics. A subculture may be an ethnic group or a group organized in other ways. For example, in the United States and Canada, many ethnic subcultures such as African-Americans, Asian-Americans, Hispanic-Americans, and Native Americans exist. It is important to note that subcultures also exist within these groups. In addition, the Caucasian population in America has multiple subcultures of its own. Because every identified cultural group has subcultures and because it is impossible to study every subculture in depth, greater differences may exist among and between groups than is generally acknowledged. It is important to be familiar with common cultural practices within these subgroups. However, it is also important to avoid the generalization that every person practices every cultural belief within a group.

In a multicultural society, many groups can influence traditions and practices. As cultural groups come into contact with each other, acculturation and assimilation may occur.

Acculturation refers to the changes that occur within one group or among several groups when people from different cultures come into contact with one another. People may retain some of their own culture while adopting cultural practices of the dominant society. This familiarization among cultural groups results in overt behavioral similarity, especially in mannerisms, styles, and practices. Dress, language patterns,

economic context of people's lives is also part of the cultural experience.

Culture, shared beliefs and values of a group, plays a powerful role in an individual's behavior, particularly when the individual is sick. Understanding a culture can provide insight into how a person reacts to illness, pain, and invasive medical

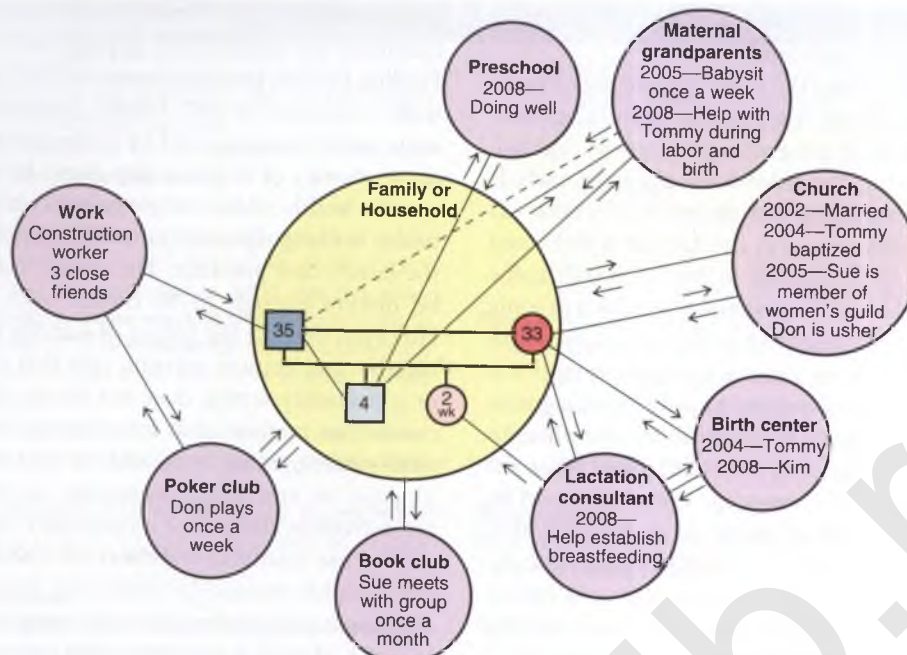

FIG 2-5 Example of an ecomap. An ecomap describes social relationships and depicts available supports.

food choices, and health practices are often much slower to adapt to the influence of acculturation. In the United States, second-generation Americans consider themselves to be fully American (Pew Research Center, 2013).

During times of family transitions such as childbearing, or during crisis or illness, a woman may rely on old cultural patterns even after becoming acculturated in many ways. This is consistent with the family developmental theory (Carter & McGoldrick, 1999) that states that during times of stress, people revert to practices and behaviors that are most comfortable and familiar.

Assimilation occurs when a cultural group loses its cultural identity and becomes part of the dominant culture. Assimilation is the process by which groups “melt” into the mainstream, thus accounting for the notion of a “melting pot,” a phenomenon that has been said to occur in the United States. This is illustrated by individuals who identify themselves as being of Irish or German descent, without having any remaining cultural practices or values linked specifically to that culture such as food preparation techniques, style of dress, or proficiency in the language associated with their reported cultural heritage. Spector (2013) asserts that in the United States, the melting pot, with its dream of a common culture, is a myth. Instead, a mosaic phenomenon exists in which we must accept and appreciate the differences among people.

Implications for Nursing

As our society becomes more culturally diverse, it is essential that nurses become culturally competent. Nurses must examine their own beliefs so that they have a better appreciation and understanding of their clients’ beliefs. Understanding the concepts of ethnocentrism and cultural relativism can help nurses care for families in a multicultural society.

Ethnocentrism is the view that one’s own culture’s way of doing things is best (Giger, 2013). Although the United States

is a culturally diverse nation, the prevailing practice of health care is based on the beliefs and practices held by members of the dominant culture, primarily Caucasians of European descent. This practice is based on the biomedical model that focuses on curing disease states.

Pregnancy and childbirth, in this biomedical perspective, are viewed as processes with inherent risks that are most appropriately managed by using scientific knowledge and advanced technology. The medical perspective stands in direct contrast with the belief systems of many cultures. Among many women, birth is viewed as a completely normal process that can be managed with a minimum of involvement from health care practitioners. When encountering behavior in women unfamiliar with the biomedical model or those who reject it, the nurse may become frustrated and impatient and may label the women’s behavior as inappropriate and believe that it conflicts with “good” health practices. If the Western health care system provides the nurse’s only standard for judgment, the behavior of the nurse is ethnocentric.

Cultural relativism is the opposite of ethnocentrism. It refers to learning about and applying the standards of another’s culture to activities within that culture. The nurse recognizes that people from different cultural backgrounds comprehend the same objects and situations differently. In other words, **culture determines viewpoint**. Cultural relativism does not require nurses to accept the beliefs and values of another culture. Instead, nurses recognize that the behavior of others can be based on a system of logic different from their own. **Cultural relativism affirms the uniqueness and value of every culture.**

Childbearing Beliefs and Practices

Nurses working with childbearing families care for families from many different cultures and ethnic groups. To provide culturally competent care the nurse must assess clients’ beliefs and practices. When working with childbearing families, a

nurse considers all aspects of culture, including communication, space, time orientation, and family roles.

Communication often creates the most challenging obstacle for nurses working with clients from diverse cultural groups. Communication is not merely the exchange of words. Instead, it involves (1) understanding the individual's language, including subtle variations in meaning and distinctive dialects; (2) appreciating individual differences in interpersonal style; and (3) accurately interpreting the volume of speech as well as the meanings of touch and gestures. For example, members of some cultural groups tend to speak loudly when they are excited, with great emotion and with vigorous and animated gestures; this is true whether their excitement is related to positive or negative events or emotions. It is important therefore for the nurse to avoid rushing to judgment regarding a person's intent when the client is speaking, especially in a language not understood by the nurse. Instead, the nurse should withhold an interpretation of what has been expressed until it is possible to clarify the client's intent. The nurse needs to enlist the assistance of a person who can help verify with the client the true intent and meaning of the communication (see Clinical Reasoning Case Study).

CLINICAL REASONING CASE STUDY

Providing Culturally Appropriate Care

Elisabeth, a 22-year-old first-generation Mexican-American, comes into your office for her initial prenatal visit. You are concerned because Elisabeth's fundal height is consistent with 32 weeks of gestation and this is her first prenatal visit. Elisabeth, who lives with her husband, four children (ages 6, 4, and 3 years and 15 months), her mother, her aunt, and her uncle, states that she has been doing well this pregnancy and did not start prenatal care in her previous pregnancies until she was almost ready to give birth. She also comments that all the babies were full term with uneventful labors and births. In obtaining the history you note the presence of a safety pin in Elisabeth's shirt and wonder what this is for. You want to provide culturally competent care to this woman and her family.

1. Evidence—Is there sufficient evidence to support the components of culturally competent care for Elisabeth?
2. Assumptions—Describe an underlying assumption about culturally competent care for Elisabeth in relation to these topics:
 - a. The view of pregnancy in Elisabeth's culture
 - b. The role of family in Elisabeth's culture
 - c. The acceptability for women of Elisabeth's age to begin having children at such young ages
 - d. The religious beliefs that Elisabeth may have that affect contraception
3. What implications and priorities for nursing care can be made at this time?
4. Does the evidence objectively support your conclusion?

Inconsistencies between the language of clients and the language of providers present a significant barrier to effective health care. For example, there are many dialects of Spanish that vary by geographic location. Because of the diversity of cultures and languages within the U.S. and Canadian populations, health care agencies are increasingly seeking the services of *interpreters* (of oral communication from one language to another) or *translators* (of written words from one language

to another) to bridge these gaps and fulfill their obligation for culturally and linguistically appropriate health care (Box 2-2). Finding the best possible interpreter in the circumstance is critically important as well. Ideally, interpreters should have the same native language and be of the same religion or have the same country of origin as the client. Interpreters should have specific health-related language skills and experience and help bridge the language and cultural barriers between the client and the health care provider. The person interpreting also should be mature enough to be trusted with private information. However, because the nature of nursing care is not always predictable and because nursing care that is provided in a home or community setting does not always allow for expert, experienced, or mature adult interpreters, ideal interpretative services sometimes are impossible to find when they are needed. In crisis or emergency situations, or when family members are extremely stressed or emotionally upset, it may be necessary to use relatives, neighbors, or children as interpreters. If this situation occurs, the nurse must ensure that the client is in agreement and comfortable with using the available interpreter to assist. Having a man or a child interpret for a woman may create embarrassment and interfere with obtaining an accurate history or detail of symptoms.

When using an interpreter the nurse respects the family by creating an atmosphere of respect and privacy. Questions should be addressed to the woman and not to the interpreter. Even though an interpreter will of necessity be exposed to sensitive and privileged information about the family, the nurse should take care to ensure that confidentiality is maintained. A quiet location free from interruptions is ideal for interpretive services to take place. Culturally and linguistically appropriate educational materials that are easy to read, with appropriate text and graphics, should be available to assist the woman and her family in understanding health care information. To ensure understanding and avoid liability issues, it is important to make certain that the material has been translated by someone who is trained appropriately.

Personal Space

Cultural traditions define the appropriate personal space for various social interactions. Although the need for personal space varies from person to person and with the situation, the actual physical dimensions of comfort zones and taboos differ from culture to culture. Actions such as touching, placing the woman in proximity to others, taking away personal possessions, and making decisions for the woman can decrease personal security and heighten anxiety. Conversely, respecting the need for distance allows the woman to maintain control over personal space and support personal autonomy, thereby increasing her sense of security. Nurses must touch clients; however, they frequently do so without any awareness of the emotional distress they may be causing clients.

Time Orientation

Time orientation is a fundamental way in which culture affects health behaviors. People in cultural groups may be relatively more oriented to past, present, or future. Those who focus on the past strive to maintain tradition or the status quo and have little motivation for formulating goals. In contrast, individuals who focus primarily on the present neither plan for the future

BOX 2-2 Working with an Interpreter**Step 1: Before the interview**

- A. Outline your statements and questions. List the key pieces of information you want/need to know.
- B. Learn something about the culture so that you can converse informally with the interpreter.

Step 2: Meeting with the interpreter

- A. Introduce yourself to the interpreter and converse informally. This is the time to find out how well he or she speaks English. No matter how proficient or what age the interpreter is, be respectful. Some ways to show respect are to ask a cultural question to acknowledge that you can learn from the interpreter, or you could learn one word or phrase from the interpreter.
- B. Emphasize that you do want the client to ask questions, because some cultures consider this inappropriate behavior.
- C. Make sure the interpreter is comfortable with the technical terms you need to use. If not, take some time to explain them.

Step 3: During the interview

- A. Ask your questions and explain your statements (see Step 1).
- B. Make sure that the interpreter understands which parts of the interview are most important. You usually have limited time with the interpreter, and you want to have adequate time at the end for client questions.
- C. Try to get a feel for how much is "getting through." No matter what the language is, if in relating information to the client, the interpreter uses far fewer or far more words than you do, something else is going on.
- D. Stop every now and then and ask the interpreter, "How is it going?" You may not get a totally accurate answer, but you will have emphasized to the interpreter your strong desire

to focus on the task at hand. If there are language problems (1) speak slowly; (2) use gestures (e.g., fingers to count or point to body parts); and (3) use pictures.

- E. Ask the interpreter to elicit questions. This may be difficult, but it is worth the effort.
- F. Identify cultural issues that may conflict with your requests or instructions.
- G. Use the interpreter to help problem solve or at least give insight into possibilities for solutions.

Step 4: After the interview

- A. Speak to the interpreter and try to get an idea of what went well and what could be improved. This will help you to be more effective in the future with this or another interpreter.
- B. Make notes on what you learned for your future reference or to help a colleague.

Remember

Your interview is a *collaboration* between you and the interpreter. *Listen* as well as speak.

NOTES:

1. The interpreter may be a child, grandchild, or sibling of the client. Be sensitive to the fact that the child is playing an adult role.
2. Be sensitive to cultural and situational differences (e.g., an interview with someone from urban Germany will likely be different from an interview with someone from a transitional refugee camp).
3. Younger females telling older males what to do may be a problem for both a female nurse and a female interpreter. This is not the time to pioneer new gender relations. Be aware that in some cultures it is difficult for a woman to talk about some topics with a husband or a father present.

Courtesy Elizabeth Whalley, PhD, San Francisco State University.

nor consider the experiences of the past. These individuals do not necessarily adhere to strict schedules and are often described as "living for the moment," or "marching to their own drummer." Individuals oriented to the future maintain a focus on achieving long-term goals.

The time orientation of the childbearing family can affect nursing care. For example, talking to a family about bringing the infant to the clinic for follow-up examinations (events in the future) may be difficult for the family that is focused on the present concerns of day-to-day survival. Because a family with a future-oriented sense of time plans far in advance, thinking about the long-term consequences of present actions, they may be more likely to return as scheduled for follow-up visits. Despite the differences in time orientation, each family can be equally concerned for the well-being of its newborn.

Family Roles

Family roles involve the expectations and behaviors associated with a member's position in the larger family system (e.g., mother, father, grandparent). Social class and cultural norms also affect these roles, with distinct expectations for men and women clearly determined by social norms. For example, culture may influence whether a man actively participates in the pregnancy and childbirth, yet maternity care practitioners working in the Western health care system

**CULTURAL CONSIDERATIONS****Questions to Ask to Elicit Cultural Expectations About Childbearing**

1. What do you and your family think you should do to remain healthy during pregnancy?
2. What can you do to improve your health and the health of your baby?
3. What foods will help make a healthy baby?
4. Who do you want with you during your labor?
5. What can your labor support person do to help you be most comfortable during labor?
6. What actions are important for you and your family after the baby's birth?
7. What do you and your family expect from the nurse(s) caring for you?
8. How will family members participate in your pregnancy, childbirth, and parenting?

expect fathers to be involved. This can create a significant conflict between the nurse and the role expectations of very traditional Mexican or Arab families, who usually view the birthing experience as a female affair (see Cultural Considerations box). The way that health care practitioners manage such a family's care molds its experience and perception of the Western health care system.

BOX 2-3 Strategies for Care Delivery and Providing Culturally Appropriate Care

Strategies for Care Delivery

- Break down the language barriers.
- Explain your rationale and reasons for suggestions.
- Integrate folk and Western treatments.
- Enlist the family caretaker and others.
- Get consent from the right person.
- Provide language-appropriate materials.

Providing Appropriate Care

- Ask about traditional beliefs, such as the role of hot and cold.
- Be sensitive regarding interpreters and language barriers.
- Ask about important dietary practices, particularly those related to events such as childbirth.
- Ask about group practices and beliefs.
- Ask about a woman's fears, and those of her family, regarding an unfamiliar care setting.

From Mattson, S. (2000). Providing culturally competent care: Strategies and approaches for perinatal clients, *AWHONN Lifelines*, 4(5), 37-39.

In maternity nursing and women's health care, the nurse supports and nurtures the beliefs that promote physical or emotional adaptation to childbearing. However, if certain beliefs might be harmful, the nurse should carefully explore them with the woman and use them in the reeducation and modification process. Strategies for care delivery and providing appropriate care are presented in Box 2-3.

Table 2-2 provides examples of some cultural beliefs and practices surrounding childbearing.

The cultural beliefs and customs in this table are categorized on the basis of distinct cultural traditions and are not practiced by all members of the cultural group in every part of the country. Women from these cultural and ethnic groups may adhere to a few, all, or none of the practices listed. In using this table as a guide, the nurse should take care to avoid making stereotypic assumptions about any person based on sociocultural-spiritual affiliations. Nurses should exercise sensitivity in working with every family, being careful to assess the ways in which they apply their own mixture of cultural traditions.

TABLE 2-2 Traditional* Cultural Beliefs and Practices: Childbearing and Parenting

PREGNANCY	CHILDBIRTH	PARENTING
<p>Hispanic (Based primarily on knowledge of Mexican-Americans; members of the Hispanic community have their origins in Spain, Cuba, Central and South America, Mexico, Puerto Rico, and other Spanish-speaking countries.)</p>		
<p>Pregnancy Pregnancy desired soon after marriage Late prenatal care Expectant mother influenced strongly by mother or mother-in-law Cool air in motion considered dangerous during pregnancy Unsatisfied food cravings thought to cause a birthmark Some pica observed in the eating of ashes or dirt (not common) Milk avoided because it causes large babies and difficult births Many predictions about sex of baby May be unacceptable and frightening to have pelvic examination by male health care provider Use of herbs to treat common complaints of pregnancy Drinking chamomile tea thought to ensure effective labor May wear ribbon or band around pregnant belly in belief that baby will be born healthy</p>	<p>Labor Use of <i>partera</i> or lay midwife preferred in some places; may prefer presence of mother rather than husband After birth of baby, mother's legs brought together to prevent air from entering uterus Loud behavior in labor</p> <p>Postpartum Diet may be restricted after birth; for first 2 days only boiled milk and toasted tortillas permitted (special foods to restore warmth to body) Bed rest for 3 days after birth Keep warm Delay bathing Mother's head and feet protected from cold air; bathing permitted after 14 days Mother often cared for by her own mother Forty-day restriction on sexual intercourse Mother may want baby's first wet diaper to wipe her face in belief that it aids in making "mask of pregnancy" go away</p>	<p>Newborn Breastfeeding begun after third day; colostrum may be considered "filthy" or "spoiled" or just not enough nourishment Olive oil or castor oil given to stimulate passage of meconium Male infant not circumcised Female infant's ears pierced Belly band used to prevent umbilical hernia Religious medal worn by mother during pregnancy; placed around infant's neck Infant protected from <i>mal de ojo</i> ("evil eye") Various remedies used to treat <i>mal de ojo</i> and fallen fontanel (depressed fontanel)</p>
<p>African-American (Members of the African-American community, many of whom are descendants of slaves, have different origins. Today a number of black Americans have immigrated from Africa, the West Indies, the Dominican Republic, Haiti, and Jamaica. There is much diversity among countries and tribes.)</p>		
<p>Pregnancy Acceptance of pregnancy depends on economic status Pregnancy thought to be state of "wellness," which is often the reason for delay in seeking prenatal care, especially by lower-income African-Americans Old-wives' tales include beliefs that having a picture taken during pregnancy will cause stillbirth and reaching up will cause cord to strangle baby Craving for certain foods, including chicken, greens, clay, starch, and dirt Pregnancy may be viewed by African-American men as a sign of their virility</p>	<p>Labor Use of "Granny midwife" in certain parts of United States Varied emotional responses: some cry out, some display stoic behavior to avoid calling attention to selves Woman may arrive at hospital in far-advanced labor Emotional support often provided by other women, especially the woman's own mother</p> <p>Postpartum Vaginal bleeding seen as sign of sickness; tub baths and shampooing of hair prohibited Sassafras tea thought to have healing power Eating liver thought to cause heavier vaginal bleeding because of its high "blood" content</p>	<p>Newborn Feeding very important: "good" baby thought to eat well Early introduction of solid foods May breastfeed or bottle-feed; breastfeeding may be considered embarrassing Parents fearful of spoiling baby Commonly call baby by nicknames May use excessive clothing to keep baby warm Belly band used to prevent umbilical hernia Abundant use of oil on baby's scalp and skin Strong feeling of family, community, and religion</p>

TABLE 2-2 Traditional* Cultural Beliefs and Practices: Childbearing and Parenting—cont'd

<i>Pregnancy</i>	<i>Labor</i>	<i>Newborn</i>
Asian-American (Typically refers to groups from China, Korea, the Philippines, Japan, Southeast Asia [particularly Thailand], Indochina, and Vietnam)		
Pregnancy Pregnancy considered time when mother “has happiness in her body” Pregnancy seen as natural process Strong preference for female health care provider Belief in theory of hot and cold May omit soy sauce in diet to prevent dark-skinned baby Prefer soup made with ginseng root as general strength tonic Milk usually excluded from diet because it causes stomach distress Inactivity or sleeping late may cause difficult birth	Labor Mother attended by other women, especially her own mother Father does not actively participate Labor in silence Cesarean birth not desired but cooperative if needed Postpartum Must protect self from <i>yin</i> (cold forces) for 30 days Ambulation limited Shower and bathing prohibited Warm room Diet: Warm fluids Some women are vegetarians Korean mother served seaweed soup with rice Chinese diet high in hot foods Chinese mother avoids fruits and vegetables	Newborn Concept of family important and valued Father is head of household; mother plays a subordinate role Birth of boy preferred May delay naming child Some groups (e.g., Vietnamese) believe colostrum is dirty; therefore, they may delay breastfeeding until milk comes in
European-American (Members of the European-American [Caucasian] community have their origins in countries such as Ireland, Great Britain, Germany, Italy, and France.)		
Pregnancy Pregnancy viewed as a condition that requires medical attention to ensure health Emphasis on early prenatal care Variety of childbirth education programs available, and participation encouraged Technology driven Emphasis on nutrition science Involvement of the father valued Written sources of information including online sources and DVDs valued	Labor Birth is a public concern Technology dominated Birthing process in institutional setting valued Involvement of father expected Physician seen as head of team Postpartum Emphasis or focus on early bonding Medical interventions for dealing with discomfort Early ambulation and activity emphasized Self-management valued	Newborn Increased popularity of breastfeeding Breastfeeding begins as soon as possible after childbirth Facilitate bonding with “sacred hour after birth” Parenting Motherhood and transition to parenting seen as stressful time Nuclear family valued, although single-parenting and other forms of parenting more acceptable than in the past Women often deal with multiple roles Early return to pre-pregnancy activities
Native American (Many different tribes exist within the Native American culture; viewpoints vary according to tribal customs and beliefs.)		
Pregnancy Pregnancy considered a normal, natural process Late prenatal care Avoid heavy lifting Herbal teas encouraged	Labor Prefers female attendant, although husband, mother, or father may assist with birth Birth may be attended by whole family Herbs may be used to promote uterine activity Birth may occur in squatting position Postpartum Herbal teas to stop bleeding	Newborn Infant not fed colostrum Use of herbs to increase flow of milk Use of cradle boards for infant Babies not handled often

NOTE: Most of these cultural beliefs and customs reflect the traditional culture and are not universally practiced. These lists are not intended to stereotype clients but rather to serve as guidelines while discussing meaningful cultural beliefs with a woman and her family.

*Variations in some beliefs and practices exist within subcultures of each group.

(2013). *Cultural diversity in health and illness* (8th ed.). Upper Saddle River, NJ: Prentice-Hall; Williams, R. (1989). Issues in women's health care. In B. Johnson (Ed.), *Psychiatric mental health nursing: Adaptation and growth*. Philadelphia: JB Lippincott.

DEVELOPING CULTURAL COMPETENCE

Cultural competence has many names and definitions, all of which have subtle shades of difference but which are essentially the same: **multiculturalism, cultural sensitivity, and intercultural effectiveness.** Cultural competence involves acknowledging,

respecting, and appreciating ethnic, cultural, and linguistic diversity. Culturally competent professionals act in ways that meet the needs of the client and are respectful of ways and traditions that may be very different from their own. In today's society it is of critical importance that nurses develop more than technical skill. At every level of preparation and throughout

their professional lives, nurses must engage in a continual process of developing and refining attitudes and behaviors that will promote culturally competent care (Giger, 2013).

Key components of culturally competent care include:

- Recognizing that disparity exists between one's own culture and that of the client
- Educating and promoting healthy behaviors in a cultural context that has meaning for clients
- Taking abstract knowledge about other cultures and applying it in a practical way, so that the quality of service improves and policies are enacted that meet the needs of all clients
- Communicating respect for a wide range of differences, including client use of nontraditional healing practices and alternative therapies
- Recognizing the importance of culturally different communication styles, problem-solving techniques, concepts of space and time, and desires to be involved with care decisions
- Anticipating the need to address varying degrees of language ability and literacy, as well as barriers to care and compliance with treatment

In addition to issues of preserving and promoting human dignity, the development of cultural competence is of equal importance in terms of health outcomes. Nurses who relate effectively with clients are able to motivate them in the direction of health-promoting behaviors. Provider competence to address language barriers facilitates appropriate tailoring of health messages and preventive health teaching. Cross-cultural experiences also present an opportunity for the health care professional to expand cultural sensitivity, awareness, and skills.

COMMUNITY HEALTH PROMOTION

Best practices in community-based health initiatives involve understanding of community relationships and resources as well as participation of community leaders. The emphasis on community-based health promotion has grown in recent years, with recognition that many health issues require the collaborative efforts of a diverse community network to achieve public health goals. These efforts are particularly relevant in relation to maternal-newborn health, which is affected by multiple public health issues: lack of health insurance, undocumented status, recent economic challenges that include job loss, teen pregnancy, substance abuse, and the consequences of no or inadequate prenatal care.

Levels of Preventive Care

In community-based health promotion, three levels of prevention of disease exist. *Primary prevention* involves promoting healthy lifestyles through immunizations, encouraging exercise, and healthy nutrition. *Secondary prevention* involves targeting populations at risk for certain diseases. For example, women are encouraged to have mammograms; men are encouraged to have prostate screening. *Tertiary prevention* focuses on rehabilitation of an individual to health as optimal as is possible in the presence of a disease or injury. For example, a person who has experienced a stroke has an optimal expectation of being able to function at his or her fullest potential. As nurses we do what we can to ensure that this occurs.

During pregnancy, primary and secondary preventions are most relevant. The goal is to maintain a healthy pregnancy by

preventing illness and screening those at risk for potential illnesses or complications that could arise during pregnancy. In pregnancy, primary prevention might involve providing influenza vaccine to women, whereas secondary prevention might involve performing an amniocentesis for a woman more than 35 years of age.

Promoting Family Health

Functioning within the social, cultural, environmental, and economic context of the community, the family becomes an integral component of community health-promotion efforts. For childbearing families, health promotion is focused primarily on early intervention through prenatal care and prevention of complications during the perinatal period. Often this early exposure to health information sets the stage for a successful birth and positive outcomes for mother, father, and baby. The nurse's role in this process is focused on collaboration with the family, identifying risk factors, and providing health information to facilitate positive health behaviors. Involving expectant mothers and fathers in identification of their learning needs is an essential first step to securing their participation in the health-promotion process.

A wide variety of strategies have been used to engage families and groups in health-promoting activities or community health programs. Some are more successful than others. Generally, participant engagement in the planning process and empowerment to create internal solutions are considered key factors in effective interventions. Many communities have organized coalitions to address specific health-promotion agendas related to sharing information, educating community members, or advocating for health policies around maternal and child health issues. The benefits of partnership with faith-based organizations for community health improvement have been demonstrated in health-promotion efforts aimed at lifestyle choices, health education, and maternal-child health outcomes.

Prepared childbirth classes are a well-established mechanism for increasing awareness of healthy behaviors during pregnancy and preparing parents for the care of themselves and their newborn during the postpartum period; these can occur through community hospitals and online courses. Mass media efforts such as those presented by the March of Dimes "Baby Your Baby," the Public Health Campaign "Safe to Sleep," and AWHONN's "40 Reasons to Go the Full 40 Weeks" are advertisements with clear consumer-friendly messages designed to reach a large target audience. Other venues include public health education in newspapers and magazines and health department programs such as the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC), which offers a variety of health education and written information to mothers.

ASSESSING THE COMMUNITY

A community assessment is a tool that is used to assess the health and well-being of a community. One can define community either geographically or as having a common characteristic. For example, one can do a community assessment of clients who live in a particular neighborhood or of women who have

developed preterm labor. In doing the community assessment, risk factors for certain diseases, patterns of illness, cultural beliefs, religious beliefs, transportation systems, and support systems are just a few factors that are assessed in order to determine how these components relate to certain patterns of illness.

In a community health assessment, data are collected, analyzed, and used to educate and mobilize communities, develop priorities, garner resources, and plan actions to improve public health. Many models and frameworks of community assessment are available, but the actual process often depends on the extent and nature of the assessment to be performed, the time and resources available, and the way the information is to be used (www.assesstoolkit.org).

Data Collection and Sources of Community Health Data

Important measures of community health, for example, are access to care, level of provider services available, availability of transportation, and family support. Consideration of a variety of these factors helps one to assess areas that may affect care so that nurses can introduce alternatives to meet clients' needs. For example, if a woman has to work Monday through Friday, from

8 AM to 5 PM, the nurse can facilitate an after-hours appointment. A community assessment model (Fig. 2-6) can be used to provide a comprehensive guide to data collection.

The most critical community indicators of perinatal health relate to access to care, maternal mortality, infant mortality, preterm birth, low birth weight, first-trimester prenatal care, and rates for mammography, Papanicolaou (Pap) smears, and other similar screening tests. Nurses can use these indicators as a reflection of access, quality, and continuity of health care in a community. For women and infants, access to a consistent source of care is critical. Those with a regular source of care are more likely to use preventive services and have more positive pregnancy outcomes, but many women lack access to a usual source of care or rely primarily on emergency services.

Access to health care relates not only to the *availability* of health department services, hospitals, public clinics, clinic hours, or other sources of care, but also to *accessibility* of care. In many areas where facilities and providers are available, geographic and transportation barriers render the care inaccessible for certain populations. This is particularly true in rural areas or other remote locations. Other barriers to care should also be evaluated including cultural and language barriers and lack

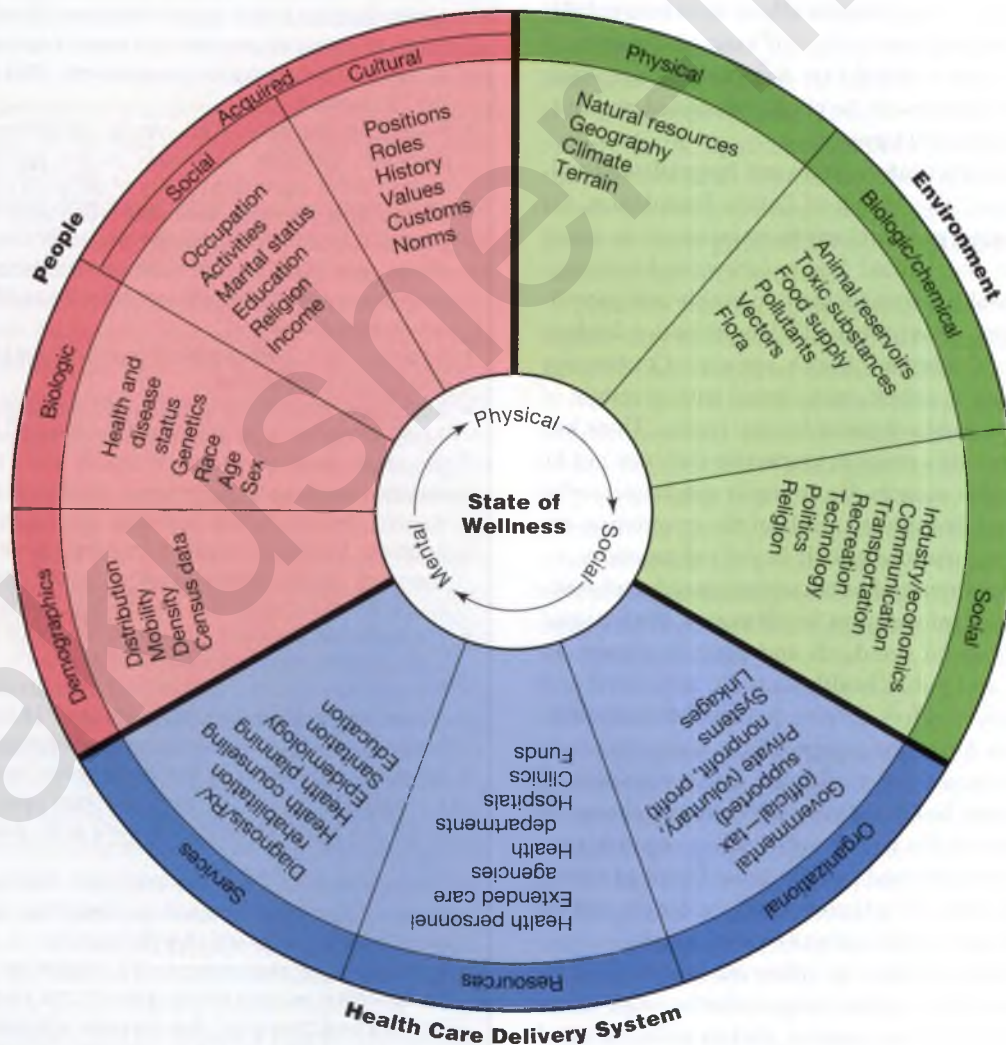

FIG 2-6 Community health assessment wheel. (From Clemen-Stone, S. [2002]. In S. Clemen-Stone, S. McGuire, & D. Eigsti. [Eds.], *Comprehensive community health nursing: Family, aggregate, & community practice* [6th ed.]. St. Louis: Mosby.)

of providers or specialty care. There is a growing trend in the United States to have walk-in clinics in grocery stores, an easily accessible location.

Health departments at the city, county, and state level are a valuable resource for annual reports of births and deaths. Local health departments also compile extensive statistics about the birth complications, causes of death, and leading causes of morbidity and mortality for each age group. Local and state health data are compiled and reported through the Centers for Disease Control and Prevention (CDC) (www.cdc.gov) to the National Center for Health Statistics (NCHS) (www.cdc.gov/nchs). The National Health Survey published annually from this source describes national health trends. However, national data are only as accurate and reliable as the local data on which they are based, so caution is needed in interpreting the data and applying it to specific population groups.

The U.S. census provides data on population size, age ranges, sex, racial and ethnic distribution, socioeconomic status, educational level, employment, and housing characteristics. Summary data are available for most large metropolitan areas, arranged by ZIP code and census tract, which usually corresponds to a neighborhood comprising approximately 3000 to 6000 people. Looking at individual census tracts within a community helps identify subpopulations or aggregates whose needs may differ from those of the larger community. For example, women at high risk for inadequate prenatal care according to age, race, and ethnic or cultural group can be readily identified and outreach activities appropriately targeted.

Other sources of useful information are hospitals and voluntary health agencies. The March of Dimes Foundation, for example, has supported perinatal needs assessments in many communities across the United States (www.modimes.org). Other community health resources include health care providers or administrators, government officials, religious leaders, and representatives of voluntary health agencies. Community or county health councils exist in many areas, with oversight of specific health initiatives or programs for that region. These **key informants** often provide a unique perspective that may not be accessible through other sources. Community gatekeepers who address the social and health care needs of the population are also critical links to population-specific health information.

Professional associations and publications are rich and readily accessible sources of information for all nurses. Professional associations publish useful standards and position papers. In addition to nursing and public health journals, behavioral and social science literature offers diverse perspectives on community health status for specific populations and subgroups. The Internet has increased the availability and accessibility of national, state, and local health data as well. However, the use of Internet-based resources for health information requires caution because data reliability and validity are difficult to verify. Guidelines for evaluation of Internet health resources can be found on the Health on the Net website (www.hon.ch).

Data collection methods may be either qualitative (e.g., by discussion, interview, observation) or quantitative (e.g., number, mean, standard deviation, percent of data collected) and may include visual surveys that can be completed by walking through a community, participant observation, interviews, focus groups, and analysis of existing data. Potential clients

and health care consumers may be asked to participate in focus groups or community forums to present their views on needed community services and programs. Formal surveys, conducted by mail, telephone, the Internet, or face-to-face interviews, can be a valuable source of information not available from national databases or other secondary sources. Several drawbacks exist with this method: surveys are generally expensive to develop and time consuming to administer. In addition to the cost of such surveys, poor response rates often preclude a sufficiently representative response on which to base nursing interventions.

A **walking survey** is generally conducted by a walk-through observation of the community (Box 2-4), taking note of specific characteristics of the population, economic and social environment, transportation, health care services, and other resources. With this type of data collection, information is gathered based on what the data collector observes and is clearly objective data.

Participant observation is another useful assessment method

BOX 2-4 Community Walk-Through

As you observe the community, take note of the following:

- **Physical environment**—Older neighborhood or newer subdivision? Sidewalks, streets, and buildings in good or poor repair? Billboards and signs? What are they advertising? Any health or safety promotion? Are lawns kept up? Is there trash in the streets? Parks or playgrounds? Parking lots? Empty lots? Industries?
- **People in the area**—Old, young, homeless, children; predominant ethnicity, language? Is the population homogeneous? What signs do you see of different cultural groups?
- **Stores and services available**—Restaurants: chain, local, ethnic? Grocery stores: neighborhood or chain? Department stores, gas stations, real estate or insurance offices, travel agencies, pawn shops, liquor stores, discount or thrift stores, newspaper stands?
- **Social**—Clubs, bars, fraternal organizations (e.g., Elks, American Legion), museums?
- **Religious**—Churches, synagogues, mosques? What denominations? Do you see evidence of their use other than on religious/holy days?
- **Health services**—Drugstores, doctors' offices, clinics, dentists, mental health services, veterinarians, urgent care facilities, hospitals, shelters, nursing homes, home health agencies, public health services, midwives, chiropractors, acupuncturists, traditional healers (e.g., herbalists, palmists)?
- **Transportation**—Cars, buses, taxis, light rail, sidewalks, bicycle paths, access for disabled persons?
- **Education**—Schools, before- and after-school sports or programs, extracurricular activities/clubs, child care, libraries, bookstores? What is the reputation of the schools?
- **Government**—What is the governance structure? Is there a mayor? City council? Are meetings open to the public? Are there signs of political activity (e.g., posters, campaign signs)?
- **Safety**—How safe is the community? What is the crime rate? What types of crimes are committed? Are police visible? Is there a fire station?
- **Evaluation of the community based on your observations**—What is your impression of the community? Is the environment pleasing? Are services and transportation adequate? How difficult is it for residents to obtain needed services, that is, how far do they have to travel? Would you want to live in this community? Why or why not?

in which the nurse actively participates in the community to understand the community more fully and to validate observations. As part of the assessment process, nurses working in multiethnic and multicultural groups need an in-depth assessment of culturally based health behaviors.

Analysis and synthesis of data obtained during the assessment process help to generate a comprehensive picture of the community's health status, needs, and problem areas, as well as its strengths and resources for addressing these concerns. The goal of this process is to assign priorities to community health needs and to develop a plan of action for correcting them. A comparison of community health data with state and national statistics can help identify appropriate target populations and develop interventions to improve health outcomes.

Vulnerable Populations in the Community

Assessment of population health includes indicators related to diverse groups and cultures, particularly disenfranchised or "vulnerable" community members. Vulnerability in terms of health status and health outcomes may take many forms, including sociocultural, economic, and environmental risk factors that contribute to disparities in health. Health disparities are conditions that disproportionately affect certain racial, ethnic, or other groups. African-Americans, Hispanic-Americans, Native Americans, Pacific Islanders, and Asian-Americans are all considered vulnerable populations because of the burden of preventable disease, death, and disability compared with non-minorities (CDC, 2013b).

Racial and ethnic disparities exist for a number of health conditions and services. According to the 2012 National Healthcare Disparities Report [AHRQ] (2013), our system of health care distributes services inefficiently and unevenly across populations. These disparities may occur for a variety of reasons, including differences in access to care, social determinants, provider biases, poor provider-client communication, and poor health literacy. A summary of the report described health care quality and access to be suboptimal, especially for minority and low-income groups. Overall quality of health care is improving and access is improving for some, however, disparities still exist. Urgent attention needs to be directed toward diabetes care, maternal and child health care, disparities in cancer care, and quality of care.

Women

Women make up 51% of the U.S. population, representing a very diverse, and largely at risk, group in relation to health (U.S. Census Bureau, 2011b). Although women assume leadership for health care decision making in most families, they also face significant challenges in accessing the health care system and meeting their own health needs and those of family members. Although there is no single contributing factor, the primary sources of health disparities for women fall into the areas of gender, socioeconomic status, and race or ethnicity. Significant gaps exist in the quality of care for women when compared with men.

The *National Report Card on Women's Health* describes significant deficiencies in women's health (National Women's Law Center [NWLC], 2010). States' performance in relation to 26 graded indicators was assessed; all but 3 were rated as

unsatisfactory in relation to women's health status and policies influencing women's health. Key indicators focused on access to services, use of preventive health care and health promotion activities, the occurrence of certain health conditions, and an assessment of the community's effect on women's health. This report suggested that one of the primary factors compromising women's health is lack of access to acceptable-quality health care, which may manifest itself in many forms: lack of health insurance, living in a medically underserved area, or an inability to obtain needed services, particularly basic services such as prenatal care. With the enactment of the Patient Protection and Affordable Care Act, many of the policy goals will be realized as the act is implemented. By mid-April 2014, 7.5 million people had enrolled in the plan (Trumbull, 2014).

Although many women report that they are in good to excellent health, statistics reveal significant disparities in health status of women from all age groups and racial and ethnic backgrounds. Low levels of educational attainment (high school or lower) are also associated with lack of resources and difficulty navigating the health care system. This is particularly true of women of ethnic and racial minorities, whose limited English proficiency may compromise provider access and quality of care.

Racial and Ethnic Minorities

In addition to social, economic, and cultural barriers to optimal health, women who are in racial and ethnic minorities experience a disproportionate burden of disease, disability, and premature death. Significant health disparities continue to exist in the health of adult women and their infants. Although positive trends are evident, disparities persist among racial and ethnic groups in early prenatal care, an important factor in achieving healthy pregnancy outcomes.

Minority women, many of whom live in poverty, also have higher rates of chronic disease including heart disease, cancer, hepatitis, and acquired immunodeficiency syndrome (AIDS), as well as mental health issues. Women with underlying health conditions are at especially high risk for poor obstetric outcomes for themselves and their infants. They have high rates of preterm labor and gestational hypertension, and often have intrauterine growth restriction, resulting in the birth of infants who are small for gestational age. These are the women for whom the community-based perinatal nurse will be providing care, and their needs are complex, demanding high levels of expertise and skill.

Adolescent Girls

The adolescent population in the United States is generally considered healthy. However, adolescents participate in riskier behaviors and their health is often compromised as a result.

Although adolescents are concerned about becoming pregnant, they still engage in unprotected sex. They use a variety of sources for health information such as the media, friends, and sex education, yet they are misinformed, particularly about sexually transmitted infections (STIs) and human immunodeficiency virus (HIV) transmission. These findings have significant implications for perinatal outcomes and emphasize the importance of aggressive prevention programs and community outreach related to sexuality, teen pregnancy, and substance abuse.

It is crucial that nurses engage adolescents in health education programs that will encourage them to make informed decisions about their sexual health. It is also vital that nurses be a resource to these young women.

Older Women

Although women have a greater life expectancy than men, they are more likely to have chronic illnesses, less likely to use preventive services, and ultimately spend more on health care. As nurses, it is important that we engage this population at all levels of prevention, from primary to tertiary.

Incarcerated Women

The number of incarcerated women in the United States has continued to climb in recent years, increasing at a significantly greater rate than for men. In 2010, there were 113,000 women incarcerated in state and federal facilities, with the highest number of these being non-Hispanic black women (Sipes, 2012). Many of these women report a history of sexual and physical abuse.

Because their relationship histories are often unstable, and because they often lack the support of family, incarcerated women or those with a history of repeated incarceration frequently have difficulty providing emotional stability, secure housing, and health promotion role modeling for their children.

The lifestyle choices of this group, including risky sexual relationships, illicit drug use, and smoking, place them at high risk for STIs, HIV, and AIDS; other chronic and communicable diseases; and complicated pregnancies.

Immigrant, Refugee, and Migrant Women

As of 2010, nearly 40 million or 13% of the population in the United States was foreign born (Grieco, Acosta, de la Cruz, et al., 2012). This accounts for a rapidly growing diverse population for which nurses will be providing care.

An *immigrant* is an individual who moves from one country to another in an effort to take up legal residency, whereas a *refugee* is an individual who is forced to leave his or her home country, often in search of a safer and more stable living environment. Both populations are often challenged with not being able to easily access health care because they are not U.S. citizens. These women often do not seek medical care for fear of deportation. Access to care is further limited by health care policies that restrict Medicaid eligibility for these groups although a number of states provide some prenatal, birth, and postpartum care.

Along with their profound resilience and determination, refugees and immigrants have brought rich diversity to the United States in several important dimensions including cultural heritage and customs, economic productivity, and enhanced national vitality. In general, refugees are more likely to live in poverty than are immigrants. Over time, measures of health and well-being actually decline for the immigrant population as they become part of American society. Many of the conditions or illnesses that they acquire contribute to the persistence of disparities in maternal and neonatal health outcomes for both immigrants and refugees.

Migrant workers are those who work outside their home country or migrate within their own country seeking seasonal work. Migrant laborers and their families face many problems, including financial instability, child labor, poor housing,

lack of education, language and cultural barriers, and limited access to health and social services. Poor dental health, diabetes, hypertension, malnutrition, tuberculosis, skin diseases, and parasitic infections are common health issues among migrant populations. Primary health care services are largely provided by a number of migrant health centers, of which there are more than 400 throughout the United States. In 2011 more than 862,000 seasonal and migrant farm workers and their families were served (HHS, 2011). Routine prenatal care and screening and treatment for hypertension and diabetes are provided. Community health nurses frequently encounter the challenges of providing culturally and linguistically appropriate care while facing numerous health issues.

Numerous reproductive health issues exist for migrant women, including less consistent use of contraception and increased rates of STIs. Migrants are less likely to receive early prenatal care and have a greater incidence of inadequate weight gain during pregnancy than do other poor women.

Rural Versus Urban Community Settings

Approximately 16% of the U.S. population lives in a rural area (Rural Assistance Center, 2011). Generally, rural residents are older, less educated, and generally in poorer health than their urban counterparts. Rural communities are disproportionately affected by poverty and poor access to health care services. Fewer physicians choosing to practice in rural areas and lack of insurance present additional factors contributing to poor health in rural areas.

Rural women are especially vulnerable to financial and transportation barriers to health care. Although women in rural counties report only *fair* to *poor* health, they pay considerably more for their health care. In rural communities women have less access to prenatal care, which contributes to higher rates of adverse pregnancy outcomes including higher rates of preterm birth, low birth weight, and infant mortality. The disproportionate distribution of poverty and of variations in race/ethnicity, age, education, and availability and access to medical resources may be the link to infant mortality in rural areas. The ACA is designed to reduce barriers to access.

Homeless Women

Homelessness among women is an increasing social and health issue in the United States. Although exact numbers are unknown because of the difficulty in tracking individuals without a permanent address, it is estimated that more than 636,000 people were homeless in 2011 (Homelessness in America, 2012). Single women make up 13% of the homeless population and are often on the street to escape domestic violence (Dray, 2012). Families with children make up the fastest-growing group of the homeless. In these families, one in five children experienced food insecurity (did not have enough to eat) in 2010 (National Coalition for the Homeless [NCH], 2011).

Health issues among the homeless are numerous and result primarily from a lack of preventive care and a lack of resources in general. Health problems include chronic illness, infectious diseases, asthma, circulatory problems, diabetes, substance abuse, and mental illness. Lifestyle factors and the vulnerability resulting from being homeless contribute to health problems. Women are at increased risk for illness and injury; many have been victims of

domestic abuse, assault, and rape. Although little is known about pregnancy in this population, women do become pregnant while homeless. In addition to risk factors related to inadequate nutrition, inadequate weight gain, anemia, bleeding problems, and preterm birth, homeless women face multiple barriers to prenatal care: transportation, distance, and wait times. Most of these women underutilize available prenatal services. The unsafe environment and high risk lifestyles often result in adverse perinatal outcomes (American College of Obstetricians and Gynecologists [ACOG], 2010; Richards, Merrill, & Baksh, 2011). The United States has initiated programs to address these problems. For example, the U.S. Interagency Council on Homelessness and its 19 member agencies launched Opening Doors, the federal strategic plan to prevent and end homelessness in 2010 and updated it in 2011 (Opening Doors, 2012).

Implications for Nursing

Working in the community or in the home with the full spectrum of family organizational styles, vulnerable populations, and cultural groups presents challenges for nurses. Whether it involves perinatal care focused on women and their newborns or women's health care directed toward treatment and prevention of other health conditions such as communicable diseases and sexually transmitted infections, nursing must exhibit a high degree of professionalism. Cultural sensitivity, compassion, and a critical awareness of family dynamics and social stressors that will affect health-related decision making are critical components in developing an effective nursing care plan.

Although the long-term consequences of contemporary immigration for American society are unclear, the successful incorporation of immigrant families depends on the resources, benefits, and policies that ensure their healthy development and successful social adjustment. Culturally competent health care and involvement of the immigrant community in health care programs are recommended strategies for improving the access to and effectiveness of health care for this population.

The use of camp volunteers has been effective in assisting families living in migrant worker camps to obtain prenatal, postpartum, and infant care. Working in partnership with health professionals such as nurses, lay camp aides have been used effectively for outreach and health education; however, more strategies are needed to link traditional practices with the formal health care system. Guidance and information about other health resources are available to health care providers through the National Center for Farmworker Health, Inc. (www.ncfh.org) and the Migrant Clinicians Network (www.migrantclinician.org).

Nurses working with homeless women and families are challenged to treat them with dignity and respect to establish a therapeutic relationship. Case management is recommended to coordinate the services and disciplines that may be involved in meeting the complex needs of these families. Whenever possible, general screening and preventive health services must be provided when the woman seeks treatment because this may be the only opportunity to provide health information and intervention. Building on existing coping strategies and strengths, the health care provider helps the woman and her family reconnect with a social support system. Nurses also have an important role in advocating for funding to support health services

for the homeless and improve access to preventive care for all homeless populations.

HOME CARE IN THE COMMUNITY

Modern home care nursing has its foundation in public health nursing, which provided comprehensive care to sick and well clients in their own homes. Specialized maternity home care nursing services began in the 1980s when public health maternity nursing services were limited and services had not kept pace with the changing practices of high risk obstetrics and emerging technology. Lengthy antepartum hospitalizations for such conditions as preterm labor and gestational hypertension created nursing care challenges for staff members of inpatient units.

Many women expressed their concern for the negative effect of antepartum hospitalizations on the family. Although clinical indications showed that a new nursing care approach was needed, home health care did not become a viable alternative until third-party payers (i.e., public or private organizations or employer groups that pay for health care) pushed for cost containment in maternity services.

In the current health care system, home care is an important component of health care delivery along the perinatal continuum of care (Fig. 2-7). The growing demand for home care is based on several factors:

- Interest in family birthing alternatives
- Shortened hospital stays
- New technologies that facilitate home-based assessments and treatments
- Reimbursement by third-party payers

As health care costs continue to rise, and because millions of American families lack health insurance, there is greater demand for innovative, cost-effective methods of health care delivery in the community. Large health care systems are developing clinically integrated health care delivery networks whose goals are: (1) improved coordination of care and care outcomes; (2) better communication among health care providers; (3) increased client, payer, and provider satisfaction; and (4) reduced cost. The integration of clinical services changes the focus of care to a continuum of services that are increasingly community based.

Communication and Technology Applications

As maternity care continues to consist of frequent and brief contacts with health care providers throughout the prenatal and postpartum periods, services that link maternity clients throughout the perinatal continuum of care have assumed increasing importance. These services include critical pathways, telephonic nursing assessments, discharge planning, specialized education programs, parent support groups, home visiting programs, nurse advice lines, and perinatal home care (Fig. 2-8). Hospitals may provide cross-training for hospital-based nurses to make postpartum home visits or to staff outpatient centers for postpartum follow-up.

Telephonic nursing through services such as warm lines, nurse advice lines, and telephonic nursing assessments is a valuable means of managing health care problems and bridging the gaps among acute, outpatient, and home care services. Providers use the Internet and Skype to communicate with clients. Newborns in distress in rural hospitals can be

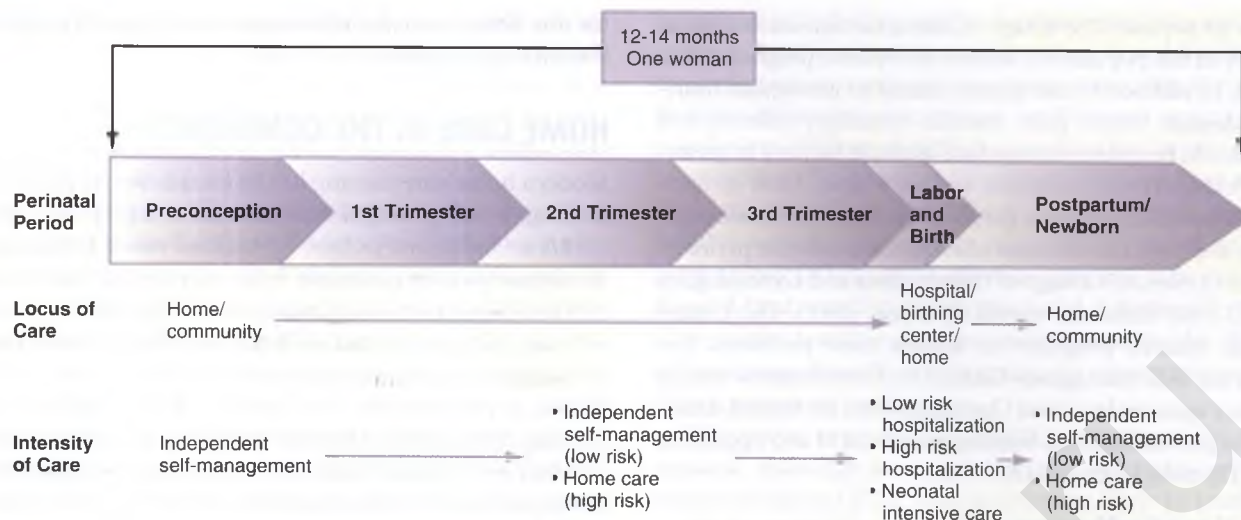

FIG 2-7 Perinatal continuum of care.

FIG 2-8 Home care nurse visits with a woman in preterm labor at home on bed rest. (Courtesy Shannon Perry, Phoenix, AZ.)

assessed by perinatologists using high-definition telemedicine robots. Nursing care that occurs by telephone is interactive and responsive to immediate health care questions about particular health care needs. **Warm lines** are telephone lines that are offered as a community service to provide new parents with support, encouragement, and basic parenting education. Nurse advice lines, or toll-free nurse consultation services, often are supported by third-party payers or health management organization/managed care organizations (HMO/MCOs) and are designed to provide answers to medical questions. Nurse care managers are prepared to guide callers through urgent health care situations, suggest treatment options, and provide health education. Telephonic nursing assessments, or nurse consultation, assessment, and health education that take place during a telephone conversation, can be added to the nursing care plan in conjunction with skilled nursing visits, or they may comprise a separate nursing contact for the woman. Telephonic nursing assessments are commonly used after a postpartum home care visit to reassess a woman's knowledge about the signs and symptoms of adequate hydration in breastfeeding or, after initiating

home phototherapy, to assess the caregiver's knowledge regarding problems with equipment.

Guidelines for Nursing Practice

The Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN, 2009) defines home care as the provision of technical, psychologic, and other therapeutic support in the woman's home rather than in an institution. The scope of nursing care delivered in the home is necessarily limited to practices deemed safe and appropriate to be carried out in an environment that is physically separated from a health care institution and its resources. Nursing practice at home is consistent with federal and state regulations that direct home care practice. The nurse demonstrates practice competence through formalized orientation and ongoing clinical education and performance evaluation in the respective home care agency. Standards for practice from key specialty organizations such as AWHONN, the National Association of Neonatal Nurses (NANN), ACNM, ACOG, the American Academy of Pediatrics (AAP), and the Intravenous Nursing Society (INS) provide the basis for clinical protocols and pathways and organizational programs in home care practice. The Joint Commission (www.jointcommission.org) provides criteria for home care operations based on Centers for Medicare & Medicaid Services (CMS) regulations (cms.hhs.gov).

A wide range of professional health care services and products can be delivered or used in the home by means of technology and telecommunication. For example, telehealth and telemedicine make it possible for clients in the home to be interviewed and assessed by a specialist located hundreds of miles away. Home health care can be viewed as an extension of in-hospital care.

Essentially the primary difference between health care in a hospital and home care is the absence of the continuous presence of professional health care providers in a client's home. Generally, but not always, home health care entails intermittent care by a professional who visits the client's home for a particular reason and/or provides care on site for fewer than

4 hours at a time. The home health care agency maintains on-call professional staff to assist home care clients who have questions about their care and for emergencies, such as equipment failure.

Perinatal Services

Home care perinatal services may be provided by hospital-based programs, independent proprietary (for-profit) agencies, or nonprofit home care agencies, and official or tax-supported agencies. Innovative programs may be supported by research grants for a period of years, but ultimately they must be sponsored by an agency with long-term funding. Home visits have advantages and disadvantages. The pregnant woman can maintain bed rest if indicated, and vulnerable neonates are not exposed to the weather or external sources of infection. The nurse can observe and interact with family members in their most natural and secure environment. Adequacy of resources and safety factors can be assessed. Teaching can be tailored to the actual home conditions, and other family members can be included. A home visit is less expensive than a day's hospitalization, but a 60- to 90-minute visit requires 2.5 to 3 hours of nursing time, including travel and documentation. Areas of challenge include limited availability of nurses with expertise in maternity care and concerns about the nurse's physical safety in the community. One alternative that is less expensive is contacting women via telephone.

Visits for outreach and health promotion are an integral part of community (or public) health nursing. In countries with national health systems, a nurse or midwife may see all women during pregnancy and after birth. In the United States, visits of this sort have been provided mainly to low-income families without health insurance and Medicaid recipients who use the clinics provided by local health departments. Until recently, private insurers did not reimburse for health promotion visits. MCOs now recognize that anticipatory guidance can be cost-effective, but home visitation programs for the most part still target specific, high risk populations, such as adolescents and women at risk for preterm labor.

Home care agencies are subject to regulation by governmental and professional organizations and provide interdisciplinary services including social work, nutrition, and occupational and physical therapy. Increasingly, their caseloads are made up of women who require high-technology care, such as infusions or home monitoring. Although the home health nurse develops the care plan, all care must be ordered by a physician. In addition, interventions must meet the insurer's criteria for reimbursement and services are limited to registered clients. Preconception care and low risk antepartum care can usually be provided more efficiently in offices. High-risk antepartum care can be provided by home care agencies; for example, women with hyperemesis gravidarum who require parenteral nutrition may be treated at home. Conditions requiring bed rest, such as preterm labor and hypertension, are other common indications for home care. Other conditions often managed with home care may include cardiac disease, substance abuse, and diabetes in pregnancy.

Insurers may reimburse for at least one postpartum visit to families after early discharge or in the presence of high risk

factors. Many neonates who require long-term high-technology care are also managed with home care.

Client Selection and Referral

The office- or hospital-based nurse is often the key person in making effective referrals to home care. When considering a referral to home care, the following factors are evaluated:

- Health status of mother and fetus or infant: Is the condition serious enough to warrant home care, and is it stable enough for intermittent observation to be sufficient?
- Availability of professionals to provide the needed services within the woman's community.
- Family resources, including psychosocial, social, and economic resources: Will the family be able to provide care between nursing visits? Are relationships supportive? Is third-party reimbursement available, or can it be negotiated with the insurer? Could a voluntary or tax-supported community agency provide needed care without payment?
- Cost-effectiveness: Is it more reasonable for the woman to receive these services at home or to go to a local outpatient facility to receive them?

Community referrals should not be limited to women with physiologic complications of pregnancy that require medical treatment. Women at risk (e.g., young adolescents, families with a history of abuse, members of vulnerable population groups, developmentally disabled individuals) may need follow-up care at home. As we move more and more into an interdisciplinary health care society, it is crucial that nurses communicate with social workers to tap into valuable community resources that women can use in their own communities after being discharged.

Standardized forms simplify the referral process and ensure that all needed information will be forwarded to the home health agency. The nursing assessment should include the woman's physical and psychologic status, her level of knowledge about self-management activities, her willingness to learn, the availability of caregivers and social support in the home, and her level of comfort with home care. If the referral is for a mother-and-infant home care visit, the nursing assessment should include newborn data.

High-technology home care requires additional information to be collected from the chart, and consultation with the referring physician and other members of the health care team, before a home care referral is made. These additional data include the medical diagnosis, medical prognosis, prescribed therapies, medication history, drug-dosing information, potential ancillary supplies, type of infusion and access device, and the available systems of social support for the woman and family. The nursing assessment and therapy data provide baseline information for the home care nurse and other health care providers involved in the care plan.

Whenever a referral is called in to a home health care agency, a member of the nursing or admissions staff determines the agency's ability to accept the woman for service. The use of telecommunication modalities such as fax machines, cell phones, electronic files, and the Internet to transmit information has eliminated delays in initiating home care services, even in more remote rural areas.

CARE MANAGEMENT

Preparing for the Home Visit

The home care nurse reviews the available clinical data, demographic information, and completed care plan form and consults with the home care pharmacist or other health care team members who have previously contacted the woman to determine the goals of the visit. At this point the nurse uses the medical diagnosis and the location of the case on the perinatal continuum as a starting point to organize the woman's care. The nurse reviews agency policies and

procedures, professional literature about diagnosis, and community resources as part of the previsit preparation work (Box 2-5).

First Home Care Visit

Making the first home care visit can be stressful for the nurse and the woman. The home care nurse is faced with an unknown environment controlled by the woman and her family. The woman and her family also experience feelings about the unknown, such as anxiety about the way the nurse will treat them or what the nurse will do during the visit. **The challenge for the home care nurse is to establish a positive nurse-client**

BOX 2-5 Protocol for Perinatal Home Visits

Previsit Interventions

1. Contact the family to arrange details for a home visit.
 - a. Identify self, credentials, and agency role.
 - b. Review purpose of home visit follow-up.
 - c. Schedule convenient time for visit.
 - d. Confirm address and route to family home.
2. Review and clarify appropriate data.
 - a. Review all available assessment data for mother and fetus or infant (i.e., referral forms, hospital discharge summaries, identified learning needs of the family).
 - b. Review records of any previous nursing contacts.
 - c. Contact other professional caregivers as necessary to clarify data (i.e., obstetrician, nurse-midwife, pediatrician, referring nurse).
3. Identify community resources and teaching materials appropriate to meet those needs already identified.
4. Plan the visit, and prepare a bag with equipment, supplies, and materials necessary for assessments of mother and fetus or infant, actual care anticipated, and teaching.

In-Home Interventions: Establishing a Relationship

1. Reintroduce yourself and establish the purpose of the visit for mother, infant, and family; offer the family the opportunity to clarify their expectations of the contact.
2. Spend a brief time socially interacting with the family to become acquainted and establish a trusting relationship.

In-Home Interventions: Working with the Family

1. Conduct a systematic assessment of the mother and the fetus or newborn to determine their physiologic adjustment and any existing complications (Fig. 2-8).
2. Throughout visit, collect data to assess the emotional adjustment of individual family members to the pregnancy or birth and lifestyle changes. Note any evidence of family-newborn bonding and sibling rivalry; note relationships among mother, father, children, and grandparents.
3. Determine the adequacy of support system.
 - a. To what extent does someone help with cooking, cleaning, and other home management tasks?
 - b. To what extent is help being provided in caring for the newborn and any other children?
 - c. Are support persons encouraging the new mother to care for herself and get adequate rest?
 - d. Who is providing helpful information? Emotional support?
4. Throughout the visit observe the home environment for adequacy of resources.
 - a. Space: privacy, safe play of children, sleeping
 - b. Overall cleanliness and state of repair

- c. Number of steps pregnant woman/new mother must climb
 - d. Adequacy of cooking arrangements
 - e. Adequacy of refrigeration and other food storage areas
 - f. Adequacy of bathing, toilet, and laundry facilities
 - g. Arrangements in home for newborn: sleeping, bathing, formula preparation (if needed), layette items, and diapers
5. Throughout the visit observe the home environment for overall state of repair and existence of safety hazards.
 - a. Storage of medications, household cleaners, and other substances hazardous to children
 - b. Presence of peeling paint on furniture, walls, or pipes
 - c. Factors that contribute to falls, such as dim lighting, broken steps, scatter rugs
 - d. Presence of vermin
 - e. Use of crib or playpen that fails to meet safety guidelines
 - f. Existence of emergency plan in case of fire; fire alarm or extinguisher
 6. Provide care to the mother, the newborn, or both as prescribed by their respective primary care provider or in accord with agency protocol.
 7. Provide teaching on the basis of previously identified needs.
 8. Refer the family to appropriate community agencies or resources, such as warm lines and support groups.
 9. Ascertain that the woman knows potential problems to watch for and who to call if they occur.
 10. Ensure that used disposable items have been handled appropriately and that reusable items are cleaned and repacked appropriately in the nurse's bag.

In-Home Interventions: Ending the Visit

1. Summarize the activities and main points of the visit.
2. Clarify future expectations, including the schedule of the next visit.
3. Review the teaching plan and provide major points in writing.
4. Provide information about reaching the nurse or agency if needed before the next scheduled visit.

Postvisit Interventions

1. Document the visit thoroughly, using the necessary agency forms to serve as a legal record of the visit and to allow third-party reimbursement, as possible.
2. Initiate the nursing care plan on which the next encounter with the woman and/or family will be based.
3. Communicate appropriately (by telephone, email, fax, letter, progress notes, or referral form) with the primary care provider, other health professionals, or referral agencies on behalf of the woman and family.

relationship and provide the prescribed home care services within the time provided for the initial home visit. One of the most important roles of the home care nurse is modeling health-related behaviors for the woman and others who are in the home during the visit.

Assessment and Nursing Diagnoses

The major areas of the assessment are demographics, medical history, general health history, medication history, psychosocial assessment (Box 2-6), home and community environment, and physical assessment. Information can be obtained from client records sent to the home care agency at the time of referral or from the previsit interview. These data will be used to develop and complete the nursing care plan, which is required for many licensed home health care agencies.

The nursing care plan is developed in collaboration with the woman, based on her health care needs. Home care nurses working in home health care agencies regulated by the CMS use a nursing care plan that includes client demographics, the health care provider's orders, home care goals, and the woman's level of functioning. This document is initiated at the time of referral to the home care agency and must be updated every 60

days or as specified by state regulations. The frequency of the skilled nursing visit may vary with the individual nursing care plan and reimbursement criteria established by the third-party payers.

Nursing Considerations

There are several areas of concern when caring for a woman in the home. In home care the woman or family members are responsible for administration of medications in the absence of the nurse. A careful medication history should be obtained to see if the woman is taking her medications correctly and understands their desired action and potential side effects. It is important that women and caretakers have a clear understanding of medication regimens and are notified when medications change in any way.

Nurses have to be skilled at performing various procedures such as venipuncture and administration of intravenous medications or fluids. Nurses must be sure that women know how to respond in emergency situations. Women need to be able to have 24-hour access to resources in the community in emergency situations. Women and family members are also encouraged to learn how to perform cardiopulmonary resuscitation (CPR), especially for infants.

The homes of women using electronic home health care equipment, such as phototherapy equipment or infusion pumps, require physical inspection of any electrical outlets, electrical cords, and extension cords that will be used. Homes with faulty electrical wiring may place the woman at risk for being involved in an electrical fire; faulty wiring may require inspection and repair by a professional electrician before electronic devices are used. Findings from the assessment are incorporated into the nursing care plan.

Verbal explanations should be supplemented with clearly written instructions. General information to promote well-being, such as nutrition and common discomforts of pregnancy, should also be included. The need for preparation for childbirth can be addressed by using books or videos and supplemented by individual teaching at home. Coping with bed rest or other limitation of activity is a problem for many women with high risk pregnancies. The nurse can share strategies that others have used such as support groups for women on bed rest using Facebook or Skype, help with time management, and provide information about support services. Teaching about infant care or the special needs of the preterm infant may be appropriate during the prenatal period.

BOX 2-6 Psychosocial Assessment

Language

- Identify the primary language spoken in the home.
- Assess whether there are any language barriers to receiving support.

Community Resources/Access to Care

- Identify primary and secondary means of transportation.
- Identify community agencies family uses for health care and support.
- Assess cultural and psychosocial barriers to receiving care.

Social Support

- Determine the people living with the pregnant woman.
- Identify who assists with household chores.
- Identify who assists with child care and parenting activities.
- Identify who the pregnant woman turns to for problems or during a crisis.

Interpersonal Relationships

- Identify the way decisions are made in the family.
- Identify the family's perception of the need for home care.
- Identify roles of adults in caring for family members.

Caregiver

- Identify the primary caregiver for home care treatments.
- Identify other caregivers and their roles.
- Assess the caregiver's knowledge of treatments and the care process.
- Identify potential strain from the caregiver role.
- Identify the level of satisfaction with the caregiver role.

Stress and Coping

- Identify what the woman perceives as lifestyle changes and their effect on her and her family.
- Identify the changes she and her family have made to adjust to her health condition and home health care treatments.

SAFETY ALERT

In caring for the home care client, Occupational Safety and Health Administration (OSHA) guidelines should be followed. The use of strict handwashing techniques, sharps containers, gloves, personal protective equipment (PPE), and proper equipment is essential in preventing the spread of disease to the care provider, the woman, and her family.

Use personal safety measures such as parking the car for access for a quick departure; never enter a home where guns are visible.

Clear documentation of assessments, problems identified, treatments and interventions performed, and the woman's response is essential. Third-party payers base reimbursement on the nurse's written record of providing skilled nursing care and assessments that support the woman's continuing need for those services. The nurse must promptly inform the

health care provider by telephone, fax, or electronic file of any significant changes. When new orders are transmitted by telephone, a written copy must be sent for the physician's signature.

See the Nursing Care Plan for examples of nursing diagnoses related to home care and the community.

NURSING CARE PLAN

Community and Home Care

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Readiness for Enhanced Family Coping related to family growth and development in new community</i>	The family will identify at least three community groups that can serve as appropriate resources for an expectant family with small children.	<p>Assess family structure and availability of significant others, friends, or family members to assist family with new baby and siblings.</p> <p>Encourage family to enlist assistance of individuals who are available to help family at birth of new baby.</p> <p>Using therapeutic communication, assist family to assess coping strategies used in the past for new situations.</p> <p>Suggest strategies to find resources available in community.</p>	<p>To provide database for further interventions</p> <p>To provide physical and emotional support</p> <p>To provide clarification and promote empowerment of family in new situations</p> <p>To assist family during pregnancy, with new baby, and with small siblings</p>
<i>Deficient Community Health related to resettlement of refugees in the community</i>	The community will develop programs to meet the needs of new members of the community.	<p>Give information regarding community workshops, classes, or support groups.</p> <p>Conduct needs assessment of community.</p> <p>Initiate health education programs based on topics identified in needs assessment.</p> <p>Prepare client education materials in a variety of languages.</p> <p>Identify risks in community (e.g., environmental hazards, drug sales).</p> <p>With community leaders, develop plan to cope with and reduce environmental hazards.</p> <p>Develop monitoring or surveillance system.</p>	<p>To promote networking, community bonding, and support</p> <p>To identify priority needs for new members of community</p> <p>To meet needs of members of community</p> <p>To enhance understanding of community members</p> <p>To provide target for community improvement</p> <p>To improve public health and safety</p> <p>To ensure that progress will continue and new problems will be identified</p>
<i>Ineffective Community Coping related to presence of gangs and lack of community programs to redirect activities of youth</i>	The health status of the community will improve.	<p>Initiate health screening programs for community members.</p> <p>Work with politicians and policymakers to develop community.</p> <p>Initiate programs such as Block Watch, Safe Houses, and Neighborhood Watch.</p> <p>Work with community leaders to develop or clean up playgrounds.</p> <p>With community leaders and gang members, develop community grassroots initiatives for gang prevention.</p> <p>Identify sites of lead exposure.</p> <p>Participate in immunization or vaccination clinics.</p> <p>Develop community education programs on drugs, alcohol, and tobacco.</p>	<p>To identify effects of environmental hazards in community</p> <p>To provide safe environment with means of economic survival for community members</p> <p>To enhance safety of environment</p> <p>To provide safe place for children to play</p> <p>To enable community members to take ownership in community</p> <p>To decrease potential for lead poisoning in children</p> <p>To reduce risk in community of infectious diseases</p> <p>To reduce exposure of young people to these products</p>

KEY POINTS

- The family is a social network that acts as an important support system for its members.
- Family theories provide nurses with useful guidelines for understanding family function.
- Family socioeconomics, response to stress, and culture are key factors influencing family health.
- The economic, religious, kinship, and political structures are embedded in the reproductive beliefs and practices of a culture.
- Nurses must develop cultural competence and integrate it into the nursing care plan.
- Of necessity, most changes aimed at improving community health involve partnerships among community residents and health workers.
- Methods of collecting data useful to the nurse working in the community include walking surveys, analysis of existing data, informant interviews, and participant observation.
- Vulnerable populations are groups who are at higher risk for developing physical, mental, or social health problems.
- Social and economic factors affect the scope of perinatal nursing practice.
- Perinatal home care is a unique nursing practice that incorporates knowledge from community health nursing, acute care nursing, family therapy, health promotion, and client education.
- Telephonic nurse advice lines, telephonic nursing assessments, and warm lines are low-cost health care services that facilitate continuous client education, support, and health care decision making, even though health care is delivered in multiple sites.

Nursing and Genomics

Marcia Van Riper

© <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Explore how recent advances in genetics have changed the field of health care.
- Discuss the essential competencies in genetics and genomics for all nurses.
- Describe expanded roles for nurses in genetics and genetic counseling.
- Discuss key findings of the Human Genome Project.
- Describe the different types of genetic testing.
- Identify genetic disorders commonly tested for in maternity and women's health nursing.
- Explore the possible benefits and risks of pharmacogenomics.
- Discuss the current status of gene therapy.
- Examine the ethical, legal, and social implications of the Human Genome Project.
- Explain the key concepts of basic human genetics.
- Discuss the education and counseling needs of individuals and families who undergo genetic testing.
- Explore the availability of genetic testing for individuals and families from diverse backgrounds.
- Describe the role of genomics in cancer care for women.
- Identify genetics resources for nurses and other health care professionals.

Remarkable advances in genomics and technology have revolutionized the field of health care and nursing practice by providing the tools needed to determine the hereditary component of many diseases, as well as improve our ability to predict susceptibility to disease, onset and progression of disease, and response to medications (Calzone, Jenkins, Nicoli, et al., 2013; Feero, Guttmacher, & Collins, 2010; Green & Guyer, 2011; McCarthy, McLeod, & Ginsburg, 2013). Since the human genome was sequenced, there has been a gradual shift from genetics to genomics. **Genetics** refers to the study of a particular gene, whereas **genomics** refers to the study of the entire genome. **Genes** are the basic physical units of inheritance that are passed from parents to offspring and contain the information needed to specify traits. The **genome** is the entire set of genetic instructions found in a cell. For these and other definitions of genetic terms, check out the *Talking Glossary of Genetic Terms* (www.genome.gov/Glossary).

With growing public interest in *personalized genomic information* (information about much or all of a person's genome), increasing development of practice guidelines, mounting commercial pressures, and ever-increasing opportunities for individuals, families, and communities to participate in the direction and design of their genomic health care, genetic services are rapidly becoming an integral part of routine health care (Guttmacher, McGuire, Ponder, & Stefansson, 2010; Manolio, Chisholm, Ozenberger, et al., 2013). Moreover, many

individuals and families have participated in *direct-to-consumer genetic testing* (testing marketed directly to consumers through television, print advertisements, and websites for companies such as DNA Direct) (www.dnadirect.com) and 23 and Me (www.23andme.com). Although much of the information provided by direct-to-consumer testing companies is recreational (ancestry information, information about types of ear wax, and bitter taste perception), some of the information provided is health related and could be interpreted as diagnosis (Evans & Green, 2009). Because of this, direct-to-consumer testing that is provided without the involvement of competent health care professionals may be not only unhelpful, but also harmful (Beery, 2013; Guttmacher et al., 2010; McGuire & Burke, 2010).

Because of their frontline position in the health care system and their long-standing history of providing holistic family-centered care, nurses are likely to be one of the first health care professionals to whom individuals and families turn with questions about genetic risk and susceptibility and to seek guidance regarding the complexities of genetic testing and interpretation. Nowhere is this more apparent than in maternity and women's health care (Lewis, 2011). A growing number of maternity and women's health nurses provide information about the availability of genetics tests, answer question about them, and order and interpret genetic tests. Although most of these tests are used to determine a client's risk of having a child affected by a genetic condition such as Down syndrome, cystic fibrosis (CF),

or sickle cell disease, the number of genetic tests used to determine the presence of, or susceptibility to, adult-onset disorders (e.g., hereditary colorectal cancer, hereditary breast and ovarian cancer, and Huntington's disease [HD]) continues to rise. Additionally, nurses working in maternity and women's health are caring for an increasing number of individuals and families who are dealing with complex ethical, legal, and social issues associated with genetic testing and the experience of living with someone who has a genetic condition (Sparbel & Tluczek, 2011; Sparbel & Williams, 2009; Van Riper, 2012; Van Riper & Choi, 2011; Wilke, Gallo, Yao, et al., 2013).

NURSING EXPERTISE IN GENETICS AND GENOMICS

Essential Competencies in Genetics and Genomics for All Nurses

Nearly 50 organizations, including the Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) and the National Association of Neonatal Nurses (NANN), have endorsed the *Essential Nursing Competencies and Curriculum Guidelines for Genetics and Genomics* (www.genome.gov/17517146). According to these guidelines, which were developed by an independent panel of nurse leaders from clinical, research, and academic settings and published by the American Nurses Association and the National Human Genome Research Institute of the National Institute of Health (Consensus Panel on Genetic/Genomic Nursing Competencies, 2009), all nurses need to have minimal competencies in genetics and genomics regardless of their academic preparation, practice setting, or specialty. Some of the competencies most relevant to nurses in the area of maternity and women's health include:

- Constructs a pedigree from collected family history information using standardized symbols and terminology
- Develops a plan of care that incorporates genetic and genomic assessment information
- Recognizes when one's own attitudes and values related to genetics and genomic science may affect care provided to clients
- Provides clients with credible, accurate, appropriate, and current genetic and genomic information, resources, services, and/or technologies that facilitate decision making
- Demonstrates in practice the importance of tailoring genetic and genomic information and services to clients based on their culture, religion, knowledge level, literacy, and preferred language
- Assesses clients' knowledge, perceptions, and responses to genetic and genomic information
- Facilitates referrals for specialized genetic and genomic services for clients as needed

Expanded Roles for Maternity and Women's Health Nurses

Expanded roles for nurses with expertise in genetics and genomics are developing in many areas of maternity and women's health nursing. These areas include but are not limited to prenatal screening and testing; carrier testing during pregnancy; newborn screening; palliative care for infants with life-threatening genetic conditions and their families; the identification and care of individuals with genetic conditions

and their families; and the care of women with genetic conditions who require specialized care during pregnancy, such as women with neuromuscular disease, cystic fibrosis, and factor V Leiden (DeLuca, Zanni, Bonhomme, & Kemper, 2013; Frazer, Porter, & Goss, 2013; Johnson, Giarelli, Lewis, & Rice, 2013; Prows, Hopkin, Barnoy, & Van Riper, 2013; Sparbel & Tluczek, 2011; Sparbel & Williams, 2009; Van Riper, 2007, 2012; Weinstein, 2009; Wilke et al., 2013). The Oncology Nursing Society (ONS) (www.ons.org) has taken an active role in providing oncology nurses with the education and resources they need to integrate genetics and genomics into all phases of care for individuals and families affected by cancer, including information specifically related to cancers affecting women.

HUMAN GENOME PROJECT AND IMPLICATIONS FOR CLINICAL PRACTICE

Two key findings from the Human Genome Project (www.genome.gov/12011238) were that (1) all human beings are >99% identical at the deoxyribonucleic acid (DNA) level, and (2) there are probably about 20,500 genes in the human genome. The finding that human beings are >99% identical at the DNA level should help discourage the use of science as a justification for drawing biologically precise racial boundaries around certain groups of people. Originally, scientists had estimated that there were 50,000 to 140,000 genes in the human genome. It had been assumed that the main reason that humans are more evolved and more highly sophisticated than other species is that they have more genes. A new explanation for human complexity, given the relatively small number of genes, is that humans are more efficient with their genes. Humans are able to do much more with their genes than are other species. Instead of producing only one protein per gene, most human genes produce at least three proteins.

Importance of Family History

Completion of the Human Genome Project and the resultant identification of the inherited causes for many diseases has resulted in renewed interest in family history. Although it is easy to be impressed by the more than 3600 genetic tests currently available (www.ncbi.nlm.nih.gov/gtr), family history will most likely continue to be the single most cost-effective piece of genetic information. In 2008, Solomon, Jack, and Feero described a complete three-generation family history that includes ancestry information concerning both sides of family as the best genetic "test" applicable to preconception care. When nurses and other clinicians conduct a family history, they can gain not only valuable information about the structure of the family and diseases that affect various individuals in the family, but also a rich understanding of family relationships, social context, occupations, lifestyle, and health habits (American College of Obstetricians and Gynecologists [ACOG], 2011; De Sevo, 2009).

The process of collecting this information often facilitates the development of a relationship between the client/family and the clinician. In 2004, the U.S. Department of Health and Human Services launched the Family History Initiative by designating Thanksgiving Day as National Family History Day. The U.S. Surgeon General encouraged families to

use their family gatherings as a time to talk about and collect important family health history. A number of family history tools are available free of charge online. One of the most widely used family history tools is the *My Family Health Portrait* (<https://familyhistory.hhs.gov>). Another helpful tool is the family health history tool, *Does it run in the family?* that was developed by the Genetic Alliance (www.doesitrunithefamily.org). The Centers for Disease Control and Prevention (CDC) also provides links to family history resources (www.cdc.gov/genomics/famhistory/famhist.htm).

The preconception period is an ideal time to review family history and provide personalized recommendations based on family history (ACOG, 2011). It is also one of the best times to counsel couples about carrier testing options that are based on known population-specific risks (Bodurtha & Strauss, 2012). Finally, the preconception period is an optimal time to refer couples, when appropriate, to specialists in high risk pregnancy and genetics.

Gene Identification and Testing

Initial efforts to sequence and analyze the human genome have proven invaluable in the identification of genes involved in disease and in the development of genetic tests. In an effort to bridge the transition from discovery to diagnostics and treatments, the National Institutes of Health launched the *Genetic Testing Registry* (GTR) in 2012. The GTR (www.ncbi.nlm.nih.gov/gtr) is a free online tool that can be used to obtain a list of available genetic tests. The GTR website also includes links to other resources such as *GeneReviews* and Online Mendelian Inheritance in Man (OMIM). *GeneReviews* is a collection of expert-authored, peer-reviewed disease descriptions presented in a standardized format and focused on clinically relevant and medically actionable information on the diagnosis, management, and genetic counseling of individuals and families with specific inherited conditions. OMIM is an online catalog of human genes and genetic disorders.

Genetic testing involves the analysis of human DNA, **ribonucleic acid (RNA)**, which has a major role in protein synthesis, chromosomes (threadlike packages of genes and other DNA in the nucleus of a cell), or proteins to detect abnormalities related to an inherited condition. Genetic tests can be used to examine directly the DNA and RNA that make up a gene (direct or molecular testing), look at markers that are coinherited with a gene that causes a genetic condition (linkage analysis), examine the protein products of genes (biochemical testing), or examine chromosomes (cytogenetic testing). Cytogenetic analysis of malignant tissue has become a mainstay of oncology.

Most of the genetic tests now offered in clinical practice are tests for single-gene disorders in clients with clinical symptoms or who have a family history of a genetic disease (<http://iml.dartmouth.edu/education/cme/Genetics>). Some of these genetic tests are prenatal tests or tests used to identify the genetic status of a pregnancy at risk for a genetic condition. Current prenatal testing options include maternal serum screening (a blood test used to see if a pregnant woman is at increased risk for carrying a fetus with a neural tube defect or a chromosomal abnormality such as Down syndrome, trisomy 18 or trisomy 13), fetal ultrasound or sonogram (an imaging technique using high-frequency sound waves to produce images of the fetus inside the uterus), invasive procedures (chorionic

villus sampling and amniocentesis), and noninvasive prenatal testing for fetal aneuploidy (a blood test that uses cell-free DNA from the plasma of pregnant women to screen for Down syndrome and, in some cases, trisomy 13 and trisomy 18). The American College of Obstetricians and Gynecologists (ACOG) has recommended that all women, regardless of maternal age, be offered prenatal assessment for aneuploidy (an abnormal number of chromosomes within a cell) either by screening or invasive prenatal diagnosis. ACOG currently considers noninvasive prenatal testing for fetal aneuploidy as one option that can be used as a primary screening test in women considered to be at increased risk of aneuploidy, such as women with a history of a child affected by a trisomy or women who carry a balanced translocation. ACOG also considers this type of testing appropriate for follow-up testing for women with a positive prenatal screening test result from maternal serum screening. However, ACOG does not recommend the use of noninvasive prenatal testing for aneuploidy with low risk pregnant women or women with multiple gestations (ACOG, 2012).

Another type of genetic test is the **carrier** screening test used to identify individuals who have a gene mutation for a genetic condition but do not show symptoms of the condition because it is an autosomal recessive condition (e.g., CF, sickle cell disease, and Tay-Sachs disease). A third type of genetic testing is **predictive testing**, which is used to clarify the genetic status of asymptomatic family members. The two types of predictive testing are presymptomatic and predispositional. Mutation analysis for HD, a neurodegenerative disorder, is an example of **presymptomatic testing**. If the gene mutation for HD is present, symptoms of HD are certain to appear if the individual lives long enough. Testing for a BRCA1 gene mutation to determine breast cancer susceptibility is an example of predispositional testing. **Predispositional testing** differs from presymptomatic testing in that a positive result (indicating that a BRCA1 mutation is present) does not indicate a 100% risk of developing the condition (breast cancer).

In addition to using genetic tests to test for single-gene disorders in clients with clinical symptoms or who have a family history of a genetic disease, genetic tests are used for population-based screening. For example, each year in the United States, approximately 4 million infants undergo newborn screening (Bodurtha & Strauss, 2012; Guttmacher et al., 2010). Newborn screening is a mandatory, state-supported public health program. Initially, newborn screening in the United States was only concerned with a few conditions such as phenylketonuria (PKU). However, with the advent of tandem mass spectrometry, the number of conditions tested for during newborn screening grew rapidly (DeLuca et al., 2013). Currently, most states test newborns for 31 core disorders and 26 secondary disorders (McCarthy et al., 2013). A complete list of conditions tested for in each state is available on the National Newborn Screening and Genetics Resource website (<http://genes-r-us.uthscsa.edu>).

Another type of population-based screening is carrier screening for single-gene disorders such as CF, sickle cell disease, and Tay-Sachs disease either preconceptionally or prenatally. In 2001, the ACOG and the American College of Medical Genetics (ACMG) recommended that clinicians offer carrier screening for CF to individuals with a family history of CF, reproductive partners of individuals who have CF, and couples in whom one

or both partners are Caucasian and are planning a pregnancy or seeking prenatal care (ACOG/ACMG, 2001). Recommendations for newborn screening for cystic fibrosis appeared in 2004, and soon after this many newborn screening programs in the United States began offering newborn screening for CF. One outcome of this broader carrier and newborn screening for CF is that more and more individuals are being informed they have a CF mutation. However the correlation between genotype (an individual's collection of genes) and phenotype (an individual's observable traits) is poor for many of the more than 1900 CF mutations identified to date. That is, whereas some CF mutations are associated with significant health problems (poor growth, greasy stools, and chronic respiratory problems), others are not. Because of this, the significance of many CF mutations is uncertain. As a result, nurses and other health care professionals are increasingly being asked to communicate results with uncertain significance to individuals and families during the preconception, prenatal, and newborn periods (Sparbel & Tluczek, 2011). In 2008 the National Human Genome Research Institute held a workshop to discuss lessons learned and new opportunities for population-based carrier screening (www.genome.gov/27026048). One of the main conclusions from this workshop was that a more coherent and systematic approach is needed for the introduction of new tests into population-based screening programs.

The use of genome sequencing (e.g., whole genome sequencing and next-generation sequencing), is entering the clinical setting (Conley, Biesecker, Gonsalves, et al., 2013; McCarthy et al., 2013; Wade, Tarini, & Wilfond, 2013). The cost of sequencing a human genome dropped from \$100 million in 2001 to less than \$10,000 in 2012. Current indications suggest that soon it may be possible to sequence a person's entire genome for around \$1,000. The cost of sequencing has already dropped to the point that sequencing the whole genome may be cheaper and more efficient than testing a client who has a complex condition of unknown origin for a select group of genetic conditions.

Pharmacogenomics

One of the most promising clinical applications of the Human Genome Project has been pharmacogenomic testing (the use of genetic information to guide a client's drug therapy) (Ginsburg & Willard, 2009). Associations between genetic variation and drug effect have been observed for a number of commonly used drugs, including warfarin, an anticoagulant commonly used to reduce the risk of thromboembolic events in clients with a history of deep vein thrombosis, pulmonary embolism, myocardial infarction, or atrial fibrillation (McCarthy et al., 2013; Meckley, Gudgeon, Anderson, et al., 2010). Warfarin is a drug with a narrow therapeutic index; it can result in serious bleeding with supratherapeutic doses and thromboembolic events with subtherapeutic doses. Because of this and the fact that there is a great deal of inter- and inpatient dose variation, warfarin is one of the most common causes of serious adverse drug reactions. There is mounting evidence that genotype-guided warfarin dosing may not only help reduce the serious adverse drug reactions commonly associated with warfarin, but also increase dosing accuracy, shorten the time to dose stabilization, and help identify individuals who may require more frequent monitoring. In August 2007, the U.S. Food and Drug Administration (FDA) approved updated labeling for warfarin. The updated

labeling acknowledges that individuals with variations in their CYP2C9 and VKORC1 genes may require a lower initial dose of warfarin. However, there are not enough clinical data yet to recommend that this type of testing be mandatory.

Pharmacogenomic testing can also be used to target therapies. Trastuzumab (Herceptin), a monoclonal antibody that specifically targets HER2/neu overexpressing breast tumors, is an example of a drug for which an obligatory genetic test has been developed (McCarthy et al., 2013). The purpose of this obligatory genetic test is to identify the subset of women with breast cancer who overexpress HER2/neu. Women who overexpress HER2/neu are most likely the only breast cancer clients who will benefit from taking trastuzumab (www.herceptin.com/index.jsp).

Gene Therapy

In the early 1990s a great deal of optimism was felt about the possibility of using gene therapy to correct a long list of inherited diseases. Generally, **gene therapy** involves inserting a healthy copy of the defective gene into the **somatic cells** (any cell of the body except sperm and egg cells) of the affected individual. Although the early optimism about gene therapy was probably never fully justified, gene therapy has moved from preclinical to clinical studies for many diseases ranging from hemophilia and other single-gene disorders to complex disorders such as cancer, human immunodeficiency virus (HIV), and cardiovascular disorders (Gillet, Macadangang, Fathke, et al., 2009). Early hype, failures, and tragic events, such as the death of Jesse Gelsinger (18-year-old male with an X-linked genetic liver disease who was the first person publicly identified as having died in a gene therapy clinical trial) have now largely been replaced by step-wise progress in carefully developed, scientifically precise clinical trials (Gillet et al; Kohn & Candotti, 2009). Major challenges to gene therapy include figuring out how to target the right gene to the right location in the right cells, expressing the transferred gene at the right time, and minimizing adverse reactions.

Ethical, Legal, and Social Implications

Before the beginning of the Human Genome Project, widespread concern about misuse of the information gained through genetics research resulted in 5% of the Human Genome Project budget being designated for the study of the **ethical, legal, and social implications (ELSI)** of human genome research. Two large ELSI programs were created to identify, analyze, and address the ELSIs of human genome research at the same time that the basic science issues were being studied. Since 2004, issues of high priority for these programs have been privacy and fairness in the use and interpretation of genetic information; clinical integration of new genetics technologies; issues surrounding genetics research, such as possible discrimination and stigmatization; and education for professionals and the general public about genetics, genetics health care, and ELSI of human genome research. Both ELSI programs have excellent websites that include vast amounts of educational information, as well as links to other informative sites (www.genome.gov/10001618; www.ornl.gov/sci/techresources/Human_Genome/elsi/elsi.shtml).

The major risk associated with genetic testing concerns what happens with the information gained through testing: it may result in increased anxiety and altered family relationships; it may be difficult to keep confidential; and it may result in discrimination and

stigmatization. More important, there is still a large gap between the ability to test for a genetic condition and the ability to treat the same condition. In addition, informed consent is difficult to ensure when some of the outcomes, benefits, and risks of genetic testing remain unknown. Also, many of the tests being used are as yet imperfect—few have a 100% detection rate. Individuals and families who receive false-positive results (the test results indicate that a person or fetus is affected by a genetic condition when he or she is not) may terminate an unaffected pregnancy or undergo unwarranted extreme measures such as bilateral prophylactic mastectomy. Individuals and families who receive false-negative results (the test results indicate that a person or fetus is not affected by a genetic condition when he or she is) may fail to follow surveillance strategies designed to improve their health outcomes because they have been falsely reassured that they are not at increased risk for a specific condition (see Community Activity).

COMMUNITY ACTIVITY

Select two web addresses for resources on genetics for parents. Access the sites.

- Compare and contrast the appearance, readability, and information contained in the sites.
- Is the information available for parents who do not read English?
- Do you agree that these sites are appropriate for parents?
- Is the information contained culturally relevant?
- How could you, as a nurse, use this information?
- Role play with a classmate, reviewing the information with a parent undergoing genetic testing.

Factors Influencing the Decision to Undergo Genetic Testing

The decision to undergo genetic testing is seldom an autonomous decision based solely on the needs and preferences of the individual being tested. Instead, it is often a decision based on feelings of responsibility and commitment to others (Van Riper, 2005). For example, a woman who is receiving treatment for breast cancer may undergo BRCA1/BRCA2 mutation testing not because she wants to find out if she carries a BRCA1 or BRCA2 mutation, but because her two unaffected sisters have asked her to be tested, and she feels a sense of responsibility and commitment to them. A female airline pilot with a family history of HD, who has no desire to find out if she has the gene mutation associated with HD, may undergo mutation analysis for HD because she feels she has an obligation to her family, her employer, and the people who fly with her.

Decisions about genetic testing are shaped, and in many instances constrained, by factors such as social norms, where care is received, and socioeconomic status. Most pregnant women in the United States now have at least one ultrasound examination, many undergo some type of multiple-marker screening, and a growing number undergo other types of prenatal testing. The range of prenatal testing options available to a pregnant woman and her family may vary significantly based on where the pregnant woman receives prenatal care and her socioeconomic status. Certain types of prenatal testing may not be available in smaller communities and rural settings (e.g., chorionic villus sampling and fluorescent in situ hybridization [FISH] analysis). In addition, certain types of genetic testing

may not be offered in conservative medical communities (e.g., preimplantation genetic screening). Some types of genetic testing are expensive and typically not covered by health insurance. Because of this, these tests may be available only to a relatively small number of individuals and families: those who can afford to pay for them (Badzek, Henaghan, Turner, & Monsen, 2013).

Cultural and ethnic differences also have a significant effect on decisions about genetic testing. When prenatal diagnosis was first introduced, the principal constituency was a self-selected group of Caucasian, well-informed, middle- to upper-class women. Today the widespread use of genetic testing has introduced prenatal testing to new groups of women, women who had not previously considered genetic services. The fact that many of the women currently undergoing prenatal testing may not share mainstream U.S. views about the role of medicine and prenatal care, the meaning of disability, or how to respond to scientific risks and uncertainties further amplifies the complexity of ethical issues associated with prenatal testing.

The genetic testing experience raises fundamental questions about the mutual obligations of kin. Are individuals morally obligated to alert extended family members about inherited health risks? Conversely, do extended family members have a moral obligation to participate in research designed to determine genetic risk when unwanted information about them may be generated in the process? Another important question that must be considered is “Whose gene is it?” This question is likely to stimulate a great deal of debate, especially in the area of preimplantation genetic diagnosis (when one or both parents has a known genetic abnormality and testing is performed on an embryo to determine if it also carries a genetic abnormality).

CLINICAL GENETICS

Genetic Transmission

Human development is a complicated process that depends on the systematic unraveling of instructions found in the genetic material of the egg and the sperm. Development from conception to birth of a healthy, typically developing baby occurs without incident in most cases; however, the baseline risk of some type of birth defect is estimated to be 3% to 4% for all pregnancies.

Genes and Chromosomes

The hereditary material carried in the nucleus of each of the somatic cells determines an individual’s characteristics. This material, called **deoxyribonucleic acid (DNA)**, forms threadlike strands known as **chromosomes**. Each chromosome is composed of the many smaller segments of DNA referred to as genes. Genes, or combinations of genes, contain coded information that determines an individual’s unique characteristics. The “code” is found in the specific linear order of the molecules that combine to form the strands of DNA. Genes control both the types of proteins that are made and the rate at which they are produced. Genes never act in isolation; they always interact with other genes and the environment.

All normal human somatic cells contain 46 chromosomes arranged as 23 pairs of homologous (matched) chromosomes; one chromosome of each pair is inherited from each parent. There are 22 pairs of **autosomes** that control most traits in the body, and one pair of **sex chromosomes**. Whereas the Y chromosome is primarily concerned with sex determination, the X chromosome contains

genes that are involved in much more than sex determination. The larger female chromosome is called the X; the smaller male chromosome is the Y. Generally the presence of a Y chromosome causes an embryo to develop as a male; in the absence of a Y chromosome, the individual develops as a female. Thus in a normal female, the homologous pair of sex chromosomes is XX, and in a normal male, the homologous pair is XY.

Homologous chromosomes (except the X and Y chromosomes in males) have the same number and arrangement of genes. In other words, if one chromosome has a gene for hair color, its partner chromosome also will have a gene for hair color, and these hair-color genes will have the same loci or be located in the same place on the two chromosomes. Although both genes code for hair color, they may not code for the same hair color. Genes at corresponding loci on homologous chromosomes that code for different forms or variations of the same trait are called alleles. An individual having two copies of the same allele for a given trait is said to be **homozygous** for that trait; with two different alleles, the person is **heterozygous** for the trait.

The term **genotype** typically is used to refer to the genetic makeup of an individual when discussing a specific gene pair, but at times, genotype is used to refer to an individual's entire genetic makeup or all the genes that the individual can pass on to future generations. **Phenotype** refers to the observable expression of an individual's genotype, such as physical features, a biochemical or molecular trait, and even a psychologic trait. A trait or disorder is considered **dominant** if it is expressed or phenotypically apparent when only one copy of an allele associated with the trait is present. It is considered **recessive** if it is expressed only when two copies of the alleles associated with the trait are present.

As more is learned about genetics and genomics, the concepts of dominance and recessivity have become more complex, especially in X-linked disorders. For example, traits considered to be recessive may be expressed even when only one copy of a gene located on the X chromosome is present. This occurs frequently in males because males have only one X chromosome; thus they have only one copy of the genes located on the X chromosome. Whichever gene is present on the one X chromosome determines which trait is expressed. Females, conversely, have two X chromosomes, so they have two copies of the genes located on the X chromosome. However, in any female somatic cell, only one X chromosome is functioning (otherwise, there would be inequality in gene dosage between males and females). This process, known as X-inactivation or the Lyon hypothesis, is generally a random occurrence. That is, there is a 50/50 chance as to whether the maternal X or the paternal X is inactivated. Occasionally the percentage of cells that have the X with an abnormal or mutant gene is very high. This helps explain why hemophilia, an X-linked recessive disorder, can clinically manifest itself in a female known to be a heterozygous carrier (a female who has only one copy of the gene mutation). It also helps explain why traditional methods of carrier detection are less effective for X-linked recessive disorders; the possible range for enzyme activity values can vary greatly, depending on which X chromosome is inactivated.

Chromosomal Abnormalities

Chromosomal abnormalities are a major cause of reproductive loss, congenital problems, and gynecologic disorders; the incidence is approximately 0.6% in newborns, 6% in stillbirths, and 60% in

spontaneous abortions (Martin, 2008). Errors resulting in chromosomal abnormalities can occur during mitosis (cell division occurring in somatic cells that results in two identical daughter cells containing a diploid number of chromosomes) or meiosis (division of a sex cell into two and four haploid cells). These errors can occur in either the autosomes or the sex chromosomes. Even without the presence of obvious structural malformations, small deviations in chromosomes can cause problems in fetal development.

The pictorial analysis of the number, form, and size of an individual's chromosomes is known as a **karyotype**. Cells from any nucleated, replicating body tissue (not red blood cells, nerves, or muscles) can be used. The most commonly used tissues are white blood cells and fetal cells in amniotic fluid. The cells are grown in a culture and arrested when they are in metaphase (during metaphase, the chromosomes are condensed and visible with a light microscope), and then the cells are dropped onto a slide. This breaks the cell membranes and spreads the chromosomes, making them easier to visualize. Next the cells are stained with special stains (e.g., Giemsa stain) that create striping or "banding" patterns. These patterns aid in the analysis because they are consistent from person to person. Once the chromosome spreads are photographed or scanned by a computer, they are cut out and arranged in a specific numeric order according to their length and shape. The chromosomes are numbered from largest to smallest, 1 to 22, and the sex chromosomes are designated by the letter X or Y. Each chromosome is divided into two "arms" designated by p (short arm) and q (long arm). A female karyotype is designated as 46, XX and a male karyotype is designated as 46, XY. Figure 3-1 illustrates the chromosomes in a body cell.

Autosomal Abnormalities

Autosomal abnormalities involve differences in the number or structure of autosome chromosomes (pairs 1 to 22). They result from unequal distribution of genetic material during **gamete** (egg and sperm) formation.

Abnormalities of Chromosome Number. A **euploid cell** is a cell with the correct or normal number of chromosomes within the cell. Because most gametes are **haploid** (1N, 23 chromosomes) and most somatic cells are **diploid** (2N, 46 chromosomes), they are both considered euploid cells. Deviations from the correct number of chromosomes per cell can be one of two types: (1) **polyploidy**, in which the deviation is an exact multiple of the haploid number of chromosomes or one chromosome set (23 chromosomes); or (2) **aneuploidy**, in which the numerical deviation is not an exact multiple of the haploid set. A **triploid** (3N) cell is an example of a polyploidy. It has 69 chromosomes. A **tetraploid** (4N) cell, also an example of a polyploidy, has 92 chromosomes.

Aneuploidy is the most commonly identified chromosome abnormality in humans and the leading genetic cause of intellectual disability. A **monosomy** is the product of the union between a normal gamete and a gamete that is missing a chromosome. Monosomic individuals have only 45 chromosomes in each of their cells. The product of the union of a normal gamete with a gamete containing an extra chromosome is a **trisomy**. The most common autosomal aneuploid conditions involve trisomies. Trisomic individuals have 47 chromosomes in most or all their cells.

The vast majority of trisomies occurs during oogenesis (the process by which a premeiotic female germ cell divides into a mature egg) and the incidence of these types of chromosomal errors increases exponentially with advancing maternal age

FIG 3-1 Chromosomes during cell division. A, Example of photomicrograph. B, Chromosomes arranged in karyotype; female and male sex-determining chromosomes.

(Hassold & Hunt, 2009; Hunt & Hassold, 2008). Although variation exists among trisomies with regard to the parent and stage of origin of the extra chromosome, most trisomies are maternal meiosis I (MI) errors. This means that most trisomies are caused by **nondisjunction** during the first meiotic division. The first meiotic division involves the segregation of homologous or similar chromosomes. One pair of chromosomes fails to separate. One resulting cell contains both chromosomes, and the other contains none. The fact that most trisomies are maternal MI errors is not that surprising, because maternal MI occurs over a long time span. It is initiated in precursor cells during fetal development, but it is not completed until the time those cells undergo ovulation after menarche.

The most common trisomal abnormality is **Down syndrome (DS)**. In the United States, approximately 1 in every 691 newborns has DS, and it is estimated that there are more than 400,000 individuals with DS living in the United States (Prows et al., 2013; www.cdc.gov/ncbddd/birthdefects/Down-Syndrome.html; <http://ndsccenter.org>; www.ndss.org). Current estimates suggest there are around 6 million people with DS in the world. Approximately 95% of individuals with DS have trisomy 21 or an extra chromosome 21 (47, XX +21, female with DS; or 47, XY +21, male with DS). Another type of DS, translocation, occurs when extra chromosome 21 material is present in every cell of the individual but it is attached to another chromosome. This type of DS affects approximately 3% to 4% of individuals with DS. In the third type of DS, mosaicism, extra chromosome 21 material is found in some but not all of the cells. Only 1% to 2% of individuals with DS have mosaicism.

Although the clinical presentation of DS is complex and variable (Bull & Committee on Genetics, 2011; Ivan & Cromwell 2013a), all individuals with DS have some level of intellectual disability. Common characteristics seen in individuals with Down syndrome are as follows:

- Oblique palpebral fissures or an upward slant to the eyes
- Epicanthal folds or small skinfolds on the inner corners of the eyes

FIG 3-2 Infant with Down syndrome. Note upward slant to eyes, flat nasal bridge, slightly protruding tongue, and mottled skin. (Courtesy Thomas and Christie Coghill, Clayton, NC.)

- Small, white, crescent-shaped spots on the irises called Brushfield spots
- A flat facial profile that usually includes a somewhat depressed nasal bridge and a small nose
- Enlargement of the tongue in relationship to size of the mouth
- Small ears, which may be abnormally shaped or abnormally rotated
- Short, broad hands with a fifth finger that has one flexion crease instead of two
- A single deep crease across the center of the palm, often referred to as a simian crease
- Excessive space between the large and second toes
- Hyperflexibility, an excessive ability to extend the joints
- Muscle hypotonia or low muscle tone

Some individuals with DS have all of these characteristics, but others have only a few. Figure 3-2 is a picture of an infant with DS who has some of the characteristics commonly associated with that syndrome (see Nursing Care Plan).

 **NURSING CARE PLAN**
The Family Living with a Neonate with Down Syndrome

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Interrupted Family Processes related to birth of a neonate with Down syndrome</i>	The couple will verbalize accurate information about Down syndrome, including implications for future pregnancies.	<p>Assess knowledge base of couple regarding the clinical signs and symptoms of Down syndrome.</p> <p>Provide information throughout the genetic evaluation regarding risk status and clinical signs and symptoms of Down syndrome.</p> <p>Use therapeutic communication during discussions with the couple.</p> <p>Refer to support groups, social services, or counseling.</p> <p>Refer to child development specialist.</p>	<p>To correct any misconceptions and establish basis for teaching plan</p> <p>To give couple a realistic picture of neonate's defects and assist with decision making for future pregnancies</p> <p>To provide opportunity for expression of concern</p> <p>To assist family with cohesive actions and decision making</p> <p>To provide family with realistic expectations regarding cognitive and behavioral abilities of child with Down syndrome</p>
<i>Situational Low Self-Esteem related to diagnosis of Down syndrome as evidenced by parents' statements of guilt and shame</i>	The parents will express an increased number of positive statements regarding their neonate with Down syndrome.	<p>Assist parents to list strengths and coping strategies that have been helpful in past situations.</p> <p>Encourage expression of feelings using therapeutic communication.</p> <p>Clarify and provide information regarding Down syndrome.</p> <p>Refer for further counseling as needed.</p>	<p>To use appropriate strategies during this situational crisis</p> <p>To provide clarification and emotional support</p> <p>To decrease feelings of guilt and gradually increase feelings of positive self-esteem</p> <p>To provide more in-depth and ongoing support</p> <p>To promote bonding</p>
<i>Risk for Impaired Parenting related to birth of neonate with Down syndrome</i>	Parents will bond with and provide appropriate care for the infant.	<p>Assist parents to see and describe normal aspects of infant.</p> <p>Encourage and assist with breastfeeding if that is parents' choice of feeding method.</p> <p>Assure parents that information regarding the neonate will remain confidential.</p> <p>Discuss and role-play with parents ways of informing family and friends of infant's diagnosis and prognosis.</p>	<p>To facilitate closeness with infant and provide benefits of breast milk</p> <p>To assist the parents to maintain some situational control and allow for time to work through their feelings</p> <p>To promote positive aspects of infant and decrease potential isolation from social interactions</p>
<i>Spiritual Distress related to situational crisis of child born with Down syndrome</i>	Parents will seek appropriate support persons (family members, priest, minister, rabbi) for assistance.	<p>Provide anticipatory guidance about what to expect as infant develops.</p> <p>Listen for cues indicative of parents' feelings ("Why did God do this to us?").</p> <p>Acknowledge parents' spiritual concerns and encourage expression of feelings.</p> <p>Facilitate visits from clergy and provide privacy during visits.</p> <p>Encourage parents to discuss concerns with clergy.</p> <p>Facilitate interaction with family members and other support persons.</p>	<p>To assist family to provide appropriate stimulation to enhance development</p> <p>To identify messages indicating spiritual distress</p> <p>To help build a therapeutic relationship</p> <p>To demonstrate respect for parents' relationship with clergy</p> <p>To use expert spiritual care resources to help the parents</p> <p>To encourage expressions of concern and seek comfort</p>
<i>Social Isolation related to full-time caretaking responsibilities for a neonate with Down syndrome</i>	Parents will describe a plan to use resources to prevent social isolation.	<p>Provide opportunity for parents to express feelings about caring for a neonate with Down syndrome.</p> <p>Discuss with parents their expectations about caring for the neonate.</p> <p>Assist parents to identify potential caregiving resources</p> <p>Identify appropriate referrals for home care.</p>	<p>To facilitate effective communication and trust</p> <p>To identify potential areas of concern</p> <p>To permit parents to return to a routine at home</p> <p>To provide continuity of care</p>

Although the risk of having a child with Down syndrome increases with maternal age, children with Down syndrome can be born to mothers of any age: 80% of children with Down syndrome are born to mothers younger than 35 years (National Down Syndrome Society, 2013). The risk of a mother having a second child with Down syndrome is about 1% when the cause of the Down syndrome is trisomy 21 (see also Chapter 36).

Other autosomal trisomies that maternity and newborn nurses may see in practice are trisomy 18 and trisomy 13. Trisomy 18 (Edward syndrome) is more common than trisomy 13 (Patau syndrome); it occurs in about 1 out of every 3000 live births versus 1 out of every 10,000 live births for trisomy 13. Infants with trisomy 18 may exhibit more than 130 different anomalies, but some of the major phenotypic features and medical complications are small for gestational age or low birth weight; craniofacial abnormalities including cleft lip and/or palate, small mouth, and small jaw; weak cry; feeding difficulties; cardiac malformations; central nervous system manifestations including hypertonia, seizures, and apnea; and extremity malformations such as small fingernails and toenails, clenched fist with index finger overlapping the third finger, and rocker-bottom feet (<http://trisomy.org>; www.hopefortrisomy13and18.org; www.trisomy18.org/site/PageServer?pagename=homepage).

As with trisomy 18, infants with trisomy 13 have numerous abnormalities, the most common of which are central nervous system anomalies, visual abnormalities, microcephaly (small head), absent nasal bridge, cleft lip and palate, holoprosencephaly (one large eyelike structure in the center of the face due to fusion of the developing eyes), capillary hemangiomas, cardiac defects, extremity deformities including polydactyly (extra fingers or toes), renal abnormalities, and genital abnormalities (<http://trisomy.org>; <http://www.hopefortrisomy13and18.org>).

Infants with trisomy 18 and trisomy 13 usually have severe to profound intellectual disabilities. Although both conditions have a poor prognosis, with the vast majority of affected infants dying before they reach their first birthday, a growing number of infants with these trisomies are living longer and a small number are actually living into their 20s and 30s.

Nondisjunction also can occur during mitosis. If this occurs early in development when cell lines are forming, the individual has a mixture of cells, some with a normal number of chromosomes and others either missing a chromosome or containing an extra chromosome. This condition is known as **mosaicism**. The most common form of mosaicism in autosomes is mosaic Down syndrome.

Depending on when the nondisjunction occurs during development, different body tissues will have different numbers of chromosomes. The clinical characteristics of Down syndrome may be mild or with varying degrees of severity, depending on the number and location of the abnormal cells. An individual with mosaic Down syndrome may have normal intelligence. Mosaicism of both trisomy 18 and trisomy 13 has been reported. Both situations usually lead to a partial clinical expression of the phenotype. Infants who have mosaic trisomy 18 or trisomy 13 usually have a longer life span than infants with these disorders who are not mosaic.

Abnormalities of Chromosome Structure. Structural abnormalities can occur in any chromosome. Types of structural abnormalities include translocation, duplication, deletion, microdeletion, and inversion. **Translocation** results when there is an exchange of chromosomal material between two chromosomes. Exposure to certain drugs, viruses, and radiation can cause translocations, but often they arise for no apparent reason. The two major types of translocations are reciprocal and robertsonian. Reciprocal translocations are the most common. In a reciprocal translocation, either the parts of the two chromosomes are exchanged equally (**balanced translocation**) or a part of a chromosome is transferred to a different chromosome, creating an **unbalanced translocation** because there is extra chromosomal material—extra of one chromosome but the correct or deficient amount of the other chromosome. In a balanced translocation the individual is phenotypically normal because there is no extra chromosome material; it is just rearranged. In an unbalanced translocation, the individual will be both genotypically and phenotypically abnormal.

In a *robertsonian translocation*, the short arms (p arms) of two different acrocentric chromosomes (chromosomes with very short p arms) break, leaving sticky ends that then cause the two long arms (q arms) to stick together. This forms a new, large chromosome that is made of the two long arms. The individual with a balanced robertsonian translocation has 45 chromosomes. Because the short arm of acrocentric chromosomes contains genes for ribosomal RNA and these genes are represented elsewhere, the individual usually does not show any symptoms. The individual may produce an unbalanced gamete (sperm or egg with too many or too few genes). This can lead to reproductive difficulties such as miscarriages or birth defects. Of all cases of Down syndrome, 3% to 4% occur because one parent has a balanced robertsonian translocation, a translocation between chromosomes 21 and 14. The child with this type of Down syndrome has an unbalanced translocation because there is an extra part of chromosome 21. The second most common robertsonian translocation occurs between chromosomes 13 and 14.

Deletions result in the loss of chromosomal material and partial monosomy for the chromosome involved. Loss of chromosomal material at the end of a chromosome is referred to as a **terminal deletion**. In contrast, loss of chromosomal material anywhere else in the chromosome is called an **interstitial deletion**. The resulting clinical phenotype of either a terminal or an interstitial deletion will depend on how much of the chromosome has been lost and the number and function of the genes contained in the missing segment. **Microdeletions** are deletions too small to be detected by standard cytogenetic techniques. These deletions can be identified with FISH analysis. FISH technology uses a single-stranded piece of DNA with a fluorescent label that will adhere to its complementary piece of DNA in the chromosome being investigated.

Whenever a portion of a chromosome is deleted from one chromosome and added to another, the gamete produced may have either extra copies of genes or too few copies. The clinical effects produced can be mild or severe, depending on the amount of genetic material involved. Two of the

more common conditions are the deletion of the short arm of chromosome 5 (*cri du chat syndrome*) and the deletion of the long arm of chromosome 18. Cri du chat syndrome, so named after the typical mewing cry of the affected infant, causes severe intellectual disability with microcephaly and unusual facial appearance. Deletion of the long arm of chromosome 18 causes severe psychomotor delay with multiple organ malformations. *Velocardiofacial syndrome*, characterized by cardiac and craniofacial abnormalities, is an example of a microdeletion. In this syndrome, a very small piece of the long arm of chromosome 22 is missing. Microdeletions in the Y chromosome have been found in men with infertility problems.

Inversions are deviations in which a portion of the chromosome has been rearranged in reverse order. Few birth defects have been attributed to the presence of inversions, but it is suspected that inversions may be responsible for problems with infertility and miscarriages. Some inversions can be detected prenatally. Inversions do not appear to occur randomly; it is estimated that more than 40% of all inversions involve chromosome 9.

Sex Chromosome Abnormalities

Several sex chromosome abnormalities are caused by nondisjunction during gametogenesis in either parent. The most common deviation in females is *Turner syndrome* or monosomy X (45, X). The affected female is missing an X chromosome. She usually exhibits juvenile external genitalia with undeveloped ovaries. She is short and often has webbing of the neck, a low hairline in the back, low-set ears, and lymphedema of her hands and feet. Intelligence may be impaired (www.turnersyndrome.org; www.genetic.org). Most affected embryos miscarry spontaneously. In most cases of Turner syndrome, it is the paternal X or Y that is lost.

The most common deviation in males is *Klinefelter syndrome*, or trisomy XXY. The affected male has an extra X chromosome and exhibits poorly developed secondary sexual characteristics and small testes. He is infertile, usually tall, and may be slow to learn (www.genetic.org). Males who have mosaic Klinefelter syndrome may be fertile.

Patterns of Genetic Transmission

Heritable characteristics are those that can be passed on to offspring. The patterns by which genetic material is transmitted to the next generation are affected by the number of genes involved

in the expression of the trait. Many phenotypic characteristics result from two or more genes on different chromosomes acting together (referred to as **multifactorial inheritance**); others are controlled by a single gene (referred to as **unifactorial inheritance**). Specialists in genetics (e.g., geneticists, genetic counselors, and nurses with advanced expertise in genetics and genomics) predict the probability of the presence of an abnormal gene from the known occurrence of the trait in the individual's family and the known patterns by which the trait is inherited.

Multifactorial Inheritance

Most common congenital malformations result from multifactorial inheritance, a combination of genetic and environmental factors. Examples are cleft lip, cleft palate, congenital heart disease, neural tube defects, and pyloric stenosis. Each malformation may range from mild to severe, depending on the number of genes for the defect present or the amount of environmental influence. A neural tube defect may range from spina bifida, a bony defect in the lumbar region of the vertebrae with little or no neurologic impairment, to anencephaly, absence of brain development, which is always fatal. Some malformations occur more often in one sex. For example, pyloric stenosis and cleft lip are more common in males, and cleft palate is more common in females.

Unifactorial Inheritance

If a single gene controls a particular trait or disorder, its pattern of inheritance is referred to as *unifactorial mendelian*, or single-gene inheritance. The number of single-gene disorders far exceeds the number of chromosomal abnormalities. Potential patterns of inheritance for single-gene disorders include autosomal dominant, autosomal recessive, and X-linked dominant and recessive modes of inheritance.

Autosomal Dominant Inheritance. **Autosomal dominant inheritance disorders** are those in which only one copy of a variant allele is needed for phenotypic expression. The variant allele may be a result of a **mutation**, a spontaneous and permanent change in the normal gene structure, in which case the disorder occurs for the first time in the family. Usually an affected individual comes from multiple generations having the disorder. An affected parent who is heterozygous for the trait has a 50% chance of passing the variant allele to each offspring (Fig. 3-3, B and C). There is a vertical pattern of inheritance (there is no skipping of generations; if an individual has an autosomal dominant disorder such as HD, so must one of his or her parents). Males and females are equally affected.

FIG 3-3 Possible offspring in three types of matings. **A**, Homozygous-dominant parent and homozygous-recessive parent. Children all heterozygous, displaying dominant trait. **B**, Heterozygous parent and homozygous-recessive parent. Children 50% heterozygous, displaying dominant trait; 50% homozygous, displaying recessive trait. **C**, Both parents heterozygous. Children 25% homozygous, displaying dominant trait; 25% homozygous, displaying recessive trait; 50% heterozygous, displaying dominant trait.

Autosomal dominant disorders are not always expressed with the same severity of symptoms. For example, a woman who has an autosomal dominant disorder may show few symptoms and may not become aware of her diagnosis until after she gives birth to a severely affected child. Predicting whether an offspring will have a minor or severe abnormality is not possible. Sometimes an individual can acquire a de novo mutation (new mutation that spontaneously occurred in a gene carried by an individual germ cell) that can result in an autosomal dominant disorder (Prows et al., 2013). Examples of autosomal dominant disorders are HD, Marfan syndrome, neurofibromatosis, myotonic dystrophy, Stickler syndrome, Treacher Collins syndrome, and achondroplasia (dwarfism).

Neurofibromatosis (NF) is a progressive disorder of the nervous system that causes tumors to form on nerves anywhere in the body. NF affects all races, all ethnic groups, and both sexes equally. Half of the cases of NF result from a spontaneous genetic mutation, whereas the other half of cases are inherited in an autosomal dominant manner. Individuals with NF due to a spontaneous mutation have a 50% chance of transmitting the variant allele to the next generation with each pregnancy. Two genetically distinct forms of NF include NF1, the most common type, with an incidence of 1 in 3000 (Prows et al., 2013) and NF2, with an incidence of 1 in 40,000 (Clarke, 2009). The most distinctive features of NF1 are multiple **neurofibromas** (benign, soft tumors), freckles in the axilla or groin, and patches of skin pigmentation called **café-au-lait** spots (www.understandingnf1.org). Generally, symptoms of NF1 are mild and affected individuals are able to live healthy, productive lives. Individuals with NF2 typically develop bilateral **vestibular schwannomas** (tumors on the eighth cranial nerves, which are hearing and balance nerves); these tumors often cause pressure damage to nearby nerves that may result in the individual with NF2 experiencing headaches, facial pain, and facial numbness. Other symptoms typically experienced by individuals with NF2 include tinnitus (ringing noise in the ear) and poor balance. Some individuals with NF2 experience hearing loss in their teen years.

NF1 is inherited in an autosomal dominant manner with almost complete penetrance by age 5 years. Penetrance is defined as the proportion of heterozygotes for a dominant trait who express a trait, even mildly. Expression of NF1 is very variable. Affected members of the same family can look strikingly different as far as disease severity is concerned. The NF2 gene has been mapped to chromosome 22. The gene product, merlin, is thought to be a cytoskeleton protein that acts as a tumor suppressor. No treatment for NF is available, other than the surgical removal of the tumors. Once removed, the tumors may grow back.

Factor V Leiden (FVL) is the most common inherited risk factor for primary and recurrent venous thromboembolisms (Moll, 2009; www.fvleiden.org). It is an autosomal dominant disorder that markedly increases an individual's risk for deep vein thrombosis (blood clots in the large veins of the legs) and pulmonary emboli (blood clots that travel through the bloodstream and become embedded in the lungs), especially if the individual is a woman who (a) uses oral contraceptives, (b) is pregnant, or (c) is on hormone replacement therapy during

menopause. FVL is due to a mutation in the factor V gene, which leads to activated protein C (APC) resistance. If a woman is heterozygous (has inherited one copy of the FVL mutation), she has a 4- to 8-fold increase in her chance of developing venous blood clots, but her risk increases by a factor as high as 75- to 80-fold if she is homozygous (has inherited two copies of the FVL mutation) (National Institutes of Health, 2010). Women who carry the FVL mutation should not take oral contraceptives. In addition, if they become pregnant and they have a history of blood clots, it is recommended that they receive prophylactic anticoagulation (with low-molecular-weight heparin) during their pregnancy and for 6 weeks postpartum (Marik & Plante, 2008).

FVL can be accurately detected with genetic testing, but the most cost-effective way to screen for FVL is taking a careful individual and family history. Women with a personal or close family history of venous blood clots, pulmonary emboli, early onset and recurrent preeclampsia, recurrent fetal growth restriction, recurrent pregnancy loss and stillbirth, or placental abruption should be screened for FVL.

Autosomal Recessive Inheritance. **Autosomal recessive inheritance disorders** are those in which both genes of a pair are forms associated with the disorder to be expressed. Heterozygous individuals have only one variant allele and are unaffected clinically because their normal gene (wild-type allele) overshadows the variant allele. They are known as carriers of the recessive trait. Because these recessive traits are inherited by generations of the same family, an increased incidence of the disorder occurs in consanguineous matings (closely related parents). For the trait to be expressed, two carriers must each contribute a variant allele to the offspring (see Fig. 3-3, C). The chance of the trait occurring in each child is 25%. A clinically normal offspring may be a carrier of the gene. Autosomal recessive disorders have a horizontal pattern of inheritance rather than the vertical pattern seen with autosomal dominant disorders. That is, autosomal recessive disorders are usually observed in one or more siblings, but not in earlier generations. Males and females are equally affected. Most recessive disorders tend to have severe clinical manifestations, and affected offspring may not be able to, or choose not to, reproduce. If they do, all their offspring will at least be carriers for the disorder. Most inborn errors of metabolism (IEMs), such as PKU, galactosemia, maple syrup urine disease, Tay-Sachs disease, sickle cell anemia, and CF, are autosomal recessive inherited disorders.

Inborn Errors of Metabolism. More than 350 **inborn errors of metabolism** have been recognized (Jorde, Carey, & Bamshad, 2010). Individually, IEMs are relatively rare, but collectively, they are common (1 in 5000 live births). Archibald Garrod first used the term "*inborn errors of metabolism*" in 1908 when he described variants of metabolism. Garrod recognized that IEMs illustrate our "chemical individualities." As noted, most IEMs are inherited in an autosomal recessive pattern. IEMs occur when a gene mutation reduces the efficiency of encoded enzymes to a level at which normal metabolism cannot occur. Defective enzyme action interrupts the normal series of chemical reactions from the affected point onward. The result may be an accumulation of a damaging product, such as phenylalanine in

PKU, or the absence of a necessary product, such as the lack of melanin in albinism caused by lack of tyrosinase. Diagnostic and carrier testing is available for a growing number of IEMs. In addition, many U.S. states have started screening for specific IEMs as part of their expanded newborn screening programs using tandem mass spectrometry. However, many of the deaths caused by IEMs are due to enzyme variants not currently screened for in many of the newborn screening programs (Jorde et al.).

Phenylketonuria is a relatively uncommon autosomal recessive disorder. A deficiency in the liver enzyme phenylalanine hydroxylase results in failure to metabolize the amino acid phenylalanine, allowing its metabolites to accumulate in the blood. The incidence of this disorder is 1 in every 10,000 to 20,000 births. The highest incidence is found in Caucasians (from northern Europe and the United States). It is rarely seen in Jewish, African, or Japanese populations. Screening for PKU is routinely performed as part of state-mandated newborn screening in the United States.

Tay-Sachs disease is a lipid-storage disease that occurs more commonly in Ashkenazi Jews and French-Canadians from Quebec. It results from a deficiency in hexosaminidase. Until age 4 to 6 months, infants with Tay-Sachs disease appear normal; their facial features are considered very beautiful. Then the clinical symptoms appear: apathy and regression in motor and social development and decreased vision. Death occurs between ages 3 and 4 years. No treatment exists for Tay-Sachs disease.

X-Linked Dominant Inheritance. **X-linked dominant inheritance** mimics autosomal dominant inheritance, except that male-to-male transmission cannot occur unless the father has Klinefelter syndrome due to XY disomy. X-linked dominant inheritance disorders occur in males and heterozygous females, but because of X inactivation, affected females are usually less severely affected than affected males and they are more likely to transmit the abnormal gene (variant allele) to their offspring. Heterozygous females (females who have one wild-type allele and one variant allele) have a 50% chance of transmitting the abnormal gene (variant allele) to each offspring. Mating of an affected male and an unaffected female is uncommon as a result of the tendency for the variant allele to be lethal in affected males because they have no normal gene (wild-type allele). Relatively few X-linked dominant disorders have been identified. Two examples are vitamin D-resistant rickets and Rett syndrome.

X-Linked Recessive Inheritance. Abnormal genes for **X-linked recessive inheritance disorders** are carried on the X chromosome. Females may be heterozygous or homozygous for traits carried on the X chromosome because they have two X chromosomes. Males are hemizygous because they have only one X chromosome, which carries genes with no alleles on the Y chromosome. Therefore, X-linked recessive disorders are most commonly manifested in the male, with the abnormal gene on his single X chromosome. Hemophilia, color blindness, and Duchenne muscular dystrophy are X-linked recessive disorders.

The male with an X-linked recessive disorder receives the disease-associated allele from his carrier mother on her affected X chromosome. Female carriers (those heterozygous for the trait) have a 50% probability of transmitting the disease-associated

allele to each offspring. An affected male can pass the disease-associated allele to his daughters but not to his sons. The daughters will be carriers of the trait if they receive a normal gene on the X chromosome from their mother. They will be affected only if they receive a disease-associated allele on the X chromosome from both their mother and their father.

Fragile X syndrome (FXS), the leading monogenic cause of intellectual disability and autism, is an X-linked disorder that has a complex pattern of inheritance (Bagni & Oostra, 2013). FXS is almost exclusively caused by a trinucleotide repeat expansion (CGG) at a “fragile site” on the long arm of the X chromosome. Most people have 5 to 40 CGG repeats. Individuals with FXS have more than 200 CGG repeats. The abnormally expanded CGG segment inactivates or silences the **FMR1** (fragile X intellectual disability) gene, which prevents the gene from producing a protein called fragile X intellectual disability protein. Loss of this protein leads to the characteristic physical features (large ears, long face, prominent forehead, protruding ears, hypermobile joints, and macroorchidism or increased testicular volume in postpubertal males) and behavior problems (poor eye contact, hyperactivity, social avoidance, repetitive speech, and self-injurious behavior) associated with FXS (Jorde et al., 2010; Schneider, Hagerman, & Hess, 2009). Males and females can be affected by FXS, but because males have only one X chromosome, a CGG repeat expansion on one X is likely to affect males more severely than females. Also the degree of intellectual disability tends to be milder and more variable in females than in males. Unlike Down syndrome, FXS is not generally detectable through a physical examination at birth. Delays and behavioral abnormalities gradually become apparent during the first 2 years of life, but ultimately the diagnosis of FXS can be verified only through DNA testing.

Individuals with more than 55 but fewer than 200 CGG repeats are said to be permutation carriers. These individuals were originally thought to be unaffected, but research has shown that about 20% of adult carrier females may develop premature ovarian failure (cessation of menses before 40 years of age). Elderly male permutation carriers may manifest fragile X-associated tremor/ataxia syndrome (FXTAS), which consists of parkinsonism, intention tremors, autonomic dysfunction, peripheral neuropathy, weakness in the legs, cognitive decline, and cerebellar ataxia (www.fragilex.org).

CANCER GENOMICS

Gene Mutations That Can Lead to Cancer

There are three main ways that people acquire gene mutations that can lead to cancer. The first is from the environment. Known factors in the environment that cause cancer are ultraviolet (UV) light (skin cancer) and tobacco smoke (lung cancer). The second way that people acquire mutations is by chance. Normal metabolic processes can generate chemicals that damage DNA. Third, people inherit mutations from their parents; hereditary mutations are thought to be a major factor in about 5% to 10% of all cancers.

The two main types of genes that have been recognized as playing a critical role in the development of cancer are **oncogenes** and **tumor suppressor genes** (American Cancer Society [ACS],

2013). Oncogenes are mutated forms of proto-oncogenes. The main functions of proto-oncogenes are to encourage and promote normal growth and development. When proto-oncogenes mutate to become carcinogenic oncogenes, the result is excessive cell multiplication. The activation of oncogenes has been compared to a jammed accelerator in a car. Most mutations of proto-oncogenes are acquired mutations, such as mutations in the *KIT* gene which are thought to cause most cases of gastrointestinal stromal tumor (GIST). This type of cancer can be treated with drugs that target the *KIT* gene, such as imatinib (Gleevec). Two examples of inherited mutations of proto-oncogenes are *ERBB2*, located on chromosome 13, and *KRAS2*, located on chromosome 12. *ERBB2* is involved in breast, ovarian, lung, gastric, and salivary gland cancers. *KRAS2* is involved in breast, pancreatic, thyroid, colorectal, bladder, and lung cancers, as well as acute myeloid leukemia.

Tumor suppressor genes normally function to inhibit or “put the brakes on” the cell growth and division cycle. They function to prevent the development of tumors. Mutations in tumor suppressor genes cause the cell to ignore one or more of the components of the network of inhibitory signals, removing the brakes from the cell cycle. This results in a higher rate of uncontrolled growth: cancer. Acquired mutations of the tumor protein p53 gene appear in a wide range of cancers, including lung, colorectal, and breast cancer. Examples of inherited tumor suppressor genes include *APC*, located on chromosome 5 and involved with familial adenomatous polyposis of the colon (FAP); *BRCA1*, located on chromosome 17 and associated with hereditary breast cancer and ovarian cancer; and *RB1*, found on chromosome 13 and involved with familial retinoblastoma.

Hereditary Breast and Ovarian Cancer (HBOC)

Breast cancer is a common disease and a central concern in women’s health. In the United States, breast cancer is the most common form of cancer for women and the second most common cause of death. Hereditary mutations are considered to be a key factor in approximately 5% to 10% of all breast and ovarian cancers. Another 15% to 20% of female breast cancers occur in women who have a family history of breast and ovarian cancer but do not carry a mutation in one of the genes that are known to be strongly associated with breast and ovarian cancer susceptibility.

BRCA1 and *BRCA2* mutations account for approximately 20% to 25% of hereditary breast cancers and about 5% to 10% of all breast cancers (National Cancer Institute, 2013). These mutations are inherited in an autosomal dominant pattern, thus each offspring of an individual found to carry a *BRCA* mutation has a 50% chance of inheriting the same mutation. According to estimates of lifetime risk, approximately 12% of women in the general population will develop breast cancer sometime during their lifetime, compared to about 55% to 65% women who have inherited a deleterious mutation in their *BRCA1* or *BRCA2* gene. Another way of saying this is that a woman with a deleterious *BRCA1* or *BRCA2* mutation is about five times more likely to develop breast cancer than a woman who does not carry a deleterious *BRCA1* or *BRCA2* mutation. Even though only about 6% of the men who carry a *BRCA* mutation develop breast cancer, men who carry a *BRCA* mutation have a 50% chance of passing the mutation on to their offspring. As

far as lifetime risk estimates for ovarian cancer, about 1.4% of women in the general population will be diagnosed with ovarian cancer during their lifetime, compared with 39% of women who have a deleterious *BRCA1* or *BRCA2* mutation. Carriers of *BRCA1* mutations may also be at increased risk for pancreatic, prostate, peritoneal, and uterine tube cancer.

Genetic testing for HBOC has been commercially available in the United States since 1995. The cost for testing usually ranges from several hundred to several thousand dollars. Although some insurance policies cover the cost of this type of genetic testing, others do not. Individuals who are considering undergoing *BRCA1* and *BRCA2* testing are encouraged to check their insurance coverage prior to undergoing testing. Women newly diagnosed with breast cancer are increasingly being asked to consider undergoing *BRCA1* and *BRCA2* testing before they make decisions about their treatment options because there is growing evidence that a woman’s short-term risk of developing a second breast cancer is substantially affected by whether she carries a *BRCA1* or *BRCA2* mutation, and prophylactic surgery has been found to decrease the risk of breast and ovarian cancer by more than 90%. The main advantage to offering *BRCA1* and *BRCA2* testing before the onset of treatment is that it gives women who are found to carry a deleterious mutation the option of choosing risk-reduction surgery concurrent with therapeutic surgical treatment.

Colon Cancer

Colon cancer is the third most common cancer in women and the third cause of cancer-related deaths in women. Only 10% of colon cancer cases are likely to involve a mutation in one of several predisposing genes. Two examples of predisposing genes are mutations in the *APC* tumor suppressor gene and mutations in a mismatch repair gene. Mutations in the *APC* tumor suppressor gene have been associated with FAP, a rare, autosomal dominant syndrome that accounts for about 1% of all colon cancer. It is typically diagnosed clinically. Affected individuals have 100 to 1000 polyps in their colon by the time they are 20 to 30 years old. Genetic testing is greater than 80% sensitive. Identification of high risk individuals guides surveillance strategies and the timing of a prophylactic colectomy. Low risk individuals can stop the increased surveillance.

Hereditary nonpolyposis colon cancer (HNPCC) results from mutations in one of many mismatch repair (MMR) genes. Mutations in two of these MMR genes (i.e., *MSH2* and *MLH1*) account for 50% to 60% of HNPCC. Families at high risk for HNPCC often have three or more relatives with colorectal cancer; colorectal cancer present in at least two generations; and a diagnosis of colorectal cancer before age 50 years in at least one case. HNPCC is characterized by an increased risk of colon cancer and other cancers that include cancers of the ovary, endometrium, stomach, small intestine, upper urinary tract, hepatobiliary tract, brain, and skin. The lifetime risk of colon cancer for individuals with HNPCC is approximately 80%. The majority of these cancers occurs in the proximal colon. Genetic tests are available to test for *MSH2* and *MLH1*. Testing should be done first on the affected family member. At-risk clients should be offered a prophylactic colectomy. Women may be offered a total abdominal hysterectomy with a salpingo-oophorectomy to decrease cancer risk. If colon cancer develops, a total colectomy is recommended.

GENETIC COUNSELING

Genetic counseling is a service that grew out of a need for professionals who could provide genetics information, education, and support to individuals and families with ongoing or potential genetic health concerns. In 2014, there were 32 accredited genetic counseling programs in the United States and 3 in Canada. At the same time, there were more than 3000 American Board of Genetic Counseling (ABGC)–certified genetic counselors. The National Society of Genetic Counselors was formed in 1979 (www.nsgc.org) and the International Society of Nurses in Genetics (ISONG) was formed in 1988 (www.isong.org/index.php). The number of nursing programs offering courses in genetics and genomics is growing rapidly. A small number of graduate nursing programs offer advanced practice courses and/or specialty options in genetics and genomics. Examples of these are the University of California, San Francisco, School of Nursing and the University of Pittsburgh School of Nursing.

Definition of Genetic Counseling

In 2006, the Genetic Counseling Definition Task Force of the National Society of Genetic Counselors developed the following definition of genetic counseling. According to this definition:

“Genetic counseling is the process of helping people understand and adapt to the medical, psychological and familial implications of genetic contributions to disease. This process integrates:

- Interpretation of family and medical histories to assess the chance of disease occurrence or recurrence;
- Education about inheritance, testing, management, prevention, resources and research; and
- Counseling to promote informed choices and adaptation to the risk or condition” (Resta, Biesecker, Bennett, et al., 2006).

Access and Referral to Genetic Counseling

Genetic counseling is typically provided by a team of genetics specialists that includes clinical geneticists (physicians with an MD or DO), medical geneticists with a PhD, genetics fellows, genetics counselors, and, in a growing number of cases, advanced practice genetics nurse specialists. Cytogeneticists, biochemical geneticists, and molecular geneticists support the clinical genetics team by providing laboratory expertise that helps with the diagnosis and management of individuals and families affected by genetic conditions.

Until recently most individuals and families interested in receiving genetic counseling went to regional genetics centers or major medical centers. Genetic counseling also was provided in outreach or satellite genetics clinics, public health clinics, and some community hospitals. Now that genetics is entering the mainstream of health care, genetic counseling is being offered in a wide variety of other settings. These include, but are not limited to, managed health care organizations, commercial facilities, and private practices. A number of specialized groups provide genetics education and counseling for individuals and families affected by specific genetic disorders, such as Down syndrome, CF, diabetes, muscular dystrophy, HD, and cancer. Genetic counseling also is offered over the Internet.

Individuals and families seek out, or are referred for, genetic counseling for a wide variety of reasons and at all stages of their lives. Some seek preconception or prenatal information; others are referred after the birth of a child with a birth defect or a suspected genetic condition; still others seek information because they have a family history of a genetic condition. Regardless of the setting or the individual and family's stage of life, genetic counseling should be offered and available to all individuals and families who have questions about genetics and their health. However, there is a shortage of appropriately trained genetics professionals who can provide genetic counseling. This means that many individuals and families will not be offered genetic counseling when they undergo genetic testing. Moreover, some of the genetics education and counseling that is provided will be less than adequate.

It may take years before a sufficient number of health care professionals feel comfortable and are proficient in providing genetics, genomics, and genetic counseling (Calzone, Jenkins, Yates, et al., 2012). Until then it is imperative that all health care professionals become familiar with existing genetics resources, such as the CDC (www.cdc.gov/genomics/default.htm), the Genetic Alliance (www.geneticalliance.org), the Jackson Laboratory (www.jax.org), Genetics Program for Nursing Faculty Cincinnati Children's Hospital Medical Center (www.cincinnatichildrens.org/ed/clinical/gpnf/default.htm), National Human Genome Research Institute Education (www.genome.gov/Education), and GenomeTV (www.genome.gov/genometv).

Estimation of Risk

Most families with a history of genetic disease want an answer to the following: What is the chance that our future children will have this disease? Because the answer to this question may have profound implications for individual family members and the family as a whole, health care professionals must be able to answer as accurately as they can in a timely manner. In some cases, estimation of risk is rather straightforward; in other cases, it becomes rather complicated. Because of this, health care professionals should be prepared to refer families with a history of genetic disease to genetics professionals if they are at all unsure. Again, the answer to this question can have profound implications for individual family members and the family as a whole, so health care professionals must do their best to ensure that the answer is accurate.

If a couple has not yet had children but they are known to be at risk for having children with a genetic disease, they will be given an **occurrence risk**. Once the mating of a couple has produced one or more children with a genetic disease, the couple will be given a **recurrence risk**. Both occurrence and recurrence risks are determined by the mode of inheritance for the genetic disease in question. For genetic diseases caused by a factor that segregates during cell division (genes and chromosomes), risk can be estimated with a high degree of accuracy by application of the mendelian principles.

In an autosomal dominant disorder, both the occurrence and recurrence risk is 50%, or one in two, when one parent is affected and the other is not. The recurrence risk for autosomal recessive disorders is 25%, or one in four, if both parents are carriers (they each have one recessive disease gene and one normal gene). Occasionally an individual homozygous for a

recessive disease gene mates with an individual who is a carrier of the same recessive gene. In this case the recurrence risk is 50%, or one in two. If two individuals affected by an autosomal recessive disorder mate, all of their children will be affected. For X-linked disorders, recurrence risk is related to the sex of the child. Translocation disorders have a high risk of recurrence.

A number of autosomal disorders display fairly complex patterns of inheritance, making estimation of risk somewhat difficult. For example, if a child is born with a genetic disease and there has been no history of the disease in the family, the disease may have been caused by a new mutation (this is more likely if the disease in question is an autosomal dominant disorder, such as achondroplasia). If the child's genetic disease has been caused by a new mutation, the recurrence risk for the parents' subsequent children is low (1% to 2%), but it is not as low as that for the general population. Offspring of the affected child may have a substantially elevated occurrence risk.

The risk of recurrence for multifactorial conditions can be estimated empirically. An empiric risk is based not on genetics theory but rather on experience and observation of the disorder in other families. Recurrence risks are determined by applying the frequency of a similar disorder in other families to the case under consideration.

An important concept to be emphasized to individuals and families during a genetic counseling session is that *each pregnancy is an independent event*. For example, in monogenic disorders in which the risk factor is one in four that the child will be affected, the risk remains the same no matter how many affected children are already in the family. Families may maintain the erroneous assumption that the presence of one affected child ensures that the next three will be free of the disorder. However, "chance has no memory." The risk is one in four for each pregnancy. Conversely, in a family with a child who has a disorder with multifactorial causes, the risk increases with each subsequent child born with the disorder.

Interpretation of Risk

The guiding principle for genetics counselors has traditionally been **nondirectiveness**. According to the principle of nondirectiveness, the individual who is providing genetic counseling respects the right of the individual or family being counseled to make autonomous decisions. Counselors using a nondirective approach avoid making recommendations, and they try to communicate genetics information in an unbiased manner. The first step in providing nondirective counseling is becoming aware of one's own values and beliefs. Another important step is recognizing how one's values and beliefs can influence or interfere with the communication of genetics information.

If the individual who is providing genetic counseling has difficulty being nonjudgmental and objective, he or she may either intentionally or unintentionally influence the decision-making process. Individuals and families also may pressure the counselor to make decisions for them with questions such as, "What would you do if you were me?" Families and individuals need education, guidance, and support throughout the counseling process. They should be given the facts and possible consequences, as well as all of the assistance they need in problem solving, but the final decision regarding a course of action must be their own.

CLINICAL REASONING CASE STUDY

Counseling About Genetic Risk

Camille has presented for her routine yearly physical examination and tells you she and her husband are planning to become pregnant within the next year. She confides in you that several infants have been born into her family with serious anomalies. She is interested in finding out more about her risks of having a baby with an anomaly and wants to know whom she should consult for that information.

1. Evidence—Is there sufficient evidence to provide Camille with answers to her questions about her risks of having a baby with an anomaly?
2. Assumptions—What assumptions can be made about estimating and interpreting risk?
 - a. The appropriate person to provide this information
 - b. The accuracy of this information
 - c. The benefits of this information
3. What implications and priorities for nursing can be made at this time?
4. Does the evidence objectively support your conclusion?

Multiple Roles for Nurses in Genetics

Nurses play many roles in genetics. Some nurses play a key role in identifying families in need of genetic counseling, and they collaborate with other health care professionals to make referrals to genetics specialists. Other nurses take a more active role in genetic counseling; they might provide appropriate genetics information before, during, and after the initial genetics counseling session; construct family pedigrees of three or more generations; clarify the genetics information that family members receive during counseling sessions or from other sources such as the public library, the Internet, or support groups; help families manage the ongoing challenges associated with living with a genetic disorder; make referrals to support groups and national organizations; and provide long-term follow-up of families affected by genetic conditions.

Probably the most important of all nursing functions is to provide emotional support during all aspects of the counseling process. Feelings that are generated under the real or imagined threat posed by a genetic disorder are as varied as the people being counseled. Responses may include a variety of stress reactions, such as apathy, denial, anger, hostility, fear, embarrassment, grief, and loss of self-esteem. Guilt and self-blame are universal reactions. Many look on the disorder as a stigma, especially if the disorder is visible to others. Old-wives' tales, superstitions, and long-held misconceptions may influence a family's reaction to a genetic disorder.

FUTURE PROMISE OF GENETICS

Overall, the Human Genome Project and other sequencing efforts have been a huge success. Our understanding of the human genome, as well as other genomes, has grown exponentially in recent years. The increased availability of genetic testing and other genetics services gives individuals and families unprecedented opportunities to learn whether they have heightened risk for certain diseases or the potential to transmit gene mutations to their offspring. Awareness of genetic risk also can facilitate informed health care decisions and, in some cases,

can promote risk reduction behaviors that have the potential to reduce morbidity and mortality. Ultimately it is hoped that advances in molecular biology and genomics will make it possible to offer diagnostic, preventive, and treatment options not only for genetic diseases but also for common diseases such as cancer, atherosclerosis, diabetes, and Alzheimer's disease.

Advances made possible through the Human Genome Project have been remarkable, but our ability to offer treatment options, even for single-gene disorders, remains very limited. Progress in the acquisition of genetics information and the development of genetics technology continue to outpace the development of therapeutic interventions. For most genetic conditions, therapeutic interventions are nonexistent or disappointingly limited. Consequently the most useful means of reducing the incidence of genetic disorders now is preventing transmission. Only three reproductive options exist for individuals at risk for transmitting a genetic disorder: the avoidance of pregnancy; genetic diagnosis during an ongoing pregnancy; and prevention of transmission of an altered gene or genes through preimplantation genetics. For many families none of these options is viewed as acceptable.

Dialogue among pregnant women, expectant families, health care professionals, and disability advocates concerning prenatal testing for Down syndrome and other genetic disorders is urgently needed. Clinical and technical information must be complemented by social understanding of the experience of disability in contemporary society. The picture of life with a disability should be more balanced than that currently portrayed. It is critical that the voices of individuals and families living with disabilities be heard.

Nurses are in an ideal position to help individuals and families maximize the benefits of the genetics revolution, but first, nurses need (1) a working knowledge of human genetics, (2) an awareness of recent advances in genetics and genomics, and (3) an understanding of the potential effects of genomic discoveries on individual and family well-being. More research is needed concerning the family experience of genetic testing. Nurses must understand why individuals and families decide to undergo genetic testing. Nurses also need to be aware of how individuals and families define and manage ethical, legal, and social issues that emerge during the genetic testing experience.

KEY POINTS

- Advances in molecular biology and genomics have revolutionized the field of health care by providing the tools needed to determine the hereditary component of many diseases.
- Increasingly, nurses from all specialty areas, as well as all practice settings, are expected to have competencies in genetics and genomics.
- The major force behind the genetics revolution has been the Human Genome Project.
- All humans are >99% identical at the DNA level.
- Approximately 20,000 to 25,000 genes are found in the human genome.
- Most of the genetic tests being offered in clinical practice are tests for single-gene disorders.
- Pharmacogenomics will probably be the most immediate clinical application of the Human Genome Project.
- The decision to undergo genetic testing is often based on feelings of responsibility and commitment to others.
- Genes are the basic units of heredity responsible for all human characteristics. They comprise 23 pairs of chromosomes: 22 pairs of autosomes and 1 pair of sex chromosomes.
- Chromosomal abnormalities occur in both autosomes and sex chromosomes.
- Multifactorial inheritance includes genetic and environmental contributions.
- Advances in genetics have complex ethical, legal, and social implications.
- Cancer genetics is an important emerging field.

LEARNING OBJECTIVES

- Identify the structures and functions of the female reproductive system.
- Describe the menstrual cycle in relation to hormonal, ovarian, and endometrial response.
- Identify the phases of the sexual response cycle.
- Describe common reasons that women enter the health care system.
- Analyze barriers that may affect a woman's decision to seek health care.
- Describe risk factors for women's health in the childbearing years.
- Describe the components of the history and physical examination.
- Describe how to adapt the history and physical examination for women with special needs.
- Describe how to screen for signs of abuse and how to refer to community agencies.
- Identify the steps for assisting with and collecting specimens for Papanicolaou (Pap) testing.
- Outline the health-screening and immunization recommendations for women across the life span.
- Describe anticipatory guidance that prevents disease and promotes health and self-management.

Care of the well woman is focused on health promotion and illness prevention, recognizing that a woman is a biopsychosocial-spiritual being, requiring a holistic approach to nursing care. To encourage appropriate health-promotion activities, it is important to conduct systematic health assessments and screenings. This chapter presents an overview of the nurse's role in encouraging health promotion and illness prevention in women. It provides guidelines for how to conduct a complete history and physical examination. This chapter also includes a schedule of screening tests recommended for women at different stages of their lives. As background to understanding assessment, a review of female anatomy and physiology as well as the menstrual cycle is presented. Barriers that women encounter when they try to enter the health care system and risk factors for women's health during the childbearing years are described. Anticipatory guidance suggestions, including nutrition, exercise, and stress management, are included. Examples of health-promotion efforts in the community are presented in an effort to emphasize community health approaches to care, especially because much of well-woman care occurs in the community.

FEMALE REPRODUCTIVE SYSTEM

The female reproductive system consists of external structures visible from the pubis to the perineum and internal structures

located in the pelvic cavity. The external and internal female reproductive structures develop and mature in response to estrogen and progesterone. This process starts in fetal life and continues through puberty and the childbearing years. Reproductive structures atrophy with age or in response to a decrease in ovarian hormone production. A complex nerve and blood supply supports the functions of these structures. The appearance of the external genitalia varies greatly among women. Heredity, age, race, and the number of children a woman has borne influence the size, shape, and color of her external organs.

External Structures

The external genital organs, or *vulva*, include all structures visible externally from the pubis to the perineum. These include the *mons pubis*, *labia majora*, *labia minora*, clitoris, vestibular glands, vaginal vestibule, vaginal orifice, and urethral opening. The external genital organs are illustrated in Figure 4-1.

The mons pubis is a fatty pad that lies over the anterior surface of the symphysis pubis. In the postpubertal female the mons is covered with coarse, curly hair. The labia majora are two rounded folds of fatty tissue covered with skin that extend downward and backward from the mons pubis. The labia are highly vascular structures that develop hair on the outer surfaces after puberty. They protect the inner vulvar structures. The labia minora are two flat, reddish folds of tissue visible when the labia majora are separated. There are no hair follicles on the labia

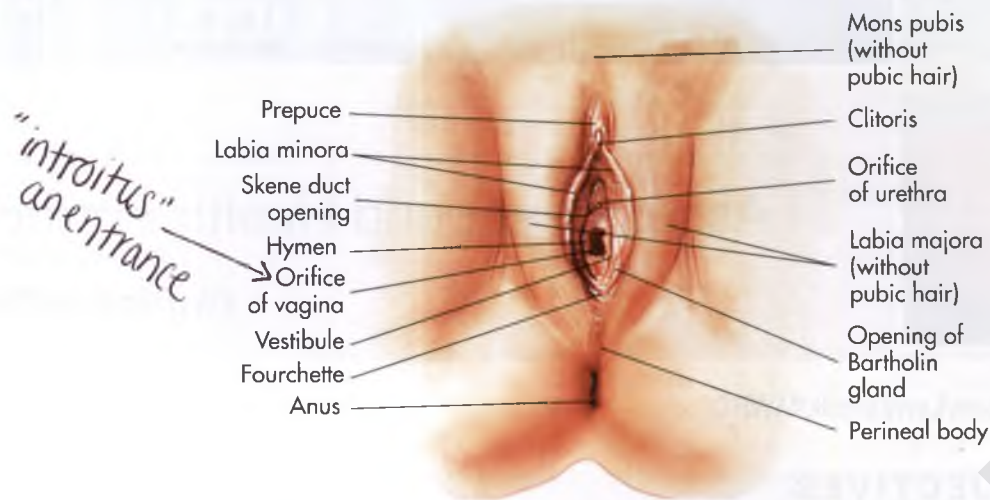

FIG 4-1 External female genitalia.

minora, but many sebaceous follicles and a few sweat glands are present. The interior of the labia minora comprises connective tissue and smooth muscle and is supplied with extremely sensitive nerve endings. Anteriorly, the labia minora fuse to form the *prepuce* (the hoodlike covering of the clitoris) and the *frenulum* (the fold of tissue under the clitoris). The labia minora join to form a thin, flat tissue called the *fourchette* underneath the vaginal opening at midline. The clitoris is located underneath the prepuce. It is a small structure composed of erectile tissue with numerous sensory nerve endings. During sexual arousal, the clitoris increases in size.

The vaginal *vestibule* is an almond-shaped area enclosed by the labia minora that contains openings to the urethra, Skene glands, vagina, and Bartholin glands. The urethra is not a reproductive organ but is discussed here because of its location. It usually is found about 2.5 cm below the clitoris. Skene glands are located on each side of the urethra and produce mucus, which aids in lubrication of the vagina. The vaginal opening is in the lower portion of the vestibule and varies in shape and size. The hymen, a connective tissue membrane that surrounds the vaginal opening, can be perforated during strenuous exercise, insertion of tampons, masturbation, and vaginal intercourse. Bartholin glands lie under the constrictor muscles of the vagina and are located posteriorly on the sides of the vaginal opening, although the ductal opening usually is not visible. During sexual arousal, the glands secrete clear mucus to lubricate the vaginal introitus.

The area between the fourchette and the anus is the **perineum**, a skin-covered muscular area that covers the pelvic structures. The perineum forms the base of the perineal body, a wedge-shaped mass that serves as an anchor for the muscles, fascia, and ligaments of the pelvis. The muscles and ligaments form a sling that supports the pelvic organs.

Internal Structures

The internal structures include the vagina, uterus, uterine tubes, and ovaries. The description of these structures follows.

The vagina is a fibromuscular, collapsible tubular structure that lies between the bladder and rectum and extends from the vulva to the uterus. During the reproductive years the mucosal

lining is arranged in transverse folds called *rugae*. These rugae allow the vagina to expand during childbirth. Estrogen deprivation that occurs after childbirth, during lactation, and at menopause causes dryness and thinning of the vaginal walls and smoothing of the rugae. The vagina, particularly the lower segment, has few sensory nerve endings. Vaginal secretions are slightly acidic (pH 4 to 5) so that vaginal susceptibility to infections is limited. The vagina serves as a passageway for menstrual flow, as a female organ of copulation, and as a part of the birth canal for vaginal childbirth. The uterine cervix projects into a blind vault at the upper end of the vagina. Anterior, posterior, and lateral pockets called fornices (singular: *fornix*) surround the cervix. The internal pelvic organs can be palpated through the thin walls of these fornices.

The *uterus* is a muscular organ shaped like an upside-down pear that sits midline in the pelvic cavity between the bladder and rectum and above the vagina. Four pairs of ligaments support the uterus: cardinal, uterosacral, round, and broad. Single anterior and posterior ligaments also support the uterus. The cul-de-sac of Douglas is a deep pouch, or recess, posterior to the cervix formed by the posterior ligament.

The uterus is divided into two major parts: an upper triangular portion called the *corpus* and a lower cylindrical portion called the *cervix* (Fig. 4-2). The *fundus* is the dome-shaped top of the uterus and is the site at which the uterine tubes (fallopian tubes) enter the uterus. The isthmus, or lower uterine segment, is a short, constricted portion that separates the corpus from the cervix.

The uterus serves for reception, implantation, retention, and nutrition of the fertilized ovum and later of the fetus during pregnancy and for expulsion of the fetus during childbirth. It is also responsible for cyclic menstruation.

The uterine wall is made up of three layers: the endometrium, the myometrium, and part of the peritoneum. The endometrium is a highly vascular lining made up of three layers, the outer two of which are shed during menstruation. The myometrium is made up of layers of smooth muscles that extend in three different directions (longitudinal, transverse, and oblique) (Fig. 4-3). Longitudinal fibers of the outer myometrial

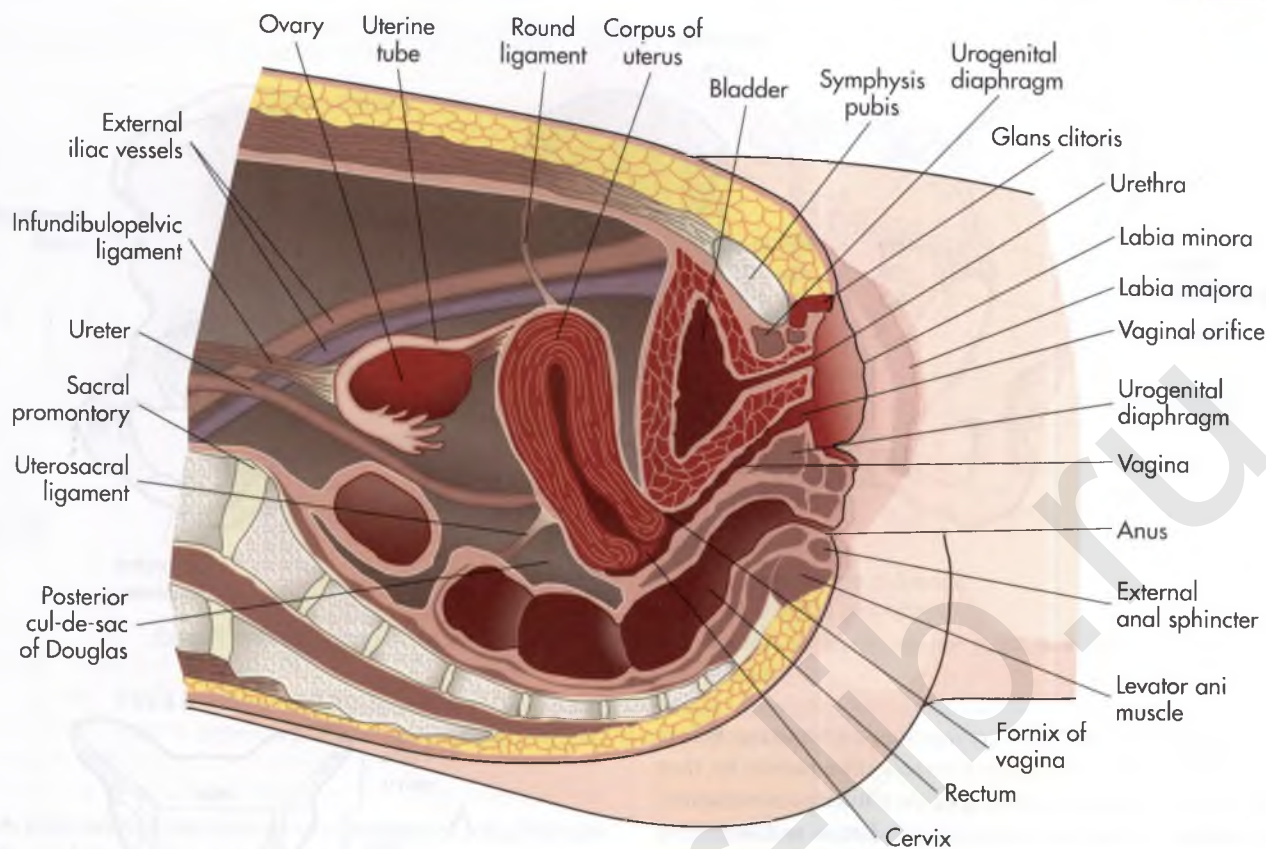

FIG 4-2 Midsagittal view of female pelvic organs with woman lying supine.

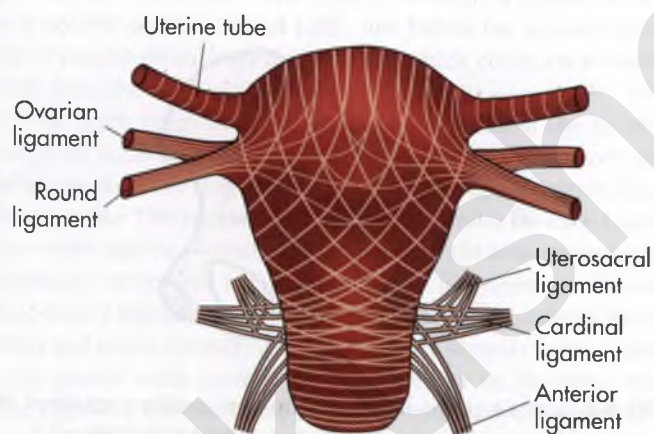

FIG 4-3 Schematic arrangement of directions of muscle fibers. Note that uterine muscle fibers are continuous with supportive ligaments of uterus.

layer are found mostly in the fundus, and this arrangement assists in expelling the fetus during the birth process. The middle layer contains fibers from all three directions, which form a figure-eight pattern encircling large blood vessels. These fibers assist in ligating blood vessels after childbirth and control blood loss. Most of the circular fibers of the inner myometrial layer are around the site where the uterine tubes enter the uterus and around the internal cervical os (opening). These fibers help keep the cervix closed during pregnancy and prevent menstrual blood from flowing back into the uterine tubes during menstruation.

The cervix is made up of mostly fibrous connective tissues and elastic tissue, making it possible for the cervix to stretch

during vaginal childbirth. The opening between the uterine cavity and the canal that connects the uterine cavity to the vagina (endocervical canal) is the internal os. The narrowed opening between the endocervix and the vagina is the external os, a small circular opening in women who have never been pregnant. The cervix feels firm (like the end of a nose) with a dimple in the center that marks the external os.

The outer cervix is covered with a layer of squamous epithelium. The mucosa of the cervical canal is covered with columnar epithelium and contains numerous glands that secrete mucus in response to ovarian hormones. The squamocolumnar junction, where the two types of cells meet, is usually located just inside the cervical os. This junction is also called the transformation zone and is the most common site for neoplastic changes. Cells from this site are scraped for the Papanicolaou (Pap) test (see later discussion).

The uterine tubes attach to the uterine fundus. The tubes are supported by the broad ligaments and range from 8 to 14 cm in length. The tubes are divided into four sections: the interstitial portion is closest to the uterus; the isthmus and the ampulla are the middle portions; and the infundibulum is closest to the ovary. The uterine tubes provide a passage between the ovaries and the uterus for the movement of the ovum. The infundibulum has fimbriated (fringed) ends, which pull the ovum into the tube. The ovum is pushed along the tubes to the uterus by rhythmic contractions of muscles of the tubes and by the current produced by the movement of the cilia that line the tubes. The ovum is usually fertilized by the sperm in the ampulla portion of one of the tubes.

The ovaries are almond-shaped organs located on each side of the uterus below and behind the uterine tubes. During the reproductive years they are approximately 3 cm long, 2 cm wide,

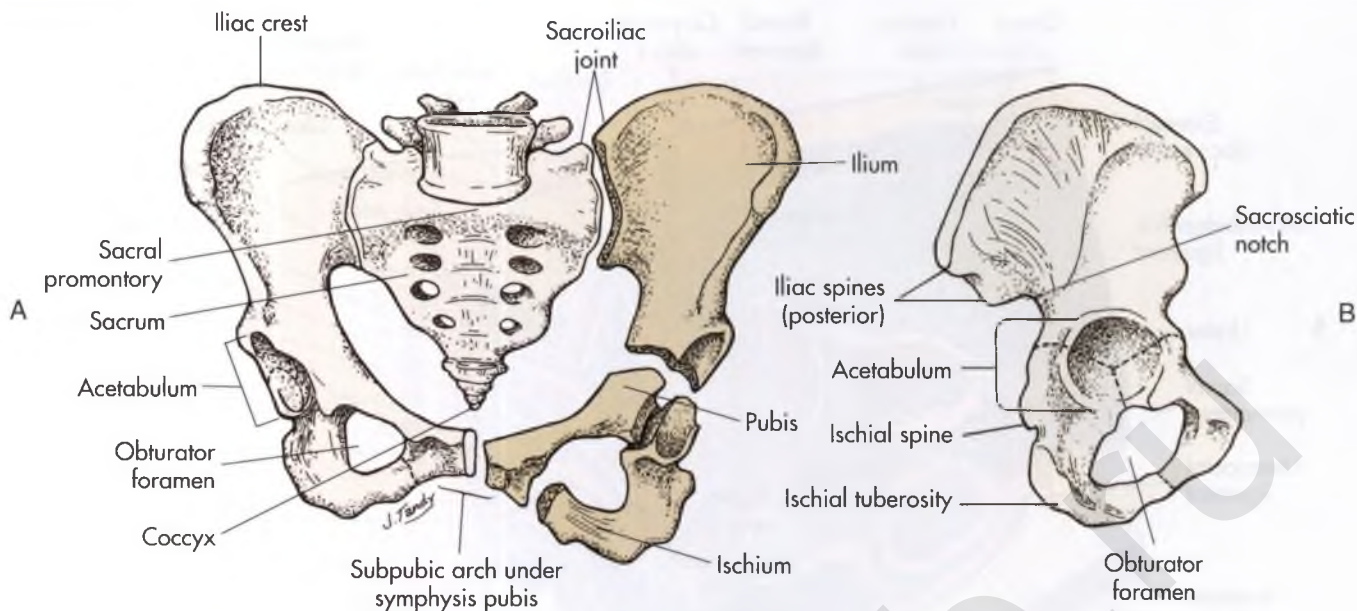

FIG 4-4 Adult female pelvis. A, Anterior view. B, External view of innominate bone (fused).

and 1 cm thick; they diminish in size after menopause. Before menarche, each ovary has a smooth surface; after menarche, they are nodular because of repeated ruptures of follicles at ovulation. The two functions of the ovaries are ovulation and hormone production. **Ovulation** is the release of a mature ovum from the ovary at intervals (usually monthly). Estrogen, progesterone, and androgen are the hormones produced by the ovaries.

The Bony Pelvis

The bony pelvis serves three primary purposes: protection of the pelvic structures, accommodation of the growing fetus during pregnancy, and anchorage of the pelvic support structures. The two innominate (hip) bones (consisting of ilium, ischium, and pubis), the sacrum, and the coccyx make up the four bones of the pelvis (Fig. 4-4). Cartilage and ligaments form the symphysis pubis, sacrococcygeal joint, and two sacroiliac joints that separate the pelvic bones.

The pelvis is divided into two parts: the false pelvis and the true pelvis (Fig. 4-5). The false pelvis is the upper portion above the pelvic brim or inlet. The true pelvis is the lower, curved, bony canal, which includes the inlet, the cavity, and the outlet through which the fetus passes during vaginal birth. The upper portion of the outlet is at the level of the ischial spines, and the lower portion is at the level of the ischial tuberosities and the pubic arch. Variations that occur in the size and shape of the pelvis are usually related to age, race, and sex. Pelvic ossification is complete at about 20 years of age.

Breasts

The breasts are paired mammary glands located between the second and sixth ribs (Fig. 4-6). About two thirds of the breast overlies the pectoralis muscle, between the sternum and midaxillary line, with an extension to the *tail of Spence*. The lower one third of the breast overlies the serratus anterior muscle. The breasts are attached to the muscles by connective tissue or fascia.

The breasts of the healthy, mature woman are approximately equal in size and shape but often are not absolutely

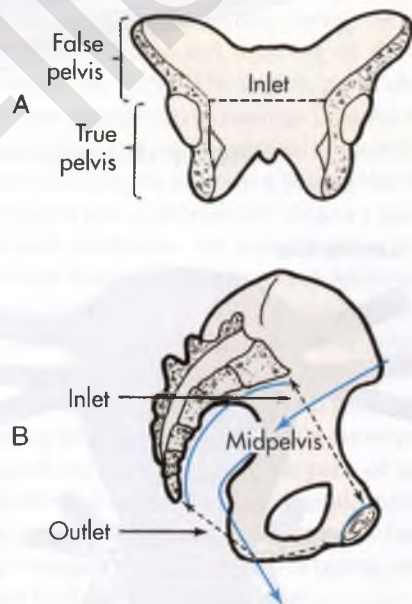

FIG 4-5 Female pelvis. A, Cavity of false pelvis is shallow. B, Cavity of true pelvis is an irregularly curved canal (arrows).

symmetric. The size and shape vary with the woman's age, heredity, and nutrition. However, the contour should be smooth with no retractions, dimpling, or masses. Estrogen stimulates growth of the breast by inducing fat deposition in the breasts, development of stromal tissue (i.e., increase in its amount and elasticity), and growth of the extensive ductile system. Estrogen also increases the vascularity of breast tissue.

Once ovulation begins in puberty, progesterone levels increase. The increase in progesterone causes maturation of mammary gland tissue, specifically the lobules and acinar structures. During adolescence fat deposition and growth of fibrous tissue contribute to the increase in the size of the glands. Full development of the breasts is not achieved until after the end of the first pregnancy or in the early period of lactation.

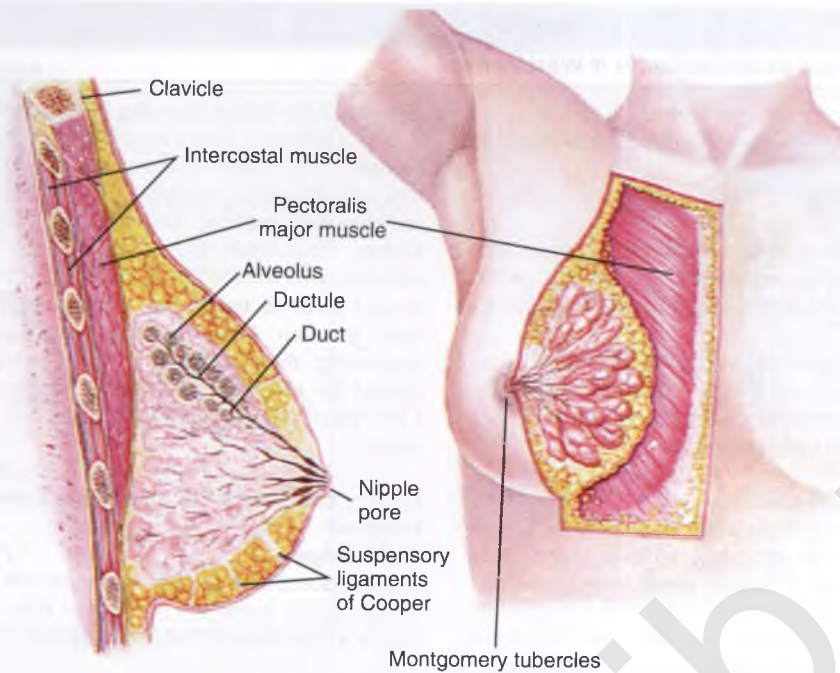

FIG 4-6 Anatomy of the breast, showing position and major structures. (Adapted from Seidel, H., et al. [2011]. *Mosby's guide to physical examination* [7th ed.]. St. Louis: Mosby.)

Each mammary gland is made of a number of lobes that are divided into lobules. Lobules are clusters of acini. An acinus is a saclike terminal part of a compound gland emptying through a narrow lumen or duct. The acini are lined with epithelial cells that secrete colostrum and milk. Just below the epithelium is the myoepithelium (*myo*, or muscle), which contracts to expel milk from the acini.

The ducts from the clusters of acini that form the lobules merge to form larger ducts draining the lobes. Ducts from the lobes converge in a single nipple (mammary papilla) surrounded by an areola. The anatomy of the ducts is similar for each breast but varies among women. Protective fatty tissue surrounds the glandular structures and ducts. *Cooper ligaments*, or fibrous suspensory ligaments, separate and support the glandular structures and ducts. Cooper ligaments provide support to the mammary glands while permitting their mobility on the chest wall (see Fig. 4-6). The round nipple is usually slightly elevated above the breast. On each breast the nipple projects slightly upward and laterally. It contains 4 to 20 openings from the milk ducts. The nipple is surrounded by fibromuscular tissue and covered by wrinkled skin (the areola). Except during pregnancy and lactation, there is usually no discharge from the nipple.

The nipple and surrounding areola are usually more deeply pigmented than the skin of the breast. The rough appearance of the areola is caused by sebaceous glands, *Montgomery tubercles*, directly beneath the skin. These glands secrete a fatty substance thought to lubricate the nipple. Smooth muscle fibers in the areola contract to stiffen the nipple to make it easier for the breastfeeding infant to grasp.

The vascular supply to the mammary gland is abundant. In the nonpregnant state there is no obvious vascular pattern in the skin. The normal skin is smooth without tightness or shininess. The skin covering the breasts contains an extensive superficial lymphatic network that serves the entire chest wall and

is continuous with the superficial lymphatics of the neck and abdomen. The lymphatics form a rich network in the deeper portions of the breasts. The primary deep lymphatic pathway drains laterally toward the axillae.

Besides their function of lactation, breasts function as organs for sexual arousal in the mature adult female. The breasts change in size and nodularity in response to cyclic ovarian changes throughout reproductive life. Increasing levels of both estrogen and progesterone in the 3 to 4 days before menstruation increase the vascularity of the breasts, induce growth of the ducts and acini, and promote water retention. The epithelial cells lining the ducts proliferate in number, the ducts dilate, and the lobules distend. The acini become enlarged and secretory, and lipid (fat) is deposited within their epithelial cell lining. As a result, breast swelling, tenderness, and discomfort are common symptoms just before the onset of menstruation. After menstruation, cellular proliferation begins to regress, acini begin to decrease in size, and retained water is lost. After breasts have undergone changes numerous times in response to the ovarian cycle, the proliferation and involution (regression) are not uniform throughout the breast. In time, after repeated hormonal stimulation, small, persistent areas of nodulations may develop. This normal physiologic change must be remembered when breast tissue is examined. Nodules may develop just before and during menstruation, when the breast is most active. The physiologic alternations in breast size and activity reach their minimum level about 5 to 7 days after menstruation stops. Therefore, **breast self-examination (BSE)** (systematic palpation of breasts to detect signs of breast cancer or other changes) is best carried out during this phase of the menstrual cycle (see Evidence-Based Practice box). Although monthly BSE used to be recommended to all women, the current guidelines recommend BSE as an option (American Cancer Society [ACS], 2013a), mostly because the

EVIDENCE-BASED PRACTICE

Teaching Women Breast Self-Examination: Is It Worthwhile?**Ask the Question**

Does teaching women breast self-examination actually result in fewer deaths from breast cancer?

Search for the Evidence

Search Strategies Professional organization guidelines, meta-analyses, systematic reviews, randomized controlled trials, nonrandomized prospective studies, and retrospective studies since 2011.

Databases Used CINAHL, Cochrane, MEDLINE, National Guideline Clearinghouse, and websites for the Association for Women's Health, Obstetric and Neonatal Nurses, American Cancer Society (ACS), and National Cancer Institute

Critical Appraisal of the Evidence

The ideal screening test for breast cancer would have a high sensitivity for breast cancer in an early, curable stage, thus decreasing mortality. Moreover, it would have a high specificity, meaning few false positives and thus few unnecessary diagnostic tests. Screening for breast cancer has conventionally consisted of breast self-examination monthly, clinical breast examination (CBE) yearly, and screening mammogram every 1 to 2 years after 40 years of age. Although a screening mammogram has been considered the gold standard, believed to be responsible for a 15% decrease in mortality, a review (Gotzsche & Jorgensen, 2013) concluded that because of the large incidence of overdiagnosis and overtreatment, estimated to be 30%, over a 10-year period, for every 2000 women screened, 1 will actually avoid death from breast cancer and 10 healthy women will be treated unnecessarily.

Mammograms are usually accompanied by a CBE by a trained examiner. Since the 1970s, women were also routinely taught to do breast self-examination (BSE). The assumption was the BSE was a low-tech screening tool for women to detect tumors in the early, more treatable stages. This theory was challenged by a classic metaanalysis of two randomized controlled trials that involved 388,535 women in Russia and Shanghai, which found no difference in cancer mortality between groups taught BSE and control groups without BSE education (Kosters & Gotzsche, 2003; updated 2007). In fact, the BSE group was twice as likely to undergo unnecessary biopsy with benign results as the control group. The authors noted the poor compliance with BSE, but also acknowledged that it was possible that BSE may have decreased mortality in some countries. The ACS noted that all women should be informed about the benefits as well as the limitations of BSE so that even if BSE alone does not save lives, women learn what normal breasts feel like and may detect any changes. Also, breastcancer.org continues to recommend that women do BSE.

Apply the Evidence: Nursing Implications

BSE is a low-tech, low-cost technique that can empower some women to discover breast changes earlier. It is not clear that this will decrease mortality. BSE and CBE also may result in unnecessary testing. Organizations such as the Susan G. Komen Foundation (2013) emphasize "understanding breast cancer," which includes having regular screening tests. Nurses should offer to teach the technique of BSE to women who wish to learn. However, some women are not comfortable examining their breasts or find it frightening. All women should be taught to follow the recommended guidelines for CBE yearly and mammograms based on age and personal history.

Quality and Safety Competencies: Evidence-Based Practice***Knowledge**

Nurses must be up to date on the current evidence that supports or does not support the efficacy of BSE and especially must be able to synthesize conflicting evidence.

Skills

Nurses must continue to be able to teach BSE to women and must be able to explain why BSE may be something that a woman would choose to do.

Attitudes

Nurses must be able to help women understand their breasts, including what breasts feel and look like, creating an attitude of comfort with their own bodies, helping them to be able to notice any changes.

ACS believes that many unnecessary biopsies and other procedures result. However, breastcancer.org (2012) continues to recommend that all women perform BSE monthly (see Teaching for Self-Management box).

MENSTRUATION AND MENOPAUSE**Menarche and Puberty**

Although young girls secrete small, rather constant amounts of estrogen, a marked increase occurs between 8 and 11 years of age. The term **menarche** denotes first menstruation.

Puberty is a broader term that denotes the entire transitional stage between childhood and sexual maturity. Increasing amounts and variations in gonadotropin and estrogen secretion develop into a cyclic pattern at least a year before menarche. In North America this occurs in most girls at about 13 years of age.

Initially, menstrual periods are irregular, unpredictable, painless, and **anovulatory** (no ovum is released from the ovary). After 1 or more years, a hypothalamic-pituitary rhythm develops and the ovary produces adequate cyclic estrogen to make a mature ovum. **Ovulatory** (ovum released from the ovary)

TEACHING FOR SELF-MANAGEMENT

Breast Self-Examination

If you choose to perform a breast self-examination, the best time is when breasts are not tender or swollen.

How to examine your breasts:

1. Lie down and put a pillow under your right shoulder. Place your right arm behind your head (Fig. 1).

2. Use the finger pads of your three middle fingers on your left hand to feel for lumps or thickening. Your finger pads are the top third of each finger. Use circular motions of the finger pads to feel the breast tissue.
3. Press firmly enough to know how your breast feels. Use light pressure to feel the tissue just under the skin, medium pressure for a little deeper, and firm pressure to feel the breast tissue close to the chest and ribs. A firm ridge in the lower curve of the breast is normal.
4. Move around the breast in a set way, such as using an up-and-down or vertical line pattern (Fig. 2). Go up to the collar bone and down to the ribs and from your underarm on the side to the middle of your chest. Use the same technique every time. It will help you to make sure that you have gone over the entire breast area and to remember how your breast feels.

5. Now examine your left breast. Put a pillow under your left shoulder. Place your right arm behind your head and use your finger pads of your right hand, similar to the description in Step 2.
6. You may want to check your breasts while standing in front of a mirror. See if there are any changes in the way your breasts look: dimpling of the skin, changes in the nipple, or redness or swelling.
7. Checking the area between the breast and the underarm and the underarm itself is important. Examine the area above the breast to the collarbone and to the shoulder while you are standing or sitting up with your arms lightly raised.
8. If you find any changes, see your health care provider right away.

Adapted from American Cancer Society: Breast awareness and self-exam, 2014, www.cancer.org.

periods tend to be regular, with estrogen dominating the first half of the cycle and progesterone dominating the second half.

Although pregnancy can occur in exceptional cases of true precocious puberty, most pregnancies in young girls occur after the normally timed menarche. All young adolescents of both sexes would benefit from knowing that pregnancy can occur at any time after the onset of menses.

Menstrual Cycle

Menstruation is the periodic uterine bleeding that begins approximately 14 days after ovulation. It is controlled by a feedback system of three cycles: endometrial, hypothalamic-pituitary, and ovarian. The average length of a menstrual cycle is 28 days, but variations are normal. The first day of bleeding is designated as day 1 of the menstrual cycle, or **menses** (Fig. 4-7). The average duration of menstrual flow is 5 days (with a range of 3 to 6 days) and the average blood loss is 50 ml (with a range of 20 to 80 ml), but this duration of flow and blood loss vary greatly. For about 50% of women, menstrual blood does not appear to clot. The menstrual blood clots within the uterus, but the clot usually liquefies before being discharged from the uterus. Uterine discharge includes mucus and epithelial cells in addition to blood.

The menstrual cycle is a complex interplay of events that occur simultaneously in the endometrium, the hypothalamus, the pituitary glands, and the ovaries. The menstrual cycle prepares the uterus for pregnancy. When pregnancy does not occur, menstruation follows. A woman's age, physical and emotional status, and environment influence the regularity of her menstrual cycles.

Hypothalamic-Pituitary Cycle

Toward the end of the normal menstrual cycle, blood levels of estrogen and progesterone decrease. Low blood levels of these ovarian hormones stimulate the hypothalamus to secrete gonadotropin-releasing hormone (GnRH). In turn, GnRH stimulates anterior pituitary secretion of follicle-stimulating hormone (FSH). FSH stimulates development of ovarian graafian follicles and their production of estrogen. Estrogen levels begin to decrease, and hypothalamic GnRH triggers the anterior pituitary to release luteinizing hormone (LH). A marked surge of LH and a smaller peak of estrogen (day 12) (see Fig. 4-7) precede the expulsion of the ovum from the graafian follicle by about 24 to 36 hours. LH peaks at about day 13 or 14 of a 28-day cycle. If fertilization and implantation of the ovum have not occurred by this time, regression of the corpus luteum follows. Levels of

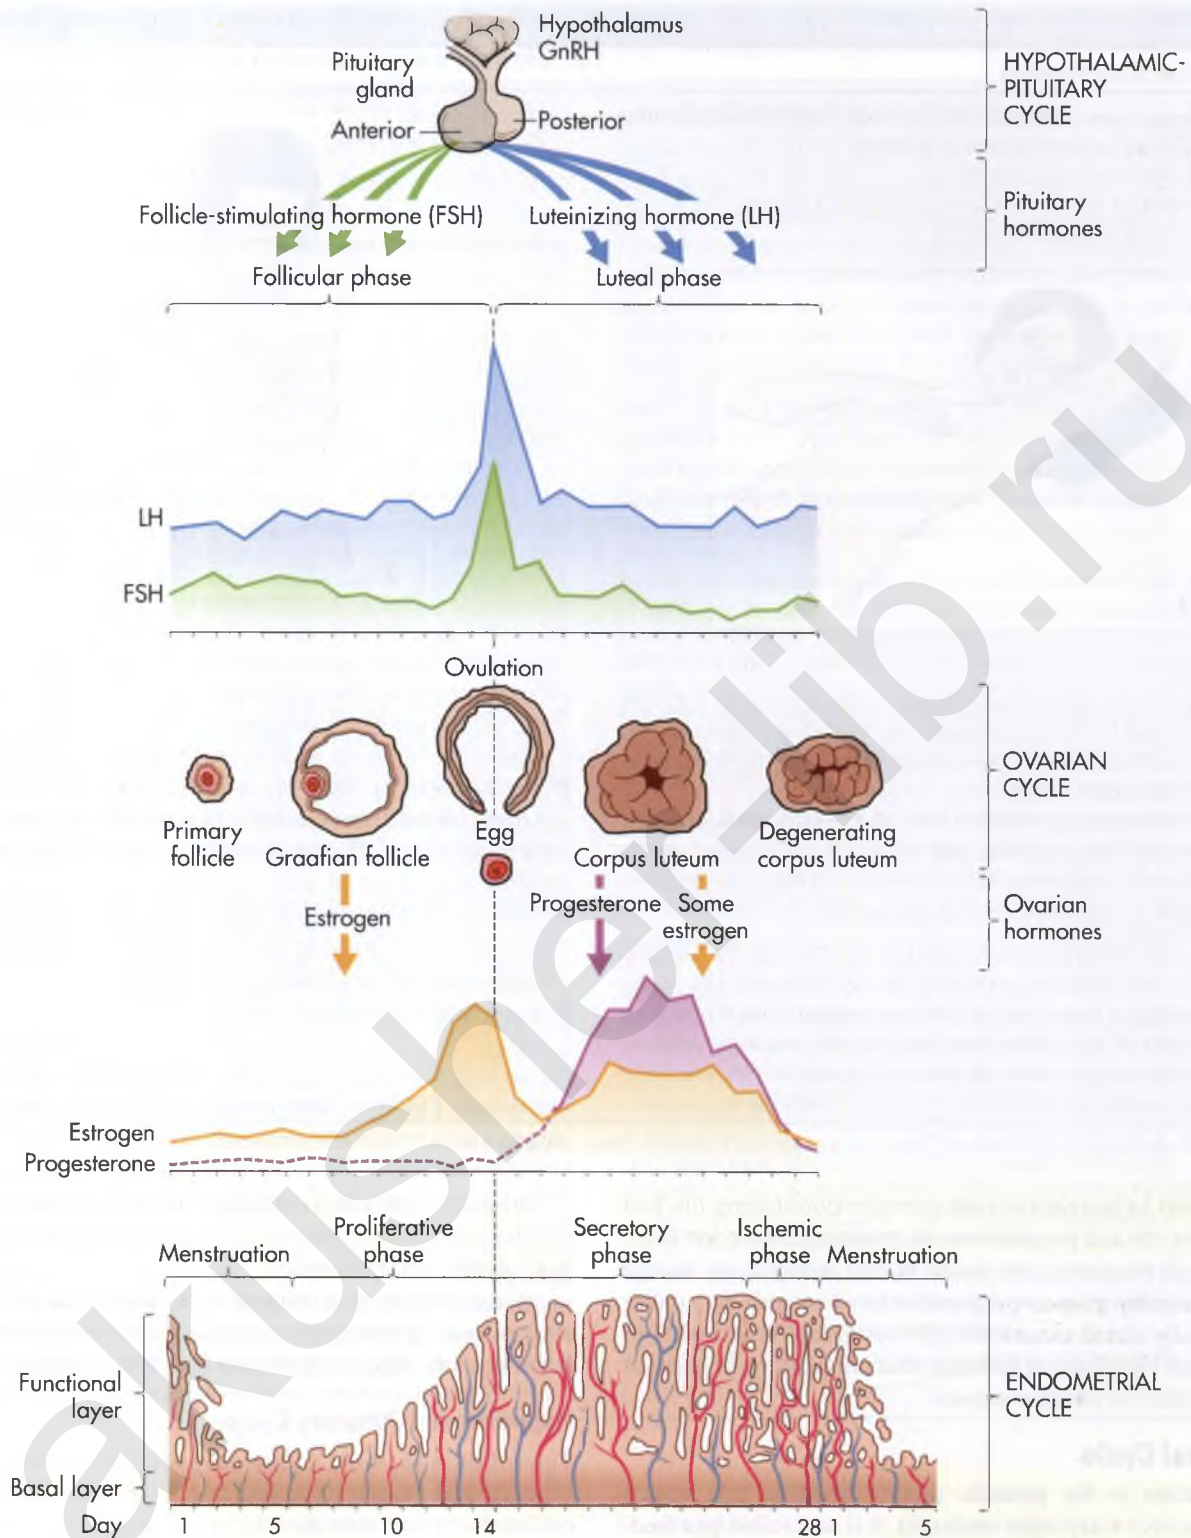

FIG 4-7 Menstrual cycle: hypothalamic-pituitary, ovarian, and endometrial. *GnRH*, Gonadotropin-releasing hormone.

progesterone and estrogen decline, menstruation occurs, and the hypothalamus is once again stimulated to secrete GnRH. This process is called the *hypothalamic-pituitary cycle*.

Ovarian Cycle

The primitive graafian follicles contain immature oocytes (primordial ova). Before ovulation, from 1 to 30 follicles begin to

mature in each ovary under the influence of FSH and estrogen. The preovulatory surge of LH affects a selected follicle. The oocyte matures, ovulation occurs, and the empty follicle begins its transformation into the corpus luteum. This follicular phase (preovulatory phase) (see Fig. 4-7) of the ovarian cycle varies in length from woman to woman. Almost all variations in ovarian cycle length are the result of variations in the length of

the follicular phase. On rare occasions (i.e., 1 in 100 menstrual cycles), more than one follicle is selected and more than one oocyte matures and undergoes ovulation.

After ovulation, estrogen levels drop. For 90% of women, only a small amount of withdrawal bleeding occurs, and it goes unnoticed. In 10% of women, there is sufficient bleeding for it to be visible, resulting in what is termed *midcycle bleeding*.

The luteal phase begins immediately after ovulation and ends with the start of menstruation. This postovulatory phase of the ovarian cycle usually requires 14 days (range 13 to 15 days). The corpus luteum reaches its peak of functional activity 8 days after ovulation, secreting the steroids *estrogen* and *progesterone*. Coincident with this time of peak luteal functioning, the fertilized ovum is implanted in the endometrium. If no implantation occurs, the corpus luteum regresses and steroid levels drop. Two weeks after ovulation, if fertilization and implantation do not occur, the functional layer of the uterine endometrium is shed through menstruation.

Endometrial Cycle

The four phases of the endometrial cycle are: (1) the menstrual phase, (2) the proliferative phase, (3) the secretory phase, and (4) the ischemic phase (see Fig. 4-7). During the menstrual phase shedding of the functional two thirds of the endometrium (the compact and spongy layers) is initiated by periodic vasoconstriction in the upper layers of the endometrium. The basal layer is always retained, and regeneration begins near the end of the cycle from cells derived from the remaining glandular remnants or stromal cells in this layer.

The proliferative phase is a period of rapid growth lasting from about the fifth day to the time of ovulation. The endometrial surface is completely restored in approximately 4 days, or slightly before bleeding ceases. From this point on, an 8- to 10-fold thickening occurs, with a leveling off of growth at ovulation. The proliferative phase depends on estrogen stimulation derived from ovarian follicles.

The secretory phase extends from the day of ovulation to about 3 days before the next menstrual period. After ovulation, large amounts of progesterone are produced. An edematous, vascular, functional endometrium is now apparent. At the end of the secretory phase, the fully matured secretory endometrium reaches the thickness of heavy, soft velvet. It becomes luxuriant with blood and glandular secretions, creating a suitable protective and nutritive bed for a fertilized ovum.

Implantation of the fertilized ovum generally occurs about 7 to 10 days after ovulation. If fertilization and implantation do not occur, the corpus luteum, which secretes estrogen and progesterone, regresses. With the rapid decrease in progesterone and estrogen levels, the spiral arteries go into spasm. During the ischemic phase, the blood supply to the functional endometrium is blocked and necrosis develops. The functional layer separates from the basal layer, and menstrual bleeding begins, marking day 1 of the next cycle (see Fig. 4-7).

Other Cyclic Changes

When the hypothalamic-pituitary-ovarian axis functions properly, other tissues undergo predictable responses. Before ovulation a woman's basal body temperature is often less than 37° C (98.6° F); after ovulation, with increasing progesterone levels,

her basal body temperature rises. Changes in the cervix and cervical mucus follow a generally predictable pattern. Preovulatory and postovulatory mucus is viscous (thick) so that sperm penetration is discouraged. At the time of ovulation, cervical mucus is thin and clear. It looks, feels, and stretches like egg white. This stretchable quality is termed *spinnbarkeit*. Some women have localized lower abdominal pain called *mittelschmerz* that coincides with ovulation. Some spotting may occur.

Prostaglandins

Prostaglandins (PGs) are oxygenated fatty acids classified as hormones. The different kinds of PGs are distinguished by letters (PGE and PGF), numbers (PGE₂), and letters of the Greek alphabet (PGF_{2α}).

PGs are produced in most organs of the body, including the uterus. Menstrual blood is a potent PG source. PGs are metabolized quickly by most tissues. They are biologically active in minute amounts in the cardiovascular, gastrointestinal, respiratory, urogenital, and nervous systems. They also exert a marked effect on metabolism, particularly on glycolysis. PGs play an important role in many physiologic, pathologic, and pharmacologic reactions. PGF_{2α}, PGE₄, and PGE₂ are most commonly used in reproductive medicine.

PGs affect smooth muscle contractility and modulation of hormonal activity. Indirect evidence indicates that PGs have an effect on ovulation, fertility, changes in the cervix, and cervical mucus that affect receptivity to sperm, tubal and uterine motility, sloughing of endometrium (menstruation), onset of miscarriage and induced abortion, and onset of labor (term and preterm). After exerting biologic actions, newly synthesized PGs are rapidly metabolized by tissues in such organs as the lungs, kidneys, and liver.

PGs may play a key role in ovulation. If PG levels do not rise along with the surge of LH, the ovum remains trapped within the graafian follicle. After ovulation, PGs may influence production of estrogen and progesterone by the corpus luteum.

The introduction of PGs into the vagina or the uterine cavity (from ejaculated semen) increases the motility of uterine musculature, which may assist the transport of sperm through the uterus and into the oviduct.

PGs produced by a woman cause regression of the corpus luteum and regression and sloughing of the endometrium, resulting in menstruation. PGs increase myometrial response to oxytocic stimulation, enhance uterine contractions, and cause cervical dilation. They may be a factor in the initiation of labor, the maintenance of labor, or both. They may also be involved in dysmenorrhea (see Chapter 6) and preeclampsia/eclampsia (see Chapter 27).

Climacteric and Menopause

The **climacteric** is a transitional phase during which ovarian function and hormone production decline. This phase spans the years from the onset of premenopausal ovarian decline to the postmenopausal time when symptoms stop. **Menopause** (from Latin *mensis*, month, and Greek *pauses*, to cease) refers only to the last menstrual period. However, unlike menarche, menopause can be dated with certainty only 1 year after menstruation ceases. The average age at natural menopause is 51.4 years, with an age range of 35 to 60 years. **Perimenopause** is a period preceding menopause that lasts about 4 years. During

this time ovarian function declines. Ova slowly diminish, and menstrual cycles may be anovulatory, resulting in irregular bleeding. The ovary stops producing estrogen, and eventually menses no longer occur.

SEXUAL RESPONSE

The hypothalamus and anterior pituitary glands in females regulate the production of FSH and LH. The target tissue for these hormones is the ovary, which produces ova and secretes estrogen and progesterone. A feedback mechanism that consists of hormone secretion from the ovaries, hypothalamus, and anterior pituitary controls the production of sex cells and steroid sex hormone secretion.

Although the first outward appearance of maturing sexual development occurs at an earlier age in females, both females and males achieve physical maturity at approximately 17 years of age; however, individual development varies greatly. Anatomic and reproductive differences notwithstanding, women and men are more alike than different in their physiologic response to sexual excitement and orgasm. For example, the glans clitoris and the glans penis are embryonic homologs. Little difference exists between female and male sexual response; the physical response is essentially the same whether stimulated by coitus, fantasy, or masturbation. Physiologic sexual response can be analyzed in terms of two processes: vasocongestion and myotonia.

Sexual stimulation results in increase in circulation to circumvaginal blood vessels (lubrication in the female), causing engorgement and distention of the genitals. Venous congestion is localized primarily in the genitalia, but it also occurs to a lesser degree in the breasts and other parts of the body. Arousal is characterized by myotonia (increased muscular tension), resulting in

voluntary and involuntary rhythmic contractions. Examples of sexually stimulated myotonia are pelvic thrusting, facial grimacing, and spasms of the hands and feet (carpopedal spasms).

The **sexual response cycle** is classically divided into four phases: excitement, plateau, orgasmic, and resolution, according to the seminal work of Masters and Johnson (1966). The four phases occur progressively, with no sharp dividing line between any two phases. The time, intensity, and duration for cyclic completion also vary for individuals and situations. Other researchers have suggested different models to explain sexual response. Leeman and Rogers (2012) emphasized the need to address sexuality and possible sexual difficulties with women in the postpartum period. Specific issues related to this period (and prior procedures such as episiotomy) must be considered in counseling to promote healthy sexuality during the postpartum period. Despite these alternate models of sexual response, it is still common to describe the classic four stages in which specific body changes take place in sequence, and this description is useful in educating and talking with women who may have concerns about possible sexual dysfunction. Table 4-1 compares male and female body changes during each of the four phases of the sexual response cycle.

REASONS FOR ENTERING THE HEALTH CARE SYSTEM

Women enter the health care system for myriad reasons, including those specifically related to women's reproductive health, but also for general well-woman care. Nurses play a key role in working with women who enter the health system (Box 4-1). The following section describes common reasons that women enter the health care system.

TABLE 4-1 Four Phases of Sexual Response

REACTIONS COMMON TO BOTH SEXES	FEMALE REACTIONS	MALE REACTIONS
Excitement Phase Heart rate and blood pressure increase. Nipples become erect. Myotonia begins.	Clitoris increases in diameter and swells. External genitalia become congested and darken. Vaginal lubrication occurs; upper two thirds of vagina lengthens and extends. Cervix and uterus pull upward. Breast size increases.	Erection of the penis begins; penis increases in length and diameter. Scrotal skin becomes congested and thickens. Testes begin to increase in size and elevate toward the body.
Plateau Phase Heart rate and blood pressure continue to increase. Respirations increase. Myotonia becomes pronounced; grimacing occurs.	Clitoral head retracts under the clitoral hood. Lower one third of vagina becomes engorged. Skin color changes occur—flush may be observed across breasts, abdomen, or other surfaces.	Head of penis may enlarge slightly. Scrotum continues to grow tense and thicken. Testes continue to elevate and enlarge. Preorgasmic emission of two or three drops of fluid appears on the head of the penis.
Orgasmic Phase Heart rate, blood pressure, and respirations increase to maximum levels. Involuntary muscle spasms occur. External rectal sphincter contracts.	Strong rhythmic contractions are felt in the clitoris, vagina, and uterus. Sensations of warmth spread through the pelvic area.	Testes elevate to maximum level. Point of "inevitability" occurs just before ejaculation and an awareness of fluid in the urethra. Rhythmic contractions occur in the penis. Ejaculation of semen occurs.
Resolution Phase Heart rate, blood pressure, and respirations return to normal. Nipple erection subsides. Myotonia subsides.	Engorgement in external genitalia and vagina resolves. Uterus descends to normal position. Cervix dips into seminal pool. Breast size decreases. Skin flush disappears. Women do not have a refractory period before they can have another orgasm.	Fifty percent of erection is lost immediately with ejaculation; penis gradually returns to normal size. Testes and scrotum return to normal size. Refractory period (time needed for erection to occur again) varies according to age and general physical condition.

Preconception Counseling and Care

Preconception health promotion provides women and their partners with information that is needed to make decisions about their reproductive future. Preconception counseling and care guide couples on how to avoid unintended pregnancies, identify and manage risk factors in their lives and their environment, and identify healthy behaviors that promote the well-being of the woman and her potential fetus. Approximately half of all pregnancies in the United States are unintended (Guttmacher Institute, 2012a). **Preconception care** targets all women of reproductive age, from menarche to menopausal transition. It has been estimated that 31% of pregnant women experience some complications of pregnancy, including mental health issues (mostly depression) and factors that lead to the need for cesarean birth (HealthyPeople.gov, 2012b). In addition, 12% of births result in preterm infants and 8.2% result in low-birth-weight (LBW) infants (HealthyPeople.gov, 2012a).

Activities that promote healthy mothers and babies must be initiated before the period of critical fetal organ development, which is between 17 and 56 days after fertilization. By the end of the eighth week after conception and certainly by the end of the first trimester, any major structural anomalies in the fetus are already present. Because many women do not realize that they are pregnant and do not seek prenatal care until well into the first trimester, the rapidly growing fetus may be exposed to many types of intrauterine environmental hazards during this most vulnerable developmental phase. These hazards include drugs, viruses, and chemicals. In many instances, counseling can promote behavior modification before damage is done or the woman can make an informed decision about her willingness to accept potential hazards.

Preconception care is important for women who have had a problem with a previous pregnancy (e.g., miscarriage or preterm birth). Although causes are not always identifiable, in many cases problems can be discovered and treated and do not recur in subsequent pregnancies. Preconception care is also important to minimize fetal malformations. For example, the offspring of women who have type 1 diabetes mellitus have significantly more congenital anomalies than do children of mothers without diabetes. The rate of malformation is greatly reduced when the insulin-dependent woman with diabetes has excellent blood glucose control at the time she becomes

pregnant and maintains euglycemia (normal blood sugar level) throughout the period of organ development in the fetus. The incidence of neural tube defects such as spina bifida and anencephaly is decreased significantly with the intake of 600 mcg of supplemental folic acid.

The components of preconception care such as health promotion, risk assessment, and interventions are outlined in Box 4-2.

BOX 4-2 Components of Preconception Care

Health Promotion: General Teaching

- Nutrition
 - Healthy diet, including folic acid
 - Optimal weight
- Exercise and rest
- Avoidance of substance abuse (tobacco, alcohol, "recreational" drugs)
- Use of risk-reducing sex practices
- Attending to family and social needs

Risk Factor Assessment

- Chronic diseases
 - Diabetes, heart disease, hypertension, asthma, thyroid disease, kidney disease, anemia, mental illness
- Infectious diseases
 - HIV/AIDS, other sexually transmitted infections, vaccine-preventable diseases (e.g., rubella, hepatitis B)
- Reproductive history
 - Contraception
 - Pregnancies—unplanned pregnancy, pregnancy outcomes
 - Infertility
- Genetic or inherited conditions (e.g., sickle cell anemia, Down syndrome, cystic fibrosis)
- Medications and medical treatment
 - Prescription medications (especially those contraindicated in pregnancy), over-the-counter medication use, radiation exposure
- Personal behaviors and exposures
 - Smoking, alcohol consumption, illicit drug use
 - Overweight or underweight; eating disorders
 - Folic acid supplement use
 - Spouse or partner and family situation, including intimate partner violence
 - Availability of family or other support systems
 - Readiness for pregnancy (e.g., age, life goals, stress)
 - Environmental (home, workplace) conditions
 - Safety hazards
 - Toxic chemicals
 - Radiation

Interventions

- Anticipatory guidance or teaching
 - Treatment of relevant medical conditions
 - Medications
 - Cessation or reduction in substance use and abuse
 - Immunizations (e.g., rubella, hepatitis)
- Nutrition, diet, weight management
- Exercise
- Referral for genetic counseling
- Referral to and use of:
 - Family planning services
 - Family and social needs management

BOX 4-1 Role of Nurses in Women's Health Promotion and Illness Prevention

Registered nurses work with women to promote wellness by:

- Integrating various modalities of care ("integrative nurse coaching")
- Collaborating with other health care practitioners
- Providing care in the community; working with individuals, families, communities
- Working to influence health policy

Advanced practice nurses work with women to promote wellness by:

- Providing comprehensive primary care
- Coordinating care in communities (from hospitals to home to communities)
- Working with social service resources for clients in the community; influencing health policy

BOX 4-3 Major Goals of Prenatal Care

- Define health status of the mother and fetus.
- Determine the gestational age of the fetus, and monitor fetal development.
- Identify the woman at risk for complications, and minimize the risk whenever possible.
- Provide appropriate education and counseling.

Pregnancy

A woman's entry into the health care system is often associated with pregnancy, for either diagnosis or actual prenatal care. Early entry into prenatal care (i.e., within the first 12 weeks) allows for identification of the woman at risk for complications and initiation of measures to prevent problems or treat them if they arise. The U.S. Department of Health and Human Services (HHS, 2012) has emphasized the importance of early and consistent prenatal care to improve outcomes for both mother and infant. Major goals of prenatal care are listed in Box 4-3 and should be addressed in the first visit. Extensive discussion of pregnancy is found in Chapter 15.

Well-Woman Care

Current trends in women's health care have expanded beyond a reproductive focus. A holistic approach to women's health care includes a woman's health needs throughout her lifetime. This view goes beyond simply her reproductive needs. This restructuring places women's health within the primary health care delivery system. Women's health assessment and screening focus on a multisystem evaluation emphasizing the maintenance and enhancement of wellness.

Health care needs vary with culture, religion, age, and personal differences. The changing responsibilities and roles of women, their socioeconomic status, and their personal lifestyles also contribute to differences in the health and behavior of women. Employment outside of the home, physical disability, inadequate or no health insurance, divorce, single parenthood, and sexual orientation also can affect women's ability to seek and receive health care in clinical settings. As women age, many continue to address their primary health care needs within their established gynecologic care setting; therefore, well-women's health care should include a complete history, physical examination, age-appropriate screening, and health promotion.

Fertility Control and Infertility

As noted, almost half of the pregnancies in the United States each year are unintended (Guttmacher Institute, 2012a), and the majority of these occurs in women who either do not use contraception or who experienced a contraceptive failure. Education is the key to encouraging women to make family planning choices based on preference and actual benefit-to-risk ratios. Providers can influence the user's motivation and ability to use the method correctly.

The concept of health promotion applies to contraception, as can be seen in Box 4-4. The nurse can influence women positively regarding the need for child spacing, methods of family planning that are consistent with religious and personal

BOX 4-4 Contraceptive Health Promotion

- Child spacing and quality maternity care improve perinatal outcomes and health in general of mother and children.
- Achieving desired family size enables a better sharing of all resources, with attendant increases in education, health care, and other positive societal parameters
- Contraceptives themselves may positively affect future health. For example, use of condoms may prevent acquisition of HIV infection; combined OCs may provide some protection against later development of cancer of ovary and endometrium; barrier methods decrease transmission of STIs, which can develop into pelvic inflammatory disease with resultant infertility or sterility and thus affect future childbearing capacity.

HIV, Human immunodeficiency virus; OCs, oral contraceptives; STIs, sexually transmitted infections.

preferences, noncontraceptive benefits of certain methods, the appropriate use of methods selected, and the protection of future fertility when so desired.

Women also enter the health care system because of their desire to become pregnant. Approximately 15% of couples in the United States have some degree of infertility. Many couples have delayed starting their families until they are in their 30s or 40s, which allows more time to be exposed to factors that affect fertility negatively (including age-related infertility for the woman). In addition, STIs, which can predispose to decreased fertility, are becoming more common and many women and men are in workplaces and home settings, where they may be exposed to reproductive environmental hazards.

Infertility can cause emotional pain for many couples, and the inability to produce offspring sometimes results in feelings of failure and places inordinate stress on the couple's relationship. Much time, money, and emotional investment can be used for testing and treatment in efforts to build a family.

Steps toward prevention of infertility should be undertaken as part of ongoing routine health care, and information about how women may prevent some causes of infertility is especially appropriate in preconception counseling. Primary care providers can undertake initial evaluation and counseling before couples are referred to specialists. (For additional information about infertility, see Chapter 9.)

Menstrual Problems

Irregularities or problems with the menstrual period are among the most common concerns of women and often cause them to seek help from the health care system. Common menstrual disorders include amenorrhea, dysmenorrhea, premenstrual syndrome, endometriosis, and menorrhagia or metrorrhagia. Simple explanation and counseling may handle the concern; however, history and examination must be completed, as well as laboratory or diagnostic tests, if indicated. Questions should never be considered inconsequential, and age-specific reading materials are recommended, especially for teenagers. (See Chapter 6 for an in-depth discussion of menstrual problems.)

Perimenopause

The body responds to this natural transition in a number of ways, most of which are caused by the decrease in estrogen.

abnormal absence of menstruation

abnormal bleeding from uterus

4 years before menopause

part of the menstrual cycle

Most women seeking health care during the perimenopausal period do so because of irregular bleeding. Others are concerned about vasomotor symptoms (hot flashes and flushes). Although fertility is greatly reduced during this period, women are urged to maintain some method of birth control because pregnancies still can occur. All women need to have factual information, the dispelling of myths, a thorough examination, and periodic health screenings thereafter. (See Chapter 6 for an in-depth discussion of perimenopausal problems.)

BARRIERS TO ENTERING THE HEALTH CARE SYSTEM

Access to care varies greatly, depending on type and size of the system, source of payment for services, private versus public programs, availability of and accessibility to providers, individual preferences, and insurance coverage or ability to pay. The existing system continues to be oriented to treatment of acute or episodic conditions rather than to the promotion of health and comprehensive care, despite the fact that people are discharged earlier from hospitals, requiring more care in homes and community settings. With a greater focus on preventive health care services and with 32,000,000 formerly uninsured clients having access to health care, nurses, advanced practice nurses, including nurse practitioners, nurse-midwives, and clinical nurse specialists, are critical to the provision of high-quality, safe, effective, and accessible health care (see Box 4-1).

Financial Issues

In the United States, disparity among races and socioeconomic classes affects many facets of life including health. Limited finances are associated with lack of access to care, delay in seeking care, few prevention activities, and little accurate information about health and the health care system. Women use health care services more often than men but are more likely than men to have difficulty in financing the services. Many poor women have traditionally been underinsured or uninsured, but rules about health insurance and who and what are covered are undergoing a transition with the Affordable Care Act (healthcare.gov, 2012). People will not be denied insurance because of preexisting conditions, and various preventive health services will be covered under health insurance. However, this legislation is far from decided, and its effect on the American people will not be known for years.

Cultural Issues

We live in a multicultural society with constantly changing demographics, and for nursing care of women to be optimal, cultural differences must be addressed with great sensitivity and competency. Nurses are in excellent positions to be responsible for providing culturally sensitive and competent health care (Escallier, Fullerton, & Messina, 2011). A variety of reasons are given to explain some of the differences in accessing care when financial barriers are adjusted. Some women experience racial discrimination or disrespectful, disillusioning, or discouraging encounters with community service providers such as social services and health care providers. Many women do not seek

care from the health care system because of lack of trust (Yang, Matthews, & Hillemeier, 2011). A lack of cross-cultural communication also presents problems. Desired health outcomes are best achieved when the health care provider has knowledge of and understanding about the culture, language, values, priorities, and health beliefs of those in various ethnic groups. Conversely, members of these various groups should understand the health goals to be achieved and the methods proposed to do so. Language differences can produce profound barriers between clients and providers. Even with an interpreter, misinformation can occur on both sides of the communication.

Providers must consider culturally based differences that could affect the treatment of diverse groups of women, and the women themselves must share practices and beliefs that could influence their responses to treatment or willingness to adhere to treatment. For example, women in some cultures value privacy to such an extent that they are reluctant to disrobe and, as a result, avoid physical examination unless absolutely necessary. Other women rely on their husbands to make major decisions, including those affecting the woman's health. Religious beliefs may dictate a plan of care, as with birth control measures or blood transfusions. Some cultural groups prefer folk medicine, homeopathy, or prayer to traditional Western medicine, and others attempt combinations of some or all practices. Nurses can integrate into their own practice various holistic approaches to care, in accordance with Dossey's (2013) *Theory of Integral Nursing*. It is critically important to be sensitive to cultural differences and at the same time not stereotype and assume that a woman has certain beliefs because of her ethnic background. Although the amount of health information on the Internet is increasing, information in languages other than English is limited and not all information on the Internet is accurate, making health literacy an important issue in culturally competent care.

Gender Issues

Gender influences provider-client communication and may influence access to health care in general. Researchers have reported significant male-female differences in receipt of major diagnostic and therapeutic interventions, especially with cardiac and kidney problems. Women tend to use primary care services more often than do men and, some believe, more effectively. The gender of the provider plays a role. The concept of "gender concordance," in which the client's gender matches the health care provider's gender, was found to be important for women seeking Pap tests (McAlearney, Oliveri, Post, et al., 2011). McAlearney and associates found that women were more comfortable having a Pap test performed by a female physician and having a female nurse present.

Sexual orientation may produce another barrier. Nurses need to understand the specific health care needs and issues related to sexual orientation (Brennan, Barnsteiner, de Leon Siantz, et al., 2012). Some lesbians may not disclose their sexual orientation to health care providers because they feel they may be at risk for hostility, inadequate health care, or breach of confidentiality. In many health care settings, heterosexuality is assumed, and the setting may be one in which the woman does not feel welcome (magazines, brochures, and environment reflect heterosexual couples, or the health care provider

shows discomfort interacting with the woman). Lesbians themselves may hold beliefs that are incorrect (e.g., that they have immunity to human immunodeficiency virus [HIV], sexually transmitted infections [STIs], and certain cancers [e.g., cervical]). The perceived lack of risk can result in lesbians avoiding health care, as well as in health care providers giving incorrect advice or not providing appropriate screening for these women. Not all gynecologic cancers are related to sexual activity; lesbians who have never had children may still be at risk for breast, ovarian, and endometrial cancer. Their risk for heart disease, cancer of the lung, and colon cancer is not different from that of the heterosexual woman. To offset stereotypes, it is necessary for providers to develop an approach that does not assume that all clients are heterosexual. More content related to this issue needs to be included in nursing curricula.

HEALTH RISKS TO WOMEN

Maintaining optimal health is a goal for all women. Essential components of health maintenance are the identification of unrecognized problems and potential risks and the education and health promotion needed to reduce them. Current trends in women's health care have expanded beyond a reproductive focus. A holistic approach to women's health care goes beyond simple reproductive needs and includes a woman's health needs throughout her lifetime, with attention to physical, mental/emotional, social, and spiritual health. Women's health is considered to be part of the primary health care delivery system with assessment and screening focusing on a multisystem evaluation that emphasizes the maintenance and enhancement of wellness. Prevention of cardiovascular disease, promotion of mental health, and prevention of cancers beyond just reproductive-related cancers are all components of well-woman care. It is important to consider all aspects of women's health, particularly in light of the fact that the leading causes of death in women in the United States include more than just reproductive health conditions (Box 4-5).

Even when focusing on reproductive health, it is critical to take a holistic approach to the health of women. This is especially important for women in their childbearing years because

BOX 4-5 Top 10 Leading Causes of Death in Women in the United States

1. Heart disease
2. Malignant neoplasm (cancer)
3. Cardiovascular disease (stroke)
4. Chronic lower respiratory disease
5. Alzheimer's disease
6. Unintentional injury
7. Diabetes mellitus
8. Influenza and pneumonia
9. Nephritis
10. Septicemia

Data from U.S. Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau. (2011). *Women's health USA*. Rockville, MD; U.S. Department of Health and Human Services. (2013). *Leading causes of death in females, United States, 2009*. Available at www.cdc.gov/women/lcod/2009/index.htm; mchb.hrsa.gov/whusa11.

conditions that increase a woman's health risks are related not only to her well-being but also the well-being of both mother and baby in the event of a pregnancy. Prenatal care is an example of prevention that is practiced after conception. However, prevention and health maintenance are needed before conception because many of the mother's risks can be identified and eliminated, or at least modified.

As a female progresses through developmental ages and stages, she is faced with conditions that are age related. An overview of conditions and circumstances that increase health risks in women across the life span is presented in the next section. In a later section, tips for promoting health and preventing illness are presented.

Age Adolescence

All teens undergo progressive development of sex characteristics. They experience the developmental tasks of adolescence such as establishing identity and sexual orientation, emancipating from family, and establishing career goals. Some of these processes can produce great stress for the adolescent, and the health care provider should treat her very carefully. Female teenagers who enter the health care system usually do so for screening or because of a problem such as episodic illness or accidents. Previous guidelines recommended that young women should be screened with Pap tests at age 18 or when they become sexually active. Guidelines now suggest that Pap tests begin at age 21, but controversy exists about the evidence to support these new guidelines, with some health care providers providing evidence for earlier testing (Zhao, Kalpos-Novak, & Austin, 2011). Gynecologic problems are often associated with menses (either bleeding irregularities or dysmenorrhea), vaginitis or leukorrhea, STIs, contraception, or pregnancy. The adolescent is also at risk for use of street drugs, for eating disorders, and for stress, depression, and anxiety.

Many women first enter the health care delivery system for a Pap test or for contraception. Visits to the nurse may be their only contact with the system unless they become ill. Some women postpone examination until a specific need arises such as pregnancy, infertility, pain, abnormal bleeding, or vaginal discharge. The availability of the human papillomavirus (HPV) vaccine has created another reason for young women to enter the health care system (Saraiya, Rosser, & Cooper, 2012).

Teenage Pregnancy. Most young women begin having sex in their mid- to late teens. At age 15, 13% of teens have had sex, but by age 19, 70% of teens have had sexual intercourse (Guttmacher Institute, 2012b). A sexually active teen who does not use contraception has a 90% chance of pregnancy within 1 year. The United States has the highest teen pregnancy rate in the industrialized world. By age 20, one third of all American girls get pregnant; most of these pregnancies are unintended (Centers for Disease Control and Prevention [CDC], 2012a).

Effective educational programs about sex and family life are imperative to control the rate of teen pregnancy and STIs. The nurse can provide information regarding methods of family planning that are consistent with religious and personal preferences, noncontraceptive benefits of certain methods, the appropriate use of methods selected, the need for child spacing, and the protection of future fertility when so desired.

Pregnancy in the teenager who is 16 years of age or younger often introduces additional stress into an already stressful developmental period. The emotional level of such teens is commonly characterized by impulsiveness and self-centered behavior, and they often place primary importance on the beliefs and actions of their peers. In attempts to establish a personal and independent identity, many teens do not realize the consequence of their behavior; their thinking processes do not include planning for the future.

Teenagers usually lack the financial resources to support a pregnancy and may not have the maturity to avoid teratogens or have prenatal care and instruction or follow-up care. Children of teen mothers may be at risk for abuse or neglect because of the teen's inadequate knowledge of growth, development, and parenting. Implementation of specialized adolescent programs in schools, communities, and health care systems is demonstrating continued success in reducing the birth rate in teens.

Young and Middle Adulthood

Because women ages 20 to 40 years have a need for contraception, pelvic and breast screening, and pregnancy care, they may prefer to use their gynecologic or obstetric provider as their primary care provider. During these years the woman may be juggling family, home, and career responsibilities, with resulting increases in stress-related conditions. Health maintenance includes not only pelvic and breast screening but also promotion of a healthy lifestyle (i.e., good nutrition, regular exercise, no smoking, moderate or no alcohol consumption, sufficient rest, stress reduction, and referral for medical conditions and other specific problems). Common conditions requiring well-woman care include vaginitis, urinary tract infections, menstrual variations, obesity, sexual and relationship issues, and pregnancy.

Parenthood After Age 35. The woman older than 35 years does not have a different physical response to a pregnancy per se but, rather, may have health status changes as a result of time and the normal aging process. These changes may be responsible for age-related pregnancy conditions. For example, a woman with type 2 diabetes may not have had expression of her diabetes at age 22 but may have the full-blown disease at age 38. Other chronic or debilitating diseases or conditions increase in severity with time, and these in turn may predispose to increased risks during pregnancy. Of significance to women in this age group is the risk for certain genetic anomalies (e.g., Down syndrome). The opportunity for genetic counseling should be available to all (see Chapter 3).

Late Reproductive Age

Women of later reproductive age are often experiencing change and reordering personal priorities. In general, the goals of education, career, marriage, and family have been achieved and now the woman has increased time and opportunity for new interests and activities. Divorce rates are high at this age, and children leaving home may produce an "empty nest syndrome," resulting in increased levels of depression. Chronic diseases also become more apparent. Most problems for the well woman are associated with perimenopause (e.g., bleeding irregularities and vasomotor symptoms). Health maintenance screening continues to be of importance because some

conditions such as breast disease or ovarian cancer occur more often during this stage.

Social, Cultural, Economic, and Genetic Factors

Differences exist among people from different socioeconomic levels and ethnic groups with respect to risk for illness and distribution of disease and death. Some diseases are more common among people of selected ethnicity (e.g., sickle cell anemia in African-Americans, Tay-Sachs disease in Ashkenazi Jews, adult lactase deficiency in Chinese, beta thalassemia in Mediterranean people, and cystic fibrosis in northern Europeans). Cultural and religious influences also increase health risks because the woman and her family may have life and societal values and a view of health and illness that dictate practices different from those expected in the Judeo-Christian Western model. These may include food taboos or frequencies, methods of hygiene, effects of climate, care-seeking behaviors, willingness to undergo screening and diagnostic procedures, and conflicts in values.

Socioeconomic status affects birth outcomes. The rates of perinatal and maternal deaths, preterm births, and LBW babies are considerably higher in disadvantaged populations (Hogue & Silver, 2011). Social consequences for poor women as single parents are great because many mothers with few skills are caught in the bind of insufficient income to afford child care. These families generate fewer and fewer resources and increase their risks for health problems. Multiple roles for women in general produce overload, conflict, and stress, resulting in higher risks for psychologic illness.

Substance Use and Abuse

Use of illicit drugs and inappropriate use of prescription drugs continue to increase and are found in all ages, races, ethnic groups, and socioeconomic strata. Addiction to substances is seen as a biopsychosocial disease, with several factors contributing to risk. These include biogenetic predisposition, lack of resilience to stressful life experiences, and poor social support. Women are less likely than men to abuse drugs, but the rate in women is increasing significantly. Substance-abusing pregnant women create severe problems for themselves and their offspring, including interference with optimal growth and development and addiction. In many instances, the use of substances is identified through screening programs in prenatal clinics and obstetric units.

COMMUNITY ACTIVITY

- Visit the National Women's Health Resource Center website at www.healthywomen.org. Go to the conditions and treatments link and select a condition. Review the client information sections about diagnosis, treatment, prevention, facts to know, questions to ask, and lifestyle tips.
- Visit the WomensHealth.gov and go to the various women's health topics and publications. Review the information to see what areas of women's health might be of interest to you, including how you might advocate in the community on behalf of a women's health issue.
- Visit the smokefree.gov website to learn about smoking in your state. How does your state rank compared to other states?
- Visit the Office of Women's Health Research website at <http://orwh.od.nih.gov> and view the various research that is being conducted in women's health.

Smoking

Tobacco use is the leading cause of preventable death and illness. Smoking is linked to cardiovascular disease, various types of cancers (especially lung and cervical), chronic lung disease, and negative pregnancy outcomes. Premature death is estimated to occur in 443,000 people annually because of either smoking or being exposed to secondhand smoke, and 8.6 million people are estimated to be seriously ill as a result of smoking. However, it is also estimated that 46.6 million adults in the United States smoke; 17.3% of women are smokers (CDC, 2011). The American Cancer Society (ACS, 2013b) notes that women who smoke decrease their life span by 14.5 years compared with nonsmokers. Tobacco contains nicotine, which is an addictive substance that creates physical and psychologic dependence. Smoking in pregnancy is known to cause a decrease in placental perfusion and is one cause of LBW in infants. During pregnancy, women seem to be highly motivated to stop or at least to limit smoking. If a pregnant woman is able to stop smoking during the first trimester, she decreases the chance of having a LBW baby (ACS, 2013b). (Chapter 31 discusses other aspects of smoking.)

Cigarette smoking impairs fertility in both women and men, may reduce the age for menopause, and increases the risk for osteoporosis after menopause. Passive, or secondhand, smoke (environmental tobacco smoke) contains similar hazards and presents additional problems for the smoker and harm for the nonsmoker.

Alcohol Consumption

Women ages 35 to 49 have the highest rates of chronic alcoholism, but women ages 21 to 34 have the highest rates of specific alcohol-related problems. About one third of alcoholics are women, and many relate the onset of their drinking problem to stressful events. Women who are problem drinkers are often depressed, have more motor vehicle injuries, and have a higher incidence of attempted suicide than do women in the general population. They are also at risk for alcohol-related liver damage. Early case finding and treatment are important in alcoholism for both the ill individual and family members. (Additional discussion about alcohol consumption is included in Chapter 31.)

Prenatal alcohol exposure has been found to increase the chance of birth defects significantly, with one study reporting a fourfold increase (O'Leary, Nassar, Kurinczuk, et al., 2011). Although fetal alcohol syndrome (FAS) is a known consequence of prenatal alcohol intake, studies also indicate that other consequences include increased risk for miscarriage, stillbirth, preterm birth, and sudden infant death syndrome (SIDS). Clearly, alcohol consumption during pregnancy has wide-reaching effects (Bailey & Sokol, 2011). A 2020 national health objective is to have 98.3% of pregnant women abstain from alcohol use (HealthyPeople.gov, 2012c).

Alcohol use during pregnancy can lead to fetal alcohol spectrum disorder (FASD), which includes FAS, fetal alcohol effects, and alcohol-related neurologic developmental disabilities. Approximately 40,000 babies per year are born with FASD; however, recent research reveals that multivitamin supplement use during pregnancy may lessen the effects of prenatal alcohol exposure in the children of women who are unable or unwilling to curtail their alcohol abuse when pregnant (Avalos, Kaskutas, Block, et al., 2011). LBW, intellectual disability, behavior

problems, and learning and physical problems are some of the symptoms of FAS babies (see Chapter 35). Severe facial deformities of FAS occur at day 20 of conception when women may not even suspect that they are pregnant.

Caffeine

Caffeine is found in society's most popular drinks: coffee, tea, and soft drinks. It is a stimulant that can affect mood and interrupt body functions by producing anxiety and sleep interruptions. Heart dysrhythmias may be made worse by caffeine, and there can be interactions with certain medications such as lithium. Birth defects have not been related to caffeine consumption; however, high intake has been related to a slight decrease in birth weight and may also increase risk for miscarriage. The March of Dimes (2013) recommends that pregnant women, or women who are trying to conceive, limit their caffeine intake to no more than 200 mg/day, which is the equivalent of one 12-ounce cup of coffee.

Prescription Drug Use

Psychotherapeutic medications such as stimulants, sleeping pills, tranquilizers, and pain relievers are used by an estimated 2% of American women. Such medications can bring relief from undesirable conditions such as insomnia, anxiety, and pain. Because the medications have mind-altering capacity, misuse can produce psychologic and physical dependency in the same manner as illicit drugs. Risk-to-benefit ratios should be considered when such medications are used for more than a very short period. Depression and anxiety are the most common mental health problems in women (depression used to be considered the most common, but recently it has been noted that depression occurs comorbidly with anxiety). Many kinds of medications are used to treat depression and anxiety. All of these psychotherapeutic drugs can have some effect on the fetus and must be monitored very carefully.

Illicit Drugs

Illicit drugs are taken for unlawful purposes. When they are unprescribed they are usually obtained on the street for the purpose of getting high or for their body-mind-altering characteristics. Almost any drug can be abused or even illegal if taken in excess, including alcohol and prescription medication. See Chapter 31 for further discussion of substance abuse.

Nutritional Deficiencies

Good nutrition is essential for optimal health. A well-balanced diet helps prevent illness and treat certain health problems. Conversely, poor eating habits, eating disorders, and obesity are linked to disease and debility. Environmental factors play an important role in nutrition. Dubowitz, Ghosh-Dastidar, Eibner, and colleagues (2012) presented data from the Women's Health Initiative (WHI) clinical trial that indicated availability of healthy food was correlated with decreased obesity in women. These data suggest that social conditions and access to nutritious food are important contributors to women's health.

Overt disease caused by a lack of certain nutrients is rarely seen in the United States. However, insufficient amounts or imbalanced nutrients do pose problems for individuals and families. Overweight or underweight status, malabsorption,

listlessness, fatigue, frequent colds and other minor infections, constipation, dull hair and nails, and dental caries are examples of problems that can be related to nutrition and indicate the need for further nutritional assessment. Poor nutrition, especially related to obesity and high fat and cholesterol intake, may lead to more serious conditions in later life, which supports the need to ensure healthy nutrition as a preventive measure. The Academy of Nutrition and Dietetics (2012) noted that five of the eight most common causes of death in adults ages 65 and older are related to nutritional problems.

Obesity

During the past 20 years, obesity has increased dramatically in the United States. More than one third of women in the United States are obese (body mass index [BMI] of 30 or greater), with adults ages 40 to 59 having the highest prevalence. The BMI is defined as a measure of an adult's weight in relation to his or her height, specifically the adult's weight in kilograms divided by the square of his or her height in meters (see Chapter 14). It is estimated that one third of adults and one sixth of children and adolescents are in the obese range (HealthyPeople.gov, 2012b). Overweight and obesity are known risk factors for premature death, diabetes, heart disease, stroke, hypertension, type 2 diabetes, gallbladder disease, diverticular disease, some anemias, oral disease, constipation, osteoarthritis, gout, osteoporosis, respiratory dysfunction, sleep apnea, and some types of cancer (uterine, breast, colorectal, kidney, and gallbladder) (ACS, 2013c). In addition, obesity is associated with high cholesterol, menstrual irregularities, hirsutism (excess body/facial hair), stress incontinence, depression, complications of pregnancy, increased surgical risk, and shortened life span. Pregnant women who are morbidly obese are at increased risk for hypertension, diabetes, gallbladder disease, postterm pregnancy, musculoskeletal problems, intrauterine growth restriction, and intrauterine fetal demise (American College of Obstetricians and Gynecologists [ACOG], 2013).

Other Considerations: Eating Disorders

Anorexia nervosa and bulimia are two forms of eating disorders, although there are additional forms, such as subclinical eating disorders. Some women, especially adolescents, do not have symptoms that lend themselves to a diagnosis of anorexia nervosa or bulimia. These women are diagnosed as having a subclinical eating disorder, which is usually associated with disorders of mood and anxiety and requires accurate diagnosis and prompt treatment (Touchette, Henegar, Godart, et al., 2011). Research suggests that eating disorders are often associated with difficulties in intimate relationships, and interpersonal psychotherapy has been considered as an approach to treatment of women with eating disorders (Murphy, Straebler, Basden, et al., 2012).

It is important to assess for and treat women with eating disorders early because they are at increased risk for serious physical problems as well as diminished quality of life (Vallance, Latner, & Gleaves, 2011). Eating disorders during pregnancy are also associated with increased risk to the pregnant woman and her fetus (Pasternak, Weintraub, Shoham-Vardi, et al., 2012).

Anorexia Nervosa. Some women have a distorted view of their bodies and, no matter what their weight, perceive themselves to be much too heavy. As a result, they undertake strict and

severe diets and rigorous extreme exercise. This chronic eating disorder is known as anorexia nervosa. Women can carry this condition to the point of starvation, with resulting endocrine and metabolic abnormalities. If not corrected, significant complications of dysrhythmias, amenorrhea, cardiomyopathy, and congestive heart failure occur and, in the extreme, can lead to death. The condition commonly begins during adolescence in young women who have some degree of personality disorder. They gradually lose weight over several months, have amenorrhea, and are abnormally concerned with body image. A coexisting depression usually accompanies anorexia.

There are no specific tests to diagnose anorexia nervosa. A medical history, physical examination, and screening tests help identify women at risk for eating disorders. Several tools are available to use in primary care settings. The SCOFF questionnaire, developed by Morgan, Reid, and Lacey (1999) is easy to administer and can help the nurse decide whether an eating disorder is likely and whether the woman needs further assessment and possibly psychiatric and medical intervention. More recently Hautala, Junnila, Alin and colleagues (2009) provided further evidence for the validity and usefulness of the SCOFF. See Box 4-6 for a description of the SCOFF.

Bulimia Nervosa. Bulimia refers to secret, uncontrolled binge eating alternating with methods to prevent weight gain: self-induced vomiting, laxatives or diuretics, strict diets, fasting, and rigorous exercise. During a binge episode, a large number of calories are consumed, usually consisting of sweets and junk foods. Binges occur at least twice per week. Bulimia usually begins in early adulthood (ages 18 to 25 years) and is found primarily in females. Complications can include dehydration and electrolyte imbalance, gastrointestinal abnormalities, and cardiac dysrhythmias. Bulimia is somewhat similar to anorexia in that it is an eating disorder and usually involves some degree of depression (Skinner, Haines, Austin, et al., 2012). Unlike those with anorexia, individuals with bulimia may feel shame or disgust about their disorder and tend to seek help earlier. The SCOFF screening assessment also can be used to assess clients with bulimia (see Box 4-6).

Binge-Eating Disorder. The hallmark of binge-eating disorder is eating large amounts of food in a short period (a couple of hours) and not being able to stop eating. The woman may eat when she's not hungry or until uncomfortably full. She may choose to eat alone because she is embarrassed about how much she eats. Binge-eating disorder involves bingeing

BOX 4-6 Screening for Eating Disorders

SCOFF Questions

Each question scores 1 point. A score of 2 or more indicates the person may have anorexia nervosa or bulimia.

1. Do you make yourself Sick (i.e., induce vomiting) because you feel too full?
2. Do you worry about loss of Control over the amount you eat?
3. Have you recently lost more than One stone (6.4 kg [14 lb]) in a 3-month period?
4. Do you think you are too Fat even if others think you are too thin?
5. Does Food dominate your life?

From Morgan, J.F., & Lacey, J. (1999). The SCOFF questionnaire: Assessment of a new screening tool for eating disorders. *BMJ*, 319(7223), 1467-1468.

that alternates with a restricted dietary intake. An associated syndrome called *night eating syndrome* is when limited food is eaten early in the day and most of the day's food intake is consumed after the evening meal. Over time, obesity and related complications of being overweight can develop. Common personality traits found in those with binge-eating disorder include excessive concern about body size and shape and low self-esteem. Depression and anxiety commonly occur along with binge eating, which makes treatment and recovery more difficult. Binge eating is not associated with anorexia nervosa or bulimia nervosa.

Lack of Exercise

Lack of adequate exercise is an important risk factor to women's health. Exercise contributes to good health by lowering risks for a variety of conditions that are influenced by obesity and a sedentary lifestyle. It is effective in the prevention of cardiovascular disease and in the management of chronic conditions such as hypertension, arthritis, diabetes, respiratory disorders, and osteoporosis. Exercise also contributes to stress reduction and weight maintenance. Women report that engaging in regular exercise improves their body image and self-esteem and acts as a mood enhancer. Aerobic exercise produces cardiovascular involvement because an increased amount of oxygen is delivered to working muscles. Anaerobic exercise such as weight training improves individual muscle mass without stress on the cardiovascular system. Because women are concerned about both cardiovascular and bone health, weight-bearing aerobic exercises such as walking, running, racquet sports, and dancing are preferred. However, excessive or strenuous exercise can lead to hormone imbalances, resulting in amenorrhea and its consequences. Physical injury is also a potential risk.

SAFETY ALERT

Before beginning any planned physical activity program, a woman should see her primary care nurse practitioner (NP) or physician for a thorough medical evaluation to prevent potential injuries or harm.

Stress

The modern woman faces increasing levels of stress and, as a result, is prone to a variety of stress-induced complaints and illnesses. Stress often occurs because of multiple roles in which coping with job and financial responsibilities conflicts with parenting and duties at home. To add to this burden, women are socialized to be caregivers, which is emotionally draining, creating additional stress. They also may find themselves in positions of minimal power that do not allow them control over their everyday environments. Some stress is normal and contributes to positive outcomes. Many women thrive in busy surroundings. However, excessive or high levels of ongoing stress trigger physical reactions such as rapid heart rate, elevated blood pressure, slowed digestion, release of additional neurotransmitters and hormones, muscle tenseness, and a weakened immune system. Consequently, constant stress can contribute to clinical illnesses such as flare-ups of arthritis or asthma, frequent colds or infections, gastrointestinal upsets, cardiovascular problems,

and infertility. Box 4-7 lists symptoms that may be related to chronic or extreme stress. Psychologic symptoms such as anxiety, irritability, eating disorders, depression, insomnia, and substance abuse have also been associated with stress.

Depression, Anxiety, and Other Mental Health Conditions

Women experience depression and/or anxiety frequently. In addition, depression is sometimes described as a co-traveler because it exists comorbidly with other physical conditions. Depression and/or anxiety create difficulties for quality of life and, at the extreme, create a risk for suicide. Research (Berecki-Gisolf, McKenzie, Dobson, et al., 2012) suggests that women with comorbid anxiety and depression are at greater risk for developing cardiac disease. In addition to depression and anxiety, women experience other mental health disorders, such as bipolar disease (see Chapter 31).

BOX 4-7 Stress Symptoms

Physical

- Perspiration/sweaty hands
- Increased heart rate
- Trembling
- Nervous tics
- Dryness of throat and mouth
- Tiring easily
- Urinating frequently
- Sleeping problems
- Diarrhea, indigestion, vomiting
- Butterflies in stomach
- Headaches
- Premenstrual tension
- Pain in the neck and lower back
- Loss of appetite or overeating
- Susceptibility to illness

Behavior

- Stuttering and other speech difficulties
- Crying for no apparent reason
- Acting impulsively
- Startling easily
- Laughing in a high-pitched and nervous tone of voice
- Grinding teeth
- Increased smoking
- Increased use of drugs and alcohol
- Being accident-prone
- Losing appetite or overeating

Psychologic

- Feeling anxious
- Feeling scared
- Feeling irritable
- Feeling moody
- Low self-esteem
- Fear of failure
- Inability to concentrate
- Embarrassed easily
- Worrying about the future
- Preoccupation with thoughts or tasks
- Forgetfulness

Adapted from State University of New York Counseling Center. (2002). *Stress management*. University of Buffalo, NY: State University of New York.

Sleep Disorders

Many women suffer from sleep disorders, including difficulty initiating sleep or staying asleep and experiencing nonrestorative sleep. Restless leg syndrome may be a cause of sleep disorders or a comorbid condition. Sleep disorders are correlated with physical and mental health problems, including depression, pain, and fibromyalgia. Mong, Baker, Mahoney and associates (2011) presented a review of studies conducted on gender differences related to sleep, suggesting that, although further research is needed, women experience insomnia significantly more than do men. It is important that the nurse talk with the woman about her sleep patterns and discuss ways to improve sleep, such as avoiding alcohol before going to sleep and sleeping in a regular pattern.

Environmental and Workplace Hazards

Environmental hazards in the home, the workplace, and the community can contribute to poor health at all ages. Categories and examples of health-damaging hazards include the following: (1) pathogenic agents (viruses, bacteria, fungi, parasites); (2) natural and synthetic chemicals (natural toxins from animals, insects, and plants; consumer and industrial products such as pesticides and hydrocarbon gases; medical and diagnostic devices; tobacco; fuels; and drugs and alcohol); (3) radiation (radon, heat waves, sound waves); (4) food substances (added components that are not necessary for nutrition); and (5) physical objects (moving vehicles, machinery, weapons, water, and building materials).

Environmental hazards can affect fertility, fetal development, live birth, and the child's future mental and physical development. Children are at special risk for poisoning from lead found in paint and soil. Everyone is at risk from air pollutants such as tobacco smoke, carbon monoxide, smog, suspended particles (dust, ash, and asbestos), and cleaning solvents; noise pollution; pesticides; chemical additives; and poor food preparation. Workers also face safety and health risks caused by ergonomically poor work stations and stress. It is important that risk assessments continue to be in effect to identify and understand environmental problems in public health. The March of Dimes (2011) has published a helpful resource that summarizes the various risks posed in the environment to pregnant women and their fetuses.

Sexual Practices

Potential risks related to sexual activity include undesired pregnancy and STIs. The risks are particularly high for adolescents and young adults who engage in sexual intercourse at earlier and earlier ages. Adolescents report many reasons for wanting to be sexually active: peer pressure, desire to love and be loved, experimentation, to enhance self-esteem, and to have fun. However, many teens do not have the decision-making or values-clarification skills needed to take this important step. They may also lack knowledge about contraception and STIs. Many do not believe that becoming pregnant or getting an STI will happen to them.

Although some STIs can be cured with antibiotics, many cause significant problems. Possible sequelae include infertility, ectopic pregnancy, neonatal morbidity and mortality, genital cancers, acquired immunodeficiency syndrome (AIDS), and even death. The incidence of STIs is increasing rapidly and reaching epidemic proportion. Choice of contraception has an

effect on the risk for contracting an STI. No method of contraception offers complete protection. (See Chapter 7 for a discussion of STIs and Chapter 8 for a discussion of contraception.)

Prevention of STIs is predicated on the reduction of high risk behaviors by educating toward a behavioral change. Behaviors of concern include multiple and casual sexual partners and unsafe sexual practices. The abuse of alcohol and drugs is a high risk behavior, resulting in impaired judgment and thoughtless acts. Behavioral changes must come from within; therefore, the nurse must provide sufficient information for the individual or group to “buy into” the need for change. Education is a powerful tool in health promotion and prevention of STIs and pregnancy. However, it works best when delivered in a way that considers the language, culture, and lifestyle of the intended listener.

! NURSING ALERT

A comprehensive sexual assessment should be integrated into all health histories.

Medical Conditions

Most women of reproductive age are relatively healthy. Heart disease; lung, breast, colon, and other nongynecologic cancers; chronic lung disease; and diabetes are all concerns for adult women because they are among the leading causes of death in women. Certain medical conditions present during pregnancy can have deleterious effects on both the woman and the fetus. Of particular concern are risks from all forms of diabetes, urinary tract disorders, thyroid disease, hypertensive disorders of pregnancy, cardiac disease, and seizure disorders. Effects on the fetus vary and include intrauterine growth restriction, macrosomia, anemia, prematurity, immaturity, and stillbirth. Effects on the woman also can be severe. These conditions are discussed in later chapters. See Clinical Reasoning Case Study on cardiovascular disease in women.

? CLINICAL REASONING CASE STUDY

Cardiovascular Disease—The Leading Cause of Death in Women

Selena is a 56-year-old Hispanic menopausal client who presents for her annual well-woman examination. She is a nonsmoker and nondrinker who lives a sedentary lifestyle. She does not exercise. Her mother died of a heart attack at age 60.

Body mass index (BMI) at today's visit is 33, blood pressure (BP) 150/100, high-density lipoprotein (HDL) 25.

She says she knows that she is overweight and should probably exercise and lose weight. How would you respond to her statement?

- Evidence—Is there evidence that supports how the nurse should respond?
- Assumptions—What assumptions can be made about the following issues?
 - Effects of primary and secondary cardiovascular risk factors
 - Elevated blood pressure
 - Low HDL
 - Role of her culture
- What implications and priorities for nursing care can be made at this time?
- Does the evidence objectively support your conclusion?

Gynecologic Conditions

Women are at risk throughout their reproductive years for pelvic inflammatory disease, endometriosis, STIs and other vaginal infections (see Chapter 7), uterine fibroids, uterine deformities such as bicornuate uterus, ovarian cysts, interstitial cystitis, and urinary incontinence related to pelvic relaxation. These gynecologic conditions may contribute negatively to pregnancy by causing infertility, miscarriage, preterm labor, and fetal and neonatal problems. Gynecologic cancers also affect women's health, although the risk for most cancers is low in pregnancy. Risk factors depend on the type of cancer. The impact of developing a gynecologic problem or cancer on women and their families is shaped by a number of factors, including the specific type of problem or cancer, the implications of the diagnosis for the woman and her family, and the timing of the occurrence in the woman's and the family's lives. These conditions are discussed in Chapter 11.

Female Genital Mutilation

Female genital mutilation is practiced in more than 45 countries, the majority of which are in Africa. As emigrants from these countries arrive in North America, nurses in the United States and Canada will see clients who have had such procedures performed (see the Culture box).

CULTURAL CONSIDERATIONS

Female Genital Mutilation

Defined by the World Health Organization (WHO, 2013), female genital mutilation (FGM) is "all procedures that involve partial or total removal of the external female genitalia, or other injury to the female genital organs for non-medical reasons" (2013). It is a recognized violation of girls and women and is something that is done intentionally to alter or cause injury to female genital organs. There are no medical reasons for this procedure and it can have many untoward consequences, including severe pain, shock, hemorrhage (bleeding), tetanus or sepsis (bacterial infection), urine retention, open sores in the genital region, and injury to nearby genital tissue. Long-term consequences include bladder and urinary tract infections, cysts, infertility, and increased risk for complications of childbirth and newborn death.

It is an attempt to control women through controlling their sexuality. FGM is supposed to remove sexual desire so that the girl will not become sexually active until married.

FGM is illegal in the United States and punishable by fines, prison, and deportation. An obstetrician may incise the closed labia to allow for a vaginal birth, or remove cysts, but may not sew the labia back to its previous state of reinfibulation. If performed on a minor, FGM is considered child abuse in the United States. "The practice also violates the rights to health, security and physical integrity of the person, the right to be free from torture and cruel, inhuman or degrading treatment, and the right to life when the procedure results in death" (WHO).

Nurses are providing care to a growing number of women who have emigrated from the Middle East, Asia, and Africa, where female circumcision is more common. Nurses must be sensitive to the unique needs of these clients, especially if these women have concerns about maintaining or restoring the intactness of the circumcision after childbirth.

Data from World Health Organization. (2013). *Female genital mutilation*. World Health Organization, Fact Sheet # 241. Available at www.who.int/mediacentre/factsheets/fs241/en.

Violence Against Women

Intimate partner violence (IPV) is the most common form of violence experienced by women worldwide, with a reported incidence of 1 of every 6 women having been a victim of domestic violence. In the United States, IPV is a significant social problem and a major health care problem that affects millions of women and men each year and costs millions of dollars in annual medical costs. Statistics from the U.S. Department of Justice, Office of Violence Against Women (2012) reported that 1 in 4 women in the United States has experienced severe physical violence by a current or former intimate partner. In addition, 5.2 million women were victimized by stalkers. It is estimated that 1.3 million women are raped in the United States annually.

Women of all races and of all ethnic, educational, religious, and socioeconomic backgrounds are affected. Pregnancy is often a time when violence begins or escalates. The magnitude of the problem is far greater than the statistics indicate because violent crimes against women are the most underreported data as a result of fear, lack of understanding, and stigma surrounding violent situations. Maternity and women's health nurses, by the very nature of their practice, are in a unique position to conduct case finding, provide sensitive care to women experiencing abusive situations, engage in prevention activities, and influence health care and public policy toward decreasing the violence. For further discussion of violence against women, see Chapter 5.

HEALTH ASSESSMENT

Trends in women's health have expanded beyond a reproductive focus to include a holistic approach to health care across the life span and place women's health within the scope of primary care. Women's health assessment and screening focus on a systems evaluation that begins with a careful history and physical examination. During assessment and evaluation, the responsibility for self-care and management, health promotion, and enhancement of wellness is emphasized. Nursing care includes assessment, planning, education, counseling, and referral as needed, as well as commendations for good self-care that the woman has practiced. This enables women to make informed decisions about their own health care.

In a market-driven system such as managed care, specific guidelines may be provided for health screening by the insurer or the managed care organization. A nurse often takes the history, orders diagnostic tests, interprets test results, makes referrals, coordinates care, and directs attention to problems requiring medical intervention. Advanced practice nurses who have specialized in women's health, such as nurse practitioners, clinical nurse specialists, and nurse-midwives, perform complete physical examinations, including gynecologic examinations.

Interview

Contact with the woman usually begins with an interview, which is an integral part of the history. This interview should be conducted in a private, comfortable, and relaxed setting (Fig. 4-8). The nurse is seated and makes sure that the woman is comfortable. The woman is addressed by her title and name

(e.g., Mrs. Martinez), and the nurse introduces herself or himself using name and title. It is important to phrase questions in a sensitive and nonjudgmental manner. Body language should match oral communication. The nurse is aware of a woman's vulnerability and assures her of strict confidentiality. For many women, fear, anxiety, and modesty make the examination a dreaded and stressful experience. Many women are uninformed, misguided by myths, or afraid they will appear ignorant by asking questions about sexual or reproductive functioning. The woman is assured that no question is irrelevant. Cultural considerations must be addressed in the interview process (see Culture box).

FIG 4-8 Nurse interviews woman as part of history-taking prior to physical examination. (Courtesy Ed Lowdermilk, Chapel Hill, NC.)

CULTURAL CONSIDERATIONS

Communication Variations

- **Conversational style and pacing:** Silence may show respect or acknowledgment that the listener has heard. In cultures in which a direct “no” is considered rude, silence may mean no. Repetition or loudness may mean emphasis or anger.
- **Personal space:** Cultural conceptions of personal space differ. Based on one's culture, for example, someone may be perceived as distant for backing off when approached, or aggressive for standing too close.
- **Eye contact:** Eye contact varies among cultures from intense to fleeting. Consistent with the effort to refrain from invading personal space, avoiding direct eye contact may be a sign of respect.
- **Touch:** The norms about how people should touch each other vary among cultures. In some cultures, physical contact with the same sex (embracing, walking hand in hand) is more appropriate than that with an unrelated person of the opposite sex.
- **Time orientation:** In some cultures involvement with people is more valued than being “on time.” In other cultures, life is scheduled and paced according to clock time, which is valued over personal time.

Data from Galanti, G. (2008). *Caring for patients from different cultures* (4th ed.). Philadelphia: University of Pennsylvania Press; Mattson, S. (2000). Striving for cultural competence: Providing care in the changing face of the U.S. *AWHONN Lifelines*, 4(3), 48-52.

The history begins with an open-ended question such as “What brings you into the office/clinic/hospital today?” and is furthered by other questions such as “Anything else?” and “Tell me about it.” Additional ways to encourage women to share information include:

- **Facilitation:** Using a word or posture that communicates interest such as leaning forward, making eye contact, or saying “Mm-hmmm” or “Go on”
- **Reflection:** Repeating a word or phrase that a woman has used
- **Clarification:** Asking the woman what is meant by a stated word or phrase
- **Empathic responses:** Acknowledging the feelings of a woman by statements such as “That must have been frightening”
- **Confrontation:** Identifying something about the woman's behavior or feelings not expressed verbally or apparently inconsistent with her history
- **Interpretation:** Putting into words what you infer about the woman's feelings or about the meaning of her symptoms, events, or other matters

Direct questions may be necessary to elicit specific details. These should be worded in language that is understandable to the woman and expressed neutrally so that the woman will not be led into a specific response. The nurse asks about one item at a time and proceeds from the general to the specific (Seidel, Ball, Dains, et al., 2011).

Nurses need to develop rapport and trust with their clients as they take a history; because communication within a caring context is core to nursing practice, nurses are well suited to taking a comprehensive client history. Nurses should ask questions incrementally to build a comprehensive understanding. They should also share insights with the woman by eliciting her concerns or thoughts as well as offering clarification (Fawcett & Rhynas, 2012).

Cultural Considerations

Recognizing signs and symptoms of disease and deciding when to seek treatment are influenced by cultural perceptions. It is essential that a nurse have respect for the rich and unique qualities that cultural diversity brings to individuals. In recognizing the value of these differences, the nurse can modify the plan of care to meet the needs of each woman.

To understand the woman's point of view, it is important to ask the right questions. Galanti (2008) suggests the use of the 4 C's of Cultural Competence. These include:

1. **Call**—What do you call your problem?
2. **Cause**—What do you think caused your problem?
3. **Cope**—How do you cope with your condition?
4. **Concerns**—What are your concerns regarding your condition?

Using the 4 C's of Cultural Competence along with cultural proficiency, biomedical values, and evidence-based practice allows the nurse to individualize care with a client-focused approach. Trust that the woman is the expert on her life, culture, and experiences. If the nurse asks with respect and a genuine desire to learn, the woman will tell the nurse how to care for her.

Modifications may be necessary for the physical examination. In some cultures it may be considered inappropriate for the woman to disrobe completely for the physical examination. In many cultures a female examiner is preferred. Communication

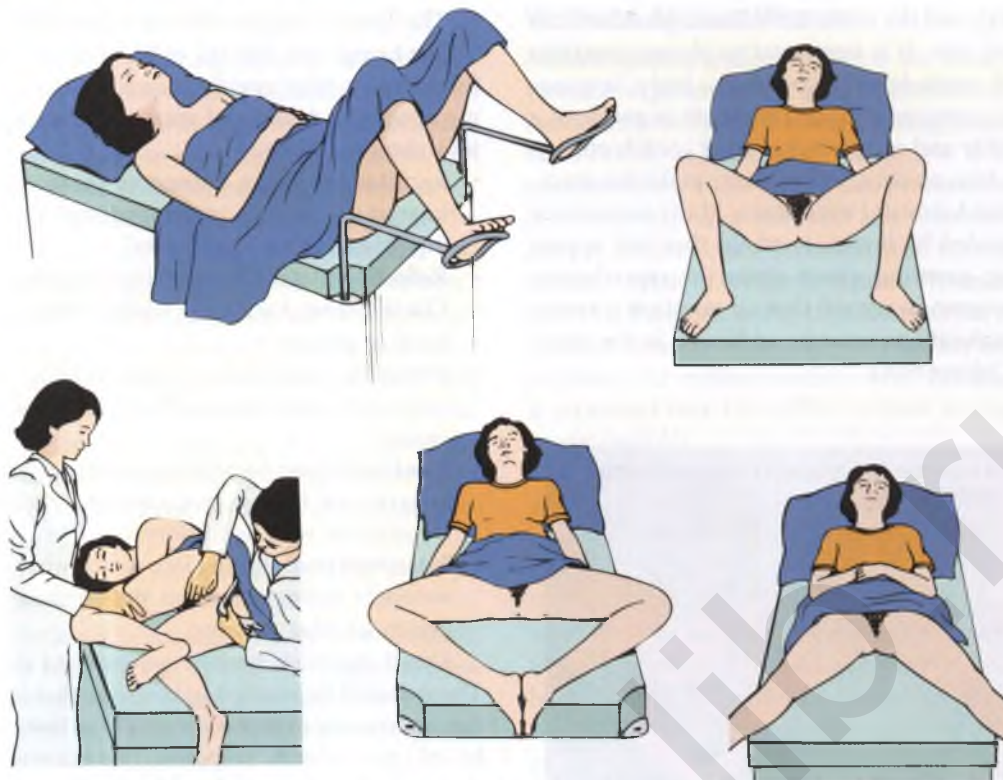

FIG 4-9 Lithotomy and variable positions for women who have a disability.

may be hindered by different beliefs even when the nurse and woman speak the same language (see Cultural Considerations: Strategies for Care Delivery and Providing Cultural Appropriate Care in Chapter 2, Box 2-3).

Women with Special Needs

Women with Disabilities

Women with emotional or physical disorders have special needs. Women who have vision, hearing, emotional, or physical disabilities should be respected and involved in the assessment and physical examination to the full extent of their abilities. The nurse should communicate openly and directly with sensitivity. It is often helpful to learn about the disability directly from the woman while maintaining eye contact (if eye contact is culturally appropriate). Family and significant others should be relied on only when absolutely necessary. The assessment and physical examination can be adapted to each woman's individual needs.

Communication with a woman who is hearing impaired can be accomplished without difficulty. Most of these women read lips, write, or both; thus an interviewer who speaks and enunciates each word slowly and in full view may be easily understood. If a woman is not comfortable with lip reading, she may use an interpreter. In this case it is important to continue to address the woman directly, avoiding the temptation to speak directly with the interpreter.

The visually impaired woman needs to be oriented to the examination room and may have her guide dog with her. As with all women, the visually impaired woman needs a full explanation of what the examination entails before proceeding. Before touching her, the nurse explains, "Now I am going to

take your blood pressure. I am going to place the cuff on your right arm." The woman can be asked if she would like to touch each of the items that will be used in the examination.

Many women with physical disabilities cannot comfortably lie in the lithotomy position for the pelvic examination. Several alternative positions may be used, including a lateral (side-lying) position, a V-shaped position, a diamond-shaped position, and an M-shaped position (Piotrowski & Snell, 2007) (Fig. 4-9). The woman can be asked what has worked best for her previously. If she has never had a pelvic examination, or has never had a comfortable pelvic examination, the nurse proceeds by showing her a picture of various positions and asking her which one she prefers. The nurse's support and reassurance can help the woman relax, which will make the examination go more smoothly.

Abused Women

Nurses should screen all women entering the health care system for potential abuse. Nelson, Bougatsos, and Blazina (2012), representing the U.S. Preventive Services Task Force, recommended that screening women for potential abuse can have beneficial consequences with minimal negative outcomes. Help for the woman may depend on the sensitivity with which the nurse screens for abuse, the discovery of abuse, and subsequent intervention. The nurse must be familiar with the laws governing abuse in the state in which she or he practices.

Pocket cards listing emergency numbers (abuse counseling, legal protection, and emergency shelter) may be available from the local police department, a women's shelter, or an emergency department. It is helpful to have these on hand in the setting where screening is done. An abuse-assessment screen (Fig. 4-10) can be used as part of the interview or written history.

ABUSE ASSESSMENT SCREEN

- Are you with a spouse or partner who threatens or physically hurts you?
 - Yes _____ No _____
- Are you with a spouse or partner who emotionally hurts you?
 - Yes _____ No _____
- Within the past year or in this pregnancy (if the woman is pregnant) has anyone hit, slapped, kicked, or otherwise hurt you?
 - Yes _____ No _____
 - If yes, by whom _____
 - Number of times _____
 - Mark the area of injury on the body map.
- Has anyone forced you to have sexual activities that made you uncomfortable?
 - Yes _____ No _____
 - If yes, by whom _____
 - Number of times _____
- Are you afraid of your partner or anyone you listed above?
 - Yes _____ No _____

FIG 4-10 Abuse assessment screen. Screening for Intimate Partner Violence. (Adapted from American College of Obstetricians and Gynecologists [ACOG], 2012). *Are you being abused? Screening tools for domestic violence.* Available at www.acog.org/About_ACOG/ACOG_Departments/Violence_Against_Women/Are_you_Being_Abused.)

If a male partner is present, he should be asked to leave the room because the woman may not disclose experiences of abuse in his presence, or he may try to answer questions for her to protect himself. The same procedure would apply for partners of lesbians, parents of teens, or adult children of older women.

Fear, guilt, and embarrassment may keep many women from giving information about family violence. Clues in the history and evidence of injuries on physical examination should give a high index of suspicion. The areas most commonly injured in women are the head, the neck, the chest, the abdomen, the breasts, and the upper extremities. Burns and bruises in patterns resembling hands, belts, cords, or other weapons may be seen as well as multiple traumatic injuries. Attention should be given to women who repeatedly seek treatment for somatic complaints such as headaches, insomnia, choking sensation, hyperventilation, gastrointestinal symptoms, and pain in the chest, back, and pelvis. During pregnancy the nurse should assess for injuries to the breasts, the abdomen, and the genitals. (See Chapter 5 for further discussion of violence.)

Adolescents (Ages 13 to 19 Years)

As a young woman matures, she should be asked the same questions that are included in any history. Particular attention should be paid to hints about risky behaviors, eating disorders, and depression. Do not assume that a teenager is not sexually active. After rapport has been established, it is best to talk to a teen with the parent (partner or friend) out of the room. Questions should be asked with sensitivity and in a gentle and non-judgmental manner (Seidel et al., 2011).

A teen's first speculum examination is the most important because she will develop perceptions that will remain with her

for future examinations. What the examination entails should be discussed with the teen while she is dressed. Models or illustrations can be used to show exactly what will happen. All of the necessary equipment should be assembled so that there are no interruptions. Pediatric speculums that are 1 to 1.5 cm wide can be inserted with minimal discomfort. If the teen is sexually active, a small adult speculum may be used.

Injury prevention should be a part of the counseling at routine health examinations, with special attention to seat belts, helmets, firearms, recreational hazards, and sports involvement. The use of drugs and alcohol and the nonuse of seat belts contribute to motor vehicle injuries, accounting for the greatest proportion of accidental deaths in women. Contraceptive use and STI prevention information may be needed for teens who are sexually active.

To provide developmentally appropriate care, it is important to review the major tasks for women in this stage of life. Major tasks for teens include values assessment; education and work goal setting; formation of peer relationships that focus on love, commitment, and becoming comfortable with sexuality; and separation from parents. Individuality may be reflected in areas such as sexuality, politics, and career choices. Conflict exists between making and keeping commitments to keep options open. The teen is egocentric as she progresses rapidly through emotional and physical changes. Her feelings of invulnerability may lead to serious misconceptions, such as that unprotected sexual intercourse will not lead to pregnancy.

Midlife and Older Women (Ages 50 Years and Older)

The assessment of women ages 50 and older presents unique challenges. Women may be experiencing major lifestyle

changes, such as children leaving home, caring for their aging parents, job change, retirement, separation, divorce or death of a partner, and aging-related changes and health problems. The nurse uses reflection and empathy to communicate in an open and caring manner. It may be necessary to schedule a longer appointment time because older women have longer histories or have a need to talk. Some women may fail to report symptoms because they fear their complaints will be attributed to old age, or they feel that they have lived with a chronic condition (e.g., incontinence, dyspareunia, interstitial cystitis, decreased libido, depression) for so long that nothing can be done. Women may choose to ignore a problem if they have symptoms that are life threatening (e.g., chest pain or a breast lump) because they traditionally put the needs of others first. As a result, the nurse should encourage the woman to express her concerns and fears and reassure her that her problems are important and will be addressed. Exercise, hormone therapy, diet, vitamins, calcium with vitamin D supplementation, daily aspirin, breast self-examination, Pap and mammogram recommendations, colonoscopy, immunization updates, and sun protection should be discussed.

Functional assessment is included as part of the history in women older than 70 years and those with disabilities. In the review of systems, the nurse should ask about self-management activities such as walking, getting to the bathroom, bathing, hair combing, dressing, and eating. Questions about driving, using public transportation, using the telephone or the Internet, hanging up clothes, buying groceries, taking medications, and meal preparation should be included.

Sexual assessment continues to be important in women 50 and older. Unless directly asked, women may omit mention of sexual concerns. Questions asked with sensitivity may invite responses regarding changes in sexual desire or response or physical issues that challenge her sexual enjoyment. Open and reflective questions also affirm a woman's right to sexual enjoyment throughout the life span.

Women older than 50 years commonly experience menopause and have physical changes associated with decreased estrogen. A decrease in estrogen causes numerous cytologic and structural changes of the vagina, vulva, and lower urinary tract. Estrogen deficiency leads to a narrowing and shortening of the vagina and thinning of the vaginal walls. This can result in vaginal dryness, itching, burning, and dyspareunia. Estrogen loss also causes reduced smooth muscle relaxation, decreased vaginal blood flow and decreased vaginal secretions. Estrogen plays a role in the formation of bone matrix, and a decrease may lead to osteoporosis. The risk for heart disease increases because of changes in lipid metabolism related to declining estrogen levels. Decreases in estrogen can cause a relaxation of ligaments and connective tissue, which affects the support of the bladder and uterus. Decreases in estrogen affect the hypothalamus, causing hot flashes, which are disturbing to most women (see Chapter 6).

Physical changes can result in increased discomfort during the pelvic examination. It is important to be both gentle and thorough during the examination. A small adult speculum may be used to view the cervix. The uterus in a menopausal woman is small and firm, and the ovaries are nonpalpable. In postmenopausal women the specimen from the vaginal pool may be useful to detect endometrial cells. A woman with palpable

adnexal masses or vaginal bleeding after menopause needs immediate gynecologic referral.

A respectful and reassuring approach toward caring for women ages 50 and older will ensure their continued participation in seeking health care. Because the risk of breast, ovarian, uterine, cervical, colon, and skin cancers increases with age, the nurse has the opportunity to educate women about the importance of preventive screening. It is the nurse's responsibility to ensure a positive health care experience that encourages future visits for prevention and chronic and acute care.

Advance directives can be introduced on any entry into a health care system. It is a good idea to have a formal statement in the medical record regarding a woman's wishes in the event of accident or illness regarding life-maintaining measures or organ donation. Most states have laws formalizing such statements in writing. A woman can designate the durable power of attorney for health care authority to a trusted relative or friend.

Many women find that spirituality is helpful in maintaining wellness as well as coping with illness. Spirituality refers to the essence of our being and humanity, reflected in a connection to a Sacred Source. The concept of Sacred Source is experienced in different ways, with some experiencing it as a person, some as a presence, and some as a nondescribable mystery (Burkhardt & Nagai-Jacobson, 2013). The idea of connection is important, and experiencing this connection in a sacred space is central to spirituality. Spirituality may be experienced within a context of organized religion. Nurses, taking a holistic approach to women's wellness, must be sensitive and nonjudgmental to the spiritual aspect of their clients. In an optimal healing approach to care, nurses can facilitate and encourage the client to express her spirituality in a way that is comfortable for her. Box 4-8 presents a spiritual wellness self-assessment guide.

BOX 4-8 Spiritual Wellness Self-Assessment

1. How do you describe your purpose in life?
2. What activities do you do regularly that bring you joy?
3. What goals do you have for 6 months from now?
4. What goals do you have for 2 years from now?
5. What activities make you feel nourished?
6. What kinds of things do you do for yourself every day?
7. What do you hope for in the future?
8. Are there people you can reach out to?
9. On whom can you count for encouragement and/or support?
10. Are there others to whom you give encouragement and/or support?
11. Who loves you?
12. Whom do you love or care about?
13. In what areas are you growing?
14. How do you go about forgiving yourself?
15. How do you go about forgiving others?
16. To whom do you confide your hopes, dreams, and pain?
17. Do you believe in some kind of higher power?
18. What do you hope for in the future?
19. When do you reach out to people?
20. Do you look forward to getting up in the morning?
21. Would you like to live to be 100?

The more questions you answer in the positive, the higher the level of spiritual wellness.

Adapted from Condon, M. (2004). *Women's health: Body, mind, spirit: An integrated approach to wellness and illness*. Upper Saddle River, NJ: Prentice-Hall.

Healthy Aging

Women in the United States can expect on average to live to be 80 years old and may spend one third of their lives as postmenopausal women. With a healthy lifestyle, many women are living to be 100 years old or older. Proper nutrition, exercise, and mental and social stimulation are critical to keeping the body healthy and the mind active and alert into old age. Menopause is a time in which women can integrate wisdom and become wise women as they look toward the future (McCloskey, 2012).

History

At a woman's first visit, she is often expected to fill out a form with biographic and historical data before meeting with the examiner. This form aids the health care provider in completing the history during the interview. Most forms include information about these categories:

- Biographic data
- Reason for seeking care
- Present health or history of present illness
- Past health
- Family history
- Screening for abuse
- Review of systems
- Functional assessment (activities of daily living)

Box 4-9 describes a complete health history.

Physical Examination

In preparation for the physical examination, the woman is instructed to undress and is given a gown to wear during the examination. She is usually given the opportunity to undress privately. Objective data are recorded by system or location. A general statement of overall health status is a good way to start. Findings are described in detail.

- General appearance: age, race, sex, state of health, posture, height, weight, development, dress, hygiene, affect, alertness, orientation, cooperativeness, and communication skills
- Vital signs: temperature, pulse, respiration, blood pressure
- Skin: color; integrity; texture; hydration; temperature; edema; excessive perspiration; unusual odor; presence and description of lesions; hair texture and distribution; nail configuration, color, texture, and condition; presence of nail clubbing
- Head: size, shape, trauma, masses, scars, rashes, or scaling; facial symmetry; presence of edema or puffiness
- Eyes: pupil size, shape, reactivity, conjunctival injection, scleral icterus, fundal papilledema, hemorrhage, lids, extraocular movements, visual fields and acuity
- Ears: shape and symmetry, tenderness, discharge, external canal, and tympanic membranes; hearing—Weber should be midline (loudness of sound equal in both ears) and Rinne negative (no conductive or sensorineural hearing loss); should be able to hear whisper at 3 feet
- Nose: symmetry, tenderness, discharge, mucosa, turbinate inflammation, frontal or maxillary sinus tenderness; discrimination of odors
- Mouth and throat: hygiene; condition of teeth; dentures; appearance of lips, tongue, buccal and oral mucosa; erythema; edema; exudate; tonsillar enlargement; palate; uvula; gag reflex; ulcers

- Neck: mobility, masses, range of motion, tracheal deviation, thyroid size, carotid bruits
 - Lymphatic: cervical, intraclavicular, axillary, trochlear, or inguinal adenopathy; size, shape, tenderness, and consistency
 - Breasts: skin changes, dimpling, symmetry, scars, tenderness, discharge, masses; characteristics of nipples and areolae
 - Heart: rate, rhythm, murmurs, rubs, gallops, clicks, heaves, or precordial movements
 - Peripheral vascular: jugular vein distention, bruits, edema, swelling, vein distention, Homans sign, or tenderness of extremities
 - Lungs: chest symmetry with respirations, wheezes, crackles, rhonchi, vocal fremitus, whispered pectoriloquy, percussion, and diaphragmatic excursion; breath sounds equal and clear bilaterally
 - Abdomen: shape, scars, bowel sounds, consistency, tenderness, rebound, masses, guarding, organomegaly, liver span, percussion (tympany, shifting, dullness), or costovertebral angle tenderness
 - Extremities: edema, ulceration, tenderness, varicosities, erythema, tremor, or deformity
 - Genitourinary: external genitalia, perineum, vaginal mucosa, cervix; inflammation, tenderness, discharge, bleeding, ulcers, nodules, or masses; internal vaginal support, bimanual and rectovaginal palpation of cervix, uterus, and adnexa
 - Rectal: sphincter tone, masses, hemorrhoids, rectal wall contour, tenderness, and stool for occult blood
 - Musculoskeletal: posture, symmetry of muscle mass, muscle atrophy, weakness, appearance of joints, tenderness or crepitus, joint range of motion, instability, redness, swelling, or spinal deviation
 - Neurologic: mental status, orientation, memory, mood, speech clarity and comprehension, cranial nerves II to XII, sensation, strength, deep tendon and superficial reflexes, gait, balance, and coordination with rapid alternating motions
- Table 4-2 highlights physical assessment findings that differ in women across the life span.

Pelvic Examination

Many women fear the gynecologic portion of the physical examination. The nurse can be instrumental in allaying these fears by providing information and assisting the woman to express her feelings to the examiner (Box 4-10).

The woman is assisted into the lithotomy position (see Fig. 4-9) for the pelvic examination. When she is in the lithotomy position, her hips and knees are flexed, with buttocks at the edge of the table, and her feet are supported by heel or knee stirrups.

Some women prefer to keep their shoes or socks on, especially if the stirrups are not padded. Many women express feelings of vulnerability and strangeness when in the lithotomy position. During the procedure the nurse assists the woman with relaxation techniques.

Many women find it distressing to attempt to converse in the lithotomy position. Most women appreciate an explanation of the procedure as it unfolds, as well as coaching for the types of sensations they may expect. Generally, however, women prefer not to have to respond to questions until they are again upright and at eye level with the examiner. Being asked questions during

Identifying data: Name, age, race, sex, marital status, occupation, religion, and ethnicity

Reason for seeking care: A response to the question, "What problem or symptom brought you here today?" If the woman lists more than one reason, focus on the one she thinks is most important.

Present health: Current health status is described with attention to the following:

- *Use of safety measures:* seat belts, bicycle helmets, designated driver
- *Exercise and leisure activities:* regularity
- *Sleep patterns:* length and quality
- *Sexuality:* Is she sexually active? With men, women, or both? Risk-reducing sex practices?
- *Diet, including beverages:* 24-hour dietary recall; caffeine: coffee, tea, cola, or chocolate intake
- *Nicotine, alcohol, illicit or recreational drug use:* type, amount, frequency, duration, and reactions
- *Environmental and chemical hazards:* home, school, work, and leisure setting; exposure to extreme heat or cold, noise, industrial toxins such as asbestos or lead, pesticides, diethylstilbestrol (DES), radiation, cat feces, or cigarette smoke

History of present illness: A chronologic narrative that includes the onset of the problem, the setting in which it developed, its manifestations, and any treatments received are noted. The woman's state of health before the onset of the present problem is determined. If the problem is long standing, the reason for seeking attention at this time is elicited. The principal symptoms should be described with respect to the following:

- Location
- Quality or character
- Quantity or severity
- Timing (onset, duration, frequency)
- Setting
- Factors that aggravate or relieve
- Associated factors
- Woman's perception of the meaning of the symptom

Past health:

- *Infectious diseases:* measles, mumps, rubella, whooping cough, chickenpox, rheumatic fever, scarlet fever, diphtheria, polio, tuberculosis (TB), hepatitis
- *Chronic disease and system disorders:* arthritis, cancer, diabetes, heart, lung, kidney, seizures, thyroid, stroke, ulcers, sickle cell anemia
- *Adult injuries, accidents*
- *Hospitalizations, operations, blood transfusions*
- *Obstetric history*
- *Allergies:* medications, previous transfusion reactions, environmental allergies
- *Immunizations:* diphtheria, pertussis, tetanus, polio, hepatitis B, varicella, influenza, pneumococcal vaccine, last TB skin test, measles, mumps, rubella (MMR)
- *Last date of screening tests:* Pap test, mammogram, stool for occult blood, sigmoidoscopy or colonoscopy, hematocrit, hemoglobin, rubella titer, urinalysis, cholesterol test; electrocardiogram; last vision, dental, hearing examination
- *Current medications:* name, dose, frequency, duration, reason for taking, and compliance with prescription medications; home remedies, over-the-counter drugs, vitamin and mineral or herbal supplements used over a 24-hour period

Family history: Information about the ages and health of family members may be presented in narrative form or as a family tree or genogram: age, health or death of parents, siblings, spouse, children. Check for history of diabetes; heart disease; hypertension; stroke; respiratory, renal, or thyroid problems; cancer; bleeding disorders; hepatitis; allergies; asthma; arthritis; TB; epilepsy; mental illness; human immunodeficiency virus infection; or other disorders.

Screen for abuse: Has she ever been hit, kicked, slapped, or forced to have sex against her wishes? Has she been verbally or emotionally abused? Does she have a history of childhood sexual abuse? If yes, has she received counseling or does she need referral?

Review of systems: It is probable that all questions in each system will not be included every time a history is taken. Some questions regarding each system should be included in every history. The essential areas to be explored are listed in the following head-to-toe sequence. If a woman gives a positive response to a question about an essential area, more detailed questions should be asked.

- *General:* weight change, fatigue, weakness, fever, chills, or night sweats
- *Skin:* skin, hair, and nail change; itching, bruising, bleeding, rashes, sores, lumps, or moles
- *Lymph nodes:* enlargement, inflammation, pain, suppuration (pus), or drainage
- *Head:* trauma, vertigo (dizziness), convulsive disorder, syncope (fainting); headache: location, frequency, pain type, nausea and vomiting, or visual symptoms present
- *Eyes:* glasses, contact lenses, blurriness, tearing, itching, photophobia, diplopia, inflammation, trauma, cataracts, glaucoma, or acute visual loss
- *Ears:* hearing loss, tinnitus (ringing), vertigo, discharge, pain, fullness, recurrent infections, or mastoiditis
- *Nose and sinuses:* trauma, rhinitis, nasal discharge, epistaxis, obstruction, sneezing, itching, allergy, or smelling impairment
- *Mouth, throat, and neck:* hoarseness, voice changes, soreness, ulcers, bleeding gums, goiter, swelling, or enlarged nodes
- *Breasts:* masses, pain, lumps, dimpling, nipple discharge, fibrocystic changes, or implants; breast self-examination practice
- *Respiratory:* shortness of breath, wheezing, cough, sputum, hemoptysis, pneumonia, pleurisy, asthma, bronchitis, emphysema, or TB; date of last chest x-ray
- *Cardiovascular:* hypertension, rheumatic fever, murmurs, angina, palpitations, dyspnea, tachycardia, orthopnea, edema, chest pain, cough, cyanosis, cold extremities, ascites, intermittent claudication (leg pain caused by poor circulation to the leg muscles), phlebitis, or skin color changes
- *Gastrointestinal:* appetite, nausea, vomiting, indigestion, dysphagia, abdominal pain, ulcers, hematochezia (bleeding with stools), melena (black, tarry stools), bowel-habit changes, diarrhea, constipation, bowel movement frequency, food intolerance, hemorrhoids, jaundice, or hepatitis; sigmoidoscopy, colonoscopy, barium enema, ultrasound
- *Genitourinary:* frequency, hesitancy, urgency, polyuria, dysuria, hematuria, nocturia, incontinence, stones, infection, or urethral discharge; menstrual history (e.g., age at menarche, length and flow of menses, last menstrual period [LMP], dysmenorrhea, intermenstrual bleeding, age at menopause or signs of menopause), dyspareunia, discharge, sores, itching
- *Sexual health and sexual activity:* with men, women, or both; contraceptive use; sexually transmitted infections
- *Peripheral vascular:* coldness, numbness and tingling, leg edema, claudication, varicose veins, thromboses, or emboli
- *Endocrine:* heat and cold intolerance, dry skin, excessive sweating, polyuria, polydipsia, polyphagia, thyroid problems, diabetes, or secondary sex characteristic changes
- *Hematologic:* anemia, easy bruising, bleeding, petechiae, purpura, or transfusions
- *Musculoskeletal:* muscle weakness, pain, joint stiffness, scoliosis, lordosis, kyphosis, range-of-motion instability, redness, swelling, arthritis, or gout
- *Neurologic:* loss of sensation, numbness, tingling, tremors, weakness, vertigo, paralysis, fainting, twitching, blackouts, seizures, convulsions, loss of consciousness or memory
- *Mental status:* moodiness, depression, anxiety, obsessions, delusions, illusions, or hallucinations
- *Functional assessment:* ability to care for self

TABLE 4-2 Female Reproductive Physical Assessment Across the Life Cycle

	ADOLESCENT	ADULT	POSTMENOPAUSAL
Breasts	Tender when developing; buds appear; small, firm; one side may grow faster; areola diameter increases; nipples more erect	Grow to full shape in early adulthood; nipples and areola become pinker and darker	Become stringy, irregular, pendulous, and nodular; borders less well delineated; may shrink, become flatter, elongated, and less elastic; ligaments weaken; nipples are positioned lower
Vagina	Vagina lengthens; epithelial layers thicken; secretions become acidic	Growth complete by age 20	Introitus constricts; vagina narrows, shortens, loses rugation; mucosa is pale, thin, and dry; walls may lose structural integrity
Uterus	Musculature and vasculature increase; lining thickens	Growth complete by age 20	Size decreases; endometrial lining thins
Ovaries	Increase in size and weight; menarche occurs between 8 and 16 years of age; ovulation occurs monthly	Growth complete by age 20	Size decreases to 1 to 2 cm; follicles disappear; surface convolutes; ovarian function ceases between 40 and 55 years of age
Labia majora	Become more prominent; hair develops	Growth complete by age 20	Labia become smaller and flatter; pubic hair sparse and gray
Labia minora	Become more vascular	Growth complete by age 20	Become shinier and drier
Uterine tubes	Increase in size	Growth complete by age 20	Decrease in size

BOX 4-10 Procedure: Assisting with Pelvic Examination

1. Wash hands. Assemble equipment (see below).

Equipment used for pelvic examination. (Courtesy Michael S. Clement, MD, Mesa, AZ.)

2. Ask the woman to empty her bladder before the examination (obtain clean-catch urine specimen as needed).
3. Assist with relaxation techniques. Have the woman place her hands on her chest at about the level of the diaphragm and breathe deeply and slowly.
4. Encourage the woman to become involved with the examination if she shows interest. For example, a mirror can be placed so that she can see the area being examined.
5. Assess for and treat signs of problems such as supine hypotension.
6. Warm the speculum in warm water if a prewarmed one is not available.
7. Instruct the woman to bear down when the speculum is being inserted.
8. Apply gloves and assist the examiner with collection of specimens for cytologic examination, such as a Pap test. After handling specimens, remove gloves and wash hands.
9. Put gloves on. Lubricate the examiner's fingers with water or water-soluble lubricant before bimanual examination.
10. Assist the woman at completion of the examination to a sitting position and then a standing position.
11. Provide tissues to wipe lubricant from perineum.
12. Provide privacy for the woman while she is dressing.

FIG 4-11 External examination: separation of the labia. (From Wilson, S., & Giddens, J. [2013]. *Health assessment for nursing practice* [5th ed.]. St. Louis: Mosby.)

the procedure, especially if they cannot see their questioner's eyes, may make women tense.

External Inspection. The examiner wears gloves and sits at the foot of the table for the inspection of the external genitalia and the speculum examination. In good lighting, the external genitalia: clitoris, labia, and perineum, are examined and inspected for sexual maturity, and lesions indicative of STIs are noted. After childbirth or other trauma, healed scars may be present.

External Palpation. Before touching the woman, the examiner explains what is going to be done and what the woman should expect to feel (e.g., pressure). The examiner may touch the woman in a less sensitive area such as the inner thigh to alert her that the genitalia examination is beginning. This gesture may put the woman more at ease. The labia are spread apart to expose the structures in the vestibule: urinary meatus, Skene glands, vaginal orifice, and Bartholin glands (Fig. 4-11). To assess Skene glands, the examiner inserts one finger into the vagina and "milks" the area of the urethra. Any exudate from the urethra or the Skene glands is cultured. Masses and erythema of either structure are assessed further. Ordinarily the openings to

the Skene glands are not visible; prominent openings may be seen if the glands are infected (e.g., with gonorrhea). During the examination the examiner keeps in mind the data from the review of systems such as history of burning on urination.

The vaginal orifice is examined. Hymenal tags are normal findings. With one finger still in the vagina, the examiner repositions the index finger near the posterior part of the orifice. With the thumb outside the posterior part of the labia majora, the examiner compresses the area of Bartholin glands located at the 8 o'clock and 4 o'clock positions and looks for swelling, discharge, and pain.

The support of the anterior and posterior vaginal wall is assessed. The examiner spreads the labia with the index and middle finger and asks the woman to strain down. Any bulge from the anterior wall (urethrocele or cystocele) or posterior wall (rectocele) is noted and compared with the history, such as difficulty starting the stream of urine or constipation.

The perineum (area between the vagina and anus) is assessed for scars from old lacerations or episiotomies, thinning, fistulas, masses, lesions, and inflammation. The anus is assessed for hemorrhoids, hemorrhoidal tags, and integrity of the anal sphincter. The anal area is also assessed for lesions, masses, abscesses, and tumors. If there is a history of STI, the examiner may want to obtain a culture specimen from the anal canal at this time. Throughout the genital examination the examiner notes any odor, which may indicate infection or poor hygiene.

Vulvar Self-Examination. The pelvic examination provides a good opportunity for the practitioner to emphasize the need for regular **vulvar self-examination (VSE)** and to teach this procedure. Because there has been a dramatic increase in cancerous and precancerous conditions of the vulva, VSE should be an integral part of preventive health care for all women who are sexually active or 18 years of age or older. VSE should be performed monthly between menses or more often if there are symptoms or a history of serious vulvar disease. Most lesions, including malignancy, condyloma acuminatum (wartlike growth), and Bartholin cysts, can be seen or palpated and are easily treated if diagnosed early.

The VSE can be performed by the practitioner and woman together by using a mirror. A simple diagram of the anatomy of the vulva can be given to the woman, with instructions to perform the examination herself that evening to reinforce what she has learned. She does the examination in a sitting position with adequate lighting, holding a mirror in one hand and using the other hand to expose the tissues surrounding the vaginal introitus. She then systematically examines the mons pubis, clitoris, urethra, labia majora, perineum, and perianal area and palpates the vulva, noting any changes in appearance or abnormalities such as ulcers, lumps, warts, and changes in pigmentation.

Internal Examination. A vaginal speculum consists of two blades and a handle. Specula come in a variety of types and styles. A vaginal speculum is used to view the vaginal vault and cervix. The speculum is gently placed into the vagina and inserted to the back of the vaginal vault. The blades are opened to reveal the cervix and are locked into the open position. The cervix is inspected for position and appearance of the os: color, lesions, bleeding, and discharge (Fig. 4-12, A-D). Cervical

findings that are not within normal limits include ulcerations, masses, inflammation, and excessive protrusion into the vaginal vault. Anomalies such as a cockscomb (a protrusion over the cervix that looks like a rooster's comb), a hooded or collared cervix (seen in diethylstilbestrol [DES] daughters), or polyps are noted.

Collection of Specimens. The collection of specimens for cytologic examination is an important part of the gynecologic examination. Infection can be diagnosed by examination of specimens collected during the pelvic examination. These infections include candidiasis, trichomoniasis, bacterial vaginosis, group B streptococcus, gonorrhea, chlamydia, and herpes simplex virus. Once the diagnoses have been made, treatment can be instituted.

Papanicolaou Test. Carcinogenic conditions, whether potential or actual, can be determined by examination of cells from the cervix collected during the pelvic examination (i.e., a Pap test) (Box 4-11).

Vaginal Wall Examination. After the specimens are obtained, the vagina is viewed when the speculum is rotated. The speculum blades are unlocked and partially closed. As the speculum is withdrawn, it is rotated; the vaginal walls are inspected for color, lesions, rugae, fistulas, and bulging.

Bimanual Palpation. The examiner stands for this part of the examination. A small amount of lubricant is placed on the first and second fingers of the gloved hand for the internal examination. To avoid tissue trauma and contamination, the thumb is abducted, and the ring and little fingers are flexed into the palm (Fig. 4-13).

The vagina is palpated for distensibility, lesions, and tenderness. The cervix is examined for position, shape, consistency, motility, and lesions. The fornix around the cervix is palpated.

The other hand is placed on the abdomen halfway between the umbilicus and symphysis pubis and exerts pressure downward toward the pelvic hand. Upward pressure from the pelvic hand traps reproductive structures for assessment by palpation. The uterus is assessed for position, size, shape, consistency, regularity, motility, masses, and tenderness.

With the abdominal hand moving to the right lower quadrant and the fingers of the pelvic hand in the right lateral fornix, the adnexa is assessed for position, size, tenderness, and masses. The examination is repeated on the woman's left side.

Just before the intravaginal fingers are withdrawn, the woman is asked to tighten her vagina around the fingers as much as she can. If the muscle response is weak, the woman is assessed for her knowledge about Kegel exercises.

Rectovaginal Palpation. To prevent contamination of the rectum from organisms in the vagina (e.g., *Neisseria gonorrhoeae*), it is necessary to change gloves, add fresh lubricant, and then reinsert the index finger into the vagina and the middle finger into the rectum (Fig. 4-14). Insertion is facilitated if the woman strains down. The maneuvers of the abdominovaginal examination are repeated. The rectovaginal examination permits assessment of the rectovaginal septum, the posterior surface of the uterus, and the region behind the cervix and the adnexa. The vaginal finger is removed and folded into the palm, leaving the middle finger free to rotate 360 degrees. The rectum is palpated for rectal tenderness and masses.

FIG 4-12 Insertion of speculum for vaginal examination. **A**, Opening of the introitus. **B**, Oblique insertion of the speculum. **C**, Final insertion of the speculum. **D**, Opening of the speculum blades. (From Wilson, S., & Giddens, J. [2013]. *Health assessment for nursing practice* [5th ed.]. St. Louis: Mosby.)

After the rectal examination the woman is assisted into a sitting position, given tissues or wipes to cleanse herself, and afforded privacy to dress. The examiner returns after the woman is dressed to discuss findings and the plan of care.

Pelvic Examination During Pregnancy

The pelvic examination during pregnancy is done in the same way as it is during a routine examination on a nonpregnant woman. Pelvic measurements are completed, and uterine size is estimated. A Pap test may be done initially and cytologic specimens collected to test for gonorrhea, chlamydia, human papillomavirus, herpes simplex virus, and group B streptococcus. As the pregnancy progresses, the nurse inspects the woman's abdomen, palpates fetal size and position, auscultates fetal heart tones, and measures fundal height at each visit.

While the pregnant woman is in lithotomy position, the nurse must watch for supine hypotension (decrease in blood pressure) caused by the weight of the uterus pressing on the vena cava and aorta. Symptoms of supine hypotension include pallor, dizziness, faintness, breathlessness, tachycardia, nausea, clammy skin, and sweating. The woman should be positioned on her side until symptoms resolve and vital signs stabilize. The vaginal examination can be done with the woman in lateral position.

Pelvic Examination After Hysterectomy

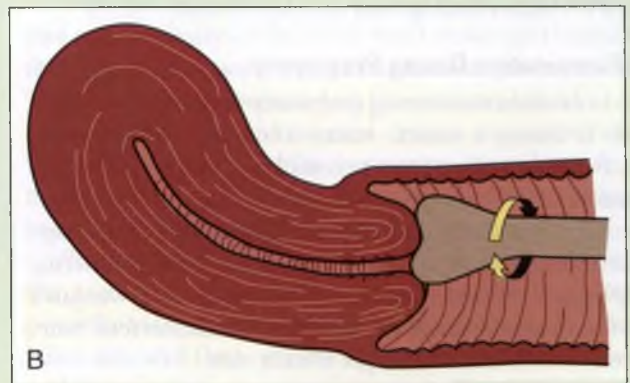

The pelvic examination after hysterectomy is done much as it is done on a woman with a uterus. Vaginal screening using the Pap test is not recommended in women who have had a total hysterectomy with removal of the cervix for benign disease. Because of the epidemic of human papillomavirus, which causes vaginal intraepithelial neoplasia, sampling of the vaginal walls after hysterectomy may still be practiced, with schedules varying from every year to every 2 to 3 years.

Laboratory and Diagnostic Procedures

The following laboratory and diagnostic procedures are ordered at the discretion of the clinician, considering the client and family history: hemoglobin, fasting blood glucose, total blood cholesterol, lipid profile, urinalysis, syphilis serology (Venereal Disease Research Laboratories [VDRL] or rapid plasma reagent [RPR]) and other screening tests for STIs, mammogram, tuberculosis skin testing, hearing, visual acuity, electrocardiogram, chest x-ray, pulmonary function, fecal occult blood, flexible sigmoidoscopy, and bone mineral density (dual energy x-ray absorptiometry [DEXA] scan). Results of these tests may be reported in person, by phone call, or by letter. Tests for HIV, hepatitis B, and drug screening may be offered with informed consent in high risk populations. These test results are usually

BOX 4-11 Procedure: Papanicolaou Test

- In preparation, make sure the woman has not douched, used vaginal medications, or had sexual intercourse for 24 to 48 hours before the procedure. Reschedule the test if the woman is menstruating. Midcycle is the best time for the test.
- Explain to the woman the purpose of the test and what sensations she will feel as the specimen is obtained (e.g., pressure but not pain).
- The woman is assisted into a lithotomy position. A speculum is inserted into the vagina.
- The cytologic specimen is obtained before any digital examination of the vagina is made or endocervical bacteriologic specimens are taken. A cotton swab may be used to remove excess cervical discharge before the specimen is collected.
- The specimen is obtained by using an endocervical sampling device (Cytobrush, Cervex-brush, spatula, or broom) (see Fig. A and B). If the two-sample method of obtaining cells is used, the Cytobrush is inserted into the canal and rotated 90 to 180 degrees, followed by a gentle smear of the entire transformation zone by using a spatula. Broom devices are inserted and rotated 360 degrees five times. They obtain endocervical and ectocervical samples at the same time. If the woman has had a hysterectomy, the vaginal cuff is sampled. Areas that appear abnormal on visualization will require colposcopy and biopsy. If using a one-slide technique, the spatula sample is smeared first. This is followed by applying the Cytobrush sample (rolling the brush in the opposite direction from which it was obtained), which is less subject to drying artifact; then the slide is sprayed with preservative within 5 seconds.
- The ThinPrep or SurePath Pap test is a liquid-based method of preserving cells that reduces blood, mucus, and inflammation. The Pap specimen is obtained in the manner described above except that the cervix is not swabbed before collection of the sample. The collection device (brush, spatula, or broom) is rinsed in a vial of preserving solution that is provided by the laboratory. The sealed vial with solution is sent off to the appropriate laboratory. A special processing device filters the contents, and a thin layer of cervical cells is deposited on a slide, which is then examined microscopically. The AutoPap and Papnet tests are similar to the ThinPrep test. If cytology is abnormal, liquid-based methods allow follow-up testing for human papillomavirus (HPV) DNA with the same sample.
- Label the slides or vial with the woman's name and site. Include on the form to accompany the specimens the woman's name, age, parity, and chief complaint or reason for taking the cytologic specimens.
- Send specimens to the pathology laboratory promptly for staining, evaluation, and a written report, with special reference to abnormal elements, including cancer cells.
- Advise the woman that repeated tests may be necessary if the specimen is not adequate.
- Instruct the woman concerning routine checkups for cervical and vaginal cancer. Women vaccinated against HPV should follow the same screening guidelines as unvaccinated women. Current recommendations of the U.S. Preventive Services Task Force (USPSTF, 2012) and the American Cancer Society (ACS, 2013d) for Pap tests are that women ages 21 through 65 be screened every 3 years, or for women ages 30 through 65 every 5 years (if they had a Pap test plus HPV test that were both negative). These guidelines recommend no screening in women younger than 21, although if a girl becomes sexually active, the guidelines recommend that she get a Pap test within 3 years of initiating sexual activity or at age 21—whichever comes first. Women with high risk factors such as exposure to diethylstilbestrol (DES) in utero, those treated for cervical intraepithelial neoplasia (CIN) 2, CIN 3, cervical cancer, or human immunodeficiency virus (HIV) may need more frequent screening.
- Young women who have been treated with excisional procedures for dysplasia have an increase in premature births. A large majority of the cervical dysplasias in adolescents caused by HPV resolve on their own without treatment. It is important to avoid unnecessary instrumentation and procedures that negatively affect the cervix. Women who have had a complete hysterectomy for noncancerous reasons who have no history of high-grade CIN may have routine cervical cytology testing discontinued. Women who are older than 65 years who have not had serious cervical precancer or cancer in the past 20 years may discontinue cervical cancer screening (ACS, 2014).
- Record the examination date on the woman's record.
- Communicate findings to the woman per agency protocol.

reported in person. The CDC (2012b) has developed new guidelines that recommend testing people who were born in 1945 through 1965 for hepatitis C.

To promote wellness and prevent illness, it is imperative that women adhere to specific screening guidelines to detect conditions that, if found early, are amenable to treatment and/or cure. Table 4-3 summarizes the screening procedures for women across the life span.

ANTICIPATORY GUIDANCE FOR HEALTH PROMOTION AND ILLNESS PREVENTION

Over the past several decades women have made tremendous strides in education, careers, policymaking, and overall participation in today's complex society. There have been costs for these advances, and although women are living longer, they may not be living better.

As a result, the health care system must pay greater attention to the health consequences for women. In addition, women must be active participants in their own health promotion and illness prevention. **Health promotion** is the motivation to increase well-being and actualize health potential. **Illness prevention** is the desire to avoid illness, detect it early, or maintain optimal functioning when illness is present.

Nurses have a major opportunity and responsibility to help women understand risk factors and to motivate them to adopt healthy lifestyles that prevent disease. Lifestyle factors that affect health over which the woman has some control include diet; tobacco, alcohol, and substance use; exercise; sunlight exposure; stress management; and sexual practices. Other influences, such

as genetic and environmental factors, may be beyond the woman's control, although some opportunities for prevention exist (e.g., through environmental legislation activism or genetic counseling services).

Knowledge alone is not enough to bring about healthy behaviors. The woman must be convinced that she has some control over her life and that healthy life habits, including periodic health examinations, are a sound investment. She must believe in the efficacy of prevention, early detection, and therapy and in her ability to perform self-management practices, such as BSE. Many people believe that they have little control over their health, or they become immobilized by fear and anxiety in the face of life-threatening illnesses, such as cancer, so they delay seeking treatment. The nurse must explore the reality of each woman's perceptions about health behaviors and individualize teaching if it is to be effective. In an earlier section of this chapter, risk factors to women's health were described. The following section describes actions that women can take to promote their health and prevent illness, along with the nurse's role in facilitating such actions.

Nutrition

Dietary Guidelines for Americans (U.S. Department of Agriculture, 2010) provides evidence-based recommendations to promote health and reduce risks for chronic diseases through diet and physical activity. This guide, published by the U.S. government, contains resources for health professionals and consumers on dietary guidelines. New guidelines will be issued after the Department of Health and Human Services in collaboration with the Department of Agriculture have established the 2015 Dietary Guidelines Advisory Committee (DGAC). They convened an initial meeting in June 2013, but the guidelines have not yet been made public (www.health.gov/DietaryGuidelines). The Food Guide Pyramid has been replaced by MyPlate (myplate.gov), a guide to healthy eating recommended by the *Dietary Guidelines for Americans* (HealthyPeople.gov, 2012b).

TABLE 4-3 Health Screening Guidelines and Immunization Recommendations for Women Ages 18 Years and Older

ASSESSMENT	RECOMMENDATION*
Physical Examination	
Blood pressure	Every visit, but at least every 2 years
Height and weight	Every visit, but at least every 2 years
Pelvic examination	Annually until age 70; recommended for any woman who has ever been sexually active
Breast Examination	
Clinical examination	Every 3 years, ages 20 to 39; after age 40 with periodic examination, preferably annually
High risk	Annually after age 18 with history of premenopausal breast cancer in first-degree relative
Risk Groups	
Skin examination	Family history of skin cancer or increased exposure to sunlight every 3 years between ages 20 and 40; annually after age 40; monthly mole self-examinations also recommended
Oral cavity examination	History of mouth lesions or exposure to tobacco or excessive alcohol at least annually
Laboratory and Diagnostic Tests	
Blood cholesterol (fasting lipoprotein analysis)	Between ages 20 and 45 only if high risk; beginning at age 45 if level is within normal limits, every 5 years; more often if abnormal levels or have risk factors for coronary artery disease
Papanicolaou (Pap) test	Between ages 21 and 65—every 3 years with Pap test done Between ages 30 and 65—every 5 years if Pap test plus human papillomavirus (HPV) test done After age 65 and 3 negative tests and no risks and after total hysterectomy for benign disease—women may choose to stop screening
Mammography†	Every 1 to 2 years between ages 40 and 49 or earlier if at high risk Annually after age 40 Annually after age 50 Biennially, ages 50 to 74 After age 75, discuss with your health care provider
Colon cancer screening	Use 1 of these 3 methods: <ul style="list-style-type: none"> • Fecal occult blood test annually ages 50 to 74 • Flexible sigmoidoscopy every 5 years ages 50 to 74 • Colonoscopy every 10 years ages 50 to 74 Screen more often if family history of colon cancer or polyps After age 75, discuss with your health care provider
Hearing screen	Starting at age 18, then every 10 years until 49 Every 3 years after age 50
Vision screen	Annually with exposure to excessive noise or when loss is suspected At least once between ages 20 and 29; at least twice between ages 30 and 39 Every 2 to 4 years between ages 40 and 64; every 1 to 2 years after age 65
Risk Groups	
Fasting blood sugar	Annually with family history of diabetes or gestational diabetes or if significantly obese; every 3 to 5 years for all women older than 45 years
Thyroid-stimulating hormone (TSH) test	As determined by the health care provider
Sexually transmitted infection test (e.g., gonorrhea, syphilis, herpes)	As needed if sexually active with multiple partners and engaging in risky sexual behaviors
Chlamydia test	If sexually active, yearly until age 25; after age 25, test as needed when sexually active with new or multiple partners
Human immunodeficiency virus (HIV) test	At least once between ages 18 and 64 to determine HIV status; test if there is a high risk for HIV infection
Tuberculin skin test	Annually with exposure to persons with tuberculosis or in risk categories for close contact with the disease
Endometrial biopsy	At menopause for women at risk for endometrial cancer; repeat as needed
Bone mineral density testing	All women ages 65 and older at least once; repeat testing as needed; younger women with risk for osteoporosis may need periodic screenings
Hepatitis C testing	All people born between 1945 and 1965, one test
Immunizations	
Tetanus-diphtheria-pertussis (Td/Tdap)	Tdap vaccine once, then booster is given every 10 years
Measles, mumps, rubella	Once if born after 1956 and no evidence of immunity
Hepatitis A	Primary series of two injections for all who are in risk categories
Hepatitis B	Primary series of three injections for all who are in risk categories
Influenza	Annually

TABLE 4-3 Health Screening Guidelines and Immunization Recommendations for Women Ages 18 Years and Older—cont'd

ASSESSMENT	RECOMMENDATION*
Pneumococcal	1 or 2 doses between ages 19 and 64; 1 dose after age 65
Herpes zoster (shingles)	One dose at age 65
Human papillomavirus (HPV) vaccine	Primary series of three injections for girls ages 9 to women 26 years old; intended for those not previously exposed to HPV

*The information in this table is only a guide; health care providers will individualize the timing of tests and immunizations for each woman.

Note: No consensus has been reached regarding mammograms for women between 40 and 49 years of age; therefore, various recommendations are listed. Women are urged to discuss circumstances with their health care providers.

These guidelines recommend that half of the plate be filled with fruits and vegetables, one quarter with grains, and one quarter with protein.

Folic acid helps reduce high levels of homocysteine, an amino acid that damages the heart and blood vessels and increases the risk of heart disease, stroke, and dementia. Folic acid is present in citrus fruits, broccoli, spinach, asparagus, peas, lettuce, beans, whole grains, and orange juice. It is in many fortified grains and pasta or can be taken as a daily vitamin supplement (USDHHS, 2010).

Antioxidants are thought to be effective in helping to prevent oxidative damage in the body such as cancer, heart disease, and stroke; however, more research is needed in this area. Vitamins C and E, selenium (a mineral), and a group known as beta-carotenes (carotenoids) can be found in a diet containing fruits, vegetables, and whole grains.

Most women do not recognize the importance of calcium to health, and their diets are insufficient in calcium. Women who are unlikely to have enough calcium in the diet may need calcium supplements in the form of calcium carbonate with vitamin D, which contains more elemental calcium than do other preparations. Although calcium and vitamin D are still recommended for women's health, research has raised some concerns about the efficacy of its preventive effect of fractures in premenopausal women (Moyer for the U.S. Preventive Services Task Force, 2013). Nestle and Nesheim (2013), also working with the U.S. Preventive Services Task Force, suggested that insufficient evidence exists for the currently recommended doses of vitamin D and calcium to be effective in preventing fractures, and further stated that there is a small risk of developing renal stones due to these recommended dosages.

The diet can be assessed by using a standard assessment form—a 24-hour recall is adequate and quick—and then food likes and dislikes, including cultural variations and typical food portions and dietary habits should be discussed and incorporated into counseling (see Chapter 14).

Exercise

Physical activity and exercise counseling for persons of all ages should be undertaken at schools, worksites, and primary care settings. Specific recommendations include 150 minutes per week of moderate exercise or 75 minutes per week of vigorous exercise. For moderate exercise, this can be practically achieved through 30 minutes a day, five times a week. The American Heart Association (AHA) notes that dividing the 30 minutes per day into two or three segments of 10 to 15 minutes each is also beneficial (AHA, 2013). Few Americans exercise this often, and physical inactivity increases with age, especially during adolescence and early adulthood. Even small increases in activity can be beneficial. The nurse should stress the importance of daily exercise throughout life for weight management and health promotion, suggesting exercises that are enjoyable to the individual (Fig. 4-15). Physical activity builds healthy bones, muscles, and joints and reduces the risk of colon and breast cancer. It also reduces feelings of depression and anxiety and improves mood and promotes a feeling of well-being.

During pregnancy, an ongoing exercise regimen can be continued but intensity and duration should be decreased. Sedentary women should obtain medical clearance to initiate exercise during pregnancy and should begin with low-intensity and low-impact workouts.

Activities do not need to be strenuous to bring health benefits. What is important is to include activities as part of a regular health routine. Activities that are especially beneficial when performed regularly include brisk walking, hiking, stair climbing, aerobic exercise, jogging, running, bicycling, rowing, swimming, soccer, and basketball. Before beginning any planned activity program, a woman should see her primary care nurse practitioner (NP) or physician for a thorough medical evaluation to prevent potential injuries or harm.

For women who are sedentary or are not able to exercise vigorously, even moderate- and low-intensity activities, when performed daily, can have long-term health benefits such as

FIG 4-15 Exercise should be a part of one's regular health routine. A cycle class is fun and provides moderate to vigorous exercise. (Courtesy Shari Rivera Sharpe, Chapel Hill, NC.)

lowering the risk of cardiovascular disease. Regular physical activity can reduce or eliminate some of these risk factors by lowering blood pressure, maintaining a reasonable weight or facilitating weight loss, and lowering cholesterol levels to less than 200 mg/dl.

Home maintenance, yard work, and gardening are other activities that promote health and a sense of well-being, especially for older adults. Attention to safety factors and wearing clothing and shoes appropriate to each activity are advised. Care should be taken not to aggravate existing conditions or create muscle and joint discomfort by an overly aggressive approach to exercise.

Kegel Exercises

Kegel exercises, or pelvic muscle exercises, were developed to strengthen the supportive pelvic floor muscles to control or reduce incontinent urine loss. These exercises also are beneficial during pregnancy and postpartum. They strengthen the muscles of the pelvic floor, providing support for the pelvic organs and control of the muscles surrounding the vagina and urethra. Educational strategies for teaching women how to perform Kegel exercises (compiled by nurse researchers who conducted a research utilization project for the Association of Women's Health, Obstetric and Neonatal Nurses [AWHONN]) are described in the Teaching for Self-Management box).

Stress Management

Because it is neither possible nor desirable to avoid all stress, women must learn how to manage it. The nurse should assess each woman for signs of stress, using therapeutic communication skills to determine risk factors and the woman's ability to function. Box 4-5 lists symptoms of stress. Some women must be referred for counseling or other mental health therapy. Women are twice as likely as men to suffer from depression, anxiety, or panic attacks (WebMD, 2012, 2013). Nurses must be alert to the symptoms of serious mental disorders such as depression and anxiety and make referrals to mental

TEACHING FOR SELF-MANAGEMENT

Kegel Exercises

Description and Rationale

Kegel exercises, or pelvic muscle exercise, is a technique used to strengthen the muscles that support the pelvic floor. This exercise involves regularly tightening (contracting) and relaxing the muscles that support the bladder and urethra. By strengthening these pelvic muscles a woman can prevent or reduce accidental urine loss.

Technique

The woman needs to learn how to target the muscles for training and how to contract them correctly. One suggestion for teaching is to have the woman pretend she is trying to prevent the passage of intestinal gas. Have her use this tightening motion on the muscles around her vagina and the upper pelvis. She should feel these muscles drawing inward and upward. Other suggested techniques are to have the woman pretend she is trying to stop the flow of urine in midstream or to have her think about how her vagina is able to contract around and move up the length of the penis during intercourse.

The woman should avoid straining or bearing-down motions while performing the exercise. She should be taught how bearing down feels by having her take a breath, hold it, and push down with her abdominal muscles as though she were trying to have a bowel movement. Then the woman can be taught how to avoid straining down by exhaling gently and keeping her mouth open each time she contracts her pelvic muscles.

Specific Instructions

1. Each contraction should be as intense as possible without contracting the abdomen, thighs, or buttocks.
2. Contractions should be held for at least 10 seconds. The woman may have to start with as little as 2 seconds per contraction until her muscles get stronger.
3. The woman should rest for 10 seconds or more between contractions so that the muscles have time to recover and each contraction can be as strong as she can make it.
4. The woman should feel the pulling up over the three muscle layers so that the contraction reaches the highest level of her pelvis.

health practitioners when necessary. Women experiencing major life changes such as separation and divorce, bereavement, serious illness, and unemployment also need special attention.

For many women, the nurse is able to provide comfort, reassurance, and advice concerning helping resources, such as support groups. Many centers offer support groups to help women prevent or manage stress. Social support and good coping skills can improve a woman's self-esteem and give her a sense of mastery. Anticipatory guidance for developmental or expected situational crises can help her plan strategies for dealing with potentially stressful events. Role playing, relaxation techniques, biofeedback, meditation, desensitization, imagery, assertiveness

BOX 4-12 Interventions for Smoking Cessation: the Five A's

Ask

- What was her age when she started smoking?
- How many cigarettes does she smoke a day? When was her last cigarette?
- Has she tried to quit?
- Does she want to quit?

Assess

- What were her reasons for not being able to quit before, or what made her start again?
- Does she have anyone who can help her?
- Does anyone else smoke at home?
- Does she have friends or family who have quit successfully?

Advise

- Give her information about the effects of smoking on pregnancy and her fetus, on her own health, and on the members of her household.

Assist

- Provide support; give self-help materials.
- Encourage her to set a quit date.
- Refer to a smoking cessation program, or provide information about nicotine replacement products (not recommended during pregnancy) if she is interested.
- Teach and encourage use of stress-reduction activities.
- Provide for follow-up with a phone call, letter, or clinic visit.

Arrange follow-up

- Arrange to follow the woman to find out about her smoking-cessation status.
- Make a phone call around the time of her quit date. Assess her status at every prenatal visit.
- Congratulate her on her success, or provide support for her if she relapses.
- Referral to intensive treatment may be necessary.

From Fiore, M.C., Jaen, C.R., Baker, T.B., Bailey, W.C., Benowitz, N.L., Curry, S.J., et al (2008). *Treating tobacco use and dependence: 2008 update. Clinical Practice Guideline*. Rockville, MD: U.S. Department of Health and Human Services, Public Health Service. Available at http://www.surgeongeneral.gov/tobacco/treating_tobacco_use08.pdf.

training, yoga, diet, exercise, and weight control are all techniques nurses can include in their repertoire of helping skills. Some women must be referred for counseling or other mental health therapy. Careful follow-up of all women experiencing difficulty in dealing with stress is important.

Substance Use Cessation

All women of all ages will receive substantial and immediate benefits from smoking cessation. However, this task is not easy, and most people stop several times before they accomplish their goal. Many are never able to do so. Box 4-12 describes an intervention, referred to as the Five A's to encourage smoking cessation. Those who wish to stop smoking can also be referred to a smoking-cessation program where individualized methods can be implemented. At the very least, individuals should be guided to self-help materials available from the March of Dimes, the American Lung Association, and the ACS.

New approaches to increase cessation among smokers and to discourage smoking among young women—especially in adolescence and during pregnancy—are needed. Health care

providers can have a positive effect on smoking behavior and should attempt to motivate smokers to stop.

Counseling women who appear to be drinking alcohol excessively or using drugs may include promoting strategies to increase self-esteem and teaching new coping skills to resist and maintain resistance to alcohol abuse and drug use. Appropriate referrals should be made, with the health care provider arranging the contact and then following up to be sure that appointments are kept. General referral to sources of support also should be provided. National groups that provide information and support for those who are chemically dependent have local branches or contacts that can be found on the internet.

Anticipatory guidance includes teaching about the health and safety risks of alcohol and mind-altering substances and discouraging drug experimentation among preteen and high school students, because the use of drugs at an early age tends to be a predictor of greater involvement later.

Sexual Practices That Reduce Risk

Prevention of STIs has been discussed earlier in this chapter. The nurse plays an important role in educating women about how to practice safer sex. Chapter 7 includes more detail related to STI prevention. In addition to the prevention of STIs, women of childbearing years need information regarding contraception and family planning (see Chapter 8). A comprehensive sexual assessment should be integrated into all health histories. Women and girls also will benefit from being encouraged to be vaccinated with the HPV series of three vaccinations to prevent cervical cancer.

Health Screening Schedule

Periodic health screening includes history, physical examination, education, counseling, immunizations, and selected diagnostic and laboratory tests. This regimen provides the basis for overall health promotion, prevention of illness, early diagnosis of problems, and referral for appropriate management. Such screening should be customized according to a woman's age and risk factors. In most instances it is completed in health care offices, clinics, or hospitals; however, portions of the screening are now being carried out at events such as community health fairs. An overview of health screening recommendations and immunizations for women 18 years and older is provided in Table 4-3.

Health Risk Prevention

Simple safety factors often are forgotten or perceived not to be important, yet injuries continue to have a major effect on the health status of all age groups. Being aware of hazards and implementing safety guidelines will reduce risks. The nurse should frequently reinforce the following commonsense concepts that will protect the individual:

- Wear seat belts at all times in a moving vehicle.
- Wear safety helmets when riding a motorcycle, bicycle, or inline skates.
- Follow driving "rules of the road."
- Place smoke alarms throughout the home and workplace. Avoid secondhand smoke.
- Lock doors and windows to ensure personal safety.

- Reduce noise pollution or safeguard against hearing loss.
- Protect skin and eyes from ultraviolet light with the use of sunscreen, protective clothing, sunglasses, and hats.
- Practice water safety.
- Never walk or run alone, especially at night.
- Consider storing personal health information (PHI) in a digital database that can be accessed from anywhere you travel.
- Never share computer passwords with strangers, to safeguard financial, personal, and health data.
- Take precautions and avoid dangerous situations.

Health Protection

Nurses can make a difference in stopping violence against women and preventing further injury. Educating women

that abuse is a violation of their rights and facilitating their access to protective and legal services constitutes a first step. Encouraging health care institutions to implement appropriate domestic violence screening programs also is of great value (see Chapter 5). Other helpful measures for women to discourage their entry into abusive relationships include promoting assertiveness and self-defense courses; suggesting support and self-help groups that encourage positive self-regard, confidence, and empowerment; and recommending educational and skills development classes that will enhance independence and self-care.

Numerous national and local organizations provide information and assistance for women in abusive situations. All nurses who work in women's health care should become familiar with local services and legal options.

KEY POINTS

- Normal feedback regulation of the menstrual cycle depends on an intact hypothalamic-pituitary-gonadal mechanism.
- The female's reproductive tract structures and breasts respond predictably to changing levels of sex steroids across her life span.
- The myometrium of the uterus is uniquely designed to expel the fetus and promote hemostasis after birth.
- The changing status and roles of women affect their health, needs, and ability to cope with problems.
- Anticipatory guidance is enhanced in a private, safe environment in which the interaction is culturally competent, non-judgmental, and confidential.
- Culture, religion, socioeconomic status, personal circumstances, the uniqueness of the individual, and the stage of development influence a person's recognition of need for care and the response to the health care system and therapy.
- Preconception counseling allows identification and possible remediation of potentially harmful personal and social

conditions, medical and psychologic conditions, environmental conditions, and barriers to care before pregnancy occurs.

- Conditions that increase a woman's health risks also increase risks for her offspring.
- Effective educational programs about sex and family life are imperative to control the rate of teen pregnancy and STIs.
- Health promotion and prevention of illness assist women to actualize health potential by increasing motivation, providing information, and suggesting how to access specific resources.
- IPV against women is a major social and health care problem in the United States and includes physical, sexual, emotional, psychologic, and economic abuse.
- Periodic health screening, including history, physical examination, and diagnostic and laboratory tests, provides the basis for overall health promotion, prevention of illness, early diagnosis of problems, and referral for management.

Violence Against Women

Noreen Esposito

© <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Describe the beliefs and practices that historically have perpetuated violence against women.
- Examine the prevalence and effects of intimate partner violence.
- Contrast the theoretic premises underlying the victimization of women.
- Discuss theories of violence and how they can be used in assessment and intervention for women who are abused.
- Develop a nursing care plan for a woman who is experiencing intimate partner violence.
- Review the dynamics of sexual assault.
- Describe the rape-trauma syndrome.
- Develop a nursing care plan for a woman in the acute phase of rape-trauma syndrome.
- Evaluate resources available to women experiencing abuse.
- Describe human sex trafficking and implications for health care providers.

Violence against women (VAW) is a public health problem that exists worldwide. It has been more than twenty years since the United Nations defined VAW as “any act of gender-based violence that results in or is likely to result in physical, sexual, or mental harm or suffering to women including threats of such acts, coercion, or arbitrary deprivation of liberty whether occurring in public or private” (Blanchfield, 2008; United Nations, 1993). Since then research efforts have increased what is known about the various dimensions of VAW. Around the globe VAW takes many different forms including, but not limited to, intimate partner violence, sexual assault, marital rape, dowry-related violence, sexual trafficking and exploitation, and female genital mutilation. This chapter focuses on intimate partner violence, sexual assault, and trafficking of women.

INTIMATE PARTNER VIOLENCE

Intimate partner violence (IPV) is the most common form of VAW, with a reported global prevalence of 30% and rates ranging from 36% in poorer regions such as Africa, Central and South America, and Southeast Asia to 23% in higher-income regions such as Australia, Canada, the United States, and developed countries of Western Europe (World Health Organization [WHO], 2013a). The National Violence Against Women Survey (NVAWS) defines IPV as “the actual or threatened physical, sexual, psychological, or emotional abuse by a spouse, ex-spouse, boyfriend, girlfriend, ex-boyfriend, ex-girlfriend, date, or cohabiting partner” (Tjaden & Thoennes, 2006). The National Intimate Partner and Sexual Violence

Survey (NISVS) expanded on that work with an ongoing telephone survey that focuses on five types of IPV: sexual violence, physical violence, stalking, psychological aggression, and control of reproductive or sexual health (Black, Basile, Breiding, et al., 2011). The survey added stalking and IPV among same-sex partners, information that was not tracked in the past. IPV can be thought of as “a continuum ranging from one hit that may or may not impact the victim to chronic, severe battering” (Centers for Disease Control and Prevention [CDC], 2010a). Other terms such as partner abuse and domestic or family violence are common. Older terms such as wife battering or spouse battering are generally not used. Battery has been used in the past to refer to physical contact with another with the intent of harm, but the World Health Organization (WHO) has an updated definition of battery to refer to an escalation of violence with increasing threats and increasing terror. IPV is the preferred term in that it encompasses not only physical contact but also emotional and other forms of violence previously ignored (WHO, 2012).

IPV is a complex, stigmatizing problem involving issues of emotional distress, personal safety, and social isolation. In many places in the United States and abroad IPV has been socially tolerated or ignored. Lack of reporting and inconsistent definitions have made it difficult to get an accurate count of the number of victims, as there are wide ranges of estimates.

In the United States the prevalence of some form of IPV (rape, physical violence, and/or stalking) during a woman’s lifetime is estimated to be 35.6% (Black et al., 2011). In a prospective survey of 2737 urban public hospital emergency department

(ED) clients, 548 (20%) identified themselves as victims of IPV. Greater victim-perceived danger was associated with lower physical and mental health functioning in the 216 of those who returned for follow-up (Straus, Cerulli, McNutt, et al., 2009). Throughout the world more than one third of female homicides occur at the hands of an intimate partner (Stockl, Devries, Rotskein, et al., 2013). In 2010, there were 1095 women murdered by an intimate partner in the United States (U.S. Department of Justice, 2011).

Abusive relationships exist in couples who are dating, living together, or married. The abuse, which may be physical, sexual, psychologic, or financial, can continue after the relationship ends. One partner behaves in a way that injures, intimidates, humiliates, frightens, or terrorizes the other partner. These behaviors can be insidious, slowly happening over time. Emotional abuse may include name calling, acting in a jealous or possessive manner, trying to isolate the woman from her family or friends, putting her down in front of others, threatening her children or alienating her children from her, not wanting her to go out or go to work, or insisting that she account for every minute she is away from home. Physical violence may never be used, or used rarely, but threats can be as effective as actual violence. If the abuser becomes physically violent, the threat of recurrence always exists.

CLINICAL REASONING CASE STUDY

Intimate Partner Violence

Elena, a 17-year-old Hispanic client, is in the clinic for her fifth month prenatal visit. She missed her last two appointments. She is accompanied by her boyfriend, with whom she lives. The nurse suggests that he wait outside while she asks intake questions about Elena's health. Elena looks down and says quietly, "It's fine if he stays, really it is." The nurse notices that he is very attentive to Elena, is very nice to the nurse, and answers for Elena most of the time she is asked a question. You explain that the clinic has a policy that the interviews are done in private. He reluctantly leaves the room. After some routine questions about her general health since her last prenatal visit, the nurse asks her about intimate partner violence and safety. "Have you been hit, slapped, kicked, or in other ways physically hurt by someone?" Elena shakes her head and says, "No" in a quiet voice. The nurse notices Elena glance at a small bruise on the inner part of her arm. The nurse asks Elena if she is being physically hurt or threatened in her relationship. She gets teary but says, "No." What is the nurse's responsibility in this instance regarding confidentiality, questioning Elena about intimate partner violence, and risks to Elena if she discloses that she has been hurt by her boyfriend? What is the nurse's responsibility to report the incident to the police?

1. Evidence—Is there sufficient evidence to draw conclusions about Elena as a woman experiencing abuse?
2. Assumptions—What assumptions can be made about the following?
 - a. Characteristic behaviors of a woman in an abusive relationship
 - b. Cultural considerations
 - c. Pregnancy and abuse
 - d. Relationship expectations—adolescents and abuse
3. What implications and priorities for nursing care can be made at this time?
4. Does the evidence objectively support your conclusion?

IPV may begin in pregnancy or may have already begun before the pregnancy. If it already exists, IPV may increase, decrease, or stay the same during the pregnancy (Macy, Martin, Kupper, et al., 2007; Taylor & Nabors, 2009) (see later discussion in section Intimate Partner Violence in Pregnancy.)

The consequences of IPV are profound. Approximately 28% of women in the NISVS linked the experience of IPV with some type of negative consequence including fear (26%), safety concerns (22%), posttraumatic stress disorder (PTSD) symptoms (22%), an injury (15%), the need for medical care (8%), lack of housing (2.4%), legal services (7.6%), missed days at work or school (10%), pregnancy (1.7%), or contracting a sexually transmitted infection (1.5%) (Black et al., 2011). In a study comparing abused women with never abused women, abused women had a higher incidence of social and family problems, substance abuse, menstrual and other reproductive disorders, sexually transmitted infections (STIs), musculoskeletal and gastrointestinal (GI) disorders, chest pain, abdominal pain, urinary tract infections (UTIs), and headaches (Bonomi, Anderson, Reid, et al., 2009). Prolonged exposure to acute or chronic stress like IPV is linked with structural changes in the brain now associated with mental health problems, emotion regulation, and cognitive problems. In one study abused women with PTSD who were shown angry faces and angry male faces during functional magnetic resonance imaging (fMRI) had hyperresponsiveness in the amygdala and the entire limbic system compared with women who had no abuse history (Fonzo, Simmons, Thorp, et al., 2010). Based on a review of multiple large population-based surveys, the WHO developed pathways suggesting links between exposures to violence and adverse health effects of IPV (WHO, 2013a).

Medical costs alone in the United States for interpersonal violence are estimated to be \$2.7 to \$7 billion for the first 12 months after victimization, and annual medical costs for any past intimate partner victimization, not limited to the last year, range from \$25 to \$59 billion (Brown, Finkelstein, & Mercy, 2008). These figures do not include the cost of police and court costs, shelters, foster care, sick leave, and non-productivity. Reducing the rates of IPV and sexual violence are *Healthy People 2020* sub-objectives under the main objective of violence prevention (U.S. Department of Health and Human Services [USDHHS], 2013).

Historical Perspective

Women have been treated inhumanely throughout history. In ancient Rome, wives were divorced or killed by husbands for adultery, public drunkenness, or attending public games, whereas men could engage in these activities daily. In the 1700s, under English common law, the "rule of thumb" gave men permission to chastise their wives physically as long as the implement they used was no wider than their thumbs. In the late 1600s, Pilgrims and Puritans directed male heads of the family to use force when needed to maintain conduct of their wives. Although American law prohibited beating wives, the Puritans supported physical force by husbands as legitimate. In the 1800s men gradually lost the right to beat their wives. Slow progress was made in the early 20th century. There was little awareness from both health care professionals and the legal and justice systems to the plight of women in intimate relationships. As late

as the 1960s, it was believed that violence in the family was rare and committed only by the mentally ill.

The first shelter for women opened in London in 1971, and books and articles on domestic violence began to appear in the 1970s. Battered woman syndrome was described by Lenore Walker in 1979 and battered women programs emerged in the 1980s. In the 1990s the American Nurses Association issued a position statement against VAW, the American Medical Association declared that physicians were liable if they did not recognize IPV, and The Joint Commission issued standards to identify and manage IPV clients. The National Domestic Violence Hotline was established in 1996. The CDC promotes the phrase intimate partner violence over domestic violence (CDC, 2013). Health care providers, law enforcement, the legal system, and the general public are slowly acknowledging IPV, but power imbalances, persistent beliefs that family problems are private matters, the victim's feelings of shame, and fear continue to keep women from disclosing abuse.

Conceptual and Theoretic Perspectives

In the late 1970s little was known about IPV. Lenore Walker, a pioneer in the field, interviewed 120 victims, from which she generated the phrase “battered woman syndrome,” which identified victim characteristics such as learned helplessness and abuser characteristics such as mental health problems. At the time Walker proposed a model of how IPV might appear in some families. The model, referred to as the *cycle of violence*, described three phases in an IPV relationship: tension building, acute battering, and the honeymoon phase. In her proposed model, violence was neither random nor constant but occurred in repeated cycles. Her continued research led to modifications in her early interpretations. Ongoing research from different disciplines has expanded today's understanding of IPV. Current thought does not support the general applicability of the cycle of violence.

IPV is heterogeneous. Not all batterers are alike, not all victims are alike, and not all relationships and patterns of abuse are alike. In some relationships physical and psychologic abuse happen on a regular basis. In other relationships, physical abuse or the threat of abuse may happen rarely, but emotional abuse is more persistent. In some relationships abuse happens after stressful events or pregnancy. Walker's work was an important first step and helped raise awareness and concern. Because the cycle of violence was the only available explanation for IPV, the model became a core part of IPV training for health professionals, social workers, law enforcement officers, and judges. Despite limited evidence of its usefulness many professionals still believe that the cycle of violence explains IPV (Dutton, 2009).

There is a growing body of literature about the characteristics and dynamics of IPV. Along with feminist ideologies that play a critical role in gender-based violence, theories from biology, psychology, and sociology all help to partially explain various aspects of violence against women. No single theory can completely explain this complex problem. Following is a brief discussion of some of these theoretic perspectives.

Biologic Factors

A complete explanation of the biologic perspective is beyond the scope of this chapter, but evidence indicates that neurobiologic

and hormonal factors influence aggression in men. Areas in the brain believed to play a role in aggressive behavior are the limbic system, the frontal lobes, and the hypothalamus. Changes in structural functioning of the limbic system, such as occur with brain lesions, substance use, epilepsy, and head injuries, affect the emotional experience and behavior of the individual and thus can increase or decrease the potential for aggressive behavior (Stuart & Hamolia, 2009).

Neurochemical factors also can play a role in aggressive behavior so that dysfunction or dysregulation of certain neurotransmitters can result in aggression. Increased levels of norepinephrine and L-dopa foster aggressive behavior. Reducing the levels of serotonin in animals causes aggressive behavior. The amino acid gamma-aminobutyric acid (GABA) inhibits aggressive behavior. The occurrence of violence in neurologic disorders also is reported, especially when violent reactions are out of proportion to the provoking events (Stuart & Hamolia, 2009).

In animal studies, aggression is associated with abnormally high levels of testosterone. Soler, Vinayak, & Quadagno (2000) reported higher testosterone levels in abusive male subjects and suggested that heritability is an issue that warrants the inclusion of this variable in future studies of violent behavior. There is no conclusive evidence in biologic theory, except perhaps in instances of neurologic damage, that it is impossible to control aggressive behavior.

Psychologic Perspective

Psychology, the study of emotion and behavior, places responsibility for behaviors such as aggression on the individual. Early psychoanalytic theory suggested that aggression is a basic instinctual drive leading to mastery and accomplishment. In men aggression was seen as a positive force that connoted boldness, forcefulness, energy, and enterprise. Thus early psychologic theory saw aggression in men as normal. Early psychoanalytic theory promoted gender-stereotypic expectations for women to be caring and nurturing; aggression in women was and still is viewed negatively, and aggressive women are often labeled as hostile and belligerent.

The myth that abuse is committed by people who have some type of mental illness perpetuates the notion that violence occurs among people who are not “normal.” Mental illness accounts for a very small percentage of IPV. Men who batter vary from having modest personality dysfunction to having significant personality pathology such as borderline and antisocial personality disorders (Capaldi & Kim, 2007). Population-based Canadian studies suggest demographic risk factors include a partner who is underemployed, low income, or alcohol or substance abuse (Stewart, MacMillan, & Wathen, 2013). Although a diagnosis of alcohol abuse is frequently found in abusers, it should not be misconstrued as the cause of violence. There is some evidence that alcohol may increase the risk of violent behavior because survivors of violence often report substance abuse by the abuser (Torres & Han, 2003). There is no diagnostic profile of an abuser, but Box 5-1 provides some characteristics of men who batter that nurses may consider when assessing clients' relationships.

Women with severe and persistent mental illness are likely to be more vulnerable to being involved in controlling and violent

BOX 5-1 Characteristics of a Potential Male Batterer

- Low self-esteem
- Problems with abandonment, loss, helplessness, dependency, insecurity, and intimacy
- Inadequate verbal skills, especially difficulty expressing feelings
- Deficits in assertiveness
- Personality disorders frequently diagnosed
- Low frustration tolerance (loses temper easily)
- Higher incidence of growing up in an abusive or violent home
- Denies, minimizes, blames, and lies about own actions
- Violence is consistent with his view of himself and the world; it is an acceptable way of dealing with everyday life
- Inability to empathize with others
- Rigidity in male and female behaviors (sex-role stereotypes)
- Perception of self as "special" and deserving special attention for being the provider, protector
- Substance abuse problems are common
- Displays of an unusual amount of jealousy (e.g., expects partner to spend all of her time with him or to keep him informed of her whereabouts)

relationships. However, numerous mental health problems (such as depression, psychophysiological illnesses, substance abuse, eating disorders, PTSD, and anxiety reactions) experienced by women with abusive partners are more likely to be consequences of long-term abuse rather than causes (WHO, 2013a). Relationship violence differs by severity and frequency, the individual's characteristics, and whether it is confined to the family or occurs outside the family. Not all victims see their violence experiences in the same way; different women experience violence differently. Women with dependent personality traits as well as independent women have been victims of IPV. Although there may be shared characteristics, each person's experience and response is individual (Nurius & Macy, 2008).

Newer studies in psychology are exploring the unique differences among individuals who are in violent relationships. We know that men who are involved in relationship violence are not all alike. Heterogeneity is seen in the characteristics of the men, in their partners, and in the relationship dynamics. When trying to understand some types of violence, there is growing interest in considering both members of a relationship. In one conceptual model Capaldi and Kim (2007) explored the typologies of couples experiencing violence. They offered a dynamic systems model that considers what each person brings to a relationship. For example, personal characteristics such as depression or antisocial behavior might be combined with a person's emotional development to create a unique individual. Individuals come together to create a pattern of interactions, and these interactions occur in the context of various social stresses such as substance use, financial stress, or separation. The dynamics can lead to some type of incident that is potentially or actually violent. Viewed this way, this dynamic model provides many potential areas for intervention. Research is needed to further explore the possibilities of this approach.

Sociologic Perspective

The social structure and conditions in Western society provide the basis for many of the prevailing attitudes toward violent

behavior. U.S. history is filled with examples of violence, such as war, as a means of social control. Social acceptance and promotion of violence in men are double standards because women are expected to be nonviolent. Thus psychologic theories of gender-based behaviors can influence social beliefs and responses to particular behaviors. Because men are socially expected to be aggressive, their violence is sometimes treated with more leniency and less stigma than violence in women, particularly in the justice system. The use of physical force in normal societal encounters can lead to the acceptance of violence in society.

Family dynamics in which there are certain roles assumed within the family, the amount of time spent together, the degree of privacy, emotional involvement, and stress and conflict may all contribute to violence. Power and violence, or even the threat of physical force, contribute to the persistent patriarchal view of a woman's place in the home and in the rest of society. Gender inequality, in both economic opportunities and physical strength, serves to perpetuate the power imbalance in relationships.

Another family issue is the multigenerational transmission of violence; some perpetrators of violence and some victims learn about violence in families of origin by either witnessing or experiencing violence while growing up (Cannon, Bonomi, Anderson, & Rivara, 2009). In families in which violence occurs, both the lack of emotional support experienced by children and the awareness that people who love each other can be violent are important factors. Children in these environments do not have role models to help them develop mental models of healthy family dynamics. Abuse as a child, however, does not consistently determine later violent behavior because many children who were abused grow up to avoid violent behavior.

Feminist Perspective

One contemporary view of violence is derived from feminist theory. This view, with the primary theme of male dominance and coercive control, enhances our understanding of all forms of violence against women, including IPV, stranger and acquaintance rape, incest, and sexual harassment in the workplace. A gender and power perspective is taken as a way to understand the victimization that occurred. In numerous cases, power and control tactics were central events leading to the violence. The power and control wheel developed by the Duluth, Minnesota, Domestic Abuse Intervention Project identifies ways that men may exercise the power and control that underlie many types of IPV and has been used to help women, men, and care providers understand violence (Fig. 5-1).

As our understanding of the complexity of violence against women has evolved over time, so has the need for an evolving feminist viewpoint. Using frontline workers' perspectives of current feminist thought, one study proposed an integrative feminist model. Keeping gender and other forms of oppression as the roots of IPV, an integrative model offers flexibility in exploring multiple additional models emerging in violence research (McPhail, Busch, Kulkarni, & Rice, 2007).

Ecologic Model

An ecologic model is a useful tool when trying to understand a complex social issue like IPV. Ecologic models help make apparent the dynamic relationship between the individual and the environment. Bronfenbrenner (1979, 2005) explained how

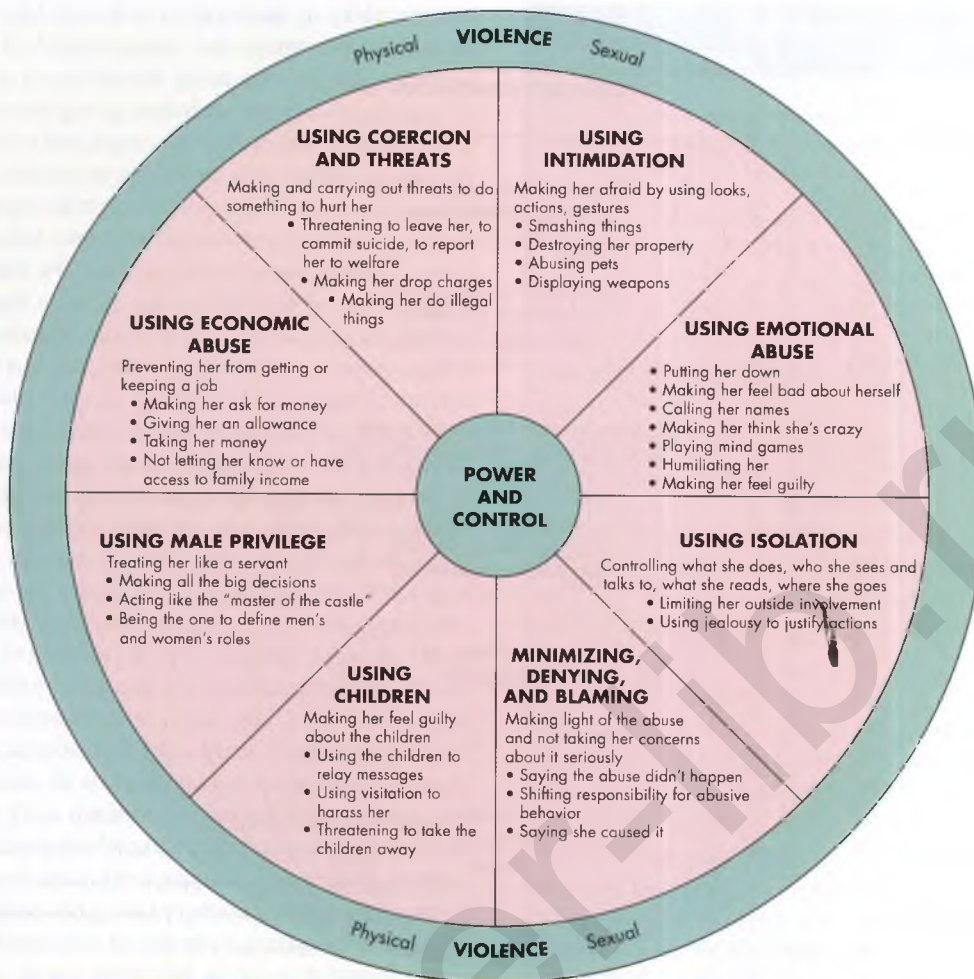

FIG 5-1 Model of how power and control issues perpetuate battering. (Developed by the Duluth Domestic Abuse Intervention Project, Duluth, MN.)

an ecologic model might explain child development. An ecologic model is sometimes drawn as nested circles that represent characteristics of the individual and the factors in that person's immediate and larger environment that influence the phenomenon of concern. The model has been adapted and used to understand a variety of health behaviors and social issues. The WHO (2010) uses an ecologic model to examine and understand various communities. Heise (1998) adapted one for IPV and Campbell, Dworkin, & Cabral (2009) developed a similar model for sexual assault.

Figure 5-2 is an ecologic model of IPV. The individual woman is at the center of the model. Her unique characteristics, such as age, life experience, race/ethnicity, social class, education, personality, emotional well-being, finances, and others influence who she is and how she is in the world. In her immediate environment is her intimate partner, his characteristics, and the characteristics of their relationship. At the next level (*microsystem*) are her children, family, friends, and the people, such as her neighbors, employer, or coworkers, and activities in her daily life that are important. Surrounding the social network are community resources such as women's groups, violence prevention programs, and local resources (*mesosystem*). The *exosystem* refers to organizations and formal agencies, health care systems, and providers such as nurses, the police, and the legal system, all of which are influenced by the larger

sociocultural beliefs, myths, and media (*macrosystem*). Finally, the *chronosystem* represents the influence of events over time.

For example, a woman (individual) experiencing IPV over time may develop chronic depression and hopelessness, finding it more difficult to mount the energy needed to change or leave the relationship. Her partner interactions may have pushed away her friends, and her emotional state makes it difficult to rebuild relationships. Perhaps her family or friends are influenced by social or cultural expectations not to interfere in someone else's marriage, express disbelief, or blame the woman (Sylaska & Edwards, 2014). The woman is socially isolated. She may hear about IPV issues from a local women's group, helping to destigmatize her perception of the issue. If she risks disclosing her experience to a nurse and receives validation and support, she may be more likely to seek help again in the future, perhaps with the health care system, or with another social agency. The nurse who interacted with the woman is also influenced by that experience in providing support to a victim of IPV. All facets of the model are influenced by one another, and those influences change over time.

Women Experiencing Intimate Partner Violence Characteristics of Women in Abusive Relationships

Every segment of society has people experiencing abuse. Race, religion, social background, age, and educational level do not

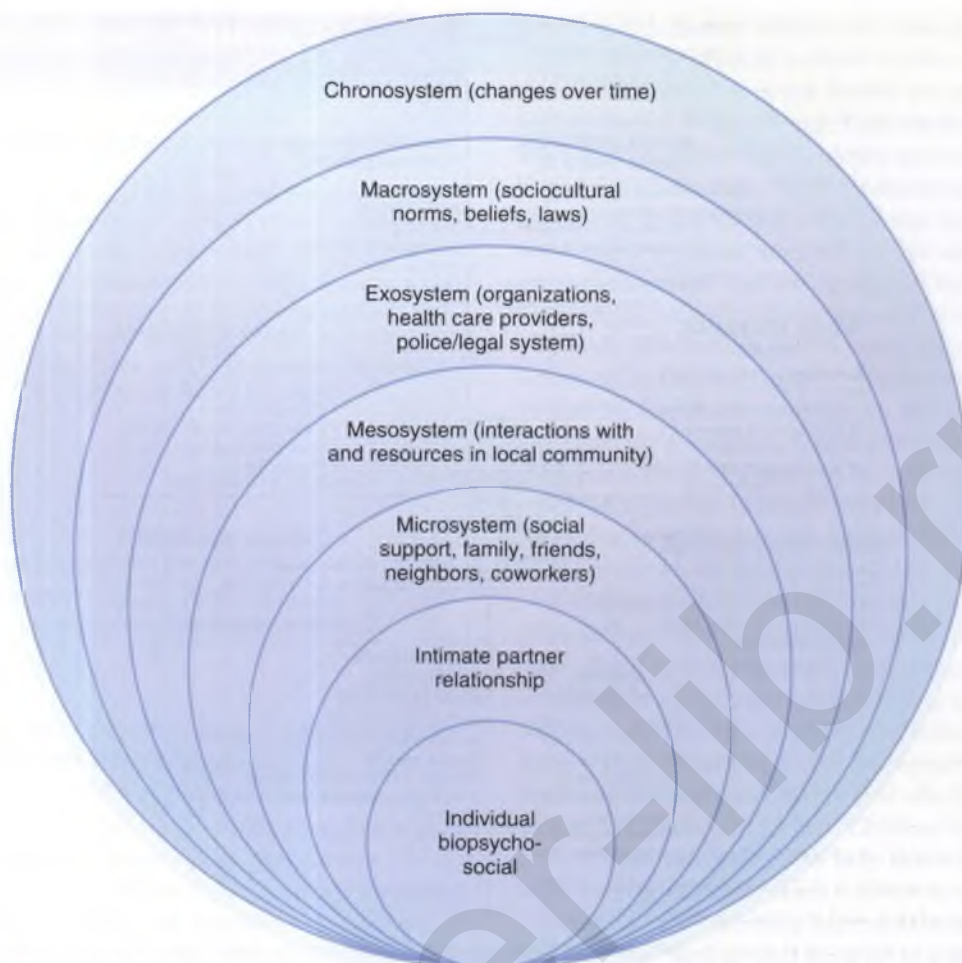

FIG 5-2 Ecologic framework for intimate partner violence. (Adapted from Bronfenbrenner, U. [1979]. *The ecology of human development: Experiments by nature and design*. Cambridge, MA: Harvard University Press; Bronfenbrenner, U. [2005]. *Making human beings human: Bioecological perspectives on human development*. Thousand Oaks, CA: Sage; Heise, L. [1998]. Violence against women: An integrated, ecological framework. *Violence Against Women*, 4(3), 262-290; Campbell, R., Dworkin, E., & Cabral, G. [2009]. An ecological model of the impact of sexual assault on women's mental health. *Trauma Violence and Abuse*, 10(3), 225-246.)

differentiate women at risk. Poor and uneducated women tend to be disproportionately represented because they are seen in EDs, are financially more dependent, have fewer resources and support systems, and may have fewer problem-solving skills. Women with educational or financial resources have been hidden from public awareness but can just as easily be victims (Thompson, Bonomi, Anderson, et al., 2006). They may be disadvantaged in other ways in that they do not fit the stereotype of an abused woman and find it difficult to come to terms with the idea that they are in an abusive relationship (Steiner, 2009). Health care providers may even dismiss this possibility.

The value women place on their social roles may have some influence in IPV. Traditional feminine characteristics such as compassion, sympathy, and yielding often result in greater tolerance of male dominance and more acceptance of partner violence. In contrast the traits of assertiveness, independence, and willingness to take a stand have been viewed as more characteristic in women who are in nonviolent relationships (Faramarzi, Esmailzadeh, & Mosavi, 2005.) There is little research that tells us how these characteristics might change if independent,

assertive women found themselves in abusive relationships. Although women who are in abusive relationships may appear passive or even helpless to an outside observer, their behaviors can represent attempts to reduce the risk of violence as they survive day to day (Dutton, 2009). It is important therefore not to attach causation to traditional feminine characteristics.

Survivors of IPV may believe they are to blame for their situations because they are “not good enough, not efficient enough, not pretty enough.” The woman may blame herself for bringing on the violent behavior in her relationship because she believes she must try harder to please the abuser. In many cases, a traumatic bonding with the man hinges on loyalty, fear, and terror. Some women have low self-esteem. Some may have histories of domestic violence in their families of origin. Often abused women are socially isolated. This may be the result of stigma, fear, restrictions placed on them by their partners, or partner behaviors that discourage others from being involved.

Based on the self-appraisal of 448 victims who filed police reports, Nurius and Macy (2008) identified five subgroups of victims. Each group varied in their feelings of vulnerability, sense of power, symptoms of depression, social relationships

with others, type and duration of exposure to violence, and physical health. The largest group was composed of women who felt vulnerable to continued abuse and had high depression scores. The second group included women struggling with depression but with a low sense of vulnerability. A third group felt vulnerable to violence or abuse but were otherwise healthy with low rates of depression and strong social relationships. The fourth group included women with multiple resources including good health, low depression scores, lower sense of being vulnerable, and high social support. The last group included women with high rates of vulnerability, physical injury, depression, and negative social relationships. Some survivors of IPV may be formally diagnosed as having PTSD if their symptoms meet the criteria in the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association [APA], 2013).

Some characteristics of PTSD sufferers include a re-experiencing of the traumatic event through dreams, flashbacks, or recollections. They also may have a distorted sense of self-blame or blame of others, become estranged from others, have diminished interest in activities, difficulty sleeping, or being aggressive, reckless, or engage in self-destructive behavior (APA, 2013).

Leaving an abusive relationship is extremely difficult and the most dangerous time because most homicides occur shortly after separation (Campbell, 2004b). Most women report IPV to at least one person in their social network, often a family member or friend. They disclose less frequently to health professionals. In a study on disclosure, women found that the most helpful reactions were emotional support, allowing the woman to talk, giving helpful advice and providing useful or practical support. Negative responses included encouraging the woman to leave the abuser, giving unhelpful advice or minimizing the problem, avoiding the victim, or showing annoyance when the woman did not leave or take advice, or being angry at the abuser (Sylaska & Edwards, 2013).

Health professionals can also become frustrated by women they see repeatedly who have numerous signs of abuse but seem unable to liberate themselves from the battering relationships. As with other human dynamics that are not easily explained, health professionals and others may rationalize the woman's behaviors to justify their own lack of involvement. A number of misconceptions are used to account for the woman's perceived self-destructive behavior. If nurses and other professionals believe these misconceptions, they may become judgmental (such as blaming the victim) or respond in unhelpful ways, rather than being empathic and empowering women to take control over their lives (Westbrook, 2009). Empowerment is built on respect for the woman. Providing supportive empathy, validation, and information that can be lifesaving is empowering behavior. Table 5-1 lists some myths and facts about IPV.

Cultural Considerations

IPV is seen in all countries, cultures, races, ethnicities, religions, and socioeconomic backgrounds (Breiding, Ziembrocki, & Black, 2009; WHO, 2013a). In the United States, Caucasian women report less IPV than do non-Caucasians. Native American and Alaska Native women report significantly more instances of IPV than do women of any other racial background; Asian women report significantly less IPV than do other racial groups (Montalvo-Liendo, 2009; Tjaden & Thoennes, 2006).

TABLE 5-1 Myths and Facts about Intimate Partner Violence

MYTHS	FACTS
Intimate partner violence (IPV) occurs in a small percentage of the population.	One fourth of all women experience IPV.
Being pregnant protects a woman from IPV.	From 4% to 8% of all women who experience violence experience it during pregnancy. IPV frequently begins or escalates in frequency and intensity during pregnancy. Pregnancy may be the result of forced sex or of the man's control of contraception.
IPV occurs only in "problem" or lower-class families.	IPV can occur in any family. Although lower-class families have a higher reported incidence of IPV, it also occurs in middle- and upper-income families. Incidence is not really known because of the tendency of middle- and upper-income families to hide their IPV.
IPV women like to be beaten and deliberately provoke the attack. They are masochistic.	Women are terrified of their assailants and go to great lengths to avoid a confrontation. In some cases the woman may provoke her partner to release tension that if left unchecked might lead to a more severe beating and possible death.
Only men with psychological problems abuse women.	Many batterers are successful professionals, including politicians, ministers, physicians, and lawyers. Research indicates that only a small number of abusers have psychological problems.
Only people who come from abusive families end up in abusive relationships.	Most abused women report that their partner was the first person to abuse them.
Alcohol and drug abuse cause IPV.	Although alcohol may be involved in abusive incidents, it is not the cause. Many batterers use alcohol as an excuse to be violent, and shift the blame to the alcohol.
Women would leave the relationship if the abuse were really that bad.	Those women who stay in the relationship do so out of fear and financial dependence. Shelters have long waiting lists.
Victims and perpetrators of IPV cannot change.	Counseling may effectively help both victims and abusers of women.

Data from Gelles, R. (1997). *Intimate violence in families* (3rd ed.). Thousand Oaks, CA: Sage; National Institute on Alcohol Abuse and Alcoholism. (1997). Alcohol, violence, and aggression. *Alcohol Alert*, 38, 1-6; Office of Women's Health, U.S. Department of Health and Human Services. (2011). *Violence against women*. Available at www.womenshealth.gov/violence-against-women/index.html

Reporting rates may not reflect the magnitude of the problem because many women do not disclose violence out of fear or embarrassment or because they are not asked about IPV by their health care providers.

Since 1994 there has been a growing official acknowledgment of IPV across the globe. In 1994 the United States enacted the Violence Against Women Act (VAWA), followed by Guatemala and El Salvador in 1996, China in 1997, Colombia in 2000, and Japan in 2001. Mexico passed its first law in 2007 (Montalvo-Liendo, 2009). Women from almost all cultures identify fear as a common factor in IPV.

An important cultural consideration relates to refugees and immigrants. Immigrant women face unique challenges related

to their noncitizen status as well as their unfamiliarity with the health care and legal systems. The objectification of women and power inequalities in human social arrangements support the abuse of women. These are especially apparent in any social or cultural system of oppression. The cross-cultural meaning of violence is difficult to ascertain because cultures also differ in their perceptions and definitions of abuse. Finding accurate data about the incidence and prevalence of violence in ethnic groups has been challenging because the groups are infrequently represented in research studies, and violence may be underreported as a result of cultural norms. For example, groups that distrust police or immigration officials may not report abuse because they fear repercussions.

Nurses must be sensitive to immigrant women and their intimate partners because acculturation is gradual, and cultural expectations from their birth countries may heavily influence beliefs and behaviors. Nurses must consider all forces that shape a woman's identity—ethnicity, race, class, language, citizenship, religion, and culture—while recognizing that abuse is against the law and injurious to the health and well-being of women and children (and men). Becoming familiar with the client's cultural influences and increasing the numbers of nurses from various ethnic groups will increase the opportunity to provide culturally appropriate care. The following paragraphs describe some of the cultural variations, but this must be understood with caution in that not all members of a cultural group conform to the general norms of that group. In other words, it is important to understand and respect cultural differences, while also recognizing that there can be individual variation within a group.

African-American Culture. The African-American culture supports unity among humans, nature, and the spiritual world, and social connectedness and relatedness as important norms. African-American men are more likely to be psychologically, socially, and economically oppressed and discriminated against. Violence may occur more frequently as a result of anger generated by environmental stresses and limited resources (Campbell, D., Sharps, Gary, et al., 2002). Respondents to the NISVS reported 43.7% lifetime prevalence of rape, physical violence, and/or stalking by an intimate partner (Black, Basile, & Breiding, et al., 2011). The devalued status of the female survivor, racial stereotype, and fear of putting another African-American man in jail, may be barriers to African-American women seeking and receiving help (Morrison, Luchok, Richter, & Parra-Medina, 2006). In a study of 431 women of African descent, the severity of abuse was significantly associated with mental health problems but not associated with the use of mental health services (Sabri, Bolyard, McFadgion, et al., 2013).

Hispanic (and Latino) Cultures. Hispanic (or Latino) describes someone whose country of origin is Mexico, the largest group at 63%, followed by Puerto Rico, Cuba, Spanish-speaking Central and South American countries, or other Spanish cultures (U.S. Census Bureau, 2011). Thus Hispanics range from newly immigrated and strongly influenced by their native culture to second-generation or later Americans steeped in U.S. popular culture. It is difficult to generalize on culture among these groups. When data are collected, Americans who are of Hispanic descent may be grouped with those born in other countries. Despite the rapidly changing

Hispanic population in the United States there have been few studies of IPV differences based on Hispanic country of origin (Cummings, Gonzalez-Guarda, & Sandoval, 2013; Kantor, Jasinski, & Aldarondo, 1994). In a study of South and Central American women, Colombian women reported less IPV than other Central or South American countries (Gonzalez-Guarda, Vermeesch, Florom-Smith, et al., 2013).

Hispanics as a group are described as family oriented with a strong family network in which unity, cooperation, respect, and loyalty are important. Traditional families, as with most immigrant groups, are very hierarchic, with authority often given to older adults, parents, and men. Sex roles are clearly delineated. Employment, higher income, being retired, and marriage are consistently found to be protective factors against IPV in Hispanics (Caetano, Ramisetty-Mikler, & Harris, 2010). Hispanics in the United States have been found to have a slightly higher prevalence of IPV (37%) than non-Hispanic white women (34.6%) (Black et al., 2011). In one study, researchers found that they had significantly more mental health issues than non-Hispanic women who experienced IPV (Bonomi, Anderson, Cannon, et al., 2009). Another difference is in the characteristics of the abusive relationship. In one study the partners of Hispanic women were more likely to have alcohol problems and to force sex but less likely to own a gun, use illegal drugs, or threaten suicide than non-Hispanics in abusive relationships (Glass, Perrin, Hanson, et al., 2009).

Native American Culture. Empiric evidence about abuse in the Native American culture is limited (Duran, Oetzel, Parker, et al., 2009). Native American and Alaska Native women report the highest rates of IPV in the United States with the prevalence of physical violence by an intimate partner at 46%. Rape and stalking were not reported by this group (Black et al., 2011). Research indicates the IPV occurs within the context of complex racial and unique sociocultural factors. Oetzel and Duran (2004) proposed an ecologic framework to guide health care providers in understanding the causes and possible areas for intervention with Native Americans and Alaska Natives.

Asian Culture. Asian women in the United States have the lowest prevalence of IPV at 19.6% (Black et al., 2011). In contrast, the international rates are significantly higher. The prevalence of IPV in Southeast Asia is the highest in the world at 37.7% (WHO, 2013a). It is likely that the lower rate is a function of underreporting. One challenge in the United States is that Asian women are often artificially grouped into one homogeneous group despite their vast and varied cultures. The reasons for not disclosing IPV vary across cultures. Women from South Asia, including Afghanistan, Bangladesh, Bhutan, Sri Lanka, India, the Maldives, Nepal, and Pakistan, were reported to be worried about immigrant laws, were concerned about family honor, and believed that men had the right to abuse. Urban women from Bangladesh were fearful of being killed, felt helpless, and were worried about community retaliation and judgment (Naved, Azim, Bhuiya, & Persson, 2006). Jordanian women expressed fear, shame, religious beliefs, and lack of social support as reasons for not disclosing. The majority of Jordanian men and women deny the problem of wife abuse and oppose discussions of it in society, a reflection of this patriarchal society (Btoush & Haj-Yahia, 2008). Chinese women reported they were worried that

they would be criticized and were fearful of not saving face and disappointing relatives. Japanese women reported feeling shame, fearful of escalating violence, and victim blaming (Yoshihama, 2002). Vietnamese women put the needs of the family before their individual needs and kept the woman's role subordinate to men to maintain harmony in the family (Shiu-Thornton, Senturia, & Sullivan, 2005).

Intimate Partner Violence During Pregnancy

IPV has serious consequences for the health of the mother and fetus. The prevalence of IPV during pregnancy is unclear, but the CDC (2012) estimates that 324,000 pregnant women experience it annually and may be more common than the conditions for which pregnant women are normally screened, such as gestational diabetes and preeclampsia. Daoud, Urquia, O'Campo, et al., (2012) estimated that there was a prevalence of 6% of abuse in pregnant women. Women who are abused before pregnancy may continue to be abused during the pregnancy.

Some clinicians believe that abuse may begin or escalate with pregnancy, but some studies suggest that both lethal and non-lethal abuse can actually decrease during pregnancy in some couples (Taylor & Nabors, 2009). In a small longitudinal study, Macy, Martin, Kupper, Casanueva, & Guo (2007) found that rates of physical abuse among women with a history of recent abuse peaked during the first 3 months of pregnancy, then declined, whereas women without a recent history of abuse had low rates of abuse during pregnancy. Thus pregnancy may be protective for some women. In the same study, rates of psychological abuse were highest in the first month after the birth, as was sexual abuse. Rates of IPV in pregnancy vary by country, from 1% in Japan to 28% in Peru (WHO, 2011).

It is clear that IPV has negative effects on pregnancy. Maternal complications of depression, suicide, low weight gain, infections, and substance abuse have been related to being in an abusive relationship (Campbell, J., Jones, Dienemann, et al., 2002; Plichta, 2004). GI symptoms may occur from chronic stress, as may hypertension and chest pain. Other conditions are gynecologic problems such as STIs, bleeding, UTIs, chronic pelvic pain, and genital trauma. A history of abuse prior to the pregnancy is associated with a higher risk of postpartum depression (Records & Rice, 2009).

Homicide is the leading cause of trauma death in pregnancy and postpartum (Chang, Berg, Saltzman, & Herndon, 2005; Horon & Cheng, 2005). Estimates are that 16% to 66% of pregnancy-related murders are by intimate partners. IPV may be a risk factor for suicide attempts in pregnancy (Martin, Macy, Sullivan, & Magee, 2007).

Not only is physical abuse harmful to the mother, the risk of fetal injury also is very high. Trauma can result in low birth weight, preterm birth, fetal demise, premature separation of placenta, hemorrhage, infections, and other injuries (Morland, Leskin, Block, et al., 2008; Shah & Shah, 2010). Higher rates of IPV at 6 months postpartum have been associated with more depression in mothers at 15 months and subsequent harsh parenting at 24 months (Gustafsson & Cox, 2012).

Pregnant adolescents may be abused at higher rates than adult women, so they should be considered at higher risk. There is a greater likelihood of unintended pregnancy in adolescents

who often delay prenatal care (Plichta, 2004). Physical abuse and pregnancy in teenagers constitute a particularly difficult situation. Adolescents may be more trapped in the abusive relationship than adult women because of their inexperience. They may ignore the violence because the jealous and controlling behavior is interpreted as love and devotion. Because pregnancy in adolescent girls is frequently the result of sexual abuse, feelings about the pregnancy should be assessed. Teens report abuse from partners, former partners, and family members (Renker, 2002). Many who had been abused throughout the pregnancy also were abused afterward, and others who were not abused during pregnancy reported initial abuse after giving birth (Harrykissoon, Rickert, & Wiemann, 2002). Adolescents have been found to be at very high risk for abuse in the postpartum period. Quinlivan and Evans (2005) found that IPV and drug abuse in adolescents affected maternal attachment and infant temperament.

CARE MANAGEMENT

The nurse has an important role in assisting victims and survivors of IPV. Preparation for that role begins with the nurse's own self-assessment. Dienemann, Glass, & Hyman (2005) found that women want health care providers who provide documentation, protection, and immediate response; give options; and be there for the survivor later. They also want to be treated with respect and concern. An exploration of attitudes toward women in abusive situations, awareness of thoughts and emotions that can lead to unhelpful communication, and knowledge about the many aspects of IPV are preparations for care. One challenge for health care providers such as nurses is the tension between wanting to make things better and the reality that IPV is complex and not easily fixed (Williston & Lafreniere, 2013).

Exactly what drives a woman to seek assistance is not clear. Women who belong to any of the following three groups are more likely to seek assistance: (1) those who are beaten frequently and severely; (2) those who have not experienced or witnessed family violence in their family of origin; and (3) those who see an alternative to life in an abusive relationship, specifically women with jobs. Sometimes women seek help after their children have been hurt or when their children start imitating the abuser's behavior.

Women experiencing IPV may be reluctant to seek help for various reasons, including the need to avoid the stigma associated with the nature of the family violence; the fear that they will not be believed; the fear of reprisal from their husbands or partners; and in some states in which battering is a reportable crime, the desire to avoid involvement with police.

Assessment

Clients in any women's health care setting may be at risk for abuse. Nurses are encouraged to assess for abuse in all women entering the health care system (McFarlane, Campbell, Sharps, & Watson, 2002). Health care providers may be the first and only contact that a socially isolated woman makes with someone outside the relationship (ACOG, 2012). Failure to identify IPV and to recognize the risk of serious injury or even death further endangers the lives of women and their children.

LEGAL TIP: Mandatory Reporting of Domestic Violence

Domestic violence is considered a crime in all states, but it varies between being categorized a misdemeanor and a felony, the majority calling it a misdemeanor. Mandatory reporting of domestic violence is controversial. Mandatory reporting is considered appropriate in child abuse because a minor is unable to make an informed decision about his or her own safety. In domestic violence situations involving adults, mandatory reporting takes away a woman's right to make informed decisions and may put her in danger. The Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) and the American College of Obstetricians and Gynecologists (ACOG) oppose mandatory reporting (ACOG, 2012; AWHONN Board of Directors, 2007). Few states have mandatory reporting for domestic violence of any kind. Forty states and the District of Columbia have laws that mandate reporting by health care providers only in situations in which the woman has an injury that may be caused by a deadly weapon. Some states also require reports when there is a reason to believe that the woman's injury may have resulted from an illegal act or an act of violence. California has the strongest reporting law. Colorado, New Mexico, and Kentucky mandate that health care providers report injuries resulting from IPV to law enforcement or public welfare. Ohio mandates that IPV be documented in the medical record. Rhode Island requires that domestic violence injuries be reported for statistical purposes only. Texas mandates that IPV be documented and that clients be informed that IPV is against the law and be offered shelter referral.

Because of the wide variation from state to state in mandatory reporting, nurses must be knowledgeable about the reporting requirements of the state in which they practice. The website www.futureswithoutviolence.org can be a useful resource for nurses.

A woman suspected of being emotionally abused or physically threatened or abused should be examined and interviewed in private. Some women with male partners may feel safer with a female health care provider. Nurses should *never* ask about abuse with a partner present because this may place the woman in danger and decrease the likelihood for disclosure. When one is taking a psychosocial history, the following information provides clues to violence or potential for violence: does the woman feel safe at home with her partner, how do the woman and her partner resolve conflict, what happens when the woman's partner becomes angry, does fighting occur during disagreements, and if fighting occurs, does it ever escalate to restraining or physical means. It may help the woman to disclose information if these events are normalized by the nurse stating, "Many people [families] have difficulty in expressing anger or dealing with conflict. What is that like for you and your partner?" The nurse listens for any evidence of power and control in the relationship. While inquiring about abuse, trauma, or injuries, the nurse should ask directly if the woman has been injured by her husband or intimate partner. Have you ever been physically abused by your partner or someone important to you? Confusion can occur when vague terms like "he disrespects me" or even labels like "domestic violence" or "abuse" are used. The following are examples of direct questions the nurse can ask:

- Has your partner hit, slapped, kicked, or otherwise hurt you?
- Do you (or did you) feel controlled or isolated by your partner?

- Do you feel safe in your relationship? Do you ever feel afraid of your partner?

- Has your partner or anyone forced you to have sexual activities that made you uncomfortable?

Women who are safe in a current relationship may still carry the physical and emotional consequences of previous trauma.

- Has any of this happened to you in previous relationships?

These questions give a woman permission to disclose sensitive information (Chamberlain & Levenson, 2010).

The Center for Research on Women with Disabilities (2002) recommends the following additional questions for women with disabilities:

- Has anyone ever prevented you from using a wheelchair, cane, or other devices you need?

- Has your partner refused to help you or threatened to not help you with important personal needs like taking medicine, getting dressed, getting food, or other personal needs?

Assessment tools such as the one in Figure 4-10 in Chapter 4 give the nurse useful information and are an important part of the interview. Patterns of violence in relationships can change over time and reports show an increase in the identification of victims of domestic violence when the nurse inquires at each visit whether a woman has been hit or threatened since her last visit (Macy et al., 2007; Walton-Moss & Campbell, 2002). Cues to abuse are delay in seeking medical assistance (hours or days), missed appointments, vague explanation of injuries, nonspecific somatic complaints, social isolation, lack of eye contact, a husband or partner who does not want to leave the woman alone with the primary health care provider, and substance abuse.

For some abused women, day-to-day survival is exhausting. They may cope by denying to the nurse the probabilities of impending abuse, severity of injury, future recurrence, and death. Women may be embarrassed about their abusive relationships and believe the abuse is caused by their inadequacies. Other abused women may cope by denying to themselves that their partner's violent behavior will happen again. By asking a woman directly about abuse, telling her that similar injuries are common in women who have been abused, and pointing out that she is not responsible for another's violent behavior, the nurse may help her to disclose the violence she is experiencing.

In the United States a pregnant woman may be accompanied by her husband to the antepartum appointment. This is especially true if the woman does not speak English and the husband does. The use of an interpreter is preferred over the partner, child, or other person accompanying the woman; it may be useful for the interpreter to be a woman and important that the interpreter communicate the nurse's sensitivity and concern accurately. All women should be seen for some part of the visit without the partner or children present.

During pregnancy the nurse should assess for abuse at each prenatal visit and on admission to labor, although it is not appropriate to ask questions during active labor. Assessment for abuse continues after birth because abuse may begin or escalate then; well-baby clinics and pediatric settings may be important settings for screening women for abuse (Cruz, Cruz, Weirich, et al., 2013; Martin, Macy, Sullivan, & Magee, 2007).

Assessment techniques are straightforward but do require the nurse to be comfortable asking about this socially stigmatized issue. Of utmost importance for women who disclose that they are experiencing or have experienced IPV (or sexual assault, another hidden trauma) is to validate that they have been heard. The nurse might say something like, “What you have just told me is very important, I’m glad you have shared this with me; no one has the right to hurt you this way.” It can be demoralizing when, despite taking the risk to disclose, the health care provider does not acknowledge the importance of what has just been said. The next important step is to establish the woman’s safety at the moment and in the future. Psychosocial assessment findings may indicate symptoms of anxiety, insomnia, self-directed abuse, depression, smoking, and drug or alcohol abuse (Downs & Rindels, 2004; Gerber, Gantz, Lichter, et al., 2005; WHO, 2013b). During the physical examination, the woman should be observed for injuries to the face, breasts, abdomen, and buttocks. These injuries may be old or new and may range from minor bruising to serious. Other physical signs include fractures that required significant force or that would rarely occur by accident; multiple injuries at various stages of healing; and patterns left by whatever might inflict injury, such as teeth, utensils, fists, or hot objects.

Nursing Interventions

A therapeutic relationship and skillful interviewing help women disclose and describe their abuse. Language is important when talking with women. A major factor in addressing abuse is to identify the woman as a survivor, not a victim. Victim connotes someone who is harmed, is made to suffer, and may have little or no control. Survivor is an empowering term that connotes coping and decision making in relation to taking control of one’s life. The nurse might ask the woman how she sees herself. Women who have identified their abuse may appear passive, hostile, anxious, depressed, or hysterical because they may think they are at the mercy of the man’s temper. In addition, they may be embarrassed, afraid, angry, sad, or shocked. Transitioning to a different self-image takes time, persistence, and support. A tool that provides a framework for sensitive nursing interventions is the *ABCDES* of caring for the abused woman (Campbell & Furniss, 2002):

- **A** is reassuring the woman that she is not *alone*. The isolation and denigration by the abuser keep her from knowing that others are in the same situation and that health care providers can help.
- **B** is expressing the *belief* that violence against the woman is not acceptable in any situation and that it is not her fault; no one deserves to be hurt or mistreated. This may be the first step in empowering her to think about self-protection and acceptable boundaries.
- **C** is *confidentiality* of the information being shared, particularly because the woman may believe that if the abuse is reported, the perpetrator will retaliate (and in reality, this may happen). Explain the mandatory reporting laws, when applicable.
- **D** is for descriptive *documentation* and includes the following: (1) the woman’s quoted statement, “My husband punched me,” a clear statement by the woman about

the abuse. It should not include her subjective opinion, such as “I provoked the abusive behavior”; (2) accurate descriptions of injuries and a history of the first, worst, and most recent incident of violence may be included; and (3) with the woman’s consent, evidence, or photographs (Box 5-2).

- **E** is for *education*, especially that violence is likely to recur and escalate. Education about options including community resources such as where a woman can be referred for help and information about local shelters; for example, National Domestic Violence/Abuse Hotline—800-799-SAFE. Ask if she knows how to obtain a restraining order.
- **S** is for *safety*, the most significant part of the intervention because one of the most dangerous times for a woman is when she decides to leave. Tell the woman to call 911 if she is in imminent danger, and to consider alerting neighbors to call the police if they hear or see signs of conflict. A safety plan should be developed. The safety plan will be adapted based on whether the woman chooses to stay in the relationship or leave. The woman may be conflicted and need support as she goes through a decision-making process (Glass, Eden, Bloom, & Perrin, 2009). The woman can be offered a telephone to call the shelter if she chooses. If she chooses to go back to the abuser, a safety plan includes necessities for a quick escape: a bag packed with personal items for an overnight stay (can be hidden or left with a neighbor), money or a checkbook, an extra set of car keys, and any legal documents to use for identification. Legal

BOX 5-2 Documenting Abuse

Documentation can be useful to women later in court should they choose to press charges or obtain child support, custody, or alimony. Medical records are most helpful if the examiner:

- Takes photographs of the injuries known or believed to have been caused by domestic violence
- Writes clearly
- Sets off the woman’s words in quotation marks and uses such phrases as “client states” to indicate the information recorded reflected the woman’s words. Describes the offender and the event in the words of the woman, for example, the client said, “My husband kicked me in the stomach.”
- Avoids such legalistic phrases as “woman claims” or “woman alleges” that cast doubt about the truth of the statements. Avoids terms such as “alleged perpetrator.” If the health care provider’s observations differ from the woman’s account of the victimization, states the reason for the difference.
- Does not summarize a client’s report in conclusive terms that lack the supporting factual information, for example, “the client is a battered woman” because it will render the report inadmissible. In the same theme, does not place the term “domestic violence” in the diagnosis section of the medical record because it does not convey factual information and is not medical terminology.
- Describes the woman’s demeanor, whether she is crying, shaking, angry, calm, laughing, or sad, even if it belies the evidence of abuse
- Records the time of day of the examination and indicates whenever possible how much time has passed since the abuse

 **NURSING CARE PLAN**
The Woman Experiencing Intimate Partner Violence

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Risk for Self-Directed Violence related to history of abuse by partner as evidenced by physical injuries</i>	Woman will identify dynamics of violence in her unique relationship and develop plan for safety	Provide opportunity to verbalize feelings in a nonthreatening atmosphere. Be alert for cues indicative of abuse. Provide information on options available to women experiencing intimate partner violence (IPV) (e.g., counseling, shelters, legal assistance). Refer to social services and support groups.	To give emotional support To provide database for interventions To provide information in developing a plan for safety for herself and any children
<i>Social Isolation related to stigma of abuse as evidenced by behaviors of withdrawal</i>	Woman will demonstrate an increase in social contacts	Provide private opportunity to express feelings of aloneness. Support opportunities for social interaction. Encourage interaction with groups for socialization and support.	To give further information and share experiences To initiate and maintain a therapeutic relationship To increase feelings of self-worth and self-confidence To increase number of social contacts
<i>Compromised Family Coping related to situational crisis</i>	Family will identify feelings and the need for support during this situational crisis	Provide an appropriate time and place for therapeutic communication. Identify effective coping mechanisms. List support systems available. Refer the woman and family to counseling and social services.	To promote trust and allow expression of feelings To provide the family with a foundation of familiar interventions To assist the family to use outside resources To provide ongoing support

options, such as those for restraining orders or arrest of the perpetrator, also are important aspects of the safety plan. A restraining order can be obtained 24 hours a day from the county court or police department. Many communities have battered women's hotlines where they can get counseling. Pennell and Francis (2005) identified safety conferencing as a means of building the individual and collective strength to assist women to reshape connections, make sound choices, and promote their safety (see Nursing Care Plan).

One part of safety planning is trying to sort out the potential danger in a relationship. A validated danger assessment tool (Fig. 5-3) was designed to assess the level of violence in a relationship and to identify abused women who are at risk of being murdered (Campbell, 2004a; Campbell, Webster, & Glass, 2009). The nurse and the abused woman can go through the tool collaboratively. Online training and permission to use the tool are available at www.dangerassessment.com.

If the woman is pregnant, collaboration with maternity nurses who will be involved in her care during the pregnancy may be helpful. Each nurse can plan care that will point out the woman's strengths and increase her self-esteem. The husband or partner may attend prenatal visits and classes and is included in other ways if the woman chooses to stay with him. The first days after birth are particularly crucial because

the mother is physically and emotionally vulnerable and usually tired, and the baby's crying may be intolerable to both the father and the mother. The danger of abuse to mother and child is acute during this time. Facilitating the woman's establishment of a support network of maternity and pediatric staff, community health nurses, and shelter and parental crisis center personnel is important during this crucial period. Referral to resources and provision for follow-up examination by health care providers also should be part of the nursing intervention.

Nurses sometimes become frustrated when a woman returns to a previously abusive situation (Davis, Park, Kaups, et al., 2003; Williston & Lafreniere, 2013). It is important to remember that many women have been abused for a long time, which may make it difficult for them to seek and accept help. Women in repeatedly abusive situations may have lost their ability to perceive the possibility of success and may have become very passive. In addition to understanding the many reasons women stay in abusive relationships, recognizing that the most dangerous period for a woman is when she is in the process of leaving may help nurses to be less judgmental about the woman's dilemma.

A woman may indicate her readiness to leave the relationship when she believes that she is capable of planning for herself, investing in herself, and recognizing that the abuse is part

DANGER ASSESSMENT

Jacquelyn C. Campbell, Ph.D., R.N.
Copyright, 2003; www.dangerassessment.com

Several risk factors have been associated with increased risk of homicides (murders) of women and men in violent relationships. We cannot predict what will happen in your case, but we would like you to be aware of the danger of homicide in situations of abuse and for you to see how many of the risk factors apply to your situation.

Using a calendar, please mark the approximate dates during the past year when you were abused by your partner or ex-partner. Write on that date how bad the incident was according to the following scale:

1. Slapping, pushing; no injuries and/or lasting pain
2. Punching, kicking; bruises, cuts, and/or continuing pain
3. "Beating up"; severe contusions, burns, broken bones
4. Threat to use weapon; head injury, internal injury, permanent injury
5. Use of weapon; wounds from weapon

(If **any** of the descriptions for the higher number apply, use the higher number.)

Mark **Yes** or **No** for each of the following. ("He" refers to your husband, partner, ex-husband, ex-partner, or whoever is currently physically hurting you.)

- _____ 1. Has the physical violence increased in severity or frequency over the past year?
 - _____ 2. Does he own a gun?
 - _____ 3. Have you left him after living together during the past year?
3a. (If you have *never* lived with him, check here _____)
 - _____ 4. Is he unemployed?
 - _____ 5. Has he ever used a weapon against you or threatened you with a lethal weapon?
(If yes, was the weapon a gun? _____)
 - _____ 6. Does he threaten to kill you?
 - _____ 7. Has he avoided being arrested for domestic violence?
 - _____ 8. Do you have a child that is not his?
 - _____ 9. Has he ever forced you to have sex when you did not wish to do so?
 - _____ 10. Does he ever try to choke you?
 - _____ 11. Does he use illegal drugs? By drugs, I mean "uppers" or amphetamines, "meth", speed, angel dust, cocaine, "crack", street drugs or mixtures.
 - _____ 12. Is he an alcoholic or problem drinker?
 - _____ 13. Does he control most or all of your daily activities? For instance: does he tell you who you can be friends with, when you can see your family, how much money you can use, or when you can take the car? (If he tries, but you do not let him, check here: _____)
 - _____ 14. Is he violently and constantly jealous of you? (For instance, does he say "If I can't have you, no one can.")
 - _____ 15. Have you ever been beaten by him while you were pregnant? (If you have never been pregnant by him, check here: _____)
 - _____ 16. Has he ever threatened or tried to commit suicide?
 - _____ 17. Does he threaten to harm your children?
 - _____ 18. Do you believe he is capable of killing you?
 - _____ 19. Does he follow or spy on you, leave threatening notes or messages on answering machine, destroy your property, or call you when you don't want him to?
 - _____ 20. Have you ever threatened or tried to commit suicide?
- _____ Total "Yes" Answers

Thank you. Please talk to your nurse, advocate or counselor about what the Danger Assessment means in terms of your situation.

FIG 5-3 Danger assessment tool. (From Campbell, J. [2004]. *Danger assessment*. Available at www.dangerassessment.org; Campbell, J., Webster, D., & Glass, N. [2009]. The danger assessment: Validation of a lethality risk assessment instrument for intimate partner femicide. *Journal of Interpersonal Violence*, 24(4), 653-674.)

of a continuing pattern. She also needs to believe that she will have economic and other resources to "make it" on her own. Going to a shelter may be an option; however, shelter stays are typically limited to 30 to 90 days, and therefore a long-term plan must be in place. Also, her being in a shelter may make the

husband or partner angrier. Nurses can be helpful in directing women to sources of information, continuing to be expert listeners, and offering encouragement as women struggle in their decision-making process toward freedom and control in their lives.

Prevention

Screening is a common approach to preventing the progression of health problems. Currently because research is limited and screening studies were not paired with interventions, there is insufficient evidence to say that universal screening prevents further incidents of IPV in asymptomatic women (ACOG, 2012; MacMillan, Wathen, Jamieson, et al., 2009; Moyer & Force, 2013; WHO, 2013a). Nevertheless, major health care organizations including the U.S. Preventive Services Task Force recommend universal screening of all women (ACOG, 2012; Moyer & Force). Screening alone is not enough, but assessment with adequate intervention can be useful in improving outcomes (Klevens & Saltzman, 2009). Because IPV has been linked to many other health problems such as headaches, GI problems, chronic pain, arthritis, STIs, pelvic pain, substance abuse, depression, PTSD and suicide, women with any of these symptoms should be carefully assessed.

Nurses can make a difference in stopping the violence and preventing further injury. Educating women that abuse is a violation of their rights and facilitating their access to protective and legal services constitute a first step. Other measures that may help women to discourage the risk of abusive relationships are promoting assertiveness and self-defense courses; suggesting support and self-help groups that encourage positive self-regard, confidence, and empowerment; and recommending educational and skills development classes that will enhance independence or at least the ability to take care of oneself (Pennell & Francis, 2005). Classes for learning English can be particularly helpful to immigrant women. Nurses can offer information on local classes. Preventive education with children encourages and teaches them androgynous gender roles: men and women are equal; both can be nurturing; and neither needs to dominate the other or to engage in violent behavior to have needs met. Helping children to gain problem-solving and conflict management skills may eliminate the need for violent solutions to life stresses. Encouraging schoolchildren to form Students Against Violence Everywhere (SAVE) groups (<http://nationalsave.org>), which is a nationwide pro-peace effort that promotes justice, respect, and love, gives them an appreciation for these qualities in all facets of life. Adolescents benefit from discussion about sex roles, their relationships, and the consequences of the "macho" concept. School nurses can be instrumental in developing and implementing informational activities for adolescents (Walton-Moss & Campbell, 2002). Other means of prevention are to advocate against violence in all arenas and to participate actively in promoting legislation and policies toward stopping violent acts.

SEXUAL VIOLENCE

Sexual violence is a broad term that encompasses a wide range of sexual victimization including sexual harassment, sexual assault, and rape. *Sexual harassment* includes unwelcome degrading sexual remarks, contact, or behavior such as exhibitionism that makes the work or other environment uncomfortable or difficult. **Sexual assault** refers to intentional unwanted completed or attempted touching of the victim's genitals, anus, groin, or breasts, directly or through clothing as well as by voyeurism (Basile, Chen, Black, & Saltzman, 2007). It also includes

exhibitionism, exposing someone to pornography, or displays of images taken of the victim in a private context (CDC, 2014).

Rape is a legal term that is defined differently by each state. It usually refers to forced sexual intercourse or penetration of the mouth, anus, or vagina by a body part or object without consent; it may or may not include the use of a weapon. It involves the use of force, threats, or a victim who is incapable of giving consent. The term is a legal and not a medical one. *Molestation* consists of noncoital sexual activity between a child and an adolescent or adult. *Statutory rape* involves penetration as described above by a person who is 18 years or older of a person younger than the age of consent, and the specifics vary from state to state.

The National Intimate Partner and Sexual Violence Survey reported almost 1 of 5 women experienced rape at some time in their lives, and about 1 in 20 women experienced sexual assault other than rape (Black et al., 2011). Based on another national survey of 5000 women, researchers estimated that more than 1 million women from diverse ethnic and social backgrounds are raped each year in the United States (Kilpatrick, Resnick, Ruggiero, et al., 2007). McCauley, Amstadter, Danielson, et al. (2009) reported that almost one third of all sexual assault victims were adolescents when the assault occurred. Rape may occur within intimate, casual, or work relationships. Rapists may be intimate partners or spouses. They may be family members or acquaintances such as friends, neighbors, or dates. Or they may be strangers, police, prison guards, or soldiers. Rape occurs in the general population, in institutional settings such as colleges, in the military, and in prisons.

Why Do Some Men Rape?

Multiple theories exist on the causes of sexual violence from the perspective of the perpetrator (Stinson, Sales, Becker, & American Psychological Association, 2008). Some risk factors for perpetrators include having themselves been sexually abused in childhood; seeing women as sex objects and viewing them negatively, with hostility, or as dangerous; supporting beliefs that justify rape such as male entitlement to sex or that a woman is asking or deserving to be raped because she dresses provocatively. Some perpetrators are conditioned to become aroused to forced sexual violence. Using violent pornography may normalize preexisting sexually aggressive impulses (Casey & Lindhorst, 2009).

Acquaintance rape involves persons who know one another such as friend, neighbor, family member, classmate, date, or acquaintance. If there is a relationship, then trust is violated. Victims may fear retaliation from the assailant or harassment from family or friends who know the person (Rape, Abuse, and Incest National Network [RAINN], 2009).

Stranger rape is the least common type of rape. The assailant may be a total stranger who suddenly attacks the victim in a public place or in the home. Other stranger rapes occur when the assailant has brief contact with the victim prior to the assault, for example, engaging the victim in conversation to earn trust at a bar or party. Women are more likely to report stranger rape than acquaintance rape (Jones, Wynn, Kroeze, et al., 2004).

Sexual assault and rape are considered forcible when there is threat or actual use of force on an unwilling victim. An incapacitated sexual assault or rape occurs when the victim is under

(spying on people engaged in intimate behavior)

the influence of alcohol or drugs, rendering the person unconscious or otherwise unable to give consent. Estimates are that more than half of rapes involve alcohol—as many as half of reported rapes are either drug facilitated or the result of self-induced intoxication. Alcohol is the most common drug associated with sexual assault (Hindmarch, El Sohly, Gambles, & Salamone, 2001; McCauley, Kilpatrick, Walsh, & Resnick, 2013). Alcohol makes it more difficult for women to identify potentially dangerous situations and to resist unwanted sexual advances. A drug-facilitated sexual assault occurs when alcohol and/or drugs are taken unwillingly or unknowingly. The use of date rape drugs such as flunitrazepam (Rohypnol, or “roofies”), gamma-hydroxybutyrate (GHB), ketamine, and carisoprodol (Soma) incapacitate the victim and may produce amnesia. These drugs are potentiated by alcohol, and the combination can be lethal. The frequency with which these drugs are used can be underestimated because they are rapidly excreted, and lab testing has to be done within a few hours of ingestion (Crawford, Wright, & Birchmeier, 2008). Signs indicating that a woman may have been drugged include having no recall after taking a drink laced with the drug, feeling as if sex has occurred but not having any memory of the incident, feeling more intoxicated than what would be a usual response to the amount of alcohol consumed, or feeling fuzzy on awakening.

Not all women report sexual assault to police. Kilpatrick and coworkers (2007) found that only 16% of victims reported. Many factors deter a woman from reporting the crime, so data regarding sexual assaults may underestimate the magnitude of the problem. Women do not report rape because of the associated stigma; embarrassment; guilt that in some way they provoked the assault; fear of retribution from the rapist or his friends; dread of being humiliated and figuratively “raped” again by the criminal justice system publicly; distrust of law enforcement; involvement in illegal substance use; and discouragement generated by the dismally small number of convictions. Rape survivors often fear the reactions of husbands, lovers, friends, family, and children and prefer to suffer alone.

Mental Health Consequences of Sexual Assault

Rape produces long-term mental health consequences similar to those experienced by combat veterans. Most sexual assaults result in minor physical injuries; genital trauma may or may not be apparent. However, the psychologic effect can be severe. Sexual assault and rape are associated with depression, rape-trauma syndrome (RTS) and PTSD, substance abuse, suicidality, and a host of physical disorders including chronic pelvic pain and sexual dysfunction. One third of women seek counseling as a direct result of their sexual assault (Tjaden & Thoennes, 2006).

Why is rape so traumatic? Victims may have been threatened by a weapon, pushed, shoved, overpowered, or coerced. The assailant may have threatened to return and kill the victim if the incident is reported to anyone. In the aftermath victims can be frightened, angry, embarrassed, or ashamed. They can feel betrayed if there was a preexisting relationship with the assailant. Some may withdraw, feeling socially isolated, unable to tell the people closest to them, fearful of being judged or rejected. Some victims are afraid to return to their homes, workplace, or wherever the assault happened. The emotional suffering can take over women’s lives and whereas some seek support from

family, friends, health care professionals, or police, others may carry this experience silently, never telling anyone (Esposito, 2005).

Rape-Trauma

When humans experience fear, horror, or helplessness after a life-threatening traumatic event such as rape or combat, there is an intense initial stress response. In the first few hours and days an initial neurobiologic dysregulation in the brain interferes with learning new information, making memories, responding to stress, and regulating the level of arousal. In some survivors this dysregulation and other neurobiologic changes persist (Heim & Nemeroff, 2009). For example, in most trauma survivors cortisol levels in the brain rise in response to stress. Emerging research suggests that in people who then develop PTSD, brain cortisol levels, rather than being elevated during stressful events, are low. Some theories suggest that the brain may become oversensitive to cortisol, and minor stress events may cause the person to overreact and major traumas may produce an underreaction (Wheeler, 2008). Variations in brain function and structure are important in understanding the trauma-related symptoms seen in some but not all rape victims. Why do some victims not recover? Suggested possibilities include genetic differences, neuroanatomic differences, sex differences, personality styles, past exposures to stress, and the characteristics and context of the specific trauma and subsequent experiences. Researchers are working on finding specific neurobiopsychologic strategies such as medications and/or therapies that can prevent and treat trauma sequelae like PTSD.

The neurobiologic changes that occur produce an array of symptoms. In the 1970s RTS was identified as a cluster of characteristic symptoms and related behaviors seen in the weeks and months after a rape (Burgess & Holmstrom, 2000). These researchers described three phases (see following). Understanding the pattern of responses that victims may experience is crucial in helping the nurse provide woman-centered supportive and responsive care.

Acute Phase: Disorganization

According to Burgess and Holmstrom (2000) the assault itself marks the beginning of the acute phase of RTS, which can last for several days or up to 3 weeks. Reactions such as shock, denial, and disbelief are common. The rape survivor feels embarrassed, degraded, fearful, angry, and vengeful, and she can blame herself. The victim can feel unclean and want to bathe and douche, although this can destroy evidence. Fear is the primary feeling. Observable reactions can be controlled, expressed, or disoriented. In *controlled emotions* the survivor hides her emotions; has a subdued, calm demeanor; and seems to act as if nothing happened. She may answer questions and interact in a matter-of-fact way. Her affect seems incongruent with what she has just experienced. The second type of acute phase reaction is *expressed emotions*. Here the survivor can appear agitated or hysterical. She can be restless, crying, tense, or anxiously smiling. Her affect can change rapidly from crying to being calm and controlled. She relives the scene over and over in her mind and considers things she “should have done.” *Shocked disbelief* or *disorientation* marks the third type of reaction. The victim can feel disoriented, have difficulty concentrating or making

decisions, and can have poor recall of the event. Memory can be fragmented and intrusive thoughts can provide bits and pieces of information (Campbell, 2012). Physiologically she can be uncomfortable, experiencing skeletal muscle pain or tension, GI irritability, sighing, hyperventilation, and flushing.

Outward Adjustment Phase

During the adjustment phase the survivor may appear to have resolved her crisis. She may return to a job or to maintaining a household, or both, but she is denying and suppressing her thoughts and feelings. She needs this time to regain some control in her life. She may move, change jobs, buy a weapon to protect herself, or install an alarm system in her home. She may not be able to stop talking about the assault, letting it dominate her life, or she may minimize or suppress the event, refusing to discuss it, acting as if it did not happen. She may try to analyze the details of how it happened, trying to explain how it happened and what the rapist was thinking. She may seek safety by fleeing her job, her home, or making other radical changes. She may experience fear, anxiety, phobias, mood swings, anger and rage, depression, insomnia, hypervigilance, and continued flashbacks. She may withdraw from support systems and be afraid to leave her home or go to certain places. She may develop sexual problems.

Long-Term Process: Reorganization Phase

The third phase is reorganization. Denial and suppression are difficult to maintain. Disclosing personal thoughts and feelings has a profound effect on improving health and reducing stress. As a rape survivor's suppression of feelings and emotions starts to deteriorate, she becomes depressed and anxious. Her own healthy spirit pressures her to discuss the rape with someone. Because she is losing her control of denial, her fears start to surface; she may be afraid to be alone or in a crowd or may fear being attacked from behind. Nightmares and eating disorders are common in these last two phases.

The recovery process can take years and can be difficult and painful. The victim has progressed through recovery when the physical distress and the constant memories of the rape have diminished. She no longer blames herself for what happened and can truly call herself a survivor. These phases are not necessarily linear and survivors can move back and forth between the phases. RTS can meet the criteria for PTSD and be formally diagnosed.

CARE MANAGEMENT

Nurses in women's health care and EDs are most likely to see rape victims in the acute phase. However, all women who manifest any of the signs of other phases should be assessed for posttraumatic experiences (Esposito, 2006). It is important to remember that sexual assault acute care has a dual purpose. First and foremost is to address the health care needs of the woman. The second purpose is to facilitate the collection of evidence and documentation of findings for use by the justice system. Health care is the nurse's first priority.

Facilities that provide initial treatment for rape victims vary in protocols and resources. In its 1992 guidelines, The Joint Commission (TJC) required EDs and ambulatory care departments to have protocols on physical assault; rape or sexual assault; and

domestic abuse of older adults, spouses, partners, and children. These protocols must address client consent, examination, and treatment guidelines and the health care facility's responsibility for collecting evidence, photographing injuries, and releasing evidence to law enforcement officials. In addition, the EDs and ambulatory care departments must provide to victims a referral list of community-based and private service agencies dealing with family violence. The nurse interacting with the sexual assault client should be guided by the particular treatment center's protocol. The *National Protocol for Sexual Assault Medical Forensic Exams, Adults/Adolescents*, identifies the unique roles of the many different professionals including sexual assault nurse examiners (SANEs), physicians, police, forensic specialists, prosecutors, and counseling advocacy in the aftercare of a sexual trauma victim (U.S. Department of Justice & Office of Violence Against Women, 2013). Agency or state recommendations for care are continually evolving as new research and forensic techniques emerge.

Many treatment centers have initiated the use of SANEs as described in the above protocols. A SANE is educated in the specialty of forensic nursing and is prepared to examine clients; recognize, collect, and preserve evidence; counsel the client; link the client with vital community resources; follow up cases; and, if necessary, testify in court. When cared for by a SANE, victims receive better quality care, appropriate prophylaxis for infection and pregnancy, and are more satisfied than when cared for in settings without SANEs (Campbell, 2008). Information on becoming a SANE, which currently requires a 40-hour course, is available at www.iafn.org. If a SANE is not available in a particular facility, TJC member organizations must implement a plan for educating an appropriate staff member about identifying, treating, and referring abuse victims. Additional resources can include a social worker who is called when a woman who has been raped is admitted. A local rape crisis center may have volunteers on call who can provide emotional support; provide transportation; help the woman interact with her family, friends, and various authorities; inform her of RTS; and find other resources for her as needed. Male volunteers may counsel male members of the victim's family and her male friends.

Psychologic First Aid

When victims seek help from people in their social network, from the police or from health care settings, the response they get is critical to their healing process. The goal of supportive care is to help victims feel less threatened, feel safer, and have lower levels of anxiety. We do not know which victims will go on to develop PTSD but we do know that negative experiences in the law enforcement and health care system are associated with an increase in PTSD. Research indicates that victims who report and have negative experiences have worse mental health outcomes. The neurobiology of trauma can create for victims a flood of intrusive thoughts. Interviewers, whether law enforcement or health care providers may try to clarify the victim's fragmented story that comes out in bits and pieces. Repeated retelling as well as negative or judgmental feedback has a powerful impact on survivors, and can be experienced as secondary victimization (Campbell, 2008, 2012).

The nurse may be one of the first people to talk with a victim of sexual trauma. Initial distress is not abnormal and most

sexual assault victims are able to recover. Even though there is limited evidence for specific treatments to prevent PTSD in sexual assault victims, trauma experts suggest that one promising approach is Psychological First Aid (Litz, 2008). Psychological First Aid has eight core goals that are consistent with and can be easily adapted to nursing practice. They are to: (1) respond when a survivor reaches out to you or when you initiate contact with the survivor, in a nonintrusive, compassionate, and helpful manner; (2) enhance the survivor's safety and provide physical and emotional comfort; (3) stabilize by calming and orienting the survivor if she is emotionally overwhelmed; (4) identify immediate needs and concerns and gather information; (5) offer practical help in addressing needs; (6) offer to help establish contact with personal supports; (7) provide information about stress and coping responses to sexual assault; and (8) link the survivor with community and other services (National Child Traumatic Stress Network and National Center for PTSD, 2006; Ruzek, Brymer, Jacobs, et al., 2007). Nurses who understand postassault experiences can influence the responses of their nursing units, hospital, or institution and community.

The Sexual Assault Examination

Because sexual assault is a crime, the first nurse to see the sexually assaulted client must consider the need to preserve evidence. However, the preservation of evidence should not overshadow a survivor's rights to be treated as a human being with respect, courtesy, and dignity. Client-centered care takes into consideration the psychologic needs of the victim, and the nurse adapts the examination accordingly. There are short- and long-term physical, emotional, and legal implications of this examination. Details are described in the National Protocol for Sexual Assault Medical Forensic Exams, Adults and Adolescents. The following discussion is an overview of the protocol.

LEGAL TIP: Collector of Evidence

Consent forms must be signed before evidence can be collected and released to the police and before photographs can be taken. If the victim is a minor (see individual state laws for age cutoff) a pediatric SANE, or a child sexual assault pediatrician is notified. Child sexual assault is beyond the scope of this chapter. A parent or guardian is required to sign the consent forms. A children's protective service may need to be called to facilitate consent.

Any health care and/or evidence collection is done only with the permission of the woman. She should be informed of all the steps involved in the sexual assault examination, treatment, and follow-up care. Written informed consent for medical care and human immunodeficiency virus (HIV) testing must be obtained. In addition, consent must be obtained for collection and storage of sexual offense evidence, including forensic photography. A signed consent for release of evidence must be obtained. Unless there is a court order, medical records are confidential. The woman can choose to stop her care or the evidence examination at any time. Informed consent includes information on what will happen during the examination, what tests will be done, what treatments can be offered, what risks occur without treatment, and what evidence collection may provide. It is important for the nurse to remember that the examination

cannot determine if an assault (nonconsensual sexual encounter) has happened. That is a legal determination that happens in court. The examination provides information that may or may not be consistent with sexual contact. Not all sexual assaults produce trauma, and not all sexual trauma is nonconsensual.

History. History taking is an important step in early care. History includes a statement of the traumatic event whether or not evidence will be collected. The woman needs privacy but should not be left alone. It is important to tell the woman that she is safe, that the incident is not her fault, and that she is not alone in what she has experienced. She also needs assurance of confidentiality and may need a great deal of support and patience in verbalizing the offender's acts. For example, giving the woman permission to describe the situation however she chooses and restating what the client has said (without minimizing) tells the woman she has been heard and ensures that what the nurse documents accurately reflects what she said. It also is important to obtain sexual, gynecologic, and obstetric histories (see Chapter 4).

The medicolegal record in a sexual assault case is likely to be used in court. A key feature used in court to establish rape is the absence of consent. The victim who is developmentally delayed, who is unconscious or otherwise physically unable to move, who has been drugged without her knowledge, or who is a minor (statutory rape) is not capable of giving consent. Bribery, threat, or coercion implies the lack of consent. The nurse's documentation is an important part of the medicolegal record. The wording of the history should reflect the woman's report, and her exact words should be used as often as possible (New York State Department of Health, 2008). When documenting, it is important for the nurse to remember that care is provided to the woman without judgment. Thus nurses should avoid using legal terms or words that suggest value judgments when documenting or referring to the woman. For example use of the term "alleged" or "claims" suggests that the nurse questions the woman's report. It is not the role of the nurse to determine whether a sexual assault occurred but to treat the woman as any other trauma victim. The court must prove absence of consent.

LEGAL TIP: Documentation

Clear, legible, accurate documentation is imperative. The woman's name should be on each page, and date, times, and signatures should be legible. Document an interpreter's name if one was used.

Physical Examination and Laboratory Tests. The nurse can assist with or, if trained, perform the physical examination, which is conducted after the procedure is explained to the woman and consent is obtained. Some victims may view the examination as a second traumatic event. Preservation of the woman's dignity is of utmost importance during the examination. The woman can choose a female attendant, rape counselor, or other person to remain with her during the examination. The room will require standard examination equipment, comfort supplies for the woman, a sexual assault evidence collection kit, a method to dry evidence, a camera, lab testing supplies, a light source, and an anoscope. Some settings also have a colposcope, a microscope, and toluidine blue dye (U.S. Department of Justice &

Office of Violence Against Women, 2013). The physician, nurse practitioner, or SANE informs her of every step of the procedure. The content of the examination is based on the history. For example, if there was oral penetration but no removal of clothing and genital contact, a speculum exam may not be appropriate. However many victims do not recall what happened during parts or all of the assault, and examination of all orifices is suggested. A standardized sexual assault evidence collection kit is used to obtain and package specimens. The kit gives detailed instructions on how to collect and package specimens and other evidence.

If the woman needs to urinate or defecate prior to the examination, the nurse should ask her to avoid wiping away vaginal or other secretions until after evidence is collected. Collect the first voided specimen for possible drug-facilitated sexual assault testing and document the time it was collected. If the woman has a tampon, panty liner, or contraceptive device in the vagina, she should not remove or discard them. The woman remains clothed while her vital signs and blood pressure are determined, and her clothing is inspected for stains, tears, and foreign material. Clothing is handled only by the woman and if pertinent to the assault may be collected, allowed to air dry, and sealed in a bag to be checked for evidence. She is assisted to undress and is draped for the physical examination. Her body is inspected for bruises, swelling, scratches, lacerations, or other wounds. A head-to-toe examination is performed as indicated. Victims can have injuries to other parts of their body including the head, face, and neck. An ultraviolet light (Wood's lamp) is used to find dried secretions on the victim's skin. External genitals, thighs, buttocks, and lower abdomen are assessed, and if there are injuries, bruises, or marks, photographs can be taken or drawings made. Pubic and scalp hair is combed for collection. Perianal, oral, and vaginal swabs are collected. If the victim scratched her attacker, her nails are scraped to obtain material that can aid in identification.

A speculum examination, often using magnification, is performed gently to detect tears or bruises and to collect appropriate specimens. Many victims have some type of genital injury, even if it is asymptomatic. A bimanual pelvic examination is not usually performed for evidence collection if a SANE is doing the examination. Internal pelvic assessment may be done by the nurse practitioner or physician if internal injury is suspected.

Laboratory tests can include oral swabs for the victim's deoxyribonucleic acid (DNA) to distinguish her DNA from the suspect's DNA; a urine or blood pregnancy test; blood tests for hepatitis B virus; and oral or blood tests for HIV (CDC, 2010b). A preexisting pregnancy will affect treatment decisions for possible HIV prophylaxis. Testing for HIV is a typical part of the sexual assault exam; however, HIV status should be checked within 72 hours if the assault was high risk. Cultures for gonorrhea, chlamydia, and syphilis are not recommended because women are treated prophylactically, test results will not change treatment, and testing can have negative consequences in court (Lewis-O'Connor, Franz, & Zuniga, 2005; New York State Department of Health, 2008; U.S. Department of Justice & Office of Violence Against Women, 2013).

During the examination, the woman's emotional status is assessed, and findings are recorded: what reactions she exhibits

to the assault; her orientation to time and place; and her attention span, affect, and verbal description and feelings about the assault. The availability of family or peer-support systems is assessed. She is asked about her plans to report the crime to the police. After the examination, the woman should be allowed to shower and offered fresh clothes or a gown. She can be given time to rest and to talk with the nurse, rape crisis counselor, family, or friends.

It is important that the chain of custody be maintained. *Chain of custody* is a legal term that refers to the continual guarding of evidence and describes evidence from the moment that it is first collected until it appears in court. All items of evidence are individually labeled with the name of examiner, client, date, and source. The evidence is never left unattended or with the family, woman, or support person such as an advocate. During the examination chain of custody is the responsibility of the examiner. When evidence is turned over to the next custodian, each person signs that the evidence was given and received. Signing indicates that no one touched or tampered with the evidence during that person's watch. This ensures that the evidence can be used in court.

Immediate Care. Nursing diagnoses for the rape victim during the immediate and later posttrauma period are listed in Box 5-3. Consent is needed for treatment and medical management that includes (1) treating the physical injuries, including tetanus toxoid booster if indicated; (2) providing prophylactic antibiotic therapy for STIs (e.g., chlamydia, gonorrhea); and (3) providing prophylaxis for pregnancy if the woman is not pregnant. If physical trauma is life threatening, appropriate intervention takes precedence over collecting evidence. A pregnancy test

BOX 5-3 Nursing Diagnoses for the Rape Victim During the Immediate and Later Posttrauma Periods

Immediate Posttrauma Period

- *Anxiety/fear* related to:
 - Rape-trauma experience
 - Interactions with police and caregivers
 - Physical examination to assess injury and collect evidence
- *Acute pain* related to:
 - Physical injury from rape
 - Examination
- *Disturbed body image* related to:
 - The rape
- *Rape-trauma* related to:
 - Aftermath of being sexually assaulted
 - Feelings of being unclean and humiliated
 - Silent reaction of being unable to discuss the rape
- *Decisional conflict* related to:
 - Discussing rape with family
 - Possible pregnancy

Later Posttrauma Period

- *Risk for infection* related to:
 - Sexually transmitted infections
 - Sexual assault by an assailant of unknown sexual history
- *Impaired social interaction* related to:
 - The rape
 - Strained relationships with family, friends, intimate partners

should be done on all women at risk for pregnancy (with their consent). Most pregnancy tests are sensitive by 9 days after conception. If the woman is at risk for pregnancy and the pregnancy test is negative, emergency contraception should be offered to her. Emergency contraception (see Table 8-2, Chapter 8) is most effective if used within 120 hours after intercourse. The earlier it is taken, the more effective. The woman should be advised that emergency contraception does not guarantee pregnancy prevention, and that she should repeat the pregnancy test if she has not had a menstrual period within 3 to 4 weeks. She is apprised of the availability of abortion or menstrual extraction as a backup measure. If the woman is pregnant at the time of the assault, she should be observed for several hours for uterine contractility.

The woman can be provided with prophylactic antibiotic therapy to prevent STIs, hepatitis B postexposure prophylaxis (PEP), and if there is a high risk of exposure, for example, if the assailant is known to be infected with HIV, the PEP for HIV may be offered.

Discharge. The woman is discharged with medications and printed instructions about their use, printed instructions for self-care, and names and telephone numbers of resource people if she requires assistance. Money and transportation to wherever she is staying (an alternative place may be found for her) add to the woman's comfort and perception of being in control. A medical follow-up examination in the gynecology or pediatric clinic is scheduled in 1 to 2 weeks for cultures for gonorrhea and other STIs; at 6 weeks for assessment of healing injuries; and at 6, 12, and 24 weeks for repeated serology tests for syphilis and HIV infection if initial test results were negative. The woman and her counselor determine whether there is a need for an additional medical or psychologic follow-up examination between the scheduled visits. The woman has a choice of site for follow-up testing. Some women choose to continue with the health care provider who first performed the examination, some prefer their primary health care provider, and others need referral to a clinic in the area (city, state) in which they live.

Nurses must be aware that responses to sexual assault are variable. Self-blame and humiliation can alternate with anger and fear. The woman needs to be reassured again before she leaves that her feelings are normal and that she is not alone. The initial care of a woman will affect her recovery and her decision to return for follow-up care. Nurses can assist women through an examination that is as nontraumatic as possible, with kindness, skill, and empathy.

After Discharge. Because of the phases of recovery, telephone contact by the health care provider to whomever the woman is referred is continued until the woman has no further need for such help. Education in prevention strategies is often offered by community agencies or rape-awareness groups. The focus of the classes is usually on increasing women's awareness of situations that put them at high risk for rape or sexual assault. Other courses teach self-defense methods or how to change personal behaviors to reduce the risk of being victimized, such as avoiding being alone in isolated places and being alert to unusual activities or persons in one's environment. Still other courses focus on changing societal attitudes about rape. Nurses can play a role

in preventive education by offering courses or participating in courses offered by community or health care groups. Nurses must be knowledgeable about the epidemiology of sexual assault, reporting requirements, and services available in their community for victims, and should screen all women for a history of assault and any sequelae.

SEX TRAFFICKING

Human trafficking is a \$32 billion business in the United States and internationally (Dovydaitis, 2010). Although the number of U.S. victims is unknown, it is estimated that 14,000 to 50,000 individuals are trafficked each year (ACOG, 2011; National Human Trafficking Resource Center [NHTRC], 2012). Trafficked individuals, mostly women and children, are forced into hard labor, sex work, and even organ donation (Budiani-Saberi, Raja, Findley, et al., 2014; Macy & Graham, 2012). Human sex trafficking is a serious and understudied phenomenon. It is actually the most prevalent form of what is referred to as "modern-day slavery" (USDHHS, 2012; Walker-Rodriguez & Hill, 2011). Sex trafficking refers to a commercial sex act, which is defined as a sex act that is performed under coercion and in exchange for the promise of something of value, such as a job, or if the person is less than 18 years old. Coercion can be psychologic or physical and includes human bondage and threats of serious harm (USDHHS).

Although victims of sex trafficking can be male or female, the vast majority are women and girls, who are lured by false promises, such as a job or a marriage, or are sold by parents or kidnapped by traffickers. Often, once they are enslaved by the traffickers, many of them begin to experience what is referred to as the "Stockholm Syndrome" in which the slaves become attached to their enslavers (De Fabrique, Romano, Vecchi, & Van Hasselt, 2007). It is important to understand that these sex slaves are usually isolated and may not even know where they are (e.g. what city).

The traffickers are often people involved in organized crime internationally but also in the United States (Walker-Rodriguez & Hill, 2011). The three primary sex trafficking U.S. networks are Asian, Latino, and domestic (U.S. citizen) networks (NHTRC, 2012). Sex trafficking can occur in one's neighborhood without neighbors' awareness.

Health care professionals may interact with victims who are in captivity. This provides an opportunity to identify victims, intervene to help them obtain necessary health services, and provide information about ways to escape from their situation. The nurse or other health care provider must be alert to signs and symptoms, such as being accompanied to the visit by another person who appears very controlling, showing signs of being fearful, not being comfortable with answering questions, difficulty communicating, presenting with signs of abuse, and lacking documentation of citizenship (Crane & Moreno, 2011). Victims of sex trafficking also may be younger than 18 years of age and report multiple sex partners, and multiple episodes of STIs, or have evidence of sexual abuse (ACOG, 2011).

The nurse is challenged to create an opportunity to assess for victimization and establish a trusting climate while also

COMMUNITY ACTIVITY

- Research the laws regarding intimate partner violence in your state. Is it considered a misdemeanor or felony crime? Is mandatory reporting of domestic violence by health care providers required? What is the definition of statutory rape in your state? Visit www.futureswithoutviolence.org for information on state statutes and policies on domestic violence.
- What are the resources for victims of intimate partner violence in your community?
- Visit <http://nhtrc.polarisproject.org>. Find out about the National Human Trafficking Resource Center and the resources and services that may be available in your community.

speaking with the client alone. In 2000 the U.S. government enacted the Trafficking Victims Protection Act, which makes trafficking, including sex trafficking, a federal crime. Health care providers play a critical role in identifying perpetrators and victims of this crime. The NHTRC (1-888-373-7888) can provide assistance.

KEY POINTS

- Violence against women is a major social and health care problem in the United States, costing thousands of lives and billions of dollars in direct and indirect health care costs.
- IPV includes physical, sexual, emotional, psychological, and economic abuse.
- To provide effective care, nurses must increase awareness of their own beliefs and values regarding victimization of women.
- Theoretic frameworks—psychologic, sociologic, biologic, and feminist perspectives—provide the foundation for understanding the complexity of the victimization of women.
- Cultural influences regarding violent behaviors and relationships sensitize the nurse to the special needs of women from various ethnic groups.
- IPV affects young, middle-aged, and older women of all races; all socioeconomic, educational, and religious groups; and pregnant women.
- All states have mandatory reporting of the abuse of children and older adults; some states have initiated mandatory reporting of domestic abuse. Mandatory reporting is controversial and takes away the right for women to choose.
- Rape is a legal term defined by each state differently but usually refers to penetration of an orifice against someone's will.
- Nurses in all professional areas should respond with sensitivity and caring to women who experience abuse and victimization.
- Follow-up and collaborative care are important in all instances of abuse.
- Nurses should be knowledgeable about reporting requirements and available community services for women who have been sexually assaulted.
- Health care professionals may have an opportunity to identify victims of human sex trafficking, intervene to help them obtain necessary health services, and provide information about ways to escape from their situation.

Reproductive System Concerns

Ellen Frances Olshansky

© <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Describe and differentiate signs and symptoms of common menstrual disorders.
- Develop a nursing care plan for a woman with primary dysmenorrhea.
- Describe premenstrual syndrome (PMS) and premenstrual dysphoric disorder (PMDD).
- Relate the symptoms of endometriosis to the associated pathophysiology.
- Develop a nursing care plan for a woman with endometriosis.
- Summarize the therapies for menstrual disorders and menopausal symptoms, including risks and benefits.
- Differentiate the various causes of abnormal uterine bleeding.
- Identify health risks of perimenopausal women.
- Describe the common signs and symptoms of perimenopause.
- Develop a teaching plan for managing symptoms in menopausal women.
- Examine the risks and benefits of menopausal hormone therapy.
- Summarize client teaching strategies for prevention of osteoporosis.

Problems may occur at any point in the menstrual cycle. In addition, many factors, including anatomic abnormalities, physiologic imbalances, and lifestyle, can affect the menstrual cycle. Many women seek out nurses as advisers, counselors, and health care providers for information about menstrual cycle experiences, concerns, or disorders. If they are to meet their clients' needs, nurses must have accurate, up-to-date information. This chapter provides information on menstrual cycle experiences, including menarche through postmenopause; common menstrual disorders; abnormal bleeding problems; and problems associated with perimenopause and postmenopause.

Knowledge of the normal parameters of menstruation is essential to the assessment of menstrual cycle experiences and disorders. The menstrual cycle is a result of a complex interplay among the reproductive, neurologic, and endocrine systems. The hypothalamus produces gonadotropin-releasing hormone (GnRH), which stimulates the pituitary gland to produce follicle-stimulating hormone (FSH) and luteinizing hormone (LH). In turn, FSH and LH stimulate the ovaries to produce first estrogen and then progesterone. In response to the hormones, the endometrium, or lining of the uterus, proliferates and then sheds. Chapter 4 provides additional information on the menstrual cycle and endocrine physiology.

Normal menstrual patterns are averages based on observations and reports from large groups of healthy women. When counseling an individual woman, remember that these values

are averages only. Generally a woman's menstrual frequency stabilizes at every 28 days within 1 to 2 years after puberty, with a range from 26 to 34 days (Blackburn, 2013). Although no woman's cycle is exactly the same length every month, the typical month-to-month variation in an individual's cycle is usually plus or minus 2 days. However, greater but still normal variations are noted frequently.

During her reproductive years a woman may have more than one physiologic variation in her menstrual cycle. It is essential that nurses understand the physiologic variations that occur in several age groups. Menstrual cycle length is most irregular at the extremes of the reproductive years including the 2 years after menarche and the 5 years before menopause, when anovulatory cycles are most common. Irregular bleeding, both in length of cycle and amount, is the rule rather than the exception in early adolescence. It takes approximately 15 months for completion of the first 10 cycles and an average of 20 cycles before ovulation occurs regularly. Cycle lengths of 15 to 45 days are not unusual, and during the first 2 years after menarche intervals of 3 to 6 months between menses can be normal.

Women's knowledge and understanding of the menstrual cycle may be limited and are often influenced by myths and misunderstandings. Women typically have menstrual cycles for about 40 years. Once the irregular nature of menses in the first 1 to 2 years after menarche subsides and a cyclic, predictable pattern of monthly bleeding is established, women may

worry about any deviation from that pattern, or from what they have been told is normal for all menstruating women. A woman may be concerned about her ability to conceive and bear children or she may believe that she is not really a woman without monthly evidence. A sign such as amenorrhea or excess menstrual bleeding can be a source of severe distress and concern for women.

COMMON MENSTRUAL DISORDERS

Amenorrhea

Amenorrhea, the absence of menstrual flow, is a clinical sign of a variety of disorders. Although these criteria for a clinical problem of amenorrhea are not universal, these circumstances should generally be evaluated: (1) the absence of both menarche and secondary sexual characteristics by age 14 years; (2) absence of menses by age 16, regardless of presence of normal growth and development (primary amenorrhea); or (3) a 3- to 6-month absence of menses after a period of menstruation (secondary amenorrhea) (Fritz & Speroff, 2011; Lobo, 2012d).

A moderately obese girl (20% to 30% above ideal weight) may have early-onset menstruation, whereas delay of onset is known to be related to malnutrition (starvation such as that with anorexia). Girls who exercise strenuously before menarche can have delayed onset of menstruation until about age 18 (Lobo, 2012d).

Although amenorrhea is not a disease, it is often the sign of one. Still, most commonly and most benignly, amenorrhea is a result of pregnancy. It also can result from anatomic abnormalities such as outflow tract obstruction, anterior pituitary disorders, other endocrine disorders such as polycystic ovary syndrome, hypothyroidism or hyperthyroidism, chronic diseases such as type 1 diabetes, medications such as phenytoin (Dilantin), drug abuse (alcohol, tranquilizers, opiates, marijuana, cocaine), or oral contraceptive use.

Hypogonadotropic amenorrhea reflects a problem in the central hypothalamic-pituitary axis. In rare instances a pituitary lesion or genetic inability to produce FSH and LH is at fault. More commonly it results from hypothalamic suppression as a result of two principal influences: stress (in the home, school, or workplace) or a sudden and severe weight loss, eating disorders, strenuous exercise, or mental illness (Wambach & Alexander, 2012). Research has demonstrated a biologic basis for the relationship of stress to physiologic processes. Amenorrhea is one of the classic signs of anorexia nervosa, and the interrelatedness of disordered eating, amenorrhea, and altered bone mineral density has been described as the female athlete triad (American College of Sports Medicine [ACSM], 2011; Mencias, Noon, & Hoch, 2012). Calcium loss from bone, comparable to that seen in postmenopausal women, may occur with this type of amenorrhea.

Exercise-associated amenorrhea can occur in women undergoing vigorous physical and athletic training. The pathophysiology is complex and is thought to be associated with many factors, including body composition (height, weight, and percentage of body fat); type, intensity, and frequency of exercise; nutritional status; and the presence of emotional or physical stressors (Lobo, 2012d). In addition, it is probably due to diminished secretion of GnRH. Women

who participate in sports emphasizing low body weight are at greatest risk (Quinn, 2011), including the following (Bonci, Bonci, Granger, et al., 2008):

- Sports in which performance is subjectively scored (e.g., distance running, cycling)
- Endurance sports favoring participants with low body weight (e.g., distance running, cycling)
- Sports in which body contour-revealing clothing is worn (e.g., swimming, diving, volleyball)
- Sports with weight categories for participation (e.g., rowing, martial arts)
- Sports in which prepubertal body shape success (e.g., gymnastics, figure skating)

Assessment of amenorrhea begins with a thorough history and physical examination. An important initial step, often overlooked, is to be sure that the woman is not pregnant. Specific components of the assessment process depend on a client's age—adolescent, young adult, or perimenopausal—and whether she has previously menstruated.

Once pregnancy has been ruled out by a β -human chorionic gonadotropin (β -hCG) pregnancy test, diagnostic tests can include FSH level, thyroid-stimulating hormone (TSH) and prolactin levels, radiographic or computed tomography scan of the sella turcica, and a progesterone challenge (Lobo, 2012d).

Management

When amenorrhea is a result of hypothalamic disturbances, the nurse is an ideal health professional to assist women because many of the causes are potentially reversible (e.g., stress, weight loss for nonorganic reasons). Counseling and education are primary interventions and appropriate nursing roles. When a stressor known to predispose a client to hypothalamic amenorrhea is identified, initial management involves addressing the stressor. Together the woman and the nurse plan how the woman can decrease or discontinue medications known to affect menstruation, correct weight loss, deal more effectively with psychologic stress, address emotional distress, and alter her exercise routine (Vorvick, Storck, & Zieve, 2012).

The nurse works with the woman to help her identify, cope with, and possibly resolve sources of stress in her life. Deep-breathing exercises and relaxation techniques are simple yet effective stress-reduction measures. Referral for biofeedback or massage therapy also may be useful. In some instances, referrals for psychotherapy may be indicated.

If a woman's exercise program is thought to contribute to her amenorrhea, several options exist for management. The American College of Sports Medicine (ACSM) recommends increasing nutritional intake to increase energy availability and reducing exercise energy expenditure as the first line of treatment (Quinn, 2011). Therefore, the woman may decide to decrease the intensity or duration of her training if possible or to gain 2% to 3% in body weight. Coming to accept this alternative may be difficult for one who is committed to a strenuous exercise regimen, and the nurse and the client may have several sessions before the woman elects to try exercise reduction. Many young female athletes may not understand the consequences of low bone density or osteoporosis; nurses can point out the connection between low bone density and stress fractures. The nurse and the woman also should investigate other factors that

may be contributing to the amenorrhea and develop plans for altering lifestyle and decreasing stress.

Although research on effectiveness is inconclusive, a daily calcium intake of 1200 to 1500 mg plus 400 to 800 International Units of vitamin D and 60 to 90 mg of potassium are recommended for women experiencing amenorrhea associated with the **female athlete triad**. Oral contraceptives have a positive effect on bone density in amenorrheic women but are usually not used in young women with amenorrhea associated with female athlete triad unless the woman is not willing to comply with dietary and exercise recommendations or she continues to be amenorrheic even with compliance (Joy, 2012).

Cyclic Perimenstrual Pain and Discomfort

Cyclic perimenstrual pain and discomfort (CPPD) is a useful concept to describe women's experiences of discomfort during the menstrual cycle and therefore the literature has been updated to reflect the relevance of CPPD (Association of Women's Health, Obstetric and Neonatal Nurses [AWHONN], 2013). This concept includes dysmenorrhea, premenstrual syndrome (PMS), and premenstrual dysphoric disorder (PMDD) as well as symptom clusters that occur before and after the menstrual flow starts. Symptoms occur cyclically and can include mood swings as well as pelvic pain and physical discomforts. These symptoms can range from mild to severe and can last a day or two or up to 2 weeks (Marshall & Jones, 2011). CPPD is a health problem that can have a significant effect on a woman's quality of life. The following discussion focuses on the three main conditions of CPPD.

Dysmenorrhea

Dysmenorrhea, pain during or shortly before menstruation, is one of the most common gynecologic problems in women of all ages. Many adolescents have dysmenorrhea in the first 3 years after menarche. Young adult women ages 17 to 24 are most likely to report painful menses. Approximately 75% of women report some level of discomfort associated with menses, and approximately 15% report severe dysmenorrhea (Lentz, 2012); however, the amount of disruption in women's lives is difficult to determine. Researchers have estimated that as many as 10% of women with dysmenorrhea have severe enough pain to interfere with their functioning for 1 to 3 days a month. Menstrual problems, including dysmenorrhea, are relatively more common in women who smoke and are obese. Severe dysmenorrhea is also associated with **early menarche, nulliparity, and stress** (Lentz). Traditionally dysmenorrhea is differentiated as primary or secondary. Symptoms usually begin with menstruation, although some women have discomfort several hours before onset of flow. The range and severity of symptoms are different from woman to woman and from cycle to cycle in the same woman. Symptoms of dysmenorrhea may last several hours or several days.

Pain is usually located in the suprapubic area or lower abdomen. Women describe the pain as sharp, cramping, or gripping or as a steady dull ache. For some women pain radiates to the lower back or upper thighs.

Primary Dysmenorrhea

Primary dysmenorrhea is a condition associated with ovulatory cycles. Research has shown that primary dysmenorrhea has a biochemical basis and arises from the release of prostaglandins with

menses. During the luteal phase and subsequent menstrual flow, prostaglandin F₂-alpha (PGF_{2α}) is secreted. Excessive release of PGF_{2α} increases the amplitude and frequency of uterine contractions and causes vasospasm of the uterine arterioles, resulting in ischemia and cyclic lower abdominal cramps. Systemic responses to PGF_{2α} include backache, weakness, sweats, gastrointestinal symptoms (anorexia, nausea, vomiting, and diarrhea), and central nervous system symptoms (dizziness, syncope, headache, and poor concentration). Pain usually begins at the onset of menstruation and lasts 8 to 48 hours (Lentz, 2012).

Primary dysmenorrhea usually appears 6 to 12 months after menarche when ovulation is established. Anovulatory bleeding, common in the few months or years after menarche, is painless. Because both estrogen and progesterone are necessary for primary dysmenorrhea to occur, it is experienced only with ovulatory cycles. This problem is more common among women in their late teens and early 20s than in women in older age groups; the incidence declines with age. Psychogenic factors may influence symptoms, but symptoms are definitely related to ovulation and do not occur when ovulation is suppressed.

Management. Management of primary dysmenorrhea depends on the severity of the problem and an individual woman's response to various treatments. Important components of nursing care are information and support. Because menstruation is so closely linked to reproduction and sexuality, menstrual problems such as dysmenorrhea can have a negative influence on sexuality and self-worth. Nurses can correct myths and misinformation about menstruation and dysmenorrhea by providing facts about what is normal. Nurses must support their clients' feelings of positive sexuality and self-worth.

Often more than one alternative for alleviating menstrual discomfort and dysmenorrhea can be offered. Women can then try options and decide which ones work best for them. Heat (heating pad or hot bath) minimizes cramping by increasing vasodilation and muscle relaxation and minimizing uterine ischemia. Massaging the lower back can reduce pain by relaxing paravertebral muscles and increasing the pelvic blood supply. Soft, rhythmic rubbing of the abdomen (effleurage) is useful because it provides a distraction and an alternative focal point. Biofeedback, transcutaneous electrical nerve stimulation (TENS), progressive relaxation, Hatha yoga, acupuncture, and meditation are also used to decrease menstrual discomfort, although evidence is insufficient to determine their effectiveness (Lentz, 2012). Research findings from Chien Change, and Liu (2013) concluded that an 8-week yoga intervention decreased serum homocysteine levels, alleviating dysmenorrhea in women with primary dysmenorrhea.

Exercise helps relieve menstrual discomfort through increased vasodilation and subsequent decreased ischemia. It also releases endogenous opiates (specifically beta-endorphins), suppresses prostaglandins, and shunts blood flow away from the viscera, resulting in reduced pelvic congestion. One specific exercise that nurses can suggest is pelvic rocking.

In addition to maintaining good nutrition at all times, specific dietary changes are helpful in decreasing some of the systemic symptoms associated with dysmenorrhea. Decreased salt and refined sugar intake 7 to 10 days before expected menses may reduce fluid retention. Natural diuretics such as asparagus, cranberry juice, peaches, parsley, or watermelon

may help reduce edema and related discomforts. A low-fat vegetarian diet may also help minimize dysmenorrheal symptoms (Lentz, 2012).

A major role of the nurse is to assist the client in managing her menstrual discomfort. The Clinical Reasoning Case Study provides an example of how a nurse can help the woman.

Medications used to treat primary dysmenorrhea in women not desiring contraception include prostaglandin synthesis inhibitors, primarily nonsteroidal antiinflammatory drugs (NSAIDs) (Lentz, 2012) (Table 6-1). NSAIDs are effective if begun 2 to 3 days before menses or with the sign of first bleeding; this regimen decreases the possibility of a woman taking these drugs early in pregnancy (Fritz & Speroff, 2011). All NSAIDs have potential gastrointestinal side effects, including nausea, vomiting, and indigestion. All women taking NSAIDs should be warned to report dark-colored stools because this may be an indication of gastrointestinal bleeding.

CLINICAL REASONING CASE STUDY

Management of Dysmenorrhea

Cheri, 16, has come to the adolescent health clinic for a checkup. She reports that she has “really bad cramps” for the first 2 days of her period. She has been taking Midol Menstrual Complete but says that it does not help “a lot.” She wants to know if anything else can be done to relieve her pain. How should the nurse respond?

1. Evidence—Is evidence sufficient to draw conclusions about what advice the nurse should give?
2. Assumptions—Describe underlying assumptions about the following issues:
 - a. Causes and symptoms of primary dysmenorrhea
 - b. Cyclic perimenstrual pain and discomfort
 - c. Self-help strategies (e.g., comfort measures, medications)
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

TABLE 6-1 Nonsteroidal Antiinflammatory Agents Used to Treat Dysmenorrhea

DRUG	BRAND NAME AND STATUS	RECOMMENDED DOSAGE (ORAL)*	COMMON SIDE EFFECTS†	COMMENTS	CONTRAINDICATIONS
Diclofenac	Cataflam Rx	50 mg tid or 100 mg initially, then 50 mg tid up to 150 mg/day	Nausea, diarrhea, constipation, abdominal distress, dyspepsia, heartburn, flatulence, dizziness, tinnitus, itching, rash	Enteric coated; immediate release	For all NSAIDs: Do not give if woman has hemophilia or bleeding ulcers; do not give if woman has had an allergic or anaphylactic reaction to aspirin or another NSAID; do not give if woman is taking anticoagulant medication
Ibuprofen	Motrin Rx, Advil OTC, Nuprin OTC, Motrin IB OTC	400 mg q6-8h, 200 mg q4-6h up to 1200 mg/day	See <i>diclofenac</i>	If GI upset occurs, take with food, milk, or antacids; avoid alcoholic beverages; do not take with aspirin; stop taking and call care provider if rash occurs	
Ketoprofen	Orudis Rx	25-50 mg q6-8h up to 300 mg/day	See <i>diclofenac</i>	See <i>ibuprofen</i>	
	Orudis KT OTC, Actron OTC	12.5 mg q6-8h up to 75 mg/day			
Meclofenamate	Meclomen Rx	100 mg tid up to 300 mg	See <i>diclofenac</i>	See <i>ibuprofen</i>	
Mefenamic acid	Ponstel Rx	500 mg initially, then 250 mg q6h up to 1000 mg/day	See <i>diclofenac</i>	Very potent and effective prostaglandin-synthesis inhibitor; antagonizes already formed prostaglandins; increased incidence of adverse GI side effects	
Naproxen	Naprosyn Rx	500 mg initially, then 250 mg q6-8h up to 1250 mg/day	See <i>diclofenac</i>	See <i>ibuprofen</i>	
Naproxen sodium	Anaprox Rx	550 mg initially, then 275 mg q6-8h or 550 mg q12h up to 1375 mg/day	See <i>diclofenac</i>	See <i>ibuprofen</i>	
	Aleve OTC	440 mg initially, then 220 mg q6-8h up to 660 mg/day			
Celecoxib	Celebrex	400 mg initially, then 200 mg bid	See <i>diclofenac</i>	See <i>ibuprofen</i>	

*Dosages are current recommendations and should be verified before use. Recommended doses for over-the-counter preparations are generally less than recommendations for therapeutic doses. As-needed dosing is recommended by manufacturer; scheduled dosing may be more effective.

†Risk with all NSAIDs is gastrointestinal ulceration, possible bleeding, and prolonged bleeding time. Incidence of side effects is dose related. Reported incidence, 1% to 10%. GI, Gastrointestinal; NSAID, nonsteroidal antiinflammatory drug; OTC, over the counter.

(Eds.), *Comprehensive gynecology* (6th ed.). Philadelphia: Mosby; U.S. Department of Health and Human Services, U.S. Food and Drug Administration. (2008). *Medication guide for nonsteroidal antiinflammatory drugs (NSAIDs)*. Available at www.fda.gov/CDER/drug/infopage/COX2/NSAIDmedguide.htm.

MEDICATION ALERT

If one NSAID is ineffective, a different one may often be effective. If the second drug is unsuccessful after a 6-month trial, combined oral contraceptive pills (OCPs) may be used. Women with a history of aspirin sensitivity or allergy should avoid all NSAIDs.

OCPs are a reasonable choice for women who want to use a contraceptive agent. The benefits of their use are attributed to decreased prostaglandin synthesis associated with an atrophic decidualized endometrium (Lentz, 2012). OCPs are effective in relieving symptoms of primary dysmenorrhea for approximately 90% of women. No single OCP has been shown to be superior to another for the relief of primary dysmenorrhea, including low-dose and extended-cycle OCPs (Lentz). OCPs are a particularly good choice for therapy because they combine contraception with a positive effect on dysmenorrhea, menstrual flow, and menstrual irregularities. Adolescents may benefit from use of the long-acting injectable contraceptive (depot medroxyprogesterone), but more research is needed. Because OCPs have side effects, women may not wish to use them for dysmenorrhea. They may be contraindicated for some women. (See Chapter 8 for a complete discussion of OCPs.)

Over-the-counter (OTC) preparations that are indicated for primary dysmenorrhea include the same active ingredients (e.g., ibuprofen, naproxen sodium) as prescription preparations; however, the labeled recommended dose may be subtherapeutic. Preparations containing acetaminophen are less effective because acetaminophen does not have the antiprostaglandin properties of NSAIDs.

If dysmenorrhea is not relieved by one of the NSAIDs, further investigation into the cause of the symptoms is necessary. Conditions associated with dysmenorrhea include müllerian duct anomalies, endometriosis, and pelvic inflammatory disease.

Alternative and complementary therapies are increasingly popular and used in developed countries. Chinese medicine, including herbal preparations, have been used in Western integrative medicine, an approach that combines complementary and allopathic approaches (Dobos & Tao, 2011). Therapies such as acupuncture, acupressure, biofeedback, desensitization, hypnosis, massage, Reiki, relaxation exercises, and therapeutic touch have been used to treat pelvic pain. Herbal preparations have long been used for management of menstrual problems including dysmenorrhea (Table 6-2). Herbal medicines may be valuable in treating dysmenorrhea; however, it is essential that women understand that these therapies are not without potential toxicity and may cause drug interactions. Additional study is needed to generate the evidence for the use of these various alternative methods (Smith & Kaunitz, 2013).

NURSING ALERT

Nurses must routinely ask women about use of herbal and other alternative therapies and document their use.

Secondary Dysmenorrhea

Secondary dysmenorrhea is acquired menstrual pain that develops later in life than primary dysmenorrhea, typically after age 25 years. This condition is associated with pelvic pathology, such as adenomyosis, endometriosis, pelvic inflammatory disease, endometrial polyps, or submucous or interstitial myomas (fibroids). Women with secondary dysmenorrhea often have other symptoms that may suggest an underlying cause. For example, heavy menstrual flow with dysmenorrhea suggests a diagnosis of leiomyomata, adenomyosis, or endometrial polyps. Pain associated with endometriosis often begins a few days before menses, but can be present at ovulation and continue through the first days of menses or start after menstrual flow has begun. In contrast to primary dysmenorrhea, the pain of secondary dysmenorrhea is often characterized by dull, lower abdominal aching radiating to the back or thighs. Often women experience feelings of bloating or pelvic fullness. In addition to a physical examination with a careful pelvic examination, diagnosis may be assisted by ultrasound examination, dilation and curettage, endometrial biopsy, or laparoscopy. Treatment is directed toward removing the underlying pathology. Many of the measures described for pain relief of primary dysmenorrhea also are helpful for women with secondary dysmenorrhea.

Premenstrual Syndrome and Premenstrual Dysphoric Disorder

Approximately 30% to 80% of women experience mood or somatic symptoms (or both) that occur with their menstrual cycles (Lentz, 2012). Establishing a universal definition of

TABLE 6-2 Herbal Medicinals Taken Orally for Menstrual Disorders

SYMPTOMS OR INDICATIONS	HERBAL THERAPY*	ACTION
Menstrual cramping, dysmenorrhea	Black haw	Uterine antispasmodic
	Fennel	Uterotonic
	Catnip	Uterine antispasmodic
	Dong quai	Uterotonic; antiinflammatory
	Ginger	Antiinflammatory
	Motherwort	Uterotonic
	Wild yam	Uterine antispasmodic
Premenstrual discomfort, tension	Valerian	Uterine antispasmodic
	Black cohosh root	Estrogen-like luteinizing hormone suppressant; binds to estrogen receptors
Breast pain	Chamomile	Antispasmodic
	Chaste tree fruit	Decreases prolactin levels
Menorrhagia, metrorrhagia	Bugleweed	Antigonadotropic; decreases prolactin levels
	Lady's mantle	Uterotonic
	Raspberry	Uterotonic
	Shepherd's purse	Uterotonic

*Many herbs do not have rigorous scientific studies backing their use; most uses and properties of herbs have not been validated by the U.S. Food and Drug Administration.

Data from Annie's Remedy. (2012). *Herbal remedies for dysmenorrhea*. Available at www.anniesremedy.com; National Center for Complementary and Alternative Medicine. (2010). *Herbs at a glance*. Available at www.nccam.nih.gov.

premenstrual syndrome (PMS) is difficult, given that so many symptoms have been associated with the condition, and at least two different syndromes have been recognized: PMS and **premenstrual dysphoric disorder (PMDD)**.

PMS is a complex, poorly understood condition that includes one or more of a large number (more than 100) of physical and psychologic symptoms beginning in the luteal phase of the menstrual cycle, occurring to such a degree that lifestyle or work is affected, and followed by a symptom-free period. Symptoms include fluid retention (abdominal bloating, pelvic fullness, edema of the lower extremities, breast tenderness, and weight gain); behavioral or emotional changes (depression, crying spells, irritability, panic attacks, and impaired ability to concentrate); premenstrual cravings (sweets, salt, increased appetite, and food binges); and headache, fatigue, and backache.

All age groups are affected, with women in their 20s and 30s most frequently reporting symptoms. Ovarian function is necessary for the condition to occur because it does not occur before puberty, after menopause, or during pregnancy. The condition is not dependent on the presence of monthly menses: women who have had a hysterectomy without bilateral salpingo-oophorectomy (BSO) still can have cyclic symptoms.

The American College of Obstetricians and Gynecologists (ACOG 2011) has noted that a diagnosis of PMS must include:

- A pattern in which the woman's symptoms are present in the 5 days before menses begins
- This pattern must occur for at least three menstrual cycles in a row
- Symptoms must end within 4 days after menses begins
- This pattern is cyclic
- Symptoms must interfere with some of her normal activities

PMDD is a more severe variant of PMS in which 3% to 8% of women have marked irritability, dysphoria, mood lability, anxiety, fatigue, appetite changes, and a sense of feeling overwhelmed (Lentz, 2012). The most common symptoms are those associated with mood disturbances. Gallenberg (2012) notes that extreme mood shifts associated with PMDD can be disruptive in work and relationships.

PMDD is included as a diagnosis in the American Psychiatric Association [APA] Diagnostic and Statistical Manual (DSM). This is important because it recognizes that women do experience some specific symptoms that coincide with the week before onset of menses, with a decrease in such symptoms within a few days after onset of menses (American Psychiatric Association [APA], 2013). Symptoms can be related to mood or physical changes, with the key factor being the cyclical nature of the symptoms.

The actual diagnosis of PMDD requires that a woman notes at least five specific symptoms (derived from a list of symptoms) and that one of those is related to mood state. These symptoms include (Storck, 2012):

- No interest in daily activities and relationships
- Fatigue or low energy
- Feelings of sadness or hopelessness, possible suicidal thoughts
- Feelings of tension or anxiety
- Feeling out of control

- Food cravings or binge eating
- Mood swings with periods of crying
- Panic attacks
- Irritability or anger that affects other people
- Physical symptoms, such as bloating, breast tenderness, headaches, and joint or muscle pain
- Problems sleeping
- Trouble concentrating

The causes of PMS and PMDD are not known, but there is general agreement that they are distinct psychiatric and medical syndromes rather than an exacerbation of an underlying psychiatric disorder. They do not occur if there is no ovarian function. A number of biologic and neuroendocrine etiologies have been suggested; however, none has been conclusively substantiated as the causative factor. It is likely that biologic, psychosocial, and sociocultural factors contribute to PMS and PMDD (Lentz, 2012).

Management

There is little agreement on management. A careful, detailed history and daily log of symptoms and mood fluctuations spanning several cycles may give direction to a plan of management. Any changes that assist a woman with PMS to exert control over her life have a positive effect. For this reason, lifestyle changes are often effective in the treatment of PMS.

Education is an important component of the management of PMS. Nurses can advise women that self-help modalities often result in significant symptom improvement. Women have found a number of complementary and alternative therapies to be useful in managing the symptoms of PMS. Nurses can suggest that women:

- Not smoke and limit their consumption of refined sugar (less than 5 tablespoons/day), salt (less than 3 g/day), red meat (up to 3 ounces/day), alcohol (less than 1 ounce/day), and caffeinated beverages
- Include whole grains, legumes, seeds, nuts, vegetables, fruits, and vegetable oils in their diet
- Eat three small to moderate-sized meals and three small snacks a day that are rich in complex carbohydrates and fiber (ACOG, 2011; Lentz, 2012)
- Use natural diuretics (see section on dysmenorrhea management on earlier in the chapter) to help reduce fluid retention

Nutritional supplements may assist in symptom relief. Calcium (1200 mg daily) and vitamin B₆ have been shown to be moderately effective in relieving symptoms, to have few side effects, and to be safe. Daily supplements of evening primrose oil are reportedly useful in relieving breast symptoms with minimal side effects, but research reports are conflicting (Biggs & Demuth, 2011; Lentz, 2012). The Mayo Clinic (2013) noted that evening primrose oil changes the balance of fatty acids, which may explain why it alleviates breast pain. Other herbal therapies have long been used to treat PMS; however, research on effectiveness is lacking, or studies are flawed (Dante & Facchinetti, 2011).

Regular exercise (aerobic exercise three or four times a week), especially in the luteal phase, is widely recommended for relief of PMS symptoms (Lentz, 2012). A monthly program that varies in intensity and type of exercise according

to PMS symptoms is best. Women who exercise regularly seem to have less premenstrual anxiety than do nonathletic women. Researchers believe aerobic exercise increases beta-endorphin levels to offset symptoms of depression and elevate mood.

Yoga, acupuncture, hypnosis, light therapy, chiropractic therapy, and massage therapy have all been reported to have a beneficial effect on PMS. Further research is needed to determine the effectiveness of these suggested therapies.

Nurses can explain the relation between cyclic estrogen fluctuation and changes in serotonin levels, that serotonin is one of the brain chemicals that assist in coping with normal life stresses, and the ways in which the different recommended management strategies help maintain serotonin levels. Support groups or individual or couples counseling may be helpful. Stress reduction techniques also may assist with symptom management (Lentz, 2012).

If these strategies do not provide significant symptom relief in 1 to 2 months, medication is often added. Many medications have been used in treatment of PMS, but no single medication alleviates all PMS symptoms. Medications often used in the treatment of PMS include diuretics, prostaglandin inhibitors (NSAIDs), progesterone, and OCPs. These have been used mainly for the physical symptoms. Studies of progesterone have not shown that it is an effective treatment (Ford, Lethaby, Roberts, & Mol, 2012). Serotonergic-activating agents, including the selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine (Prozac or

Sarafem), sertraline (Zoloft), citalopram (Celexa), escitalopram (Lexapro), and paroxetine (Paxil CR) are approved by the U.S. Food and Drug Administration (FDA) as agents for PMS and are first-line pharmacologic therapy. Use of these medications during the luteal phase of the menstrual cycle results in a decrease in emotional premenstrual symptoms, especially depression (Biggs & Demuth, 2011; Lentz, 2012). Common side effects are headaches, sleep disturbances, dizziness, weight gain, dry mouth, and decreased libido (see Nursing Care Plan).

Endometriosis

Endometriosis is characterized by the presence and growth of endometrial glands and stroma outside of the uterus. The tissue may be implanted on the ovaries; the anterior and posterior cul-de-sac; the broad, uterosacral, and round ligaments; the uterine tubes; the rectovaginal septum; the sigmoid colon; the appendix; the pelvic peritoneum; the cervix; and the inguinal area (Fig. 6-1). Endometrial lesions have been found in the vagina and on surgical scars, as well as on the vulva, the perineum, and the bladder, and sites far from the pelvic area such as the thoracic cavity, the gallbladder, and the heart. A chocolate cyst is a cystic area of endometriosis in the ovary. Old blood causes the dark coloring of the cyst's contents.

Endometrial tissue contains glands and stroma and responds to cyclic hormonal stimulation in the same way that the uterine endometrium does. During the proliferative and secretory phases of the cycle, the endometrial tissue grows. During or

NURSING CARE PLAN

Premenstrual Syndrome

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Acute Pain related to cyclic breast changes as evidenced by woman's report</i>	Woman will report a decrease in the intensity of pain or discomfort after interventions.	Assess timing and intensity of pain or discomfort. Counsel woman to take medications if prescribed. Suggest that woman wear a supportive bra.	To validate relation to cyclic changes To minimize breast tenderness
<i>Situational Low Self-esteem related to cyclic hormonal changes as evidenced by woman's verbal report</i>	Woman will report increased number of feelings of self-worth.	Provide therapeutic communication. Encourage woman to limit caffeine and eat small, frequent meals. Refer woman to support groups.	To validate feelings of depression and mood swings To lessen irritability aggravated by caffeine and hypoglycemia To encourage the sharing of experiences, feelings, and self-help tips
<i>Excess Fluid Volume related to cyclic hormonal influences as evidenced by weight gain before start of menstrual period</i>	Woman will report no significant changes in body weight before start of menstrual period.	Encourage woman to limit intake of salt and sodium-containing foods. Counsel woman to take diuretics as prescribed. Encourage consumption of natural diuretic foods.	To decrease fluid retention To facilitate fluid excretion To encourage fluid excretion
<i>Anxiety related to anticipation of cyclic pain</i>	Woman will report a decrease in anxiety level.	Teach woman to recognize anxiety. Identify relaxation techniques. Encourage woman to attend support groups.	To prompt early preventive interventions in order to decrease anxiety To encourage expression of feelings and self-help interventions

FIG 6-1 Common sites of endometriosis. (From Lentz, G.M., Lobo, R.A., Gershenson, D.M., et al. [Eds.]. (2012). *Comprehensive gynecology* [6th ed.]. Philadelphia: Elsevier.)

immediately after menstruation, the tissue bleeds, resulting in an inflammatory response with subsequent fibrosis and adhesion to adjacent organs.

The overall incidence of endometriosis is 5% to 15% in reproductive-age women, 30% to 45% in infertile women, and 33% in women with chronic pelvic pain (Lobo, 2012b). Although the condition usually develops in the third or fourth decade of life, endometriosis has been found in adolescents with disabling pelvic pain or abnormal vaginal bleeding (Steenberg, Tanbo, & Qvigstad, 2013). Endometriosis may worsen with repeated cycles, or it may remain asymptomatic and undiagnosed, eventually disappearing after menopause. However, it has been reported to occur in about 5% of postmenopausal women receiving menopausal hormone therapy. There appears to be a familial tendency to develop endometriosis; the condition is seven times more prevalent in women who have a first-degree relative with endometriosis as compared with the general population (Lobo).

Several theories concerning the cause of endometriosis have been suggested. However, the etiology and pathology of this condition continue to be poorly understood. One of the most widely accepted theories is transplanted or retrograde menstruation. According to this theory endometrial tissue is refluxed through the uterine tubes during menstruation into the peritoneal cavity, where it implants on the ovaries and other organs. Retrograde menstruation has been documented in a number of surgical studies and is estimated to occur in 90% of menstruating women. For most women endometrial tissue outside the uterus is disintegrated before it can implant or seed in the peritoneal cavity or elsewhere. Other theories include genetic disposition, immunologic changes, and hormonal influences (Lobo, 2012b).

Symptoms vary among women, from nonexistent to incapacitating. Severity of symptoms can change over time and may be disproportionate to the extent of the disease. The major symptoms of endometriosis are pelvic pain, dysmenorrhea, dyspareunia (painful intercourse), abnormal menstrual bleeding, and infertility. Women also may experience chronic noncyclic pelvic pain, pelvic heaviness, or pain radiating to the thighs. Many women report bowel symptoms such as diarrhea, pain with defecation, and constipation caused by avoiding defecation because of the pain. Less common symptoms include abnormal bleeding (hypermenorrhea, menorrhagia, or premenstrual staining) and pain during exercise as a result of adhesions (Lobo, 2012b).

Women, especially adolescents, who have endometriosis often have other comorbid conditions, including pain, mood disorders, and asthma (Smorgick, Marsh, As-Sanie, et al., 2013).

Impaired fertility may result from adhesions around the uterus that pull the uterus into a fixed, retroverted position. Adhesions around the uterine tubes may block the fimbriated ends or prevent the spontaneous movement that carries the ovum to the uterus.

Management

Treatment is based on the severity of symptoms and the goals of the woman or couple. Women without pain who do not want to become pregnant need no treatment. In women with mild pain who may desire a future pregnancy, treatment may be limited to use of NSAIDs during menstruation (see earlier discussion of these medications).

Suppression of endogenous estrogen production and subsequent endometrial lesion growth is the cornerstone of management of the disease. Two main classes of medications are used to suppress endogenous estrogen levels: GnRH agonists and androgen derivatives. GnRH agonist therapy (leuprolide [Lupron], nafarelin acetate [Synarel], goserelin acetate [Zoladex]) acts by suppressing pituitary gonadotropin secretion. FSH and LH stimulation of the ovary declines markedly, and ovarian function decreases significantly. A medically induced menopause develops, resulting in anovulation and amenorrhea. Shrinkage of already established endometrial tissue, significant pain relief, and interruption in further lesion development follow. The hypoestrogenism results in hot flashes in almost all women. Trabecular bone loss is common, although most loss is reversible within 12 to 24 months after the medication is stopped (Lobo, 2012b).

Leuprolide (3.75 mg intramuscular injection given once a month for up to 6 months), nafarelin (200 mg administered twice daily by nasal spray for up to 6 months), and goserelin 3.6 mg every 28 days for up to 6 months by subcutaneous implant are effective and well tolerated. These medications reduce endometrial lesions and pelvic pain associated with endometriosis and have posttreatment pregnancy rates similar to that of danazol (Danocrine) therapy (Lobo, 2012b). Common side effects of these drugs are those of natural menopause—hot flashes and vaginal dryness. Occasionally women report headaches and muscle aches. Treatment is usually limited to 6 months to minimize bone loss. Although unlikely, it is possible for a woman to become pregnant while taking a GnRH agonist. Because the potential teratogenicity of this drug is unclear, women should use a barrier contraceptive during treatment.

Danazol, a mildly androgenic synthetic steroid, suppresses FSH and LH secretion, thus producing anovulation and hypogonadotropism. This results in decreased secretion of estrogen and progesterone and regression of endometrial tissue. Danazol can produce side effects severe enough to cause a woman to discontinue the drug, including masculinizing traits (weight gain, edema, decreased breast size, oily skin, hirsutism, and deepening of the voice), all of which often disappear when treatment is discontinued. Other side effects are amenorrhea, hot flashes, vaginal dryness, insomnia, and decreased libido. Migraine headaches, dizziness, fatigue, and depression are also reported. Danazol treatment has been reported to adversely affect lipids, with a decrease in high-density lipoprotein levels and an increase in low-density lipoprotein levels. Danazol should never be prescribed when pregnancy is suspected, and barrier contraception should be used with it because ovulation may not be suppressed. Danazol can produce pseudohermaphroditism in female fetuses. The medication is contraindicated in women with liver disease and should be used with caution in women with cardiac and renal disease. Danazol is used less frequently to treat endometriosis than other medical therapies (Lobo, 2012b).

Women who have early symptomatic disease and who can postpone pregnancy may be treated with continuous OCPs that have a low estrogen-to-progestin ratio to shrink endometrial tissue. Any low-dose OCPs can be used if taken for 15 weeks, followed by 1 week of withdrawal. This therapy is associated with minimal side effects and can be taken for extended periods (Lobo, 2012b). Limited data exist on the effectiveness of progestagen-only medications for treating pain related to endometriosis (Brown, Kives, & Akhtar, 2012).

Continuous combined hormone therapy (OCPs, estrogen/progestin patch, estrogen/progestin vaginal ring) for menstrual suppression and administration of NSAIDs is the usual treatment for adolescents younger than the age of 16 who have endometriosis. GnRH agonist therapy for severe symptoms may have possible adverse effects on bone mineralization in adolescents, and bone mineral density should be carefully monitored (Laufer, 2008).

Fritz and Speroff (2011) described an “add-back therapy” with low-dose estrogen-progestin combinations as leading to a normal bone mineral density while on GnRH agonist therapy.

Surgical intervention is often needed for severe, acute, or incapacitating symptoms. Decisions regarding the extent and type of surgery are influenced by a woman's age, desire for children, and location of the disease. For women who do not want to preserve their ability to have children, the only definite cure is total abdominal hysterectomy with BSO (TAH with BSO). In women in their childbearing years who want children and in whom the disease does not prevent bearing children, reproductive capacity should be retained through careful removal by laparoscopic surgery or laser therapy (coagulation, vaporization, or resection) of all endometrial tissue possible with retention of ovarian function (Lobo, 2012b).

Regardless of the type of treatment (short of TAH with BSO), endometriosis recurs in approximately 40% of women. Thus for many women endometriosis is a chronic disease with conditions such as chronic pain or infertility. Counseling and

education are critical components of nursing care for women with endometriosis. Women need an honest discussion of treatment options, with review of the potential risks and benefits of each option. Because pelvic pain is a subjective, personal experience that can be frightening, support is important. Sexual dysfunction resulting from dyspareunia is common and may necessitate referral for counseling. Support groups for women with endometriosis may be found in some locations. Resolve (www.resolve.org), an organization for infertile couples, or the Endometriosis Association (www.ivf.com/endohtml.html) may also be helpful (see Nursing Care Plan).

Alterations in Cyclic Bleeding

Women often experience changes in amount, duration, interval, or regularity of menstrual cycle bleeding. Commonly women worry about menstruation that is infrequent (oligomenorrhea), is scanty at normal intervals (hypomenorrhea), is excessive (menorrhagia), or occurs between periods (metrorrhagia).

Oligomenorrhea/Hypomenorrhea

The term **oligomenorrhea** often is used to describe decreased menstruation, either in amount, time, or both. However, oligomenorrhea more correctly refers to infrequent menstrual periods characterized by intervals of 40 to 45 days or longer, and hypomenorrhea to scanty bleeding at normal intervals. The causes of oligomenorrhea are often abnormalities of hypothalamic, pituitary, or ovarian function. Oligomenorrhea also can be physiologic, or part of a woman's normal pattern for the first few years after menarche or for several years before menopause.

Treatment is aimed at reversing the underlying cause, if possible. Hormonal therapy using progestins, with or without estrogens, also may be used to prevent complications of unopposed estrogen production (endometrial hyperplasia or carcinoma) or of absent estrogen (vaginal dryness, hot flashes or flushes, or osteoporosis).

Women with menstruation characterized by prolonged intervals between cycles need education and counseling. The cause of the condition and the rationale for a specific treatment should be discussed, as should advantages and disadvantages of hormonal therapy. If a woman chooses medical intervention, she should be provided with written instructions, taught how to take the medications, and made aware of their side effects. Teaching and counseling should emphasize the importance of the woman keeping careful records of her vaginal bleeding.

One of the most common causes of scanty menstrual flow is OCPs. If a woman is considering OCPs for contraception, it is important to explain in advance that the use of OCPs can decrease menstrual flow by as much as two thirds. This effect is caused by the continuous action of the progestin component, which produces a decidualized endometrium with atrophic glands.

Hypomenorrhea also may be caused by structural abnormalities of the endometrium or the uterus that result in partial disintegration of the endometrium. These conditions include Asherman syndrome, in which adhesions resulting from curettage or infection obliterate the endometrial cavity, and congenital partial obstruction of the vagina.

NURSING CARE PLAN

Endometriosis

NURSING DIAGNOSIS	EXPECTED OUTCOMES	NURSING INTERVENTIONS	RATIONALES
<i>Acute Pain related to menstruation secondary to endometriosis</i>	Woman will verbalize a decrease in intensity and frequency of pain during each menstrual cycle.	Assess location, type, and duration of pain and history of discomfort. Administer analgesics. Administer hormone-altering medications if ordered. Provide nonpharmacologic methods such as heat.	To determine severity of dysmenorrhea To assist with pain relief To suppress ovulation To increase blood flow to the pelvic region
<i>Deficient Knowledge related to unfamiliarity with treatment, as evidenced by woman's statements</i>	Woman will verbalize correct understanding of the use of self-care methods and prescribed therapies.	Assess woman's current understanding of the disorder and related therapies. Give information to woman regarding the disorder and treatment regimen. Provide therapeutic communication. Refer to support group.	To validate the accuracy of knowledge base To empower the client to become a partner in her own care To validate feelings and provide support To enhance feelings of self-worth through group communication
<i>Situational Low Self-esteem related to infertility as evidenced by woman's statements of decreased self-worth</i>	Woman will verbalize positive feelings of self-worth.	Provide opportunity to discuss feelings. Reinforce information provided. Provide emotional support.	To identify source of anxiety To keep expectations realistic and dispel myths or inaccuracies To encourage verbalization of feelings
<i>Anxiety related to possible invasive surgical procedure as evidenced by woman's verbal report</i>	Woman will report a decreased number of anxious feelings.	Teach woman to report any changes in health status. Review side effects of medications. Encourage ongoing communication.	To initiate prompt treatment To recognize possible causes for changes in health status To promote trust and comfort
<i>Risk for Injury related to disease progression</i>	Woman will report any changes in health status to health care provider.		

Metrorrhagia

Metrorrhagia, or intermenstrual bleeding, refers to any episode of bleeding, whether spotting, menses, or hemorrhage, that occurs at a time other than the normal menses. *Mittlestaining*, also referred to as *mittelschmerz*, a small amount of bleeding or spotting that occurs at the time of ovulation (14 days before onset of the next menses), is considered normal. The cause of mittlestaining is not known; however, its common occurrence can be documented by its repetition in the menstrual cycle.

Women taking OCPs may have midcycle bleeding or spotting. (See Chapter 8 for a discussion of the side effects of OCPs.) If the OCP does not maintain a sufficiently hypoplastic endometrium, the endometrium will begin to shed, usually in small amounts at a time, a process termed *breakthrough bleeding*, which is most common in the first three cycles of OCPs. The reduced potency of OCPs (resulting in increased safety) has decreased the amount of available hormones, making it more important that blood levels be kept constant. Taking the pill at exactly the same time each day may alleviate the woman's problem. If the spotting continues, a different formulation of the OCP that increases either the estrogen or progestin component of the pill can be tried.

Progestin-only contraceptive methods (oral and injectable) also may cause midcycle bleeding, especially in the first several cycles. Women should be advised of this and counseled to report continuation of breakthrough bleeding after the first three to six cycles to their health care provider.

Women with an intrauterine device (IUD) may have spotting between their periods and possibly heavier menstrual flow.

The causes of intermenstrual bleeding are varied (Table 6-3). It is important that the nurse always consider the possibility

TABLE 6-3 Causes of Intermenstrual Bleeding

REPRODUCTIVE DISORDER	PREGNANCY PROBLEMS	INFECTIONS
Functional ovarian cyst	Pregnancy implantation	Endometritis
Cervical erosion	Miscarriage	Sexually transmitted infections
Leiomyoma	Ectopic pregnancy	
Polyps, uterine or endocervical	Molar pregnancy	
Trauma	Retained placenta, miscarriage, or induced abortion	
Foreign body		
Malignancy of reproductive tract	Retained placenta, birth	

EVIDENCE-BASED PRACTICE

Treatments for Heavy Menstrual Bleeding**Ask the Question**

For young women with heavy menstrual bleeding, what are the safest and most beneficial medical and surgical interventions?

Search for the Evidence

Search Strategies English language research-based publications since 2011 on dysfunctional uterine bleeding, heavy menstrual bleeding, and menorrhagia were included.

Databases Used Cochrane Database of Systematic Reviews, National Guideline Clearinghouse (AHRQ), CINAHL, PubMed, UpToDate, and the professional websites for ACOG and AWHONN.

Critical Appraisal of the Evidence

Heavy menstrual bleeding (HMB) can occur from reproductive hormonal imbalance, local uterine pathology, or clotting disorders. HMB may be linked to the inflammatory processes of the menstrual cycle, in which endometrial immune cells facilitate tissue breakdown, repair, and remodeling for menstruation (Berbic & Fraser, 2013).

- First-line treatment for HMB is nonsurgical. The most effective nonsurgical treatments, in order of efficacy, are:
 1. levonorgestrel-releasing intrauterine system (LNR-IUS), an intrauterine device (IUD) placed to deliver progestogen locally to the endometrium
 2. danazol, an oral progestogen derivative that shortens bleeding duration but can cause significant masculinizing side effects
 3. antifibrinolytic (tranexamic acid)
 4. nonsteroidal antiinflammatories (Lethaby, Duckitt, & Farquhar, 2013; Matteson, Rahn, Wheeler, et al., 2013)
- If medical therapy does not stop the bleeding, surgical interventions become necessary. Hysterectomy is the most effective but involves costly hospitalization and risk for surgical complications.
- Women who do not desire any more children can be offered an outpatient procedure in which the uterine lining is ablated (destroyed) to stop the bleeding.
- Direct visualization of the uterine lining, using a hysteroscope through the cervix, has been the gold standard technique for endometrial ablation. This requires a skilled practitioner. The endometrial lining is cauterized using
 - Laser
 - Rollerball electrocautery
 - Loop electrocautery (also called transcervical resection)
- Several newer techniques that do not require a hysteroscope include thermal ablation using a heated balloon, radiofrequency, or microwave. These are easier, shorter, and less likely to perforate or damage local tissue. However, technical difficulties with equipment erase any clear advantage the newer techniques offer women (Lethaby, Penninx, Hickey, et al., 2013).
- Endometrial ablation is best done when the endometrium is 4 mm or less. To facilitate endometrial thinning and ease of surgery, women may be prescribed one of the following
 - Gonadotropin-releasing hormone analogue (GnRH α), which competes for natural GnRH receptor sites, decreasing estrogen production, or danazol (Tan & Lethaby, 2013)

Apply the Evidence: Nursing Implications

- HMB negatively affects quality of life: women report physical, social, and sexual distress; pain; and anemia. The woman and her family may feel isolated and embarrassed. They may be fearful of serious disease, such as cancer.
- Nonsurgical treatments are frequently ineffective. This can be very frustrating and discouraging to women whose activities of daily living such as work, school, travel, and social activities may become restricted.
- Surgical interventions that ablate the endometrium result in loss of ability to become pregnant. For women who do not desire future pregnancy, the resulting amenorrhea can be a great relief. For women who planned future pregnancies, this alteration in their life plan is a life-altering loss, requiring sensitivity.
- Couples and significant others, such as parents, may benefit from grief counseling and group support. See Chapter 9 for more information about the psychologic implications of infertility.

Quality and Safety Competencies: Evidence-Based Practice* Knowledge

Demonstrate comprehensive understanding of the concepts of pain and suffering, including physiologic models of pain and comfort.

The nurse should ask the woman and her family what meaning this disorder and its treatment have for them.

Skills

Initiate effective treatments to relieve pain and suffering in light of client values, preferences, and expressed needs.

Explaining the treatments and answering questions can help the family understand and cope with disease and life change.

Attitudes

Recognize that women's expectations influence outcomes in management of pain or suffering.

Collaborative decision making requires that the woman and her family expectations and goals be addressed in all aspects of care.

that any woman who has not undergone menopause and who seeks care for intermenstrual bleeding is or recently has been pregnant.

Treatment of intermenstrual bleeding depends on the cause and may include reassurance and education concerning miltlestaining, observation of three menstrual cycles for suspected functional ovarian cyst, adjustment of an OCP, removal of foreign bodies, and treatment for vaginal infections. More complex treatment may consist of removal of polyps; evaluation and treatment of an abnormal Papanicolaou (Pap) test, including colposcopy, biopsy, cautery, cryosurgery, or conization; and surgery, chemotherapy, or radiation treatment for malignancy. Important nursing roles include reassurance, counseling, education, and support.

Menorrhagia

Menorrhagia (hypermenorrhea) is defined as excessive menstrual bleeding, in either duration or amount. The causes of heavy menstrual bleeding are many, including hormonal disturbances, systemic disease, benign and malignant neoplasms, infection, and contraception (IUDs). A single episode of heavy bleeding may occur, or a woman may have regular flooding as a pattern in which she changes tampons or pads every few hours for several days.

! NURSING ALERT

If the woman herself considers the amount or duration of bleeding to be excessive, the problem should be investigated.

Hemoglobin and hematocrit provide objective indicators to actual blood loss and should always be assessed.

A single episode of heavy bleeding may signal an early pregnancy loss. This type of bleeding is often thought to be a period that is heavier than usual, perhaps delayed, and is associated with abdominal pain or pelvic discomfort. When early pregnancy loss is suspected, a hematocrit and serum β -hCG pregnancy test should be done.

Infectious and inflammatory processes such as acute or chronic endometritis and salpingitis may cause heavy menstrual bleeding. Although rare, systemic diseases of nonreproductive origin such as blood dyscrasias, hypothyroidism, and lupus erythematosus also can cause hypermenorrhea. In obese women anovulation caused by increased peripheral conversion of androstenedione to estrogen may develop and manifest as menorrhagia. Medications also may cause abnormal bleeding. Chemotherapy, anticoagulants, neuroleptics, and steroid hormone therapy all have been associated with excessive flow.

Uterine *leiomyomata* (fibroids or myomas) are a common cause of menorrhagia. Fibroids are benign tumors of the smooth muscle of the uterus, the etiology of which is unknown. Fibroids are estrogen sensitive and commonly develop during the reproductive years and shrink after menopause. Other uterine growths ranging from endometrial polyps to adenocarcinoma and endometrial cancer are common causes of heavy menstrual bleeding, as well as of intermenstrual bleeding.

Treatment for menorrhagia depends on the cause of the bleeding. If the bleeding is related to the contraceptive method, the nurse provides factual information and reassurance and discusses other contraceptive options. If bleeding is related to the presence of fibroids, the degree of disability and discomfort associated with the fibroids and the woman's plans for childbearing will influence treatment decisions. Treatment options include medical and surgical management. Most fibroids can be monitored by frequent examinations to judge growth, if any, and correction of anemia, if present. Women with menorrhagia should be warned not to use aspirin because of its tendency to increase bleeding. Medical treatment depends on the cause, client preferences, possibility of pregnancy, and future desire to have children (UpToDate, 2012). This reduction in bleeding is often accomplished with the use of a GnRH agonist. If the woman wishes to retain childbearing potential, a myomectomy may be done. Myomectomy, or removal of the tumors only, is particularly difficult if multiple myomas must be removed. If the woman does not want to preserve her childbearing function, or if she has severe symptoms (severe anemia, severe pain, considerable disruption of lifestyle), hysterectomy or endometrial ablation (laser surgery or electrocoagulation) may be done (see Chapter 11). Uterine artery embolization, based on the assumption that control of arterial blood flow to the fibroid will control symptoms, has been reported to result in reduced menorrhagia, less dysmenorrhea, and reduced pelvic pressure and urinary symptoms. This method of treatment is used for women who have completed their childbearing because there is a risk for loss of fertility (see Chapter 11).

Dysfunctional Uterine Bleeding

Abnormal uterine bleeding (AUB) is any form of uterine bleeding that is irregular in amount, duration, or timing and not related to regular menstrual bleeding. Box 6-1 lists possible causes of AUB. Although often used interchangeably, the terms AUB and **dysfunctional uterine bleeding (DUB)** are not synonymous. DUB is a subset of AUB defined as "excessive uterine bleeding with no demonstrable organic cause, genital or extragenital" (Lobo, 2012a). DUB is most frequently caused by anovulation. When there is no surge of LH, or if insufficient progesterone is produced by the corpus luteum to support the endometrium, it will begin to involute and shed. This process most often occurs at the extremes of a woman's reproductive years—when the menstrual cycle is just becoming established at menarche or when it draws to a close at menopause. DUB also can be found with any condition that gives rise to chronic anovulation associated with continuous estrogen production. Such conditions include obesity, hyperthyroidism and hypothyroidism, polycystic ovary syndrome, and any of the endocrine conditions discussed in the sections on amenorrhea and oligomenorrhea. A diagnosis of DUB is made only after ruling out all other causes of abnormal menstrual bleeding (Lobo).

When uterine bleeding is profuse and a woman's hemoglobin level is less than 8 g/dL (hematocrit of 23% or 24%), the woman may be hospitalized and given conjugated estrogens (e.g., Premarin), 25 mg intravenously. The dose may be repeated every 4 to 6 hours until bleeding stops or slows significantly (Estephan

BOX 6-1 Possible Causes of Abnormal Uterine Bleeding**Pregnancy-Related Conditions**

- Threatened or spontaneous miscarriage
- Retained products of conception after elective abortion
- Ectopic pregnancy
- Placenta previa/placenta abruptio
- Trophoblastic disease

Lower Reproductive Tract Infections

- Cervicitis
- Endometritis
- Myometritis
- Salpingitis

Benign Anatomic Abnormalities

- Adenomyosis
- Leiomyomata
- Polyps of the cervix or endometrium

Neoplasms

- Endometrial hyperplasia
- Cancer of cervix and endometrium
- Hormonally active tumors (rare)
- Vaginal tumors (rare)

Malignant Lesions

- Cervical squamous cell carcinoma
- Endometrial adenocarcinoma
- Estrogen-producing ovarian tumors

- Testosterone-producing ovarian tumors
- Leiomyosarcoma

Trauma

- Genital injury (accidental, coital trauma, sexual abuse)
- Foreign body
- Lacerations

Systemic Conditions

- Adrenal hyperplasia and Cushing disease
- Blood dyscrasias
- Coagulopathies
- Hypothalamic suppression (from stress, weight loss, excessive exercise)
- Polycystic ovary disease
- Thyroid disease
- Pituitary adenoma or hyperprolactinemia
- Severe organ disease (renal or liver failure)

Iatrogenic Conditions

- Medications with estrogenic activity
- Anticoagulants
- Exogenous hormone use (oral contraceptives, menopausal hormone therapy)
- Selective serotonin reuptake inhibitors
- Tamoxifen
- Intrauterine devices
- Herbal preparation (ginseng)

Modified from Albers, J.R., Hull, S.K., & Wesley, R.M. (2004). Abnormal uterine bleeding. *American Family Physician*, 69, 1915-1926; 1931-1932.

& Sinert, 2012). If the bleeding has not stopped in 12 to 24 hours, dilation and curettage (D&C) may be done to control severe bleeding and hemorrhage. An endometrial biopsy may be collected at the same time to evaluate endometrial tissue or rule out endometrial cancer. After this treatment, oral conjugated estrogen, 2.5 mg, is given daily, followed by the addition of progesterone (e.g., medroxyprogesterone [Provera], 10 mg by mouth), given in the final 10 days of therapy to initiate withdrawal bleeding. Alternatively, a combined OCP is given for 21 days after intravenous therapy. Once the acute phase has passed, the woman is maintained on cyclic low-dose OCPs for 3 to 6 months. Such long-term treatment helps prevent recurrence of the pattern of DUB and hemorrhage. If the woman wants contraception, she should continue to take OCPs. If the woman has no need for contraception, the treatment may be stopped to assess her bleeding pattern. If menstruation does not resume, a progesterone regimen (e.g., medroxyprogesterone, 10 mg/day for 10 days before the expected date of her menstrual period) may be prescribed after ruling out pregnancy. This is done to prevent persistent anovulation with chronic unopposed endogenous estrogen hyperstimulation of the endometrium, which can result in eventual atypical tissue changes (Lobo, 2012a).

If the recurrent, heavy bleeding is not controlled by hormonal therapy or D&C, ablation of the endometrium through laser treatment may be performed. Nursing roles include counseling and educating women about their options as needed and referring women to the appropriate specialists and health care services.

CARE MANAGEMENT

Medical and nursing management has been discussed with each menstrual problem. It is important that the health care provider completes a systematic assessment, including a thorough menstrual, obstetric, sexual, and contraceptive history; the woman's perceptions of her condition; and cultural, ethnic, and lifestyle influences and patterns of coping. Assessment also involves evaluating the amount of pain or bleeding and noting ways the woman tries to alleviate pain and/or bleeding, including home remedies and prescriptions. It is helpful to ask the woman to keep a diary of her symptoms and ways that she alleviates those symptoms. Nursing care involves accepting the woman's symptoms as valid, correlating data from the daily diary of emotional status, subjective feelings, and physical state with physiologic changes, encouraging the woman to express her feelings about her symptoms, providing information about therapeutic options she chooses, and providing information about local support groups.

MENOPAUSE

With the increasing life span of American women, most can expect to live one third of their lives after their reproductive years. As women age many experience transitions that present challenges and require adaptation such as changing health, work, or marital status. Nowhere is this more true than with the changes associated with menopause. In the United States, menopause usually occurs during the late 40s and early 50s, with the

median age being 51 to 52 years (Lobo, 2012c). The average age for the onset of the perimenopausal transition is 46 years; 95% of women experience the onset between ages 39 and 51. The average duration of the perimenopause period is 4 to 5 years, with 95% of women postmenopausal by age 58 (Lobo). Cigarette smoking and a history of short intermenstrual intervals seem to decrease the age at onset of menopause. African-American and Hispanic women in the United States experience menopause earlier than Caucasian women. However, heredity is the major determinant of age at menopause; genetics may explain most of the variation in menopause age (Lobo).

Perimenopause is the period that encompasses the transition from normal ovulatory cycles to cessation of menses and is marked by irregular menstrual cycles. Another term used to signal the period when a woman moves from the reproductive stage of life through the perimenopausal transition and menopause to the postmenopausal years is the **climacteric**. Menopause refers to the complete cessation of menses and is a single physiologic event said to occur when women have not had menstrual flow or spotting for 1 year, and it can be identified only in retrospect. **Surgical menopause** occurs with hysterectomy and bilateral oophorectomy. **Postmenopause** is the time after menopause.

Although all women have similar hormonal changes with menopause, the experience of each woman is influenced by her age, cultural background, health, type of menopause (spontaneous or surgical), childbearing desires, and relationships. Women may view menopause as a major change in their lives—either positive, such as freedom from troublesome dysmenorrhea and the need for contraception, or negative, such as feeling “old” or losing childbearing possibilities.

Physiologic Characteristics

Knowledge of the normal changes that occur during perimenopause is essential in assessing menopausal experiences and problems. Natural menopause is a gradual process with progressive increases in anovulatory cycles and eventual cessation of menses. In the 2 to 8 years preceding menopause, subtle hormonal changes eventually lead to altered menstrual function and later to amenorrhea. When women are in their 40s, anovulation occurs more often, menstrual cycles increase in length, and ovarian follicles become less sensitive to hormonal stimulation from FSH and LH. Because of these changes, a follicle is stimulated to the point that an ovum grows to maturity and is released in some months, whereas in other months, no ovulation takes place. Without ovulation and release of an ovum, progesterone is not produced by the corpus luteum. The lining continues to grow until it lacks a sufficient blood supply, at which point it bleeds. During this time a woman's cycle becomes more irregular. She may skip or miss periods; have shorter or lighter periods or longer, heavier periods; and have clotting. FSH levels become elevated, reflecting an attempt to stimulate a follicle to produce estrogen.

Physical Changes During the Perimenopausal Period

Bleeding

During the perimenopausal years, women may have longer menstrual periods that differ in the type of bleeding. They may

have 2 to 3 days of spotting followed by 1 to 2 days of heavy bleeding, or they may have regular menses followed by 2 to 3 days of spotting. Such symptoms are characteristic of degenerating corpus luteum function. After menopause women continue to have small amounts of circulating estrogen. Although the ovaries do not produce estrogen, androgens (androstenedione and testosterone) are produced for some time after menopause. Androgens produced by the adrenal glands are converted to estrone, a form of estrogen, in the liver and fat cells. With advanced age the ovaries stop producing androstenedione, which further limits the amount of estrone in the body. Obese women are more likely to have dysfunctional uterine bleeding and endometrial hyperplasia because women with more body fat have higher circulating levels of estrone. This occurs because the estrogen that is stored in the body's fat cells is converted into a form of estrogen (estrone) that is available to the estrogen receptors within the endometrium.

Genital Changes

The vagina and urethra are estrogen-sensitive tissues, and low levels of estrogen can cause atrophy of both. Age-related vaginal changes not affected by estrogen also occur. Through both processes the vaginal membranes thin, hold less moisture, and lubricate more slowly. However, not all women have symptoms of genital atrophy. Women who are sexually active have less vaginal atrophy and fewer problems related to intercourse. Thin women are more likely to have more symptoms related to reduced estrogen levels such as vaginal dryness because of lack of adipose tissue and thus stored estrogen. Additionally, vaginal pH increases, lactobacillus growth can be depressed, and other bacteria tend to multiply. This combination of factors can lead to vaginitis.

Dyspareunia (painful intercourse) can occur because the vagina becomes smaller, the vaginal walls become thinner and drier, and lubrication during sexual stimulation takes longer. Intercourse becomes painful and may result in postcoital bleeding. Some women decide to forgo intercourse altogether.

In some women the shrinking of the uterus, the vulva, and the distal portion of the urethra associated with aging leads to disturbing symptoms, including urinary frequency, dysuria, uterine prolapse, and stress incontinence. Vaginal relaxation with cystocele, rectocele, and uterine prolapse is not caused by reduced estrogen levels but may be a delayed result of childbearing or other cause of weakness of pelvic support structures. Urinary frequency sometimes occurs after menopause because the distal portion of the urethra, which has the same embryologic origin as the reproductive organs, shortens and shrinks. Irritants have easier access to the urinary tract with its short urethra and may cause frequency and urinary tract infections.

Urinary incontinence and uterine displacement are two other common age-related rather than menopause-related findings in the postmenopausal period. These conditions are discussed in Chapter 11.

Vasomotor Instability

Investigators have devoted significant attention to identifying ovarian, hypothalamic, and pituitary hormonal mechanisms that produce symptoms related to menopause. Two

symptoms appear to increase in incidence as women progress through menopause: hot flashes and night sweats. Many of the other changes commonly associated with menopause, such as decrease in size of genital structures, skin changes, and changes in breast size, are more correctly attributed to aging.

Vasomotor instability in the form of **hot flashes** or **flushes** is a result of fluctuating estrogen levels and is the most common disturbance of the perimenopausal years, occurring in up to 75% of women having natural menopause and 90% of women who have a surgical menopause. In the United States, Hispanic and African-American women report a higher incidence of these symptoms than Caucasian women; Asian women have the lowest incidence (Lobo, 2012c). Vasomotor instability occurs most frequently in the first 2 postmenopausal years; the number of episodes decreases over time. However, some women have hot flashes before menopause and continue to have them for 10 or more years afterward. During this time women experience changeable vasodilation and vasoconstriction as a hot flush (visible red flush of skin and perspiration) or hot flash (sudden warm sensation in neck, head, and chest) and night sweats. For some women hot flashes may be an infrequent, possibly pleasant, sensation of warmth; for others, they may be an intensely unpleasant sensation of heat or warmth that may occur 20 to 50 times a day, create intense anxiety, and significantly decrease quality of life. Several factors can precipitate or aggravate an episode, including crowded or warm rooms, alcohol, hot drinks, spicy foods, proximity to a heat source, and stress.

Night sweats, characterized by profuse perspiration and heat radiating from the body during the night, are another form of vasomotor instability experienced by many women. Sleep may be interrupted nightly because nightclothes and bed linens are soaked. Women may find that they are not able to go back to sleep. Sleep deprivation is a primary complaint of women experiencing hot flashes (Lobo, 2012c). Other problems associated with perimenopausal fluctuations of vasoconstriction or vascular spasms include dizziness, numbness and tingling in fingers and toes, and headaches.

Mood and Behavioral Responses

The tendency to associate hormonal changes with psychologic symptoms in midlife that has been prevalent in medical literature for decades and continues today was fueled by a belief that postmenopausal women have “estrogen deficiency.” However, there is no concrete evidence that menopause has a deleterious effect on mental health of midlife women. Reviews of epidemiologic studies on menopause and depression found no causal association between menopause and depression (Lobo, 2012c). Women with hot flashes and night sweats do report insomnia, fatigue from loss of sleep, and depressed mood. They complain of feeling more emotionally labile, nervous, or agitated, with less control of their emotions. However, the interaction of psychologic, biologic, and sociocultural factors is so complex that it is difficult to determine whether a woman's reported mood shifts are the result of hormonal changes, normal aging, or cultural conditioning. Most likely a woman's psychologic makeup, cultural background, intercurrent stresses, and changing life roles and circumstances are more

important than estrogen levels. Dealing with teenage children; having teenagers leave home; helping aging parents; becoming widowed or divorced; the onset of a major illness or disability (even death) in a spouse, relative, or friend; grieving for friends and family who are ill or dying; retirement; and financial insecurity are among the many stresses of women in their 40s and 50s.

Cultural messages also influence a woman's perception of menopause. Experiences with menopause are not universal and vary among cultural groups. Women do not find symptoms to be a cause for concern; however, they do report that symptoms are bothersome. Many women have accepted childbearing and childrearing as their major role in life, and the inability to bear children is a significant loss. Others see menopause as the first step to old age and associate it with a loss of attractiveness, physical ability, and energy. Western culture values youth and physical attractiveness; the wisdom gained from life experience is not valued, and older adults have a loss of status, function, and role. No rituals give older women a special place and function. In cultures in which postmenopausal women gain status, such as India, the Far East, and the South Pacific islands, depression among menopausal women is not observed. Western women, however, may have little to compensate for their losses.

For other women, menopause is not a loss or a symbol of losses, but a relief. For some, menopause is a relief from the fear of pregnancy, the discomfort and bother of menstruation, and the inconveniences of contraception.

The ability to cope with any stress involves three factors: the person's perception or understanding of the event, the support system, and coping mechanisms. Nurses counseling a woman in the perimenopausal years must therefore assess her understanding of perimenopausal changes, her perceptions of stressful experiences, her support systems, and her coping skills.

Health Risks of Perimenopausal Women

Osteoporosis and coronary heart disease are the major health risks of perimenopausal women and the focus of the following discussion.

Osteoporosis

Aging is associated with a progressive decrease in bone density in men and women. **Osteoporosis** is a generalized, metabolic disease characterized by decreased bone mass and increased incidence of bone fractures. Normally there is a dynamic balance between bone formation (osteoblastic activity) and bone resorption (osteoclastic activity). Because one of the functions of estrogen is to stimulate the osteoblasts, the postmenopausal decrease in estrogen levels causes an imbalance between bone formation and resorption. Old bone deteriorates faster than new bone is formed, resulting in a slow thinning of the bones. Estrogen also is required for the conversion of vitamin D into calcitonin, which is essential in the absorption of calcium by the intestine. Reduced calcium absorption from the gut, in addition to the thinning of the bones, places postmenopausal women at risk for problems associated with osteoporosis.

Osteoporosis is a major health problem in the United States, affecting more than 9 million people, the majority of whom

are women (National Osteoporosis Foundation [NOF], 2013). Osteoporosis, is one of the key diseases that predominantly affect women. In fact, half of all women ages 50 and older will break a bone due to osteoporosis in their lifetime and 2 million bone breaks are caused by osteoporosis every year. Approximately 50% of U.S. women have some degree of osteoporosis, making women who are older than 50 at particular risk in their lifetimes for breaking a bone as a result of osteoporosis (NOF). One in two Caucasian women will have changes severe enough to predispose them to fractures. In the United States, the incidence of osteoporosis-related fractures has increased.

It has been estimated that 5.75% of older women who suffer hip fractures will die during the first 3 months following the fracture, with 1-year mortality rates ranging from 12% to 37% (Walker, 2013). During the first 5 to 6 years after menopause, women lose bone six times more rapidly than men. By age 65, one third of women have had a vertebral fracture; by age 81, one third have had a hip fracture. By the time women reach age 80, they have lost 47% of their trabecular bone, concentrated in the vertebrae, the pelvis and other flat bones, and the epiphyses. The most well-defined risk factor for osteoporosis is the loss of the protective effect of estrogen associated with cessation of ovarian function, particularly at menopause. Women at risk are likely to be Caucasian or Asian, small boned, and thin. Obese women have higher estrogen levels resulting from the conversion of androgens in adipose tissue; mechanical stress from extra weight also helps preserve bone mass. A family history of the disease is common. Much more research needs to be done to determine genetic testing for those at higher risk for osteoporosis (Fritz & Speroff, 2011).

Inadequate calcium intake is a risk factor, particularly during adolescence and into the third and fourth decades, when peak bone mass is attained. An excessive caffeine intake increases calcium excretion, causing a systemic acidosis that stimulates bone resorption. Vitamin D deficiency can affect the physiologic regulation and stimulation of intestinal absorption of calcium (NOF, 2010). Smoking is associated with earlier and greater bone loss and decreases estrogen production. Excessive alcohol intake interferes with calcium absorption and depresses bone formation. A greater phosphorus than calcium intake, which occurs with soft drink consumption, may be a risk factor. Other risk factors include steroid therapy and disorders such as hypogonadism, hyperthyroidism, and diabetes mellitus.

The first sign of osteoporosis is often loss of height resulting from vertebral fracture and collapse (Fig. 6-2). Back pain, especially in the lower back, may or may not be present. Later signs include “dowager’s hump,” in which the vertebrae can no longer support the upper body in an upright position, and fractured hip, in which the fracture often precedes a fall. Damage to the vertebrae usually precedes bone loss in the hip by an average of 10 years. Osteoporosis cannot be detected by radiographic examination until 30% to 50% of the bone mass has been lost; thus routine screening is not warranted in women younger than age 65. However, bone density testing is recommended for women who are age 65 and older or in younger women who are at a risk that is equal to or greater than a 65-year-old Caucasian woman without additional risk factors (U.S. Preventive Health Services Task Force, 2011).

COMMUNITY ACTIVITY

- Visit the Office of Women’s Health website at www.WomensHealth.gov. Select menopause from the list of topics on women’s health issues to understand better the resources available to women who have questions about menopause.
- Visit the National Osteoporosis Foundation website at www.nof.org. Review the client information regarding osteoporosis, prevention, management, and finding a doctor. What are the resources for women with osteoporosis in your community?
- Visit the North American Menopause Society (NAMS) website at www.menopause.org. Review Memo Note and the Menopause Guidebook. How can this information help you in teaching your clients about how to manage menopausal symptoms?

FIG 6-2 Skeletal changes secondary to osteoporosis assessed by height and body shape at A, age 55 years; B, age 65 years; and C, age 75 years.

Coronary Heart Disease

A woman’s risk of developing and dying of cardiovascular disease increases after menopause. Diseases of the heart are the leading cause of death for U.S. women. The lifetime risk is 31% versus 3% for breast cancer in postmenopausal women. Known risk factors for coronary heart disease include obesity, cigarette smoking, elevated cholesterol and blood pressure levels, diabetes mellitus, family history of cardiac disease, alcohol abuse, and the effects of aging on the cardiovascular system (Lobo, 2012c). Estrogen has a favorable effect on circulating lipids, decreasing low-density lipoprotein (LDL) and total cholesterol and increasing high-density lipoprotein (HDL), and has a direct antiatherosclerotic effect on arteries. Postmenopausal women are at risk for coronary artery disease because of changes in lipid metabolism: a decline in serum levels of HDL cholesterol and an increase in LDL levels (Lobo). These changes can be favorably reduced by diet and exercise.

Menopausal Hormonal Therapy

Until 2002 **menopausal hormonal therapy (MHT)**—either as *estrogen replacement therapy (ERT)* or *estrogen therapy*

(ET), in which a woman takes only estrogen, or *hormonal replacement therapy (HRT)* or *hormonal therapy (HT)*, in which she takes both estrogen and progestins—was widely prescribed for discomforts associated with the perimenopausal years, including hot flashes and vaginal and urinary tract atrophy. Further, MHT was aggressively used for therapeutic and preventive management. At the same time its use remained highly controversial in women's health. Some authorities recommended HT or ET for all women; these proponents viewed the perimenopause as a disease or deficiency state. Others insisted that the use of hormones was never indicated for menopausal symptoms. The middle-ground approach advocated the use of MRT for women who have specific discomforts (therapeutic management) and for women in certain high risk groups (preventive management). Research studies challenged these beliefs in the preventive and beneficial effects of HT. Findings from the Women's Health Initiative (WHI), a study by the National Institutes of Health (NIH), documented an increase in heart disease with use of continuous combined estrogen plus progestin (NIH, 2010). There is also an increased risk for breast cancer in women taking hormone therapy, although that risk returns to normal 3 years after discontinuation of hormonal therapy (American Cancer Society [ACS], 2013a). These findings changed the way MHT is used. Many women stopped taking MHT and sought alternative therapies to treat their menopausal symptoms. Others chose to continue with the MHT but had questions about the available regimens and associated risks.

The North American Menopause Society (NAMS, 2012) supports the use of estrogen therapy beyond 3 to 5 years for menopausal women to prevent osteoporosis, but they do not support this long-term use of estrogen-progesterone therapy because of its correlation with increased risk for breast cancer. Chen, Chou, and Chang (2013), however, disagree with the recommendations of NAMS.

The U.S. Preventive Services Task Force (2013) recommends against using hormone therapy (combined estrogen and progestin) for postmenopausal women for the prevention of chronic conditions, and against the use of estrogen to prevent chronic conditions in postmenopausal women who have had a hysterectomy.

Recommendations from ACOG (2014) continue to support the use of MHT, but encourages greater use of nonhormonal alternatives, such as SSRI as well as selective serotonin and norepinephrine reuptake inhibitors. The recommendations also mention newer combined estrogen drugs, referred to as selective estrogen receptor modulators. Specifically mentioned are two new drugs: bazedoxifene for hot flashes and osteoporosis. The other is ospemifene for vaginal dryness and atrophy. The report recommends against the use of progestin by itself as well as testosterone, and it indicates that more research is needed regarding the use of bioidentical hormones. (See later discussion on bioidentical hormones.)

Decision to Use Hormone Therapy

All women considering ET or HT must understand that studies on MHT are ongoing, and there is still much to be learned. Nurses can provide information and counseling to assist women

to make decisions regarding MHT use. Important teaching points include the following:

- For women taking MHT for short-term (1 to 3 years) relief of menopausal discomforts and who do not have increased risks for cardiovascular disease, the benefits may outweigh the risks. The decision to use MRT should be made between a woman and her health care provider.
- If used, MHT should be taken at the lowest effective dose for the shortest possible duration.
- When a woman decides to stop MHT, a recurrence of symptoms will occur whether the medication is tapered or discontinued abruptly. NAMS makes no recommendation on how to discontinue the medication, although some clinicians recommend a gradual withdrawal.
- Older women who are taking or considering MHT only for the prevention of cardiovascular disease should be counseled on other methods to reduce their risks of cardiovascular disease.
- Alternatively there may be beneficial cardiovascular effects associated with MHT for younger, more recently menopausal women, but more research is needed in this area.
- Women who are taking MHT only for prevention of osteoporosis or other chronic conditions should be counseled regarding their personal risks and benefits for continuing the therapy because there are conflicting recommendations (Chen, Chou, & Chang, 2013; NAMS, 2012; U.S. Preventive Services Task Force, 2013). These women should be reassured that there are effective alternatives for long-term prevention. Bone density studies also may be indicated to determine the degree of risk in an individual woman (U.S. Preventive Health Services Task Force, 2011).
- Women with a high risk for breast cancer or who have had breast cancer should be informed of the current research that links MHT to breast cancer (ACS, 2013a).
- Conjugated estrogens are associated with an increased incidence of gallbladder disease, and women with a known history of gallbladder disease should not use MHT (MacReady, 2013).

Side Effects

Side effects associated with estrogen use include headaches, nausea and vomiting, bloating, ankle and foot swelling, weight gain, breast soreness, brown spots on the skin, eye irritation with contact lenses, and depression. The type of estrogen used for postmenopausal hormonal therapy is much less potent than ethinyl estradiol used in OCPs and has fewer serious side effects. Side effects that occur with MHT may disappear with a change in estrogen preparation or a decrease in the dose prescribed.

Treatment Guidelines

Research in MHT continues; however, nurses who counsel women about MHT must understand what is available and teach women who choose to continue MHT how to take the medications correctly. Thus the following discussion about the different regimens of MHT is included.

Many different estrogen preparations, natural and synthetic, and ways of administering them—oral tablets, topical creams, transdermal preparations, suppositories, and vaginal rings—are available (Table 6-4).

There are multiple dosing regimen options for combining progesterone with estrogen for women who have a uterus.

TABLE 6-4 Hormone Medications for Menopausal Symptoms

MEDICATION NAME	COMPOSITION	AVAILABLE DOSES
Estrogens		
Oral		
Premarin	Conjugated estrogens	0.3 mg; 0.45 mg; 0.625 mg; 0.9 mg; 1.25 mg
Cenestin, Congest, C.E.S., PMS-Conjugated	Synthetic conjugated estrogens, A	0.3 mg; 0.45 mg; 0.625 mg; 0.9 mg; 1.25 mg; 0.3 mg; 0.625 mg; 0.9 mg; 1.25 mg, 2.5 mg; 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg; 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg
Enjuvia	Synthetic conjugated estrogens, B	0.3 mg; 0.45 mg; 0.625 mg; 0.9 mg; 1.25 mg
Estrace, various generics	Micronized estradiol	0.5 mg; 1 mg; 2 mg
Menest	Esterified estrogens	0.3 mg; 0.625 mg; 1.25 mg; 2.5 mg
Femtrace	Estradiol acetate	0.45 mg; 0.9 mg; 1.8 mg
Ortho-Est	Estropipate	0.625 mg; 1.25 mg; 2.5 mg
Transdermal		
Estraderm	Estradiol reservoir patch	0.05 mg; 0.1 mg twice weekly
Climera, Esclim, Estradot	Estradiol matrix patch	0.025 mg; 0.0375 mg; 0.05 mg; 0.075 mg; 0.1 mg once weekly
Vivelle	Estradiol matrix patch	0.05 mg; 0.1 mg twice weekly
Vivelle-Dot	Estradiol matrix patch	0.025 mg; 0.0375 mg; 0.05 mg; 0.1 mg twice weekly
Menostar	Estradiol matrix patch	0.014 mg once weekly
Alora	Estradiol matrix patch	0.0025 mg; 0.05 mg; 0.075 mg; 0.1 mg twice weekly
Divigel	Estradiol gel 0.1%	0.003 mg; 0.009 mg; 0.027 mg daily
EstroGel	Estradiol gel 0.06%	0.035 mg daily
Elestrin	Estradiol gel 0.06%	0.0125 mg daily
Evamist	Estradiol spray	0.021 mg per spray daily; may increase to 2 or 3 sprays daily
Estrasorb	Estradiol emulsion	0.05 mg/2 packets daily
Vaginal		
Premarin cream	Conjugated estrogens	0.5 g to 2 g/day (0.0625 mg/g)
Estrace cream	Estradiol	1 g/day (0.1 mg/g)
Femring vaginal ring	Estradiol acetate	12.4 mg or 24.8 mg; releases 0.05 mg/day or 0.10 mg/day for 90 days
Estring vaginal ring	Estradiol	2 mg; releases 7.5 mcg daily for 90 days
Vagifem vaginal tablet	Estradiol hemihydrate	25-mcg tablet twice a week
Progestogens		
Oral		
Provera	Medroxyprogesterone acetate	2.5 mg; 5 mg; 10 mg
Aygestin	Norethindrone acetate	5 mg
Micronor	Norethindrone	0.35 mg
Norgestrel	Ovrette	0.075 mg
Progesterone capsule (in peanut oil)	Prometrium	100 mg; 200 mg
Intrauterine		
Levonorgestrel	Mirena	Approximately 20 mcg/day
Vaginal		
Progesterone gel	Prochieve 4%	45 mg/applicator
Combination Estrogen-Progestin		
Oral		
Premphase	Conjugated estrogens (E) Medroxyprogesterone acetate (P)	0.625 mg E daily for 28 days 5 mg P on day 14 through day 28
Prempro	Conjugated estrogens (E) Medroxyprogesterone acetate (P)	0.0625 mg E plus 2.5 or 5 P daily 0.3 mg or 0.45 mg E plus 1.5 P daily
Activella	Estradiol (E) and norethindrone acetate (NETA)	1 mg E plus 0.5 mg NETA daily
Femhrt	Ethinyl estradiol and norethindrone acetate (NETA)	2.5 mcg E plus 0.5 mg NETA daily
Transdermal		
CombiPatch	Estradiol/norethindrone acetate (NETA)	0.05 mg estradiol/0.14 mg NETA or 0.05 mg estradiol/0.25 mg NETA twice weekly
Climera Pro	Estradiol and levonorgestrel	0.045 mg/0.015 mg weekly

Modified from North American Menopause Society. (2012). *Hormone products for postmenopausal use in the United States and Canada*. Available at www.menopause.org/docs/professional/htcharts.pdf?sfvrsn=6. Copyright © The North American Menopause Society, November 19, 2012.

According to NAMS, estrogen therapy is the treatment of choice for vulvar and vaginal atrophy, and low-dose local vaginal estrogen therapy is best if the woman is only experiencing vaginal symptoms. In addition, NAMS (2012) recommends transdermal or low-dose estrogen for women at risk for venous thromboembolism or stroke, although this recommendation is given with caution because there is still not enough research. There is evidence to recommend keeping exposure to progesterone at a minimum. An oral continual-cyclic regimen that is most commonly prescribed is estrogen on days 1 to 28 and a progestogen (e.g., medroxyprogesterone) on days 14 to 28. Women usually do not have cyclic bleeding with this regimen and are less likely to have progestin side effects.

There are also multiple regimen options for ET for women who have had a hysterectomy. The transdermal estrogen patch is applied once or twice a week to a hairless area of skin. Transdermal gels and sprays are applied daily. Any site on the trunk or upper arms provides adequate absorption. Sites should be rotated. The patches should not be placed on the breasts because of their sensitivity. Some women report minor skin irritation and reddening at the patch site. Generally transdermal estrogen offers the same relief of menopausal symptoms as the oral preparation. The transdermal method of delivery of estrogen does not have the same side effects such as breast tenderness and fluid retention. Oral progestin therapy can be used with transdermal ET. Combined estrogen-progestin transdermal patches also are available.

Vaginal creams and tablets are inserted daily or twice a week. Usually these local administrations of low-dose estrogen are used for vaginal symptoms of dryness and atrophy. Vaginal rings are inserted and left in place for 90 days. Although minimal systemic absorption is possible, there are no reports of adverse effects when a low dose is used (NAMS, 2012).

Bioidentical and Custom-Compounded Hormones

Bioidentical hormones, sometimes referred to as natural hormones, are structurally identical to those produced by the ovary. Bioidentical hormone preparations are available as government-approved, well-tested brand-name prescription medications. Others are made at compounding pharmacies. Custom-compounded hormones are custom mixes of one or more hormones in varying amounts. These mixes can provide individualized doses and mixtures of hormones that are not available commercially. They also include ingredients that are nonhormonal (e.g., dyes, preservatives). The risks are that these mixtures have not been studied to confirm whether appropriate absorption occurs or if predictable levels can be detected in blood and tissue (NAMS, 2012). Preparations may vary from one pharmacy to another, meaning that a woman may not get consistent amounts of medication. These preparations are not approved by any regulatory agency (NAMS). Although these hormones may relieve menopausal symptoms, more research is needed to determine their effects on the body. Women who choose to take these hormones need to understand and accept the potential risks. Expense is also an issue because these drugs often are more expensive and are not covered by third-party payers.

Controversy continues in regard to the use of herbal preparations and bioidentical hormone therapy for menopause.

ACOG's (2012) Committee Opinion concluded that there is not enough evidence to support the efficacy and safety of compounded bioidentical hormones as better than conventional hormone therapy, and customized preparations are too variable (i.e., lacking standardization), creating greater risks and difficulty determining correct dosage.

Alternative Therapies

Many complementary and alternative therapies are useful for relieving some of the changes associated with altered estrogen levels. Homeopathy, acupuncture, and herbs have been used with varying degrees of success for menopausal problems such as heavy bleeding, hot flashes, irritability, and headaches.

Homeopathy views menopausal symptoms as the body's efforts to heal itself from the hormonal changes it is experiencing. Examples of remedies commonly prescribed during menopause by homeopaths are *sepia*, made from the inky juice of the cuttlefish, to relieve symptoms such as dry mouth, eyes, and vagina; *nux vomica*, derived from the poison nut, to relieve backaches, constipation, and frequent awakenings; and *pulsatilla*, made from the windflower, to relieve severe menstrual symptoms and hot flashes. Homeopathic remedies are subject to regulation by the U.S. Food and Drug Administration (FDA), although the FDA does not require proof of effectiveness. More study is needed to determine the effectiveness of homeopathic remedies.

Acupuncturists also treat hot flashes, but it is important that women evaluate their acupuncturists carefully. The American Association of Acupuncturists and Oriental Medicine will supply a list of acupuncturists in a given state. Questions to ask are: Is the acupuncturist certified by the National Commission for the Certification of Acupuncture? Is the acupuncturist certified in the state in which he or she practices? Does the acupuncturist carry malpractice insurance? Hendrick (2011) reported on a study of 53 menopausal women, comparing those who received acupuncture with those who received a sham acupuncture. The women who received acupuncture experienced fewer hot flashes as well as a lessening of other symptoms. More research is necessary in this area.

Herbal therapy also has been used to treat menopausal discomforts. Herbs can be ingested as teas or tinctures. Many herbal preparations also are available in capsule form. It is important that women understand mechanisms of action, contraindications, and potential side effects of each herb.

SAFETY ALERT

Most herbal preparations have not undergone long-term testing for safety and efficacy. Benefits and risks are not completely known. Women should always consult with their health care provider before beginning herbal therapy. Questions regarding the use of herbal therapy and other supplements must be a component of a client history.

In addition to resolving physical symptoms, herbs also are used to combat mood swings and depression. Ginseng has been claimed to be helpful in alleviating hot flashes, although research studies have not supported this assertion. Women should be advised against prolonged use of ginseng in high doses because

it can increase blood pressure. Oriental herbal teas composed of licorice, ginseng, coptis, red raspberry leaf, and Chinese rhubarb may be of some help in relieving hot flashes.

Dong quai has been recognized as possibly helping to alleviate menopausal symptoms, although research has not provided evidence for a safe and effective dose (Mayo Clinic, 2012). Black cohosh, too, has been recognized as possibly being effective to treat menopausal symptoms, but evidence is lacking to justify its use without further systematic clinical trials (Leach & Moore, 2012).

Some plant foods contain **phytoestrogens** (isoflavones) and are capable of interacting with estrogen receptors in the body. These foods include red clover, wild yams, dandelion greens, cherries, alfalfa sprouts, black beans, and soybeans. Use of soy-rich foods as an alternative to traditional hormonal therapy for menopause has been studied. NAMS (2011), in a report on the role of isoflavones in menopause, concluded that more study is needed to demonstrate evidence for beneficial effects on menopausal symptoms.

For women who want to add soy to their diets, tofu, roasted soy nuts, and soy milk are good sources. Foods should be added gradually because some women have gastrointestinal discomfort from the high fiber content of these foods. Spreading out the daily intake over several meals may be the best way to include soy products in the diet.

Vitamin E is a popular alternative among women who do not take MHT. Nihira (2012) reviewed a variety of treatments for hot flashes, and included vitamin E as a possible treatment. Vitamin E is found in a variety of foods, including spinach, peanuts, wheat germ, vegetable oils, and soybeans, or it may be taken as a supplement. Dosage varies widely, from 400 to 800 International Units per day.

Layered clothing, ice packs, ice water, and fans may offer symptomatic relief from hot flashes (see Teaching for Self-Management box). Women can be counseled to avoid hot curries and other spicy foods. Reassurance that hot flashes will not last forever may be of comfort even if duration of the problem cannot be predicted accurately. Many women find that hot flashes lessen in frequency and intensity or disappear within 4 to 6 years after menopause.

Nurses should be aware of the availability of natural remedies for menopausal symptoms and be knowledgeable about the indications for complementary and alternative therapies so clients can be counseled appropriately.

CARE MANAGEMENT

Most women know little about menopause, and misinformation can cause anxiety. They need to know what to expect, why it happens, and what measures will help make them more comfortable. Women appreciate the opportunity to discuss what they are experiencing. They need to know that their discomforts have a normal physiologic basis and that other women experience similar discomforts.

Planning for nursing care requires knowledge of the perimenopausal period and great sensitivity. Treatment must be individualized for the specific woman. A thorough health history, physical examination, and laboratory tests are essential to distinguish pathologic conditions from the normal perimenopausal experiences. Informed consent regarding MHT, weight-bearing exercise, and calcium supplements is a major concern because treatment may involve tests, inconvenience, and side effects. Menopause clinics are needed where research

TEACHING FOR SELF-MANAGEMENT

Comfort Measures for Menopausal Symptoms

Hot Flashes/Flushes

During the Day

- Wear layered clothing so you can take things off if you get warm.
- Avoid “triggers” that bring on a flash/flush; these include vigorous exercise on hot days and eating spicy foods, caffeine, hot beverages, and alcohol.
- Splash your face with cool water, drink ice water, or take a cool shower if you get warm.
- Try slow, deep breathing.

At Night

- Sleep in cotton clothes, use cotton sheets, and keep room cool.
- Avoid heavy blankets that make you too warm at night.
- Keep a thermos of water by the bed.

Insomnia

- Avoid caffeine, alcohol, or tobacco in the evening.
- Avoid liquids after dinner.
- Exercise regularly but limit exercise to the daytime and early evening.
- Develop a bedtime routine.
- Establish a regular time to go to bed.
- Try drinking warm milk or taking a hot bath.

- Use your bed only for sleeping or sexual activity; don't watch TV, read, etc.
- Encourage your body's circadian rhythm.
- If you can't sleep, get up and do something until you feel tired.
- Avoid naps during the day.
- Sprinkle lavender oil on the pillow.
- Drink chamomile tea (do not use if allergic to ragweed or chrysanthemums).

Headaches

- Try to avoid stress and get plenty of rest.
- Eat or drink foods that contain natural diuretics (parsley).

Urogenital Symptoms

- Drink lots of water (i.e., at least 8 glasses a day), and empty bladder frequently.
- Practice Kegel exercises daily.
- Wear cotton underwear and avoid wearing wet bathing suits for a prolonged time.
- Use water-soluble lubricants for vaginal dryness.

Nervousness, Irritability

- Practice yoga or other meditation.
- Do relaxation or deep-breathing exercises.
- Practice guided imagery.

on the effects of various treatments can be developed and evaluated and where care by the various specialty groups involved, such as endocrinology, radiology, psychosocial resources, exercise physiology, and nutrition, can be effectively coordinated. Women's support groups also are needed. Sexual counseling, nutrition, exercise, and support are topics that are included for further discussion.

Sexual Counseling

Sexuality is a lifelong behavior, and contrary to common stereotypes, sex does not end with menopause. Many women remain sexually active throughout their entire lives. However, women and their partners may change their expression of sexuality during and after menopause, depending on physical changes, changes in the partner, and cultural myths and messages. Some women report decreases in interest and desire. These decreases in sexuality with aging are influenced more by culture and attitudes than by nature and physiology (hormones). Although some women report that it takes longer to reach orgasm and that the orgasm is not so intense, the capacity for orgasm is not decreased. There is no way to prevent the inevitable aging process that the body undergoes. For people who see aging as loss, sexuality may become difficult to incorporate into what they perceive to be a less attractive identity. The fear of rejection may be present.

Changes in a male partner may influence whether he continues to want to engage in sexual activity. As men age, they, too, take longer to reach orgasm; erections take longer to occur and are less firm. Men may believe they are becoming impotent or ill and give up sexual activity, viewing it as too frustrating. Women may believe their partners are losing interest in them. Couples may need counseling to understand these changes. Although women tend to outlive men, that is not always the case, and some men may lack available female partners.

The two most important influences on older women's sexual activity are the strength of a relationship and the physical condition of each partner. The lack of available male partners can have a negative effect on sexual expression for many midlife and older women. Women outlive men, and older widowed and divorced women frequently have fewer opportunities to develop relationships because they are less sought after. In counseling older women who do engage in intercourse, the nurse cannot assume that new or nonmonogamous partners are free of sexually transmitted infections (STIs) and should inform women of their risk for human immunodeficiency virus infection (HIV) and other STIs and the need to use condoms.

As long as women are able to bear children, some accept intercourse as part of their responsibility as wives. When menopause frees them from this duty, they may choose to forgo intercourse. For other women, libido may increase without the fuss of contraception, fear of pregnancy, or interruption from menses.

Older lesbian women largely have been a silent group whose sexual needs and special social circumstances have not been acknowledged or recognized. Although lesbian women in midlife and in later years do not face the problem of a lack of available male partners, they are faced with negative attitudes accompanying being old, female, and lesbian—all of which can adversely affect sexuality and sexual expression.

Nurses must give accurate information on matters such as appropriate contraception, sexuality, and the physiology of

menopause and should offer support and nonjudgmental guidance. Women need advice about contraception because ovulation may not cease for a year after the last menstrual cycle, and menopausal women can still become pregnant. The nurse's attitude toward sex and the older woman is important. Negative attitudes can reinforce the woman's misgivings about maintaining an active and satisfying sex life. The nurse can reassure the woman grieving over lost youth and attractiveness that the desire for sex into old age is a natural one and that the body has the capacity for sexual satisfaction. Only minor adjustments may be required.

Muscle tone around the reproductive organs decreases after menopause. Kegel exercises (see Chapter 4 for more detailed information) strengthen these muscles, improve tone, and, if practiced regularly, help prevent prolapsed uterus and stress incontinence. This is a low-cost, effective, noninvasive intervention to control symptoms. However, symptoms return if exercises are discontinued.

Lubricating jelly (e.g., K-Y, Femglide, Aqualube) is a water-soluble lubricant that provides relief from painful intercourse. It may be applied directly to the vulva and the penis. Vaginal moisturizers may be water based but also contain other products such as vitamin E and aloe (e.g., K-Y Longlasting, Replens, Astroglide). They are inserted into the vagina using a prefilled applicator. Oil-based lubricants such as petroleum jelly (Vaseline) should not be used because they clog vaginal glands, which can then be sites for bacterial infection.

Prolonged hospitalization of an older adult partner may have a significant effect on the couple's sexual relationship. They may have difficulty renewing sexual activity when the separation is over and may need counseling or referral. In the event that a couple is admitted to a nursing home, the nurse should encourage placement of the couple together. With the aging of the American population and changing attitudes about the appropriateness of lifelong sexual expression, long-term care, extended care, and full-time care facilities are more receptive to providing opportunities for sexual activity between marital partners.

The nurse can refer couples to a counselor or physician for problems beyond the scope of nursing practice.

Nutrition

Obesity and osteoporosis are common health problems of midlife and older women. As women move out of their childbearing years, they may need to change their diets. Because metabolic rates decrease with age and many women exercise less, fewer calories are needed for weight maintenance as women age. In general, foods chosen should be high in nutrients, fiber, and calcium but moderate in calories and low in fat to allow adequate nutritional intake while maintaining body weight. Nurses can suggest that women substitute skim for whole milk or chicken without skin for steak. Excessive protein should be avoided. Fat-free milk and yogurt are good sources of calcium and vitamin D. Women should avoid excessive intake of alcohol, soft drinks, and caffeinated coffee.

Calcium is an essential part of any therapeutic regimen for women with osteoporosis and those who want to prevent osteoporosis. The best source of calcium is food; however, it is difficult to eat other foods that contain calcium (sesame seeds, spinach, greens, broccoli, and seaweed) in quantities sufficient to meet daily requirements. Calcium supplements are recommended when a woman's diet does not supply recommended amounts

of calcium. Although calcium cannot reverse loss of bone mass or prevent fractures, calcium supplementation may retard the development of osteoporosis after menopause. Menopausal women without contraindications to calcium supplementation (history of kidney stones, kidney failure, hypercalcemia) should be encouraged to consume a diet that has 1200 to 1500 mg of calcium a day or to add an amount of calcium supplementation that will increase their daily intake to this level. Calcium supplements are best taken in divided doses and with meals because of the increase in acid secretions and extended time in the stomach. At least 8 ounces of water to increase solubility is recommended. Calcium supplements should not be taken with caffeinated beverages. Calcium is most commonly available as calcium carbonate, calcium lactate, and calcium phosphate.

The *Osteoporosis Report* (Feb 2011) states that the Institute of Medicine (IOM) recommends 600 International Units of vitamin D for healthy adults up to age 70 and 800 International Units for those who are 71 and older. NOF (2013), however, recommends that women younger than 50 take 400 to 800 International Units daily and those older than age 50 take vitamin D 800 to 1000 International Units daily. Sources of vitamin D include sunlight, food (e.g., fortified dairy products, fatty fish, liver, egg yolks), and supplements. Usually a supplement is needed to get the required daily dose. A combination of vitamin D and calcium is available, and most multivitamins contain some vitamin D.

Exercise

All too often midlife women are sedentary—the demands of family and work constraints increase, and energy levels decrease. Unfortunately little or no exercise predisposes women to weight gain and does not help prevent cardiac disease or osteoporosis. Exercise alone cannot prevent or reverse osteoporosis, but data indicate that weight-bearing exercise, such as walking and stair climbing, may delay bone loss and increase bone mass at any age. Aerobics and strength training have positive effects on midlife women's health, including cardiorespiratory function, weight, bone density, and quality of life (Mishra, Mishra, & Devanshi, 2011). Mishra and colleagues recommended that women exercise 2 hours and 30 minutes per week, doing moderate aerobic exercise.

Water aerobics is excellent for cardiovascular fitness and is a good choice for older women who may be unable to engage in weight-bearing exercises. The nurse can help women plan an exercise program. Examples of exercises are available from the NOF (Fig. 6-3).

Medications for Osteoporosis

In addition to calcium and exercise, there are a number of FDA-approved medications for preventing and treating osteoporosis (Box 6-2). The medications assist in delaying bone loss, increasing bone mass, and preventing fractures. These include salmon calcitonin (Miacalcin); bisphosphonates (alendronate sodium [Fosamax], risedronate sodium [Actonel]),

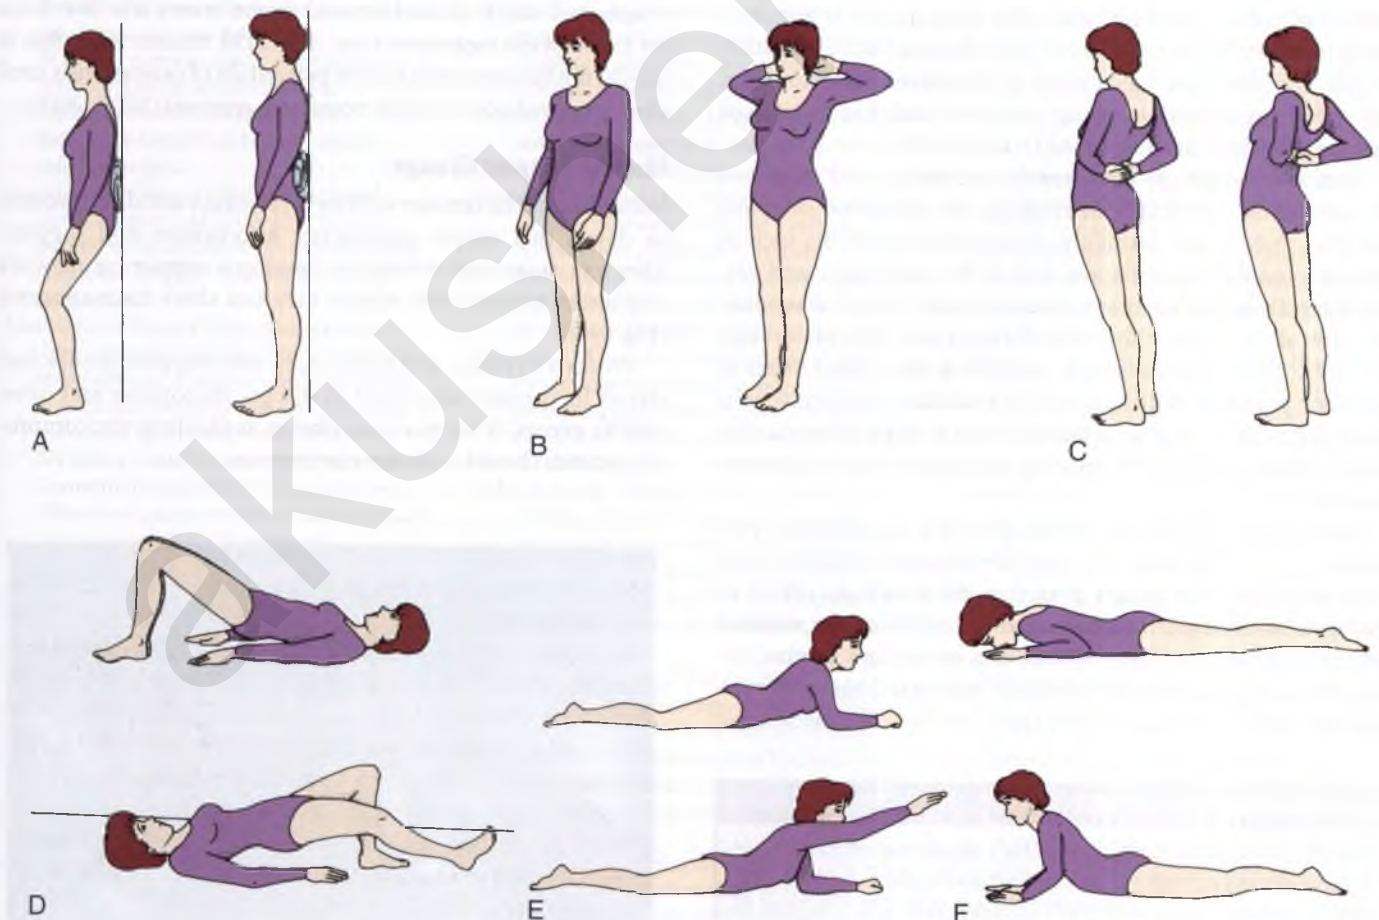

FIG 6-3 Posture exercises. A, Wall standing and pelvic tilt. B, Isometric posture correction. C, Standing back bend. D, The bridge. E, The elbow prop. F, Prone press-ups with deep breathing. (From *Boning Up on Osteoporosis*. Courtesy the National Osteoporosis Foundation.)

BOX 6-2 Prevention of Osteoporosis

- All postmenopausal women should be evaluated clinically for risk for osteoporosis and to determine the need for bone mineral density (BMD) testing.
- A BMD test is the only way to diagnose osteoporosis and determine risk for future fracture. The U.S. Preventive Services Task Force and the National Osteoporosis Foundation recommend testing for postmenopausal women and all women ages 65 and older.
- To protect bone health it is important that all individuals have a nutritionally balanced diet, which includes calcium-rich foods and vitamin D. Adults 50 and older need 1200 mg of calcium and 800 to 1000 International Units of vitamin D daily. Adults younger than 50 need 1000 mg of calcium and 400 to 800 International Units of vitamin D daily.
- A program of regular weight-bearing and muscle-strengthening exercises further helps promote bone health. Weight-bearing

exercises may increase bone density and weight-bearing exercise and muscle strengthening can increase balance and agility and reduce the risk of falls and fractures. Eliminating environmental hazards in the home can decrease the risk of falls.

- Avoidance of excessive alcohol intake and tobacco smoking is advised.
- U.S. Food and Drug Administration (FDA)-approved medications for the prevention and/or treatment of osteoporosis include:
 - Bisphosphonates: alendronate, alendronate plus D; risedronate, risedronate with 500 mg calcium; ibandronate; zoledronic acid (prevention and treatment)
 - Calcitonin (treatment)
 - Estrogens (estrogen or hormone therapy) (prevention)
 - Estrogen agonist-antagonist (prevention and treatment)
 - Parathyroid hormone (treatment)

ibandronate [Boniva], zoledronic acid [Reclast]); estrogen agonist/antagonists such as raloxifene (Evista), parathyroid hormone (teriparatide [Fortéo]), and ET or HT (NOF, 2014).

Calcitonin reduces the rate of bone turnover and stabilizes bone mass in women with osteoporosis and may have some analgesic effects. Although calcitonin can reduce the incidence of spinal fractures, no data are available about its use to protect against hip fractures. Calcitonin may be used with women who are at least 5 years postmenopausal and in whom estrogen is contraindicated or not tolerated. The drug usually is administered intranasally on a daily basis; subcutaneous administration is also available. The medication is considered safe; however, side effects of nausea, vomiting, anorexia, and rhinitis (if used intranasally) have been reported (NOF, 2010).

Bisphosphonates are approved for prevention and treatment of osteoporosis, especially in reducing the incidence of spinal fractures. Side effects include gastrointestinal problems such as difficulty swallowing, inflammation of the esophagus, and gastric ulcer. Depending on the medication used, the oral drugs may be taken daily or monthly. Some formulations contain vitamin D (NOF, 2010). Alendronate is available in the United States in a generic preparation. Ibandronate is available as an intravenous injection every 3 months; zoledronic acid is given intravenously yearly for treatment of osteoporosis and every 2 years for prevention (NOF).

Raloxifene is approved by the FDA for osteoporosis prevention and treatment in postmenopausal women only. This medication seemingly preserves the beneficial effects of estrogen, including protection against cardiovascular diseases and osteoporosis, without stimulating breast and uterine tissues. Studies have shown that raloxifene may lower the relative risk of breast cancer by 40% (ACS, 2013b). The medication

modestly increases bone density. Calcium supplements up to 1500 mg should be taken if dietary intake is inadequate.

Parathyroid hormone is approved for the treatment of osteoporosis in postmenopausal women at high risk for fractures. It is administered by daily subcutaneous injection. It can be used for a maximum of 2 years. The drug is well tolerated although some women report dizziness and leg cramps (NOF, 2010).

Estrogen/hormone therapy is approved for the prevention of osteoporosis. It should be used in the lowest effective doses for the shortest treatment time. The FDA recommends that it should not be used solely for the prevention of osteoporosis until after approved nonestrogen treatments are tried (NOF, 2010).

Midlife Support Groups

Nurses should be familiar with local resources and direct women to classes that supply appropriate information and support. They can encourage women to develop a supportive network with other women with whom they can share their concerns (Fig. 6-4).

Women's centers and clinics may have support groups and classes for women who want to discuss menopause and other midlife events. If no group or class is available in the community, nurses should consider starting one.

MEDICATION ALERT

Because food and certain minerals reduce the absorption of bisphosphonates, women must take alendronate sodium and risedronate sodium on an empty stomach with 6 to 8 ounces of plain water only, at least 30 minutes before eating or drinking to improve absorption; remaining upright for these 30 minutes also is recommended (NOF, 2010).

FIG 6-4 Midlife women can develop a supportive network. (Courtesy Dee Lowdermilk, Chapel Hill, NC.)

KEY POINTS

- Menstrual disorders diminish the quality of life for affected women and their families.
- Amenorrhea is most commonly a result of pregnancy.
- Dysmenorrhea is one of the most common gynecologic problems in women.
- PMS is a disorder with symptoms that begin in the luteal phase of the menstrual cycle and end with the onset of menses.
- Endometriosis is characterized by secondary amenorrhea, dyspareunia, abnormal uterine bleeding, and infertility.
- Perimenopause is a normal developmental phase during which a woman passes from the reproductive to the nonreproductive stage.
- During perimenopause women seek care for symptoms that arise from bleeding irregularities, vasomotor instability, fatigue, genital changes, and changes related to sexuality.
- Menopausal hormonal therapy, if used, should be taken at the lowest effective dose for the shortest possible time.
- Alternative therapies are beneficial in relieving discomforts associated with menstrual disorders and menopause.
- Osteoporosis, a progressive loss of bone mass that results from decreasing levels of estrogen after menopause, can be prevented or minimized with lifestyle changes and medication.
- Postmenopausal women are at increased risk for coronary artery disease because of changes in lipid metabolism.
- Sexuality and the capacity for sexual expression continue after menopause.

Sexually Transmitted and Other Infections

Deitra Leonard Lowdermilk

© <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Describe prevention of sexually transmitted infections in women, including risk reduction measures.
- Differentiate signs, symptoms, diagnosis, and management of nonpregnant and pregnant women with selected sexually transmitted bacterial infections (chlamydia, gonorrhea, syphilis).
- Examine the care of nonpregnant and pregnant women with selected sexually transmitted viral infections (human immunodeficiency virus [HIV]; hepatitis A, B, and C; human papillomavirus; genital herpes).
- Compare and contrast signs, symptoms, and management of selected vaginal infections in nonpregnant and pregnant women.
- Discuss the effect of group B streptococci (GBS) on pregnancy and management of pregnant women with GBS.
- Identify the effects of TORCH infections on pregnancy and the fetus.
- Describe the health consequences (e.g., ectopic pregnancy, infertility) for women who are infected with reproductive tract infections.
- Develop a nursing care plan for a woman who is 12 weeks pregnant and has been diagnosed with HIV.
- Review principles of infection control for HIV and blood-borne pathogens.

Reproductive tract infection is a term that encompasses both sexually transmitted infections and other common genital tract infections (Marrazzo & Cates, 2011). **Sexually transmitted infections (STIs)** include more than 30 organisms that cause infections or infectious disease syndromes primarily transmitted by close, intimate contact (World Health Organization [WHO], 2013b) (Box 7-1). Caused by a wide spectrum of bacteria, viruses, protozoa, and ectoparasites (organisms that live on the outside of the body, such as a louse), STIs are a direct cause of tremendous human suffering, place heavy demands on health care services, and cost society hundreds of millions of dollars to treat. Despite the U.S. Surgeon General's targeting STIs as a priority for prevention and control efforts, STIs are among the most common health problems in the United States, especially for young people. The Centers for Disease Control and Prevention (CDC) estimate that almost 20 million Americans are infected with STIs every year; almost half of those infected are between the ages of 15 and 24. About 51% of infections for this age group are in young women who, if untreated, could face serious long-term consequences, specifically infertility (CDC, 2013d).

The most common STIs in women are chlamydia, gonorrhea, human papillomavirus, herpes simplex virus type 2, syphilis, and human immunodeficiency virus (HIV) infection; these are

discussed in this chapter. Common vaginal infections are also discussed. Neonatal effects of STIs are discussed in Chapter 35.

PREVENTION

Preventing infection (primary prevention) is the most effective way of reducing the adverse consequences of STIs for women and for society. With the advent of serious and potentially lethal STIs that are not readily cured or are incurable, primary prevention becomes critical. Prompt diagnosis and treatment of current infections (secondary prevention) also can prevent personal complications and transmission to others.

Preventing the spread of STIs requires that women at risk for transmitting or acquiring infections change their behavior. A critical first step is for the nurse to include questions about a woman's sexual history, risky sexual behaviors, and drug-related risky behaviors as a part of her assessment. The Five P's—Partners, Prevention of Pregnancy, Protection from STIs, Practices, and Past History of STIs—approach to obtaining a sexual history is an example of an effective strategy for eliciting information concerning five key areas of interest (CDC, 2010c) (Box 7-2). Techniques that are effective in providing prevention counseling include using open-ended questions, using understandable language, and reassuring the woman that treatment

Data from Planned Parenthood. (2013). *Sexually transmitted diseases (STDs)*. Available at www.plannedparenthood.org/health-topic/stds-hiv-safer-sex-101.htm; World Health Organization. (2013). *Sexually transmitted infections (STIs)*. Available at www.who.int/mediacentre/factsheets/fs110/en/index.html.

will be provided regardless of factors such as ability to pay, language spoken, or lifestyle (Marrazzo & Cates, 2011). Prevention messages should include descriptions of specific actions to be taken to avoid acquiring or transmitting STIs (e.g., refraining from sexual activity when STI-related symptoms are present) and should be individualized for each woman, giving attention to her specific risk factors.

To be motivated to take preventive actions, a woman must believe that acquiring a disease will be serious for her and that she is at risk for infection. However, most individuals tend to underestimate their personal risk of infection in a given situation; thus many women, and especially adolescents, may not perceive themselves as being at risk for contracting an STI. Telling them that they should carry condoms may not be well received. Although levels of awareness of STIs are generally high, widespread misconceptions or specific gaps in knowledge also exist. Therefore, nurses have a responsibility to ensure that their clients have accurate, complete knowledge about transmission and symptoms of STIs and behaviors that place them at risk for contracting an infection.

Primary preventive measures are individual activities aimed at deterring infection. Risk-free options include complete abstinence from sexual activities that transmit semen, blood, or other body fluids or that allow skin-to-skin contact (Marrazzo & Cates, 2011). Alternatively, involvement in a mutually monogamous relationship with an uninfected partner also eliminates risk of contracting STIs. When neither of these options is realistic for a woman, however, the nurse and woman must focus on other, more feasible measures.

Risk-Reduction Measures

An essential component of primary prevention is counseling women regarding risk-reduction practices, including knowledge of her partner, reduction of the number of partners, low

BOX 7-2 Assessing Sexually Transmitted Infections and HIV Risk Behaviors Using the 5 P'S**The Five P's: Partners, Prevention of Pregnancy, Protection from Sexually Transmitted Infections (STIs), Practices, and Past History of STIs****1. Partners**

- Do you have sex with men, women, or both?
- In the past 2 months, how many partners have you had sex with?
- In the past 12 months, how many partners have you had sex with?
- Is it possible that any of your sex partners in the past 12 months had sex with someone else while they were still in a sexual relationship with you?

2. Prevention of Pregnancy

- What are you doing to prevent pregnancy?

3. Protection from STIs

- What do you do to protect yourself from STIs and human immunodeficiency virus (HIV)?

4. Practices

- To understand your risks for STIs, I need to understand the kind of sex you have had recently.
- Have you had vaginal sex, meaning 'penis in vagina sex'? If yes, "do you use condoms: never, sometimes, or always?"
- Have you had anal sex, meaning 'penis in rectum/anus sex'? If yes, "do you use condoms: never, sometimes, or always?"
- Have you had oral sex, meaning "mouth on penis/vagina"?

For condom answers:

- If "never", why don't you use condoms?
- If "sometimes", in what situations (or with whom) do you not use condoms?

5. Past History of STIs

- Have you ever had an STI?
- Have any of your partners had an STI?

Additional questions to identify HIV and viral hepatitis risk include:

- Have you or any of your partners ever injected drugs?
- Have any of your partners exchanged money or drugs for sex?
- Is there anything else about your sexual practices that I need to know about?

From Centers for Disease Control and Prevention (CDC). (2010). Sexually transmitted diseases treatment guidelines 2010. *MMWR Morbidity and Mortality Weekly Report*, 59(RR-12), 1-109.

risk sex, avoiding the exchange of body fluids, and vaccination (CDC, 2010c).

No aspect of prevention is more important than knowing one's partner. Reducing the number of partners and avoiding partners who have had many sexual partners decreases a woman's chance of contracting an STI. Deciding not to have sexual contact with casual acquaintances also may be helpful. Discussing each new partner's previous sexual history and exposure to STIs augments other efforts to reduce risk; however, sexual partners may not always be truthful about their sexual history. Women must be informed that practicing risk-reduction measures is always advisable, even when partners insist otherwise. Critically important is whether male partners resist or accept wearing condoms. This is crucial when women are not sure about their partners' history. Women should be cautioned

TABLE 7-1 Risk-Reduction Practices

SAFEST	LOW BUT POTENTIAL RISK	HIGH RISK (UNSAFE)
Abstinence	Wet kissing*	Unprotected anal intercourse;
Self-masturbation	Vaginal intercourse with condom; anal intercourse with condom	unprotected vaginal intercourse
Monogamous (both partners and no high risk activities) and tested negative for HIV and other STIs	Monogamous (both partners and no high risk activities) but not tested for HIV or other STIs	Oral-anal contact
Hugging, massage, touching (assuming no break in skin)	Oral sex with woman wearing female condom	Multiple sexual partners, no HIV or STI testing
Dry kissing	Oral sex with man wearing condom	Any sex (fisting, rough vaginal or anal intercourse, rape) that causes tissue damage or bleeding
Mutual masturbation without contact with semen or vaginal secretions and no broken skin	Mutual masturbation without contact with semen or vaginal secretions; healthy intact skin or use of latex or plastic barrier	Oral sex on man or woman without a latex or plastic barrier
Drug abstinence	Urine contact with intact skin	Sharing sex toys, douche equipment
Sexual fantasy		Sharing needles
Erotic conversation, books, movies		Blood contact, including menstrual blood
Erotic bathing, showering		
Eroticizing feet, fingers, buttocks, abdomen, ears		

*Assumes no breaks in skin.

HIV, Human immunodeficiency virus; STI, sexually transmitted infection.

Data from Centers for Disease Control and Prevention. (2010). Sexually transmitted diseases treatment guidelines, 2010. *MMWR Morbidity and Mortality Weekly Report*, 59(RR-12), 1-109; Marrazzo, J.M., & Cates, W. (2011). Reproductive tract infections, including HIV and sexually transmitted infections. In R. Hatcher, J. Trussell, A. Nelson, et al. (Eds.), *Contraceptive technology* (20th ed.). New York: Ardent Media.

against making decisions about a partner's sexual and other behaviors based on appearances and unfounded assumptions such as the following (Marrazzo & Cates, 2011):

- Single people have many partners and risky practices.
- Older people have few partners and infrequent sexual encounters.
- Sexually experienced people know how to use risk-reduction measures.
- Married people are heterosexual, low risk, and monogamous.
- People who look healthy are healthy.
- People with good jobs do not use drugs.

Sexually active people also may benefit from carefully examining a partner for lesions, sores, ulcerations, rashes, redness, discharge, swelling, and odor before initiating sexual activity. Teach women about low risk sexual practices and which sexual practices to avoid (Table 7-1).

The physical barrier promoted for the prevention of sexual transmission of HIV and other STIs is the condom (male and female). Nurses can help motivate clients to use condoms by initiating a discussion with them. This gives women permission to discuss any concerns, misconceptions, or hesitations they may have about using condoms. Information to be discussed includes the importance of using latex or plastic male condoms rather than natural skin condoms for STI protection. The nurse should remind women to use a condom with every sexual encounter, to use each one only once, to use a condom with a current expiration date, and to handle it carefully to avoid

damaging it with fingernails, teeth, or other sharp objects. Condoms should be stored away from high heat. Although it is not ideal, women may choose to safely carry condoms in wallets, shoes, or inside a bra. Women can be taught the differences among condoms: price ranges, sizes, and where they can be purchased. Explicit instructions for how to apply a male condom are included in Box 8-3.

The female condom—a lubricated polyurethane sheath with a ring on each end, one that is inserted into the vagina and the other covering the labia (see Figure 8-7)—has been shown in laboratory studies to be an effective mechanical barrier to viruses, including HIV. Although no clinical studies have been completed to evaluate the efficacy of female condoms in protecting against STIs, laboratory studies have demonstrated that polyurethane can block smaller viruses such as the herpesvirus and HIV (Cates & Harwood, 2011). The CDC (2010c) stated that when used correctly and consistently, the female condom may reduce STI risk and recommended its use when a male condom cannot be used properly. What is important and should be stressed by nurses is the consistent use of condoms for every act of sexual intimacy when there is the possibility of transmission of disease.

Despite concern about the potential for cervicovaginal epithelial disruption with nonoxynol-9 (N-9)-based spermicides, interest in vaginally applied chemical barriers that provide dual contraceptive and protection against bacterial STIs remains. Evidence has shown, however, that vaginal spermicides do not protect against certain STIs such as cervical gonorrhea and chlamydia and are not effective in preventing HIV infection. Condoms lubricated with N-9 are not recommended for prevention of HIV and STIs (CDC, 2010c).

A key issue in condom use as a preventive strategy is to stress to women that in sexual encounters men must comply with a woman's suggestion or request that they use a condom. Moreover, condom use must be renegotiated with every sexual contact, and women must address the issue of control of sexual decision making every time they request a male partner to use a condom. Women may fear that their partner would be offended if a condom were introduced. Some women may fear rejection and abandonment, conflict, potential violence, or loss of economic support if they suggest the use of condoms to prevent STI transmission. For many individuals, condoms are symbols of extra-relationship activity. Introduction of a condom into a long-term relationship in which one has not been used previously threatens the trust assumed in most long-term relationships.

Nurses must suggest strategies to enhance a woman's condom negotiation and communication skills. It can be suggested that she talk with her partner about condom use at a time removed from sexual activity, which may make it easier to bring up the subject. Role-playing possible partner reactions with a woman and her alternative responses can be helpful. Asking a woman who appears particularly uncomfortable to rehearse how she might approach the topic is useful, particularly when a woman fears her partner may be resistant. The nurse might suggest the woman begin by saying, "I need to talk with you about something that is important to both of us. It's hard for me, and I feel embarrassed, but I think we need to talk about reducing risk during sex." If women are able to sort

out their feelings and fears before talking with their partners, they may feel more comfortable and in control of the situation. Women can be reassured that it is natural to be uncomfortable and that the hardest part is getting started. Nurses should help their clients clarify what they will and will not do sexually because it will be easier to discuss their concerns with their partners if they have thought about what to say. Women can be reminded that their partner may need time to think about what they have said and that they must pay attention to their partner's response.

Many women do not anticipate or prepare for sexual activity in advance; embarrassment or discomfort in purchasing condoms may prevent some women from using them. Cultural barriers also may impede the use of condoms; for example, Hispanic gender roles may make it difficult for Hispanic women to suggest using condoms to a partner. In general, suggesting condom use implies that a woman is sexually active, that she is "available" for sex, and that she is "seeking" sex; these are messages that many women are uncomfortable conveying, given the prevailing mores of our country. In a society that commonly

views a woman who carries a condom as overprepared, possibly oversexed, and willing to have sex with any man, expecting her to insist on the use of condoms in a sexual encounter is somewhat optimistic at best and unrealistic at worst.

Finally, women should be counseled to watch out for situations that make it hard to talk about and to practice safer sex. These include romantic times when condoms are not available and when alcohol or drugs make it impossible to make wise decisions about safer sex.

Preexposure vaccination is an effective method for the prevention of some STIs such as hepatitis B and human papillomavirus (HPV). Hepatitis B vaccine is recommended for women at high risk for STIs (CDC, 2010c). Two HPV vaccines are available for females aged 9 to 26 years to prevent cervical precancer and cancer: the quadrivalent (HPV types 6, 11, 16, and 18) HPV vaccine (Gardasil) and the bivalent (HPV types 16 and 18) HPV vaccine (Cervarix). Gardasil also prevents

genital warts. Routine vaccination of females ages 11 or 12 years is recommended with either vaccine, as is catch-up vaccination for females ages 13 to 26 years (CDC, 2012c). It is also approved for males ages 9 to 26. (See later discussion).

SEXUALLY TRANSMITTED BACTERIAL INFECTIONS

Chlamydia

Chlamydia trachomatis is the most commonly reported STI in American women. In 2011 there were more than 1.4 million cases reported; the rate of infection was more than 2½ times the rate for men (CDC, 2012e). These infections are often silent and highly destructive; their sequelae and complications can be very serious. In women, chlamydial infections are difficult to diagnose; the symptoms, if present, are nonspecific, and the organism is expensive to culture.

Early identification of *C. trachomatis* is important because untreated infection often leads to acute salpingitis or pelvic inflammatory disease. Pelvic inflammatory disease (PID) is the most serious complication of chlamydial infections, and past chlamydial infections are associated with an increased risk of ectopic pregnancy and tubal factor infertility. Furthermore, chlamydial infection of the cervix causes inflammation, resulting in microscopic cervical ulcerations, and thus may increase the risk of acquiring HIV infection. More than half of infants born to mothers with chlamydia will develop conjunctivitis or pneumonia after perinatal exposure to the mother's infected cervix. *C. trachomatis* is the most common infectious cause of ophthalmia neonatorum. Neonatal ocular prophylaxis with silver nitrate solution or antibiotic ointment does not prevent perinatal transmission from mother to infant, nor does it adequately treat chlamydial infection (see Chapter 35).

Sexually active women ages 15 to 24 have the highest rates of infection, with women ages 18 to 20 years having the highest rates. In 2011, the rates were highest in black women at more than 7 times the rate of white women. American Indian, Alaska Native, and Hispanic women also had higher rates than white women (CDC, 2012e). Women older than 30 years have the lowest rate of infection. Risky behaviors, including multiple partners and nonuse of barrier methods of birth control, increase a woman's risk of chlamydial infection. Lower socioeconomic status may be a risk factor, especially with respect to treatment-seeking behaviors.

Screening and Diagnosis

In addition to obtaining information regarding the presence of risk factors, the nurse should inquire about the presence of any symptoms. The CDC (2010c) strongly recommends screening of asymptomatic women at high risk in whom infection would otherwise go undetected (see www.cdc.org). CDC guidelines recommend yearly screening of all sexually active adolescents, women between ages 20 and 25 years, and women older than 25 years who are at high risk (e.g., those with new or multiple partners). In addition, whenever possible, all women with two or more of the risk factors for chlamydia should be cultured. All pregnant women should have cervical cultures for chlamydia at the first prenatal visit. Screening late in the third trimester (36 weeks) may be carried out if the woman was positive previously, or if she is younger than 25 years, has a new sex partner, or has multiple sex partners.

Although chlamydial infections are usually asymptomatic, some women may experience spotting or postcoital bleeding, mucoid or purulent cervical discharge, or dysuria. Bleeding results from inflammation and erosion of the cervical columnar epithelium.

Laboratory diagnosis of chlamydia is by culture (expensive and labor intensive), deoxyribonucleic acid (DNA) probe (relatively less expensive but less sensitive), enzyme immunoassay (also relatively less expensive but less sensitive), and nucleic acid amplification tests (NAATs) (expensive but has relatively higher sensitivity) (CDC, 2010c; Fantasia, Fontenot, Sutherland, & Harris, 2011). Special culture media and proper handling of specimens are important, so the nurse should always know what is required in his or her individual practice site.

Chlamydial culture testing is not always available, primarily because of expense.

Management

The CDC recommendations for treatment of urethral, cervical, and rectal chlamydial infections are azithromycin or doxycycline (CDC, 2010c) (see Table 7-2). Azithromycin is often prescribed when compliance may be a problem, because only one dose is needed; however, expense is a concern with this medication. If the woman is pregnant, azithromycin or amoxicillin is used. Pregnant women should be retested in 3 weeks to determine if treatment was effective; if at high risk for reinfection, the pregnant woman should be retested in the third trimester (Ruhl, 2013). Women who have a chlamydial infection and also are infected with HIV should be treated with the same regimen as those who are not infected with HIV.

Because chlamydia is often asymptomatic, the woman should be cautioned to take all medication prescribed. All exposed sexual partners should be treated.

Gonorrhea

Gonorrhea is probably the oldest communicable disease in the United States and second to chlamydia in reported cases. In 2012, a total of 334,826 cases of gonorrhea was reported in the United States (CDC, 2014). The incidence of drug-resistant cases of gonorrhea, in particular, penicillinase-producing *Neisseria gonorrhoeae* (PPNG), is increasing dramatically in the United States. Only a single class of antibiotics now meets CDC's standard for treatment—the cephalosporins (CDC, 2012e).

Gonorrhea is caused by the aerobic gram-negative diplococcus, *N. gonorrhoeae*. Gonorrhea is almost exclusively transmitted by sexual contact. The principal means of communication is genital-to-genital contact; however, it also is spread by oral-to-genital and anal-to-genital contact. There also is evidence that infection can spread in females from vagina to rectum. Age is probably the most important risk factor associated with gonorrhea. In the United States the highest reported rates of infection are among sexually active teenagers, young adults, and blacks. In 2012, the highest rates were in young women ages 15 to 24 and the rate in blacks was 15 times higher than for whites. American Indian, Alaska Native, and Hispanic rates were also higher than the rate for whites (CDC, 2014). Women are often asymptomatic, with one third of infections in adolescent women going unnoticed. When symptoms are present they are often less specific than are the symptoms in men. Women may have a purulent endocervical discharge, but discharge is usually minimal or absent. Menstrual irregularities may be the presenting symptom, or women may complain of pain—chronic or acute severe pelvic or lower abdominal pain or longer, more painful menses. Infrequently, dysuria, vague abdominal pain, or low backache prompts a woman to seek care. Gonococcal rectal infection may occur in women after anal intercourse. Individuals with rectal gonorrhea may be completely asymptomatic or, conversely, have severe symptoms with profuse purulent anal discharge, rectal pain, and blood in the stool. Rectal itching, fullness, pressure, and pain also are common symptoms, as is diarrhea. A diffuse vaginitis with vulvitis is the most common form of gonococcal infection in prepubertal girls. There may be few signs of infection, or vaginal discharge, dysuria, and swollen, reddened labia may be present.

Gonococcal infections in pregnancy can affect mother and fetus. In women with cervical gonorrhea, salpingitis may develop in the first trimester. Perinatal complications of gonococcal infection include premature rupture of membranes, preterm birth, chorioamnionitis, neonatal sepsis, intrauterine growth restriction, and maternal postpartum sepsis. Amniotic infection syndrome manifested by placental, fetal, and umbilical cord inflammation after premature rupture of the membranes may result from gonorrheal infections during pregnancy. Ophthalmia neonatorum, the most common manifestation of neonatal gonococcal infections, is highly contagious and, if untreated, may lead to blindness of the newborn (see Chapter 35).

Screening and Diagnosis

Because gonococcal infections in women often are asymptomatic, the CDC recommend screening all women at risk for gonorrhea (CDC, 2010c). All pregnant women should be screened at the first prenatal visit, and infected women and those not infected but identified with risky behaviors should be rescreened at 36 weeks of gestation. Gonococcal infection cannot be diagnosed reliably by clinical signs and symptoms alone. Individuals may have “classic” symptoms, vague symptoms that can be attributed to a number of conditions, or no symptoms at all. Cultures with selective media are considered the gold standard for diagnosis of gonorrhea.

Specific diagnosis of infection with *N. gonorrhoeae* can be performed by testing endocervical, vaginal, or urine specimens. Culture and nonculture tests (nucleic acid hybridization tests and NAATs) are available for the detection of genitourinary infection with *N. gonorrhoeae*. Cultures should be obtained from the endocervix, the rectum, and when indicated, the pharynx. Thayer-Martin cultures are recommended to diagnose gonorrhea in women. NAATs allow testing of the widest variety of specimen types including endocervical swabs, vaginal swabs, and urine (CDC, 2010c). Because coinfection is common, any woman suspected of having gonorrhea should have a chlamydial culture and serologic test for syphilis if one has not been done in the past 2 months.

Management

Management of gonorrhea is straightforward, and the cure is usually rapid with appropriate antibiotic therapy (see Table 7-2). Single-dose efficacy is a major consideration in selecting an antibiotic regimen for women with gonorrhea. Another important consideration is the high percentage of women with coexisting chlamydial infections. The treatment of choice for uncomplicated urethral, endocervical, and rectal infections in pregnant and nonpregnant women is ceftriaxone (CDC, 2012f). The CDC recommends concomitant treatment for chlamydia (CDC, 2010c). A test of cure in 3 to 4 weeks after treatment is not recommended for pregnant women (Ruhl, 2013). All women with both gonorrhea and syphilis should be treated for syphilis according to CDC guidelines (see discussion of syphilis in this chapter).

Gonorrhea is a highly communicable disease. It is important to notify partners if a woman is diagnosed with a gonorrheal infection. Recent (past 30 days) sexual partners should be examined, cultured, and treated with appropriate regimens. Most treatment failures result from reinfection. The woman must be informed of this, as well as of the consequences of reinfection in terms of chronicity, complications, and potential

infertility. Women are counseled to use condoms. All clients with gonorrhea should be offered confidential counseling and testing for HIV infection.

LEGAL TIP: Reporting Communicable Diseases

Gonorrhea is a reportable communicable disease. Health care providers are legally responsible for reporting all cases to the health authorities, usually the local health department in the client's county of residence. Women should be informed that the case will be reported, told why, and informed of the possibility of being contacted by a health department epidemiologist.

Syphilis

Syphilis, one of the earliest described STIs, is caused by *Treponema pallidum*, a motile spirochete. Transmission is thought to be by entry in the subcutaneous tissue through microscopic abrasions that can occur during sexual intercourse. The disease also can be transmitted through kissing, biting, or oral-genital sex. Transplacental transmission can occur at any time during pregnancy; the degree of risk is related to the quantity of spirochetes in the maternal bloodstream.

In 2012, a total of 49,903 cases of syphilis were reported in the United States; this number included 15,667 cases of primary and secondary syphilis (CDC, 2014). The rates of primary and secondary syphilis were highest among women ages 20 to 24 years. The rates were highest in black women (CDC, 2014).

Syphilis is a complex disease that can lead to serious systemic disease and even death when untreated. Infection manifests itself in distinct stages with different symptoms and clinical manifestations. *Primary* syphilis is characterized by a primary lesion, the chancre, that appears 5 to 90 days after infection. This lesion often begins as a painless papule at the site of inoculation and then erodes to form a nontender, shallow, indurated, clean ulcer several millimeters to centimeters in size (Fig. 7-1, A). *Secondary* syphilis occurs 6 weeks to 6 months after the appearance of the chancre and is characterized by a widespread, symmetric maculopapular rash on the palms and soles and generalized lymphadenopathy. The infected individual also may experience fever, headache, and malaise. Condylomata lata (broad, painless, pink-gray wartlike infectious lesions) may develop on the vulva, the perineum, or the anus (see Fig. 7-1, B). If the woman is untreated, she enters a latent phase that is asymptomatic for the majority of individuals. Latent infections are those that lack clinical manifestations but are detected by serologic testing. If the infection was acquired in the preceding year, the infection is termed an *early latent* infection. If it is left untreated, tertiary syphilis will develop in about one third of these women. Neurologic, cardiovascular, musculoskeletal, or multiorgan system complications can develop in the third stage.

Screening and Diagnosis

All women who are diagnosed with another STI or with HIV should be screened for syphilis. All pregnant women should be screened for syphilis at the first prenatal visit and again early in the third trimester and at the time of giving birth if high risk (CDC, 2010c). Diagnosis is dependent on microscopic examination of primary and secondary lesion tissue and serology during latency and late infection. A test

for antibodies may not be reactive in the presence of active infection because it takes time for the body's immune system to develop antibodies to any antigens. Up to one third of people with early primary syphilis may have nonreactive serologic tests. Two types of serologic tests are used: nontreponemal and treponemal. Nontreponemal antibody tests such as the Venereal Disease Research Laboratories (VDRL) or rapid plasma reagin (RPR) are used as screening tests. False-positive results are not unusual, particularly when acute infection, autoimmune disorders, malignancy, pregnancy, and drug addiction exist and after immunization or vaccination. The treponemal tests, fluorescent treponemal antibody-adsorbed (FTA-ABS), and microhemagglutination assays for antibody to *T. pallidum* (MHA-TP), are used to confirm positive results. Test results in clients with early primary or incubating syphilis can be negative. Seroconversion usually takes place 6 to 8 weeks after exposure, so testing should be repeated in 1 to 2 months when a suggestive genital lesion exists. Tests for concomitant STIs (e.g., chlamydia and gonorrhea) should be done (e.g., wet preps and cultures) and HIV testing offered if indicated.

Management

Penicillin G is the preferred drug for treating clients with syphilis (see Table 7-2). It is the only proven therapy that has been widely used for clients with neurosyphilis, congenital syphilis, or syphilis during pregnancy. Intramuscular benzathine penicillin G is used to treat primary, secondary, and early latent syphilis. Although doxycycline, tetracycline, and erythromycin are alternative treatments

for penicillin-allergic clients, both tetracycline and doxycycline are contraindicated in pregnancy, and erythromycin is unlikely to cure a fetal infection. Therefore, pregnant women should, if necessary, receive skin testing and be treated with penicillin or be desensitized (CDC, 2010c). Specific protocols are recommended by the CDC.

MEDICATION ALERT

Clients treated for syphilis with penicillin may experience a Jarisch-Herxheimer reaction. This acute febrile reaction is often accompanied by headache, myalgias, and arthralgias that develop within the first 24 hours of treatment. The reaction can be treated symptomatically with analgesics and antipyretics. If the treatment precipitates this reaction in the second half of pregnancy, women are at risk for preterm labor and birth. They should be advised to contact their health care provider if they notice any change in fetal movement or have any contractions.

Monthly follow-up is mandatory so that repeated treatment may be given if needed. The nurse should emphasize the necessity of long-term serologic testing even in the absence of symptoms. The woman should be advised to practice sexual abstinence until treatment is completed, all evidence of primary and secondary syphilis is gone, and serologic evidence of a cure is demonstrated. Women should be told to notify all partners who may have been exposed. They should be informed that the disease is reportable. Preventive measures should be discussed.

CLINICAL REASONING CASE STUDY

Sexually Transmitted Infection Counseling in Pregnancy

Shawanda is an 18-year-old African-American, gravida 1 para 0, who has come to the prenatal clinic for her first visit. She has a history of drug use (marijuana). She says her current boyfriend is her support person but he is not the father of the baby. Shawanda is unemployed and living with her mother. She has been given an explanation of the prenatal laboratory tests that will be done during her examination. She says that she does not see why she has to have the tests for sexually transmitted infections (STIs) because she has not had these infections.

1. Evidence—Is there sufficient evidence to draw conclusions about what advice the nurse should give?
2. Assumptions—Describe underlying assumptions about the following issues:
 - a. STI effects on pregnancy and the fetus
 - b. STI risk factors
 - c. Risk-reduction measures to prevent transmission of STIs
 - d. Prevention of maternal-fetal transmission of human immunodeficiency virus (HIV)
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is an infectious process that most commonly involves the uterine (fallopian) tubes (salpingitis), uterus (endometritis), and more rarely, the ovaries and peritoneal surfaces. Multiple organisms have been found to cause PID, and most cases are associated with more than one organism. In the past, the most common causative agent was thought to be *N. gonorrhoeae*; however, *C. trachomatis* is now

estimated to cause half of all cases of PID. In addition to gonorrhea and chlamydia, a wide variety of anaerobic and aerobic bacteria are recognized to cause PID. PID encompasses a wide variety of pathologic processes; the infection can either be acute, subacute, or chronic and can have a wide range of symptoms.

Most PID results from ascending spread of microorganisms from the vagina and endocervix to the upper genital tract. This spread most frequently happens at the end of or just after menses following reception of an infectious agent. During the menstrual period several factors facilitate the development of an infection: the cervical os is slightly open, the cervical mucus barrier is absent, and menstrual blood is an excellent medium for growth. PID also can develop after a miscarriage or an induced abortion, pelvic surgery, or childbirth.

Risk factors for acquiring PID are those associated with the risk of contracting an STI, including young age (most cases of acute PID are in women younger than age 25), nulliparity, multiple partners, high rate of new partners, and a history of STIs and PID. Women who use intrauterine devices (IUDs) may be at increased risk for PID up to 3 weeks after insertion (Eckert & Lentz, 2012). PID tends to recur.

Women who have had PID are at increased risk for ectopic pregnancy, infertility, and chronic pelvic pain. After a single episode of PID, a woman's risk for ectopic pregnancy increases sevenfold compared with the risk for women who have never had PID. Other problems associated with PID include dyspareunia (painful intercourse), pyosalpinx (pus in the uterine tubes), tuboovarian abscess, and pelvic adhesions.

The symptoms of PID vary, depending on whether the infection is acute, subacute, or chronic; however, pain is common to all types of infections. It may be dull, cramping, and intermittent (subacute) or severe, persistent, and incapacitating (acute). Women may also report one or more of the following: fever, chills, nausea and vomiting, increased vaginal discharge, symptoms of a urinary tract infection, and irregular bleeding. Abdominal pain is usually present (Eckert & Lentz, 2012).

Screening and Diagnosis

PID is difficult to diagnose because of the accompanying wide variety of symptoms. The CDC recommends treatment for PID in all sexually active young women and others at risk for STIs if the following criteria are present and no other cause or causes of the illness are found: lower abdominal tenderness, bilateral adnexal tenderness, and cervical motion tenderness. Other criteria for diagnosing PID include an oral temperature of 38.3° C or above, abnormal cervical or vaginal discharge, elevated erythrocyte sedimentation rate, elevated C-reactive protein, and laboratory documentation of cervical infection with *N. gonorrhoeae* or *C. trachomatis* (CDC, 2010c).

Management

Perhaps the most important nursing intervention is prevention. Primary prevention includes education about preventing the acquisition of STIs, and secondary prevention involves preventing a lower genital tract infection from ascending to the upper genital tract. Instructing women in self-protective behaviors such as practicing risk-reduction measures and using barrier methods is critical. Also important is the detection of asymptomatic gonorrheal and chlamydial infections through

TABLE 7-3 Treatment of Pelvic Inflammatory Disease

PARENTERAL TREATMENT	ORAL TREATMENT
Regimen A	
Cefotetan , 2 g IV q12h <i>OR</i>	Ceftriaxone 250 mg IM in a single dose <i>PLUS</i>
cefoxitin , 2 g IV q6h for at least 24 hours after improvement <i>PLUS</i>	Doxycycline 100 mg orally twice a day for 14 days <i>WITH or WITHOUT</i>
doxycycline , 100 mg orally or IV q12h for 14 days	Metronidazole 500 mg orally twice a day for 14 days <i>OR</i>
Regimen B	
Clindamycin , 900 mg IV q8h <i>PLUS</i>	Cefoxitin 2 g IM in a single dose and probenecid , 1 g orally administered concurrently in a single dose <i>PLUS</i>
Gentamicin , loading dose IV or IM (2 mg/kg of body weight), followed by maintenance dose (1.5 mg/kg) q8h. Single daily dosing may be substituted.	Doxycycline 100 mg orally twice a day for 14 days <i>WITH or WITHOUT</i>
Parenteral therapy can be discontinued 24 hours after clinical improvement; ongoing oral therapy should consist of doxycycline 100 mg orally twice a day, or clindamycin 450 mg orally four times a day to complete a total of 14 days of therapy.	Metronidazole 500 mg orally twice a day for 14 days <i>OR</i>
	Other parenteral third-generation cephalosporin (e.g., ceftizoxime or cefotaxime) <i>PLUS</i>
	Doxycycline 100 mg orally twice a day for 14 days <i>WITH or WITHOUT</i>
	Metronidazole 500 mg orally twice a day for 14 days

IM, Intramuscular; IV, intravenous.

Data from Centers for Disease Control and Prevention. (2010). Sexually transmitted diseases treatment guidelines, 2010. *MMWR Morbidity and Mortality Weekly Report*, 59(RR-12), 1-109; Marrazzo, J.M., & Cates, W. (2011). Reproductive tract infections, including HIV and other sexually transmitted infections. In R. Hatcher, J. Trussell, A. Nelson, et al. (Eds.), *Contraceptive technology* (20th ed.). New York: Ardent Media.

routine screening of women with risky behaviors or specific risk factors such as age.

Although treatment regimens vary with the infecting organism, a broad-spectrum antibiotic is generally used (Table 7-3). Treatment for mild to moderately severe PID may be oral, or a combination of oral and parenteral, and regimens can be administered in inpatient or outpatient settings (CDC, 2010c; Marrazzo & Cates, 2011). The woman with acute PID should be on bed rest in a semi-Fowler position. Comfort measures include analgesics for pain and all other nursing measures applicable to a woman confined to bed. The woman should have as few pelvic examinations as possible during the acute phase of the disease. During the recovery phase the woman should restrict her activity and make every effort to get adequate rest and a nutritionally sound diet. Follow-up laboratory work after treatment should include endocervical cultures for a test of cure.

Health education is central to effective management of PID. Explain to women the nature of their disease, and encourage them to comply with all therapy and prevention recommendations, emphasizing the necessity of taking all medication, even if symptoms disappear. Counsel women to refrain from sexual intercourse until their treatment is completed. Provide contraceptive counseling. Suggest that the woman select a barrier method such as condoms, contraceptive sponge, or a diaphragm. A woman with a history of PID may choose an IUD

as her contraceptive method: however, the rate of treatment failure and recurrent PID in women continuing to use an IUD is unknown. There are no data regarding treatment outcomes by type of IUD (e.g., copper or levonorgestrel) (CDC, 2010c).

The potential or actual loss of reproductive capabilities can be devastating and can adversely affect a woman's self-concept. The woman may need help in adjusting her self-concept to fit reality and accept alterations in a way that promotes health. Because PID is so closely tied to sexuality, body image, and self-concept, the woman diagnosed with it will need supportive care. She should be encouraged to discuss her feelings. Referral to a support group or for counseling may be appropriate.

SEXUALLY TRANSMITTED VIRAL INFECTIONS

Human Papillomavirus

Human papillomavirus (HPV) infections, also known as *condylomata acuminata*, or *genital warts*, is the most common viral STI seen in ambulatory health care settings. An estimated 79 million Americans are infected with HPV, and about 14.1 million new infections occur every year (CDC, 2013b). The CDC estimates that 50% of sexually active women will become infected in their lifetimes. The highest rate of HPV infections occurs in women ages 20 to 24 years (CDC, 2013b).

HPV, a double-stranded DNA virus, has more than 40 serotypes that can be sexually transmitted, 5 of which are known to cause genital wart formation, and 8 of which are thought to have oncogenic potential (CDC, 2013b). HPV infection, types 16 and 18 are responsible for almost all cervical cancers (American Cancer Society [ACS], 2014).

HPV lesions in women are most commonly seen in the posterior part of the introitus; however, lesions also are found on the buttocks, the vulva, the vagina, the anus, and the cervix (Fig. 7-2). Typically the lesions are small—2 to 3 mm in diameter and 10 to 15 mm in height—soft, papillary swellings occurring singly or in clusters on the genital and anorectal region. Infections of long duration may appear as a cauliflower-like mass. In moist areas such as the vaginal introitus, the lesions may appear to have multiple, fine finger-like projections. Vaginal lesions are often multiple. Flat-topped papules, 1 to 4 mm in diameter, are seen most often on the cervix

FIG 7-2 Human papillomavirus infection. Genital warts or *condylomata acuminata*.

and often are visualized only under magnification. Warts are usually flesh colored or slightly darker on Caucasian women, black on African-American women, and brownish on Asian women. The lesions are often painless but may be uncomfortable, particularly when very large, inflamed, or ulcerated. Chronic vaginal discharge, pruritus, or dyspareunia can occur.

HPV infections are thought to be more frequent in pregnant than in nonpregnant women, with an increase in incidence from the first trimester to the third. Furthermore, a significant proportion of preexisting HPV lesions enlarge greatly during pregnancy, a proliferation presumably resulting from the relative state of immunosuppression present during pregnancy. Lesions can become so large during pregnancy that they affect urination, defecation, mobility, and fetal descent, and can obstruct the birth canal, necessitating a cesarean birth (Marrazzo & Cates, 2011). HPV infection may be acquired by the neonate during birth; the frequency of such transmission is unknown. The preventive value of cesarean birth is unknown, and it is not recommended solely to prevent transmission of HPV infection to newborns (Marrazzo & Cates).

Screening and Diagnosis

A woman with HPV lesions may complain of symptoms such as a profuse irritating vaginal discharge, itching, dyspareunia, or postcoital bleeding. She also may report “bumps” on her vulva or labia. History of a known exposure is important; however, because of the potentially long latency period and the possibility of subclinical infections in men, the lack of a history of known exposure cannot be used to exclude a diagnosis of HPV infection.

Physical inspection of the vulva, the perineum, the anus, the vagina, and the cervix is essential whenever HPV lesions are suspected or seen in one area. Because speculum examination of the vagina may block some lesions, it is important to rotate the speculum blades until all areas are visualized. When lesions are visible, the characteristic appearance previously described is considered diagnostic. However, in many instances, cervical lesions are not visible, and some vaginal or vulvar lesions also may be unobservable to the naked eye. Because of the potential spread of vulvar or vaginal lesions to the anus, gloves should be changed between vaginal and rectal examinations.

Viral screening and typing for HPV are available but not standard practice. History, evaluation of signs and symptoms, Papanicolaou (Pap) test, and physical examination are used in making a diagnosis. The HPV-DNA test can be used in women older than age 30 in combination with the Pap test to screen for types of HPV that are likely to cause cancer or in women with abnormal Pap test results (ACS, 2014). The only definitive diagnostic test for the presence of HPV is histologic evaluation of a biopsy specimen.

HPV lesions must be differentiated from molluscum contagiosum and *condylomata lata*. Molluscum contagiosum lesions are half-domed, smooth, flesh-colored to pearly white papules with depressed centers. *Condylomata lata* are a form of secondary syphilis and generally flatter and wider than genital warts. A serologic test for syphilis confirms the diagnosis of secondary syphilis.

EVIDENCE-BASED PRACTICE

Age-Based Cervical Screening Recommendations Using Cytology and/or Human Papillomavirus Typing

Ask the Question

How does cytology screening (conventional or liquid-based) compare to human papillomavirus (HPV) typing in sensitivity and specificity for detection and treatment of cervical cancer? Does age make a difference in recommendations?

Search for the Evidence

Search Strategies English language reviews, systematic reviews, metaanalyses, and Practice Guidelines on cervical cytology and HPV typing were included.

Databases Used Cochrane Database of Systematic Reviews, National Guideline Clearinghouse (AHRQ), PubMed, UpToDate, CINAHL, and the professional website for AWHONN

Critical Appraisal of the Evidence

Whitlock, Vesco, Eder, et al. (2011):

- Cervical abnormalities that may progress to cervical cancer are caused by certain high risk oncogenic HPV types.
- Cervical screening includes conventional Papanicolaou (Pap) slide preparation, liquid-based cytology (LBC), and HPV typing.
- Conventional cytology is equal to LBC for sensitivity and specificity for cervical intraepithelial neoplasia (CIN), but LBC is superior for adequate cell capture.
- HPV typing is a trade-off: It is more sensitive at detecting cervical abnormality, but its lower specificity means more false positives, and therefore more overdiagnosis and possible overtreatment. All studies lack data on harm from overuse of colposcopy and treatment procedures.
- Using HPV typing first, with follow-up cytology for high risk HPV results, enhances the detection of severe precancerous cervical changes (CIN 3).
- The major benefit from using HPV typing as the primary screen may be a longer screening interval for a low risk population.
- Ongoing research in HPV subtypes, markers, and clinical history can further focus screening targets.

Schwaiger, Aruda, LaCoursiere, & Rubin (2012):

- HPV is very commonly found in women younger than 30 years of age, yet 90% resolve within 2 years; progression to cervical cancer is rare in this age group.

ACOG Committee on Practice Bulletins (2012): Women with normal immune systems and no history of risk factors are tested based on the following guidelines, regardless of HPV vaccine status:

- Cytology screening alone is recommended every 3 years for women 21 to 29 years old.
- For women ages 30 to 65, cytology and HPV typing are recommended every 5 years. Alternately, cytology alone every 3 years is acceptable.

- In the presence of hysterectomy and no history of CIN 2 or higher, screening may be discontinued.
- Screening may be discontinued for women after age 65, if adequate testing has been negative for 10 years.

Apply the Evidence: Nursing Implications

Schwaiger, Aruda, LaCoursiere, & Rubin (2012):

- Nurses can help update textbooks and protocols to reflect the targeted use of HPV typing and the change away from routine yearly Pap testing.
- The appropriate cancer prevention focus for adolescents is sexually transmitted infection (STI) protection and HPV vaccination.
- Women's health exams are an ideal time to educate clients about the risks of smoking and substance abuse in increasing HPV morbidity, as well as prevention of concurrent STIs, including human immunodeficiency virus (HIV).

Quality and Safety Competencies: Evidence-Based Practice* Knowledge

Explain the role of evidence in determining best clinical practice. Describe targeted cervical screening recommendations that result from research on the sensitivity and specificity of HPV typing.

Skills

Participate in structuring the work environment to facilitate integration of new evidence into standards of practice.

Educate clients about best practices for screening and prevention of HPV and cervical cancer.

Attitudes

Value the need for continuous improvement in clinical practice based on new knowledge.

Keep up with changes in recommendations as further research on targeting HPV subtypes, markers, and risk factors is published.

Management

Untreated HPV infection resolves spontaneously in young women because their immune systems may be strong enough to fight the HPV infection. However, if the virus persists, depending on the type of virus, genital warts or cancer can develop months or years after the person has been infected with HPV (CDC, 2013b). No therapy has been shown to eradicate HPV. The goal of treatment for genital warts is removal of warts and relief of signs and symptoms. Treatment for cervical cancer is discussed in Chapter 11.

Treatment of genital warts should be guided by preference of the woman, available resources, and experience of the health care provider. The woman often must make multiple office visits, and many different treatment modalities will be used. None of the treatments is superior to all other treatments, and no one treatment is ideal for all warts (CDC, 2010c).

Available treatments are outlined in Table 7-2. Imiquimod, podophyllin, podofilox, and sinecatechins should not be used during pregnancy (CDC, 2010c; Fantasia, 2012). Because the lesions can proliferate and become friable during pregnancy,

many experts recommend their removal by using cryotherapy or various surgical techniques during pregnancy (CDC).

Women with discomfort associated with genital warts may find that bathing with an oatmeal solution and drying the area with a cool hair dryer provides some relief. Keeping the area clean and dry also decreases growth of the warts. Cotton underwear and loose-fitting clothes that decrease friction and irritation also may decrease discomfort. Women should be advised to maintain a healthy lifestyle to aid the immune system; women can be counseled regarding diet, rest, stress reduction, and exercise.

Royer and Falk (2012) found that young women tend to have misconceptions about HPV. Client counseling is essential to reducing the prevalence of HPV and in improving the management of HPV in women who are infected. Women need to know that HPV infection is very common, and in most cases, will clear up spontaneously. Some infections will progress to genital warts, precancerous lesions, or cancers. Women must understand how the virus is transmitted, that no immunity is conferred with infection, and that reacquisition of the infection is likely with repeated contact. Because HPV is highly contagious, the majority of partners of women with HPV will be infected even if they are asymptomatic. All sexually active women with multiple partners or a history of HPV should be encouraged to use latex condoms for intercourse to decrease the risk of acquisition or transmission of genital HPV.

Instructions for all medications and treatments must be detailed. Women should be told that treatments are for the conditions caused by the virus but not HPV itself. Women should be informed before treatment of the possibility of posttreatment pain associated with specific therapies. The importance of thorough treatment of concurrent vaginitis or STI should be emphasized. The link between cervical cancer and some HPV infections and the need for close follow-up should be discussed. Annual health examinations are recommended to assess disease recurrence and screening for cervical cancer. Women should be counseled to have regular Pap screening, as recommended for women without genital warts (CDC, 2010c). Preventive strategies such as those presented in the following section should also be discussed.

Prevention

Preventive strategies include abstinence from all sexual activity, staying in a long-term monogamous relationship, limiting the number of sexual partners, and prophylactic vaccination (CDC, 2010c, 2013b).

Two vaccines, Cervarix and Gardasil, are available and other vaccines continue to be investigated. The two vaccines are recommended for 11- and 12-year-old girls and boys and are safe and effective in protecting against some of the most common types of HPV that can lead to genital warts and cancers. Cervarix protects against types 16 and 18 HPV infections while Gardasil protects against types 6, 11, 16, and 18. The vaccines are most effective if given before the woman has her first sexual contact (CDC, 2012c). The vaccines can be given to girls as early as 9 years of age and can also be given to young women ages 13 to 26 years if they did not receive the vaccine previously. The vaccine is given in three doses over a 6-month period (CDC, 2012c).

Genital Herpes Simplex Virus

Unknown until the middle of the 20th century, genital herpes simplex virus (HSV) infection is now widespread in the United States. HSV infection results in painful recurrent genital ulcers and is caused by two different antigen subtypes of herpes simplex virus: herpes simplex virus 1 (HSV-1) and herpes simplex virus 2 (HSV-2). HSV-2 is usually transmitted sexually, and HSV-1, nonsexually. Although HSV-1 is more commonly associated with gingivostomatitis and oral labial ulcers (fever blisters; cold sores) and HSV-2 with genital lesions, neither type is exclusively associated with the respective sites.

Although HSV infection is not a reportable disease, it is estimated that about 50 million people or about 1 in 6 people ages 14 to 49 years in the United States are infected with genital herpes (CDC, 2010c). Genital HSV is more common in women: approximately 1 in 5 women ages 14 to 49 are infected (CDC, 2013a). Non-Hispanic black women have the highest rates of any racial group. Women between the ages of 15 and 34 are most likely to become infected, especially if they have multiple sex partners.

Many persons infected with HSV-2 are asymptomatic and therefore undiagnosed. They can transmit the infection unaware that they are infected.

An initial HSV genital infection is characterized by multiple painful lesions, fever, chills, malaise, and severe dysuria and may last 2 to 3 weeks. Women generally have a more severe clinical course than men. Women with primary genital herpes have many lesions that progress from macules to papules, then forming vesicles, pustules, and ulcers that crust and heal without scarring (Fig. 7-3). These ulcers are extremely tender, and primary infections may be bilateral. Women also can have itching, inguinal tenderness, and lymphadenopathy. Severe vulvar edema may develop, and women may have difficulty sitting. HSV cervicitis also is common with initial HSV-2 infections. The cervix may appear normal or be friable, reddened, ulcerated, or necrotic. A heavy watery-to-purulent vaginal discharge is common. Extragenital lesions may be present because of autoinoculation. Urinary retention and dysuria may occur secondary to autonomic involvement of the sacral nerve root.

Women with recurrent episodes of HSV infections commonly have only local symptoms that are usually less severe than those associated with the initial infection. Systemic symptoms are usually absent, although the characteristic prodromal genital tingling is common. Recurrent lesions are unilateral, less severe, and usually last 5 to 7 days. Lesions begin as vesicles and

FIG 7-3 Herpes genitalis.

progress rapidly to ulcers. Few women with recurrent disease have cervicitis.

During pregnancy, maternal infection with HSV-2 can have adverse effects on both the mother and fetus. Viremia occurs during the primary infection, and congenital infection is possible, though rare. Primary infections during the first trimester have been associated with increased miscarriage rates (CDC, 2010c). The most severe complication of HSV infection is neonatal herpes, a potentially fatal or severely disabling disease occurring in 1 in 2000 to 1 in 10,000 live births. Most mothers of infants who contract neonatal herpes lack histories of clinically evident genital herpes. Risk of neonatal infection is highest among women with primary herpes infection who are near term and is low among women with recurrent herpes (CDC 2010c).

Screening and Diagnosis

A history provides much information when making a diagnosis of herpes. A history of exposure to an infected person is important, although infection from an asymptomatic individual is possible. A history of having viral symptoms such as malaise, headache, fever, or myalgia is suggestive. Local symptoms such as vulvar pain, dysuria, itching or burning at the site of infection, and painful genital lesions that heal spontaneously also are highly suggestive of HSV infections. The nurse should ask about a history of a primary infection, prodromal symptoms, vaginal discharge, and dyspareunia. Women should be asked whether they or their partner(s) have had genital lesions.

During the physical examination the nurse should assess for inguinal and generalized lymphadenopathy and elevated temperature. The entire vulvar, perineal, vaginal, and cervical areas should be carefully inspected for vesicles or ulcerated or crusted areas. A speculum examination may be very difficult for the woman because of the extreme tenderness often associated with herpes infections. Any suggestive or recurrent lesions found during pregnancy should be cultured to verify HSV. Although a diagnosis of herpes infection may be suspected from the history and physical, it is confirmed by laboratory studies. A viral culture is obtained by swabbing exudate during the vesicular stage of the disease. Type-specific serologic tests for HSV-2 antibodies are also available (CDC, 2010c).

Management

Genital herpes is a chronic and recurring disease for which there is no known cure. Management is directed toward specific treatment during primary and recurrent infections, prevention, self-help measures, and psychologic support.

Systemic antiviral medications partially control the symptoms and signs of HSV infections when used for the primary or recurrent episodes or when used as daily suppressive therapy. However, these medications do not eradicate the infection nor do they alter subsequent risk or frequency of recurrences after the medication is stopped. Three antiviral medications provide clinical benefit: acyclovir, valacyclovir, and famciclovir. Treatment recommendations are given in Table 7-2. The safety of acyclovir, valacyclovir, and famciclovir therapy during pregnancy has not been established; however, acyclovir may be used to reduce the symptoms of HSV if the benefits to the woman outweigh the potential harm to the fetus (CDC, 2010c).

Continued investigation of HSV therapy with these medications in pregnancy is needed.

Cleaning lesions twice a day with saline helps prevent secondary infection. Bacterial infection must be treated with appropriate antibiotics. Measures that may increase comfort for women when lesions are active include warm sitz baths with baking soda; keeping lesions dry by blowing the area dry with a hair dryer set on cool or patting dry with a soft towel; wearing cotton underwear and loose clothing; using drying aids such as hydrogen peroxide, Burow solution, or oatmeal baths; applying cool, wet, black tea bags to lesions; and applying compresses with an infusion of cloves or peppermint oil and clove oil to lesions.

Oral analgesics such as aspirin, acetaminophen, or ibuprofen may be used to relieve pain and systemic symptoms associated with initial infections. Because the mucous membranes affected by herpes are extremely sensitive, any topical agents should be used with caution. Nonantiviral ointments, especially those containing cortisone, should be avoided. A thin layer of lidocaine ointment or an antiseptic spray may be applied to decrease discomfort, especially if walking is painful.

Counseling and education are critical components of the nursing care of women with herpes infections. Information regarding the etiology, signs and symptoms, transmission, and treatment should be provided. The nurse should explain that each woman is unique in her response to herpes and emphasize the variability of symptoms. Women should be helped to understand when viral shedding and thus transmission to a partner are most likely. They should be counseled to refrain from sexual contact from the onset of prodrome until complete healing of lesions. Suppressive therapy may be an option because it can decrease the risk of transmission to partners (CDC, 2010c).

Some authorities recommend consistent use of condoms for all persons with genital herpes. Condoms may not prevent transmission, particularly male-to-female transmission; however, this does not mean that the partners should avoid all intimacy. Women can be encouraged to maintain close contact with their partners while avoiding contact with lesions. They should be taught how to look for herpetic lesions using a mirror and good light source and a wet cloth or finger covered with a finger cot to rub lightly over the labia. The nurse should ensure that women understand that when lesions are active, sharing intimate articles (e.g., washcloths or wet towels) that come into contact with the lesions should be avoided. Only plain soap and water are needed to clean hands that have come into contact with herpetic lesions; isolation is neither necessary nor appropriate.

Stress, menstruation, trauma, febrile illnesses, chronic illnesses, and ultraviolet light have all been found to trigger genital herpes. Women may wish to keep a diary to identify stressors that seem to be associated with recurrent herpes attacks so that they can then avoid these stressors when possible. The role of exercise in reducing stress can be discussed. Referral for stress-reduction therapy, yoga, or meditation classes may be indicated. Avoiding excessive heat and sun and hot baths and using a lubricant during sexual intercourse to reduce friction also may be helpful. Women in their childbearing years should be counseled regarding the risk of herpes infection during pregnancy. They should be instructed to use condoms if there is any

risk of contracting an STI from a sexual partner. If they become pregnant while taking acyclovir, the risk of birth defects does not appear to be higher than for the general population; however, continued use should be based on whether the benefits for the woman outweigh the possible risks to the fetus. Acyclovir does enter breast milk but the amount of medication ingested during breastfeeding is very low and is usually not a health concern (Weiner & Buhimschi, 2009).

Because neonatal HSV infection is such a devastating disease, prevention is critical. Recommendations include carefully examining and questioning all women about symptoms at onset of labor. If visible lesions are not present at onset of labor, vaginal birth is acceptable. Cesarean birth is recommended if visible lesions are present (CDC, 2010c). Infants who are born through an infected vagina should be carefully observed and cultured (see Chapter 35).

The emotional effect of contracting an incurable STI such as herpes is considerable. At diagnosis, many emotions may surface—helplessness, anger, denial, guilt, anxiety, shame, or inadequacy. Women need the opportunity to discuss their feelings and help in learning to live with the disease. Herpes can affect a woman's sexuality, her sexual practices, and her current and future relationships. She may need help in raising the issue with her partner or with future partners.

Viral Hepatitis

Five different viruses (hepatitis viruses A, B, C, D, and E) account for almost all cases of viral hepatitis in humans. Hepatitis viruses A, B, and C are discussed. Hepatitis D and E viruses, common among users of intravenous (IV) drugs and recipients of multiple blood transfusions, are not included in this discussion.

COMMUNITY ACTIVITY

Visit the Centers for Disease Control and Prevention website at www.cdc.gov. Select a sexually transmitted infection. What is the prevalence of the disease in your state? Evaluate the rank, number of cases, rate per 100,000 population, and cumulative percent. Review the client information about facts and treatment, including concerns and treatment during pregnancy. Locate an STI treatment clinic in your area. Is the location easily accessible by public transportation? Are the hours convenient for clients who are not available in the daytime? What is included in the appointment? What, if any, are the costs of care?

Hepatitis A

Hepatitis A virus (HAV) infection is acquired primarily through a fecal-oral route by ingestion of contaminated food, particularly milk, shellfish, or polluted water, or person-to-person contact (CDC, 2012a). Women living in the western United States, Native Americans, Alaska Natives, and children and employees in daycare centers are at high risk. Hepatitis A, like other enteric infections, can be transmitted during sexual activity.

HAV infection is characterized by flulike symptoms with malaise, fatigue, anorexia, nausea, pruritus, fever, and right upper quadrant pain. Serologic testing to detect the immunoglobulin M (IgM) antibody is done to confirm acute infections. The IgM antibody is detectable 5 to 10 days after exposure and

can remain positive for up to 6 months. Because HAV infection is self-limited and does not result in chronic infection or chronic liver disease, treatment is usually supportive. Women who become dehydrated from nausea and vomiting or who have fulminating hepatitis A may need to be hospitalized. Medications and other ingested substances that might cause liver damage or that are metabolized in the liver (e.g., acetaminophen, ethyl alcohol) should be avoided. A well-balanced diet is recommended. Hepatitis A vaccine (two doses) is recommended for women at high risk for being exposed to HAV infection. The safety of the vaccine has not been established in pregnancy; therefore, immune globulin (gamma globulin) or immune-specific globulin is indicated for a pregnant woman exposed to HAV. All household contacts of the woman also should receive gamma globulin (CDC, 2010c).

Hepatitis B

Hepatitis B virus (HBV) is the virus most threatening to the fetus and neonate. It is caused by a large DNA virus and is associated with three antigens and their antibodies: hepatitis B surface antigen (HBsAg), HBV antigen (HBeAg), HBV core antigen (HBcAg), antibody to HBsAg (anti-HBs), antibody to HBeAg (anti-HBe), and antibody to HBcAg (anti-HBc). Screening for active or chronic disease or disease immunity is based on testing for these antigens and their antibodies.

Populations at risk include women of Asian, Pacific Island (Polynesian, Micronesian, Melanesian), or Alaskan-Inuit descent and women born in Haiti or Sub-Saharan Africa. Women who have a history of acute or chronic liver disease, who work or receive treatment in a dialysis unit, or who have household or sexual contact with a hemodialysis client are at greater risk. Women who work or live in institutions for the mentally challenged are considered to be at risk, as are women with a history of multiple blood transfusions. Health care workers and public safety workers exposed to blood in the workplace are at risk. Behaviors such as having multiple sexual partners and a history of IV drug use increase the risk of contracting HBV infections.

HBsAg has been found in blood, saliva, sweat, tears, vaginal secretions, and semen. Drug abusers who share needles are at risk, as are health care workers who are exposed to blood and needles. Perinatal transmission most often occurs in infants of mothers who have acute hepatitis infection late in the third trimester or during the intrapartum or postpartum period from exposure to HBsAg-positive vaginal secretions, blood, amniotic fluid, saliva, and breast milk. HBV has also been transmitted by artificial insemination. Although HBV can be transmitted via blood transfusion, the incidence of such infections has decreased significantly since testing of blood for HBsAg became routine.

HBV infection is a disease of the liver and is often a silent infection. In an adult the course can be sudden and severe, and the outcome fatal. Symptoms of HBV infection are similar to those of hepatitis A: arthralgias, arthritis, lassitude, anorexia, nausea, vomiting, headache, fever, and mild abdominal pain. Later the woman may have clay-colored stools, dark urine, increased abdominal pain, and jaundice. Between 5% and 10% of individuals with HBV have persistence of HBsAg and become chronic hepatitis B carriers.

Screening and Diagnosis. All women at high risk for contracting HBV should be screened regularly. However, screening only individuals at high risk may not identify up to 50% of HBsAg-positive women. Screening for the presence of HBsAg is recommended on all pregnant women at the first prenatal visit, regardless of whether they have been tested previously; screening should be done on admission for labor and birth for women at high risk for infection who were not tested in pregnancy or if prenatal test results are not available (CDC, 2012a).

The HBsAg screening test is usually performed, given that a rise in HBsAg occurs at the onset of clinical symptoms and usually indicates an active infection. If HBsAg persists in the blood, the woman is identified as a carrier. If the HBsAg test result is positive, further laboratory studies may be ordered: anti-HBe, anti-HBc, serum glutamic-oxaloacetic transaminase (SGOT), alkaline phosphatase, and liver panel.

Management. There is no specific treatment for hepatitis B. Recovery is usually spontaneous in 3 to 16 weeks. Pregnancies complicated by acute viral hepatitis are managed on an outpatient basis. Women should be advised to increase rest periods; eat a high-protein, low-fat diet; and increase their fluid intake. They should avoid medications metabolized in the liver, and alcohol. Pregnant women with a definite exposure to HBV should be given hepatitis B immune globulin and should begin the hepatitis B vaccine series within 14 days of the most recent contact to prevent infection (CDC, 2010a). Vaccination during pregnancy is not thought to pose risks to the fetus.

All nonimmune women at high or moderate risk of hepatitis should be informed of the availability of hepatitis B vaccine. Vaccination is recommended for all individuals who have had multiple sex partners within the past 6 months (CDC, 2010c). In addition, IV drug users, residents of correctional or long-term care facilities, people seeking care for an STI, prostitutes, women whose partners are IV drug users or bisexual, and women whose occupation exposes them to high risk should be vaccinated. The vaccine is given in a series of three (four if rapid protection is needed) doses over a 6-month period, with the first two doses given at least 1 month apart. The vaccine is given in the deltoid muscle (CDC).

Client education includes explaining the meaning of hepatitis B infection, including transmission, state of infectivity, and sequelae. The nurse also should explain the need for immunoprophylaxis for household members and sexual contacts. To decrease transmission of the virus, women with hepatitis B or who test positive for HBV should be advised to maintain a high level of personal hygiene (e.g., wash hands after using the toilet; carefully dispose of tampons, pads, and bandages in plastic bags; do not share razor blades, toothbrushes, needles, or manicure implements; have male partner use a condom if unvaccinated and without hepatitis; avoid sharing saliva through kissing, or sharing of silverware or dishes; and wipe up blood spills immediately with soap and water). They should inform all health care providers of their carrier state. Postpartum women should be reassured that breastfeeding is not contraindicated if their infants received prophylaxis at birth and are currently on the immunization schedule.

Hepatitis C

Hepatitis C virus (HCV) infection has become an important health problem as increasing numbers of persons acquire the

disease. The CDC estimates that individuals born between 1945 and 1965 make up about 75% of all HCV infections. Hepatitis C is responsible for nearly 50% of the cases of chronic viral hepatitis. Risk factors include having STIs such as HBV and HIV, multiple sexual partners, history of blood transfusions, and history of IV drug use. HCV is readily transmitted through exposure to blood and much less efficiently via semen, saliva, or urine (CDC, 2012a).

Most clients with HCV are asymptomatic or have general influenza-like symptoms similar to those of HAV. Previously HCV testing was done on people based on known risk factors and clinical manifestations. In August 2012, the CDC recommended that one-time testing of adults born between 1945 and 1965 be instituted without prior determination of HCV risk factors (CDC, 2012d). HCV infection is confirmed by the presence of anti-C antibody during laboratory testing.

Interferon alfa alone or with ribavirin for 6 to 12 months is the main therapy for chronic HCV-related liver disease, although effectiveness of this treatment varies (CDC, 2010c). Currently, no vaccine is available for HCV. Transmission of HCV through breastfeeding has not been reported.

Human Immunodeficiency Virus

Approximately 47,500 new HIV infections occur in the United States each year. An estimated 20% of these new infections occur in women. Black women are estimated to have 64% of these infections, white women are estimated to have 18%, Hispanic women, 15%, and American Indian women less than 1% (CDC, 2013c).

Severe depression of the cellular immune system associated with HIV infection characterizes acquired immunodeficiency syndrome (AIDS). Although behaviors that place women at risk have been well documented, all women should be assessed for the possibility of HIV exposure. The most commonly reported opportunistic diseases are *Pneumocystis (jirovecii)* pneumonia (PCP), *Candida* esophagitis, and wasting syndrome. Other viral infections such as HSV and cytomegalovirus infections seem to be more prevalent in women than men (CDC, 2010c). PID is often more severe in HIV-infected women than in the general population, and rates of HPV and cervical dysplasia are sometimes higher in non-HIV-infected women (Eckert & Lentz, 2012). The clinical course of HPV infection in women with HIV infection is accelerated, and recurrence is more frequent in non-HIV-infected women.

Once HIV enters the body, seroconversion to HIV positivity usually occurs within 6 to 12 weeks. Although HIV seroconversion may be totally asymptomatic, it usually is accompanied by a viremic influenza-like response. Symptoms include fever, headache, night sweats, malaise, generalized lymphadenopathy, myalgias, nausea, diarrhea, weight loss, sore throat, and rash.

Laboratory studies may reveal leukopenia, thrombocytopenia, anemia, and an elevated erythrocyte sedimentation rate. HIV has a strong affinity for surface-marker proteins on T lymphocytes. This affinity leads to significant T-cell destruction. Both clinical and epidemiologic studies have shown that declining CD4 levels are strongly associated with increased incidence of AIDS-related diseases and death in many different groups of HIV-infected people.

Transmission of the virus from mother to child can occur throughout the perinatal period. Exposure may occur to the

fetus through the maternal circulation as early as the first trimester of pregnancy, to the infant during labor and birth by inoculation or ingestion of maternal blood and other infected fluids, or to the infant through breast milk (CDC, 2013f).

Screening and Diagnosis

Screening, teaching, and counseling regarding HIV risk factors, indications for being tested, and testing are major roles for nurses caring for women today. A number of behaviors place women at risk for HIV infection, including IV drug use, high risk sexual partners, multiple sex partners, and a history of multiple STIs. HIV infection is usually diagnosed by using HIV-1 and HIV-2 antibody tests. Antibody testing is first done with a sensitive screening test such as the enzyme immunoassay (EIA). Reactive screening tests must be confirmed by an additional test, such as the Western blot or an immunofluorescence assay. If a positive antibody test is confirmed by a supplemental test, it means that a woman is infected with HIV and is capable of infecting others. HIV antibodies are detectable in at least 95% of individuals within 3 months after infection. Although a negative antibody test usually indicates that a person is not infected, antibody tests cannot exclude recent infection. Although HIV antibody crosses the placenta, definitive diagnosis of HIV in children younger than 18 months is based on laboratory evidence of HIV in blood or tissues by culture, nucleic acid, or antigen detection (CDC, 2010c).

The U.S. Food and Drug Administration (FDA) (2008) approves six rapid HIV antibody screening tests for clinical use. These tests use a blood sample obtained by fingerstick or venipuncture, an oral fluid sample, or a urine sample to provide test results within 20 minutes, with sensitivity and specificity rates of more than 99%. If the results are reactive, further testing is necessary (CDC, 2010c). Quicker results mean that clients do not have to make extra visits for follow-up standard tests, and the oral test provides an option for clients who do not want to have a blood test.

The CDC (2010c) recommends offering HIV testing to all women whose behavior places them at risk for HIV infection. It may be useful to allow women to self-select for HIV testing. On entry to the health care system, a woman can be handed written information about the risk factors for HIV and asked to inform the nurse if she believes she is at risk. She should be told that she does not have to say why she may be at risk, only that she thinks she might be.

All pregnant women in the United States should be tested for HIV infection as early during pregnancy as possible. The woman should first be informed that she will be tested for HIV as part of the panel of prenatal tests, unless she declines, or opts-out of, screening. For women who decline, providers should continue to encourage testing and address her concerns about testing (CDC, 2010c).

Counseling for HIV Testing

Counseling before and after HIV testing is standard nursing practice today. It is a nursing responsibility to assess a woman's understanding of the information such a test would provide and to be sure the woman thoroughly understands the emotional, legal, and medical implications of a positive or negative result before she is ready to take an HIV test.

NURSING ALERT

Counseling associated with HIV testing has two components: pretest and posttest. During pretest counseling, a personalized risk assessment is conducted, the meaning of positive and negative test results is explained, informed consent for HIV testing is obtained, and women are helped to develop a realistic plan for reducing risk and preventing infection. Posttest counseling includes informing the woman of the test results, reviewing the meaning of the results, and reinforcing prevention messages. It is important to document all pretest and posttest counseling.

Given the strong social stigma attached to HIV infection, nurses must consider the issue of confidentiality and documentation before providing counseling and offering HIV testing to clients.

LEGAL TIP: HIV Testing

If HIV test results are placed in the client's chart—the appropriate place for all health information—they are available to all who have access to the chart. Inform the woman of this availability before testing. Informed consent must be obtained before an HIV test is performed. In some states, written consent is mandated. In many states, HIV testing is performed unless women decline (i.e., opt-out). Nurses must know what procedures are being used for informed consent in their facility.

Unless rapid testing is done, there is generally a 1- to 3-week waiting period after testing for HIV, which can be a very anxious time for the woman. It is helpful if the nurse informs her that this time period between blood drawing and test results is routine. Test results, whatever they are, always must be communicated in person, and women need to be informed in advance that such is the procedure. Whenever possible, the person who provided the pretest counseling also should tell the woman her test results.

When some women are informed of negative results, they may escalate their risk behaviors because of equating negativity with immunity. Others may believe that negative means “bad” and positive means “good.” Women's reactions to a negative test should be explored, such as by asking, “How do you feel?” HIV-negative result counseling sessions are another opportunity to provide education. Emphasis can be placed on ways in which a woman can remain HIV free. She should be reminded that if she has been exposed to HIV in the past 6 months, she should be retested, and that if she continues high risk behaviors, she should have ongoing testing.

In posttest counseling to an HIV-positive woman, privacy with no interruptions is essential. Adequate time for the counseling sessions should be provided. The nurse must make sure that the woman understands what a positive test means and review the reliability of the test results. Risk-reduction practices should be reemphasized. Referral for appropriate medical evaluation and follow-up should be made, and the need or desire for psychosocial or psychiatric referrals should be assessed.

It's important to stress early medical evaluation so that a baseline assessment can be made and prophylactic medication begun. If possible, the nurse should make a referral or appointment for the woman at the posttest counseling session.

Management

During the initial contact with an HIV-infected woman, the nurse should establish what the woman knows about HIV infection and that she is being cared for by a medical practitioner or facility with expertise in caring for people with HIV infections, including AIDS. Psychologic referral also may be indicated. Resources such as counseling for financial assistance, legal advocacy, suicide prevention, and death and dying may be appropriate. All women who are drug users should be referred to a substance-abuse program. A major focus of counseling is prevention of HIV transmission to partners.

Nurses counseling seropositive women wishing contraceptive information can recommend oral contraceptives, hormonal implants, and latex condoms or tubal sterilization or vasectomy and latex condoms. Injectable progestins may be used for the HIV-positive woman, but there is not enough evidence to recommend use by women at high risk for HIV (WHO, 2013a). Female condoms or abstinence can be used by women whose male partners refuse to use condoms. Women should be reminded that of these methods suggested, only condoms offer protection from HIV and other STIs.

No cure is available for HIV infections. Rare and unusual diseases are characteristic of HIV infections. Opportunistic infections and concurrent diseases are managed vigorously with treatment specific to the infection or disease. Routine gynecologic care for HIV-positive women should include a pelvic examination every 6 months. Thorough Pap screening is essential because of the greatly increased incidence of abnormal findings on examination (CDC, 2010c). In addition, HIV-positive women should be screened for syphilis, gonorrhea, chlamydia, and other vaginal infections and treated if infections are present. General prevention strategies are an important part of care (e.g., smoking cessation, sound nutrition) as is antiretroviral therapy. Discussion of the medical care of HIV-positive women or women with AIDS is beyond the scope of this chapter because of the rapidly changing recommendations. The reader is referred to the CDC (www.cdc.gov), CDC National AIDS hotline (800-342-2437), and Internet websites such as HIV/AIDS Treatment Information Service (www.hivatis.org) for current information and recommendations.

HIV and Pregnancy

HIV counseling and testing should be offered to all women at their initial prenatal care visit as part of routine prenatal testing unless the woman opts-out of the screening (CDC, 2010c). Universal testing is recommended versus selective testing for maternal HIV because it results in a greater number of women being screened and treated and can reduce the likelihood of perinatal transmission and maintain women's health (CDC). The CDC also recommends retesting in the third trimester for women known to be at high risk for HIV and rapid HIV testing in labor for women with unknown HIV status.

Perinatal transmission of HIV has decreased significantly since 2004 because of the administration of antiretroviral prophylaxis (e.g., zidovudine) to pregnant women in the prenatal and the perinatal periods. Treatment of HIV-infected women with the triple-drug antiretroviral therapy (ART) or highly active antiretroviral therapy (HAART) during pregnancy has been reported to decrease the mother-to-child transmission to

1% to 2% (CDC, 2010c). All HIV-infected women should be treated with a combination of ART during pregnancy, regardless of their CD4 cell counts (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission [The Panel], 2012). Data are insufficient to support or refute the teratogenic risk of antiretroviral medications given for prophylaxis in the first 10 weeks of pregnancy. Research does not support major teratogenic effects for most of the antiretroviral agents (The Panel). Women who are infected with HIV and need treatment for their own health should start the therapy as soon as possible, even in the first trimester; women who are taking the therapy as prophylaxis usually start therapy after the first trimester (The Panel).

ART is administered orally and continued throughout pregnancy. The major side effect of this therapy is bone marrow suppression. Periodic hematocrit, white blood cell count, and platelet count assessments should be performed (The Panel, 2012). Women who are HIV positive should also be vaccinated against hepatitis B, pneumococcal infection, *Haemophilus influenzae* type B, and viral influenza. To support any pregnant woman's immune system, appropriate counseling is provided about optimal nutrition, sleep, rest, exercise, and stress reduction. Condom use is encouraged to minimize further exposure to HIV from a sexual partner who may be a source.

In the intrapartum period ART and cesarean birth are recommended to prevent vertical transmission of HIV (The Panel, 2012). The Panel recommends a scheduled cesarean birth at 38 weeks of gestation for women with a viral load of more than 1000 copies/ml. A vaginal birth may be an option for HIV-infected women who have a viral load of fewer than 1000 copies/ml at 36 weeks, if a woman has ruptured membranes and labor is progressing rapidly, or if she declines a cesarean birth. IV zidovudine is recommended during the intrapartum period for HIV-infected pregnant women with viral loads of more than 400 copies/ml or unknown HIV status (The Panel). The drug is administered 3 hours before a scheduled cesarean birth and continued until the baby is born. It should be given during labor if the woman is having a vaginal birth (The Panel). Artificial rupture of membranes, fetal scalp electrode, and scalp pH sampling should be avoided because these procedures may result in inoculation of the fetus with the virus. Similarly the use of forceps or vacuum extractor should be avoided when possible (The Panel). Infants should receive oral zidovudine for 6 weeks after birth. Avoidance of breastfeeding is recommended in the United States and most developed countries (CDC, 2010; The Panel).

Women who have HIV but who are without symptoms may have an unremarkable postpartum course. Immunosuppressed women with symptoms may be at increased risk for postpartum urinary tract infections (UTIs), vaginitis, postpartum endometritis, and poor wound healing. Good perineal hygiene should be stressed. Women who are HIV positive but who were not on antiretroviral drugs before pregnancy should be tested in the postpartum period to determine whether therapy that was initiated in pregnancy should be continued (The Panel, 2012). After the initial bath the newborn may be with the mother. In planning for discharge, comprehensive care and support services need to be arranged. After discharge the woman and her infant are referred to physicians who are experienced in treating HIV

and AIDS and associated conditions for intensive monitoring and follow-up (The Panel).

VAGINAL INFECTIONS

Vaginal discharge and itching of the vulva and vagina are among the most frequent reasons a woman seeks help from a health care provider. More women complain of vaginal discharge than of any other gynecologic symptom. Vaginal discharge resulting from infection must be distinguished from normal secretions. Women who have adequate endogenous or exogenous estrogen will have vaginal secretions. Normal vaginal secretions, or leukorrhea, are clear to cloudy and may turn yellow after drying; the discharge is slightly slimy, is nonirritating, and has a mild, inoffensive odor. Normal vaginal secretions are acidic, with a pH of 4 to 5. Normal vaginal secretions contain lactobacilli and epithelial cells. The amount of leukorrhea differs with phases of the menstrual cycle, with greater amounts occurring at ovulation and just before menses. Leukorrhea also is increased during pregnancy.

Vaginitis or abnormal vaginal discharge is an infection caused by a microorganism. The most common vaginal infections are bacterial vaginosis, candidiasis, and trichomoniasis. Although streptococcus B is considered normal vaginal flora, it may also cause infection. Vulvovaginitis, or inflammation of the vulva and vagina, may be caused by vaginal infection or copious amounts of leukorrhea, which can cause tissue maceration. Chemical irritants, allergens, and foreign bodies that produce inflammatory reactions can also cause vulvovaginitis.

Bacterial Vaginosis

Bacterial vaginosis (BV), formerly called nonspecific vaginitis, *Haemophilus vaginitis*, or *Gardnerella*, is the most common cause of vaginal symptoms today (Eckert & Lentz, 2012). The prevalence is most common in women of childbearing age—ages 14 to 49 in the United States. Non-white women (blacks and Hispanics) have higher rates than white women (CDC, 2010a). Women with new or multiple sexual partners are at higher risk for infection. BV can increase susceptibility to STIs such as chlamydia, gonorrhea, genital herpes, and HIV (CDC). BV is associated with preterm labor and birth. The exact etiology of BV is unknown. It is a syndrome in which normal H_2O_2 -producing lactobacilli are replaced with high concentrations of anaerobic bacteria (*Gardnerella* and *Mobiluncus*). With the increased amount of anaerobes, the level of vaginal amines is increased, and the normal acidic pH of the vagina is altered. Epithelial cells slough, and numerous bacteria attach to their surfaces (clue cells). When the amines are volatilized, the characteristic odor of BV occurs.

Many women with BV complain of the characteristic “fishy odor.” The odor may be noticed by the woman or her partner after heterosexual intercourse because semen releases the vaginal amines. When present, the BV discharge usually appears profuse, thin, and white or gray, or milky. Some women also may experience mild irritation or pruritus.

Screening and Diagnosis

A focused history may help distinguish BV from other vaginal infections if the woman is symptomatic. Reports of fishy

TABLE 7-4 Wet Smear Tests for Vaginal Infections

INFECTION	TEST	POSITIVE FINDINGS
Trichomoniasis	Saline wet smear (vaginal secretions mixed with normal saline on a glass slide)	Presence of many white blood cell protozoa
Candidiasis	Potassium hydroxide (KOH) prep (vaginal secretions mixed with KOH on a glass slide)	Presence of hyphae and pseudohyphae (buds and branches of yeast cells)
Bacterial vaginosis	Normal saline smear	Presence of clue cells (vaginal epithelial cells coated with bacteria)
	Whiff test (vaginal secretions mixed with KOH)	Release of fishy odor

odor and increased thin vaginal discharge are most significant, and a report of increased odor after intercourse is also suggestive of BV.

Microscopic examination of vaginal secretions is always performed (Table 7-4). Both normal saline and 10% potassium hydroxide (KOH) smears are made. The presence of more than 20% clue cells (vaginal epithelial cells coated with bacteria) on wet saline smear is highly diagnostic because the phenomenon is specific to BV. Vaginal secretions are tested for pH and amine odor. Nitrazine paper is sensitive enough to detect a pH of 4.5 or greater. The fishy odor of BV will be released when KOH is added to vaginal secretions on the lip of the withdrawn speculum (Eckert & Lentz, 2012).

Management

Treating bacterial vaginosis with oral metronidazole (Flagyl) is most effective (CDC, 2010c). Table 7-5 outlines treatment guidelines. Side effects of metronidazole are numerous, including sharp, unpleasant metallic taste in the mouth; furry tongue; central nervous system reactions; and urinary tract disturbances. When oral metronidazole is taken, the woman is advised not to drink alcoholic beverages or she will experience the severe side effects of abdominal distress, nausea, vomiting, and headache. Gastrointestinal symptoms are common but less severe if alcohol is not consumed. Treating sexual partners is not recommended routinely (CDC, 2010c).

Metronidazole is not recommended if the woman is breastfeeding. However, if it is necessary to prescribe it, the woman can suspend breastfeeding (pump and discard to maintain milk supply) during treatment and for 12 to 24 hours after the last dose to reduce the infant's exposure to metronidazole (CDC, 2010c).

Candidiasis

Vulvovaginal candidiasis (VVC), or yeast infection, is the second most common type of vaginal infection in the United States. Although vaginal candidiasis infections are common in healthy women, those seen in women with HIV infection are often more severe and persistent. Genital candidiasis lesions may be painful coalescing ulcerations necessitating continuous prophylactic therapy.

TABLE 7-5 Vaginal Infections and Drug Therapies for Women

DISEASE	NONPREGNANT WOMEN (13-17 yr)	NONPREGNANT WOMEN (>18 yr)	PREGNANT WOMEN	LACTATING WOMEN
Bacterial vaginosis	<i>Recommended:</i> metronidazole, 500 mg bid for 7 days (no alcohol) <i>or</i> metronidazole gel 0.75%, 5 g intravaginally bid for 7 days <i>or</i> clindamycin cream 2%, 5 g intravaginally at bedtime for 7 days (less effective)	<i>Recommended:</i> metronidazole, 500 mg bid for 7 days (no alcohol) <i>or</i> metronidazole gel 0.75%, 5 g intravaginally bid for 7 days <i>or</i> clindamycin cream 2%, 5 g intravaginally at bedtime for 7 days (less effective)	High risk asymptomatic or symptomatic women <i>Recommended:</i> metronidazole, 500 mg orally bid for 7 days (no alcohol) <i>or</i> metronidazole, 250 mg orally tid for 7 days <i>or</i> clindamycin, 300 mg orally bid for 7 days	<i>Recommended:</i> clindamycin cream or ovules
Trichomoniasis	<i>Recommended:</i> metronidazole, 2 g orally once <i>or</i> tinidazole, 2 g orally once	<i>Recommended:</i> metronidazole, 2 g orally once	<i>Recommended:</i> metronidazole, 2 g orally once	Metronidazole not recommended during lactation; stop breastfeeding treat, resume breastfeeding in 12-24 hours after drug completed Tinidazole: Stop breastfeeding and resume 3 days after treatment Pump and discard milk to maintain supply
Candidiasis	Numerous OTC intravaginal agents: butoconazole, clotrimazole, miconazole, tioconazole, terconazole; treatment with "azole" drugs more effective than nystatin Dose varies by agent from one dose a day to one dose for 3 to 7 days <i>Oral agent:</i> fluconazole 150-mg oral tablet once	Numerous OTC intravaginal agents: butoconazole, clotrimazole, miconazole, tioconazole, terconazole; treatment with "azole" drugs more effective than nystatin Dose varies by agent from one dose a day to one dose for 3 to 7 days <i>Oral agent:</i> fluconazole 150-mg oral tablet once	OTC "azole" intravaginal agents: butoconazole, clotrimazole, miconazole, terconazole Use for 3 to 7 days Oral agents not recommended	OTC "azole" intravaginal agents: butoconazole, clotrimazole, miconazole, terconazole Use for 3 to 7 days

OTC, Over the counter.

Data from Centers for Disease Control and Prevention. (2010). Sexually transmitted diseases treatment guidelines 2010. *MMWR Morbidity and Mortality Weekly Report*, 59(RR-12), 1-109.

The most common organism is *Candida albicans*; estimates indicate that more than 90% of the yeast infections in women are caused by this organism. However, since 2004, the incidence of non-*C. albicans* infections has risen steadily. Women with chronic or recurrent infections often are infected with these organisms (Eckert & Lentz, 2012).

Numerous factors have been identified as predisposing a woman to yeast infections, including antibiotic therapy, particularly broad-spectrum antibiotics such as ampicillin, tetracycline, cephalosporins, and metronidazole; diabetes, especially when uncontrolled; pregnancy; obesity; diets high in refined sugars or artificial sweeteners; use of corticosteroids and exogenous hormones; and immunosuppressed states. Clinical observations and research have suggested that tight-fitting clothing and underwear or pantyhose made of nonabsorbent materials create an environment in which a vaginal fungus can grow.

The most common symptom of yeast infections is vulvar and possibly vaginal pruritus. The itching can be mild or intense, interfere with rest and activities, and may occur during or after intercourse. Some women report a feeling of dryness. Others may experience painful urination as the urine flows over the vulva, which usually occurs in women who have excoriations resulting from scratching. Most often the discharge has a thick, white, lumpy, and cottage cheese-like consistency. The discharge may be found in patches on the vaginal walls, cervix, and labia. Commonly, the vulva is red and swollen, as are the

labial folds, vagina, and cervix. Although there is not a characteristic odor with yeast infections, sometimes a yeasty or musty smell is noted.

Screening and Diagnosis

In addition to a complete history of the woman's symptoms, their onset, and course, the history is a valuable screening tool for identifying predisposing risk factors. Physical examination should include a thorough inspection of the vulva and vagina. A speculum examination is always done. Commonly health care practitioners will obtain saline and KOH wet smears and check vaginal pH (see Table 7-4). Vaginal pH is normal with a yeast infection; if the pH is greater than 4.5, trichomoniasis or BV should be suspected. The characteristic pseudohyphae (bud or branching of a fungus) may be seen on a wet smear done with normal saline; however, they may be confused with other cells and artifacts (CDC, 2010c).

Management

A number of antifungal preparations are available for the treatment of *C. albicans*. Many of these medications (e.g., miconazole [Monistat] and clotrimazole [Gyne-Lotrimin]) are available as over-the-counter (OTC) agents. Exogenous lactobacillus (in the form of dairy products [yogurt] or powder, tablet, capsule, or suppository supplements) and garlic have been suggested for prevention and treatment of vulvovaginal candidiasis, but research is inconclusive, and no

recommendations have been developed for use in practice (Eckert & Lentz, 2012). The first time a woman suspects that she may have a yeast infection she should see a health care provider for confirmation of the diagnosis and treatment recommendations. If she has another infection, she may wish to purchase an OTC preparation and self-treat. If she elects to do this, she should always be counseled to seek care for numerous recurrent or chronic yeast infections. If vaginal discharge is extremely thick and copious, vaginal debridement with a cotton swab followed by application of vaginal medication may be effective.

Women who have extensive irritation, swelling, and discomfort of the labia and vulva may find sitz baths helpful in decreasing inflammation and increasing comfort. Adding colloidal oatmeal powder to the bath may also increase the woman's comfort. Not wearing underpants to bed may help decrease symptoms and prevent recurrences. **Completing the full course of treatment prescribed is essential to removing the pathogen.** Instruct women to continue the medication even during menstruation. Explain that they should avoid using tampons during menses because the tampon will readily absorb the medication. If possible, women should avoid intercourse during treatment; if abstinence is not feasible, the woman's partner should use a condom to prevent the introduction of more organisms (see Teaching for Self-Management box).

TEACHING FOR SELF-MANAGEMENT

Prevention of Genital Tract Infections

- Practice genital hygiene.
- Choose underwear or hosiery with a cotton crotch.
- Avoid tight-fitting clothing (especially tight jeans).
- Select cloth car seat covers instead of vinyl.
- Limit time spent in damp exercise clothes (especially swimsuits, leotards, and tights).
- Limit exposure to bath salts or bubble bath.
- Avoid colored or scented toilet tissue.
- If sensitive, discontinue use of feminine deodorant sprays.
- Use condoms.
- Void before and after intercourse.
- Decrease dietary sugar.
- Drink yeast-active milk and eat yogurt (with lactobacilli).
- Do not douche.

Trichomoniasis

Trichomonas vaginalis is almost always an STI and is also a common cause of vaginal infection (5% to 50% of all vaginitis) and discharge (Eckert & Lentz, 2012).

Trichomoniasis is caused by *T. vaginalis*, an anaerobic one-celled protozoan with characteristic flagellae. Although trichomoniasis may be asymptomatic, commonly women have characteristically yellowish to greenish, frothy, mucopurulent, copious, malodorous discharge. Inflammation of the vulva, the vagina, or both may be present, and the woman may complain of irritation and pruritus. Dysuria and dyspareunia are often present. Typically the discharge worsens during and

after menstruation. Often the cervix and the vaginal walls will demonstrate the characteristic "strawberry spots" or tiny petechiae, and the cervix may bleed on contact. In severe infections, the vaginal walls, the cervix, and occasionally the vulva may be acutely inflamed.

Screening and Diagnosis

In addition to obtaining a history of current symptoms, a careful sexual history should be obtained. Any history of similar symptoms in the past and treatment used should be noted. The nurse should determine whether the woman's partner(s) was treated and if she has had subsequent relations with new partners.

A speculum examination is always done, even though it may be very uncomfortable for the woman; relaxation techniques and breathing exercises may help the woman with the procedure. Any of the classic signs can be present on physical examination. The typical one-celled flagellate trichomonads are easily distinguished on a normal saline wet prep. Trichomoniasis also can be identified on Pap tests. Because trichomoniasis is an STI, once diagnosis is confirmed, appropriate laboratory studies for other STIs should be carried out.

Management

The recommended treatment is metronidazole or tinidazole orally in a single dose (CDC, 2010c) (see Table 7-5). Although the male partner is usually asymptomatic, it is recommended that he receive treatment also because he often harbors the trichomonads in the urethra or prostate. It is important that nurses discuss the importance of partner treatment with their clients, because if they are not treated it is likely that the infection will recur.

Women with trichomoniasis need to understand the sexual transmission of this disease. The woman must know that the organism may be present without symptoms being present, perhaps for several months, and that it is not possible to determine when she became infected. Women should be informed of the necessity for treating all sexual partners and helped with ways to raise the issue with their partner(s).

Group B Streptococcus

Group B streptococcus (GBS) may be considered a part of the normal vaginal flora in a woman who is not pregnant and is present in about 25% of healthy pregnant women (CDC, 2012b). GBS infection has been associated with poor pregnancy outcomes. These infections are an important factor in neonatal morbidity and mortality, usually resulting from vertical transmission from the birth canal of the infected mother to the infant during birth (Cunningham, Leveno, Bloom, et al., 2014).

Risk factors for neonatal GBS infection include positive prenatal culture for GBS in the current pregnancy; preterm birth of less than 37 weeks of gestation; premature rupture of membranes for a duration of 18 hours or more; intrapartum maternal fever higher than 38°C; and a positive history for early-onset neonatal GBS (Cunningham et al., 2014).

To decrease the risk of neonatal GBS infection, it is recommended that all women be screened at 35 to 37 weeks of

gestation for GBS using a rectovaginal culture, and that IV antibiotic prophylaxis (IAP) be offered during labor to all who test positive. If a culture is not available at onset of labor or if a risk factor is present, IAP is also offered. IAP is not recommended before a cesarean birth if labor or rupture of membranes has not occurred. The recommended treatment is penicillin G, 5 million units IV loading dose, and then 2.5 million units IV every 4 hours during labor. Ampicillin, 2 g IV loading dose, followed by 1 g IV every 4 hours, is an alternative therapy (CDC, 2010b).

MATERNAL AND FETAL EFFECTS OF SEXUALLY TRANSMITTED INFECTIONS

Sexually transmitted infections in pregnancy are responsible for significant morbidity and mortality. Some consequences of maternal infection, such as infertility and sterility, last a lifetime. Congenitally acquired infection may affect a child's length and quality of life. Table 7-6 describes the effects of several common STIs on the pregnant woman and the fetus. It is difficult to predict these effects with certainty. Factors such as coinfection with other STIs and when in pregnancy the infection was acquired and treated can affect outcomes.

TORCH Infections

Toxoplasmosis, other infections (e.g., hepatitis), rubella virus, cytomegalovirus (CMV), and herpes simplex virus,

known collectively as **TORCH infections**, form a group of organisms capable of crossing the placenta. TORCH infections can affect a pregnant woman and her fetus. Generally, all TORCH infections produce influenza-like symptoms in the mother, but fetal and neonatal effects are more serious. TORCH infections and their maternal and fetal effects are shown in Table 7-7. Neonatal effects are discussed in Chapter 35

CARE MANAGEMENT

Women may delay seeking care for STIs and other infections because they fear social stigma, have little accessibility to health care services, are asymptomatic, or are unaware that they have an infection. A comprehensive assessment focuses on lifestyle issues that are often personal or sensitive. A culturally sensitive, nonjudgmental approach is essential to facilitate accurate data collection. Throughout this chapter the discussion for each STI has included essential areas of assessment including signs and symptoms of the current problem, history (medical, personal, and social, and lifestyle behaviors), diagnostic tests, and physical examination.

Nursing diagnoses are derived from assessment data. The following nursing diagnoses are representative of those used in a plan of care for a woman with an STI and/or other vaginal infection:

Anxiety/Situational Low Self-Esteem/Disturbed Body Image related to:

- Perceived effects on sexual relationships and family processes
- Possible effects on pregnancy or fetus
- Long-term sequelae of infection

Deficient Knowledge related to:

- Transmission/prevention of infection/reinfection
- Behaviors that reduce risk for STIs
- Management of infection

Acute Pain/Impaired Tissue Integrity related to:

- Effects of infection process
- Scratching (excoriation) of pruritic areas
- Hygiene practices

Sexual Dysfunction related to:

- Effects of infection process

Social Isolation and Impaired Social Interaction related to:

- Perceived effects on relationships with others if STI status is unknown

Expected outcomes of care focus on physical and psychologic needs and include that the woman will:

- Be free of infection or, in the case of viral infection, have remission or stabilization of the infection
- Identify and be able to discuss the etiology, management, and expected course of the infection and its prevention
- Be able to identify her risky behaviors and discuss plans for decreasing her risk for infection

Management of the care for the woman with an STI has been discussed with each infection (see Nursing Care Plan). The Teaching for Self-Management box summarizes the important points of teaching about STIs.

TABLE 7-6 Maternal and Fetal Effects of Common Sexually Transmitted Infections

INFECTION	MATERNAL EFFECTS	FETAL EFFECTS
Chlamydia	Premature rupture of membranes Preterm labor Postpartum endometritis	Low birth weight
Gonorrhea	Miscarriage Preterm labor Premature rupture of membranes Amniotic infection syndrome Chorioamnionitis Postpartum endometritis Postpartum sepsis	Preterm birth IUGR
Group B streptococci	Urinary tract infection Chorioamnionitis Postpartum endometritis Sepsis Meningitis (rare)	Preterm birth
Herpes simplex virus	Intrauterine infection (rare)	Congenital infection (rare)
Human papillomavirus (HPV)	Dystocia from large lesions Excessive bleeding from lesions after birth trauma	None known
Syphilis	Miscarriage Preterm labor	IUGR Preterm birth Stillbirth Congenital infection

IUGR, Intrauterine growth restriction.

Data from Gilbert, E. (2011). *Manual of high risk pregnancy & delivery* (5th ed.).

St. Louis: Mosby; Duff, P., Sweet, R., & Edwards, R. (2009). Maternal and fetal infections. In R. Creasy, R. Resnik, J. Iams, et al. (Eds.), *Creasy and Resnik's maternal-fetal medicine: Principles and practice* (6th ed.). Philadelphia: Saunders.

TABLE 7-7 TORCH Infection: Maternal and Fetal

INFECTION	MATERNAL EFFECTS	FETAL EFFECTS	COUNSELING: PREVENTION, IDENTIFICATION, AND MANAGEMENT
Toxoplasmosis (protozoa)	Most infections asymptomatic Acute infection similar to mononucleosis Woman immune after first episode (except in immunocompromised clients)	Congenital infection is most likely to occur when maternal infection develops during the third trimester. The risk of fetal injury, however, is greatest when maternal infection occurs during the first trimester.	Good handwashing technique should be used. Eating raw or rare meat and exposure to litter used by infected cats should be avoided; toxoplasma titer should be checked if there are cats in the house. If titer is rising during early pregnancy, therapeutic abortion may be considered an option.
Other infections			
Hepatitis A (infectious hepatitis) (virus)	Liver failure (extremely rare) Low-grade fever, malaise, poor appetite, right upper quadrant pain and tenderness, jaundice, and light-colored stools	Perinatal transmission virtually never occurs.	Spread by fecal-oral contact especially by culinary workers; gamma globulin can be given as prophylaxis for hepatitis A. Hepatitis A vaccine is available.
Hepatitis B (serum hepatitis) (virus)	May be transmitted sexually Approximately 10% of clients become chronic carriers. Some people with chronic hepatitis B eventually develop severe chronic liver disease, such as cirrhosis or hepatocellular carcinoma.	Infection occurs during birth. Maternal vaccination during pregnancy should present no risk for fetus; however, data are not available.	Generally passed by contaminated needles, syringes, or blood transfusions; also can be transmitted orally or by coitus (but incubation period is longer); hepatitis B immune globulin can be given prophylactically after exposure. Hepatitis B vaccine recommended for populations at risk
Rubella (3-day or German measles) (virus)	Rash, fever, mild symptoms such as headache, malaise, myalgias, and arthralgias; postauricular lymph nodes may be swollen; mild conjunctivitis	Approximately 50%-80% of fetuses exposed to the virus within 12 weeks after conception will show signs of congenital infection. Very few fetuses are affected if infection occurs after 18 weeks of gestation. The most common fetal anomalies associated with congenital rubella syndrome are deafness, eye defects (e.g., cataracts or retinopathy), central nervous system defects, and cardiac defects.	Vaccination of pregnant women is contraindicated; non-immune women should be vaccinated in the early postpartum period; pregnancy should be prevented for 1 month after vaccination. Women may breastfeed after vaccination and the vaccine can be administered along with immunoglobulin preparations such as Rh immune globulin.
Cytomegalovirus (CMV) (a herpes-virus)	Most adults are asymptomatic or have only mild influenza-like symptoms. The presence of CMV antibodies does not totally prevent reinfection.	The fetus can be infected transplacentally. Infection is much more likely with a primary maternal infection. The most common indications of congenital infection include hepatosplenomegaly, intracranial calcifications, jaundice, growth restriction, microcephaly, chorioretinitis, hearing loss, thrombocytopenia, hyperbilirubinemia, and hepatitis.	The virus is transmitted by transplantation of an infected organ, transfusion of infected blood, sexual contact, or contact with contaminated saliva or urine. Virus may be reactivated and cause disease in utero or during birth in subsequent pregnancies; fetal infection may occur during passage through infected birth canal. Prevention includes use of CMV-negative blood products if transfusion of pregnant women is necessary and teaching all women to wash hands carefully after handling infant diapers and toys.
Herpes genitalis (herpes simplex virus, type 1 or type 2 [HSV-1 or HSV-2])	Primary infection with painful blisters, tender inguinal lymph nodes, fever, viral meningitis (rare) Recurrent infections are much milder and shorter.	Transplacental infection resulting in congenital infection is rare and usually occurs with primary maternal infection. The risk mainly exists with infection late in pregnancy.	As many as two thirds of women with HSV-2 antibodies acquired the infection asymptotically; however, asymptomatic women can give birth to seriously infected neonates. Risk of transmission is greatest during vaginal birth if woman has active lesions; thus cesarean birth is recommended Acyclovir can be used to treat recurrent outbreaks during pregnancy or as suppressive therapy late in pregnancy to prevent an outbreak during labor and birth.

Data from Duff, P., Sweet, R., & Edwards, R. (2009). Maternal and fetal infections. In R. Creasy, R. Resnik, J. Iams, et al. (Eds.), *Creasy and Resnik's maternal-fetal medicine: Principles and practice* (6th ed.). Philadelphia: Saunders.

INFECTION CONTROL

Interrupting the transmission of infection is crucial to STI control. Many STIs are reportable; all states require that the five traditional STIs—gonorrhea, syphilis, chancroid, lymphogranuloma venereum, and granuloma inguinale—be reported to

public health officials. Many other states require that other STIs such as chlamydial infections, genital herpes, and genital warts be reported. In addition, all states require that AIDS cases be reported. In 2013, 32 state laboratories were required to report viral load and CD4 data for people who have HIV infections (CDC, 2013e).

 **NURSING CARE PLAN**
Sexually Transmitted Infections

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Ineffective Health Maintenance related to practicing prevention of sexually transmitted infections (STIs) as evidenced by client positive diagnosis of STI</i>	Woman will verbalize which health practices directly led to positive diagnosis of an STI.	<p>Inquire about woman's sexual history and sexual health practices.</p> <p>Use therapeutic communication for private, nonjudgmental discussion.</p> <p>Provide emotional support.</p> <p>Provide information about transmission of disease, including cause, symptoms, and treatment for both partners.</p> <p>Discuss the use and importance of safe sexual practices.</p> <p>Instruct woman and sexual partner to complete medication regimen.</p>	<p>To provide database for current problem</p> <p>To facilitate learning and promote self-esteem</p> <p>To indicate awareness of woman's feelings about this sensitive topic</p> <p>To enhance woman's knowledge base and correct any misinformation</p> <p>To raise woman's awareness and motivation to avoid future risk-taking behaviors</p> <p>To completely eradicate transmitted organism</p>
<i>Impaired Social Interaction related to diagnosis of STI as evidenced by client verbal report</i>	Woman will report increased incidences of social interaction.	<p>Provide nonjudgmental, confidential therapeutic communication.</p> <p>Refer to support groups.</p>	<p>To increase woman's feelings of self-worth</p> <p>To provide group interaction, discussion, and information</p> <p>To provide database</p>
<i>Impaired Tissue Integrity related to effects of disease process as evidenced by client report of itching and vaginal discharge</i>	Woman's tissue integrity will be restored.	<p>Assess, monitor, and document characteristics of the damaged skin area, including color, lesions, drainage, and edema.</p> <p>Instruct woman in correct genital hygiene practices.</p> <p>Provide warm soaks or sitz baths.</p> <p>Administer prescribed medications.</p> <p>Provide written self-help materials and pamphlets.</p> <p>Teach woman to perform vulvar self-examination.</p>	<p>To prevent further infection of damaged tissues with other organisms</p> <p>To promote comfort, circulation, and healing</p> <p>To promote comfort and eradication of organism</p> <p>To prevent further skin integrity loss</p> <p>To encourage participation in self-care</p>
<i>Anxiety related to diagnosis of STI</i>	Woman will report decreased level of anxiety.	<p>Provide opportunity for therapeutic communication.</p> <p>Assist woman to identify effective coping mechanisms.</p> <p>Refer to support groups.</p>	<p>To promote trust and expression of feelings</p> <p>To decrease anxiety</p> <p>To share feelings and common effective strategies</p>

TEACHING FOR SELF-MANAGEMENT**Sexually Transmitted Infections**

- Take your medication as directed.
- Use comfort measures for symptom relief as suggested by your health care provider.
- Keep your appointment for repeat cultures or checkups after your treatment to make sure your infection is cured.
- Inform your sexual partner(s) of the need to be tested and treated, if necessary.
- Abstain from sexual intercourse until your treatment is completed or for as long as you are advised by your health care provider.
- Use sex practices that decrease risk when sexual intercourse is resumed.
- Call your health care provider immediately if you notice bumps, sores, rashes, or discharges.
- Keep all future appointments with your health care provider, even if things appear normal.

Infection-control measures are essential to protect care providers and to prevent health personnel–related infection of clients, regardless of the infectious agent. The risk for occupational transmission varies with the disease. Even when the risk is low, as with HIV, the existence of any risk warrants reasonable precautions. Precautions against airborne disease transmission are available in all health care agencies. Standard Precautions (to use for infection control when caring for everyone) and additional precautions for labor and birth settings are listed in Box 7-3.

LEGAL TIP: Sexually Transmitted Infection Reporting

The primary health care provider is legally responsible for reporting all cases of those diseases identified as reportable and should know what the requirements are in the state in which she or he practices. The woman must be informed when a case will be reported and be told why. Failure to inform the woman that the case will be reported is a serious breach of professional ethics.

BOX 7-3 Standard Precautions

Medical history and examination cannot reliably identify everyone infected with human immunodeficiency virus (HIV) or other blood-borne pathogens. Standard Precautions should therefore be used consistently in the care of all clients. These precautions apply to blood, body fluids, and all secretions and excretions, except sweat, nonintact skin, and mucous membranes. The following infection-control practices should be applied during the delivery of health care to reduce the risk of transmission of microorganisms from known and unknown sources of infection:

1. **Hand hygiene.** During the delivery of health care, avoid unnecessary touching of surfaces in close proximity to the client to prevent both contamination of clean hands from environmental surfaces and transmission of pathogens from contaminated hands to surfaces. Wash dirty or contaminated hands with either a nonantimicrobial or an antimicrobial soap and water. If hands are not visibly soiled, decontaminate hands with an alcohol-based handrub, or hands may be washed with an antimicrobial soap and water. Perform hand hygiene: (1) before having direct contact with clients; (2) after contact with blood, body fluids, or excretions, mucous membranes, nonintact skin, or wound dressings; (3) after contact with a client's intact skin (e.g., when taking a pulse or blood pressure or lifting a client); (4) if hands will be moving from a contaminated body site to a clean body site during client care; (5) after contact with inanimate objects (including medical equipment) in the immediate vicinity of the client; and (6) after removing gloves. Wash hands with nonantimicrobial or antimicrobial soap and water if contact with spores (e.g., *Clostridium difficile* or *Bacillus anthracis*) is likely to have occurred. The physical action of washing and rinsing hands under such circumstances is recommended because alcohols, chlorhexidine, iodophors, and other antiseptic agents have poor activity against spores. Do not wear artificial fingernails or extenders if duties include direct contact with clients at high risk for infection and associated adverse outcomes.
2. **Personal protective equipment (PPE).** Observe the following principles of use:
 - **Gloves.** Wear gloves when a reasonable possibility exists for contact with blood or other potentially infectious materials, mucous membranes, nonintact skin, or potentially contaminated intact skin (e.g., of a client incontinent of stool or urine). Gloves should be worn during infant eye prophylaxis, care of the umbilical cord, circumcision site, parenteral procedures, diaper changes, contact with colostrum, and postpartum assessments. Wear gloves with fit and durability appropriate to the task. Remove gloves after contact with a client or the surrounding environment (including medical equipment) using proper technique to prevent hand contamination. Do not wear the same pair of gloves for the care of more than one client. Change gloves during client care if the hands will move from a contaminated body site (e.g., perineal area) to a clean body site (e.g., face).

- **Gowns.** Wear a gown that is appropriate to the task to protect the skin and prevent soiling or contamination of clothing during procedures and client-care activities when contact with blood, body fluids, secretions, or excretions is anticipated. Remove the gown and perform hand hygiene before leaving the client's environment. Do not reuse gowns, even for repeated contacts with the same client. Routine donning of gowns on entrance into a high risk unit (e.g., intensive care unit [ICU], neonatal intensive care unit [NICU]) is not indicated.
 - **Mouth, nose, eye protection.** Use PPE to protect the mucous membranes of the eyes, nose, and mouth during procedures and client-care activities that are likely to generate splashes or sprays of blood, body fluids, secretions, and excretions. Select masks, goggles, face shields, and combinations of each according to the need anticipated by the task performed.
3. **Respiratory hygiene and cough etiquette.** Post signs at entrances and in strategic places (e.g., elevators, cafeterias) within ambulatory and inpatient settings with instructions to clients and others with symptoms of a respiratory infection to cover their mouth and nose when coughing or sneezing, use and dispose of tissues, and perform hand hygiene after hands have been in contact with respiratory secretions. Provide tissues and no-touch receptacles (e.g., foot pedal–operated lid or open, plastic-lined wastebasket) for disposal of tissues. Provide resources and instructions for performing hand hygiene in or near waiting areas in ambulatory and inpatient settings; provide conveniently located dispensers of alcohol-based handrubs and, where sinks are available, supplies for handwashing. During periods of increased respiratory infections in the community, offer masks to coughing clients and other symptomatic individuals (e.g., people who accompany ill clients) on entry into the facility, and encourage them to maintain special separation, ideally a distance of at least 3 feet, from others in common waiting areas.
 4. **Safe injection practices.** The following recommendations apply to the use of needles, cannulas that replace needles, and, where applicable, intravenous delivery systems:
 - Use aseptic technique to prevent contamination of sterile injection equipment. Needles, cannulas, and syringes are sterile, single-use items; they should not be reused for another client. Use fluid infusion and administration sets (i.e., intravenous bags, tubing, and connectors) for one client only, and dispose appropriately after use. Use single-dose vials for parenteral medications whenever possible. If multidose vials must be used, both the needle (or cannula) and the syringe used to access the multidose vial must be sterile. Do not keep multidose vials in the immediate client treatment area, and store in accordance with the manufacturer's recommendations; discard if sterility is compromised or questionable.

KEY POINTS

- Reproductive tract infections include STIs and common genital tract infections.
- Young, sexually active women who do not practice risk-reducing sexual behaviors and have multiple partners are at greatest risk for STIs and HIV.
- Risk-reduction sexual practices are key STI-prevention strategies.
- STIs are responsible for substantial morbidity and mortality, great personal suffering, and heavy economic burden in the United States.
- HIV is transmitted through body fluids, primarily blood, semen, and vaginal secretions.
- Prevention of mother-to-newborn HIV transmission is most effective when the woman receives antiretroviral drugs during pregnancy and labor and birth, and the infant receives the drugs after birth.
- STIs and vaginitis are biologic events for which all individuals have a right to expect objective, compassionate, and effective health care.
- Pregnancy confers no immunity against infection, and both mother and fetus must be considered when the pregnant woman contracts an infection.
- HPV is the most common viral STI.
- Syphilis has reemerged as a common STI, affecting black women more than any other ethnic or racial group.
- Because history and examination cannot reliably identify everyone with HIV or other blood-borne pathogens, blood and body-fluid precautions should be used consistently for everyone all the time.
- Chlamydia is the most common STI in women in the United States and the most common cause of PID.
- Viral hepatitis has several forms of transmission; HBV infections carry the greatest risk.

Contraception and Abortion

Lisa L. Ferguson and
Peggy Mancuso

 <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Compare various methods of contraception.
- Identify the advantages and disadvantages of commonly used methods of contraception.
- Explain the common nursing interventions that facilitate contraceptive use.
- Examine the various ethical, legal, cultural, and religious considerations of contraception.
- Describe the techniques used for medical and surgical interruption of pregnancy.
- Discuss the various ethical and legal considerations of elective abortion.
- Outline a plan of care for a woman who needs emergency contraception.

CONTRACEPTION

The Centers for Disease Control and Prevention (CDC) noted that the capability of Americans to engage in effective family planning as a result of the modern era of contraception was one of the 10 greatest public health achievements of the 20th century. Nevertheless, nearly half of all U.S. pregnancies are not planned (Woodhams & Gilliam, 2012; Finer & Zolna, 2011). Among adolescent women, approximately 80% of those who became pregnant did not intend to do so (Epidemiology and Efficacy; Fritz & Speroff, 2011b). The nurse can play a vital role in prevention of unwanted pregnancy through counseling and education regarding family planning, contraception, and effective birth control.

Family planning is the conscious decision on when to conceive or to avoid pregnancy throughout the reproductive years. **Contraception** is defined as the intentional prevention of pregnancy during sexual intercourse. **Birth control** is the device and/or practice used to decrease the risk of conceiving or bearing offspring.

With the wide assortment of birth control options available, it is possible for a woman to use several different contraceptive methods at various stages throughout her fertile years. Nurses interact with the individual as well as the couple to compare and contrast available contraceptive options. Factors to consider include reliability, relative cost of the method, any protection from sexually transmitted infections (STIs), the individual's comfort level with the method, and the partner's willingness to use a particular birth control method. Those who use contraception can still be at risk for pregnancy if their choice of

contraceptive method results in one that is not used correctly or if it is not as reliable as other methods. Expanding access to contraception, especially long-acting reversible methods, and improving accurate and reliable use of birth control methods can decrease the chance of unintended pregnancy (CDC, 2013).

COMMUNITY ACTIVITY

Nurses provide discharge planning after childbirth; they commonly staff family planning clinics and provide contraceptive information to those clients and others in the community. Education concerning contraceptive use in the postpartum period is a common component of discharge planning in many countries, with wide variation among health care delivery systems. Education at this time assumes women's receptiveness to information about contraception and that education or receptiveness to such information could be less at a later period. However, clinical trials have not demonstrated that education in the immediate postpartum period is effective. Contact a clinic in your community to see if you can talk with one of the nurses about their procedures in caring for postpartum women, focusing on what the nurses do related to education about family planning.

CARE MANAGEMENT

A multidisciplinary approach may assist a woman in choosing and correctly using an appropriate contraceptive method. Nurses, nurse-midwives, nurse practitioners, and other advanced practice nurses as well as physicians have the knowledge and

expertise to assist a woman in making decisions about contraception that will satisfy her personal, social, cultural, and interpersonal needs.

Family, friends, media, partner or partners, religious affiliation, and health care professionals influence a woman's perception of contraceptive choices. These external influences form a woman's unique view. The nurse assists in supporting the woman's decision based on her individual situation.

Evaluation of the couple desiring contraception involves assessing the woman's reproductive history (menstrual, obstetric, gynecologic, contraceptive), physical examination, and, sometimes, current laboratory tests. The nurse must determine the woman's knowledge about reproduction, contraception, and STIs, as well as her sexual partner's commitment to any particular method. Religious and cultural factors may influence a couple's choice regarding a particular contraceptive method. The couple may believe in certain reproductive myths. For example, 30% of all adolescent pregnancies were in women who engaged in unprotected intercourse because of the perception that they could not get pregnant at the time of intercourse. Unbiased client teaching is fundamental to initiating and maintaining any form of contraception.

Assessment of the client begins with the following appraisals:

- Determining the woman's knowledge about contraception and her sexual partner's commitment to any particular method
- Collecting data about the frequency of coitus, the number of sexual partners, the level of contraceptive involvement, and her or her partner's objections to any methods
- Assessing the woman's level of comfort and willingness to touch her genitals and cervical mucus
- Identifying any misconceptions, as well as religious and cultural factors, and paying close attention to the woman's verbal and nonverbal responses to hearing about the various available methods
- Considering the woman's reproductive life plan
- Completing a history (including menstrual, contraceptive, and obstetric), physical examination (including pelvic examination), and laboratory tests (as needed for identifying presence of STIs).

Informed consent is a vital component in educating a client about contraception or sterilization. The nurse often has the responsibility of documenting information provided and the understanding of that information by the client. The mnemonic BRAIDED may be useful (see Legal Tip).

Once the assessment is complete, nursing diagnoses can be identified to help develop the nursing care plan and

interventions. Nursing diagnoses related to contraception include the following:

- *Decisional Conflict* related to
 - Contraceptive alternatives; partner's willingness to agree on contraceptive method.
- *Fear* related to
 - Contraceptive method side effects.
- *Risk for Infection* related to
 - Unprotected sexual intercourse; use of contraceptive method; broken skin or mucous membrane after surgery or intrauterine device (IUD) insertion.
- *Ineffective Sexuality Patterns* related to
 - Fear of pregnancy.
- *Acute Pain* related to
 - Postoperative recovery after sterilization.
- *Risk for Spiritual Distress* related to
 - Discrepancy between religious or cultural beliefs and choice of contraceptive method.

Education is the cornerstone of the nursing care plan and planned interventions. Developing applicable interventions increases client understanding that leads to improved adherence to the contraceptive plan and increased client satisfaction. The nurse should teach about the specific contraceptive used. Following the teaching-learning session, the nurse should ask the woman to perform a return demonstration of how a device is used, if appropriate, and assess her understanding of this contraceptive method. The nurse should also provide the woman and her partner with written instructions about the contraceptive method and with contact information in case she has questions later. If a woman has difficulty understanding written instructions, offer her (and her partner, if available) graphic material and contact information (telephone number, email) for questions of the clinic if necessary, and let her know that she may return to the clinic for further instruction if needed. It is very important to provide the woman and her partner additional information about backup methods of birth control and emergency contraception.

A private setting should be provided for contraceptive counseling. The woman should feel safe and free to communicate with the nurse. Distractions should be minimized, and samples of birth control devices for interactive teaching should be available. The nurse counters myths with facts, clarifies misinformation, and fills in gaps of knowledge. The ideal contraceptive should be safe, easily available, economical, acceptable, simple to use, and promptly reversible. Although no method may ever achieve all these objectives, new contraceptive technologies are being developed, and couples have more choices available to them now than ever before (Lessard, Karasek, Ma, et al., 2012).

Contraceptive failure rate refers to the percentage of contraceptive users expected to have an unplanned pregnancy during the first year of use, even when they use a method consistently and correctly. Contraceptive effectiveness varies from couple to couple and depends on the properties of the method and the characteristics of the user (Box 8-1). Effectiveness of a method can be expressed as theoretic effectiveness, or how effective the method is with perfect use, and as typical effectiveness, or how effective the method is with typical use. Failure rates decrease over time, either because a user gains experience and uses a method more appropriately or because the less effective users

LEGAL TIP: Informed Consent

- B—Benefits: information about advantages and success rates
- R—Risks: information about disadvantages and failure rates
- A—Alternatives: information about other available methods
- I—Inquiries: opportunity to ask questions
- D—Decisions: opportunity to decide or to change her mind
- E—Explanations: information about method and how it is used
- D—Documentation: information given and client's understanding

BOX 8-1 Factors Affecting Contraceptive Method Effectiveness

- Frequency of intercourse
- Motivation to prevent pregnancy
- Understanding of how to use the method
- Adherence to method
- Provision of short- or long-term protection
- Likelihood of pregnancy for the individual woman
- Consistent use of method

stop using the method. Safety of a method may be affected by a woman's medical history (e.g., thromboembolic problems and contraceptive methods containing estrogen). In most instances, pregnancy would be more dangerous to the woman with medical problems than a particular contraceptive method, but thromboembolic problems is an example of why a certain type of contraception should be avoided. On the other hand, the use of many contraceptive methods is associated with health promotion effects. For example, barrier methods, such as the male condom, offer some protection from acquiring STIs, and oral contraceptives lower the incidence of ovarian and endometrial cancer.

SAFETY ALERT

Make sure the woman has a backup method of birth control and contraceptive pills (CPs) readily available during the initial learning phase when she uses a new method of contraception to help prevent an unintentional conception.

CLINICAL REASONING CASE STUDY

Contraception for Adolescents

Maria is a 16-year-old Hispanic client who comes to the family planning clinic seeking contraception. She has recently become sexually active and tells the nurse that she is concerned that her mother will find out. She also has many questions about the type of contraception to use. She seeks the nurse's advice to help in her decision making.

1. Evidence—Is there sufficient evidence to draw conclusions about what advice to give Maria?
2. Assumptions—What assumptions can be made about contraception for adolescents:
 - a. Types of contraception
 - b. Legal issues
 - c. Implications of culture on choice
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

Methods of Contraception

The following discussion of contraceptive methods provides the nurse with information needed for client teaching. After implementing the appropriate teaching for contraceptive use, the nurse supervises return demonstrations and practice to assess client understanding (Fig. 8-1).

The most effective contraceptive methods at preventing pregnancy are the long-acting, reversible contraceptive (LARC) methods (e.g., contraceptive implants, intrauterine

FIG 8-1 Nurse counseling woman about contraceptive methods. (Courtesy Dee Lowdermilk, Chapel Hill, NC.)

contraception). With these methods, theoretic and typical pregnancy rates are the same because the method requires no user intervention after correct insertion. Other effective methods include those that prevent pregnancy through exogenous hormones (estrogen and/or progestins), such as contraceptive injections, oral contraceptive pills, contraceptive patches, and vaginal rings. Each of these methods involves user interventions, so typical use pregnancy rates are higher than pregnancy rates with perfect use. The least effective contraceptive methods include the barrier methods and natural family planning. Examples include condoms, diaphragms, cervical caps, spermicides, withdrawal, and periodic abstinence during perceived ovulation. Effectiveness rates for these methods vary from user to user, depending on correct application of the method and consistency of use.

Coitus Interruptus

Coitus interruptus (withdrawal) involves the male partner withdrawing the penis from the woman's vagina before he ejaculates. Although coitus interruptus is one of the least effective methods of contraception, it is a good choice for couples who do not have another contraceptive available (Kowal, 2011). Effectiveness is similar to barrier methods and depends on the man's ability to withdraw his penis before ejaculation. The percentage of women who will experience an unintended pregnancy within the first year of typical use (failure rate) of withdrawal is about 22% (Trussell, 2011). Coitus interruptus does not protect against STIs or human immunodeficiency virus (HIV) infection.

Fertility Awareness–Based Methods (Natural Family Planning)

Fertility awareness–based (FAB) methods of contraception, also known as periodic abstinence or natural family planning (NFP), depend on identifying the beginning and end of the fertile period of the menstrual cycle. These methods provide contraception by relying on avoidance of intercourse during fertile periods. Natural family planning methods are the only contraceptive practices acceptable to the Roman Catholic Church.

BOX 8-2 Potential Pitfalls of Using Fertility Awareness Methods of Contraception

Potential pitfalls of using fertility awareness methods include the five R's:

- Restriction on sexual spontaneity
- Rigorous daily monitoring
- Required training
- Risk of pregnancy during prolonged training period
- Risk of pregnancy high on unsafe days

From Ziemann, M., Hatcher, R., Cwiak, C., et al. (2012). *A pocket guide to managing contraception*. Tiger, GA: Bridging the Gap Foundation.

When women who want to use FABs are educated about the menstrual cycle, three phases are identified:

1. Infertile phase: before ovulation
2. Fertile phase: about 5 to 7 days around the middle of the cycle, including several days before and during ovulation and the day afterward
3. Infertile phase: after ovulation

The human ovum can be fertilized no later than 12 to 24 hours after ovulation (Cunningham, Leveno, Bloom, et al., 2014; Schulman, 2011). Motile sperm have been recovered from the uterus and the oviducts as long as 60 hours after coitus, but their ability to fertilize the ovum probably lasts no longer than 24 to 48 hours. One problem with FABs is that the exact time of ovulation cannot be predicted accurately, and couples may find it difficult to exercise restraint for several days before and after ovulation. In addition, women with irregular menstrual periods have the greatest risk of failure with FABs.

Although ovulation can be unpredictable in many women, teaching the woman about how she can directly observe her fertility patterns is an empowering tool. There are nearly a dozen categories of FABs. To prevent pregnancy, each one uses a combination of charts, records, calculations, tools, observations, and either abstinence or barrier methods of birth control during the fertile period in the menstrual cycle (Jennings & Burke, 2011). The charts and calculations associated with these methods can also be used to increase the likelihood of detecting the optimal timing of intercourse to achieve conception. Signs and symptoms of fertility awareness most commonly used with abstinence are menstrual bleeding, cervical mucus, and basal body temperature, as described later in the chapter (Jennings & Burke).

Advantages of these methods include low to no cost, heightened awareness and understanding of personal fertility, increased self-reliance, absence of chemicals, instant availability, increased involvement and intimacy with partner, and the ability of the couple to follow religious/cultural traditions. In addition, these methods can be used to establish fertile days for conception in the couple who wants to achieve pregnancy. Disadvantages of FABs include difficulty with adherence to strict record-keeping, requirement of male partner support, lower typical effectiveness than other regimens, decreased effectiveness in women with irregular cycles (particularly adolescents who have not established regular ovulatory patterns), decreased spontaneity of coitus, and no protection from STIs including HIV infection. (Association of Reproductive Health Professionals [ARHP], 2011; Fehring, Schneider, Barron, & Pruzny, 2013; Jennings & Burke, 2011) (Box 8-2). The typical failure rate for most FABs is 24% during the first year of use (Trussell, 2011).

FABs involve several techniques to identify fertile days. The following discussion includes the most common techniques as well as some promising techniques for the future.

Calendar-Based Methods

Calendar Rhythm Method. Practice of the calendar rhythm method is based on the number of days in each cycle, counting from the first day of menses. With this method the fertile period is determined after accurately recording the lengths of menstrual cycles for at least 6 months. Increased reliability can be obtained with 8 to 12 months of menstrual data (Planned Parenthood, 2013). The beginning of the fertile period is estimated by subtracting 18 days from the length of the shortest cycle. The end of the fertile period is determined by subtracting 11 days from the length of the longest cycle (Jennings & Burke, 2011). If the shortest cycle is 24 days and the longest is 30 days, application of the formula to calculate the fertile period is as follows:

Shortest cycle: $24 - 18 =$ sixth day

Longest cycle: $30 - 11 =$ nineteenth day

To avoid conception the couple would abstain during the fertile period—days 6 through 19. If the woman has very regular cycles of 28 days each, the formula indicates the fertile days to be as follows:

Shortest cycle: $28 - 18 =$ tenth day

Longest cycle: $28 - 11 =$ seventeenth day

To avoid pregnancy the couple abstains from days 10 through 17 because ovulation occurs on day 14 plus or minus 2 days. A major drawback of the calendar method is that one is trying to predict future events with past data. The unpredictability of the menstrual cycle also is not taken into consideration. The calendar rhythm method is most useful as an adjunct to the basal body temperature or the cervical mucus method.

Standard Days Method. The Standard Days Method (SDM) is essentially a modified form of the calendar rhythm method that has a “fixed” number of days of fertility for each cycle—that is, days 8 to 19 (ARHP, 2011). A CycleBeads necklace—a color-coded string of beads—can be purchased as a concrete tool to track fertility (Fig. 8-2). Day 1 of the menstrual flow is the first day to begin counting. Women who use this device are taught to avoid unprotected intercourse on days 8 to 19 (white beads on CycleBeads necklace). Although this method is useful to women whose cycles are regular and occur at 26- to 32-day intervals, the SDM is unreliable for those who have longer or shorter cycles. Factors that may make this method less effective include the use of hormonal contraception (including emergency contraception), IUDs, breastfeeding, or a recent pregnancy (Planned Parenthood, 2013). The typical failure rate for the SDM is 12% during the first year of use (Jennings & Burke, 2011).

Symptoms-Based Methods

TwoDay Method. The TwoDay Method is based on the monitoring and recording of cervical secretions (ARHP, 2011). Unlike other methods that rely on this indicator, such as the ovulation mucus method or the symptothermal method, it does not involve analyzing the characteristics of the secretions (e.g., amount, color, consistency, slipperiness, stretchability, or viscosity) (Contracept.org, 2013). Each day the woman asks herself, (1) “Did I note secretions today?” and (2) “Did I note secretions yesterday?” If the answer to either question is

FIG 8-2 CycleBeads. Red bead marks the first day of the menstrual cycle. White beads mark days that are likely to be fertile days; therefore, unprotected intercourse should be avoided. Brown beads are days when pregnancy is unlikely and unprotected intercourse is permitted. (Courtesy Dee Lowdermilk, Chapel Hill, NC.)

yes, she should avoid coitus or use a backup method of birth control. If the answer to both questions is no, her probability of getting pregnant is very low. After 2 days without secretions, the woman may resume unprotected intercourse. The TwoDay Method appears to be simpler to teach, learn, and use than other natural methods. Results suggest that the method can be an effective alternative for low-literacy populations or for programs that find current natural family planning methods too time consuming or otherwise not feasible to incorporate into their services. Studies have found the typical failure rate of the TwoDay Method to be 24% (ARHP). This method could affect Third World fertility planning. For a more global perspective on these implications, see Institute for Reproductive Health at <http://irh.org/?q=content/twoday-method>.

Cervical Mucus Ovulation Detection Method. The cervical mucus ovulation detection method (i.e., Billings method or Creighton model ovulation method) requires that the woman recognize and interpret the cyclic changes in the amount and consistency of cervical mucus that characterize her own unique pattern of changes at the time of ovulation. Cervical mucus transforms prior to and during ovulation in order to facilitate and promote the viability and motility of sperm. Without adequate cervical mucus, coitus does not result in conception. This method requires that a woman check the quantity and character of mucus on the vulva or introitus with her fingers or tissue paper each day for several months and evaluate the mucus for cloudiness, tackiness, and slipperiness. This way she can learn how her cervical mucus responds to ovulation during her menstrual cycles. To ensure an accurate assessment of changes, the cervical mucus should be free from semen, contraceptive gels or foams, and blood or discharge from vaginal infections for at least one full cycle. Other factors that create difficulty in identifying mucus changes include douches and vaginal deodorants, being in a sexually aroused state (which thins the mucus), and taking medications such as antihistamines (which dry the mucus). Intercourse is considered safe without restriction beginning the fourth day after the last day of wet, clear, slippery mucus, which would indicate that ovulation has occurred 2 to 3 days previously (Jennings & Burke, 2011).

FIG 8-3 A, Special thermometer for recording basal body temperature, marked in tenths to enable person to read more easily. B, Basal temperature record shows drop and sharp rise at time of ovulation. Biphasic curve indicates ovulatory cycle.

Some women find this method unacceptable if they are uncomfortable touching their genitals. Whether or not a woman wants to use this method for contraception, it is to her advantage to learn to recognize mucus characteristics at ovulation (see Teaching for Self-Management). Self-evaluation of cervical mucus can be highly accurate and useful diagnostically for any of the following purposes:

- To alert the couple to the reestablishment of ovulation while breastfeeding and after discontinuation of oral contraception
- To note anovulatory cycles at any time and at the beginning of menopause
- To assist couples in planning a pregnancy

Basal Body Temperature Method. The basal body temperature (BBT) is the lowest body temperature of a healthy person, taken immediately after waking and before getting out of bed. The BBT usually varies from 36.2° to 36.3° C during menses and for approximately 5 to 7 days afterward (Fig. 8-3).

About the time of ovulation a slight drop in temperature (approximately 0.5° C) may occur in some women just prior to ovulation, but other women may have no decrease at all. After ovulation, in concert with the increasing progesterone levels of the early luteal phase of the cycle, the BBT increases slightly (approximately 0.4° to 0.8° C). Before ovulation, 96° to 98° F is normal in many women. After ovulation, temperature increases to 97° to 99° F. The temperature remains on an elevated plateau until 2 to 4 days before menstruation. Then BBT decreases to the low levels recorded during the previous cycle unless pregnancy has occurred. In pregnant women the temperature remains elevated. If ovulation fails to occur, the pattern of lower body temperature continues throughout the cycle.

To use this method, the fertile period is defined as the day of first temperature drop, or first elevation, through 3 consecutive days of elevated temperature. Abstinence begins the first day of menstrual bleeding and lasts through 3 consecutive days of sustained temperature rise (at least 0.2° C). The decrease and subsequent increase in temperature are referred

TEACHING FOR SELF-MANAGEMENT

Cervical Mucus Characteristics**Setting the Stage**

- Show charts of menstrual cycle along with changes in the cervical mucus.
- Have the woman practice with raw egg white.
- Supply her with a basal body temperature log and graph if she does not already have one.
- Explain that assessment of cervical mucus characteristics is best when mucus is not mixed with semen, contraceptive jellies or foams, or discharge from infections. Tell her to refrain from douching before the assessment.

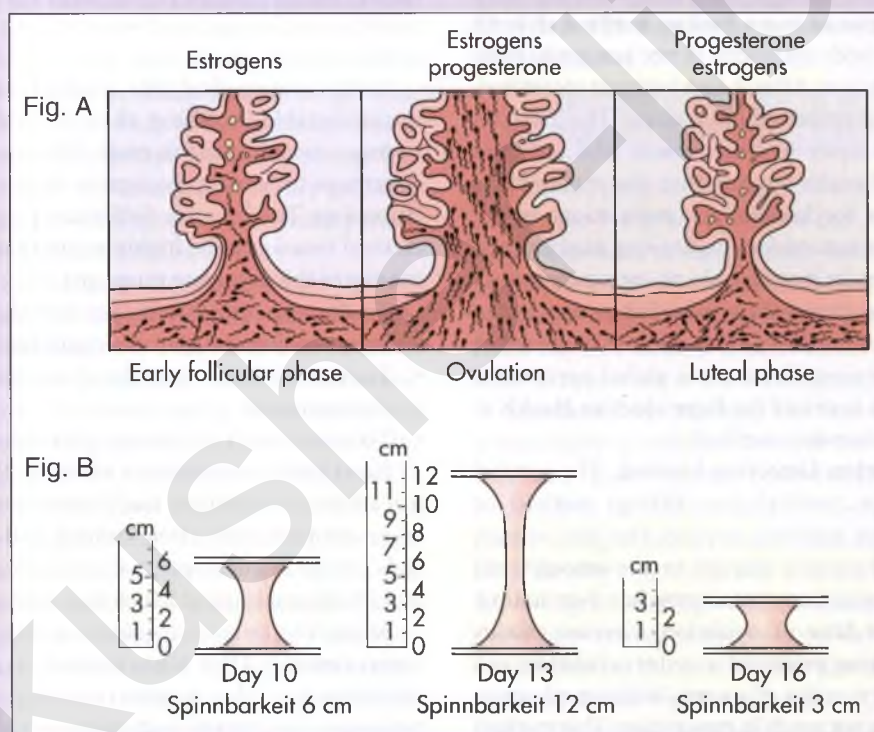

Content Related to Cervical Mucus

- Explain to the woman (couple) how cervical mucus changes throughout the menstrual cycle.
 - Postmenstrual mucus: scant
 - Preovulation mucus: cloudy, yellow or white, sticky
 - Ovulation mucus: clear, wet, sticky, slippery
 - Postovulation fertile mucus: thick, cloudy, sticky
 - Postovulation, postfertile mucus: scant

- Right before ovulation, the watery, thin, clear mucus becomes more abundant and thick (Fig. A). It feels similar to a lubricant and can be stretched 5+ cm between the thumb and forefinger; this quality of mucus is called spinnbarkeit (Fig. B), and its presence indicates the period of maximal fertility. Sperm deposited in this type of mucus can survive until ovulation occurs.

Assessment Technique

- Stress that good handwashing is imperative to begin and end all self-assessments.
- Start observation from last day of menstrual flow.
- Assess cervical mucus several times a day for several cycles. Mucus can be obtained from vaginal opening; reaching into the vagina to the cervix is unnecessary.
- Record the findings on the same record on which the basal body temperature is entered.

to as the *thermal shift*. When the entire month's temperatures are recorded on a graph, the pattern described is more apparent. It is more difficult to perceive day-to-day variations without the entire picture (see Teaching for Self-Management). Either a glass mercury thermometer or a digital thermometer may be used for BBT, but the thermometer must measure the temperature within 0.1 degree. The glass mercury thermometer needs no batteries but is fragile and can break. A digital thermometer will require batteries but may have a history recall function and an audible beep when the temperature assessment is finished. Digital thermometers that monitor temperature throughout the day combined with an accelerometer to monitor movement

have been cleared for use by the U.S. Food and Drug Administration (FDA). These devices can be wirelessly uploaded to a computer through a companion device. Their use in FABs needs further research.

Infection, fatigue, less than 3 hours of sleep per night, awakening late, and anxiety may cause temperature fluctuations and alter the expected pattern. If a new BBT thermometer is purchased, this fact is noted on the chart because the readings may vary slightly. Jet lag, alcohol taken the evening before, or sleeping in a heated waterbed must also be noted on the chart because each affects the BBT. Therefore, the BBT alone is not a reliable method of predicting ovulation.

TEACHING FOR SELF-MANAGEMENT

Basal Body Temperature

- Discuss basal body temperature (BBT) with the woman.
- Show the woman a diagram depicting the phases of the menstrual cycle.
- Discuss the hormones in the woman's body that are responsible for her menstrual cycle and ovulation. Leave time for questions.
- Show the woman a sample BBT graph (see Fig. 8-4) and the biphasic line seen in ovulatory cycles.
- Show the woman the BBT thermometer and how it is calibrated.
- Provide a demonstration.
- Encourage the woman to demonstrate taking and reading the thermometer and graphing the temperature while the nurse watches.
- Encourage the woman to start a log to keep track of any other activity that might interfere with her true BBT.

Symptothermal Method. The symptothermal method combines the BBT and cervical mucus methods with awareness of secondary phase–related signs and symptoms of the menstrual cycle. The woman gains fertility awareness as she learns the psychologic and physiologic signs and symptoms that mark the phases of her cycle. Secondary signs and symptoms include increased libido, midcycle spotting, mittelschmerz (cramplike pain prior to ovulation), pelvic fullness or tenderness, and vulvar fullness.

The woman is taught to palpate her cervix to assess for changes indicating ovulation: the cervical os dilates slightly, the cervix softens and rises in the vagina, and cervical mucus is copious and slippery. The woman notes days on which coitus, changes in routine, illness, and other changes that might affect BBT have occurred (Fig. 8-4). Calendar calculations and cervical mucus changes are used to estimate the onset of the fertile period; changes in cervical mucus or the BBT are used to estimate the end of the fertile period.

Biologic Marker Methods

Home Predictor Test Kits for Ovulation. Although the methods previously discussed are characteristic of ovulation, they do not prove that ovulation actually occurred or indicate the exact timing. The urine predictor test for ovulation is a major addition to the NFP and fertility-awareness methods to help women who want to plan the time of their pregnancies and for those who are trying to conceive (Fig. 8-5). The urine predictor test for ovulation detects the sudden surge of luteinizing hormone (LH) that occurs approximately 12 to 24 hours before ovulation. Unlike BBT, this test is not affected by illness, emotions, or physical activity. For home use, a test kit contains sufficient material for several days' testing during each cycle. A positive response indicating an LH surge is noted by a color change that is easy to interpret. Directions for use of urine predictor test kits vary with the manufacturer.

The Marquette Model. The Marquette Model (MM) is a natural family planning method that was developed through the Marquette University College of Nursing Institute for Natural Family Planning (Fehring, Schneider, & Barron, 2008). The MM uses cervical monitoring along with the ClearPlan Easy Fertility Monitor. The ClearPlan monitor is a handheld

device that uses test strips to measure urinary metabolites of estrogen and LH. The monitor provides the user with “low,” “high,” and “peak” fertility readings. The MM incorporates the use of the monitor as an aid to learning NFP and fertility awareness. The MM is currently being tested at different sites in the United States for its effectiveness in helping couples avoid pregnancy. One study has shown a typical use failure rate of 10.6% (Fehring et al.).

Spermicides and Barrier Methods

Barrier contraceptives have gained in popularity not only as a contraceptive method but also as protection against the spread of STIs such as human papillomavirus and herpes simplex virus (HSV). Some male condoms and female vaginal methods provide a physical barrier to several STIs, and some male condoms provide protection against HIV (Cates & Harwood, 2011). Spermicides serve as chemical barriers against semen and inhibit the ability of sperm to fertilize the ovum.

The nurse should remember that any user of a barrier method of contraception must also be aware of emergency contraception options in case there is a failure of the method. An example of a barrier method failure would be if a condom broke during intercourse. In this instance, emergency contraception would be indicated to prevent unplanned pregnancy.

Spermicides. Spermicides such as nonoxynol-9 (N-9) work by reducing the sperm's mobility. The chemicals attack the sperm flagella and body, thereby preventing the sperm from reaching the cervical os. N-9, the most commonly used spermicidal chemical in the United States, is a surfactant that destroys the sperm cell membrane. Results from data analyses suggest that frequent use (more than two times a day) of N-9 or the use of N-9 as a lubricant during anal intercourse may increase the transmission of HIV and can cause lesions (Cates & Harwood, 2011). There is no evidence that the addition of spermicides to male condoms decreases the risk of subsequent pregnancy. Women with high risk behaviors that increase their likelihood of contracting HIV and other STIs are advised to avoid the use of spermicidal products containing N-9, including lubricated condoms, diaphragms, and cervical caps to which N-9 is added (CDC, 2010).

Intravaginal spermicides are marketed and sold without prescriptions as aerosol foams, tablets, suppositories, creams, films, and gels (Fig. 8-6). Preloaded, single-dose applicators small enough to be carried in a small purse are available. Effectiveness of spermicides depends on consistent and accurate use. Clients should be cautioned against misunderstanding terms: contraceptive gel differs from fruit jelly, and cosmetics or hair products containing the nonspermicidal forms of nonoxynol are not adequate substitutes for contraception. The spermicide should be inserted high into the vagina so that it makes contact with the cervix. Some spermicide should be inserted at least 15 minutes before, and no longer than 1 hour before, sexual intercourse. Spermicide must be reapplied for each additional act of intercourse, even if a barrier method is used. Studies have shown varying effectiveness rates for spermicidal use alone. Typical failure rate in the first year of spermicidal use alone is 28% (Trussell, 2011). Some female barrier methods (e.g., diaphragm, cervical caps) offer more effective protection against pregnancy with the addition of spermicides.

Condoms. The male condom is a thin, stretchable sheath that covers the penis before genital, oral, or anal contact and is removed when the penis is withdrawn from the partner's orifice after ejaculation. Condoms are made of latex rubber, which provides a barrier to sperm and STIs (including HIV); polyurethane (strong, thin plastic); or natural membranes (animal tissue). In addition to providing a physical barrier for sperm, nonspermicidal latex condoms also provide a barrier for STIs (particularly gonorrhea, chlamydia, and trichomoniasis) and HIV transmission (CDC, 2010). Condoms lubricated with N-9 are not recommended for preventing STIs or HIV and do not increase protection against pregnancy. Latex condoms break down with oil-based lubricants (e.g., petroleum jelly and suntan oil) and should be used only with water-based or silicone lubricants (Warner & Steiner, 2011). Because of the growing number of people with latex allergies, condom manufacturers have begun using polyurethane, which is thinner and stronger than latex.

⚡ SAFETY ALERT

All clients should be questioned about the potential for latex allergy. Latex condom use is contraindicated for clients with latex sensitivity.

Although polyurethane condoms are as effective for STI prevention as latex condoms, they are more likely to slip or lose contour when compared with latex condoms. With perfect use, therefore, latex condoms offer better protection against pregnancy. Polyurethane condoms do offer equivalent pregnancy protection as most barrier products. A small percentage of condoms are made from lamb cecum (natural skin). Natural skin condoms do not provide the same protection against STIs and HIV infection as latex condoms. Natural skin condoms contain small pores that could allow passage of viruses such as hepatitis B, HSV, and HIV and are not recommended generally.

A functional difference in condom shape is the presence or absence of a sperm reservoir tip. To enhance vaginal stimulation, some condoms are contoured and rippled or have ribbed or roughened surfaces. Thinner construction increases heat transmission and sensitivity. A wet jelly or dry powder lubricates some condoms. Condoms must be discarded after each single use. They are available without a prescription and from a variety of sources, including vending machines. Typical failure rate for the first year of use of the male condom is 18% (Trussell, 2011). To prevent unintended pregnancy and the spread of STIs, it is essential that condoms be used consistently and correctly. Instructions, such as those listed in Box 8-3, can be used

BOX 8-3 Male Condoms

Mechanism of Action

- Sheath is applied over the erect penis before insertion or loss of preejaculatory drops of semen. Used correctly, condoms prevent sperm from entering the cervix. Spermicide-coated condoms cause ejaculated sperm to be immobilized rapidly, thus increasing contraceptive effectiveness.

Failure Rate

- Typical users: 18%
- Correct and consistent users: 2%

Advantages

- Safe
- No side effects
- Readily available
- Premalignant changes in cervix can be prevented or ameliorated in women whose partners use condoms
- Method of male nonsurgical contraception

Disadvantages

- Must interrupt lovemaking to apply sheath
- Sensation may be altered
- If used improperly, spillage of sperm can result in pregnancy
- Condoms occasionally may tear during intercourse

STI Protection

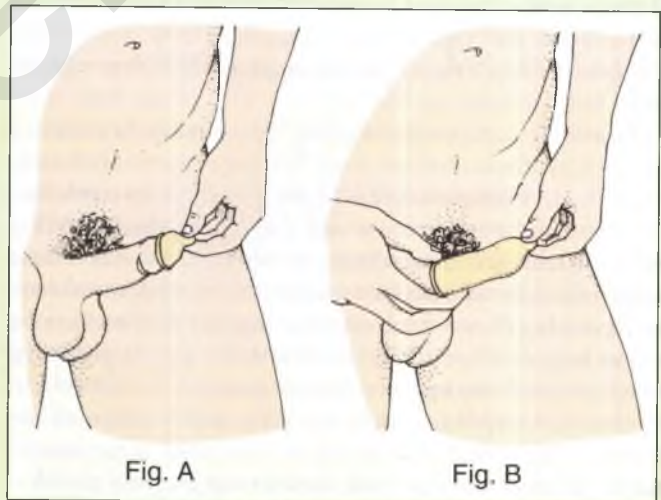

- If a condom is used throughout the act of intercourse and there is no unprotected contact with female genitals, a latex rubber condom, which is impermeable to viruses, can act as a protective measure against STIs.

Nursing Considerations

Teaching should include the following instructions:

- Use a new condom (check expiration date) for each act of sexual intercourse or other acts between partners that involve contact with the penis.

- Place condom after penis is erect and before intimate contact.
- Place condom on head of penis (Fig. A) and unroll it all the way to the base (Fig. B).

- Leave an empty space at the tip (Fig. A); remove any air remaining in the tip by gently pressing air out toward the base of the penis.
- If a lubricant is desired, use water-based products such as K-Y lubricating jelly. Do *not* use petroleum-based products because they can cause the condom to break.
- After ejaculation, carefully withdraw the still-erect penis from the vagina, holding on to condom rim; remove and discard the condom.
- Store unused condoms in cool, dry place.
- Do not use condoms that are sticky, brittle, or obviously damaged.

FIG 8-7 Barrier methods. **A**, Female condom (FC2). **B**, FemCap. **C**, Contraceptive sponge. (A, Courtesy The Female Health Company, Chicago; B, courtesy FemCap, Del Mar, CA; C, Today® vaginal contraceptive sponge. Courtesy Mayer Laboratories, Inc., 2014.)

⚡ SAFETY ALERT

It is a false assumption that everyone knows how to use condoms. To prevent unintended pregnancy and the spread of STIs, it is essential for condoms to be used correctly. Proper instruction in use must be provided. The sheath is applied over the erect penis before insertion and before the loss of preejaculatory drops of semen. All types of condoms must be discarded after each single use.

for client teaching. Effective condom use is a skill that must be taught.

The female condom is a vaginal sheath made of nitrile, a non-latex synthetic rubber, with flexible rings at both ends (Fig. 8-7, A). The closed end of the pouch is inserted into the vagina and anchored around the cervix; the open ring covers the labia. Women whose partner will not wear a male condom can use this device as a protective mechanical barrier. Rewetting drops or oil- or water-based lubricants can be used to help decrease the distracting noise that is produced during penile thrusting. The female condom is available in one size, is intended for single use only, and is sold over the counter. Male condoms should not be used concurrently because the friction from both sheaths can increase the likelihood of either or both tearing (Cates & Harwood, 2011). Typical failure rate in the first year of female condom use is 21% (Trussell, 2011).

Diaphragms. The contraceptive diaphragm is a shallow dome-shaped latex or silicone device with a flexible rim that covers the cervix. There are four types of diaphragms: coil spring, arcing spring, flat spring, and wide seal rim. Available in many sizes, the diaphragm should be the largest size the woman can wear without her being aware of its presence. The typical failure rate of the diaphragm combined with spermicide is 12% in the first year of use (Trussell, 2011). Effectiveness of the diaphragm is less when used without spermicide. Women at high risk for HIV should avoid use of N-9 spermicides with the diaphragm (AIDS.gov, 2012).

The woman is informed that she needs an annual gynecologic examination to assess the fit of the diaphragm. The device should be inspected before every use, replaced every 2 years, and may have to be refitted for a 20% weight fluctuation, after any abdominal or pelvic surgery, and after every pregnancy (World Health Organization Department of Reproductive Health & Research [WHO/RHR] & Johns Hopkins Bloomberg School of Public Health/Center for Communications Programs [CCP], 2011). Because various types of diaphragms are on the market, the nurse should use the package insert for teaching a woman how to use and care for the diaphragm (see Teaching for Self-Management box).

Disadvantages of diaphragm use include the reluctance of some women to insert and remove it. Although it can be inserted up to 6 hours before intercourse, a cold diaphragm and a cold gel temporarily reduce vaginal response to sexual stimulation if insertion of the diaphragm occurs immediately before intercourse. Some women or couples object to the messiness of the spermicide. These annoyances of diaphragm use, along with failure to insert the device once foreplay has begun, are the most common reasons for failures of this method. Side effects may include irritation of tissues related to contact with spermicides. The diaphragm is not a good option for women with poor vaginal muscle tone or recurrent urinary tract infections. For proper placement the diaphragm must rest behind the pubic symphysis and completely cover the cervix. To decrease the chance of exerting urethral pressure, the woman should be reminded to empty her bladder before diaphragm insertion and immediately after intercourse. Diaphragms are contraindicated for women with pelvic relaxation (uterine prolapse) or a large cystocele. Women with a latex allergy should not use latex diaphragms.

Toxic shock syndrome (TSS), although reported in very small numbers, can occur in association with the use of the contraceptive diaphragm and cervical caps (Cates & Harwood, 2011). The nurse should instruct the woman about ways to reduce her risk for TSS. These measures include prompt removal 6 to 8 hours after intercourse, not using the diaphragm or cervical caps during menses, and learning and watching for danger signs of TSS.

bladder nerves, buldge of bladder
 Vagina

SAFETY ALERT

The nurse should inform the woman who uses a diaphragm or cervical cap as a contraceptive method to be alert for signs of TSS. The most common signs include a sunburn type of rash, diarrhea, dizziness, faintness, weakness, sore throat, aching muscles and joints, sudden high fever, and vomiting (WHO/RHR & CCP, 2011).

Cervical Caps. The FemCap (see Fig. 8-7, B) is the only type of cervical cap available in the United States. It comes in three sizes and is made of silicone rubber. The cap fits snugly around the base of the cervix close to the junction of the cervix and vaginal fornices. It is recommended that the cap remain in place no less than 6 hours and not more than 48 hours at a time. It is left in place at least 6 hours after the last act of intercourse. The seal provides a physical barrier to sperm; spermicide inside the cap adds a chemical barrier. The extended period of wear may be an added convenience for women.

Instructions for the actual insertion and use of the cervical cap closely resemble those for a contraceptive diaphragm. Some of the differences are that the cervical cap can be inserted hours before sexual intercourse without a later need for additional spermicide, the cervical cap requires less spermicide than the diaphragm when initially inserted, and no additional spermicide is required for repeated acts of intercourse. Effectiveness of the first-generation FemCap has been found to be less than the diaphragm (Fritz & Speroff, 2011a).

The angle of the uterus, the vaginal muscle tone, and the shape of the cervix may interfere with the cervical cap's ease of fitting and use. Correct fitting requires time, effort, and skill from both the woman and the clinician. The woman must check the cap's position before and after each act of intercourse.

Because of the potential risk of TSS associated with the use of the cervical cap, another form of birth control is recommended for use during menstrual bleeding and up to at least 6 weeks postpartum. The cap should be refitted after any gynecologic surgery or birth and after major weight losses or gains. Otherwise the size should be checked at least once a year.

Women who are not good candidates for wearing the cervical cap include those with abnormal Papanicolaou (Pap) test results, those who cannot be fitted properly with the existing cap sizes, those who find the insertion and removal of the device too difficult, those with a history of TSS, those with vaginal or cervical infections, and those who experience allergic responses to the latex cap or spermicide. Failure rates the first year of use are 16% in nulliparous and 32% in multiparous women (WHO/RHR & CCP, 2011) → borne no children → borne multi

Contraceptive Sponge. The vaginal sponge is a small, round polyurethane sponge that contains N-9 spermicide (see previous discussion of N-9) (see Fig. 8-7, C). It is designed to fit over the cervix (one size fits all). The side that is placed next to the cervix is concave for better fit. The opposite side has a woven polyester loop to be used for removal of the sponge.

The sponge must be moistened with water before it is inserted. It provides protection for up to 24 hours and for

TABLE 8-1 Hormonal Contraception

COMPOSITION	ROUTE OF ADMINISTRATION	DURATION OF EFFECT
Combination estrogen and progestin (synthetic estrogens and progestins in varying doses and formulations)	Oral Transdermal Vaginal ring insertion	24 hours; extended cycle—12 weeks 7 days 3 weeks
Progestin only		
Norethindrone, norgestrel	Oral	24 hours
Medroxyprogesterone acetate	Intramuscular injection; subcutaneous injection	3 months
Progestin, etonogestrel	Subdermal implant	Up to 3 years
Levonorgestrel	Intrauterine device	Up to 5 years

repeated instances of sexual intercourse. The sponge should be left in place for at least 6 hours after the last act of intercourse. Wearing it longer than 24 to 30 hours may put the woman at risk for TSS (Cates & Harwood, 2011). The typical failure rate in the first year of use is 24% for parous women and 12% for nulliparous women (Trussell, 2011).

Hormonal Methods

More than 30 different hormonal contraceptive formulations are available in the United States. General classes are described in Table 8-1. Because of the wide variety of preparations available, the woman and the nurse must read the package insert for information about specific products prescribed. Formulations include combined estrogen-progestin medications and progestational agents. The formulations are administered orally, transdermally, vaginally, by implantation, by injection, or by intrauterine insertion.

Combined Estrogen-Progestin Contraceptives

Oral Contraceptives. The normal menstrual cycle is maintained by a feedback mechanism. Follicle-stimulating hormone (FSH) and LH are secreted in response to fluctuating levels of ovarian estrogen and progesterone. Regular ingestion of combined oral contraceptive pills (COCs) suppresses the action of the hypothalamus and anterior pituitary, leading to insufficient secretion of FSH and LH; therefore, follicles do not mature, and ovulation is inhibited.

Other contraceptive effects are induced by the combined steroids. Maturation of the endometrium is altered, making it a less favorable site for implantation. COCs also have a direct effect on the endometrium, so that from 1 to 4 days after the last COC is taken, the endometrium sloughs and bleeds as a result of hormone withdrawal. The withdrawal bleeding is usually less profuse than that of normal menstruation and may last only 2 to 3 days. Some women have no bleeding at all. The cervical mucus remains thick from the effect of the progestin (Nelson & Cwiak, 2011).

Cervical mucus under the effect of progesterone does not provide as suitable an environment for sperm penetration as does the thin, watery mucus at ovulation. The possible effect, if any, of altered tubal and uterine motility induced by COCs is not clear.

Monophasic pills provide fixed dosages of estrogen and progestin. Multiphasic pills (e.g., biphasic and triphasic oral contraceptives) alter the amount of progestin and sometimes the amount of estrogen within each cycle. These preparations reduce the total dosage of hormones in a single cycle without sacrificing contraceptive efficacy (Nelson & Cwiak, 2011). To maintain adequate hormonal levels for contraception and

enhance compliance, COCs should be taken at the same time each day.

Advantages. Because taking the pill does not relate directly to the sexual act, its acceptability may be increased. Improvement in sexual response may occur once the possibility of pregnancy is not an issue. For some women it is convenient to know when to expect the next menstrual flow.

TEACHING FOR SELF-MANAGEMENT

Use and Care of the Diaphragm

Inspection of the Diaphragm

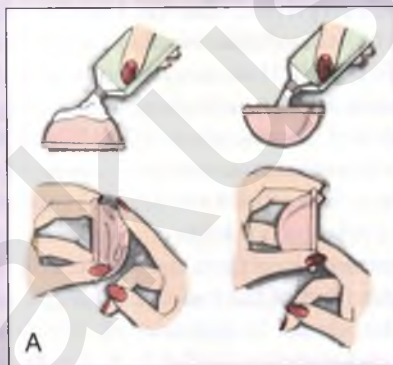

You must inspect your diaphragm carefully before each use. The best way to perform this inspection is as follows:

- Hold the diaphragm up to a light source. Carefully stretch the diaphragm at the area of the rim, on all sides, making sure there are no holes. Remember, sharp fingernails can puncture the diaphragm.
- Another way to check for pinholes is to fill the diaphragm with water carefully. If any problem develops, you will see it immediately.
- A diaphragm that is puckered, especially near the rim, could mean thin spots.
- If you see any of these problems, do not use the diaphragm; avoid sexual intercourse or use another method of birth control; consult your health care provider about replacing the diaphragm.

Preparation of the Diaphragm

Rinse off the cornstarch. Your diaphragm must always be used with a spermicidal lubricant to be effective. Pregnancy cannot be prevented effectively by the diaphragm alone.

Always empty your bladder before inserting the diaphragm. Place approximately 2 teaspoons of contraceptive jelly or contraceptive cream on the side of the diaphragm that will rest against the cervix (or whichever way you have been instructed). Spread it around to coat the surface and the rim. This measure aids in insertion and offers a more complete seal. Many women also spread some jelly or cream on the other side of the diaphragm (Fig. A).

Positions for Insertion of the Diaphragm

Squatting: Squatting is the most commonly used position, and most women find it satisfactory.

Leg-up method: Another position is to raise the left foot (if right hand is used for insertion) on a low stool, and, while in a bending position, insert the diaphragm.

Chair method: Another practical method for diaphragm insertion is to sit far forward on the edge of a chair.

Reclining: You may prefer to insert the diaphragm while in a semi-reclining position in bed.

Insertion of the Diaphragm

1. The diaphragm can be inserted up to 6 hours before intercourse. Hold the diaphragm between your thumb and fingers. The dome can be either up or down, as directed by your health care provider. Place your index finger on the outer rim of the compressed diaphragm (Fig. B).

2. Use the fingers of the other hand to spread the labia (lips of the vagina). This action will assist in guiding the diaphragm into place.

Noncontraceptive benefits of low-dose oral contraceptives (less than 35 mg estrogen) have been well demonstrated (Schindler, 2013). The noncontraceptive health benefits of COCs include decreased menstrual blood loss and decreased iron deficiency anemia, regulation of menorrhagia and irregular cycles,

and reduced incidence of dysmenorrhea and premenstrual syndrome (PMS). Oral contraceptives also offer protection against endometrial cancer and ovarian cancer, reduce the incidence of benign breast disease, improve acne, protect against the development of functional ovarian cysts and salpingitis, and decrease

TEACHING FOR SELF-MANAGEMENT — cont'd

Use and Care of the Diaphragm

3. Insert the diaphragm into the vagina. Direct it inward and downward as far as it will go to the space behind and below the cervix (Fig. C).

4. Tuck the front of the rim of the diaphragm behind the pubic bone so that the rubber hugs the front wall of the vagina (Fig. D).

5. Feel for your cervix through the diaphragm to be certain it is properly placed and securely covered by the rubber dome (Fig. E).

General Information

Regardless of the time of the month, you must use your diaphragm every time intercourse takes place. The cervix moves its position throughout the month, requiring that the angle of insertion of the diaphragm will change slightly. Your diaphragm must be left in place for at least 6 hours after the last intercourse. If you remove your diaphragm before the 6-hour period, you will greatly increase your chance of becoming pregnant. If you have repeated intercourse, you must add more spermicide for each act of intercourse.

Removal of the Diaphragm

The only proper way to remove the diaphragm is to insert your forefinger up and over the top side of the diaphragm and slightly to the side.

Next, turn the palm of your hand downward and backward, hooking the forefinger firmly on top of the inside of the upper rim of the diaphragm, breaking the suction.

Pull the diaphragm down and out. This technique prevents tearing the diaphragm with the fingernails. You should not remove the diaphragm by trying to catch the rim from below the dome (Fig. F).

Care of the Diaphragm

When using a vaginal diaphragm, avoid using oil-based products, such as certain body lubricants, mineral oil, baby oil, vaginal lubricants, or vaginitis preparations. These products can weaken the rubber.

A little care means longer wear for your diaphragm. After each use wash the diaphragm in warm water and mild soap. Do not use detergent soaps, cold-cream soaps, deodorant soaps, and soaps containing oil products because they can weaken the rubber.

After washing, dry the diaphragm thoroughly. Remove all water and moisture with a towel. Then dust the diaphragm with cornstarch. Do not use scented talc, body powder, baby powder, or similar products because they can weaken the rubber.

To clean the introducer (if one is used), wash with mild soap and warm water, rinse, and dry thoroughly.

Place the diaphragm back in the plastic case for storage. Do not store it near a radiator or heat source or in a location that is exposed to light for an extended period.

the risk of ectopic pregnancy. Oral contraceptives are considered a safe option for nonsmoking women until menopause. Perimenopausal women can benefit from regular bleeding cycles, a regular hormonal pattern, and the noncontraceptive health benefits of oral contraceptives (Nelson & Cwiak, 2011).

A pelvic examination and Pap test are not necessary before initiating COCs (WHO/RHR & CCP, 2011). If STI screening is indicated, a urine-based test can be used for some infections (e.g., chlamydia, gonorrhea); others require a pelvic examination and cultures of vaginal or cervical secretions or blood tests (Planned Parenthood, 2013). Most health care providers assess the woman 3 months after beginning COCs to detect any complications.

Use of oral hormonal contraceptives is initiated on one of the first days of the menstrual cycle (day 1 of the cycle is the first day of menses) or after childbirth or abortion. With a “Sunday start,” women begin taking pills on the first Sunday after the start of their menstrual period. If contraceptives are to be started at any time other than during normal menses or within 4 weeks after birth, miscarriage, or induced abortion, another method of contraception should be used throughout the first week to avoid the risk of pregnancy (Nelson & Cwiak, 2011). Taken exactly as directed, oral contraceptives prevent ovulation, and pregnancy cannot occur; the overall effectiveness rate is almost 100%. Almost all failures (i.e., pregnancy occurs) are caused by omission of one or more pills during the regimen. The typical failure rate of COCs due to omission is 9% (Trussell, 2011).

Disadvantages and Side Effects. Since hormonal contraceptives have come into use, the amount of estrogen and progestational agent contained in each tablet has been reduced considerably. This is important because adverse effects are, to a degree, dose related.

Women must be screened for conditions that present absolute or relative contraindications to oral contraceptive use. Contraindications for COC use include a history of thromboembolic disorders, cerebrovascular or coronary artery disease, breast cancer, gallbladder disease, jaundice with prior pill use, estrogen-dependent tumors, pregnancy, severe cirrhosis, liver tumor, lactation less than 6 weeks postpartum, smoking if older than 35 years, headaches with focal neurologic symptoms, surgery with prolonged immobilization or any surgery on the legs, hypertension (140/90 mm Hg), and diabetes mellitus (of more than 20 years' duration) with vascular disease (Curtis & Peterson, 2011; Nelson & Cwiak, 2011; WHO/RHR & CCP, 2011).

Certain side effects of COCs are attributable to estrogen, progestin, or both. Serious adverse effects documented with high doses of estrogen and progesterone include stroke, myocardial infarction, thromboembolism, hypertension, gallbladder disease, and liver tumors (Nelson & Cwiak, 2011). Common side effects of estrogen excess include nausea, breast tenderness, fluid retention, and chloasma. Side effects of estrogen deficiency include early spotting (days 1 to 14), hypomenorrhea, nervousness, and atrophic vaginitis leading to painful intercourse (dyspareunia). Side effects of progestin excess include increased appetite, tiredness, depression, breast tenderness, vaginal yeast infection, oily skin and scalp, hirsutism, and postpill amenorrhea. Side effects of progestin deficiency include late spotting and breakthrough bleeding (days 15 to 21), heavy flow with clots, and decreased breast size. One of the most common side effects of combined COCs is bleeding irregularities (Nelson & Cwiak).

In the presence of side effects, especially those that are bothersome to a woman, another product, a different drug content, or another method of contraception may be required. The “right” product for a woman contains the lowest dose of hormones that prevents ovulation and that has the fewest and least harmful side effects. There is no way to predict the right dosage for any particular woman. Issues to consider in prescribing oral contraceptives include history of oral contraceptive use, side effects during past use, menstrual history, and drug interactions (Nelson & Cwiak, 2011).

Large prospective studies have not shown a relationship between use of oral contraceptives available and diabetes or glucose intolerance (Nelson & Cwiak, 2011). The risks and benefits should be assessed before prescribing oral contraceptives for women who have diabetes with vascular problems.

The effectiveness of oral contraceptives can be negatively influenced when the following medications are taken concurrently (Nelson & Cwiak, 2011; WHO/RHR & CCP, 2011):

- **Anticonvulsants:** barbiturates, oxcarbazepine, phenytoin, phenobarbital, felbamate, carbamazepine, primidone, and topiramate
- **Systemic antifungals:** griseofulvin
- **Antituberculosis drugs:** rifampicin and rifabutin
- **Anti-HIV protease inhibitors:** nelfinavir, amprenavir

MEDICATION ALERT

Over-the-counter medications, as well as some herbal supplements (such as St. John's wort) can alter the effectiveness of COCs. Women should be asked about their use when COCs are being considered for contraception.

No strong pharmacokinetic evidence exists that shows a relation between broad-spectrum antibiotic use and altered hormonal levels among oral contraceptive users, although potential antibiotic interaction can occur. Studies on the incidence of breast cancer have not found a significant increase of breast cancer in women who use COCs (Nelson & Cwiak, 2011).

After discontinuing oral contraception, return to fertility usually happens quickly (Nelson & Cwiak, 2011). Many women ovulate the next month after stopping oral contraceptives, although it may take longer for ovulation to occur in some women. Women who discontinue oral contraception for a planned pregnancy commonly ask whether they should wait before attempting to conceive. Studies indicate that these infants have no greater chance of being born with any type of birth defect than do infants born to women in the general population, even if conception occurred in the first month after the medication was discontinued. Little evidence suggests that oral contraceptives cause postpill amenorrhea. Amenorrhea after oral contraceptive use is probably related to the woman's menstrual cycle before taking the pill (Nelson & Cwiak).

Nursing Interventions. Many different preparations of oral hormonal contraceptives are available. The nurse reviews the prescribing information in the package insert with the woman. Because of the wide variations, each woman must be clear about the unique dosage regimen for the preparation prescribed for her. Directions for care after missing one or two pills also vary. Figure 8-8 depicts an example of a simple way to manage missed pills.

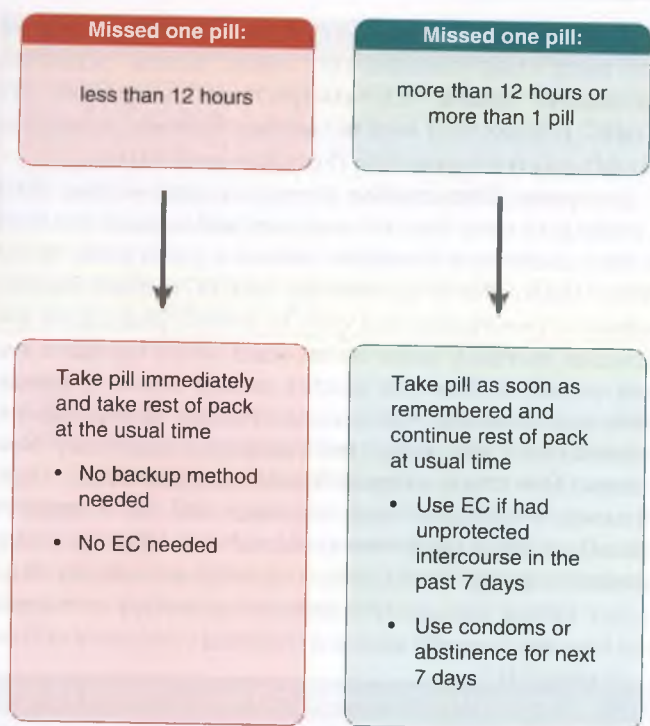

FIG 8-8 Simplified management for missed active contraceptive pills. EC, Emergency contraception. (Data from Nelson, A.L., & Cwiak, C. [2011]. In R. Hatcher, J. Trussell, A. Nelson, et al. [Eds.], *Contraceptive technology* [20th rev. ed.]. New York: Ardent Media.)

Withdrawal bleeding tends to be short and scanty when some combination pills are taken. A woman may see no fresh blood at all. A drop of blood or a brown smudge on a tampon or the underwear counts as a menstrual period.

Only about 67% of women who start taking oral contraceptives continue to take them after 1 year (Trussell, 2011). All women choosing to use oral contraceptives should be provided with a second method of birth control and be instructed in and comfortable with this backup method. Most women stop taking oral contraceptives for nonmedical reasons.

The nurse also reviews the signs of potential complications associated with the use of oral contraceptives (see Signs of Potential Complications). Oral contraceptives do not protect a woman against STIs or HIV. A barrier method such as condoms and spermicide should be used for protection.

SIGNS OF POTENTIAL COMPLICATIONS

Oral Contraceptives

Before oral contraceptives are prescribed and periodically throughout hormone therapy, alert the woman to stop taking the pill and to report any of the following symptoms to the health care provider immediately. Use the mnemonic ACHES to help remember this list:

- A—Abdominal pain may indicate a problem with the liver or gallbladder.
- C—Chest pain or shortness of breath may indicate possible clot problem within the lungs or heart.
- H—Headaches (sudden or persistent) may be caused by cardiovascular accident or hypertension.
- E—Eye problems may indicate vascular accident or hypertension.
- S—Severe leg pain may indicate a thromboembolic process.

FIG 8-9 Hormonal contraceptive transdermal patch and vaginal ring. (Courtesy Dee Lowdermilk, Chapel Hill, NC.)

Oral Contraceptive 91-Day Regimen. Some women prefer to take COCs in 3-month cycles and have fewer menstrual periods. Levonorgestrel/ethinyl estradiol (Seasonale), FDA approved for extended cycle use, contains both estrogen and progestin and is taken in 3-month cycles of 12 weeks of active pills followed by 1 week of inactive pills. Menstrual periods occur during the thirteenth week of the cycle. There is no protection from STIs, and risks are similar to COCs. Other monophasic COCs may be prescribed for extended cycle use and must be taken on a daily schedule, regardless of the frequency of intercourse (Nelson & Cwiak, 2011; WHO/RHR & CCP, 2011).

Transdermal Contraceptive System. Available by prescription only, the contraceptive transdermal patch delivers continuous levels of norelgestromin (progestin) and ethinyl estradiol. The patch can be applied to intact skin of the upper outer arm, the upper torso (front and back, excluding the breasts), the lower abdomen, or the buttocks (Fig. 8-9). Application is on the same day once a week for 3 weeks, followed by a week without the patch. Withdrawal bleeding occurs during the “no-patch” week. Mechanism of action, efficacy, contraindications, skin reactions, and side effects are similar to those of COCs. The typical failure rate during the first year of use is less than 9% in women weighing less than 198 pounds (90 kg) (Trussell, 2011).

Vaginal Contraceptive Ring. Available only with a prescription, the vaginal contraceptive ring is a flexible ring (made of ethylene vinyl acetate copolymer) worn in the vagina to deliver continuous levels of etonogestrel (progestin) and ethinyl estradiol (see Fig. 8-9). One vaginal ring remains in the vagina for 3 weeks, followed by a week without the ring. The ring is inserted by the woman and does not have to be fitted. Some wearers may experience vaginitis, leukorrhea, and vaginal discomfort (Nanda, 2011). Withdrawal bleeding occurs during the “no-ring” week. If the woman or partner notices discomfort during coitus, the ring can be removed from the vagina, but only up to 3 hours to still be effective when reinserted. Mechanism of action, efficacy, contraindications, and side effects are similar to those of COCs. The typical failure rate of the vaginal contraceptive ring is reportedly less than 9% during the first year of use (Trussell, 2011).

Progestin-Only Contraceptives. Progestin-only methods impair fertility by inhibiting ovulation, thickening and decreasing

the amount of cervical mucus, thinning the endometrium, and altering cilia in the uterine tubes (Fritz & Speroff, 2011d).

Oral Progestins (Minipill). The failure rate of progestin-only pills for typical users is about 1% to 10% in the first year of use (WHO/RHR & CCP, 2011). Effectiveness is increased if minipills are taken correctly. Because minipills contain such a low dose of progestin, the minipill must be taken at the same time every day (Fritz & Speroff, 2011d). Users often complain of irregular vaginal bleeding.

Injectable Progestins. Depot medroxyprogesterone acetate (DMPA or Depo-Provera), 150 mg, is given intramuscularly in the deltoid or the gluteus maximus muscle. A 21- to 23-gauge needle, 2.5 to 4 cm long, should be used. DMPA should be initiated during the first 5 days of the menstrual cycle and administered every 11 to 13 weeks. A subcutaneous injection is also available (Fritz & Speroff, 2011c).

MEDICATION ALERT

When administering an intramuscular injection of progestin (e.g., Depo-Provera), do not massage the site after the injection because this action can hasten the absorption and shorten the period of effectiveness.

Advantages of DMPA include a contraceptive effectiveness comparable to that of perfect use of COCs, long-lasting effects, requirement of injections only four times a year, and the improbability of lactation being impaired. Side effects at the end of a year include decreased bone mineral density, weight gain, irregular vaginal spotting, and breast changes (Bartz & Goldberg, 2011). Other disadvantages include no protection against STIs (including HIV). Return to fertility may be delayed as long as up to 18 months after discontinuing DMPA. The typical failure rate is 6% in the first year of use (Trussell, 2011).

MEDICATION ALERT

Women who use DMPA may lose significant bone mineral density with increasing duration of use. This bone loss can be regained within 2 to 4 years after discontinuation (Fritz & Speroff, 2011c). It is unknown if use of DMPA during adolescence or early adulthood, a critical period of bone accretion, will reduce peak bone mass and increase the risk of osteoporotic fracture in later life. Women who receive DMPA should be counseled about calcium intake and exercise (Bartz & Goldberg, 2011).

Implantable Progestins. Contraceptive implants consist of one or more nonbiodegradable flexible tubes or rods that are inserted under the skin of a woman's arm. These implants contain a progestin hormone and are effective for contraception for at least 3 years. They must be removed at the end of the recommended time. The FDA has approved two devices for use in the United States: a two-rod subdermal levonorgestrel implant (Jadelle) and a single-rod etonogestrel implant (Implanon, Nexplanon) that is effective for up to 3 years and is the only implant available in the United States. Implants will prevent some, but not all, ovulatory cycles and will thicken cervical mucus. Other advantages include reversibility and long-term continuous contraception that is not related to frequency

of coitus. Irregular menstrual bleeding is the most common side effect. Less common side effects include headaches, nervousness, nausea, skin changes, and vertigo. No STI protection is provided with the implant method, so condoms should be used for protection (Fritz & Speroff, 2011c).

Emergency Contraception. Emergency contraception (EC) is available in more than 100 countries, and in about one third of these countries it is available without a prescription. In the United States, Plan B has been the only EC method available without a prescription and only in limited pharmacies and clinics in pharmacy access states. States where legislation has been passed to allow this practice include Alaska, Arkansas, California, Colorado, Connecticut, Hawaii, Illinois, Maine, Massachusetts, Minnesota, New Hampshire, New Jersey, New Mexico, New York, Oregon, South Carolina, Texas, Utah, Vermont, Washington, and Wisconsin and the District of Columbia. These states have enacted legislation requiring hospitals or health care facilities to provide information about and/or initiate emergency contraception therapy to women who have been sexually assaulted (National Conference of State Legislators, 2012).

Plan B One-Step (a single 1500-mcg levonorgestrel pill) replaced the two-tablet Plan B in 2009. At the same time a generic form of Plan B was authorized for use. The following year, the FDA approved 30-mg ulipristal acetate, marketed as ella, for use as emergency contraception. On June 20, 2013, the federal government announced that Plan B One-Step can be sold over the counter in the family planning aisle of pharmacies. Anyone, regardless of age or gender, is allowed to purchase this morning-after pill at the local pharmacy (FDA, 2013). Other options that the FDA has determined to be safe for emergency contraception include high doses of oral estrogen or COCs (ECPs) and insertion of a copper IUD (Trussell & Schwarz, 2011). These options continue to be available by prescription only.

Emergency contraception should be taken by a woman as soon as possible but within 72 hours of unprotected intercourse, or birth control mishap (broken condom, dislodged ring or cervical cap, missed oral contraceptive pills, late for injection, and so on) to prevent unintended pregnancy (Trussell & Schwartz, 2011; WHO/RHR & CCP, 2011). If taken before ovulation, emergency contraception prevents ovulation by inhibiting follicular development. If taken after ovulation occurs, there is little effect on ovarian hormone production or the endometrium. Oral medication regimens with ECPs are presented in Table 8-2. To minimize the side effect of nausea that occurs with high doses of estrogen and progestin, the woman can be advised to take an over-the-counter antiemetic 1 hour before each dose. Women with contraindications for estrogen use should use progestin-only emergency contraception. No medical contraindications for emergency contraception exist, except pregnancy and undiagnosed abnormal vaginal bleeding. If the woman does not begin menstruation within 21 days after taking the pills, she should be evaluated for pregnancy. Emergency contraception is ineffective if the woman is pregnant because the pills do not disturb an implanted pregnancy. Risk of pregnancy is reduced by as much as 75% (estrogen-progestin) and 89% (progestin only) if the woman takes ECPs (Trussell & Schwarz, 2011).

MEDICATION ALERT

Emergency contraception will not protect a woman against pregnancy if she engages in unprotected intercourse in the days or weeks that follow treatment. Because ingestion of emergency contraceptive pills may delay ovulation, caution the woman that she needs to establish a reliable form of birth control in order to prevent unintended pregnancy (Trussell & Schwarz, 2011). Information about emergency contraception method options and access to providers is available at www.NOT-2-LATE.com or by calling 1-888-NOT-2-LATE.

IUDs containing copper (see later discussion) provide another emergency contraception option. The IUD should be inserted within 5 days of unprotected intercourse (Trussell & Schwarz, 2011). This method is suggested only for women who wish to have the benefit of long-term contraception. The risk of pregnancy is reduced by as much as 99% with emergency insertion of the copper-releasing IUD.

TABLE 8-2 Oral Emergency Contraceptives

BRAND NAMES	DOSE (WITHIN 120 hr)
Antiprogesterin	One Dose Only
ella	1 white pill
Progestin-Only Levonorgestrel	One Dose Only
1.5 mg/Dose	
Plan B One-Step	1 white pill
My Way	1 white pill
Next Choice One Dose	1 peach pill
Combined Progestin and Estrogen Pills	Take 2 Doses 12 Hours Apart
(100 to 120 meg Ethyl Estradiol and Levonorgestrel 0.50 to 0.60 mg/Dose)*	
Ogestrel	2 white pills
Cryselle	4 white pills
Jolessa	4 pink pills
Portia	4 pink pills

Contraceptive counseling should be provided to all women requesting emergency contraception, including a discussion of modification of risky sexual behaviors to prevent STIs and unwanted pregnancy.

Intrauterine Devices

An IUD is a small T-shaped device with bendable arms for insertion through the cervix (Fig. 8-10). Once the trained health care provider inserts the IUD against the uterine fundus, the arms open near the fallopian tubes to maintain position of the device and to adversely affect the sperm motility and irritate the lining of the uterus. Two strings hang from the base of the stem through the cervix and protrude into the vagina for the woman to feel for assurance that the device has not been dislodged (Dean & Schwarz, 2011). The woman should have had a negative pregnancy test, treatment for dysplasia if present, cervical cultures to rule out STIs, and a consent form signed before IUD insertion. Advantages to choosing this method of contraception include long-term protection from pregnancy and immediate return to fertility when removed. Disadvantages include increased risk of pelvic inflammatory disease (PID) shortly after placement, unintentional expulsion of the device, infection, and possible uterine perforation. IUDs offer no protection against HIV or other STIs. Therefore, women who are in mutually monogamous relationships are the best candidates for this device.

There are three FDA-approved IUDs: the ParaGard Copper T 380A and the hormonal intrauterine systems Mirena and Skyla. The ParaGard Copper T 380A is made of radiopaque polyethylene and fine solid copper and is approved for 10 years of use. The copper primarily serves as a spermicide and inflames the endometrium, preventing fertilization (Dean & Schwarz, 2011). Sometimes women experience more bleeding and cramping within the first year after insertion, but nonsteroidal, antiinflammatory drugs (NSAIDs) can be taken for pain relief. The typical failure rate in the first year of use of the copper IUD is less than 1% (Trussell, 2011).

Mirena and Skyla release levonorgestrel from their vertical reservoirs. Effective for up to 5 years for Mirena and 3 years for Skyla, they impair sperm motility, thicken cervical mucus, decrease the lining of the uterus, and have some anovulatory effects (Dean & Schwarz, 2011; www.skyla-us.com). Uterine cramping and bleeding are usually decreased with these devices, although irregular spotting is common in the first few months following insertion. The typical failure rate in the first year of use is less than 1% (Skyla-US, 2013; Trussell, 2011).

EVIDENCE-BASED PRACTICE BOX

Emergency Contraception and Obesity**Ask the Question**

What is the best emergency contraception for overweight and obese women?

Search for the Evidence

Search Strategies English language research-based publications since 2011 on emergency contraception, overweight, and obesity were included.

Databases Used Cochrane Collaborative Database, National Guideline Clearinghouse (AHRQ), CINAHL, PubMed, UpToDate, and the professional websites for ACOG and AWHONN

Critical Appraisal of the Evidence

One out of nine sexually active women in the United States has used a form of emergency contraception (EC) during their reproductive years. About half of these used EC because their primary method failed (Daniels, Jones, & Abma, 2013). Three options for emergency contraception are:

- Levonorgestrel (LNG-EC), a progestin commonly used in oral contraceptives, causes a delay in ovulation when taken at a higher dose (e.g., Plan B). It is most effective when taken as soon as possible after unprotected intercourse (UPIC), and can still prevent pregnancy when taken up to 96 hours.
- Ulipristal acetate (UPA) is a progesterone receptor modulator, which interrupts the action of endogenous progesterone that is necessary to ovulate and maintain pregnancy (e.g., ella). It can delay ovulation when taken up to 120 hours after intercourse. Metaanalysis of outcomes of women in the United States, United Kingdom, and Ireland have revealed that UPA is more effective than LNG-EC, particularly in obese women (Glasier, Cameron, Blithe, et al., 2011).
- Both oral ECs cause thinning of the endometrium, but research has not established whether this inhibits implantation (Moreau & Trussell, 2012). Neither LNG-EC nor UPA will disrupt an already implanted pregnancy.
- Copper intrauterine device (Cu IUD, Paragard) insertion within 5 days post intercourse disrupts uterine readiness for implantation. It is the only method of the three that provides ongoing contraception. It requires a skilled health care provider for insertion. Being overweight and obese negatively affects the ability of oral EC to prevent pregnancy.
- The risk for pregnancy after taking oral EC goes up 1.5 times for overweight (body mass index [BMI] 26-29) women and 2 to 4 times for obese (BMI 30+) women, over normal- or low-weight women (Glasier et al., 2013; Moreau & Trussell, 2012).
- In absolute weight, LNG-EG was no longer effective at preventing pregnancy at 154 pounds (70 kg), and UPA became no longer effective at 194 pounds (88 kg) (Glasier et al., 2011).

Apply the Evidence: Nursing Implications

- Oral EC is most effective at preventing pregnancy when taken early. A systematic analysis of 17 studies reveals that having a supply on hand results in 2 to 7 times greater use of EC, although pregnancy reduction was not demonstrated (Rodrigues, Curtis, Gaffield, et al., 2013).

- Male partners tend to know and approve of emergency contraception, although only a minority discuss it with their partners (Marcell, Waks, Rutlow, et al., 2012). Involving partners in any education may provide support and uptake of EC.
- The first choice EC for obese women would be a Cu IUD insertion, when available and acceptable to the women. Women should be informed that it acts to prevent implantation. If oral EC is preferred, UPA is a better choice than LNG-EC.
- Because oral EC merely delays ovulation, the other most significant factor for pregnancy is subsequent UPIC during the rest of that cycle (Glasier et al., 2011; Moreau & Trussell, 2013). Women should be provided with highly reliable contraception immediately, and cautioned that EC offers no subsequent protection against pregnancy.

Quality and Safety Competencies: Evidence-Based Practice (EBP)***Knowledge**

Describe how the strength and relevance of available evidence influences the choice of interventions in provision of client-centered care.

Use of high-level evidence to provide women in need of emergency contraception with individualized care

Skills

Locate evidence reports related to clinical practice topics and guidelines.

Relevant systematic reviews and professional guidelines provide recommendations for improving pregnancy prevention outcomes.

Attitudes

Value the concept of EBP as integral to determining best clinical practices.

EBP guides practice and fosters client confidence and efficacy.

Nursing Interventions. The woman should be taught to check for the presence of the IUD strings after menstruation to rule out expulsion of the device. If pregnancy occurs with the IUD in place, an ultrasound should confirm that it is not ectopic. Early removal of the IUD helps decrease the risk of spontaneous miscarriage or preterm labor (Dean & Schwarz, 2011). In some women who are allergic to copper, a rash develops, necessitating the removal of the copper-bearing IUD. Signs of potential complications to be taught to the woman are listed in the Signs of Potential Complications box.

SIGNS OF POTENTIAL COMPLICATIONS

Intrauterine Devices (IUDs)

Signs of potential complications related to IUDs can be remembered in the following manner:

- P—Period late, abnormal spotting or bleeding
- A—Abdominal pain, pain with intercourse
- I—Infection exposure, abnormal vaginal discharge
- N—Not feeling well, fever, or chills
- S—String missing; shorter or longer

Data from Zieman, M., Hatcher, R., Cwiak, C., et al. (2012). *A pocket guide to managing contraception*. Tiger, GA: Bridging the Gap Foundation.

Sterilization

Sterilization refers to surgical procedures intended to render a person infertile. Most procedures involve the occlusion of the passageways for the ova and sperm (Fig. 8-11). For the woman, the oviducts (uterine tubes) are occluded; for the man, the sperm ducts (vas deferens) are occluded. Only surgical removal of the ovaries (oophorectomy) or uterus (hysterectomy) or both will result in absolute sterility for the woman. All other sterilization procedures have a small but definite failure rate; that is, pregnancy may result.

Female Sterilization. Female sterilization (bilateral tubal ligation [BTL]) may be done immediately after childbirth (within 24 to 48 hours), concomitant with induced abortion, or as an interval procedure (during any phase of the menstrual cycle). If sterilization is performed as an interval procedure, the health care provider must be certain that the woman is not pregnant. Half of all female sterilization procedures are performed immediately after a pregnancy (Roncari & Hou, 2011). Sterilization procedures can be safely done on an outpatient basis.

Tubal Occlusion. A laparoscopic approach or a minilaparotomy can be used for tubal ligation (Fig. 8-12), tubal electrocoagulation, or the application of bands or clips. Electrocoagulation and ligation are considered to be permanent methods. Use of the bands or clips has the theoretic advantage of possible removal and return of tubal patency.

For the minilaparotomy, the woman is admitted the morning of surgery, having received nothing by mouth since midnight. Preoperative sedation is given. The procedure can be carried out with a local anesthetic, but a regional or general anesthetic can also be used. A small incision is made in the abdominal wall below the umbilicus. The woman may experience sensations of tugging, but no pain, and the operation is completed within 20 minutes. She may be discharged several hours later if she has recovered from anesthesia or next day if done postpartum. Any

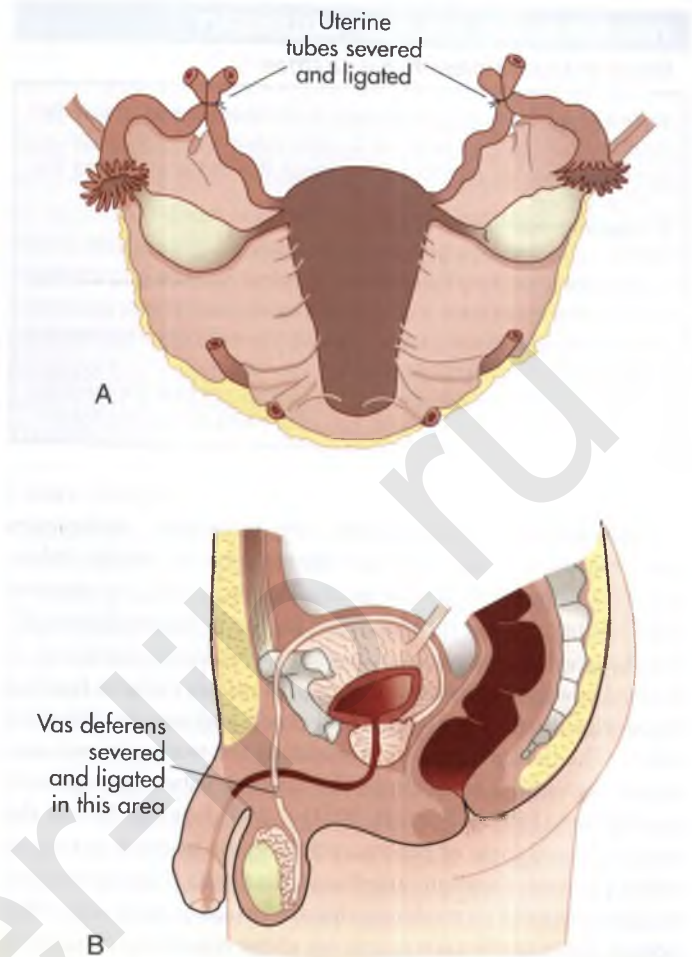

FIG 8-11 Sterilization. A, Uterine tubes severed and ligated (tubal ligation). B, Sperm duct severed and ligated (vasectomy).

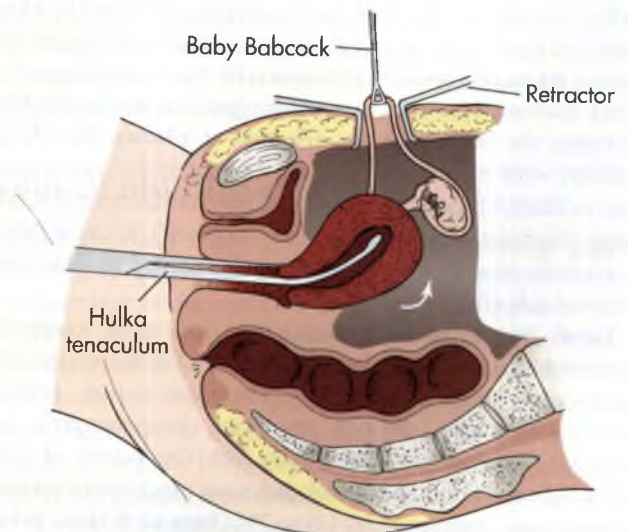

FIG 8-12 Use of minilaparotomy to gain access to uterine tubes for occlusion procedures. Tenaculum is used to lift uterus (arrow) toward incision.

abdominal discomfort usually can be controlled with a mild analgesic (e.g., acetaminophen). Within days the scar is almost invisible (see Teaching for Self-Management). As with any surgery, there is always a possibility of complications of anesthesia, infection, hemorrhage, and trauma to other organs.

TEACHING FOR SELF-MANAGEMENT

What to Expect After Tubal Ligation

- You should expect no change in hormones and their influence.
- Your menstrual period will be about the same as before the sterilization.
- You may feel pain at ovulation.
- The ovum disintegrates within the abdominal cavity.
- It is highly unlikely that you will become pregnant.
- You should not have a change in sexual functioning; you may enjoy sexual relations more because you will not be concerned about becoming pregnant.
- Sterilization offers no protection against sexually transmitted infections (STIs); therefore, you may need to use condoms.

Transcervical Sterilization. Hysteroscopic techniques can be used to inject occlusion agents into the uterine tubes. One FDA-approved device is the Essure system, an interval sterilization method (not intended for the postpartum period). The Essure device contains polyester fibers within a metal coil. A trained health care professional inserts a small catheter holding the device through the vagina and cervix and into the fallopian tubes. The device works by stimulating the woman's own scar tissue formation to occlude the uterine tubes and prevent conception (Fritz & Speroff, 2011b). An advantage is that the nonhormonal form of contraception can be inserted during an office procedure without anesthesia. Analgesia is recommended to decrease mild to moderate discomfort associated with tubal spasm. Particularly convenient for obese women or those with abdominal adhesions, the transcervical approach eliminates the need for abdominal surgery. Because the procedure is not immediately effective, it is essential that the woman and her partner use another form of contraception until tubal blockage is proven. It may take up to 3 months for tubal occlusion to fully occur, and success must be confirmed by hysterosalpingogram. Other disadvantages include possible expulsion and perforation. Providers do become more effective at placing the device correctly with experience, and approximately 96% of women have occluded tubes confirmed by hysterosalpingogram. The 1-year pregnancy rate is 1.1% (Fritz & Speroff). Because Essure is relatively new, more research may be needed to determine potential side effects.

Tubal Reconstruction. Restoration of tubal continuity (reanastomosis) and function is technically feasible except after laparoscopic tubal electrocoagulation. Sterilization reversal, however, is costly, difficult (requiring microsurgery), and uncertain. The success rate varies with the extent of tubal destruction and removal. The risk of ectopic pregnancy after tubal reanastomosis is increased by 1% to 7% (Roncari & Hou, 2011).

Male Sterilization. *Vasectomy* is the sealing, tying, or cutting of a man's vas deferens so that the sperm cannot travel from the testes to the penis (Roncari & Hou, 2011). It is considered the easiest and most commonly used operation for male sterilization. Vasectomy can be carried out with local anesthesia on an outpatient basis. Pain, bleeding, infection, and other postsurgical complications are considered the disadvantages to the surgical procedure. It is considered a permanent method of sterilization because reversal is generally unsuccessful.

Two methods are used for scrotal entry: conventional (scalpel incision) and no-scalpel (small puncture) vasectomy. The surgeon identifies and immobilizes the vas deferens through the scrotum. Then the vas is ligated or cauterized (see Fig. 8-11, B). Surgeons vary in their techniques to occlude the vas deferens: ligation with sutures, division, cautery, application of clips, excision of a segment of the vas, fascial interposition, or some combination of these methods (Roncari & Hou, 2011).

The man is instructed in self-care to promote a safe return to routine activities. To reduce swelling and relieve discomfort, ice packs are applied to the scrotum intermittently for a few hours after surgery. A scrotal support may be applied to decrease discomfort. Moderate inactivity for about 2 days is advisable because of local scrotal tenderness. The skin suture can be removed 5 to 7 days after surgery. Sexual intercourse may be resumed as desired; however, sterility is not immediate. Some sperm will remain in the proximal portions of the sperm ducts after vasectomy. One week to several months are required to clear the ducts of sperm; therefore, some form of contraception is needed until the sperm count in the ejaculate on two consecutive tests is down to zero (Roncari & Hou, 2011).

Vasectomy has no effect on potency (ability to achieve and maintain erection) or volume of ejaculate. Endocrine production of testosterone continues, so secondary sex characteristics are not affected. Sperm production continues, but sperm are unable to leave the epididymis and are lysed by the immune system. Less common are painful granulomas from accumulation of sperm (Roncari & Hou, 2011).

Complications after bilateral vasectomy are uncommon and usually not serious. They include bleeding (usually external), suture reaction, and reaction to anesthetic agent. The failure rate for male sterilization is 0.15% (Trussell, 2011).

Tubal Reconstruction. Microsurgery to reanastomose (restoration of tubal continuity) the sperm ducts can be accomplished successfully in more than 90% of cases (i.e., sperm in the ejaculate); however, the fertility rate varies widely from 38% to 89% (Roncari & Hou, 2011). The rate of success decreases as the time since the procedure increases. The vasectomy may result in permanent changes in the testes that leave men unable to father children. The changes are those ordinarily seen only in older adults (e.g., interstitial fibrosis [scar tissue between the seminiferous tubules]). In some men, antibodies develop against their own sperm (autoimmunization). The role of antisperm antibodies in fertility after vasectomy reversal has not been completely determined. Additional research is needed to explore a possible link between vasectomy and prostate cancer.

Laws and Regulations. All states have strict regulations for informed consent. Many states permit voluntary sterilization of any mature, rational woman without reference to her marital or pregnancy status. Although the partner's consent is not required by law, the man or woman is encouraged to discuss the situation with the partner, and health care providers may request the partner's consent. Sterilization of minors or mentally incompetent individuals is restricted by most states and often requires the approval of a board of eugenicists or other court-appointed individuals (see Legal Tip).

LEGAL TIP: Sterilization

If federal funds are used for female or male sterilization:

- The person must be age 21 years or older.
- Informed consent must include an explanation of the risks, benefits, and alternatives; a statement that describes sterilization as a permanent, irreversible method of birth control; and a statement that mandates a 30-day waiting period between giving consent and the sterilization.
- Informed consent must be in the man's or woman's native language, or an interpreter must be provided to read the consent form to the man or woman.

Nursing Interventions. The nurse plays an important role in assisting people with decision making so all requirements for informed consent are met. The nurse also provides information about alternatives to sterilization, such as contraception. The nurse acts as a “sounding board” for people who are exploring the possibility of choosing sterilization and their feelings about and motivation for this choice. The nurse records this information, which may be the basis for referral to a family planning clinic, a psychiatric social worker, or another professional health care provider.

Information must be given about what is entailed in various procedures, how much discomfort or pain can be expected, and what type of care is needed. Many individuals fear sterilization procedures because of the imagined effect on their sex life. They need reassurance concerning the hormonal and psychologic basis for sexual function and that uterine tube occlusion or vasectomy has no biologic sequelae in terms of sexual adequacy (Roncari & Hou, 2011). Preoperative care consists of health assessment, which includes a psychologic assessment, physical examination, and laboratory tests. The nurse assists with the health assessment, answers questions, and confirms the client's understanding of printed instructions (e.g., nothing by mouth after midnight). **Ambivalence** and extreme fear of the procedure are reported to the physician. *Mixed feelings*

Postoperative care depends on the procedure performed (e.g., laparoscopy, laparotomy for tubal occlusion, or vasectomy). General care includes recovery after anesthesia, monitoring of vital signs and fluid and electrolyte balance (intake and output, laboratory values), prevention of or early identification and treatment for infection or hemorrhage, control of discomfort, and assessment of emotional response to the procedure and recovery.

Discharge planning depends on the type of procedure performed. In general, the client is given written instructions about observing for and reporting symptoms and signs of complications, the type of recovery to be expected, and the date and time for a follow-up appointment.

Breastfeeding: Lactational Amenorrhea Method

The *lactational amenorrhea method (LAM)* can be a highly effective, *temporary* method of birth control. It is more popular in underdeveloped countries and traditional societies, where breastfeeding is used to prolong birth intervals. The method has seen limited use in the United States because most American women do not establish breastfeeding patterns that provide maximum protection against pregnancy (Kennedy & Trussell, 2011).

When the infant suckles at the mother's breast, a surge of prolactin hormone is released, which inhibits estrogen production and suppresses ovulation and the return of menses. LAM works best if the mother is exclusively or almost exclusively breastfeeding, if the woman has not had a menstrual flow since giving birth, and if the infant is younger than 6 months of age. Effectiveness is enhanced by frequent feedings at intervals of less than 4 hours during the day and no more than 6 hours during the night, long duration of each feeding, and no bottle supplementation or limited supplementation by spoon or cup. The woman should be counseled that disruption of the breastfeeding pattern or supplementation can increase the risk of pregnancy. The typical failure rate is 1% to 2% (Kennedy & Trussell, 2011).

Future Trends

Contraceptive options are more limited in the United States and Canada than in some other industrialized countries. Lack of funding for research, governmental regulations, conflicting values about contraception, and high costs of liability coverage for contraception have been cited as blocks to new and improved methods. Existing methods of contraception are being improved, however, and a variety of new methods are being developed.

Lower-dose COCs (15 mcg of ethinyl estradiol) are available in Europe. Female barrier methods (new female condoms, client-fitted diaphragms, and new vaginal sponges) are being tested. Vaginal delivery systems including progestin-only vaginal rings and progesterone daily suppositories are under investigation. Two new IUDs and spermicidal microbicides are being evaluated. Male hormonal methods are also being investigated, including hormonal injections (testosterone and progestin), targeted gene therapy, gonadotropin-releasing hormone antagonists, antisperm compounds, vas occlusion, vas muscle inhibitor, botanicals, immunologic methods, ultrasonic massage, internal/external heat, and contraceptive vaccines (Male Contraceptives.org, 2011; Schwartz & Gabelnick, 2011).

INDUCED ABORTION

Induced abortion is the purposeful interruption of a pregnancy before 20 weeks of gestation. (Spontaneous abortion or miscarriage is discussed in Chapter 28). If the abortion is performed at the woman's request, the term **elective abortion** is usually used; if performed for reasons of maternal or fetal health or disease, the term **therapeutic abortion** applies. Many factors contribute to a woman's decision to have an abortion. Indications include: (1) preservation of the life or health of the mother, (2) genetic disorders of the fetus, (3) rape or incest, and (4) the pregnant woman's request. The control of birth, dealing as it does with human sexuality and the question of life and death, is one of the most emotional components of health care. It has been the most controversial social issue in the last half of the 20th century and the beginning of the 21st century. Regulations exist to protect the mother from the complications of abortion.

Abortion is regulated in most countries, including the United States. Before 1970 legal abortion was not widely available in the United States. However, in January 1973, the U.S.

Supreme Court set aside previous antiabortion laws and legalized abortion as a result of the Roe versus Wade decision (U.S. Reports, 1973). This decision established a trimester approach to abortion. In the first trimester, abortion is permissible, the decision is between the woman and her health care provider, and a state has little right to interfere (Paul & Stein, 2011). In the second trimester, abortion is left to the discretion of the individual states to regulate procedures as long as they are reasonably related to the woman's health. In the third trimester, abortions may be limited or even prohibited by state regulation unless the restriction interferes with the life or health of the pregnant woman (Paul & Stein, 2011).

Currently 39 states legislate that abortion be performed by a licensed physician. Nurse practitioners can perform abortions (if the practice is within their scope of practice) in the states of California, Montana, Vermont, New Hampshire, and Rhode Island. Congress has legislated that Medicaid funds can only be used to pay for abortion when a woman's life is endangered. States vary on the financing of abortion, with 17 states using their own funds to pay for abortions, depending on the circumstances surrounding the procedure. States also vary regarding parental notification if a minor is requesting an abortion and/or consent regarding abortion, with 37 states providing legislation for some type parental involvement in the abortion of a fetus. Individual health care providers may refuse to participate in abortion in 46 states (Guttmacher Institute, 2013b).

In 1992, the U.S. Supreme Court made another landmark ruling, this time allowing states to restrict early abortion services as long as the restrictions did not place an "undue burden" on the woman's ability to choose abortion. Since then many bills have been introduced to limit access and funds for women seeking abortion. The Supreme Court will again play a major role in deciding the future of abortions as states introduce bills to limit or ban access to abortions.

LEGAL TIP: Induced Abortion

It is important for nurses to know the laws regarding abortion in their country or state of practice before they offer abortion counseling or nursing care to a woman choosing an abortion. Many states enforce a mandatory delay or state-directed counseling before a woman may legally obtain an abortion.

Incidence

In 2008 in the United States there were approximately 6.5 million pregnancies, and approximately 19% of these pregnancies were terminated (Sedgh, Singh, Shah, et al., 2012). The numbers of abortions in the United States have decreased from 1.31 million abortions in 2000 to 1.21 million abortions in 2008 to 784,507 in 2009 (Guttmacher Institute, 2013a; Pazol, Andreea, Creanga, et al., 2012). Most terminations were performed in women who were unmarried (84%). Non-Hispanic Caucasian women comprised 36% of those who experienced elective abortion; non-Hispanic African American women comprised 30% of those who experienced elective abortions, Hispanic women comprised 25%, and women of other races accounted for 9% of abortions (Guttmacher Institute). Most abortions occur in women who already have children, and abortion rates tend to be higher in women whose income is below the poverty level.

The Decision to Have an Abortion

Rates of biologic complications after abortions such as ectopic pregnancy, infection, or hemorrhage tend to be low if the woman aborts during the first trimester. Psychologic sequelae of induced abortion are uncommon and may be related to circumstances and support systems surrounding the pregnant woman, such as the attitudes reflected by friends, family, and health care workers. The woman facing an abortion is pregnant and will exhibit the emotional responses shared by all pregnant women, including the possibility of depression.

Nurses and other health care providers often struggle with the same values and moral convictions as those of the pregnant woman. The conflicts and doubts of the nurse can be readily communicated to women who are already anxious. Regardless of personal views on abortion, nurses who provide care to women seeking abortion have an ethical responsibility to counsel women about their options and to make appropriate referrals.

The Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN, 2009) continues to support a nurse's right to choose whether to participate in abortion procedures in keeping with his or her "personal, moral, ethical, or religious beliefs." AWHONN also advocates that "nurses have a professional obligation to inform their employers, at the time of employment, of any attitudes and beliefs that may interfere with essential job functions."

LEGAL TIP: Institutional Policies for Nurses' Rights and Responsibilities Related to Abortion

Nurses' rights and responsibilities related to caring for abortion clients should be protected through policies that describe how the institution will accommodate the nurse's ethical or moral beliefs and what the nurse should do to avoid client abandonment in such situations. Nurses should know what policies are in place in their institutions and encourage such policies to be written.

CARE MANAGEMENT

A thorough assessment is conducted through history, physical examination, and laboratory tests. The length of pregnancy and the condition of the woman must be determined to select the appropriate type of abortion procedure. An ultrasound examination should be performed before a second-trimester abortion is done. If the woman is Rh negative, she is a candidate for prophylaxis against Rh isoimmunization. She should receive Rh₀(D) immune globulin within 72 hours after the abortion if she is D negative and if Coombs' test results are negative (if the woman is unsensitized or isoimmunization has not developed).

The woman's understanding of alternatives, the types of abortions, and expected recovery are assessed. Misinformation and gaps in knowledge are identified and corrected. The record is reviewed for the signed informed consent, and the woman's understanding is verified. General preoperative, operative, and postoperative assessments are performed.

Analysis of data leads to identification of the appropriate nursing diagnoses for the woman undergoing elective abortion. Potential nursing diagnoses are listed in Box 8-4.

BOX 8-4 Selected Nursing Diagnoses for Women Having Elective Abortion

- *Decisional Conflict* related to
 - Value system
- *Fear* related to
 - Abortion procedure
 - Potential complications
 - Implications for future pregnancies
 - What others might think
- *Anticipatory Grieving* related to
 - Distress at loss or feelings of guilt
- *Risk for Infection* related to
 - Effects of the procedure
 - Lack of understanding of preoperative and postoperative self-care
- *Acute Pain* related to
 - Effects of the procedure or postoperative events

Counseling about abortion includes help for the woman in identifying how she perceives the pregnancy, information about the choices available (i.e., having an abortion or carrying the pregnancy to term and then either keeping the infant or placing the baby for adoption), and information about the types of abortion procedures.

CLINICAL REASONING CASE STUDY

Termination of Pregnancy

Angelica is a 19-year-old single client whose contraceptive method failed. An examination determines that she is 6 weeks pregnant and is seeking termination of the pregnancy. She has many questions for the nurse in the family planning clinic: Which procedure is most likely to be chosen at this gestation? What are the risks associated with the procedure? Should her boyfriend be involved in the decision to terminate the pregnancy?

1. Evidence—Is there sufficient evidence to draw conclusions about what information the nurse should provide Angelica?
2. Assumptions—What assumptions can be made about Angelica's reaction to termination of the pregnancy?
 - a. Psychologic/emotional reaction and sequelae
 - b. Physical response
 - c. Future childbearing
 - d. Relationship with her boyfriend
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

First-Trimester Abortion

Methods for performing early abortion (less than 9 weeks of gestation) include surgical (aspiration) and medical methods (mifepristone with misoprostol and methotrexate with misoprostol).

Aspiration

Aspiration (vacuum or suction curettage) is the most common procedure in the first trimester, with slightly more than 74% of all procedures being performed by this method (Pazol et al., 2012). Aspiration abortion is usually performed under local anesthesia in the physician's office, the clinic, or the hospital. The suction procedure for performing an early elective abortion

(ideal time is 8 to 12 weeks since the last menstrual period) usually requires less than 5 minutes.

A bimanual examination is done before the procedure to assess uterine size and position. A speculum is inserted and the cervix is anesthetized with a local anesthetic agent. The cervix is dilated if necessary and a cannula connected to suction is inserted into the uterine cavity. The products of conception are evacuated from the uterus.

During the procedure the nurse or physician keeps the woman informed about what to expect next (e.g., menstrual-like cramping, sounds of the suction machine). The nurse assesses the woman's vital signs. The aspirated uterine contents must be carefully inspected to ascertain whether all fetal parts and adequate placental tissue have been evacuated. After the abortion the woman rests on the table until she is ready to stand. She remains in the recovery area or waiting room for 1 to 3 hours for detection of excessive cramping or bleeding; then she is discharged.

Bleeding after the operation is normally about the equivalent of a heavy menstrual period, and cramps are rarely severe. Excessive vaginal bleeding and infection, such as endometritis or salpingitis, are the most common complications of elective abortion. Retained products of conception are the primary cause of vaginal bleeding. Evacuation of the uterus, uterine massage, and administration of oxytocin or methylergonovine (Methergine) or both may be necessary. Prophylactic antibiotics to decrease the risk of infection are commonly prescribed (Paul & Stein, 2011). Postabortion pain may be relieved with NSAIDs such as ibuprofen.

Postabortion instructions differ among health care providers (e.g., tampons should not be used for at least 3 days or should be avoided for up to 3 weeks, and resumption of sexual intercourse may be permitted within 1 week or discouraged for 2 weeks). The woman may shower daily. Instruction is given to watch for excessive bleeding and other signs of complications and to avoid douches of any type.

SAFETY ALERT

The woman who has an induced abortion should be given clear instructions to return immediately to the health care facility or emergency department for any of the following symptoms:

- Fever greater than 38° C (100.4° F)
- Chills
- Bleeding greater than two saturated pads in 2 hours or heavy bleeding lasting a few days
- Foul-smelling vaginal discharge
- Severe abdominal pain, cramping, or backache
- Abdominal tenderness (when pressure applied)

The woman may expect her menstrual period to resume 4 to 6 weeks from the day of the procedure. Information about the birth control method the woman prefers is offered, if this has not been done previously during the counseling interview that usually precedes the decision to have an abortion. Some methods can be initiated immediately such as an IUD insertion. Hormonal methods may be started immediately or within a week (Paul & Stein, 2011). The woman must be strongly encouraged to return for her follow-up visit so complications

can be detected. A pregnancy test may also be performed at that time to determine whether the pregnancy was successfully terminated.

Medical Abortion

Early medical abortion has been popular in Canada and Europe for more than 15 years, but it is a relatively new procedure in the United States. Medical abortions are available for use in the United States for up to 9 weeks after the last menstrual period. Methotrexate, misoprostol, and mifepristone are the drugs used in the current regimens to induce early abortion. About 16.5% of all reported abortion procedures in the United States in 2009 were medical procedures (Pazol et al., 2012).

Methotrexate is a cytotoxic drug that causes early abortion by blocking folic acid in fetal cells so that they cannot divide. Misoprostol (Cytotec) is a prostaglandin analog that acts directly on the cervix to soften and dilate and on the uterine muscle to stimulate contractions. Mifepristone, formerly known as RU 486, was approved by the FDA in 2000. It works by binding to progesterone receptors and blocking the action of progesterone, which is necessary for maintaining pregnancy (Paul & Stein, 2011).

Methotrexate and Misoprostol. There is no standard protocol, but methotrexate is given intramuscularly or orally (usually mixed with orange juice). Vaginal placement of misoprostol follows in 3 to 7 days. The woman returns for a follow-up visit in 1 week to confirm the abortion is complete. If not, the woman is offered an additional dose of misoprostol or vacuum aspiration is performed (Paul & Stein, 2011).

Mifepristone and Misoprostol. Mifepristone can be given up to 7 weeks after the last menstrual period. The FDA-approved regimen is that the woman takes 600 mg of mifepristone orally; 48 hours later she returns to the office and takes 400 mcg of misoprostol orally (unless abortion has already occurred and been confirmed). Two weeks after the administration of mifepristone, the woman must return to the office for a clinical examination or ultrasound to confirm that the pregnancy has been terminated. In 4% to 6% of cases, the drugs do not work, and surgical abortion (aspiration) is needed (Paul & Stein, 2011).

Research has demonstrated a more effective regimen that has fewer side effects. This regimen can be given up to 9 weeks after the last menstrual period and includes administration of 200 mg mifepristone orally followed by misoprostol 800 mcg vaginally in 24 to 48 hours. This vaginal insertion can be done at home by the woman. A follow-up visit is in 4 to 8 days (Paul & Stein, 2011).

With any medical abortion regimen, the woman usually will experience bleeding and cramping. Side effects of the medications include nausea, vomiting, diarrhea, headache, dizziness, fever, and chills. These are attributed to misoprostol and usually subside in a few hours after administration (Paul & Stein, 2011).

Second-Trimester Abortion

Second-trimester abortion is associated with more complications and costs than first-trimester abortions. Dilation and evacuation (D&E) accounts for almost all procedures performed in the second trimester in the United States. Induction of uterine contractions with hypertonic solutions

(e.g., saline, urea) injected directly into the uterus and uterotonic agents (e.g., misoprostol, dinoprostone) account for only about 0.5% of all abortions (Pazol et al., 2012).

Dilation and Evacuation

D&E can be performed at any point up to 20 weeks of gestation although this procedure is more commonly performed between 13 and 16 weeks of gestation. The cervix requires more dilation because the products of conception are larger. Often, osmotic dilators (e.g., laminaria) are inserted several hours or several days before the procedure, or misoprostol can be applied to the cervix. The procedure is similar to vaginal aspiration except a larger cannula is used and other instruments may be needed to remove the fetus and placenta. Nursing care includes monitoring vital signs, providing emotional support, administering analgesics, and postoperative monitoring. Disadvantages of D&E may include possible long-term harmful effects to the cervix.

Nursing Interventions

The woman will need help exploring the meaning of the various alternatives and consequences to herself and her significant others. It is often difficult for a woman to express her true feelings (e.g., what having an abortion means to her now, how she may feel about her decision in the future, and what support or regret her friends and peers may demonstrate). A calm, matter-of-fact approach on the part of the nurse can be helpful (e.g., "Yes, I know you are pregnant. I am here to help. Let's talk about alternatives"). Listening to what the woman has to say and encouraging her to speak are essential. Neutral responses such as "Oh," "Uh-huh," and "Umm," and nonverbal encouragement such as nodding, maintaining eye contact, and use of touch are helpful in setting an open, accepting environment. Clarifying, restating, and reflecting statements, open-ended questions, and feedback are communication techniques that can be used to maintain a realistic focus on the situation and bring the woman's concerns into the open.

Information about alternatives to abortion such as referral to adoption agencies or to support services if the woman chooses to keep her baby should be provided. If a decision is made to have an abortion, the woman must be assured of continued support. Information about what is entailed in various procedures, how much discomfort or pain can be expected, and what type of care is needed must be given. A discussion of the various feelings including depression, guilt, regret, and relief that the woman might experience after the abortion is needed. Information about community resources for postabortion counseling may be needed (Paul & Stein, 2011). If family or friends cannot be involved, scheduling time for nursing personnel to give the necessary support is an essential component of the plan for care.

After an abortion, studies have indicated that most women report relief, but some have temporary distress or mixed emotions. A systematic review of the literature found no difference in the long-term mental health outcomes of women who had abortions and women who did not have abortions (Charles, Polis, Sridhara, & Blum, 2008). Because symptoms can vary among women who have had abortions, nurses must assess women for grief reactions and facilitate the grieving process through active listening and nonjudgmental support and care.

NURSING CARE PLAN

Sexual Activity and Contraception

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Decisional Conflict related to contraceptive alternatives</i>	Woman and partner will verbalize understanding of different methods of contraception and will choose the method best suited for their needs.	Provide information regarding reliability, use, indications, contraindications, and side effects of different methods of contraception. Use privacy and therapeutic communication during discussion of sexual activity and methods of contraception.	To facilitate the decision-making process To provide clarification of information and client trust of caregiver
<i>Risk for Infection related to ongoing sexual activity as evidenced by client history</i>	Woman and her partner will remain free of sexually transmitted infections.	Provide information regarding sex practices to reduce risk of STIs and use of barrier methods.	To raise client awareness of methods to prevent infection
<i>Ineffective Health Maintenance related to unfamiliarity with contraceptive method</i>	Woman and partner will verbalize intent to use chosen contraception correctly.	Review information given regarding use, reliability, and side effects of chosen contraceptive method. Provide list of informational resources. Encourage ongoing effective communication with health care provider.	To ensure woman's and partner's understanding To promote consistency of use of chosen method To promote trust

STIs, Sexually transmitted infections.

KEY POINTS

- A variety of contraceptive methods are available with various effectiveness rates, advantages, and disadvantages.
- Women and their partners should choose the contraceptive method or methods best suited to them.
- Effective contraceptives are available through prescription and nonprescription sources.
- A variety of techniques are available to enhance the effectiveness of periodic abstinence in motivated couples who prefer this natural method.
- Hormonal contraception includes both precoital and postcoital prevention through various modalities and requires thorough client education.
- The barrier methods of diaphragm and cervical cap provide safe and effective contraception for women or couples motivated to use them consistently and correctly.
- Intrauterine devices can provide long-term (5 to 10 years) protection.
- Emergency contraception should be taken as soon as possible after unprotected intercourse, but no later than 120 hours.
- Proper, concurrent use of spermicides and latex condoms provides protection against STIs.
- Tubal ligations and vasectomies are permanent sterilization methods used by increasing numbers of women and men.
- Induced abortion performed in the first trimester is safer than an abortion performed in the second trimester.
- The most common complications of induced abortion include infection, retained products of conception, and excessive vaginal bleeding.
- Major psychologic sequelae of induced abortion are rare.

Infertility

Pat Mahaffee Gingrich

© <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- List common causes of infertility.
- Discuss the psychosocial impact of infertility.
- Identify common diagnoses and treatments for infertility.
- Identify reproductive and nonreproductive alternatives for infertile couples.
- Examine the various ethical and legal considerations of assisted reproductive therapies for infertility.

This chapter addresses infertility, associated tests, and common therapies. The available alternatives and the psychosocial implications of infertility are discussed.

INCIDENCE

Infertility is a serious medical concern that affects quality of life for approximately 15% of reproductive-age couples (American Society for Reproductive Medicine [ASRM], 2011). The term *infertility* implies subfertility, a prolonged time to conceive, as opposed to *sterility*, which means inability to conceive. Normally a fertile couple has approximately a 20% chance of conception in each ovulatory cycle. If a couple does not achieve pregnancy after a year of unprotected intercourse, they are normally advised to seek specialized fertility evaluation. This evaluation is recommended sooner, after 6 months of attempting pregnancy, for women older than 35, or who have a known risk factor such as endometriosis or male subfertility (ASRM, 2012a). Primary infertility refers to difficulty conceiving when there has never been a pregnancy; secondary infertility refers to difficulty conceiving after having had a pregnancy, regardless of the outcome.

Many factors, both male and female, contribute to infertility. In general, about 10% to 20% of couples will have idiopathic (unexplained) infertility. Among the 80% of couples who have an identifiable cause of infertility, about 40% are related to factors in the female partner, 40% are related to factors in the male partner, and 20% are related to factors in both partners. The prevalence of female infertility is relatively stable among the overall population, but increases with age, accelerating after age 35 (ASRM, 2011). Boxes 9-1 and 9-2 list factors affecting female and male infertility.

FACTORS ASSOCIATED WITH INFERTILITY

A normally developed reproductive tract in both the male and female partner is essential for fertility. Normal functioning of an intact hypothalamic-pituitary-gonadal axis supports

gametogenesis—the formation of sperm and ova. The life spans of the sperm and the ovum are short. Although sperm remain viable in the female's reproductive tract for 48 hours or more, only a few retain fertilization potential for more than 24 hours. Ova remain viable for about 24 hours. Infertility also may be caused by something as simple as poor timing or inadequate frequency of intercourse or lack of penile penetration. The couple should be taught about the menstrual cycle and the ways to detect ovulation (see Chapters 4 and 8). Basal body temperature can be assessed to help determine ovulation (see Teaching for Self-Management: Basal Body Temperature, Chapter 8).

Probable causes include the trend toward delaying pregnancy until later in life, when fertility decreases naturally due to ovulatory dysfunction, and the cumulative reproductive organ damage from toxins and diseases such as endometriosis and tubal infection (ASRM, 2012a). Male infertility can result from unfavorable sperm production due to physical or endocrine dysfunction, cumulative metabolic disease, or toxins (ASRM, 2012b).

Female Infertility Causes

Hormonal and Ovulatory Factors

Anovulation may be primary or secondary (see Chapter 6). Primary anovulation may be caused by a pituitary or hypothalamic hormone disorder or an adrenal gland disorder, such as congenital adrenal hyperplasia. It is usually seen in adolescents. Secondary anovulation, usually seen in young to midlife women, is relatively common and is caused by the disruption of the hypothalamic-pituitary-ovarian axis. Besides aging, common causes of ovulatory dysfunction include obesity, polycystic ovary syndrome, strenuous exercise, thyroid dysfunction, and hyperprolactinemia (ASRM, 2012a).

Although relatively rare, amenorrhea after the discontinuation of hormonal contraceptives is seen more frequently in women with a history of menstrual dysfunction. Because most women resume menstruating within 6 months, any workup should be delayed until that time, in the absence of other symptoms.

BOX 9-1 Factors Affecting Female Fertility**Ovarian Factors**

Developmental anomalies
 Anovulation, primary or secondary
 Pituitary or hypothalamic hormone disorder
 Adrenal gland disorder
 Congenital adrenal hyperplasia
 Disruption of hypothalamic-pituitary-ovarian axis
 Amenorrhea after discontinuing oral contraceptive pills
 Premature ovarian failure
 Increased prolactin levels

Uterine, Tubal, and Peritoneal Factors

Developmental anomalies
 Tubal motility reduced
 Inflammation within the tube
 Tubal adhesions
 Endometrial and myometrial tumors
 Asherman syndrome (uterine adhesions or scar tissue)
 Endometriosis
 Chronic cervicitis
 Hostile or inadequate cervical mucus

Other Factors

Nutritional deficiencies (e.g., anemia)
 Obesity
 Substance abuse
 Thyroid dysfunction
 Genetic disorders (e.g., Turner syndrome)
 Anxiety

Occasionally women experience menopause before they are 40 years old. In a vast majority of cases of early menopause, the ovaries do not respond to ovulation-inducing drugs. Nutritional deficits, such as eating disorders or a diet low in vegetables or high in animal protein, can also contribute to ovulatory dysfunction (Sharma, Beidenharn, Fedor, & Agarwal, 2013). Cancer treatments involving radiation and chemotherapy can decrease or halt ovarian function. Smoking, even passive exposure, is significantly associated with early menopause, infertility, and poor pregnancy outcomes (ASRM, 2012e). Environmental exposure to air pollution, heavy metals, and insecticide is associated with decreased fertility (Sharma et al.).

An increased prolactin level may cause anovulation and amenorrhea in the same way it does during lactation. Hyperprolactinemia can be a side effect of drugs, such as phenothiazine, opiates, diazepam, reserpine, methyldopa, and tricyclic antidepressants. Prolactin also may be elevated as a result of physical stressors such as surgery, cranial lesions or injury, or severe emotional stress. Benign pituitary adenoma may also cause hyperprolactinemia.

The decline in fertility rate in women accelerates after age 35 (Kimberly, Case, Cheung, et al., 2012). Decreased *ovarian reserve*, or total number and quality of follicles, is thought to be the primary reason for age-associated infertility (ASRM, 2012a).

Progesterone, produced by the ovarian corpus luteum, is necessary to mature and maintain the uterine lining. Exogenous progesterone has not been found to improve pregnancy outcomes in women with luteal phase defect, threatened miscarriage, or a history of pregnancy loss. However, synthetic progesterone is beneficial as adjunct therapy to improve the uterine lining after stimulated ovulation or when donor oocytes are

BOX 9-2 Factors Affecting Male Fertility**Poor Sperm Quality**

Substance abuse, especially tobacco
 Age
 Sexually transmitted infections
 Exposure to workplace hazards such as radiation or toxic substances
 Exposure of scrotum to high temperatures
 Nutritional deficiencies
 Obesity
 Antisperm antibodies

Structural or Hormonal Disorders

Undescended testes
 Hypospadias
 Varicocele
 Obstructive lesions of the vas deferens or epididymis
 Low testosterone levels
 Hypopituitarism
 Endocrine disorders
 Testicular damage caused by mumps
 Retrograde ejaculation

Other Factors

Genetic disorders (e.g., Klinefelter syndrome)
 Decrease in libido—heroin, methadone, selective serotonin reuptake inhibitors (SSRIs), and barbiturates
 Impotence—alcohol, antihypertensive medications

used (see later discussion of assisted reproductive technology) (Ozlu, Gungor, Donmez, & Duran, 2012).

Tubal and Peritoneal Factors

Tubal factors account for up to 25% to 35% of female infertility (ASRM, 2012d). Impaired tubal patency and motility result from infections, adhesions, scarring, tumors, or intentional sterilization. In rare instances, one tube may be congenitally absent. One tube may be relatively shorter than the other, which is often associated with an abnormally developed uterus.

Women who have used contraception (barrier methods such as condoms) are more likely to conceive than those who did not, presumably because of the protective effects against tubal damage from sexually transmitted infections (STIs), especially chlamydia (Sharma et al., 2013). Inflammation of the tube or the fimbriated ends resulting from pelvic infections may impair fertility. When infection with purulent discharge heals, scar tissue adhesions form. In the process, the tube can be blocked or kinked anywhere along its length. Adhesions may permit the tiny sperm to pass through the tube, but then prevent a larger fertilized egg from completing the journey into the intrauterine cavity. This results in an ectopic pregnancy, which can completely destroy the tube and be life threatening if untreated.

Endometriosis is the inflammatory peritoneal damage caused by endometrial tissue that has migrated out of the uterus and implanted on pelvic organs or connective tissue (see Chapter 6). Endometriosis is found in less than 5% of fertile women, but in 25% to 50% of infertile women (ASRM, 2012c; Harb, Gallos, Chu, et al., 2013). Risk factors for endometriosis include low body mass index (BMI), alcohol and tobacco use, and Caucasian race.

FIG 9-1 Abnormal uterus. **A**, Complete bicornuate uterus with vagina divided by a septum. **B**, Complete bicornuate uterus with normal vagina. **C**, Partial bicornuate uterus with normal vagina. **D**, Unicornuate uterus.

Adhesions can result in pelvic distortion. Inflammatory changes can impair ovarian function and tubal transport (ASRM).

Uterine Factors

Minor developmental anomalies of the uterus are fairly common; major anomalies occur rarely. Müllerian malformations of the uterine cavity, such as bicornuate or septate uterus (Fig. 9-1) or tumors of the endometrium and myometrium (e.g., polyps or myomas), can impair implantation and normal fetal growth. If a functional uterus can be reconstructed, pregnancy may be possible.

Asherman syndrome (uterine adhesions or scar tissue) is characterized by hypomenorrhea. The adhesions prevent normal cyclic endometrial proliferation necessary for implantation. This can result from endometriosis or surgical interventions such as too-vigorous curettage (scraping) after an elective abortion or miscarriage.

Endometritis (inflammation of the endometrium) may result from the same organisms that cause infection of the cervix or uterine tubes (e.g., chlamydia).

Vaginal-Cervical Factors

Vaginal fluid is acidic (pH 4 to 5), which is not favorable for long-term sperm survival. The more alkaline cervical mucus (pH of 7 or more) helps support sperm and permits their ascending transportation. Endocervical mucus normally obstructs or plugs the cervix, acting as a barrier against infection, until increasing estrogen levels cause the mucus to become clear, thin, and nutritionally supportive of sperm. This change occurs around the time of ovulation and lasts approximately 48 to 72 hours (see Teaching for Self-Management: Cervical Mucus Characteristics, Chapter 8).

Inflammation and white blood cells from vaginal or cervical infections often destroy or dramatically reduce the number of viable motile sperm before they enter the cervical canal. The amount of mucus and its physical changes are influenced by the presence of blood, pathogenic bacteria, and irritants such as an intrauterine device (IUD) or a polyp. Severe emotional stress, antibiotic therapy, and diseases such as diabetes mellitus diminish the supportive alkalinity of the cervical mucus.

Some infertile women develop sperm antibodies. Sperm may be immobilized or agglutinated within the cervical mucus, rendering them incapable of migration into the uterus.

Male Infertility Causes

Male infertility can be caused by structural or hormonal disorders such as undescended testes, hypospadias, varicocele (varicose veins on the spermatic vein in the groin), low testosterone levels, or previous vasectomy, all of which can cause **azoospermia** (no sperm cells produced) or **oligospermia** (few sperm cells produced). A low sperm

count may occur when spermatic fluid is ejaculated backward, or *retrograde*, into the bladder. Mumps, especially after adolescence, can result in permanent damage to the testes. Testicular cancer or pituitary tumors may present as infertility (ASRM, 2012b).

Male infertility also may be caused by some of the same health issues that affect women, such as nutritional problems, endocrine disorders, genetic disorders, psychologic disorders, and STIs. Male obesity can lead to decreased semen quality. Exposure to hazards in the workplace such as radiation, heavy metals, air pollution, or insecticides also can affect sperm production (Sharma et al., 2013). Exposure of the scrotum to high temperatures can cause a decrease in sperm production as well as abnormal sperm production. Cancer treatments can decrease production or quality of sperm.

Substance abuse can be a major factor in male infertility. Alcohol consumption can cause erectile dysfunction (impotence). Cigarette smoking has been associated with a decrease in number and quality of sperm as well as chromosomal damage (ASRM, 2012e). Recreational drugs decrease sperm quality. Heroin, methadone, selective serotonin reuptake inhibitors (SSRIs), and barbiturates decrease libido. Monoamine oxidase inhibitors (MAOIs), a class of antidepressants, adversely affect spermatogenesis. In addition, some antihypertensives may cause impotence.

Male fertility declines slowly after age 40 (Sharma et al., 2013); however, no cessation of sperm production occurs analogous to menopause in women. Advanced paternal age (greater than 40 years old) is associated with a slightly increased risk for some autosomal dominant conditions, autism spectrum disorder, and schizophrenia in their offspring (Kimberly, Casey, Cheung, et al., 2012).

CARE MANAGEMENT

The nurse begins assessment by obtaining data relevant to fertility through interview and assisting in physical examination. The database must include information to identify whether infertility is primary or secondary. Religious, cultural, and ethnic data are noted (Box 9-3). Many couples have already visited various health care providers and have read extensively on the subject. Their previous infertility experiences and knowledge should be explored and recorded.

Much of the data needed to investigate impaired fertility is of a sensitive, personal nature. Obtaining these data may be viewed as an invasion of privacy. The tests and examinations are occasionally painful and intrusive. Couples may experience some difficulty abstaining from intercourse for 2 to 4 days before expected ovulation. Timed intercourse can take the romance out of lovemaking. The medical investigation requires time (3 to 4 months) and considerable financial expense. It can cause emotional distress and strain on the couple's relationship. A high level of motivation from both partners is needed to the investigation. Preparatory and concurrent counseling support is recommended. Further discussion on psychosocial issues is presented later in this chapter.

Investigation of impaired fertility begins for the woman and the man with a complete history and physical examination. A complete general physical examination is followed by a specific assessment of the reproductive tract and laboratory data. The nurse can alleviate some of the anxiety associated with diagnostic testing by explaining to clients the timing and rationale for

BOX 9-3 Religious and Cultural Considerations of Fertility

Religious Considerations

- Civil laws and religious proscriptions about sex must always be kept in mind by the health care provider.
- Conservative and reform Jewish couples are accepting of most infertility treatment; however, the Orthodox Jewish husband and wife may face problems with infertility investigation and management because of religious laws that govern marital relations. For example, according to Jewish law, the Orthodox couple may not engage in marital relations during menstruation and through the following 7 "preparatory days." The wife then is immersed in a ritual bath (*mikvah*) before relations can resume. Fertility problems can arise when the woman has a short cycle (i.e., a cycle of 24 days or fewer; when ovulation would occur on day 10 or earlier).
- The Roman Catholic Church regards the embryo as a human being from the first moment of existence and regards as unacceptable technical procedures such as in vitro fertilization (IVF), masturbation to collect semen for husband/partner or therapeutic donor insemination, and freezing of embryos.
- Other religious groups may have ethical concerns about infertility tests and treatments. For example, most Protestant denominations and Muslims usually support infertility management as long as IVF is done with the husband's sperm, there is no

reduction of fetuses, and insemination is done with the husband's sperm. These groups are less supportive of surrogacy and use of donor sperm and eggs. Christian Scientists do not permit surgical procedures or IVF but do permit insemination with husband and donor sperm.

- Care providers should seek to understand the woman's spirituality and how it affects her perception of health care, especially in relation to infertility. Women may wish to seek infertility treatment but have questions about proposed diagnostic and therapeutic procedures because of religious proscriptions. These women are encouraged to consult their minister, rabbi, priest, or other spiritual leader for advice.

Cultural Considerations

- Worldwide cultures continue to use symbols and rites that celebrate fertility. One fertility rite that persists today is the custom of throwing rice at the bride and groom.
- In many cultures the responsibility for infertility is usually attributed to the woman. A woman's inability to conceive may be a result of her sins, of evil spirits, or of the fact that she is an inadequate person. The virility of a man in some cultures remains in question until he demonstrates his ability to reproduce by having at least one child.

Modified from D'Avanzo, C. (2008). *Mosby's pocket guide to cultural health assessment* (4th ed.). St. Louis: Mosby.

TABLE 9-1 Tests for Impaired Fertility

TEST OR EXAMINATION	TIMING (MENSTRUAL CYCLE DAYS)	RATIONALE
Hysterosalpingogram	7-10	Late follicular, early proliferative phase; will not disrupt a fertilized ovum; may open uterine tubes before time of ovulation
Sonohysterogram	7-10	Same as hysterosalpingogram
Basal body temperature	Chart entire cycle	Elevation occurs in response to progesterone, documents ovulation
Ovulation detection kit	Begin on day 11 of 28-day cycle	Detects luteinizing hormone surge, 12-36 hours prior to ovulation
Assessment of cervical mucus	Variable, ovulation	Cervical mucus should have low viscosity, high spinnbarkeit
Ultrasound diagnosis of follicular collapse	Ovulation	Collapsed follicle is seen after ovulation
Serum assay of plasma progesterone	20-25	Midluteal midsecretory phase; check adequacy of corpus luteal production of progesterone
Endometrial biopsy	21-27	Late luteal, late secretory phase; check endometrial response to progesterone and adequacy of luteal phase. Not done if chance of pregnancy. Not recommended as a routine test.
Hysteroscopy	Variable	Direct visualization of inside of uterus, via cervix
Laparoscopy	Variable	Direct visualization of outside of uterus, ovaries, and tubes, via abdomen

each test (Table 9-1). Test findings that are favorable to fertility are summarized in Box 9-4.

Couples should be cautioned that all tests can be normal and conception still may not occur. Conversely, pregnancy can occur despite poor test results.

Assessment of Female Infertility

Fertility data for the woman include evaluation of the cervix, uterus, tubes, and peritoneum; detection of ovulation; assessment of immunologic compatibility; and evaluation of

CLINICAL REASONING CASE STUDY

Infertility

Diane is a 39-year-old accountant who has recently married for the first time. Charles is 41 and has two children from a previous marriage. Diane has a history of amenorrhea when she was in college and a member of the track team. Currently her menstrual periods are irregular. She wants to have a baby "before it's too late," and she and Charles have been having unprotected sex for almost a year. They have come to the fertility clinic today for an evaluation. Diane tells the nurse that she has heard a lot about the success of in vitro fertilization (IVF) and wants to know if she will be able to have it performed. How should the nurse respond to Diane's comments and questions?

1. Evidence—Is evidence sufficient to draw conclusions about what response the nurse should give?
2. Assumptions—Describe underlying assumptions about the following issues:
 - a. Age and fertility
 - b. Infertility as a major life stressor
 - c. Success rates for IVF pregnancy and birth
 - d. Causes of female infertility
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

BOX 9-4 Summary of Findings Favorable to Fertility

1. Follicular development, ovulation, and luteal development are supportive of pregnancy:
 - a. Basal body temperature (presumptive evidence of ovulatory cycles) is biphasic, with temperature elevation that persists for 12 to 14 days before menstruation.
 - b. Cervical mucus characteristics change appropriately during phases of the menstrual cycle.
 - c. Days 3 to 10 follicle-stimulating hormone (FSH) levels are low enough to verify presence of adequate ovarian follicles.
 - d. Day 3 estradiol levels are low enough to verify presence of adequate ovarian follicles.
 - e. Woman reports a history of regular, predictable menses with consistent premenstrual and menstrual symptoms.
2. The luteal phase is supportive of pregnancy:
 - a. Levels of plasma progesterone are adequate to indicate ovulation.
 - b. Luteal phase of menstrual cycle is of sufficient duration to support pregnancy.
3. Cervical factors are receptive to sperm during expected time of ovulation:
 - a. Cervical os is open.
 - b. Cervical mucus is clear, watery, abundant, and slippery and demonstrates good spinnbarkeit and arborization (fern pattern) at time of ovulation.
 - c. Cervical examination reveals no lesions or infections.
4. The uterus and uterine tubes support pregnancy:
 - a. Uterine and tubal patency are documented by (1) spillage of dye into the peritoneal cavity, and (2) outlines of uterine and tubal cavities of adequate size and shape with no abnormalities.
 - b. Laparoscopic examination verifies normal development of internal genitals and absence of adhesions, infections, endometriosis, and other lesions.
5. The male partner's reproductive structures are normal:
 - a. There is no evidence of developmental anomalies of penis, testicular atrophy, or varicocele (varicose veins on the spermatic vein in the groin).
 - b. There is no evidence of infection in the prostate, seminal vesicles, and urethra.
 - c. Testes are more than 4 cm in largest diameter.
6. Semen is supportive of pregnancy:*
 - a. Sperm (number per milliliter) are adequate in the ejaculate (at least 15 mil/ml).
 - b. Most sperm show normal morphology.
 - c. Most sperm are motile and forward moving.
 - d. No autoimmunity exists.
 - e. Seminal fluid is normal (volume is at least 1.5 ml).

*World Health Organization. (2010). *Laboratory manual for the examination of human semen* (5th ed.). Geneva: WHO.

psychogenic factors. See the Clinical Reasoning box to explore how to assist women using evidence and best practices.

Detection of Ovulation

All infertile women should have ovulatory function assessed, because a history of monthly menstruation is inadequate to conclude that ovulation is occurring and is optimal for conception.

Documentation of time of ovulation is important in the investigation of impaired fertility. Direct proof of ovulation is pregnancy or the retrieval of an ovum from the uterine tube. Indirect or presumptive proof can be provided by over-the-counter ovulation detection kits, which test the urine for the luteinizing hormone surge at 24 to 36 hours prior to ovulation (ASRM, 2012a). When drawn at 1 week prior to the expected onset of the next menses, an elevated serum progesterone level gives reliable presumptive evidence of ovulation. Other indirect detections of ovulation include assessment of basal body temperature (BBT) and cervical mucus characteristics, as well as ultrasound imaging, described later. Occurrence of mittelschmerz and midcycle spotting provides unreliable presumptive evidence of ovulation.

Endometrial biopsy is no longer recommended as a routine test for ovulation or luteal phase endometrial development (ASRM, 2012a).

Hormone Analysis

Hormone analysis is performed to assess endocrine function of the hypothalamic-pituitary-ovarian axis when menstrual cycles are absent or irregular or to assess the woman's ovarian reserve. Determination of blood levels of prolactin and the thyroid hormones may be necessary to diagnose the cause of irregular or absent menstrual cycles. A serum progesterone level in

the latter half of the cycle verifies sufficient amounts to maintain pregnancy.

If assisted reproductive technology is anticipated, ovarian reserve is established to predict response to ovarian stimulants. Serum follicle-stimulating hormone (FSH) and estradiol (E2) are drawn on day 3 of the cycle. High FSH and low estradiol may indicate ovarian failure. Ovarian stimulation is attempted using a clomiphene citrate challenge test (CCCT). Ovarian follicle development is subsequently assessed visually using transvaginal ultrasound or via a blood test for antimüllerian hormone (AMH), produced by developing follicles (ASRM, 2012a). Poor ovarian reserve may indicate the need for donor eggs.

Ultrasonography

Transvaginal ultrasound is used to assess pelvic structures (Fig. 9-2) for abnormalities such as fibroid tumors and ovarian cysts; to verify follicular development and maturity; and to assess thickness of the endometrium around the time of ovulation. *Sonohysterography* uses fluid infused into the uterus through the cervix to help define the uterine cavity and the depth of the uterine lining, using vaginal ultrasound (ASRM, 2012a).

Hysterosalpingography

Hysterosalpingography, a radiographic (x-ray) film examination allows visualization of the uterine cavity and tubes after the instillation of radiopaque contrast material through the cervix (Fig. 9-3). The contrast material or dye is gently pushed through the uterus and out into the uterine tubes, where it can sometimes have the therapeutic effect of opening a blocked tube (ASRM, 2012a).

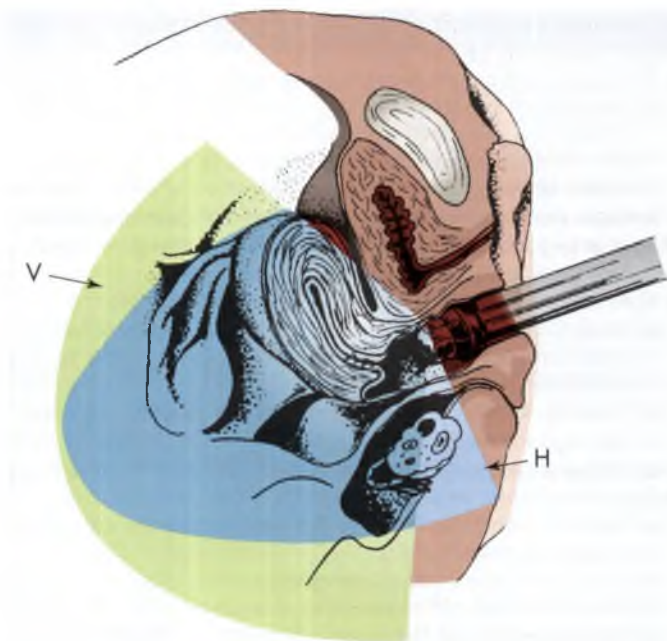

FIG 9-2 Vaginal ultrasonography. Major scanning planes of transducer. *H*, Horizontal; *V*, vertical.

Hysterosalpingography is scheduled 2 to 5 days after menstruation to avoid flushing a potential fertilized ovum out through a uterine tube into the peritoneal cavity. Endometrial blood vessels are closed at this time, and all menstrual debris has been discharged. This decreases the risk of embolism or of forcing menstrual debris into the peritoneal cavity.

! NURSING TIP

Referred shoulder pain may occur during a hysterosalpingogram. The referred pain is indicative of subphrenic irritation from the contrast media if it is spilled out of the patent uterine tubes. The discomfort can be managed with position change and mild analgesics. Pain usually subsides within 12 to 14 hours. Women with blocked tubes may have cramping for up to 48 hours.

Hysteroscopy

Hysteroscopy uses a flexible scope threaded through the cervix to directly view the uterine cavity. This is the definitive method for evaluation of leiomyomas (fibroids) and adhesions that might impair implantation. It is also the most expensive and invasive, so it is not a first-line assessment method (ASRM, 2012a).

Laparoscopy

Laparoscopy is useful to view the pelvic structures intraperitoneally, outside the uterus, which may reveal endometriosis, pelvic adhesions, tubal occlusion, leiomyomas, or polycystic ovaries. It is indicated for women with symptoms, and possibly to rule out endometriosis in long-term infertility of unknown reason (ASRM, 2012a). Performed early in the menstrual cycle, under either general or local anesthesia, a small endoscope is inserted through a small incision in the anterior abdominal wall. Cold fiberoptic light sources allow superior visualization of the internal pelvic structures

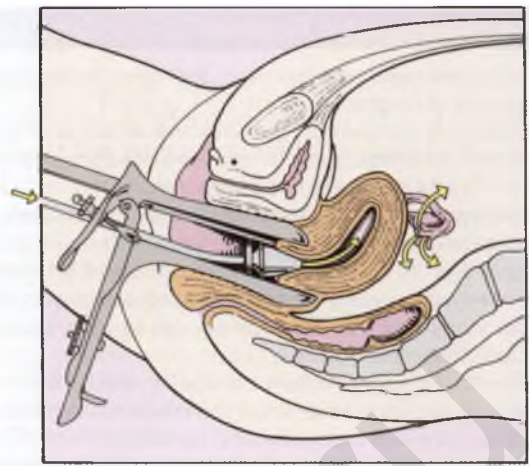

FIG 9-3 Hysterosalpingography. Note that contrast medium flows through an intrauterine cannula and out through the uterine tubes.

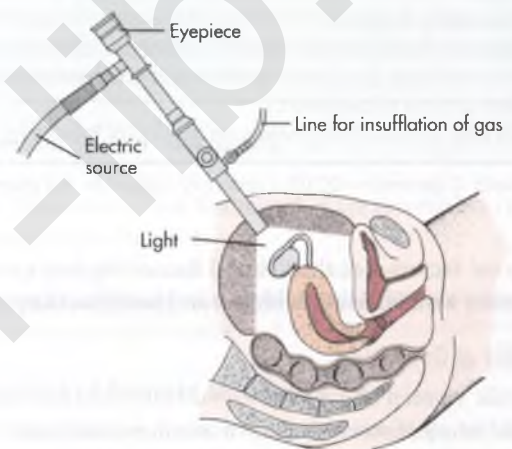

FIG 9-4 Laparoscopy.

(Fig. 9-4). A needle is inserted, and carbon dioxide gas is pumped into the peritoneum to elevate the abdominal wall from the organs, thereby creating an empty space that permits visualization and exploration with the laparoscope. If tubal patency is being assessed, a cannula is used to instill a dye contrast medium through the cervix.

After surgery, deflation of most gas is done by direct expression. Trocar and needle sites are closed with a single absorbable suture or skin clip, and an adhesive bandage is applied. Referred shoulder pain or subcostal discomfort usually lasts only 24 hours and is relieved with a mild analgesic.

Assessment of Male Infertility

Fertility data in the man include evaluation of general health, penis, meatus, testes, scrotum, prostate, hair distribution and breast development; semen analysis; assessment of immunologic compatibility; endocrine evaluations; imaging, as indicated; genetic screening; and evaluation of psychogenic factors.

Semen Analysis

The most basic test of male fertility, the complete **semen analysis**, assesses sperm number, morphology, and motility

(see Box 9-4). Semen is collected by ejaculation into a clean container or a plastic sheath that does not contain a spermicidal agent. The specimen is usually collected by masturbation after 2 to 5 days of abstinence from ejaculation. The semen is kept at room or body temperature and taken to the laboratory in a sealed container within 1 hour of ejaculation (ASRM, 2012b). If results are in the fertile range, no further sperm evaluation is necessary. Poor sperm morphology predicts a poor prognosis for assisted reproductive technology using in vitro fertilization (IVF) or intrauterine insemination, discussed later.

Semen analysis may reveal leukocytes from genital tract infection or agglutination from antisperm antibodies of the male (ASRM, 2012b).

Ultrasonography

Scrotal ultrasound is used to examine the testes for the presence of varicocele and to identify abnormalities in the scrotum and spermatic cord. Transrectal ultrasound can be used to evaluate the ejaculatory ducts, seminal vesicles, and vas deferens for obstruction.

Other Tests

Seminal deficiency can be attributable to one or more of a variety of factors. The male is assessed for these factors:

hypopituitarism; nutritional deficiency; debilitating or chronic disease, including obesity and metabolic disease; trauma; exposure to environmental hazards such as radiation and toxic substances; use of tobacco, alcohol, recreational drugs, or anabolic steroids; and gonadotropic inadequacy.

Genetic testing may reveal other reproductive problems. Hormone analyses are done for testosterone, gonadotropin, FSH, and luteinizing hormone (LH). In the presence of a mass, testicular biopsy may be warranted.

Interventions

The management of clients with infertility problems includes psychosocial, nonmedical, medical, and surgical interventions. Assisted reproductive therapies may be indicated. Nursing interventions are an important aspect of care (see Nursing Care Plan).

Psychosocial

Couples frequently refer to their experience with infertility as a "roller coaster" of emotions. Infertility is recognized as a major life stressor that can affect self-esteem, relationships, and careers. Complex feelings may stem from myths, superstitions, misinformation, or magical thinking about the causes of infertility. Individuals experiencing infertility are at risk for distress, anger, isolation, marital dysfunction, and grief. The stress of

NURSING CARE PLAN

Infertility

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Deficient Knowledge related to lack of understanding of the reproductive process with regard to conception</i>	Woman and partner will verbalize understanding of the components of the reproductive process, common problems leading to infertility, usual infertility testing, and the importance of completing testing in a timely manner.	<ul style="list-style-type: none"> Assess woman's current level of understanding of the factors promoting conception. Provide information in a supportive manner regarding factors promoting conception, including common factors leading to infertility of either partner. Identify and describe the basic infertility tests and the rationale for precise scheduling. 	<ul style="list-style-type: none"> To identify gaps or misconceptions in knowledge base To raise woman's awareness and promote trust in caregiver
<i>Ineffective Individual Coping related to inability to conceive</i>	Woman and partner will identify situational stressors and positive coping methods to deal with testing and unknown outcomes.	<ul style="list-style-type: none"> Provide opportunities through therapeutic communication to discuss feelings and concerns. Evaluate couple's support system, including support of each other during this process. Identify support groups and refer as needed. 	<ul style="list-style-type: none"> To enhance completion of the diagnostic phase of the infertility workup To identify common feelings and perceived stressors To identify any barriers to effective coping
<i>Hopelessness related to inability to conceive</i>	Woman and partner will verbalize a realistic plan to decrease feelings of hopelessness.	<ul style="list-style-type: none"> Provide support for couple while grieving for loss of fertility. Assess for behaviors indicating possible depression, anger, and frustration. Refer to support groups. 	<ul style="list-style-type: none"> To enhance coping by sharing experiences with other couples experiencing similar problems To allow couple to work through feelings To prevent impending crisis To promote a common bond with other couples during expression of feelings and concerns

infertility and its treatment can exacerbate preexisting anxiety or depression. Conversely, stress can be a cause of infertility for men and women, making it difficult to identify cause and effect (Sharma et al., 2013; Vellani, Colasante, Mamzza, et al., 2013). Table 9-2 discusses some therapeutic nursing actions in response to emotional behaviors associated with impaired fertility.

Men as well as women can experience emotional vulnerability. However, women may have more stress from tests and treatments, and often place greater importance on having children. In contrast, men more frequently express distress in their partner's suffering and the resulting changes in their partnership and sexual relationship. Either partner may exhibit grief behaviors associated with loss. The loss of one's genetic continuity with the generations to come leads to a loss of self-esteem, to a sense of inadequacy as a woman or a man, and to a loss of control over one's destiny. The investigative process leads to a loss of spontaneity and control over the couple's marital relationship and sometimes to a loss of control over progress toward career and life goals.

Same-sex couples desire pregnancy and parenthood for the same reasons as do heterosexual couples, but may feel unaccepted and marginalized in health care settings (Corbett, Frecker, Shapiro, & Yudin, 2013). This can add to the stress of fertility treatments.

Couples often need assistance in separating and reframing their concepts of success and failure related to fertility treatment. Couples making the difficult decision to undergo infertility treatments benefit significantly from instruction in stress management and coping skills (Monach, 2013; Sharma et al., 2013). Health team members must respect affected individuals' and couples' desires in choosing to stop treatment and to select other alternatives, such as adoption.

Psychologic responses to a diagnosis of infertility may tax a couple's giving and receiving of physical and sexual closeness. Sexual dysfunction can manifest as dyspareunia, decreased libido, unrealistic or rigid routines, decreased body image, depression, and ambivalence. Couples sometimes report orgasmic dysfunction or erectile disorders around the time of presumed ovulation.

To be able to deal comfortably with a couple's sexuality, nurses must be comfortable with their own sexuality so that they can better help couples understand why the private act of lovemaking must be shared with health care professionals. Nurses need up-to-date factual knowledge about human sexual practices and must be accepting and nonjudgmental of the preferences and activities of others (including same-sex couples). They need skills in interviewing and in therapeutic use of self, sensitivity to the nonverbal cues of others, and knowledge regarding each couple's sociocultural and religious beliefs. Gender-neutral and inclusive language, as well as pictures and brochures depicting all types of families, including same-sex couples, establishes a tone of respect and safety in the health care setting (Corbett, Frecker, Shapiro, & Yudin, 2013).

The support systems of the couple with impaired fertility must be explored. It is important to identify support available from family and friends, support groups, and their greater spiritual community. Individuals undergoing infertility evaluation and treatment should be encouraged to share their infertility

experiences with all other providers of health care, including mental health practitioners.

If the couple conceives, the nurse must be aware that previously infertile couples may continue to experience concerns, including anxiety. Many couples are overjoyed with the pregnancy; however, some are not. Some couples have rearranged their lives, sense of selves, and personal goals within their acceptance of their infertile state, only to be shocked to find that they feel resentment of impending parenthood. Pregnancy, once a cherished dream, now necessitates another change in goals, aspirations, and identities. Reactions of couples range from feeling overwhelmed, to worrying about miscarriage, to thinking about choosing to abort the pregnancy. The couple may need extra preparation to adjust to realities of pregnancy, labor, and parenthood because they may have idealized childbearing when they thought it was beyond their reach. A history of impaired fertility is considered to be a risk factor for pregnancy. A higher level of anxiety, noted in women with assisted pregnancies, could be a risk factor for postpartum depression; therefore, ongoing supportive psychologic therapy should be encouraged.

If the couple does not conceive, they are assessed regarding their desire to be referred for help with adoption, therapeutic intrauterine insemination, other reproductive alternatives, or choosing a child-free state. The couple may find a list of agencies, support groups, and other resources in their community helpful such as ASRM (www.asrm.org) and RESOLVE (www.resolve.org).

Nonmedical Therapy

Simple changes in lifestyle may be effective in the treatment of subfertile men. High scrotal temperatures can be caused by daily hot-tub bathing or saunas or some sports in which the testes are kept at temperatures too high for efficient spermatogenesis. Loose clothing may improve sperm count. Many commonly used lubricants can diminish sperm motility and quality. Cell phones worn at the belt or hip have been linked to decreased sperm quality (Sharma et al., 2013).

Changes in nutrition and habits may increase fertility for men and women. A well-balanced plant-based diet, exercise, stress management, decreased alcohol intake, and avoidance of smoking or recreational drugs can increase fertility for both partners (Sharma et al., 2013). Women who are overweight or obese have a reduced chance of pregnancy following IVF and a significantly greater risk of spontaneous abortion following infertility treatment as compared with women of normal weight. Even modest weight loss (5% to 10%) can be sufficient to increase their chances of achieving a successful pregnancy.

Counseling couples on optimal timing of intercourse can also help. Encouraging intercourse a day before ovulation and the day of ovulation will maximize chances of pregnancy. Sexual counseling may help couples if there is a question of sexual dysfunction that is affecting penile penetration (e.g., vaginismus, obesity).

Complementary and Alternative Measures

Most herbal remedies have not been proven clinically to promote fertility or to be safe in early pregnancy. Women should

TABLE 9-2 Nursing Actions in Response to Behavior Associated with Impaired Fertility

BEHAVIORAL CHARACTERISTIC	NURSING ACTION
<i>Surprise:</i> Each person assumes she or he is fertile and that pregnancy is an option.	Point out resemblance to grieving process—a normal, expected reaction to loss. Refer to support group. Prepare clients for length of time it may take to grieve and for types of feelings (psychologic, somatic) to expect. Encourage and allow time to talk of past and present feelings of sexuality, self-image, and self-esteem.
<i>Denial:</i> “It can’t happen to me!”	Allow time for denial, because it gives the body and mind time to adjust a little at a time. Do not feed into the client’s denial; instead say, “It must be hard to believe such a devastating report.”
<i>Anger:</i> Toward others (perhaps even the nurse) or themselves	Explain that the reaction to loss of control and to a feeling of helplessness is often anger, which can easily be projected onto another person. Anger is a natural feeling. Allow time to express anger at losing sense of control over bodies and destinies. A helpful approach may be, “It’s OK to be angry . . . at those who are pregnant, at people who want abortions, at self, at mate, at caregivers,” and so forth.
<i>Bargaining:</i> “If I get pregnant, I’ll dedicate the child to God.”	Accept bargaining statements without comment.
<i>Depression:</i> Isolation: Personal	Allow time for both woman and man to talk about how it feels whenever a sight, event, or word serves as a reminder of his or her own state of impaired fertility. Develop role-playing situations to practice interactions with others under various circumstances to increase the couple’s ability to cope and to solve problems (increases their self-confidence). The nurse may say, “You must feel so terribly alone sometimes.”
<i>Guilt or unworthiness</i>	Allow time to identify feelings that may be related to earlier behaviors (such as abortion, premarital sex, contact with sexually transmitted infections [STIs]).
<i>Acceptance (resolution)</i>	Couple or person comes to the realization that “unworthiness” and impaired fertility are unrelated. Clients need to know that grief feelings are never laid away forever; they may be activated by special reminders (such as anniversaries).

Adapted from Resolve. (2013). *Emotional aspects of infertility*. Available at www.resolve.org/support-and-services/Managing-Infertility-Stress/emotional-aspects.html.

take these only when prescribed by a physician, nurse-midwife, or nurse practitioner who has expertise in herbology. Relaxation, osteopathy, stress management (e.g., aromatherapy, yoga), and nutritional and exercise counseling have increased pregnancy rates in some women. Integrative mind-body-spirit programs for teaching attitudes of kindness, flexibility, curiosity, acceptance, and openness effectively decrease stress and anxiety related to infertility in women (Chan, Chan, Ng, et al., 2012; Galhardo, Cunha, & Pinto-Gouveia, 2013). Antioxidant vitamins E and C, selenium, zinc, coenzyme Q10, and ginseng have shown beneficial effects for male infertility (Clark, Will, Moravek, & Fisseha, 2013; Sharma et al., 2013).

Acupuncture can decrease anxiety and improve live birth rates for women undergoing IVF. Ovulation induction therapy may have better outcomes when supplemented by black cohosh, progesterone, or phytoestrogens (Clark et al., 2013).

Medical Therapy

Correcting Preexisting Factors. For women, pretreatment or surgery may be indicated to optimize conditions for conception. Infections are treated with appropriate antimicrobial formulations. Surgery or hysterosalpingogram may be necessary to correct tubal blockage or pelvic distortion. Uterine fibroids may need removal via laparotomy, laparoscopy, or hysteroscopy (accessed via the cervix) (Bosteels, Kasius, Weyers, et al., 2013). Laparoscopic removal of endometrial adhesions and implants, and draining of hydrosalpinges (endometrial fluid pockets) can normalize reproductive function (ASRM, 2012d). Weight normalization and optimal nutritional and blood sugar maintenance maximize the chance of pregnancy, especially for women with polycystic ovary syndrome.

Drug therapy may be indicated for male infertility. Problems with the thyroid or adrenal glands are corrected with appropriate medications. Infections are identified

and treated promptly with antimicrobials. Surgery may be needed to correct varicoceles, blockages, or tumors. FSH, gonadotropins, and clomiphene may be used to stimulate spermatogenesis in men with hypogonadism. Other health issues, such as weight or smoking, may need to be addressed through counseling.

The primary care provider is responsible for informing clients fully about the prescribed medications. However, the nurse must be ready to answer clients’ questions and to confirm their understanding of the drug, its administration, potential side effects, and expected outcomes.

Ovarian Stimulation. If the ovarian reserve is determined to be sufficient, pharmacologic therapy is often directed at stimulating the ovary to produce follicles. The most common ovarian stimulants include the selective estrogen receptor modulator (clomiphene citrate) or gonadotropin (FSH, LH). Clomiphene is an oral medication taken on set days early in the cycle, whereas gonadotropins are injected daily. However, if the ovarian reserve is low, interventions center on using donor eggs and IVF (see following discussion of Assisted Reproductive Technology).

Drugs supporting ovulation include metformin (an insulin sensitizing agent) or dexamethasone (a steroid) to potentiate clomiphene for anovulatory cycling women who have polycystic ovary disease (Misso, Teede, Hart, et al., 2012); bromocriptine to treat anovulation associated with hyperprolactinemia; and TSH (Synthroid) for hypothyroidism. Women with polycystic ovary syndrome, a history of recurrent miscarriage, or who have experienced oocyte retrieval may have insufficient progesterone to maintain an early pregnancy. Exogenous progesterone or human chorionic gonadotropin may be given to support early pregnancy until placental production is sufficient (Shah & Nagarajan, 2013). Commonly used medications are summarized in the Medication Guide.

MEDICATION GUIDE

Infertility Medications

DRUG	INDICATION	MECHANISM OF ACTION	DOSAGE	COMMON SIDE EFFECTS
Clomiphene citrate	Ovulation induction, treatment of luteal phase inadequacy	Thought to bind to estrogen receptors in the pituitary, blocking them from detecting estrogen	Tablets, starting with 50 mg/day by mouth for 5 days beginning on fifth day of menses; if ovulation does not occur, may increase dose next cycle-variable dosage	Vasomotor flushes, abdominal discomfort, nausea and vomiting, breast tenderness, ovarian enlargement
Menotropins (human menopausal gonadotropins [hMG])	Ovarian follicular growth and maturation	LH and FSH in 1:1 ratio, direct stimulation of ovarian follicle; given sequentially with human chorionic gonadotropin (hCG) to induce ovulation	IM or subcutaneous injections, dosage regimen variable based on ovarian response. Initial dose is 75 International Units of FSH and 75 International Units of LH (1 ampule) daily for 7-12 days followed by 10,000 International Units hCG	Ovarian enlargement, ovarian hyperstimulation, local irritation at injection site, multifetal gestations
Follitropins (purified FSH)	Treatment of polycystic ovary syndrome (PCOS); follicle stimulation for assisted reproductive techniques	Direct action on ovarian follicle	Subcutaneous or IM injections, dosage regimen variable	Ovarian enlargement, ovarian hyperstimulation, local irritation at injection site, multifetal gestations
Human chorionic gonadotropin (hCG)	Ovulation induction	Direct action on ovarian follicle to stimulate meiosis and rupture of the follicle	5000-10,000 International Units IM 1 day after last dose of menotropins; dosage regimen variable	Local irritation at injection site; headaches, irritability, edema, depression, fatigue
Exogenous progesterone	Treatment of luteal phase inadequacy	Direct stimulation of endometrium	Vaginal gel 8%, 1 prefilled applicator per day; after ovulation induction, continue through 10-12 weeks of pregnancy	Breast tenderness, local irritation, headaches
GnRH antagonists (ganirelix acetate, cetorelix acetate)	Controlled ovarian stimulation for infertility treatment	Suppress gonadotropin secretion; inhibit premature LH surges in women undergoing ovarian hyperstimulation	250 mcg daily subcutaneously usually in the early to midfollicular phase of the menstrual cycle; usually followed by hCG administration	Abdominal pain, headache, vaginal bleeding, irritation at the injection site
Metformin (off-label use)	Restores cyclic ovulation and menses in many women with PCOS	Induces ovulation through reducing insulin resistance and thus affecting gonadotropins and androgens; stimulates the ovary	Initial dose is 500 mg/day and titrated up over several weeks to 1500 mg/day. Administered orally	Nausea, vomiting, diarrhea, lactic acidosis, liver dysfunction
Letrozole (off-label use)	Ovulation induction	Aromatase inhibitor that inhibits E ₂ production, which causes an increase in LH:FSH ratio	2.5- to 5-mg tablets Administered orally for 5 days beginning on day 3 to 5 of menses	Hot flashes, headaches, breast tenderness, may increase risk of congenital anomalies

FSH, Follicle-stimulating hormone; IM, intramuscular; LH, luteinizing hormone.

Assisted Reproductive Technology

The Centers for Disease Control and Prevention (CDC) (2014) define **assisted reproductive technology (ART)** as fertility treatments in which both eggs and sperm are handled. In general, these treatments involve removing the eggs from the woman, fertilizing the eggs in the laboratory, and returning the embryo or embryos to the woman or surrogate carrier. Although vital for some patients, IVF and similar treatments account for less than 3% of infertility services (ASRM, 2013). The following discussion describes the commonly used ARTs.

Intrauterine Insemination. Ovarian stimulation therapy is then followed with timed intercourse. If sperm quality is low or female factors such as unfavorable cervical mucus, semen allergy, or endometriosis is suspected, the sperm can be introduced directly into the uterus using *intrauterine insemination (IUI)* (Veltman-Verhulst, Cohlen, Hughes, & Heineman, 2012). This is also the preferred technique for introducing donor sperm, or sperm that needs to be washed.

In Vitro Fertilization. *In vitro fertilization–embryo transfer (IVF-ET)* is used when blockage or inflammatory changes of endometriosis are suspected to impair fertilization or tubal transport or in the case of male subfertility (Pandian, Gibreel, & Bhattacharya, 2012). Ovarian follicles are monitored via ultrasound and removed at maturity through intravaginal needle aspiration or laparoscopic procedure. Fertilization with sperm occurs in a dish. If sperm are not available via ejaculation, they can be retrieved via needle from the testicle, epididymis, or vas deferens.

A micromanipulation technique of the follicle called *intracytoplasmic sperm injection (ICSI)* makes it possible to achieve fertilization even with few or poor-quality sperm by introducing sperm beneath the zona pellucida directly into the egg. ICSI offers the opportunity to enhance the chances of fertilization in cases of a severe male factor (i.e., poor sperm quality). Another micromanipulation option is *assisted hatching*. In some instances, the zona pellucida is thick or tough and the embryo cannot break through, or “hatch,” through this coating in the blastocystic phase of development. An infrared laser is used to create a hole in the zona pellucida so that the embryo can break through and implant.

Preimplantation genetic diagnosis (PGD) can be done on a single cell removed from each embryo after 3 to 4 days. PGD is a form of early genetic testing designed to screen for inherited diseases. Developing embryos without the gene associated with the disease are transferred to the uterus. Couples must be counseled about their options and choices, when genetic analysis is considered.

With the availability of extended culture medium, embryos transferred at the blastocyst stage (day 5) have a significantly

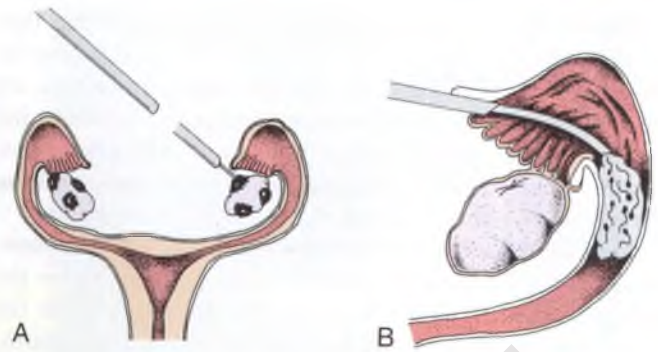

FIG 9-5 Gamete intrafallopian transfer. **A**, Through laparoscopy, a ripe follicle is located and fluid containing the egg is removed. **B**, The sperm and egg are placed separately in the uterine tube, where fertilization occurs.

better chance of live birth than the older practice of transferring the embryo at the cleavage stage (day 3) (ASRM, 2013a). Because of this improvement, the ASRM recommends no more than two embryo transfers at a time, except in women with poor fertility prognosis (ASRM, 2013b). See the Community Activity Box, which has some suggestions for further exploration about IVF.

Gamete Intrafallopian Transfer and Zygote Intrafallopian Transfer. *Gamete intrafallopian transfer (GIFT)* is similar to IVF-ET. GIFT requires women to have at least one normal uterine tube. Ovulation is induced as in IVF-ET, and the oocytes are aspirated from follicles via laparoscopy (Fig. 9-5, A). Semen is collected before laparoscopy. The ova and sperm are then transferred to one uterine tube (see Fig. 9-5, B), permitting natural fertilization and cleavage. *Zygote intrafallopian transfer (ZIFT)* is similar to GIFT except fertilization occurs in vitro, and then the zygote is placed in the uterine tube. Less than 1% of all ARTs use intrafallopian transfer (ASRM, 2011).

Legal Tip: Cryopreservation

Sperm, ovarian tissue, oocytes, or embryos can be cryopreserved for later use. Couples who have excess embryos frozen for later transfer must be fully informed before consenting to the procedure, to make decisions regarding the disposal of embryos in the event of (1) death, (2) divorce, or (3) the decision that the couple no longer wants the embryos. Embryos can be frozen for prolonged periods, and live births have occurred from embryos frozen for 20 years (ASRM, 2011).

Oocyte Donation. Women who have ovarian failure or oophorectomy, who have a genetic defect, or who fail to achieve pregnancy with their own oocytes may be eligible for the use of *donor oocytes* (eggs). Oocyte donation is usually done by women who are younger than 35 years and healthy, and who are recruited and paid to undergo ovarian stimulation and oocyte retrieval. The donor eggs are then fertilized in the laboratory with the male partner's sperm. The recipient woman undergoes hormonal stimulation to allow development of the uterine lining. Embryos are then transferred. The psychosocial issues are similar to those in therapeutic donor insemination. Historically, the courts have upheld the gestational mother as the legal mother. Sometimes the gestational mother is also a surrogate mother (see later discussion), however, which could complicate the legal aspects. It is expected that the egg donor will have no rights or responsibilities in relation to the offspring.

COMMUNITY ACTIVITY

Visit the Attain IVF website (www.attainfertility.com). Research what an Attain IVF program is. Review the client information about Attain IVF programs using the woman's own eggs and those using donor eggs. Compare success rates and costs of these programs. Use this website to find the availability of a fertility clinic in your area that offers the Attain IVF program. Is the location accessible to public transportation and are the clinic hours convenient for clients? Review the clinic information regarding treatment options, success rates, financial considerations, client support, and other client resources. Is the information written so that it can be easily understood by a client with no medical background? Do you have suggestions for other information that could be included?

Embryo Donation. On occasion a couple decides that they do not want their frozen embryos, and they release these for “adoption” by other infertile couples. Infertility centers are struggling to develop guidelines and protocols to address the various legal and ethical issues associated with these procedures. Extensive medical testing of both partners who wish to release the embryos is required as well.

Surrogate Mothers and Embryo Hosts. Surrogate motherhood can be achieved by two methods. The first is for the surrogate mother to be inseminated with semen from the infertile woman's partner and to carry the baby until the birth. The baby is then formally adopted by the infertile couple. A less common method is to retrieve an ovum from the infertile woman, fertilize it with her partner's sperm, and place it into the uterus of a surrogate, who becomes an embryo host or gestational carrier. These interventions raise considerable legal and ethical issues that require extensive counseling of couples and the women who choose to become surrogates.

Therapeutic Donor Insemination. *Therapeutic donor insemination* (TDI), previously referred to as artificial insemination by donor, is used when the male partner has no sperm or a very low sperm count (less than 20 million motile sperm/ml), the couple has a genetic defect, or the male partner has antisperm antibodies. Couples need to be counseled extensively regarding the mutuality of their decision, their ability (particularly of the male partner) to grieve the loss of a biologic child, and long-term issues relating to parenting the child conceived through TDI. Couples also must be aware of the legal status of TDI in their state.

Table 9-3 summarizes ART procedures and their possible indications.

Success Rates and Costs of Assisted Reproductive Technology

Although remarkable developments have occurred in reproductive medicine, ARTs account for about 1% of all U.S. births (CDC, 2014). They are associated with many ethical and legal issues (Box 9-5). The lack of information or misleading information about success rates and the risks and benefits of treatment alternatives create difficulties for couples in making informed decisions.

BOX 9-5 Issues to Be Addressed by Infertile Couples Before Treatment

- Risks of multiple gestation
- Possible need for multifetal reduction
- Possible need for donor oocytes, sperm, or embryos, or for gestational carrier (surrogate mother)
- Whether to or how to disclose facts of conception to offspring
- Freezing embryos for later use
- Possible risks of long-term effects of medications and treatment on women, children, and families
- Stress management techniques and recommendation for ongoing psychologic and couples counseling

TABLE 9-3 Assisted Reproductive Technologies

PROCEDURE	DEFINITION	INDICATION
Intrauterine insemination	Prepared sperm is placed in uterus at ovulation.	Male subfertility; cervical factor; vaginal factors
In vitro fertilization–embryo transfer (IVF-ET)	A woman's eggs are collected from her ovaries, fertilized in the laboratory with sperm, and transferred to her uterus after normal embryo development has occurred.	Tubal disease or blockage; severe male infertility; endometriosis; unexplained infertility; cervical factor; immunologic infertility
Intracytoplasmic sperm injection	Selection of one sperm cell that is injected directly into the egg to achieve fertilization. Used with IVF-ET.	Male partner is azoospermic or has a very low sperm count; couple has a genetic defect; male partner has antisperm antibodies.
Assisted hatching	The zona pellucida is penetrated chemically or manually to create an opening for the dividing embryo to hatch and implant into uterine wall. Used with IVF-ET.	Recurrent miscarriages; to improve implantation rate in women with previously unsuccessful IVF attempts; advanced age
Gamete intrafallopian transfer (GIFT)	Oocytes are retrieved from the ovary, placed in a catheter with washed motile sperm, and immediately transferred into the fimbriated end of the uterine tube. Fertilization occurs in the uterine tube.	Same as for IVF-ET, except there must be normal tubal anatomy, patency, and absence of previous tubal disease in at least one uterine tube
Zygote intrafallopian transfer (ZIFT)	This process is similar to IVF-ET; after in vitro fertilization the ova are placed in one uterine tube during the zygote stage.	Same as for GIFT
Donor oocyte	Eggs are donated by an IVF procedure, and the donated eggs are inseminated. The embryos are transferred into the recipient's uterus, which is hormonally prepared with estrogen/progesterone therapy.	Early menopause; surgical removal of ovaries; congenitally absent ovaries; autosomal or sex-linked disorders; lack of fertilization in repeated IVF attempts because of subtle oocyte abnormalities or defects in oocyte-spermatozoa interaction
Donor embryo (embryo adoption)	A donated embryo is transferred to the uterus of an infertile woman at the appropriate time (normal or induced) of the menstrual cycle.	Infertility not resolved by less aggressive forms of therapy; absence of ovaries; male partner is azoospermic or is severely compromised
Gestational carrier (embryo host); surrogate mother	Gestational carrier: A couple undertakes an IVF cycle, and the embryo(s) is transferred to the uterus of another woman (the carrier) who has contracted with the couple to carry the baby to term. The carrier has no genetic investment in the child. Surrogate motherhood is a process by which a woman is inseminated with semen and then carries the fetus until birth.	Congenital absence or surgical removal of uterus; a reproductively impaired uterus, myomas, uterine adhesions, or other congenital abnormalities; a medical condition that might be life threatening during pregnancy, such as diabetes, immunologic problems, or severe heart, kidney, or liver disease; or gay male couple seeking genetic offspring
Therapeutic donor insemination (TDI)	Donor sperm are used to inseminate the female partner. Can be used with IUI, IVF-ET, GIFT or ZIFT	Male partner is azoospermic or has a very low sperm count; couple has a genetic defect; male partner has antisperm antibodies; lesbian couple

Nurses can provide information so that couples have an accurate understanding of their chances for a successful pregnancy and live birth. In 2011, the success rate for live birth with ART transfer procedures ranged from 46% for women younger than 35 years, to 9% for women more than 42 years (Society for Assisted Reproductive Technology [SART], 2013). Nurses also can provide anticipatory guidance about the moral and ethical dilemmas regarding the use of ARTs.

Success rates for pregnancy and for live births vary widely from center to center. Each couple's physical status, age, whether the embryos are fresh or frozen, and from eggs of the woman or a donor all factor into their individual chances for pregnancy. Costs vary by treatment and by region of the country: one cycle of IVF-ET averages \$12,400 (ASRM, 2011).

Risks of Assisted Reproductive Technology

ART carries the established risks associated with ovarian stimulation, such as nausea, fluid retention, or ovarian hyperstimulation; invasive procedures; psychologic stress; and general anesthesia (ASRM, 2011). The more common transvaginal needle aspiration requires only local or intravenous analgesia. Evidence of increased risk of congenital malformations associated with ART is mixed: the anomalies can be related to the underlying cause of infertility. In addition, the underlying cause of infertility, such as severe male infertility factor, can be passed on to the offspring. Infertility treatment increases the risk of placental problems and miscarriage. Multiple gestations are more likely and are associated with increased risks for both the mother and fetuses. Ectopic pregnancies occur more often, and these carry a significant maternal risk.

Adoption

Couples may choose to build their family through adoption of children who are not their own biologically. With increased availability of birth control and abortion and increasing numbers of single mothers keeping their babies, however, the adoption of Caucasian infants is extremely limited. Minority infants and infants with special needs, older children, and foreign adoptions are other options (Fig. 9-6).

Most adults assume that they will be able to have children of their own. The discovery that they are unable to do so is often accompanied by feelings of guilt or blame. These

FIG 9-6 After two miscarriages, this couple chose foreign adoption. (Courtesy Shannon Perry, Phoenix, AZ.)

feelings and frustrations, combined with the anxiety of waiting for pregnancies, feelings of loss, and the multiple medical procedures to investigate infertility, plus the legal uncertainties and potential financial considerations surrounding adoption, create many challenges for the adoptive couple preparing for parenthood.

Couples who decide to adopt a child have decided that being a parent and having a child is more important than the actual process of birthing the baby. The birth process is a very small aspect of becoming a parent. Prospective parents can become so focused on attempting to become pregnant with their own genetic child that they don't see alternate ways of creating a family and parenting a child. The question for potential adoptive couples to ponder is, "What is important to you—that you become parents or that you go through the experience of pregnancy and birth?" Nurses should have information on options for adoption available for couples or refer them to community resources for further assistance.

Some couples, after undergoing infertility treatments to no avail, will decide to live without children. Although this was not a choice initially, it does become a choice for some couples as they resolve their infertility (not physically, but psychologically).

KEY POINTS

- Infertility is the inability to conceive and carry a child to term gestation when the couple has chosen to do so.
- Infertility affects approximately 15% of otherwise healthy adults. Infertility increases as the woman ages, especially after age 40.
- In the United States, about 20% of infertility causes are unexplained. Of that 80% in which causative factors are known, about 40% are related to female causes, 40% are related to male causes, and 20% are attributable to both male and female causes.
- Common etiologic factors of infertility include decreased sperm production, ovulation disorders, tubal occlusion, and endometriosis. Obesity or smoking in either partner is receiving increasing attention as a cause of infertility.
- The investigation of infertility is conducted systematically and simultaneously for male and female partners.
- The couple's relationship dynamics, sexuality, and ability to cope with the psychologic and emotional effects caused by diagnostic procedures and treatment of infertility must be considered in the plan of care. Ongoing support is recommended.
- Most infertility cases are treated with conventional medical and surgical therapies.
- Reproductive alternatives for family building include ovarian stimulation, followed by IUI, IVF-ET, GIFT, or ZIFT, oocyte donation, embryo donation, TDI, gestational or surrogate motherhood, and adoption.

Problems of the Breast

Susan McKenney

© <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Discuss the pathophysiology of both benign and malignant breast disease affecting women through the life cycle.
- Design a nursing plan of care for the woman with a benign breast disorder.
- Understand the relevance and application of assessing risk for the development of breast cancer.
- Evaluate treatment alternatives for women with breast cancer.
- Integrate critical elements for teaching clients who have undergone medical-surgical management of malignant neoplasms of the breast.
- Examine survivorship issues for the woman and her family after treatment for breast cancer.

Problems of the breast affect women throughout most of their lives; starting at early ages with variances in breast development, through the naturally occurring changes related to aging, gaining weight, or becoming pregnant. These changes continue through menopause. Variables that can affect these changes include certain foods or hormones, both endogenous and exogenous. There are variations in the presentation and management of benign breast diseases. Understanding breast disease, along with understanding how to recognize and address risk factors, is not only critical for a woman's care, but also vital in ensuring that adequate breast cancer prevention strategies are used.

This chapter explores breast conditions, including benign and malignant breast diseases, and how breast cancer diagnosis and treatment affect women of all age groups. The unique complexities of the very young and the recent changes to care of older women are addressed. Relevant survivorship issues are discussed with implications for primary women's health care.

Nurses, as important advocates in the health care team, provide expertise through education, support, and advocacy. They teach women about breast disease and cancer. They provide support and advocacy through the actual nursing care delivered, which includes holistic attention to all biopsychosocial and spiritual issues in helping women achieve quality outcomes.

BENIGN CONDITIONS OF THE BREAST

Anatomy and physiology of the normal breast is discussed in Chapter 4. The following text focuses on the normal variations of the breasts and the most common benign breast conditions.

Anatomic Variances

Micromastia and Macromastia

Micromastia, or underdevelopment of breast tissue, is a congenital condition that can affect a woman's self-esteem. Augmentation may be done to correct the variant in development, but usually it is not done until breast development is complete. Because this procedure usually is considered to be cosmetic, it may not be covered by all insurance companies. However, if there is documentation of a congenital abnormality, it might be covered.

Macromastia, or breast hyperplasia, is a condition in which women have very large, heavy, and pendulous breasts. Like the former condition, it is not usually corrected by a plastic surgeon until after complete breast development and then only if the woman chooses to have this procedure. If done too early, the breast can continue to grow after reduction. Breast reduction mammoplasty can relieve a woman of pain in the neck and shoulders. It should be noted that if reduction is done, breast feeding later in life might be difficult due to potential damage to milk-producing ducts, and there can be decreased sensations and pain secondary to scar tissue.

Developmental Anomalies

Asymmetric breast development is often seen in adolescent women and is a normal variation unless a palpable abnormality is detected (Katz & Dotters, 2012). A teenager may choose a prosthetic to achieve symmetry until she is fully matured, at which point she can decide if she still needs the prosthesis.

Supernumerary nipples or breasts are fairly common anomalies that are found along the breast or milk lines that go from the axilla to the groin area. Usually there is no treatment recommended, but if the extra nipples or breast tissue is bothersome, it can be removed surgically (Katz & Dotters, 2012).

Pathophysiology of Benign Breast Disease

In defining breast disorders from a pathologic standpoint, they are best understood as a heterogeneous group of lesions that may represent a palpable mass, a nonpalpable abnormality on imaging, or an incidental microscopic finding discovered during surgery. The two goals in the pathologic evaluation of a breast biopsy are to distinguish benign from malignant in situ or invasive tumors of the breast and to assess the risk of subsequent breast cancer associated with the lesion.

Nonproliferative lesions, including cysts, papillary apocrine change, epithelial calcifications (on mammography), or hyperplasia of the usual type, do not increase risk for breast cancer (Katz & Dotters, 2012). Proliferative lesions without atypia include intraductal papilloma, moderate hyperplasia, sclerosing adenosis, radial scar, and fibroadenomas. The estimated elevated risk is 1.5 to 2 times that of women who do not have these lesions (Katz & Dotters). Atypical hyperplasias are defined as proliferative lesions that possess some, but not all the features of carcinoma in situ. Atypical ductal hyperplasia (ADH) and atypical lobular hyperplasia (ALH) are the two most common, with a risk factor 4 to 5 times greater for developing breast cancer (Katz & Dotters).

Cystic Masses

Fibrocystic Changes

The most common benign breast problem is **fibrocystic change**, found in varying degrees in healthy women's breasts. Fibrocystic changes are characterized by lumpiness, with or without tenderness, in both breasts (Katz & Dotters, 2012). Fibrocystic breast condition involves the glandular breast tissue. The sole known biologic function of these glands is the production and secretion of milk. Except for proliferative change known as hyperplasia, which is associated with a slightly elevated risk of breast cancer, or atypical hyperplasia, which is associated with a moderately increased risk of breast cancer, the histologic findings associated with fibrocystic changes are part of the spectrum of normal involutional patterns of the breast (Katz & Dotters).

Etiology. Fibrocystic changes tend to appear most commonly in women in their second and third decades of life. The most significant contributing factor to fibrocystic breast condition is a woman's normal hormonal variation during her monthly cycle. Many hormonal changes occur as a woman's body prepares each month for a possible pregnancy. The most important of these hormones are estrogen and progesterone, which directly affect the breast tissues by causing cells to proliferate. Other hormones, however, also play an important role in fibrocystic changes. Prolactin, growth factor, insulin, and thyroid hormones can affect cell growth within the breast tissue.

Clinical Manifestations and Diagnosis. The usual clinical presentation of fibrocystic change is lumpiness in both breasts; however, single simple cysts also can occur. Symptoms usually develop about a week before menstruation begins and subside about a week after menstruation ends. They include dull, heavy pain and a sense of fullness and tenderness, often in the upper outer quadrants of the breasts, that increases in the premenstrual period. Physical examination may reveal excessive nodularity. Women in their 20s report the most severe pain. Women in their 30s have premenstrual pain and tenderness; small multiple

nodules are usually present. Women in their 40s usually do not report severe pain, but cysts will be tender and often regress in size. The woman with fibrocystic change can form cysts that manifest as painful enlarging lumps in her breasts. Cysts are common in premenopausal women who are not receiving estrogen therapy. The cysts are soft on palpation, well differentiated, and movable. Deeper cysts, especially aggregations of cysts, are indistinguishable by palpation from carcinomas, which are malignant growths that infiltrate surrounding tissue.

A first step in the workup of a breast lump is ultrasonography to determine if it is fluid filled or solid. Fluid-filled cysts are aspirated, and the woman is monitored on a routine basis for development of other cysts. If the lump is solid and the woman is older than 35 years, mammography is obtained. A fine-needle aspiration (FNA) is performed, regardless of the woman's age, to determine the nature of the lump. In some cases, a core biopsy may be necessary after FNA to harvest adequate amounts of tissue for pathologic examination (Katz & Dotters, 2012).

Therapeutic Management. Treatment for fibrocystic changes is usually conservative. Management can depend on the severity of the symptoms. Dietary changes and vitamin supplements are one management approach. Although research findings are contradictory, some practitioners advocate reducing consumption of or eliminating methylxanthines (i.e., colas, coffee, tea, chocolate) (Katz & Dotters, 2012). Some symptom relief may be achieved by refraining from both smoking and consuming alcohol. Recommended pain relief measures include analgesics or nonsteroidal antiinflammatory drugs (NSAIDs) such as ibuprofen, wearing a supportive bra, and applying heat to the breasts.

Taking vitamin E and B₆ supplements and decreasing sodium intake or taking mild diuretics before menses have been reported to reduce symptoms. Some women report relief while taking oral contraceptives, but others report worsening of symptoms. Danazol, bromocriptine, and tamoxifen have also been used with varying degrees of success (Katz & Dotters, 2012). Evening primrose oil can be effective for some women, although adequate evidence is lacking. It is important to stress that women may need to try several approaches for a number of months before noting improvement (Katz & Dotters).

Surgical removal of nodules is attempted only in rare cases. In the presence of multiple nodules, the surgical approach involves multiple incisions and tissue manipulation and may not prevent the development of more nodules.

Breast Pain (Mastalgia)

Breast pain occurs in many women at some time in their reproductive years, especially the perimenopausal years. The symptom of breast pain commonly is associated with fibrocystic changes that were previously discussed. Breast pain is unusual in breast cancer and, if it is present, is more likely (though uncommon) only in a locally advanced breast cancer. This is important information because many women fear that their breast pain is a symptom of cancer. The character and pattern of breast pain are important in understanding how to manage this symptom. It is important to distinguish between cyclic versus noncyclic, and diffuse versus focal. Patterns can clue one into whether or not the pain is hormonal or related to a specific etiology—a cyst or trauma from external injury or surgery (Katz & Dotters, 2012).

Diagnostic procedures may include serologic tests for prolactin and human chorionic gonadotropin (hCG) levels in premenopausal women, ultrasound, mammography, and aspiration and biopsy for cysts. Treatment depends on the cause of the pain and may include the measures described for pain related to fibrocystic changes. Idiopathic pain is usually treated with NSAIDs (Katz & Dotters, 2012).

Solid Masses

A benign solid mass in contrast to a cystic mass has no fluid component. It is generally described as a smooth, round, mobile, painless lesion that is discrete on palpation. It is a pseudoencapsulated or multilobulated lesion that originates in the stroma of the breast. Solid benign masses in this category with no associated increased risk for breast cancer include fibroadenomas, radial scar, granular cell tumor, fibromatosis, pseudoangiomatous stromal hyperplasia (PASH), and hamartoma. Lipoma, a fatty tumor, is also common, whereas hemangiomas or vascular lesions are less common.

Fibroadenoma

The most common solid mass of the breast is a **fibroadenoma**. It is the single most common type of tumor seen in the adolescent population, although it can also occur in women in their 20s and 30s. Fibroadenomas are discrete, usually solitary lumps less than 3 cm in diameter (Katz & Dotters, 2012). Occasionally the woman with a fibroadenoma experiences tenderness in the tumor during the menstrual cycle. Fibroadenomas do not increase in size in response to the menstrual cycle (in contrast to fibrocystic cysts). The mass tends to remain the same size or increase in size slowly over time. Fibroadenomas increase in size during pregnancy and decrease in size as a woman ages. Diagnosis is made by a review of the client history and physical examination. Mammography, ultrasonography, or magnetic resonance imaging (MRI) may be used to determine the type of lesion, and FNA may be used to determine the underlying disorder. Surgical excision may be necessary if the lump is suspicious or if the symptoms are severe. Fibroadenomas do not respond to either dietary changes or hormonal therapy. Periodic observation of masses by professional physical examination or mammography may be all that is necessary for those masses not requiring surgical intervention (Katz & Dotters).

Reactive Inflammatory Lesions

Mammary duct ectasia or periductal mastitis is the most common benign lesion in this category. Granulomatous mastitis is a rare cause for inflammation. It is characterized by granuloma and abscess formation and is more common in women ages 40 to 60 (Katz & Dotters, 2012). Other reactive inflammatory lesions include fat necrosis, which results from trauma to the fatty tissue of the breast; Mondor disease, which is phlebitis secondary to trauma; and diabetic mastopathy, which is an autoimmune, painful fibrotic mass commonly seen in women who are insulin dependent.

Mammary Duct Ectasia

Mammary duct ectasia characterized by dilated ducts and nipple inversion (acquired; not congenital) most commonly presents during middle age, usually in women who are still menstruating. It is not common in postmenopausal years. The

incidence is higher in women who smoke or who have diabetes. Pathologically, the ducts are dilated with thick walls. There is fibrotic stroma, rupture, and leakage of secretion into surrounding tissue that results in inflammation and fat necrosis. Characteristic signs include pain, redness of the skin, nipple inversion, and greenish nipple discharge. Fever can be present or absent. The breast tissue is thickened and inflamed, suggestive of mastitis, but abscess formation is also possible. Management includes pain medication and antibiotics. Applying heat to the breast, wearing a supportive bra, using a breast pad for leaking, and sleeping on the unaffected side may provide comfort. A surgical incision and drainage are usually performed for abscess. Recurrence rates are higher in women who smoke (Mayo Foundation for Medical Education and Research, 2012).

Nipple Discharge

Nipple discharge is a common occurrence that concerns many women. Though most nipple discharge is physiologic, each woman who presents with this problem must be evaluated carefully because in a small percentage of women, nipple discharge can be related to a serious endocrine disorder or malignancy. Bilateral serous discharge from multiple ducts, expressed during nipple stimulation, can be considered a normal finding. Spontaneous discharge, bloody discharge, or discharge from only one or two ducts must be evaluated (Katz & Dotters, 2012).

One form of nipple discharge not related to malignancy is **galactorrhea**, a bilaterally spontaneous, milky, sticky discharge. It is a normal finding in pregnancy. Galactorrhea can also occur as the result of elevated prolactin levels. Increased prolactin levels can be a result of a thyroid disorder, pituitary tumor, coitus, eating, stress, trauma, or chest wall surgery. Obtaining a complete medical history on each woman is essential. Certain medications may precipitate galactorrhea. Some tranquilizers (i.e., tricyclic antidepressants), narcotics, and antihypertensive medications, as well as oral contraceptives, can precipitate galactorrhea (Lobo, 2012). Diagnostic tests include a prolactin level, a microscopic analysis of the discharge from each breast, a thyroid profile, a pregnancy test, and a mammogram. Ideally, prolactin levels should not be drawn directly after a breast examination, sexual activity, or exercise because these activities may increase the levels above the normal range (Lobo).

Nipple discharge ranges from milky white to bloody and can be green and brown. If blood is suspected, Hemocult testing should be done because bloody discharge may be related to malignancy (Katz & Dotters, 2012).

Intraductal Papilloma

Intraductal papilloma is a relatively rare, benign condition that develops in the terminal nipple ducts. The cause is unknown. It usually occurs in women between ages 30 and 50. Papillomas are usually too small to be palpated (less than 0.5 cm), and present with the characteristic sign of serous, serosanguinous, or bloody nipple discharge. The discharge is unilateral and spontaneous. A ductogram (imaging technique to evaluate lesions causing nipple discharge) is a common way of making the diagnosis, along with mammography and core biopsy. After the possibility of malignancy is eliminated, treatment for papillomas includes excision of the affected segments of the ducts and breasts (Katz & Dotters, 2012).

TABLE 10-1 Comparison of Common Manifestations of Benign Breast Masses

FIBROCYSTIC CHANGES	FIBROADENOMA		INTRADUCTAL PAPILLOMA	MAMMARY DUCT ECTASIA
Multiple lumps	Single lump	Single lump	Nonpalpable	Mass behind nipple
Nodular	Well delineated	Well defined	Not well delineated	Not well delineated
Palpable	Palpable	Palpable	Nonpalpable	Palpable
Movable	Movable	Movable	Nonmobile	Nonmobile
Round, smooth	Round, lobular	Round, lobular	Small, sometimes multiple	Irregular
Firm or soft	Firm	Soft	Firm or soft	Firm
Tenderness influenced by menstrual cycle	Usually asymptomatic	Nontender	Usually nontender	Painful, burning, itching
Bilateral	Unilateral	Unilateral	Unilateral	Unilateral
May or may not have nipple discharge	No nipple discharge	No nipple discharge	Serosus or bloody nipple discharge	Thick, sticky nipple discharge

Table 10-1 compares common manifestations of benign breast masses.

Infections of the Breast

Cellulitis with and without abscess formation is very common in women in most age groups but uncommon in younger developing girls. The at-risk population has some shared characteristics such as obesity, large breasts, previous surgeries, radiation, sebaceous cysts of the chest and axillae, smoking, and diabetes. Nipple piercing has been associated with infection and abscess formation (Katz & Doters, 2012). The most common pathogen is *Staphylococcus aureus*; however, methicillin-resistant *Staphylococcus aureus* (MRSA) is becoming prevalent. Cellulitis of the breast presents as painful, red inflamed skin that is usually thickened. It feels warm or hot to touch. Abscess is present when there is a ballotable mass associated with these symptoms. Imaging studies identify a mixed fluid collection on ultrasound. If abscess is present, it can be managed by percutaneous ultrasound aspiration or, if large enough, incision and drainage. Treatment for cellulitis usually includes antibiotics.

Lactational infections are similar to cellulitis, except they occur during pregnancy and postpartum. Mastitis is discussed in Chapters 25 and 33.

CLINICAL REASONING CASE STUDY

Breast Cancer Treatment Options

Susan is a 36-year-old with stage I breast cancer. Her family history includes her mother being diagnosed with breast cancer at age 55 and her maternal aunt diagnosed with ovarian cancer at age 48. Both succumbed to their diseases. Her menstrual periods started at age 11. She has one sibling, a sister, age 40, who has had no breast health issues. Susan is divorced, has two young children, both in elementary school, and is employed full-time as a dental assistant. She states that she is scared and doesn't want to have a mastectomy but thinks she should because she has heard that is the best treatment for long-term survival. How would you respond to this statement?

- Evidence—Is there sufficient evidence to draw conclusions about what the nurse should say?
- Assumptions—What assumptions can be made about the following issues?
 - Differences between breast-conserving surgery and mastectomy for stage I cancer
 - Genetic and family risk factors
 - Psychosocial and socioeconomic needs of single parent facing breast cancer treatment
- What implications and priorities for nursing care can be made at this time?
- Does the evidence objectively support your conclusion?

CARE MANAGEMENT FOR WOMEN WITH BENIGN BREAST CONDITIONS

Assessment of the woman with a benign breast condition should include a careful history and physical examination. The history should focus on the woman's risk factors for breast diseases, events related to the breast mass, and health maintenance practices. (Risk factors for breast cancer are discussed later in this chapter.) Information related to the breast symptoms should include how, when, and by whom the symptoms were discovered. The interval between discovery and seeking care is crucial. The following client information is documented: presence of pain, whether symptoms increase with menses, dietary habits, smoking habits, use of oral contraceptives or hormone replacement therapy, personal history of breast cancer, family history of breast cancer, regularity of breast self-examination (BSE), and the examination technique used. It is important to note, however, that in regard to BSE, as mentioned later in this chapter, the American Cancer Society (2013) no longer recommends this as a monthly screening, but they do recommend clinical breast exam by a clinician. The woman's emotional status, including her stress level, fears, and concerns, and her ability to cope also should be assessed.

Physical examination may include assessment of the breasts for symmetry, masses (size, number, consistency, mobility), and nipple discharge.

Nursing actions might include the following:

- Discuss the intervals for and facets of breast screening, including professional examination and mammography (see Table 10-3). Women with breast implants may need special views (called push backs) of the breast, and precautions taken not to rupture the implant during mammography.
- Provide written educational materials.
- Encourage the verbalization of fears and concerns about treatment and prognosis.
- Provide specific information regarding the woman's condition and treatment, including dietary changes, drug therapy, comfort measures, complementary and alternative therapies, stress management, and surgery.
- Demonstrate correct BSE technique if a woman desires to practice it (see Teaching for Self-Management: Breast Self-Examination in Chapter 4).
- Describe pain-relieving strategies in detail, and collaborate with the primary health care provider to ensure effective pain control.
- Encourage discussion of feelings about body image.
- Refer to a stress management resource if needed to cope with long-term consequences of benign breast conditions.

MALIGNANT CONDITIONS OF THE BREAST

Breast cancer remains the second leading cause of cancer death in women ages 45 to 55, with 232,670 new cases estimated in 2013 (American Cancer Society [ACS], 2013a). Non-Hispanic white women have a higher incidence than other racial/ethnic groups, but mortality rates are higher among black women. The incidence has decreased since the year 2000, and is now stable at 1:8 women at risk for breast cancer. This is most likely due to adherence of American Cancer Society (ACS) screening and better targeted therapies for treatment. Statistics suggest that about 79% of breast cancers are found in women over the age of 50. There are 2.9 million survivors of breast cancer, with statistics indicating a survival rate of 83% at 10 years after diagnosis (ACS 2013a), which has implications for women's primary health care and prevention of second malignancies. Although the exact cause for breast cancer remains unknown, at least 15% are related to a genetic mutation.

Etiology of Breast Cancer and Risk Factors

The risk factors are considered a mosaic of statistical data points that, when put together and used correctly, can help one understand what groups of women need more heightened surveillance in high risk clinics or referral to a genetic counselor for genetic testing. Some risk factors cannot change, such as gender, age, the time of menarche, menopause, and time of first live birth. The length of time on unopposed estrogen is a significant risk factor. Having a personal history of breast cancer is a constant risk factor, leading to a risk for developing a second malignancy. Breast cancer affects predominantly women, but 1% of all breast cancers occur in men. Geographic differences are related to breast cancer risk. For instance, when women from Japan, where there is one of the lowest rates of breast cancer, move to Western countries, their risk equalizes to that of the native population. Whether this is due to diet or other environmental exposure is not yet clear but may be a combination of the two. Experiencing a first pregnancy after age 40 is another risk factor. Having fibrocystic disease with any of the previously discussed proliferative diseases with atypia increases one's risk fourfold. Higher breast density may make interpretation of mammography more difficult. Legislation has mandated that radiologists need to communicate this information to women, probably more as a liability protection.

Relative factors such as maintaining one's ideal body weight is important in that heavier women have higher circulating estrogens and that regular exercise reduces risk by about 20%. Dietary risk factors include high saturated fats and moderate to high alcohol consumption. The use of exogenous hormones such as oral contraception or hormone replacement for postmenopausal support becomes a risk factor when used for more than 10 years. Diethylstilbestrol (DES), a drug used years ago to maintain pregnancy, is slightly correlated with elevated risk.

Genetic Considerations

Having a genetic mutation, either BRCA1 or BRCA2, may create an 85% chance of developing breast cancer in a woman's lifetime. There are other mutations such as the Li-Fraumeni syndrome and Cowden syndrome, which have different family pedigrees. Genetic testing is complex and it is very important

BOX 10-1 Risk Factors Included in the Breast Cancer Risk Assessment Tool

- Woman's age
- Number of first-degree relatives affected
- Age of woman at menarche
- Age of woman at first live birth
- Number of breast biopsies
- History of atypical hyperplasia in biopsy specimens

that this be done in conjunction with genetic counseling. Not all women with family history of cancer are at risk, and there are statistical models that help determine the risk-benefit ratio of testing for a genetic mutation. Also if the estimated risk determines that there is probability for a mutation, it is suggested that the living family member with breast cancer be tested first. This helps validate whether additional testing is needed in the family. After testing, if the result is negative, the genetics team can determine the tested family members' estimated risk for subsequent development of breast cancer. This information uniquely tailors surveillance for women who remain at greater than a 20% risk. Women and men who carry a mutation have choices to make in how they manage their lives. They can be followed in a dedicated high risk clinic with biannual clinical breast examinations by an expert, along with imaging that alternates between diagnostic mammography at one visit and breast MRI at the other visit.

The Breast Cancer Risk Assessment Tool (Gail Model), a risk calculator used in the first- and second-generation national prevention trials, can quantify risk for development of breast cancer at 5 years and then a lifetime risk (up to age 90). (Risk factors are listed in Box 10-1; the tool is available at www.nci.nih.gov/bcrisktool.)

Chemoprevention

Some drugs are used for prevention of breast cancer, although research is ongoing to test their efficacy. Chemoprevention can be approached with either tamoxifen or raloxifene, both U.S. Food and Drug Administration (FDA) approved to prevent invasive cancers (Mayo Clinic, 2011). Both these drugs are taken once daily, but have very different side effect profiles. Tamoxifen can cause hot flashes, weight gain, cataracts, chemical hepatitis, and blood clots and carries a small risk for uterine cancer. Raloxifene can contribute to heart disease or stroke. Raloxifene is a good choice for healthier women who might be at risk for osteopenia. Tamoxifen is available for pre- and postmenopausal women, whereas raloxifene is available only for postmenopausal women. (See Medication Guides later in this chapter.) Providing comprehensive information on these drugs helps women to make informed decisions, empowering them to take charge of their lives.

Pathophysiology of Malignant Breast Disease

Although breast cancer presents within the breast, it is, in fact, considered to be a systemic disease because as it is growing in the breast, invasive tumors have the capability of traveling elsewhere in the body (Redig & McAllister, 2013). There are more than 20 types of breast cancers that can be identified and they all act and behave differently. Genetic alterations, either inherited

or spontaneous, are found in the epithelial cells, compromising ductal or lobular tissue. Researchers are investigating which oncogenes (potentially cancer-inducing genes) may cause breast cancer or change its growth pattern and how the process can be stopped.

Breast cancer begins in the epithelial cells lining the mammary ducts of the breast. The rate of breast cancer growth depends on the effects of estrogen and progesterone and other prognostic factors such as its grade, Ki67 score (a proliferative marker), human epidermal growth factor receptor 2 (HER2)/neu receptor status, and other variables. These cancers can be either invasive (infiltrating) or noninvasive/nonspreading (in situ). Invasive or infiltrating breast cancers can grow into the wall of the mammary duct and into the surrounding tissues.

Generally breast cancer is either ductal or lobular. By far the most frequently occurring cancer of the breast is invasive ductal carcinoma. Ductal carcinoma originates in the lactiferous ducts and invades surrounding breast structures. The tumor is usually unilateral, not well delineated, solid, nonmobile, and nontender.

Lobular carcinoma originates in the lobules of the breasts. This type of breast cancer can be nonpalpable and appear smaller on imaging studies than its actual size.

Nipple carcinoma (Paget disease) originates in the nipple. It usually occurs with invasive ductal carcinoma and can cause bleeding, oozing, and crusting of the nipple.

A rarer form of breast cancer is known as inflammatory breast cancer, which is diagnosed by the appearance of a rash or reddish skin of the breast. It can be misdiagnosed as mastitis. A skin punch biopsy is performed, and the pathology report will state that there are breast cancer cells in the dermal lymphatic channels. It is usually aggressive and is classified as stage II breast cancer from its onset. There are also other types of less common forms of breast cancers such as mucinous and malignant phyllodes tumors.

Breast cancer can invade surrounding tissues in such a way that the primary tumor can have tentacle-like projections (referred to as being a spiculated mass). This invasive growth pattern can result in the irregular tumor border felt on palpation. As the tumor grows, fibrosis develops around it and can shorten Cooper ligaments, which result in the characteristic peau d'orange (orange peel–like skin) changes and edema associated with some breast cancers. If the breast cancer invades the lymphatic channels, tumors can develop in the regional lymph nodes, often occupying the axillary lymph nodes. The tumor may invade the outer layers of skin, creating ulcerations. Figure 10-1 indicates the portions of the breast where most breast cancers originate.

Metastasis results from seeding of the breast cancer cells into the blood and lymph systems, leading to tumor development in the bones, the lungs, the brain, and the liver. Breast cancer can be small or large—the size doesn't always equate with aggressiveness. Some aggressive small tumors spread quickly and some large tumors spread very slowly.

Clinical Manifestations and Diagnosis

When breast cancer is detected either as a palpable lump or ill-defined thickening in the breast, it is usually painless. One might

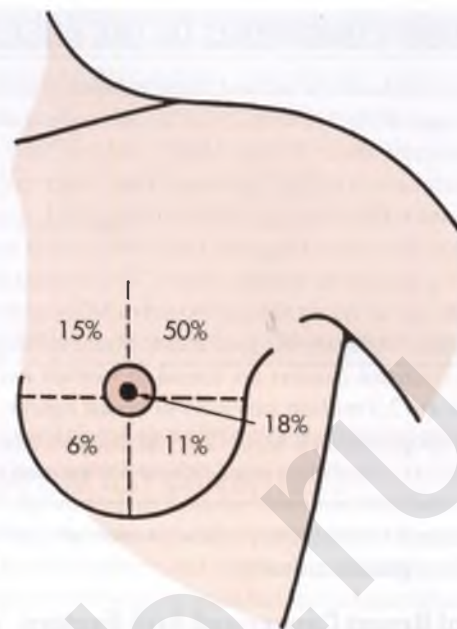

FIG 10-1 Relative location of malignant lesions of the breast. (Modified from DiSaia, P., & Creasman, W. [2007]. *Clinical gynecologic oncology* [7th ed.]. St. Louis: Mosby.)

TABLE 10-2 Staging of Breast Cancer*

STAGE	DEFINITION
Stage 0	Carcinoma in situ (intraductal carcinoma, lobular carcinoma, Paget disease) (Tis-N0-M0)
Stage I	Tumor <2 cm with negative nodes (T1-N0-M0) (includes microinvasive T1, <0.1 cm)
Stage IIA	Tumor 0 to 2 cm with positive nodes (including micrometastasis N1, or <0.2 cm), or 2 to 5 cm with negative nodes (T0-N1, T1-N1, T2-N0, all M0)
Stage IIB	Tumor 2 to 5 cm with positive nodes or >5 cm with negative nodes (T2-N1, T3-N0, all M0)
Stage IIIA	No evidence of primary tumor or tumor <2 cm with involved fixed lymph nodes, or tumor >5 cm with involved movable or nonmovable nodes (T0-N2, T1-N2, T2-N2, T3-N1, T3-N2, all M0)
Stage IIIB	Tumor of any size with direct extension to chest wall or skin, with or without involved lymph nodes, or any size tumor with involved internal mammary lymph nodes (T4-any N, any T-N3, all M0)
Stage IV	Any distant metastasis (includes ipsilateral supraclavicular nodes) (any T, any N, all M1)

*Breast cancer is most frequently staged according to the TNM classification system, which evaluates the tumor size (T), involvement of regional lymph nodes (N), and distant spread of the disease or metastases (M).

From National Cancer Institute. (2012). *What you need to know about breast cancer—Stages*. Available at www.cancer.gov/cancertopics/wyntk/breast.

see nipple retraction, skin dimpling or skin changes to the nipple, or redness with edema and pitting of the skin, which is suggestive of a locally advanced and aggressive form of breast cancer. Lymph nodes are always clinically examined to determine extent of the clinical stage. Clinical staging helps to understand the parameters of the breast problem and whether lymph node involvement is suspected. The clinical stage is what helps providers decide on how to proceed with treatment. This is referred to as the TNM system (National Cancer Institute, 2013) (Table 10-2). It sorts stage by size of tumor, lymph node, and whether metastasis is involved. It is the pathologic stage, which is determined after

TABLE 10-3 Screening Guidelines for Early Breast Cancer Detection

AGE (YR)	EXAMINATION	FREQUENCY
Average Risk for Asymptomatic Women		
20-39	Breast self-examination (BSE)	Not specified; inform women about the benefits and limitations of BSE, offer instructions; women may choose to perform regularly, irregularly, or not at all
	Clinical breast examination	At least every 3 years
40 and older	BSE	Not specified; inform women about the benefits and limitations of BSE, offer instructions; women may choose to perform regularly, irregularly, or not at all
	Clinical breast examination	Yearly
	Mammography	Yearly
High Risk Women (>20% Lifetime Risk)		
30 and older*	Clinical breast examination MRI and mammogram	Yearly

MRI, Magnetic resonance imaging.

*The best age to start should be decided between physician and woman after looking at her individual status.

Modified from American Cancer Society. (2013a). *Breast cancer facts and figures 2013-2014*. Atlanta, GA: Author. Available at <http://www.cancer.org/acs/groups/content/@research/documents/document/acspc-040951.pdf>.

surgery, that really correlates with overall prognosis and one's risk for recurrence at 2, 5, or 10 years.

Screening

Guidelines for breast cancer screening continue to evolve as new evidence is generated. BSE, once standard, has been scrutinized for its benefit in early detection and overall survival and is no longer recommended as a monthly examination (ACS, 2013). Clinical breast examinations are omitted by many clinicians, evidenced by lack of documentation in medical records and by client reports that this is not part of an annual examination. These two factors are significant in that women are often referred to breast clinics prematurely by their health care providers because there is a lack of understanding of normal variation versus real disease. Guidelines for screening mammography have changed. The U.S. Preventive Services Task Force (2009) recommends baseline mammography in average risk women at age 50, with mammograms every 2 years after that. The ACS (2013), however, continues to recommend baseline mammography at age 40 with annual mammograms after that.

Screening guidelines based on risk are outlined in Table 10-3. Nurses are key to educating women about screening. There is growing evidence among geriatric oncologists of the need to comprehensively assess older women. Women with multiple comorbidities may opt out of screening earlier, but all these decisions are individually based on discussions between the woman and her health care provider.

When caring for a woman with breast cancer, as in all situations, her cultural and ethnic background must be taken into account (see Cultural Considerations).

CULTURAL CONSIDERATIONS

Breast Screening Practices

Certain minority women tend to have low compliance rates in the use of early screening methods for breast cancer. Many factors play a role in influencing the screening practices of these women. African-American women reported not participating in early breast cancer screening because of discomfort with impersonal care from providers, lack of health care insurance, lack of funds to pay for mammograms, lack of awareness of community assistance within the health care system, lack of access to transportation, and feelings of fatalism, fear, helplessness, and powerlessness. Hispanic women cited lack of a regular physician, lack of health insurance coverage, inaccessibility of screening facilities, lack of access to transportation, and being unable to obtain time off from work. Asian women cited unawareness of mammography tests, gender and modesty concerns unique to their cultural beliefs, and fear resulting from a sense of vulnerability to breast cancer.

Interventions that will encourage minority women to participate in early breast cancer screening practices begin with the development of culturally sensitive community education programs designed to help women overcome barriers to reaching optimal levels of health. Programs should be designed to educate small groups of women about risk factors of breast cancer, prevention strategies, and early detection methods. Recruitment of women may be communicated through fliers in neighborhoods, women's groups, churches, clubs, and organizations. Use of incentives to reward participation may be helpful. Nurses and guest speakers of similar ethnicity as the attending group who are breast cancer survivors are valuable in providing meaningful information and support, and providing past, present, and future perspective to the educational content.

Mammography

Mammography remains the gold standard for breast cancer screening and early detection. New technologies that are considered for breast cancer screening must equal or exceed the performance of screen-film mammography to be accepted as screening tools. In other words, these technologies must demonstrate identification of more breast cancers that are missed by mammography, such as a higher fraction of early-stage cancers (stages 0 and I), and be cost-effective, noninvasive, and available and acceptable to clients. Full-field digital mammography (FFDM) is much like standard film mammography in that x-rays are used to produce an image of the breast. Film mammography is captured on x-ray film, however, and digital mammography is recorded with a computer.

Digital mammography is often recommended for women less than 50 years old, for women with high-density breasts, or for women who are not yet menopausal or have been in menopause for less than a year. For women in these groups, digital mammography detects more abnormalities that would otherwise go undetected, and both digital and standard mammography have the same rate of false-positive findings (WebMD, 2012). These images enable the radiologist to enlarge the image

as well as lighten and darken the background contrast and to find abnormalities that may go undetected with film mammography. An additional method to assist radiologists with reading mammograms, which can be important for facilities that do not have dedicated breast imaging radiologists, is computer-aided detection and diagnosis (CAD). For nearly two decades this device has been in use to help radiologists find suspicious changes on mammography studies. This can be especially important for film mammography evaluation. CAD electronically scans the mammogram first. It can detect tumors or other breast abnormalities and flag them for the radiologist to further investigate (ACS, 2013b).

A screening mammogram (Fig. 10-2) is performed on women who do not have any signs or symptoms of a breast abnormality. Diagnostic mammograms are performed when a screening mammogram identifies something warranting further inspection or if the woman or her physician or nurse finds a sign such as a lump, nipple discharge, or other breast symptom that is new.

One of the most valuable uses of mammography is the identification of calcifications within the breast. Though most are benign, some can be an early sign of breast cancer. There are two types of calcifications:

- **Macrocalcifications**—mineral deposits that are most likely changes in the breast caused by aging of the breast arteries, old injuries, or inflammation. They appear as large white dots or dashes. These deposits are related to noncancerous conditions and do not require a biopsy. These types of calcifications are found in about half of women older than age 50 and in 1 in 10 women younger than 50.
- **Microcalcifications**—fine white specks of calcium in the breast. They may be alone or in clusters and resemble grains of sand or salt. These can be more concerning depending on their pattern and shape. Those that are tightly clustered together and have irregular edges can be a sign of ductal carcinoma in situ (DCIS) or early stage I breast cancer and warrant biopsy.

FIG 10-2 Mammography. (Courtesy Shannon Perry, Phoenix, AZ.)

Mammography does have its limitations. It has not proven helpful in screening younger women due to the high breast density associated with youth. Roughly 78% of breast cancer can be identified through mammography, although this number is increased to 83% among women older than age 50 (Komen Foundation, 2013a). Ultrasound has become a valuable screening adjunct to mammography, especially for women with significant breast density. It is cost-effective, noninvasive, and widely available. Ultrasound has been helpful in distinguishing between fluid-filled masses (cysts) and solid masses (benign and malignant). It uses high-frequency sound waves to assess the breast tissue and axillae. The test is painless and noninvasive and requires no exposure to radiation. It has also been useful in performing image-guided biopsies (ACS, 2013a).

Magnetic Resonance Imaging

MRI has become a valuable screening adjunct to mammography and ultrasound. It may be useful in women with difficult-to-find masses, sometimes referred to as occult breast cancers (Komen Foundation, 2013b). There is growing popularity to use it for women diagnosed with breast cancer to rule out the presence of multicentric disease and determine the size of tumors (such as invasive lobular carcinomas), and it has been used increasingly for high risk women (such as those who carry a BRCA gene mutation). It is not, however, without drawbacks. One concern with MRI is that although it helps find small, difficult-to-detect abnormalities, it has been found to lead to more unnecessary mastectomies instead of lumpectomies with radiation (Komen, 2013b).

Positron emission tomography (PET) scans, which are based on glucose uptake metabolism, can help determine if breast cancer has spread to other parts of the body, identifying metastatic disease. Newer technologies for breast cancer screening are under development.

Biopsy

When a suspicious finding on a mammogram is noted or a lump is detected, diagnosis is confirmed by core needle biopsy (stereotactically or ultrasound-guided core) or by needle localization biopsy (Fig. 10-3). The latter procedure requires the collaborative efforts of both the radiologist and the surgeon. This often requires that the procedure take place in two different environments (radiology and surgery), so women need specific information regarding procedures, duration, and outcomes. In most facilities, core biopsies can be performed and the pathology results known the following day, providing the woman with

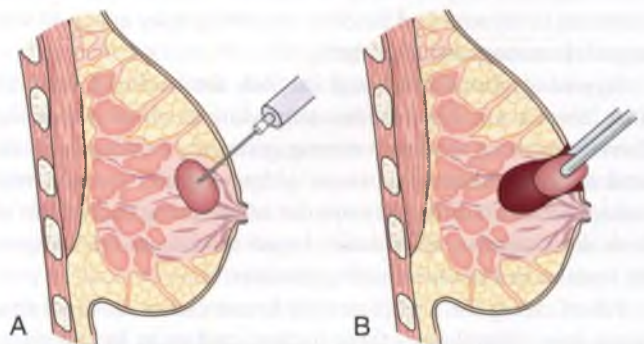

FIG 10-3 Diagnosis. A, Needle aspiration. B, Open biopsy.

rapid results. This is especially important because women are often highly anxious while waiting for biopsy results.

Prognosis

Nodal involvement and tumor size remain the most significant prognostic criteria for long-term survival (Fig. 10-4). Certain biologic factors include estrogen receptor assay, progesterone receptor assay, tumor *ploidy* (the amount of deoxyribonucleic acid (DNA) in a tumor cell compared with that in a normal cell), S-phase index or growth rate (the percentage of cells in the S phase of cellular division done by flow cytometric determinations of the S-phase fraction), Ki67 (another proliferation marker), and histologic or nuclear grade (Shockney & Tsangaris, 2008). Estrogen and progesterone receptors are proteins in the cell cytoplasm and surface of some breast cancer cells. When these receptors are present, they bind to estrogen or progesterone, which promotes cancer cell growth. A breast cancer can have estrogen or progesterone receptors (ERs, PRs) or both. It is valuable to know the ER status of the cancer to predict which women will respond to hormone therapy (Nelson, Fu, Griffin, et al., 2009). Molecular and biologic factors are valuable indicators for prognosis and treatment of breast cancer. HER2, which is associated with cell growth, is overexpressed in 30% of all breast cancers and is associated with loss of cell regulation and uncontrolled cell proliferation. Thus a positive HER2 status is associated with aggressive tumors, poor prognosis, and resistance to certain chemotherapeutic drugs (ACS, 2013a). Luminal A or B tumors are receptor-positive tumors and are for the most part less aggressive. Tumors expressing H2NU can be more aggressive. Tumors referred to as basal types are tumors that have no receptors. The basal tumors are more aggressive and there are limited therapies, usually chemotherapy based.

CARE MANAGEMENT FOR WOMEN WITH BREAST CANCER

Breast cancer is treated in a variety of ways, using one or a combination of the following approaches: surgery, radiation, systemic therapies, and plastic surgical reconstruction. The specific

FIG 10-4 Lymphatic spread of breast cancer.

treatment approach depends on the size of the abnormality and whether there is palpable lymph node involved.

Breast reconstruction, immediately with surgery or delayed, is usually an option for women with mastectomy. Delayed reconstruction is the preferred course for women with locally advanced disease that will most likely need radiation after mastectomy and those with a high chance of local recurrence. Immediate reconstruction is best suited to those women with noninvasive tumors or lymph node–negative disease.

Surgery

Surgical approaches for the treatment of breast cancer include breast-conserving surgeries (BCS) and mastectomy. BCS include **lumpectomy** (see Fig 10-5, A), which involves the removal of the small tumor and a rim of healthy tissue around it, to ensure clear margins; **segmental mastectomy** (also called partial mastectomy) (see Fig. 10-5, B), which includes *wide excision* and/or *quadrantectomy* and involves removal of the tumor, which may be larger, along with a rim of healthy tissue around it, to ensure clear margins.

BCS are used for the primary treatment of women with early-stage (I or II) breast cancer. The criteria for recommending BCS are as follows: a tumor that is relatively small compared to breast volume; no previous breast radiation; no previous mantle field radiation (area includes neck, chest, and underarm lymph nodes) as a youth; and no evidence of multicentric disease (ACS, 2013a).

Mastectomy is the removal of the breast, including the nipple and areola. Women who are advised to have mastectomy instead of BCS are women who have:

- Had radiation to the breast
- Multiple tumors in the breast occupying several quadrants of the breast
- Invasive or extensive DCIS that occupies a large area of the breast tissue
- A large tumor compared to breast volume

There are several different types of mastectomies. These include:

- **Total simple mastectomy** (see Fig. 10-5, C): This is removal of the breast, nipple, and areola. No lymph nodes from the axillae are taken. Recovery from this procedure, if no reconstruction is done at the same time, is usually 1 to 2 weeks. Hospitalization varies; for some it may be an outpatient procedure, whereas other women may require an overnight stay.
- **Modified radical mastectomy**: This procedure is removal of the breast, nipple, and areola as well as axillary node dissection. Recovery, when surgery is done without reconstruction, is usually 2 to 3 weeks.
- **Skin-sparing mastectomy**: This is the removal of the breast, nipple, and areola, keeping the outer skin of the breast intact. It is a special method of performing a mastectomy that allows for a good cosmetic outcome when combined with a reconstruction done at the same time. A tissue expander may also be placed as a space holder for later reconstruction.
- **Nipple-sparing mastectomy**: This kind of mastectomy is reserved for a smaller number of women with tumors that are not near the nipple areola area. The surgeon makes an incision on the outer side of the breast or around the edge of the areola and hollows out the breast, removing the areola

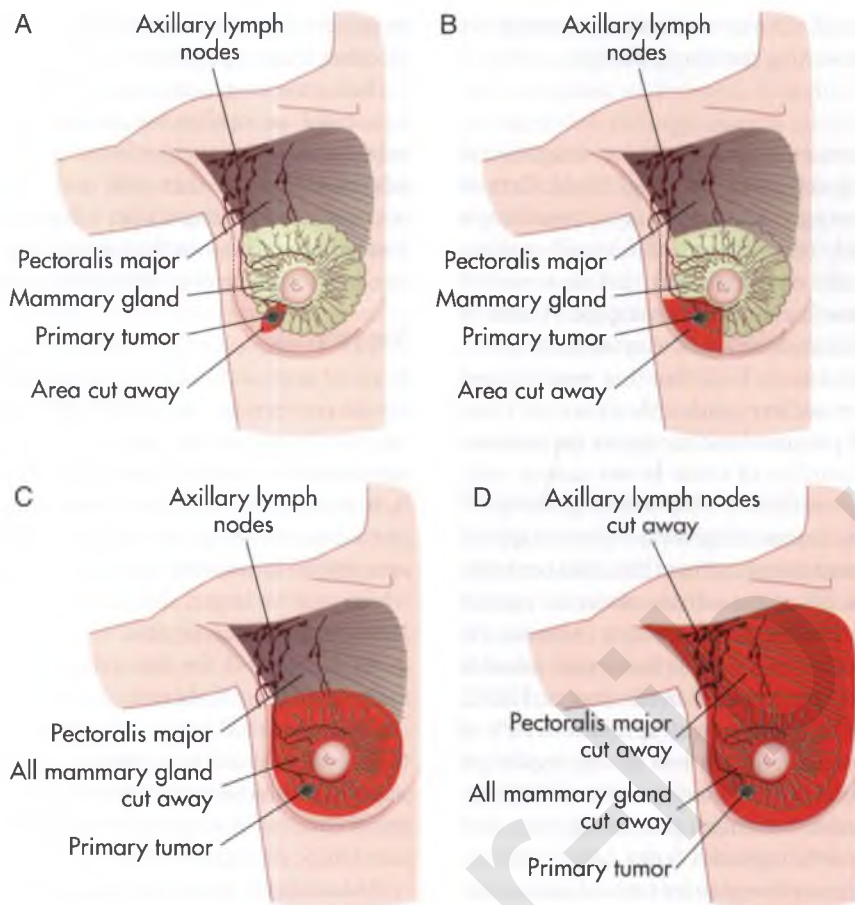

FIG 10-5 Surgical alternatives for breast cancer. A, Lumpectomy. B, Segmental mastectomy. C, Total (simple) mastectomy. D, Radical mastectomy.

and keeping the nipple intact. Sometimes the completed reconstruction is performed at the same time, and in other cases a tissue expander is inserted as a space holder for later reconstruction.

- **Preventive/prophylactic mastectomy:** Prophylactic mastectomy is designed to remove one or both breasts in order to dramatically reduce the risk of developing breast cancer. Women who test positive for certain genetic mutations like BRCA1 and BRCA2, or who have a strong family history of breast cancer, may elect this kind of surgery. When this type of mastectomy is performed, no lymph nodes need to be removed because there is no evidence of cancer present. It is necessary to have a mammogram within 90 days before the procedure to ensure that it is healthy breast tissue being removed for preventive purposes.

If there is only one area of concern that has been biopsy-proven, and it is not so large that it occupies more than 50% of a woman's breast, then a BCS is an option. For tumors greater than 50% or multiple tumors that occupy other quadrants, total mastectomy is recommended. If the tumor is invasive with no palpable lymph nodes, there is a 10% chance of having lymph node involvement, and a sentinel lymph node procedure is recommended. The sentinel node is the first node that receives lymphatic drainage from the tumor, and is identified by injecting vital blue dye and radioactive dye in the area surrounding the tumor. A small incision in the axilla allows for identification of the blue-stained lymphatic channel leading to the blue sentinel

node, both visually and by gamma probe. This node can then be removed and examined for the presence of tumor cells, as opposed to an entire axillary dissection. It is helpful to indicate whether nodes are positive for metastatic cells in determining the need for adjuvant systemic treatment. A study of more than 1000 cases of sentinel node biopsy has found an accuracy rate in detecting cancer cells of between 97% and 98.3% (Fancellu, Cottu, Feo, et al., 2012).

For women who have a palpable lymph node that is suspected of malignancy, core biopsy of the lymph node confirms the histology. If the node has cancer, a traditional axillary lymph node dissection at the time of her breast surgery is recommended. If the sentinel lymph node is positive, the next step will depend on how much tumor is present. The pathologic stage of the tumor combined with the lymph node biopsy determines the surgical options (e.g., lumpectomy versus mastectomy).

If a woman presents with a very large palpable, locally advanced tumor, positive lymph node, or medium-sized tumor (3 cm or more) and BCS would deform her, then systemic therapy before surgery or neoadjuvant therapy is an option. This approach can downstage the tumor before surgery and, through this early systemic therapy, can prevent recurrence elsewhere. Women who choose BCS will have to have cancer-free margins following surgery, before proceeding to radiation treatment. Radiation treatments are 5 days a week, and the length of courses are variable (discussed in more detail later).

Ductal carcinoma in situ (DCIS) is an early form of noninvasive breast cancer. Although DCIS does not spread, it does require management. The surgical approach is usually a BCS (e.g., lumpectomy) followed by radiation. In invasive or extensive DCIS, segmental mastectomy with radiation or mastectomy may be recommended. If the actual tumor is small on mammogram, there is no need for lymph node assessment; if it is large, the woman may be advised to have sentinel lymph node biopsy because this procedure must be done before mastectomy. If an invasive tumor is found and no sentinel was done, then she would be committed to an axillary lymph node dissection.

Breast Reconstruction

The goals of surgical breast reconstruction are achievement of symmetry and preservation of body image. Surgical reconstruction can be done immediately or at a later date. Immediate reconstruction at the time of mastectomy does not change survival rates or interfere with therapy or the treatment of recurrent disease. It is important that women be aware of this. Women choosing surgical reconstruction offer the following rationale for reconstructive surgery: to feel complete again, to avoid using an external prosthesis, to achieve symmetry, to decrease self-consciousness about appearance, and to enhance femininity.

Major achievements have been made in breast reconstruction following mastectomy surgery. No longer do women need to face long, jagged scars that affect their self-image. Instead, advanced techniques have given plastic surgeons the tools to rebuild a woman's breast in such a way that her silhouette is once again whole.

Women with breast cancer have two main considerations regarding reconstructive surgery—when to have surgery and what type of surgery to have. The options for when to have reconstruction are (Table 10-4):

- **Simultaneous reconstruction:** Women have the option to have immediate reconstruction of their breast(s) at the same time as their mastectomy. This is a reasonable option for women who do not need breast irradiation.
- **Delayed reconstruction:** A woman may opt for delayed reconstruction if, after her mastectomy, a plastic surgeon was not involved. Many women who did not know their options at the time of mastectomy fall into this category. More and more these women are discovering that surgically re-creating their breasts is possible and is required to be covered by insurance as a result of a federal law passed in 1998. Delayed reconstruction is preferred medically, if the pathologic stage requires postmastectomy radiation.

The types of surgical options for breast reconstruction include implants and flap procedures. Implants are made out of silicone or saline or a combination of both and can be inserted at the same time as a mastectomy or later. They are placed underneath the chest muscle versus on top of it, as in the case of breast augmentation. Silicone implants have been deemed safe and are an option for women having breast reconstruction following mastectomy.

Flap procedures are done by plastic and reconstructive surgeons who specialize in microsurgery. During flap reconstruction a breast is created using tissue taken from other parts of the body, such as the abdomen, back, buttocks, or thighs, which is then transplanted to the chest by reconnecting the blood vessels

to new ones in the chest region. Due to the high level of skill required for microsurgery, as well as the equipment and staff needed, these techniques are available only at specialized centers. Thus, most breast centers are still using “old fashioned” techniques—transverse rectus abdominis myocutaneous (TRAM) flaps and latissimus dorsi flaps—which result in the woman sacrificing either her abdominal muscles or her upper back muscles. Although these procedures were the best options decades ago, they result in a higher risk of hernia, weakness, abdominal bulging, and limits on physical activity.

After a woman has recovered from initial reconstructive surgery, she may choose to have nipple and areolar reconstruction. Nipple reconstruction is achieved by using an autologous skin graft to construct a nipple, either from tissue from the remaining nipple or from a donor site. Tiny flaps from the new breast itself also may be used. This outpatient procedure requires local anesthesia, intravenous sedation, or a combination of both, depending on how much sensation has returned to the breast. The procedure lasts about an hour. Following this procedure, a woman may choose to have a tattoo to create an areola and match the color of the natural nipple (Breastcancer.org, 2013b).

Radiation

Radiation to the breast destroys tumor cells remaining after manipulation and handling of the tumor during surgery. The total recommended radiation dose is 45 to 60 Gy in 1.8- to 2-Gy fractions over several weeks (Advanced Radiation Center, 2013). The risk of local recurrence depends on extent of breast resection, tumor margins, technical details of radiation therapy, and use of adjuvant systemic therapy. Although radiation after lumpectomy surgery is standard protocol, some large breast tumors (due to the disease being locally advanced) may be irradiated before surgery to facilitate easier surgical removal. Side effects of radiation therapy include swelling and heaviness in the breast, sunburn-like skin changes in the treated area, and fatigue. Changes to the breast tissue and skin usually, but not always, resolve in 6 to 12 months. The breast may become smaller and firmer after radiation therapy. Radiation therapy in the area of the axilla can cause lymphedema of the arm on the affected side. Close medical follow-up is important after conservative surgery and radiation. Recommended guidelines include a breast physical examination every 4 to 6 months for 5 years and then yearly. A mammogram is recommended 6 months after radiation and then annually (National Comprehensive Cancer Network [NCCN], 2012).

A variety of radiation methods are widely used. These include accelerated therapy and brachytherapy.

- **Accelerated breast radiation.** External beam radiation for 6 weeks, 5 days a week, can be inconvenient for a woman. Research has been conducted to develop ways to shorten this time frame and still deliver the therapy needed to prevent recurrence of this disease. Accelerated radiation was created with this goal in mind and delivers a slightly larger dose of radiation over a 3-week period. Skin changes (resembling sunburn) can be slightly more prevalent because of the more intense period of time and corresponding dosage.
- **Brachytherapy.** Initially created for other types of cancer, like prostate, this form of radiation enables the client to complete her radiation in an even shorter time and is not delivered via external beam. Instead a deflated balloon is inserted into the

space left by the lumpectomy and is filled with saline. The balloon is left in place until the margins are confirmed as clear. The balloon is removed and replaced with another balloon specifically created to allow radiation to be inserted within it. Radiation rods or seeds are inserted into the balloon each day for 5 days, and the radiation is completed, at which time the balloon is removed. This enables partial breast radiation to be delivered, recognizing that most local recurrences happen at or near the location of the original cancer.

- **Partial breast radiation.** Intraoperative radiation done at the time of surgery in the operating room. Indications are for small less aggressive tumors. This technique is still not yet standard of care.

Adjuvant Systemic Therapy

Chemotherapy administered soon after surgical removal of the tumor is referred to as **adjuvant chemotherapy**. The role of adjuvant chemotherapy (chemotherapy and endocrine therapy)

TABLE 10-4 Reconstructive Breast Surgery Options

NAME OF OPTION	BRIEF DESCRIPTION	ADVANTAGES	DISADVANTAGES
Simultaneous reconstruction	Reconstruction of the breast done at the same time as surgery to remove the cancer	<ul style="list-style-type: none"> • The woman wakes up with a breast mound already in place, having been spared the experience of seeing herself with no breast at all. • The process is done in the shortest time possible and is not a series of complex surgeries over a length of time. 	<ul style="list-style-type: none"> • If there is a recurrence of the cancer, the reconstruction may need to be modified. • If there are postsurgery complications, the woman may need to have more surgeries. • Small revision surgeries or matching procedures on the opposing breast may be required. • Rarely it is determined that a woman will need radiation, which can compromise reconstructed breast tissue.
Staged reconstruction	This reconstruction involves placement of a temporary tissue expander at time of mastectomy. The expander gradually stretches the muscle and skin in preparation for either an implant or flap reconstruction.	<ul style="list-style-type: none"> • The surgeon creates a natural "pocket" in which a permanent implant or a tissue flap may be placed. • The overall result is more symmetric, natural, and aesthetically pleasing. • It allows a woman to complete radiation treatment while having a "placeholder" implanted. • It allows enough time to make sure all of the cancer has been treated. 	<ul style="list-style-type: none"> • It takes longer to "complete" the breast cancer process. • During the time of temporary tissue expansion, the breasts do not look natural. • Small revision surgeries or matching procedures on the opposing breast may be required.
Delayed reconstruction	This reconstruction happens after all of the recommended treatment is completed.	<ul style="list-style-type: none"> • Some women aren't comfortable weighing all the options at once when they are struggling with a diagnosis of cancer. • Some women need time to come to terms with losing their breast(s). • Some women who are overweight, smokers, or who have high blood pressure may be advised to wait. • It allows enough time to make sure all of the cancer has been treated. 	<ul style="list-style-type: none"> • It takes longer to "complete" the breast cancer treatment. • Women may not feel whole without their breast(s).
Implant	A breast implant is a silicone shell filled with either silicone gel or a saltwater solution known as saline.	<ul style="list-style-type: none"> • The recovery from the initial expander placement surgery and from the permanent implant placement surgery is usually quicker than flap surgery. • It may be easier to control the final size of the reconstructed breast with implant reconstruction. • There are no additional scars on the woman's body other than those on the breasts. • For women without excess fatty tissue and who do not require radiation treatment, implants are a good choice, one with good final results. 	<ul style="list-style-type: none"> • Because most women require placement of an expander first followed by secondary replacement of the expander with an implant, this type of reconstruction almost always requires at least two surgical stages and multiple visits to the plastic surgeon's office between these stages for tissue expansion. • It is important to realize that for women who are having a unilateral (one-sided) mastectomy, matching the other natural breast with an implant can be difficult. The shape and feel of an implant are not exactly like that of a natural breast. • In the short term, implants can become infected or malpositioned and require surgery to correct these problems. • Implant-based reconstruction is not generally recommended if women require radiation, due to the risk of complications. In the longer term, implants can develop capsular contracture (tightening of the soft tissues around the implant), implant malposition, and implant rupture. • In the case of complications, secondary procedures may be required.

TABLE 10-4 Reconstructive Breast Surgery Options—cont'd

NAME OF OPTION	BRIEF DESCRIPTION	ADVANTAGES	DISADVANTAGES
Deep inferior epigastric perforator (DIEP) flap, superficial inferior epigastric artery (SIEA) flap, bilateral simultaneous superior gluteal artery perforator (SGAP) flap	The DIEP flap is the technique in which skin and tissue (no muscle) are taken from the abdomen in order to re-create the breast. Other flap techniques, called the SIEA flap and the SGAP flap, take tissue from the lower abdomen or lateral buttock regions.	<ul style="list-style-type: none"> • Because the reconstruction involves using the woman's own tissues, the risks of implant reconstruction are avoided, particularly in the case of radiation. • Most women have less postoperative pain than after a TRAM flap and are therefore able to leave the hospital sooner and return to normal activities more quickly than after a TRAM flap. • Because the abdominal muscle is not removed as in the TRAM flap, women have much less risk of developing hernias, bulges, and core weakness at the site where the flap is removed. This advantage is much greater in bilateral (both sides) reconstruction. • It is typically easier to match the contralateral natural breast with the woman's own tissue when compared with implant reconstruction. • Women essentially end up with a "tummy tuck," "bottom lift," or other cosmetic benefits at the same time as the breast reconstruction. 	<ul style="list-style-type: none"> • DIEP/SIEA/SGAP flap reconstruction generally requires a longer and more challenging surgery at the first stage when compared with implants or TRAM flaps. • Women will have a scar across the lower abdomen or the upper part of the buttock where the flap is obtained. However, this does not differ from the TRAM flap as the abdominal scars are equivalent. • Small revision surgeries or matching procedures on the opposing breast or donor site may be required. • Women who smoke, are obese, or who have diabetes are not ideal candidates for this type of surgery.
Transverse rectus abdominis myocutaneous (TRAM) flap	In a pedicle TRAM flap, the tissue remains attached to its original site, retaining its blood supply. The flap, consisting of the skin, fat, and muscle with its blood supply, is tunneled beneath the skin to the chest, creating a pocket for an implant or, in some cases, creating the breast mound itself, without need for an implant. The free TRAM flap involves less muscle.	<ul style="list-style-type: none"> • Shorter and less complex surgery than the other flaps 	<ul style="list-style-type: none"> • This was state of the art decades ago and has since been replaced by other, more advanced procedures. • The woman may have more postoperative pain and longer hospital stays. • There is a risk of abdominal bulge or hernias, and as a result there might be a limit to how much weight the woman can lift. • Other newer procedures may offer more natural results.

Data from Shockney, L., & Tsangaris, T. (2008). *Johns Hopkins breast cancer handbook for health care professionals*. Sudbury, MA: Jones and Bartlett.

in treating breast cancer is either to eradicate or impede the growth of micrometastatic (microscopic cell metastasis) disease. Often it is not possible to detect the presence of micrometastasis at the time of initial treatment, and when it is present, mutations can occur in the tumor cells. These mutations make tumor cells resistant to the effects of chemotherapeutic agents despite tumor sensitivity to drug therapy being greatest when the tumor burden is small. Consequently the prediction cannot be made with confidence that all tumors of 1 cm or less can be cured with initial local and regional treatment. The early introduction of systemic adjuvant therapy, as determined by the estimated risk of tumor recurrence in certain subsets of women with node-negative disease, is a prudent course of treatment. Adjuvant therapy may help to destroy undetected cancers that were not surgically removed (ACS, 2013a). For women diagnosed with early-stage breast cancer and favorable prognostic factors (hormone receptor positive and HER2/neu negative), a special pathology test may help determine the woman's risk of recurrence. This test, called Oncotype DX, provides a score that represents the likelihood of her specific cancer recurring. Such information can be useful for a woman whose known benefit for receiving chemotherapy may be minimal based on her prognostic factors from the tumor itself. For women with a low score, commonly only hormonal therapy is recommended, and for those with a high score, chemotherapy is strongly considered.

Neoadjuvant therapy is systemic treatment given before surgery; the goal is to reduce tumor burden, making breast-conserving treatment an option.

Hormonal Therapy. To determine whether a woman is a candidate for hormonal therapy, a receptor assay is done. After the entire tumor or a portion is removed by biopsy or excision, a pathologist examines the cancer cells for ERs and PRs.

The presence of a receptor on the cell wall indicates that the woman is positive for that type of hormone receptor. If these receptors are present, the growth of the woman's breast cancer can be influenced by estrogen, progesterone, or both. It is unknown exactly how these hormones affect breast cancer growth. Bilateral oophorectomy may benefit women diagnosed with their first breast cancer before age 50 by reducing exposure to endogenous estrogen. Studies indicate that among women with a BRCA1 mutation and no previous breast cancer, the risk of developing breast cancer was 14% for those who chose prophylactic salpingo-oophorectomy compared with a 20% risk among women who did not choose this surgery. The risk of developing breast cancer was 7% in women with BRCA2 mutation and no previous breast cancer who chose to have a prophylactic salpingo-oophorectomy as compared to a 23% risk in those women who did not choose this surgery (Komen Foundation, 2013c). Thus oophorectomy may be an option that helps decrease the odds of recurrence and improve length of survival. In addition to or instead of oophorectomy,

medications may be given to stop tumor growth that is influenced by hormones. Ovarian suppression may also be recommended by a medical oncologist as part of the hormonal therapy treatment.

There are several hormonal therapy drugs. Tamoxifen, the oldest and used the longest, is an oral antiestrogen medication that mimics progesterone and estrogen. Tamoxifen attaches to the hormone receptors on cancer cells and prevents natural hormones from attaching to the receptors. When tamoxifen fits into the receptors, the cell is unable to grow. Tamoxifen has been shown to decrease the risk of recurrence of breast cancer by 40% to 50% in postmenopausal women and by 30% to 50% in premenopausal women; and it reduces by 50% the development of a new cancer in the other breast (Breastcancer.org, 2013c). Adjuvant hormonal therapy with tamoxifen is recommended for most premenopausal women with breast cancer whose tumors are hormone receptor positive. In this age group, adjuvant tamoxifen therapy improves disease-free survival and, in some cases, length of survival. Use of hormonal therapy for 5 years in premenopausal women with breast cancer significantly reduces recurrence and mortality rates (see Medication Guide: Tamoxifen).

MEDICATION GUIDE

Tamoxifen (Nolvadex)

Action

A selective estrogen receptor modulator that exerts antiestrogenic effects; attaches to hormone receptors on cancer cells and prevents natural hormones from attaching to the receptors

Indications

For treatment of advanced-stage or metastatic breast cancer; treatment of early-stage breast cancer after breast cancer surgery and radiation therapy; to reduce the incidence of breast cancer in women at high risk

Dosage and Route

20 mg orally, daily, but can vary depending on the reason for taking tamoxifen

Adverse Reactions

Common side effects include hot flashes, night sweats, nausea, vaginal discharge, mood swings, weight gain, and cataracts. Hair loss is an uncommon effect. Serious side effects include deep vein thrombosis, increased risk of endometrial cancer, and stroke. Symptoms include abnormal vaginal bleeding, leg swelling or tenderness, chest pain, shortness of breath, weakness or numbness of extremities, sudden severe headache, and chemical hepatitis.

Nursing Considerations

The medication may be taken on an empty stomach or with food. Missed doses should be taken as soon as possible, but taking two doses at once is not recommended. A barrier or non-hormonal form of contraception is recommended in premenopausal women because tamoxifen may be harmful to the fetus if pregnancy should occur. Client counseling should concentrate on annual Pap smear (if no hysterectomy, annual eye exam, bone density every 3 years, and liver function tests (LFTs) every 6 months.

The National Cancer Comprehensive Network (NCCN) guidelines (2012) recommend adjuvant hormonal therapy for women with hormone receptor–positive breast cancer regardless of menopause status, age, or HER2/neu status, with the exception of women with lymph node–negative cancers less than or equal to 0.5 cm or 0.6 to 1 cm in diameter with favorable prognostic features. Women treated with hormonal therapy should receive therapy for at least 5 years for chemoprevention. Length of time for invasive disease may extend to 10 years if prognostically indicated (Gray, Rea, Handley, et al., 2013).

Raloxifene is an oral selective ER modulator. It is used to prevent osteoporosis in menopausal women. It was also used in a second-generation National Cancer Institute (NCI) prevention trial. It demonstrated the same 50% risk reduction in invasive breast cancer in postmenopausal women with a high risk for breast cancer with fewer thromboembolic events and lower risk of uterine cancer when compared with the use of tamoxifen (see Medication Guide: Raloxifene Hydrochloride).

Aromatase inhibitors (AIs) are a classification of hormonal therapy in use. They suppress plasma estrogen levels in postmenopausal women by inhibiting or inactivating aromatase, the enzyme responsible for synthesizing estrogens from androgens (Breastcancer.org, 2013a). AIs such as anastrozole, letrozole, and exemestane are effective agents in hormonal therapy

MEDICATION GUIDE

Raloxifene Hydrochloride (Evista)

Action

A selective estrogen receptor modulator, serving as an agonist and antagonist to estrogen receptor sites

Indications

Treatment and prevention of osteoporosis; reduction in the risk of invasive breast cancer in postmenopausal women with osteoporosis; and reduction of risk of invasive breast cancer in postmenopausal women at high risk for invasive breast cancer

Dosage and Route

60 mg orally, daily

Adverse Reactions

Common side effects include hot flashes, nausea, peripheral edema, joint pain, leg cramps, flulike symptoms, sweating. Serious and life-threatening side effects can occur from existing condition. Women who have had a heart attack or are at risk for a heart attack have increased risk of dying from a stroke. There is an increased risk of blood clots in the legs and lungs. Raloxifene is contraindicated in women with an active or past history of venous thromboembolism.

Nursing Considerations

The medication may be taken on an empty stomach or with food. Missed doses should be taken as soon as possible, but taking two doses at once is not recommended. Counsel woman to contact her physician if leg pain or feeling of warmth in lower legs, swelling of hands and feet, sudden chest pain or shortness of breath, or sudden changes in vision occur. Calcium 1500 mg plus vitamin D 400 to 800 International Units daily is recommended.

for breast cancer. Clinical trials indicate that letrozole is convincingly better than tamoxifen in treating advanced disease in postmenopausal women, and anastrozole is at least as good. In early-stage breast cancer, adjuvant therapy with anastrozole appears to be superior to adjuvant therapy with tamoxifen in reducing recurrence in postmenopausal women. AIs appear to be well tolerated with lower incidence of adverse effects as compared with tamoxifen. AIs are more commonly given to postmenopausal women whose tumors are hormone receptor positive (Ito, Blinder, & Elkin, 2012) (see Medication Guide: Letrozole).

MEDICATION GUIDE

Letrozole (Femara)

Action

An aromatase inhibitor; inhibits the conversion of androgens to estrogen

Indications

For adjuvant treatment of early breast cancer in postmenopausal women who have received 5 years of tamoxifen therapy; first-line treatment of postmenopausal women with hormone receptor–positive or hormone receptor–unknown locally advanced or metastatic cancer; adjuvant treatment of postmenopausal women with hormone receptor–positive early breast cancer

Dosage and Route

2.5 mg once a day by mouth

Adverse Reactions

Common side effects include hot flashes, nausea, increased sweating, joint or muscle pain, fluid retention, vaginal dryness, constipation, dizziness, fatigue, headache. Severe side effects include serious allergic reactions (e.g., rash, hives, difficulty breathing), vomiting, chest pain, intense bone pain, and calf pain or tenderness.

Nursing Considerations

The medication may be taken on an empty stomach or with food. Missed doses should be taken as soon as possible, but taking two doses at once is not recommended. The woman should use caution if driving or using machinery because this medication may cause drowsiness or dizziness. Women who are not postmenopausal should not take letrozole.

Chemotherapy. Chemotherapy drugs are most often given in combination regimens, which have been shown to improve or increase the disease-free survival time after therapy. The most common chemotherapy regimens used for adjuvant treatment of node-positive and node-negative tumors are listed in Box 10-2.

Adjuvant chemotherapy has been most useful in premenopausal women who have breast cancer with positive nodes, regardless of hormone receptor status. It is postulated that younger women often have tumors with a higher S-phase fraction and proliferative rate, which makes the tumors more sensitive to chemotherapy. Although adjuvant chemotherapy effectively decreases the risks for recurrence and mortality in premenopausal women with node-positive disease, postmenopausal women can also be offered chemotherapy, depending on the cancer size, nodal involvement, and morphologic and biologic factors or markers of the particular cancer (Shockney & Tsangaris, 2008).

BOX 10-2 Common Chemotherapy Regimens for Adjuvant Treatment of Breast Cancer

- CAF: cyclophosphamide, doxorubicin (Adriamycin), fluorouracil
- TAC: docetaxel, doxorubicin, and cyclophosphamide
- AC → T: doxorubicin and cyclophosphamide followed by paclitaxel or docetaxel (Herceptin may be given with the paclitaxel or docetaxel for HER2/neu-positive tumors.)
- FEC: fluorouracil, epirubicin, and cyclophosphamide (this may be followed by docetaxel)
- TC: docetaxel and cyclophosphamide
- TCH: docetaxel, carboplatin, and Herceptin for HER2/neu-positive tumors
- Less common regimens include:
 - CMF: cyclophosphamide, methotrexate, fluorouracil
 - AC: doxorubicin, cyclophosphamide
 - EC: epirubicin, cyclophosphamide
 - A → CMF: doxorubicin followed by CMF

American Cancer Society. (2013). Chemotherapy for breast cancer. Available at www.cancer.org/cancer/breastcancer/detailedguide/breast-cancer-treating-chemotherapy.

Chemotherapy with multiple drug combinations is used in the treatment of recurrent and advanced breast cancer with positive results. First-line single agents for women with locally advanced or metastatic breast cancer include paclitaxel, docetaxel, epirubicin, doxorubicin, pegylated liposomal doxorubicin, capecitabine, vinorelbine, and gemcitabine. Combination regimens and sequential single agents can be used (NCCN, 2012). The use of herceptin and bevacizumab has advanced response rates and lowered recurrences. Because chemotherapy drugs kill rapidly reproducing cells, treatment also affects normal body cells that rapidly reproduce (red and white blood cells, gastric mucosa, and hair). Thus chemotherapy can cause leukopenia, neutropenia, thrombocytopenia, anemia, gastrointestinal side effects (nausea, vomiting, anorexia, mucositis), and partial or full hair loss.

Chemotherapy treatments are usually administered in ambulatory care settings once or twice per month. During the informed consent process, before the treatment is selected, the woman and her family members should be educated about the names of the medications, routes of administration, treatment schedule, timing and ordering of medications, length of time of administration, reimbursed and unreimbursed costs of therapy, potential side effects, management of side effects, possible changes in body image (e.g., full or partial hair loss), recovery time after treatment (necessitating lost work time), and need for a caregiver to transport the woman to treatment and care for her afterward. Depending on the medications used, the treatments can include intravenous, subcutaneous, and oral administration. Often a long-term central venous catheter is inserted when the women will be receiving chemotherapy for an extended period or when she will receive medications that may damage the vein. Presence of a central venous catheter, hair loss, loss of part or all of her breast, menopause, and possible infertility all have the potential to cause a change in body image and increase emotional distress.

Treatment with chemotherapy, hormonal therapy, or a combination of the two often causes changes in reproductive function. The premenopausal woman may experience these changes

along with symptoms of menopause and possible infertility. It is not known whether hormonal therapy to ease the effects of menopause is safe for women with breast cancer; therefore, it is not recommended. For this reason the nurse must use other measures to help the woman cope with menopause (see Chapter 6).

Women receiving chemotherapy and their partners must understand that chemotherapy can be teratogenic, that is, chemotherapy agents can cause congenital birth defects. Any woman who is of childbearing age and receiving chemotherapy, even though no longer menstruating, must use birth control. Although a woman may not be menstruating, she may still be able to become pregnant.

Birth control pills are not recommended because they contain hormones that may assist in the growth of cancer. A birth control method must be chosen with the assistance of a gynecologist and a medical oncologist, and it must be used before chemotherapy begins and continue to be used until the medical oncologist and gynecologist believe it is safe to discontinue.

Special Groups

Young Women. Of the new diagnosed breast cancers, approximately 12% will affect women younger than age 40. The diagnosis of concomitant pregnancy and breast cancer is estimated at about 1 in 3000. Although the basic treatment modalities for breast cancer are used, the unique importance in this age population requires careful consideration of their developmental tasks. Nurses can identify developmental tasks and help young women cope with their disease.

In identifying special surgical concerns for young women diagnosed with breast cancer, one would have to address the timing and extent of the surgery offered. A younger woman is more likely than not to harbor a mutation, and therefore genetic testing may be an important aspect in deciding a surgical plan. She may in fact want to use the genetic results to decide on whether to consider bilateral mastectomies. If chemotherapy is planned, a neoadjuvant approach would allow enough time for surgical decision making while still actively receiving treatment. Choosing a breast-conserving approach requires a careful discussion because it leaves the woman with a higher chance for recurrence.

Systemic therapy, whether adjuvant or neoadjuvant, will affect fertility. Depending on the specific type of chemotherapeutic agent and the age of the women, the rate of premature ovarian failure ranges from 30% to 80% (Rosenberg & Partridge, 2013). It is important to include a consult to a reproductive gynecologist early after diagnosis to discuss preserving fertility.

Chapter 11 presents information about young women who are diagnosed with breast cancer during pregnancy. This is an important area for nurses to understand.

Young women with breast cancer face different challenges than do the majority of older diagnosed women. The biology of their tumors together with the genetic implications suggests a more threatening outcome. The defining difference, however, is the time of life at which the disease strikes. Independence, autonomy, integration into society, and fusion in the family are the foundations on which nursing interventions should focus in achieving the best outcomes for quality of life and survivorship.

The future might also appear different for these women. Although the risk of recurrence plagues all women with breast

cancer, younger women with this disease face the possibility of second or third malignancies if they survive long term. The consideration of undergoing prophylactic surgery can be an overwhelming decision for these young women. Successful survivorship will be defined by their ability to move beyond treatments, continue to work productively, have their families, and find meaning in their lives.

Women Ages 65 and Older. Although the occurrence of breast cancer is declining, the incidence of women being diagnosed with breast cancer at age 65 and older is increasing (ACS, 2013a). Women who are 65 years of age are expected to live another 20 years. The same standard of care in treating breast cancer applies as in treating younger women (American Society of Clinical Oncology [ASCO], 2013). There are, however, developments in which treatment for breast cancer can be modified for this aging population. The variations in treatment are largely based on comorbidities. Other variables include the woman's functional disability, socioeconomic resources, difficulties with access and transportation to health care, resulting in not having an annual clinical breast examination or mammogram (Schapira & Muss, 2013). The majority of older woman diagnosed with breast cancer will likely be estrogen receptor positive and demonstrate less aggressive forms of disease. Geriatric oncology is an emerging specialty, and the American Society of Clinical Oncology (ASCO) has supported endocrine therapy with an aromatase inhibitor, either initially adjuvantly or sequenced after tamoxifen; the optimal timing and duration remain unresolved. There is also evidence for use of an aromatase inhibitor alone as primary therapy (Balakrishnan & Ravichandran, 2011).

The overall success in treating older women is based largely on integrating geriatrics with oncology. There are available tools through ASCO and NCCN that can help with providing geriatric assessments. Older women are faced with treatment decisions based on many factors, with quality of life being a major one.

Survivorship Issues

Because women are living longer after treatment for breast cancer, survivorship issues have become very important in relation to quality of life. In the 1990s ASCO developed evidence-based guidelines that standardize surveillance and include history and physical examination every 3 to 6 months during the first 3 years, every 6 to 12 months during years 4 and 5, and annually thereafter. At that point women can be transitioned into primary care. In addition, mammography is annual, with the first at 6 months postradiation to establish a new baseline. It is recommended that women who carry a genetic mutation have MRI added to their surveillance. Routine gynecologic care is suggested. Many women suffer from many sequelae of cancer treatment, including vasomotor symptoms, sexual dysfunction, infertility, osteoporosis, musculoskeletal pain, weight gain, cognitive changes, fatigue, neuropathy, and congestive heart failure. Whether a woman is in a specialty clinic or primary care, the ability to recognize and treat these problems is critical for optimum health.

Vasomotor symptoms occur in many women treated for breast cancer, partly due to hormonal treatments. Lifestyle changes such as keeping room temperatures down, avoiding spicy food and

caffeine, and dressing in layers can be useful. Hormone replacement therapy is contraindicated. Some pharmacologic agents, including antidepressants such as paroxetine, fluoxetine, citalopram, and venlafaxine, as well as anticonvulsants such as gabapentin and the antihypertensive clonidine have been used with varying success (Stan, Loprinzi, & Ruddy, 2013).

Sexual dysfunction may be related to the endocrine changes that result from systemic therapy. The most common reported issue for women is decreased libido, followed by decreased arousal or lubrication, dyspareunia, and body image. Helping women overcome these problems requires the nurse to discuss such symptoms openly with their clients.

Osteoporosis caused by systemic chemotherapy or antiestrogen therapies is a potential major comorbidity of breast cancer treatment. The incidence of bone fractures in this population is five times higher than in the general population (Stan, Loprinzi, & Ruddy 2013). With this in mind, screening for osteoporosis with dual-energy x-ray absorptiometry (DEXA) scans every 1 to 2 years is recommended in survivors 65 years or older (60 to 64 for those women deemed at risk or on AI therapy). They should be given additional counseling for weight-bearing exercises, supplemental vitamin D and calcium, smoking cessation, and avoidance of excessive alcohol intake. Bisphosphonates can treat or prevent osteoporosis in breast cancer survivors.

Weight gain is common in women treated for breast cancer. Chemotherapy causes sarcopenic obesity, characterized by lean mass loss and fat gain. Decreased physical activity caused by fatigue and to a lesser degree overeating are considered factors (Stan, Loprinzi, & Ruddy, 2013). Most women who are actively being treated are encouraged to exercise to combat fatigue and improve symptoms. The ACS recommends strength training at least twice per week and 150 minutes of aerobic exercise per week.

Studies have demonstrated a 15% to 75% occurrence of cognitive changes associated with breast cancer treatments, including problems with concentration, attention, and memory (Afiles, Root, & Ryan, 2012). Although most of the literature suggests chemotherapy as a causative agent, data suggest pretreatment factors and hormonal therapy with tamoxifen should be included. Older women and those with lower cognitive reserve are more vulnerable to the treatment effects.

Cancer-related fatigue (CRF) is a persistent feeling of emotional, physical, and cognitive exhaustion associated with cancer diagnosis and treatment that is out of proportion to the average population. It is reported as one of the most common side effects associated with treatment and has a great effect on quality of life. The prevalence varies between 15% and 90% (NCCN, 2012). NCCN recommends routine screening for this symptom. It has long been known that radiation causes fatigue, but the combination of chemotherapy and other systemic therapies is considered synergistic.

Cardiotoxicity is well recognized as a side effect of breast cancer treatment. The most common cause is anthracycline-based regimens; however, with the addition of taxanes, this incidence has increased. Women who are on either anthracyclines or taxanes need regular heart function monitoring and dose modifications, along with cardiac management. Neuropathies, another side effect of taxanes, are chronic and may require dose modifications. Long-term drug therapy is required to manage side effects (Stan, Loprinzi, & Ruddy, 2013).

Nursing Interventions

Nursing care of a woman with breast cancer depends on the treatment chosen. Data that guide the care include a client history, a physical examination, laboratory and diagnostic test results, and psychosocial assessment.

Emotional Support After Diagnosis. When a woman is diagnosed with cancer, she confronts mortality and potential bodily changes. The emotional reaction to the diagnosis varies with each woman, but is often intense, and the many disruptions caused by the disease challenge the woman's and family's ability to cope. Disruptions may be caused by costs of treatment, loss of role function, lack of stress-relieving activities, spouse's or child's reaction to the diagnosis, change in body image and sexual function, disability, and pain. The woman may feel despair, fear, and shame. Sexuality issues related to breast cancer include a change in body image, changes in sexual function (such as decreased vaginal lubrication caused by hormonal therapy), and relational distress. Health care providers are responsible for discussing the influence of breast cancer on the woman's life and in assisting her and her family to cope effectively.

Women and their families often undergo a period of distress after the diagnosis of cancer. It is difficult to accept the diagnosis when the woman may feel and look well. This period may be characterized by anguish and shock followed by disbelief and denial. During this time absorbing information and education can be difficult, and the nurse should be sensitive as to how this may affect decision-making abilities. Flexibility is the key to sensitive nursing care. As the woman and family begin to accept her diagnosis, more and more information can be shared, and care planning with full client participation can take place, including the following:

- Validate and reinforce accurate information processing by the woman and her family.
- Assist in client decision making and arrange for the woman to speak with breast cancer survivors who have chosen a variety of treatment options (Box 10-3).
- Suggest approaches the woman might take to deal with the sexual concerns of her significant other.

BOX 10-3 Decision-Making Questions to Ask

1. What kind of breast cancer is it (invasive or noninvasive)?
2. What is the stage of the cancer (i.e., how extensive is the spread)?
3. What further tests are recommended (e.g., estrogen receptor assay, HER2 status)?
4. What are the treatment options (pros and cons of each, including side effects)?
5. If surgery is recommended, what will the scar look like?
6. If a mastectomy is done, can breast reconstruction be done (at the time of surgery or later)?
7. How long will the woman be in the hospital? What kind of postoperative care will she need?
8. How long will treatment last if radiation or chemotherapy is recommended? What effects can the woman expect from these treatments?
9. What community resources are available for support?

Data from American Cancer Society. (2013). *Questions to ask my doctor about breast cancer*. Available at www.cancer.org/acs/groups/cid/documents/webcontent/003284.pdf.

- Discuss the application of alternative therapies to alleviate stress and promote healing, such as exercise, guided imagery, meditation, and progressive muscle relaxation.
- Refer the woman to the ACS's Reach to Recovery program or other resources that provide trained survivor volunteers for one-on-one support (Box 10-4).
- Refer the woman to a cancer rehabilitation program, such as Encore, an exercise program run by the YWCA.

The NCCN (www.nccn.org) and the ACS (www.cancer.org) provide specific, up-to-date recommendations on breast cancer treatments on the Internet. These are invaluable resources for women to learn about scientifically tested treatment protocols for each stage of breast cancer.

COMMUNITY ACTIVITY

Research the availability of rehabilitation programs for breast cancer survivors in your community such as the American Cancer Society (ACS)'s Reach to Recovery program. Contact the agency (e.g., local ACS agency) to identify the services provided by the program and the requirements for becoming a volunteer. How are the resources and programs promoted in the community (e.g., brochures in waiting areas of clinics, newspaper ads)? Are nurses in the community involved and if so, how? Do women who use the services provide evaluation about their experiences, and if so, how is it collected and used?

After assisting the woman with accepting the diagnosis and obtaining support, consider nursing care in the preoperative, postoperative, and convalescent periods. The discussion that follows describes nursing care at each of these periods for a woman having a **modified radical mastectomy** (see Nursing Care Plan).

NURSING CARE PLAN

The Woman Having Breast-Conserving Surgery and Axillary Node Dissection

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Acute Pain related to surgical incision and surgical drains, as evidenced by client verbalizations</i>	Woman will report minimal intensity and decreased number of painful episodes.	Use pain scale to assess type and intensity of pain. Administer analgesics as ordered. Teach and reinforce use of relaxation techniques.	To provide accurate database To decrease perception of pain To reduce anxiety and provide distraction that may decrease the perception of pain
<i>Risk for Infection related to disruption of skin integrity and removal of lymph nodes</i>	Woman will experience no clinical manifestations of infection.	Reposition woman with affected arm elevated.	To promote comfort and lymphatic channel return
		Assess clinical manifestations of infection at the incision and drain sites that may include redness, swelling, localized heat, fever, increasing pain, and foul-smelling drainage.	To facilitate prompt treatment
		Demonstrate the procedure for emptying and recording the amount of drainage from the Jackson-Pratt drain(s).	To provide information to the surgeon as to the appropriate removal time of drains. Drains are usually removed when drainage is less than 30 ml of fluid in 24 hours.
		Explain the need to avoid trauma or irritation to the affected arm.	To reinforce to the woman that alterations in sensation and removal of some lymph nodes may affect ability to sense irritation or prevent infection
		Reinforce to the woman the need to protect the arm from injury and to avoid blood drawing or blood pressures to be taken on the affected arm.	To avoid trauma and infection because decreased sensation may be present as well as decreased lymphatic return

 **NURSING CARE PLAN—cont'd**
The Woman Having Breast-Conserving Surgery and Axillary Node Dissection

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
		Explain the importance of reporting any clinical manifestations of infection to the caregiver as soon as possible.	To provide identification and treatment of problem
<i>Disturbed Body Image related to loss of all or part of a breast as evidenced by client statements</i>	Woman will report acceptance of herself as she is and regain a positive body image.	Provide opportunity through therapeutic communication to express feelings about body image changes. Refer to support groups.	To clarify and validate feelings To facilitate verbalization of feelings with women who have similar concerns
<i>Impaired Physical Mobility related to pain and tissue trauma</i>	Woman will return to her preoperative level of mobility.	Encourage woman to do hand, arm, and wrist exercises that can be performed in the immediate postoperative period. Encourage woman to perform activities of daily living as much as possible. Teach woman exercises to be performed after the drains are removed. Teach woman to do exercises slowly and gently. Caution woman not to lift anything heavier than 10 pounds for 4 to 6 weeks.	To enhance fluid return and prevent muscle atrophy To encourage woman to focus on her strengths rather than her limitations To promote range of motion in the arm that had the axillary nodes dissected To prevent injury and pain To avoid exerting strain on affected arm

Preoperative Care. General preoperative teaching and care are given, including expectations regarding physical appearance, pain management, equipment to be used (e.g., intravenous therapy, drains), and emotional support. Some emotional support may be obtained by arranging for a visit from a member of an organization such as Reach to Recovery. The woman is reminded that when she awakens after surgery, her arm on the affected side will feel tight.

Immediate Postoperative Care. After recovery from anesthesia, the woman is returned to her room. Special precautions must be observed to prevent or to minimize lymphedema of the affected arm.

 **NURSING ALERT**

When vital signs are taken, never apply the blood pressure cuff to the arm affected by the axillary lymph node dissection.

The affected arm is elevated with pillows above the level of the right atrium. Blood is not drawn from this arm, and this arm is not used for intravenous therapy or any injections. Early arm movement is encouraged. Any increase in the circumference of that arm is reported immediately.

Nursing care of the wound involves observing for signs of hemorrhage (dressing, drainage tubes, and Hemovac or Jackson-Pratt drainage reservoirs are emptied at least every 8 hours and more frequently as needed), shock, and infection. Dressings are reinforced as necessary. The woman is asked to turn (alternating between unaffected side and back), cough (while

the nurse or the woman applies support to the chest), and deep breathe every 2 hours. Breath sounds are auscultated every 4 hours. Active range-of-motion (ROM) exercise of legs is encouraged. Parenteral fluids are given until adequate oral intake is possible. Emotional support is continued.

Care given during the immediate postoperative period is continued as necessary. Most women who undergo lumpectomy have surgery as ambulatory clients and return home a few hours after surgery. Women are discharged 24 hours or less after mastectomy without reconstruction. Women having a mastectomy with tissue expander placement will be in the hospital for 24 hours. Those having flap reconstruction at the same time will be hospitalized for 3 to 5 days. Because of the generally short time spent in the hospital, thorough teaching is important. It is best to do as much teaching as possible before surgery if the outcome is known. If this is not possible, discharge teaching should be done with the woman's caregiver present. This is to acknowledge the possibility that emotional stress or recovery from anesthesia may cause the woman to forget some of the discharge instructions. Printed information also should be provided for the woman and family to refer to at home.

Women who have had breast cancer surgery are usually seen by their surgeon within 5 to 7 days of surgery. This follow-up visit is important because it allows the physician to assess the outcome of surgical treatment as well as provide reinforcement of education and emotional support. A woman having simultaneous reconstruction will also be seen by her plastic surgeon within a week postoperatively.

Early ambulation is encouraged to improve circulation and ventilation and to prevent loss of bone calcium. The psychologic benefits of early mobility include resumption of self-care and activities of daily living that serve to reinforce the woman's control over her life and help her move from a sick role to the role of breast cancer survivor.

Arm exercises are encouraged at least four times daily (Box 10-5). Exercise is increased as tolerated and is stopped at the point of pain. Initially the woman alternately clenches and extends her fingers and then progresses to wrist and elbow exercises, gradually abducting her arm and raising it to and over her head. She is encouraged to exercise by assisting with her care—washing her face, brushing her teeth, and eating with her hand and arm on the affected side. Physical therapy may be prescribed to improve strength and mobility of the affected arm. Women having a sentinel node biopsy only should have full ROM back within a few days. A woman having axillary dissections will need to work

more vigorously at restoring ROM. She should have returned to her baseline ROM by the end of the third week postoperatively.

It is important to discuss the appearance of the woman's breast if dressings have not been removed before discharge. Some women may not want to view their surgical site, but it is important to give them the opportunity to do so and to provide emotional support at that time. The woman should be encouraged to express her emotions and verbalize her feelings. She needs to know that it will take time to become accustomed to her change of appearance. A woman who has undergone reconstruction at the same time should be encouraged to look at herself as a work in progress—swelling, positioning of tissue expanders, appearance of flaps, and presence of multiple drains initially can be difficult to accept. Over time, when drains are out and swelling subsides, she will begin to see her new silhouette take shape.

An option for restoring body image is choosing an external prosthesis to replace the lost breast or portion of breast

BOX 10-5 Arm Exercises After Lymph Node Dissection

Exercises After Breast Surgery

It is important that the woman talk to her physician before starting any exercises. A physical therapist or occupational therapist can help design an exercise program for the woman.

Exercises in Lying Position

These exercises should be performed on a bed or the floor while lying on your back with your knees and hips bent, feet flat.

Wand Exercise

This exercise helps increase the forward motion of the shoulders. You will need a broom handle, yardstick, or other similar object to perform this exercise.

- Hold the wand in both hands with palms facing up.
- Lift the wand up over your head (as far as you can) using your unaffected arm to help lift the wand, until you feel a stretch in your affected arm.
- Hold for 5 seconds.
- Lower arms and repeat 5 to 7 times.

Elbow Winging

This exercise helps increase the mobility of the front of your chest and shoulder. It may take several weeks of regular exercise before your elbows will get close to the bed (or floor).

- Clasp your hands behind your neck with your elbows pointing toward the ceiling.
- Move your elbows apart and down toward the bed (or floor).
- Repeat 5 to 7 times

Exercises in Sitting Position

Shoulder Blade Stretch

This exercise helps increase the mobility of the shoulder blades.

- Sit in a chair very close to a table with your back against the chair back.
- Place the unaffected arm on the table with your elbow bent and palm down. Do not move this arm during the exercise.
- Place the affected arm on the table, palm down, with your elbow straight.
- Without moving your trunk, slide the affected arm toward the opposite side of the table. You should feel your shoulder blade move as you do this.
- Relax your arm and repeat 5 to 7 times.

Shoulder Blade Squeeze

This exercise also helps increase the mobility of the shoulder blade.

- Facing straight ahead, sit in a chair in front of a mirror without resting on the back of the chair.
- Arms should be at your sides with elbows bent.
- Squeeze shoulder blades together, bringing your elbows behind you. Keep your shoulders level as you do this exercise. Do not lift your shoulders up toward your ears.
- Return to the starting position and repeat 5 to 7 times.

Side Bending

This exercise helps increase the mobility of the trunk/body.

- Clasp your hands together in front of you and lift your arms slowly over your head, straightening your arms.
- When your arms are over your head, bend your trunk to the right while bending at the waist and keeping your arms overhead.
- Return to the starting position and bend to the left.
- Repeat 5 to 7 times.

Exercises in Standing Position

Chest Wall Stretch

This exercise helps stretch the chest wall.

- Stand facing a corner with toes approximately 8 to 10 inches from the corner.
- Bend your elbows and place forearms on the wall, one on each side of the corner. Your elbows should be as close to shoulder height as possible.
- Keep your arms and feet in position and move your chest toward the corner. You will feel a stretch across your chest and shoulders.
- Return to starting position and repeat 5 to 7 times.

Shoulder Stretch

This exercise helps increase the mobility in the shoulder.

- Stand facing the wall with your toes approximately 8 to 10 inches from the wall.
- Place your hands on the wall. Use your fingers to "climb the wall," reaching as high as you can until you feel a stretch.
- Return to starting position and repeat 5 to 7 times.

tissue for a client who has a mastectomy without reconstruction. The external prosthesis is inserted into a mastectomy bra. Women who choose to use a partial external prosthesis after BCS or full external prosthesis after mastectomy need information about where to obtain prostheses and an appropriate bra. Usually a temporary prosthesis is worn for the first 3 months before the woman is fitted for a permanent one. Women should be advised on how to submit the cost of the prosthesis to their insurance company. Volunteers of the Reach to Recovery program are able to provide this information, as well as a list of sources for prostheses, bathing suits, and lingerie. They can offer helpful hints and suggestions for coping with prostheses and wearing apparel. Some women find that an external prosthesis does not restore body image and seek surgical reconstruction of the missing or disfigured breast (see earlier discussion). It is also important to note that some women may choose to forgo a prosthesis as well as surgical reconstruction.

Discharge Planning and Follow-up Care. Before discharge, considerable time should be spent counseling the woman and her family about self-management. These instructions are summarized in the Teaching for Self-Management box. Printed instructions should be given to the woman and her family. A referral for home nursing care may be made if the woman needs assistance caring for her incision.

Teaching Needs for the Client and Family Undergoing Adjuvant Therapies.

It is important that the woman and her family be given thorough instructions regarding side effects and avoidance of possible complications of adjuvant treatment. A common side effect of radiation therapy is skin irritation and breakdown. The woman should avoid using lotions, powders, or ointments on the skin at the radiation site unless instructed by the radiologist. The skin should be cleansed gently with mild soap and water, rinsed thoroughly, and patted dry. Skin markings that direct the placement of the radiation beam should not be removed. Soft, nonirritating clothing should be worn over the site, and the skin protected from exposure to sun and heat.

Common side effects of chemotherapy include alopecia, fatigue, nausea, vomiting, mouth sores, and immunosuppression. The woman receiving chemotherapy that produces hair loss should be encouraged to obtain a wig matching her own hair color and style before beginning treatments so that she is prepared when hair loss begins. Of course, some women may choose not to wear a wig or a scarf. The local ACS can assist in obtaining a wig and head coverings designed for women experiencing hair loss from chemotherapy. The woman should be taught the importance of rest periods when fatigue occurs. She and her family will need to know that work and family schedules may need adjustment to accommodate needed rest. Exercise

TEACHING FOR SELF-MANAGEMENT

After a Mastectomy Without Reconstruction

- Wash hands well before and after touching incision area or drains.
- Empty surgical drains twice a day and as needed, recording the date, time, drain sites (if more than one drain is present), and amount of drainage in milliliters in the diary you will take to each surgical checkup until your drains are removed. (Before discharge, you may receive a graduated container for emptying drains and measuring drainage.)
- Avoid driving, lifting more than 10 pounds, or reaching above your head until given permission by the surgeon.
- Take medications for pain as soon as pain begins.
- Perform arm exercises as directed.
- Call your physician if inflammation of incision or swelling of the incision or the arm occurs.
- Avoid tight clothing, tight jewelry, and other causes of decreased circulation in the affected arm.
- Until drains are removed, wear loose-fitting underwear (camisole or half-slip) and clothes, pinning surgical drains inside of clothing. (You will be taught how to do this safely.)
- After drains are removed and surgical sites are healing and still tender, wear a mastectomy bra or camisole with a cotton-filled, muslin temporary prosthesis. Temporary prostheses of this type are often available from Reach to Recovery.
- Avoid depilatory creams, strong deodorants, and shaving of affected chest area, axilla, and arm.
- Sponge bathe for the first 48 hours; then you may shower. Thoroughly dry yourself afterward and reapply fresh dressings.
- Return to the surgeon's office for incision check, drain inspection, and possible drain removal as directed.
- Contact Reach to Recovery or a breast center nursing staff member for assistance in obtaining external prosthesis and lingerie when dressings, drains, and staples are removed and wound is healing and nontender.
- Contact insurance company for information about coverage of prosthesis and wig if needed. Obtain prescriptions for prosthesis and wig to submit with receipts of purchase for these items to the insurance company. If insurance does not pay for these items, contact the hospital or agency social worker or local American Cancer Society for assistance.
- Practice breast self-examination (BSE) of unaffected side and affected surgical site and axilla.
- Keep follow-up visits for professional examination, mammography, and testing to detect recurrent breast cancer.
- Expect decreased sensation and tingling at incision sites and in the affected arm for weeks to months after surgery.
- Resume sexual activities as desired.
- Participate in breast cancer survivor support group if desired.
- Encourage mother, sisters, and daughters (if applicable) to learn and practice BSE and to have annual professional breast examinations and mammography (if appropriate).

Additional Nursing Care for Women Undergoing Mastectomy with Reconstruction

- No tight compression of the reconstructed breasts until approved by her plastic surgeon.
- Wear loose-fitting garments for first 3 to 4 weeks.
- Emphasize to the woman that her surgery is still a work in progress and that final cosmetic result of reconstruction takes many weeks.
- Assess the skin for potential of poor peripheral circulation that may cause skin necrosis, and report any skin changes immediately.
- See drain care instructions under axillary dissection section.

may help in increasing energy and decreasing fatigue. Nausea and vomiting should be reported to the physician and are treated with antiemetics. Mouth sores may be very painful, and the woman should be instructed to maintain good oral hygiene and avoid trauma to the oral mucosa by using a soft toothbrush. The mouth should be rinsed frequently with water or saline, and mouthwashes containing alcohol or glycerin should be avoided as well as spicy or irritating foods (see Box 11-4 for

other suggestions). Topical anesthetic medications may be prescribed by the physician. The woman with immunosuppression should be instructed to use frequent handwashing and avoid crowds and other large gatherings of people, especially during cold and flu season. She should be taught to avoid eating raw fruits and vegetables (low-bacteria diet), maintain strict personal hygiene, and recognize the signs and symptoms of infection and report them to the health care provider immediately.

KEY POINTS

- The most common benign breast problems are fibrocystic changes and fibroadenomas.
- The development of breast neoplasms, whether benign or malignant, can have a significant physical and emotional effect on a woman and her family.
- The risk of American women developing cancer of the breast is 1 in 8.
- An estimated 90% of all breast lumps are detected by the woman.
- Clinical breast examinations by a health care provider (starting in one's 20s), and routine screening mammograms (after age 40) are recommended by the ACS for early detection of breast cancer.
- Digital mammography is superior to traditional analog mammography.
- The primary therapy for most women with stage I or stage II breast cancer is breast-conserving surgery followed by radiation therapy.
- Adjuvant chemotherapy is most helpful to premenopausal women with breast cancer that has spread to the lymph nodes.
- Tamoxifen, along with raloxifene and anastrozole, provides the first real hope in preventing breast cancer.
- The emotional diagnosis of breast cancer is always intense, and the many disruptions caused by the disease challenge the woman and her family's ability to cope.
- There are more reconstruction options today than ever before.
- 85% of women diagnosed today with breast cancer will be long-term survivors.

Structural Disorders and Neoplasms of the Reproductive System

Deitra Leonard Lowdermilk

© <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Describe the various structural disorders of the uterus and vagina.
- Discuss the pathophysiology of selected benign and malignant neoplasms of the female reproductive tract.
- Compare the common medical and surgical therapies for selected benign gynecologic conditions.
- Explain diagnostic procedures in client-centered terms.
- Examine the emotional effects of benign and malignant neoplasms.
- Develop a nursing care plan for a woman with endometrial cancer who has had a hysterectomy.
- Differentiate treatments for preinvasive and invasive conditions.
- Identify critical elements for teaching clients with selected benign or malignant neoplasms.
- Investigate health-promoting behaviors that reduce cancer risk.
- Assess the effects of and treatments for malignant neoplasms during pregnancy.
- Discuss the development and sequelae of gestational trophoblastic neoplasia.

Women are at risk for structural disorders and neoplastic diseases of the reproductive system from the age of menarche through menopause and the older years. Problems may include structural disorders of the uterus and vagina related to pelvic relaxation and urinary incontinence and chronic pain related to vulvodynia. Benign neoplasms of the reproductive organs, such as fibroids and cysts, and malignant neoplasms of the reproductive system also may occur. Benign tumors usually do not endanger life, tend to grow slowly, and are not invasive. Malignant tumors (cancers) grow rapidly in a disorganized manner and invade surrounding tissues. The development of structural disorders and benign or malignant neoplasms can have far-reaching effects for the woman and her family. Beyond the obvious physiologic alterations, the woman also experiences threats to her self-concept and her ability to cope. A woman's concept of herself as a sexual being can be affected by the condition and its treatments. A woman's family also is challenged in the way it responds to her diagnosis. When cancer occurs with pregnancy, it adds to the complexity of physical and emotional responses to childbearing, with increased fears related to pregnancy and the fetus.

Nurses have important roles in teaching women about early detection and treatment and in providing supportive care to women and their families. This chapter presents information that will assist the nurse in assessing and identifying issues associated with structural problems or benign or malignant

reproductive neoplasms. Nursing care concepts related to early detection, treatment methods, and education are included.

STRUCTURAL DISORDERS OF THE UTERUS AND VAGINA

Alterations in Pelvic Support

Alterations in pelvic support include uterine displacement and prolapse, cystoceles and rectoceles, urinary incontinence, and genital fistulas. Research by Wu, Hundley, Fulton, & Myers (2009) suggested that the prevalence of these disorders will increase by as much as 55% in the United States by the year 2050 as the numbers of older women increase.

Uterine Displacement and Prolapse

The round ligaments normally hold the uterus in anteversion, and the uterosacral ligaments pull the cervix backward and upward (see Fig. 4-3). **Uterine displacement** is a variation of this normal placement. The most common type of displacement is posterior displacement, or retroversion, in which the uterus is tilted posteriorly, and the cervix rotates anteriorly. Other variations include retroflexion and antelexion (Fig. 11-1).

By 2 months postpartum the ligaments should return to normal length, but in about a third of women, the uterus remains retroverted. This condition is rarely symptomatic, but subsequent conception may be difficult because the cervix points

A

B

FIG 11-1 Types of uterine displacements. **A**, Anterior displacement. **B**, Retroversion (backward displacement of the uterus).

toward the anterior vaginal wall and away from the posterior fornix, where seminal fluid pools after coitus. If symptoms occur, they may include pelvic and low back pain, dyspareunia, and exaggeration of premenstrual symptoms.

Uterine prolapse is a more serious type of displacement. The degree of prolapse can vary from mild to complete. In complete prolapse, the cervix and body of the uterus protrude through the vagina, and the vagina is inverted (Fig. 11-2).

Uterine displacement and prolapse can be caused by congenital or acquired weakness of the pelvic support structures (often called **pelvic relaxation**). In many cases problems can be a result of vaginal childbirth-related injury. Although extensive damage may be noted and repaired shortly after birth, symptoms related to pelvic relaxation most often appear during the perimenopausal period, when the effects of ovarian hormones on pelvic tissues are lost and atrophic changes begin. Pelvic trauma, stress and strain, and the aging process also are contributing factors. Other causes of pelvic relaxation include obesity, reproductive surgery, and pelvic radiation (Lentz, 2012b).

Clinical Manifestations. Symptoms of pelvic relaxation generally relate to the structure involved: urethra, bladder, uterus, vagina, cul-de-sac, or rectum. The most common complaints are pulling and dragging sensations, pressure,

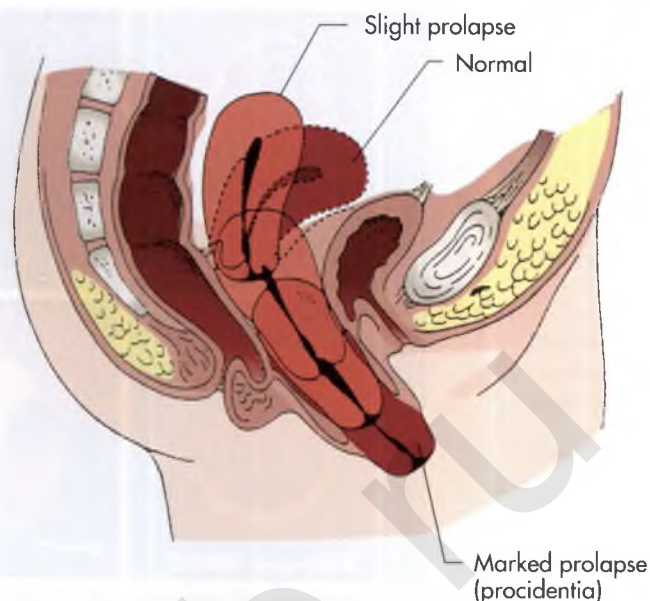

FIG 11-2 Prolapse of uterus.

protrusions, fatigue, and low backache. Symptoms may be worse after prolonged standing or deep penile penetration during intercourse. Urinary incontinence can be present.

Medical and Surgical Management. If discomfort related to uterine displacement is a problem, several interventions can be implemented to treat this condition. Kegel exercises (see Teaching for Self Management box: Kegel Exercises in Chapter 4) can be performed several times a day to increase muscular strength. A knee-chest position performed for a few minutes several times a day can correct a mildly retroverted uterus. A fitted pessary to support the uterus and hold it in the correct position may be inserted into the vagina (Fig. 11-3). Usually a pessary is used for only a short time because it can lead to pressure necrosis and vaginitis. After a period of treatment, most women are free of symptoms and do not require the pessary. Surgical correction is rarely indicated.

Treatment for uterine prolapse depends on the degree of prolapse. Pessaries can be useful in mild prolapse and are recommended by many health care providers as the first-line management of uterine prolapse (Bugge, Adams, Gopinath, & Reid, 2013). Estrogen therapy may be used in the older woman to improve tissue tone. If these conservative treatments do not correct the problem or the degree of prolapse is significant, vaginal hysterectomy with a vaginal vault suspension (see later discussion) is usually recommended (Lentz, 2012b).

Nursing Interventions. Nurses can educate women on how to perform Kegel exercises and use a pessary. Good hygiene is important when using a pessary. Some women are taught to remove the pessary at night, cleanse it, and replace it in the morning. If the pessary is always left in place, regular douching with commercially prepared solutions or weak vinegar solutions (e.g., 1 tbsp to 1 qt of water) to remove increased secretions and keep the vaginal pH at 4.0 to 4.5 can be suggested.

Cystocele and Rectocele

Cystocele and rectocele almost always accompany uterine prolapse, causing the uterus to sag even farther backward and downward into the vagina. **Cystocele** (Fig. 11-4, A) is the protrusion of the bladder downward into the vagina that develops

FIG 11-3 Examples of pessaries. A, Smith. B, Hodge without support. C, Incontinence dish without support. D, Ring without support. E, Cube. F, Gellhorn. (Courtesy Milex Products, Inc., a division of CooperSurgical, Trumbull, CT.)

FIG 11-4 A, Cystocele. B, Rectocele. (From Seidel, H., Ball, J., Dains, J., Flynn, J., Solomon, B., & Stewart, R. [2011]. *Mosby's guide to physical examination* [7th ed.]. St. Louis: Mosby.)

when supporting structures in the vesicovaginal septum are injured. Anterior wall relaxation gradually develops over time as a result of congenital defects of support structures, child-bearing, obesity, or advanced age. When the woman stands, the weakened anterior vaginal wall cannot support the weight of the urine in the bladder; the vesicovaginal septum is forced downward, and the bladder is stretched, resulting in an increase in capacity. With time the cystocele enlarges until it protrudes into the vagina. Complete emptying of the bladder is difficult because the cystocele sags below the bladder neck.

Rectocele is the herniation of the anterior rectal wall through the relaxed or ruptured vaginal fascia and rectovaginal septum; it appears as a large bulge that may be seen through the relaxed introitus (see Fig. 11-4, B).

Clinical Manifestations. Cystoceles and rectoceles often are asymptomatic. If symptoms of cystocele are present, they include complaints of a bearing-down sensation or that “something is in my vagina.” Other symptoms include urinary frequency, retention, and incontinence, as well as possible recurrent cystitis and urinary tract infections (UTIs). Pelvic examination reveals a bulging of the anterior wall of the vagina when the woman is asked to bear down. Unless the bladder neck and urethra are damaged, urinary continence is unaffected. Women with large cystoceles complain of having to push upward on the sagging anterior vaginal wall to be able to void.

Rectoceles may be small and produce few symptoms, but some are so large that they protrude outside of the vagina when the woman stands. Symptoms are absent when the woman is lying down. A rectocele causes a disturbance in bowel function, the sensation of bearing down, or the sensation that the pelvic organs are falling out. With a very large rectocele it may be difficult to have a bowel movement. Each time the woman strains during bowel evacuation, the feces are forced against the thinned rectovaginal wall, stretching it more. Some women facilitate evacuation by applying digital pressure vaginally to hold up the rectal pouch.

Medical and Surgical Management. Treatment for a cystocele includes use of a vaginal pessary or surgical repair. An anterior repair (colporrhaphy) is the surgical procedure usually done for large symptomatic cystoceles. This involves a surgical shortening of pelvic muscles to provide better support for the bladder. An anterior repair is often combined with a vaginal hysterectomy. Use of Kegel exercises helps strengthen pelvic floor muscles and may relieve some of the symptoms of pressure caused by the cystocele (Lentz, 2012b).

Small rectoceles may not need treatment. The woman with mild symptoms may get relief from a high-fiber (e.g., 25 g) diet and adequate fluid intake, stool softeners, or mild laxatives. Vaginal pessaries and Kegel exercises may be useful. Large rectoceles that are causing significant symptoms are usually repaired surgically. A posterior repair (colporrhaphy) is

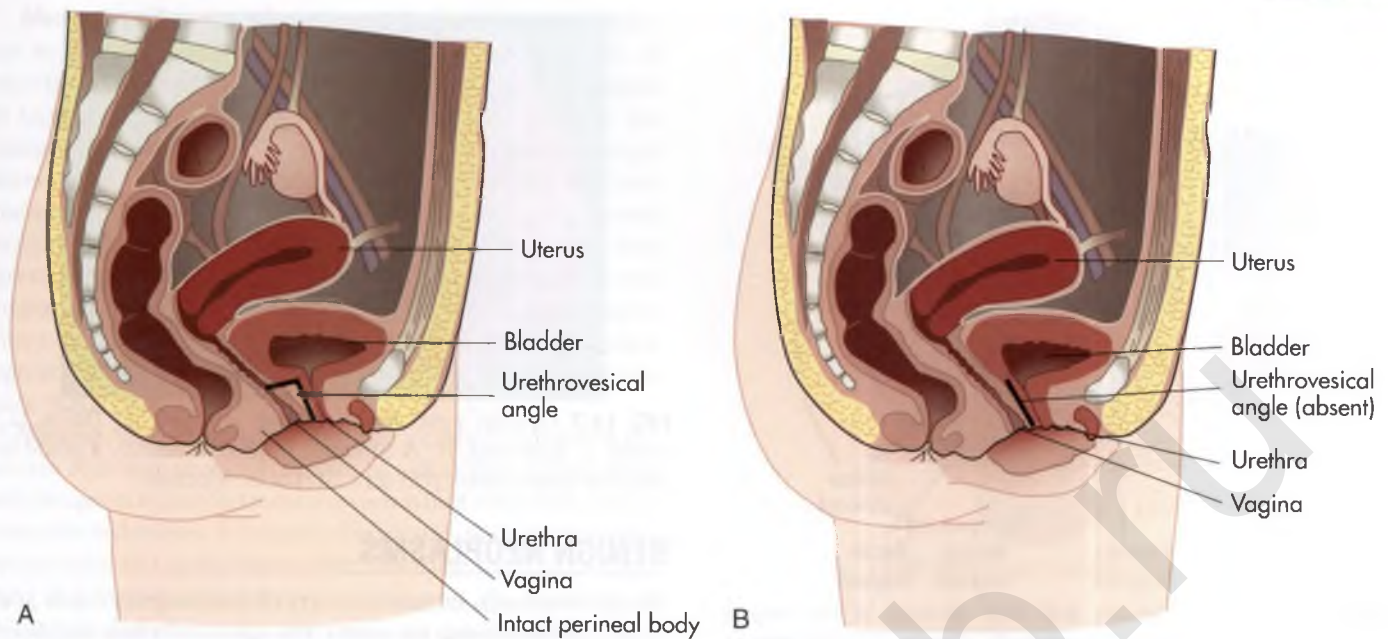

FIG 11-5 Urethrovesical angle. A, Normal angle. B, Widening (absence) of angle.

the usual procedure. This surgery is performed vaginally and involves shortening the pelvic muscles to provide better support for the rectum. Anterior and posterior repairs can be performed at the same time and with vaginal hysterectomy. Even though the surgery corrects the anatomic position, the woman may still have problems with defecation (Lentz, 2012b).

Genital Fistulas

Genital **fistulas** are perforations between genital tract organs. Most occur between the bladder and the genital tract (e.g., vesicovaginal); between the urethra and the vagina (urethrovaginal); and between the rectum or sigmoid colon and the vagina (rectovaginal) (Fig. 11-5). Genital fistulas may be a result of a congenital anomaly, gynecologic surgery, obstetric trauma, cancer, radiation therapy, gynecologic trauma, or infection (e.g., in the episiotomy).

Clinical Manifestations. Signs and symptoms of vaginal fistulas depend on the site but can include presence of urine, flatus, or feces in the vagina; odors of urine or feces in the vagina; and irritation of vaginal tissues.

Medical and Surgical Management. Management of genital fistulas depends on the location. Surgical repair is the usual treatment; however, it may not be successful.

Nursing Interventions. Nursing interventions for women with a mild cystocele or rectocele are similar to those suggested for women with uterine prolapse. However, nursing care of the woman with a rectocele or genital fistula requires great sensitivity because the woman's reactions are often intense. She can become withdrawn or hostile because of embarrassment about odors and soiling of her clothing that are beyond her control. Her sexuality is threatened; her partner may refuse sexual intimacy.

The nurse can suggest hygiene practices that reduce odor. Commercial deodorizing douches are available, or noncommercial solutions such as diluted chlorine (e.g., 1 tsp chlorine household bleach to 1 qt water) may be used. The chlorine solution is also useful for external perineal irrigation. Sitz baths and

thorough washing of the genitalia with unscented, mild soap and warm water are helpful. Sparse dusting with deodorizing powders can be useful.

If a rectovaginal fistula is present, enemas given before leaving the house may provide temporary relief from oozing of fecal material until corrective surgery is performed. Irritated skin and tissues may benefit from use of a heat lamp or application of an emollient. Hygienic care is time consuming and may need to be repeated frequently throughout the day; protective pads or pants may need to be worn. All of these activities can be demoralizing to the woman and frustrating to her and her family.

Urinary Incontinence

Urinary incontinence (UI) affects women of all ages, with the prevalence increasing as the woman ages. Although nulliparous women can have UI, the incidence is higher in women who have given birth and increases with parity. Women who are overweight and those who smoke also are at increased risk (Lentz, 2012a). There are conflicting data about ethnicity and race as contributing factors, although Caucasian women reportedly are at higher risk than women of other races (Mitchell & Woods, 2013). Conditions that disturb urinary control include stress incontinence due to sudden increases in intra-abdominal pressure (such as sneezing or coughing); urge incontinence, caused by disorders of the bladder and urethra, such as urethritis and urethral stricture, trigonitis, and cystitis; neuropathies, such as multiple sclerosis, diabetic neuritis, and pathologic conditions of the spinal cord; and congenital and acquired urinary tract abnormalities.

Stress incontinence may follow injury to bladder neck structures. A sphincter mechanism at the bladder neck compresses the upper urethra, pulls it upward behind the symphysis, and forms an acute angle at the junction of the posterior urethral wall and the base of the bladder (urethrovesical angle) (Fig. 11-6). To empty the bladder the sphincter complex relaxes, and the trigone contracts to open

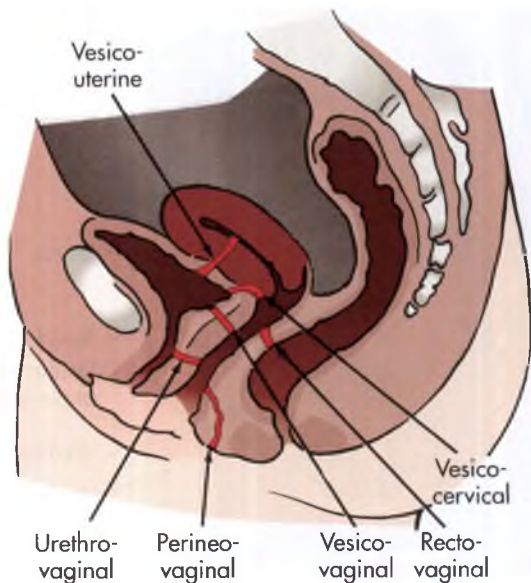

FIG 11-6 Types of fistulas that may develop in the vagina, uterus, or rectum. (From Monahan F., Sands, J.K., Neighbors, M., et al. [2007]. *Phipps' medical-surgical nursing: Health and illness perspectives* [8th ed.]. St. Louis: Mosby.)

the internal urethral orifice and pull the contracting bladder wall upward, forcing urine out. The angle between the urethra and the base of the bladder is lost or increased if the supporting pubococcygeus muscle is injured; this change, coupled with urethrocele, causes incontinence. Urine spurts out when the woman is asked to bear down or cough when she is in the lithotomy position.

Clinical Manifestations. Involuntary leaking of urine is the main sign. Episodes of leaking are common during coughing, laughing, and exercise.

Medical Management. Mild to moderate UI can be significantly decreased or relieved in many women by bladder training and pelvic muscle (Kegel) exercises (Hay-Smith, Herderschee, Dumoulin, & Herbison, 2012; Hersh & Salzman, 2013). Other management strategies include pelvic flow support devices (i.e., pessaries), vaginal estrogen therapy, serotonin-norepinephrine reuptake inhibitors, electrical stimulation, insertion of an artificial urethral sphincter, and surgery (e.g., anterior repair) (Hersh & Salzman; Tarnay & Bhatia, 2010).

Nursing Interventions. Nursing care for a woman with UI can include education about bladder training and pelvic muscle exercises and guidance in lifestyle changes (e.g., losing weight, smoking cessation). Women may need to be assessed for depression that can result from decreased quality of life and functional status.

In summary, nurses working with women who have UI or other pelvic structural problem can provide information and self-care education to prevent problems, to manage or reduce symptoms, to promote comfort and hygiene if symptoms are already present, and to recognize when further intervention is needed. This information can be part of all postpartum discharge teaching or can be provided at postpartum follow-up visits in clinics or physician/nurse-midwife/nurse practitioner offices, during postpartum home visits, or during gynecologic health examinations.

FIG 11-7 Ovarian cyst. (From Seidel, H., Ball, J., Dains, J., Flynn, J., Solomon, B., & Stewart, R. [2011]. *Mosby's guide to physical examination* [7th ed.]. St. Louis: Mosby.)

BENIGN NEOPLASMS

Benign neoplasms include a variety of nonmalignant cysts and tumors of the ovaries, the uterus, the vulva, and other organs of the reproductive system.

Ovarian Cysts

Functional ovarian cysts (Fig. 11-7) are dependent on hormonal influences associated with the menstrual cycle. These cysts may be classified as follicular cysts, corpus luteum cysts, theca-lutein cysts, endometrial cysts, and polycystic ovary syndrome (PCOS). Other benign ovarian neoplasms include dermoid cysts and ovarian fibromas.

Follicular Cysts

Follicular cysts develop most commonly in normal ovaries of young women as a result of the mature graafian follicle failing to rupture, or when an immature follicle does not resorb fluid after ovulation. A cyst is usually asymptomatic unless it ruptures, in which case it causes severe pelvic pain. If the cyst does not rupture, it usually shrinks after two or three menstrual cycles.

Corpus Luteum Cysts

Corpus luteum cysts occur after ovulation and are possibly caused by an increased secretion of progesterone that results in an increase of fluid in the corpus luteum. Clinical manifestations associated with a corpus luteum cyst include pain, tenderness over the ovary, delayed menses, and irregular or prolonged menstrual flow. A rupture can cause intraperitoneal hemorrhage. Corpus luteum cysts usually disappear without treatment within one or two menstrual cycles.

Theca-Lutein Cysts

Theca-lutein cysts are uncommon—up to 50% of cases are associated with hydatidiform mole (see Chapter 28). **Theca-lutein cysts** develop as a result of prolonged stimulation of the ovaries by human chorionic gonadotropin (hCG). They also can occur if the woman has taken ovulation induction drugs; if she is pregnant and a large placenta is present, such as in the presence of a multiple gestation; or if she has diabetes (Katz, 2012). The cysts are almost always bilateral. The woman may note a feeling of pelvic fullness if the ovary is enlarged, but most women are asymptomatic.

Medical and Surgical Management. A variety of interventions can be implemented for the woman with a functional cyst. If expectant management is the treatment, the woman is advised to keep appointments for pelvic examinations to monitor the changes in size of the cyst (enlarging or shrinking). Pharmacologic interventions such as analgesics may be prescribed for pain management. Oral contraceptives may be ordered for several months to suppress ovulation for functional cysts. Large cysts (greater than 8 cm) or cysts that do not shrink may be removed surgically (cystectomy). Corpus luteum cysts are treated similarly. Theca-lutein cysts are usually managed conservatively (they often regress without treatment) or by removal of the hydatidiform mole (Katz, 2012).

Nursing Interventions. Nursing care focuses on educating the woman regarding treatment options as well as pain management with analgesics or comfort measures such as heat to the abdomen or relaxation techniques. If surgery is performed, the nurse provides preoperative and postoperative care. Discharge teaching includes signs of infection, postoperative incision care, the possibility of recurrence, and advice regarding follow-up appointments.

Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) occurs when an endocrine imbalance results in high levels of estrogen, testosterone, and luteinizing hormone (LH) and decreased secretion of follicle-stimulating hormone (FSH). This syndrome is associated with a variety of problems in the hypothalamic-pituitary-ovarian axis and with androgen-producing tumors. The condition can be transmitted as an X-linked dominant or autosomal dominant trait (Stein-Leventhal syndrome). Multiple follicular cysts develop on one or both ovaries and produce excess estrogen. The ovaries often double in size.

Clinical Manifestations. Clinical manifestations include obesity, hirsutism (excessive hair growth), irregular menses or amenorrhea, and infertility. Impaired glucose tolerance and hyperinsulinemia occur in about 40% of women with PCOS (Lobo, 2012). Affected women are at high risk for developing type 2 diabetes mellitus, nonalcoholic fatty liver disease, and possibly cardiovascular disease (Huang & Coviello, 2012). PCOS is often diagnosed in adolescence when menstrual irregularities and other symptoms appear (Lobo).

Medical Management. The treatment for PCOS depends on what symptoms are of greatest concern to the woman. Lifestyle modifications (e.g., losing weight) and management of presenting symptoms such as infertility, irregular menses, and hirsutism are the focus. Oral contraceptives (OCs) are the usual treatment for irregular menses, if pregnancy is not desired, because they inhibit LH and decrease testosterone levels. OCs can also lessen acne to some degree. Spironolactone, an antiandrogen, is frequently used with an OC. In severe cases, gonadotropin-releasing hormone (GnRH) analogs may be used to treat hirsutism if OCs aren't effective. If pregnancy is desired, ovulation-inducing medications are given (Lobo, 2012). Metformin and other insulin medications for type 2 diabetes also are used to lower insulin, testosterone, and glucose levels, which in turn can reduce acne, hirsutism, abdominal obesity, amenorrhea, and other PCOS symptoms (Lobo).

Nursing Interventions. Nurses can provide information and counseling for women with PCOS. Information may be

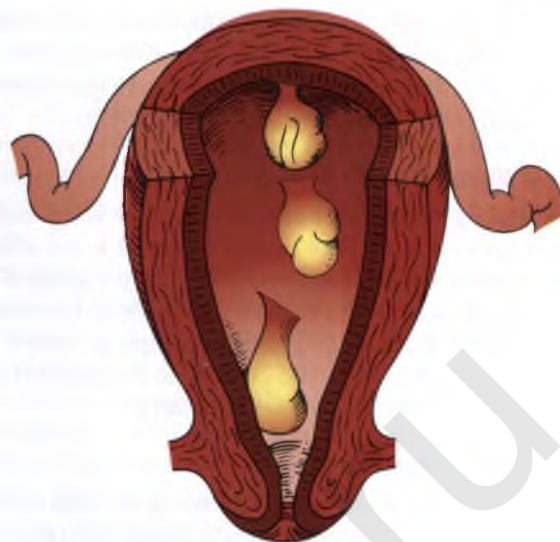

FIG 11-8 Endometrial polyps.

needed about the syndrome or about its long-term effects on the woman's health. Research has shown that women report symptoms of psychologic distress including depression, anxiety, and social fears (Benson, Hahn, Tan, et al., 2010). They may need to discuss their feelings about the physical manifestations of PCOS and may need emotional support if they have self-image problems related to the symptoms. Teaching about lifestyle modifications such as exercise and diet may be needed as well as education about the medications that are prescribed. Information about finding a support group or information on the Internet may be useful.

Other Benign Ovarian Cysts and Neoplasms

Two other ovarian neoplasms are dermoid cysts and ovarian fibromas. **Dermoid cysts** are germ cell tumors, usually occurring in childhood. These cysts contain substances such as hair, teeth, sebaceous secretions, and bones. Unless the cyst is large enough to put pressure on other organs, it is usually asymptomatic. Dermoid cysts may develop bilaterally and are often attached to the ovary. Treatment is usually surgical removal.

Ovarian fibromas are solid ovarian neoplasms developing from connective tissue, and most often occurring after menopause. Fibromas range in size from small nodules to large masses weighing more than 23 kg. Most fibromas are unilateral. They are usually asymptomatic, but if large enough, they may cause ascites, feelings of pelvic pressure, or abdominal enlargement. Treatment is usually surgical removal.

Nursing care of women who have surgery for the removal of dermoid cysts and ovarian fibromas is similar to that described for functional ovarian cysts.

Uterine Polyps

Uterine polyps may be endometrial or cervical in origin. They are tumors that are on pedicles (stalks) arising from the mucosa (Fig. 11-8). The etiology is unknown, although they may develop in response to hormonal stimulus or be the result of inflammation. Polyps are the most common benign lesions of the cervix and endometrium that occur during the reproductive years. These polyps may be single or multiple. Endocervical

polyps are most common in multiparous women older than 40 years. The woman may be asymptomatic or she may have premenstrual or postmenstrual staining, menorrhagia, postmenstrual spotting, or postcoital bleeding (Katz, 2012).

Surgical Management

Clinical management of endometrial polyps is by surgical removal. Cervical polyps are usually removed in an office or clinic procedure without anesthesia. The polyp is grasped with a clamp and twisted or cut off. All polyps should be sent for pathologic examination. Endometrial sampling (which may require local anesthesia) should be done to determine if other pathologic conditions are present (Katz, 2012).

Nursing Interventions

Nursing care includes preparing the woman for what to expect during the removal procedure, encouraging relaxation and breathing exercises, and providing support during the procedure. After the procedure the woman is advised to avoid using tampons, having sexual intercourse, and douching for up to 1 week or until the site is healed. She is taught how to identify signs of infection and to notify her health care provider if she experiences heavy bleeding (more than one pad in 1 hour).

Leiomyomas

Leiomyomas, also known as fibroid tumors, fibromas, myomas, or fibromyomas, are slow-growing benign tumors arising from the muscle tissue of the uterus (Katz, 2012). They are the most common benign tumors of the reproductive system, occurring most often after age 50. They tend to occur more often in African-American women and women who have never been pregnant. Fibroids also occur more often in women who are overweight (Katz). They rarely become malignant. Because their growth is influenced by ovarian hormones, these benign tumors can become quite large when the woman is pregnant or taking hormone therapy. They often spontaneously shrink after menopause when circulating ovarian hormones diminish (Katz).

Clinical Manifestations

The cause of leiomyomas remains unknown, although genetic factors may be involved. Most of the tumors are found in the body of the uterus. Leiomyomas are classified according to the location in the uterine wall. *Subserous* leiomyomas (Fig. 11-9, A) develop beneath the peritoneal surface of the uterus and appear as small or large masses that protrude from the outer uterine surface. *Intramural* leiomyomas (Fig. 11-9, B) are tumors that develop within the wall of the uterus. *Submucosal* leiomyomas (Fig. 11-9, C) are the least common tumors, but often cause the most symptoms; they develop in the endometrium and protrude into the uterine cavity. Leiomyomas can develop in the cervix and on the broad ligaments (Fig. 11-9, D). They can grow on pedicles or stalks (Fig. 11-9, E). Occasionally these break off the pedicle and attach to other tissues (become parasitic).

Most women are asymptomatic; abnormal uterine bleeding is the most common symptom of fibroids. If the tumor is very large, pelvic circulation may be compromised, and surrounding viscera may be displaced. A woman may complain of backache, low abdominal pressure, constipation, urinary incontinence, or

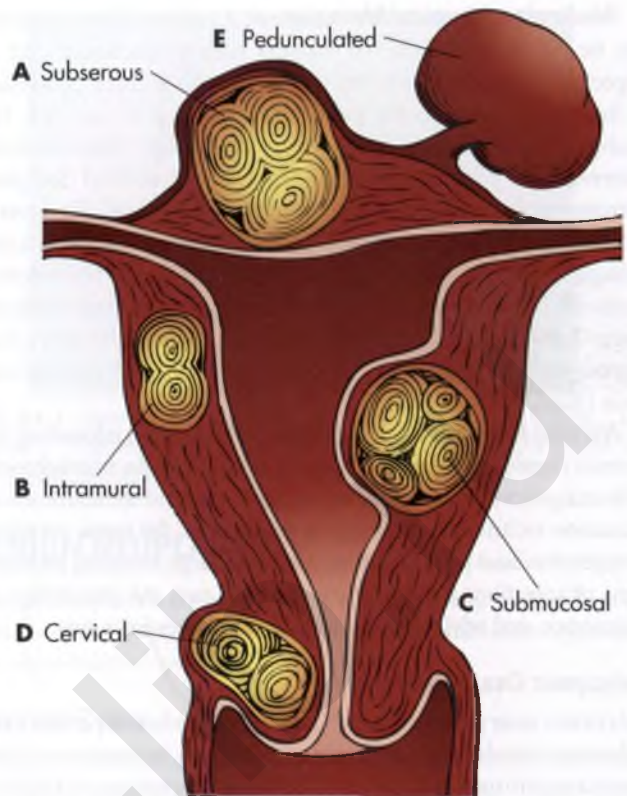

FIG 11-9 Types of leiomyomas. A, Subserous. B, Intramural. C, Submucosal. D, Cervical. E, Pedunculated.

dysmenorrhea (painful menstruation). Nausea and vomiting may occur if the tumor obstructs the intestines. The woman also may notice an abdominal mass if the tumor is large. Anemia can occur if the woman has excessive bleeding. Pedunculated tumors can twist and become necrotic, causing pain (Katz, 2012).

The tumors appear to be influenced by the presence of estrogen. Fibroids can affect implantation and maintenance of pregnancy. During pregnancy the tumors can produce complications such as preterm labor, miscarriage, or dystocia (difficult labor). The severity of the symptoms seems to be directly related to the size and location of the tumors.

CARE MANAGEMENT

Assessment should include a history of symptoms (which might include abnormal bleeding, abdominal pain, dysmenorrhea, pelvic fullness or heaviness, or problems with elimination) and a pelvic examination. Diagnosis is usually accomplished by a process of elimination. A pelvic examination usually identifies the presence of uterine enlargement. Negative pregnancy tests rule out pregnancy as the cause of the symptoms. Laparoscopy may be used to differentiate ovarian masses from uterine masses. Ultrasound examination can differentiate between inflammatory masses or endometriosis and subserous fibroids.

Possible nursing diagnoses for a woman with a leiomyoma include the following:

- *Anxiety* related to
 - Uncertain diagnosis
 - Fear of malignancy
 - Potential surgical treatment

- *Acute or chronic pain* related to
 - Leiomyomas
- *Sexual dysfunction* related to
 - Dyspareunia

Knowledge of the medical-surgical management of leiomyomas is essential in planning nursing care. This knowledge enables the nurse to work collaboratively with other health care providers and to meet the woman's informational and emotional needs. Clinical management of benign tumors of the uterus depends on the severity of the symptoms, the age of the woman, and her desire to preserve childbearing potential.

Medical Management

Medications. If symptoms are mild, regular checkups may suffice to observe for growth or changes in size. Nonsteroidal antiinflammatory drugs (NSAIDs) may be prescribed for pain; OCs inhibit ovulation and may relieve symptoms. Medical management is based on using medications to reduce circulating levels of estrogen and progesterone. GnRH agonists may be prescribed to reduce the size of the leiomyoma. Other medications include medroxyprogesterone acetate (Depo-Provera), danazol (Danocrine), antiprogesterone (mifepristone), selective estrogen receptor modulators (SERMs), and aromatase inhibitors (Katz, 2012; Sabry & Al-Hendy, 2012). The ideal medical therapy for treating fibroids has not been found, and research in this area continues. Two oral agents that show promise as treatment options for prevention of fibroids are vitamin D and green tea extract (Sabry & Al-Hendy, 2012).

Nursing Interventions. The woman who prefers medication for treatment will need information about the various medications, their actions and side effects, and routes of administration. A woman who is receiving GnRH agonists to decrease the size of the fibroid must understand that regrowth will occur after the treatment is stopped. She also must know that a small loss in bone mass and changes in lipid levels can occur; therefore, long-term use is not recommended. Amenorrhea may occur; however, women who wish to avoid pregnancy should use a nonhormonal or barrier method of contraception. A discussion of administration methods for GnRH agonists, including subcutaneous and intramuscular injections, intranasal administration, and subcutaneous implantation, will assist the woman in making a decision about her preferred method of administration (see Medication Guide: Infertility Medications in Chapter 9).

Uterine Artery Embolization. **Uterine artery embolization (UAE)** is a treatment during which polyvinyl alcohol (PVA) pellets or other embolic materials are injected into selected blood vessels to block the blood supply to the fibroid and cause shrinkage and resolution of symptoms (Katz, 2012). The procedure is done under local anesthesia and conscious sedation and can be done as an outpatient procedure, although some women will have the procedure in the hospital setting and remain overnight or be discharged within 4 to 6 hours (Katz). An incision is made into the groin, and a catheter is threaded into the femoral artery to the uterine artery. An arteriogram identifies the vessels supplying the fibroid. Most fibroids are reduced in size by 50% within 3 months. Temporary amenorrhea or early menopause can occur in some women. Although symptom improvement occurs for most women, data

are lacking about the effects on future fertility and pregnancy outcomes. Preterm birth, intrauterine growth restriction, and miscarriage have been reported. Complications are usually minor and of short duration (Katz; van der Kooij, Ankum, & Hehenkamp, 2012). There is an increase in the likelihood that further surgical intervention will be needed within 2 to 5 years of the initial procedure (Gupta, Sinha, Lumsden, & Hickey, 2012).

Nursing Interventions. Preoperative teaching includes advising the woman not to drink alcohol or smoke and not to take aspirin or anticoagulant medications 24 hours before the procedure. If the procedure is done on an outpatient basis, the woman will usually need to take acid-suppressing medications, NSAIDs, and antihistaminic drugs as well as laxatives beginning the day before the procedure (Pisco, Bilhim, Duarte, & Santos, 2009). She is told to expect cramping during injection of the PVA pellets. Explanations about what to expect postoperatively include pelvic pain, fever, malaise, and nausea and vomiting that may be caused by acute fibroid degeneration. Pain can be controlled with NSAIDs or narcotic analgesics if needed. Postoperative nursing assessments include checking for bleeding in the groin, taking vital signs, assessing pain level, and checking the pedal pulse and neurovascular condition of the affected leg. Discharge teaching includes signs of possible complications and when to notify the physician, self-care instructions, and follow-up advice (see Teaching for Self-Management).

TEACHING FOR SELF-MANAGEMENT

Care After Uterine Artery Embolization

- Take prescribed medications as ordered.
- Call your physician if you have any of the following symptoms:
 - Bleeding
 - Pain
 - Swelling or hematoma at the puncture site
 - Fever of 39° C (102.2° F)
 - Urinary retention
 - Abnormal vaginal drainage (foul odor, brown color, tissue)
- Eat a normal diet including fluids and fiber.
- Do not use tampons, douche, or have vaginal intercourse for at least 4 weeks.
- Avoid straining during bowel movements.
- Keep your follow-up appointment.

Surgical Management

In addition to the surgical options of hysterectomy and myomectomy, other techniques have been developed to treat leiomyomas. These include laparoscopic techniques; hysteroscopic techniques; myolysis by heat, cold, and laser; and magnetic resonance-guided focused ultrasound surgery. Not all of these techniques are suitable for every woman nor are all of them universally available.

Laser Surgery. Laser surgery or electrocauterization can be used to destroy small fibroids through a laparoscopic (abdominal) or hysteroscopic (vaginal) approach. Hysteroscopic uterine *ablation* (vaporization of tissues) can be performed under local or general anesthesia, usually as an outpatient procedure. Medical therapy using GnRH agonists to control bleeding temporarily and to suppress endometrial tissue may

be given for 8 to 12 weeks before surgery. Although the uterus remains in place, the vaporization process can cause scarring and adhesions in the uterine cavity, affecting future fertility. Therefore, this procedure is for women who wish to retain their uterus but no longer desire childbearing potential (Nelson & Gambone, 2010). Risks of the procedure include uterine perforation, cervical injury, and fluid overload (caused by the leaking into blood vessels of fluid used to expand the uterus during surgery). The woman may experience postoperative cramping and a slight vaginal discharge for a few days. Before discharge the following information is given:

- Analgesics or NSAIDs can be used for pain relief as needed.
- Normal activities can be resumed within several days.
- Vaginal discharge is to be expected for 4 to 6 weeks.
- Use of tampons or vaginal intercourse should be avoided for 2 weeks.
- The next menstrual period may be irregular.
- The woman should be reminded about the effects of ablation on her fertility, if appropriate.
- The physician should be called if the woman has heavy bleeding or signs of infection.

Myomectomy. If the tumor is near the outer wall of the uterus, the uterine size is no larger than the equivalent of 12 to 14 weeks of gestation, and symptoms are significant, **myomectomy** (removal of the tumor) may be performed (Katz, 2012). Myomectomy can be performed through a laparoscopic or abdominal incision approach or a vaginal (hysteroscopic) approach. Myomectomy leaves the uterine muscle walls relatively intact, thereby preserving the uterus and allowing the possibility of future pregnancies. It is usually performed in the proliferative phase of the menstrual cycle to avoid interrupting a possible pregnancy. GnRH therapy may be given before surgery to reduce the size of the fibroid. Fibroids can recur after myomectomy; further treatment may be needed (Nelson & Gambone, 2010).

Hysterectomy. A total **hysterectomy** (removal of the entire uterus) is the treatment of choice if bleeding is severe or if the fibroid is obstructing normal function of other organs. An abdominal or vaginal surgical approach depends on the size and location of the tumors. For example, abdominal hysterectomy is usually performed for leiomyomas larger than a uterus would be at 12 to 14 weeks of gestation or for multiple leiomyomas. The uterus is removed through either a vertical or transverse incision. In some circumstances the cervix is not removed, although there is a lack of evidence about the benefits of leaving the cervix over total hysterectomy for benign disease (Kives, Lefebvre, Wolfman, et al., 2010). Vaginal approaches can be used for smaller tumors. In both abdominal and vaginal approaches, the uterus is removed from the supporting ligaments (broad, round, and uterosacral). These ligaments are then attached to the vaginal cuff, allowing maintenance of normal depth of the vagina (Fig. 11-10). Alternatives to these procedures are the *laparoscopic assisted vaginal hysterectomy (LAVH)* and the *laparoscopic assisted supracervical hysterectomy (LASH)*. LAVH converts an abdominal procedure to a vaginal one by using a laparoscope in the abdomen to assist with removal of the uterus. LASH allows the cervix to remain. Both are associated with a quicker recovery and fewer postoperative complications (Guo, Tian, & Wang, 2013).

FIG 11-10 Hysterectomy. A, Vaginal. B, Abdominal.

BOX 11-1 Questions for a Woman to Ask to Ensure Informed Consent

- Why is this procedure proposed for my condition/problem?
- What are the risks/benefits of the proposed surgery?
- Are there alternatives to this surgery? If so, what are the risks and benefits of these alternatives?
- How many times have you performed this surgery?
- How long will I be hospitalized? Can the procedure be done in an outpatient setting? How long will it take to recover?
- What types of anesthesia can be used?
- What hospital and surgical procedures can I expect?
- How will the surgery affect me (e.g., any changes in physical function, sexual function, or childbearing ability)?

From Wade, J., Pletsch, P., Morgan, S., & Menting, S. (2000). Hysterectomy: What do women need and want to know? *Journal of Obstetric, Gynecologic, and Neonatal Nursing*, 29(1), 33-42.

Preoperative Nursing Interventions. Assessments needed before surgery include the woman's knowledge of treatment options, her desire for future fertility if she is premenopausal, the benefits and risks of each procedure, preoperative and postoperative procedures (Boxes 11-1 and 11-2), and the recovery process. If the woman demonstrates understanding of this information, she can make an informed decision about treatment and feel a sense of control over the surgical experience. Resources on helping women to make decisions about treatment can be found at the website for the Fibroid Treatment Collective at www.fibroid.org.

BOX 11-2 Preoperative Procedures for Hysterectomy

- Vaginal examination or physical examination
- Laboratory tests
 - Complete blood count, type, and crossmatch
 - Urinalysis
- Chest radiograph
- Electrocardiogram
- Teaching for postoperative routines
 - Turning, coughing, deep breathing
 - Passive and active leg exercises
 - Need for early ambulation
 - Pain relief options
- Nothing by mouth after midnight or as ordered
- Enema if ordered
- Douche if ordered
- Abdominal: mons or perineal shave if ordered
- Removal of makeup, nail polish
- Removal of glasses, contact lenses, dentures, etc.
- Identification band in place
- Signed consent form in chart
- Have woman empty bladder immediately before surgery

**CLINICAL REASONING CASE STUDY****Informed Decision Making for Treatment of Leiomyoma**

Selena, a 41-year-old married Hispanic (non-English speaking) client, has just been diagnosed with a uterine leiomyoma. She has expressed concern about the treatment because she does not want to have a hysterectomy and her friends have told her that she will probably have to have one. What response by the nurse would be appropriate?

1. Evidence—Is there sufficient evidence to draw conclusions about what the nurse should say?
2. Assumptions—What assumptions can be made about the following issues?
 - a. Medical therapy and observation for leiomyomas
 - b. Differences between myomectomy and hysterectomy for leiomyoma treatment
 - c. Uterine artery embolization as a treatment option for leiomyomas
 - d. Cultural implications for Selena in making a decision
3. What implications and priorities for nursing care can be made at this time?
4. Does the evidence objectively support your conclusion?

Psychologic assessment is essential, particularly for a woman who is scheduled for a hysterectomy. Areas to be explored include the significance of the loss of the uterus for the woman, misconceptions about effects of surgery, and adequacy of her support system. Women who have not completed their childbearing, who believe that their self-concept is related to having a uterus (to be a complete woman), who feel that sexual functioning is related to having a uterus, or who have too little or too much anxiety about the surgery may be at risk for postoperative emotional reactions (Pauls, 2010). Yen, Chen, Long and associates, et al. (2008) found that postoperatively most women reported positive feelings about femininity and their body image, less anxiety and depression, but still reported a worsening of sexual functioning.

Postoperative Nursing Interventions. Postoperative assessments and care after myomectomy and abdominal

BOX 11-3 Postoperative Care after Hysterectomy

- Monitor vital signs every 15 minutes until stable, then every 4 hours for 48 hours
- Maintain unobstructed airway
- Remind client to turn, cough, deep breathe every 2 hours for 24 hours
 - Assist her to splint incision with hands or pillow
- Incentive spirometry if ordered
- Leg exercises every 2 to 4 hours until ambulatory
- Assess Homans sign
- Assess bleeding
 - Abdominal: assess dressing or incision
 - Vaginal: perineal pad count (one saturated pad in less than 1 hour is excessive; vaginal bleeding is usually minimal)
- Check laboratory values, especially hematocrit
- Assess lung sounds
- Assess bowel sounds and monitor bowel function
- Monitor intake and output
 - Foley catheter may be in place for 24 hours after abdominal surgery
 - After vaginal hysterectomy, urinary retention may occur because of manipulation of the urethra during surgery
- Assess abdominal incision or vagina for signs of infection
- Observe for signs of complications
 - Abdominal hysterectomy: assess for signs of wound evisceration, pulmonary embolism, thrombophlebitis, pneumonia, bowel obstruction, bleeding (incisional or vaginal)
 - Vaginal hysterectomy: assess for signs of urinary tract infection, urinary retention, wound infection, vaginal bleeding
- Pain relief
 - Pharmacologic measures: patient-controlled analgesia (PCA) or epidural narcotics may be ordered for the first 24 hours, followed by oral analgesics and nonsteroidal anti-inflammatory drugs (NSAIDs)
 - Nonpharmacologic measures: breathing and relaxation exercises, position changes, guided imagery, application of heat to the abdomen (abdominal hysterectomy), and sitz baths or ice packs for the perineum (vaginal hysterectomy); ambulation may relieve gas pains
- Psychologic assessments
 - Assess for depression or other emotional reactions
 - Assess support systems
 - Assess sexual concerns

hysterectomy are similar to those for other abdominal surgery (Box 11-3). Specific to abdominal and vaginal hysterectomy are assessments for vaginal bleeding (one perineal pad saturated in less than 1 hour is excessive), urinary retention (especially after vaginal hysterectomy), perineal pain after vaginal hysterectomy, and psychologic assessments (e.g., depression).

Discharge Planning and Teaching. Discharge planning and teaching are similar for myomectomy and hysterectomy (see Teaching for Self-Management). Myomectomy and vaginal hysterectomy may be performed in an ambulatory setting, and women may be discharged the evening of the surgery. Women who have an abdominal hysterectomy may have a 1- to 2-day stay in the hospital before being discharged.

If a hysterectomy was performed, the woman is reminded that she will experience cessation of menses. If the woman is premenopausal, she will not experience menopause at this time unless her ovaries also were removed. If the ovaries were not removed, there will be no reason for her to consider hormone

TEACHING FOR SELF-MANAGEMENT

Care After Myomectomy or Hysterectomy

- Eat foods high in protein, iron, and vitamin C to aid in tissue healing; include foods with high fiber content; and drink six to eight 8-ounce glasses of water daily.
- Rest when tired; resume activities as comfort level permits. Avoid vigorous exercise and heavy lifting for 6 weeks. Avoid sitting for long periods. Resume driving when comfort allows or on advice from health care provider.
- Avoid tub baths, intercourse (vaginal rest), and douching until after the follow-up examination.
- When vaginal intercourse is resumed, water-soluble lubricants may decrease discomfort.
- Report the following symptoms to your health care provider: vaginal bleeding, gastrointestinal changes, persistent postoperative symptoms (cramping, distention, change in bowel habits), and signs of wound infection (redness, swelling, heat, or pain at incision site).
- Keep your follow-up appointment with your health care provider.

replacement therapy. If the ovaries are removed, the woman will need the most current information on the risks and benefits of hormone replacement therapy (see Chapter 6). Other symptoms include pain, sleep disturbance, fatigue, anxiety, and depression.

Vaginal intercourse may be uncomfortable at first, especially after vaginal procedures. Water-soluble lubricants, relaxation exercises, and positions that control penile penetration may be beneficial. Women can be assured that this discomfort will decrease over time.

The schedule for follow-up care depends on the procedure performed, but usually a postoperative visit is scheduled within a week. Vaginal screening with cytology or Papanicolaou (Pap) test after total hysterectomy for a nonmalignant reason is not recommended (American Cancer Society [ACS], 2014a). (See Table 4-3 for Pap test recommendations.)

Vulvar Problems

Bartholin Cysts

Bartholin cysts are the most common benign lesions of the vulva. They arise from obstruction of the Bartholin duct, which causes it to enlarge. Small cysts often are asymptomatic; however, large cysts or infected cysts cause symptoms such as vulvar pain, dyspareunia (painful intercourse), and a feeling of a mass in the vulvar area (Eckert & Lentz, 2012).

Medical and Surgical Management. If the woman is asymptomatic no treatment is necessary. If the cyst is symptomatic or infected, surgical incision and drainage may provide temporary relief. Cysts tend to recur; therefore, a permanent opening for drainage may be recommended. This procedure is called *marsupialization* and is the formation of a new duct opening for drainage (Eckert & Lentz, 2012).

Nursing Interventions. Nursing care after surgery includes teaching the woman about pain-relief measures such as sitz baths, heat lamps to the perineum, and use of analgesics. The woman is taught to assess the incision site for signs of healing and infection and to take antibiotics, if prescribed, to prevent infection.

Vulvodynia

Vulvar pain is a common gynecologic problem. **Vulvodynia**, also called *vulvar pain syndrome* or *vulvovestibulitis*, is reportedly experienced by about 15% of women. The incidence is thought to be the same for women of all races and ethnicities (Katz, 2012; Reed, Harlow, Sen, et al., 2012).

Vulvodynia is a complex condition thought to be a chronic pain disorder of the vulvar area. The term *vulvodynia* is used if pain is present with no visible abnormality or no identified neurologic diagnosis. Pain can be described as provoked (e.g., by inserting a tampon or having vaginal intercourse) or unprovoked and localized to the vestibule or generalized over the vulvar area (Katz, 2012).

Etiology has not been established although psychologic and biologic theories have been proposed. The most common theory is that vulvodynia is caused by a chronic neuropathic pain syndrome. Inflammation may also be a causative factor and continues to be investigated (Katz, 2012).

A feature of neuropathic pain is *allodynia*, which is a painful sensation that is from something not supposed to be painful. It commonly occurs in women with vulvodynia. Several triggers that reportedly cause allodynia in the vulvar area include use of OCs; presence of candidiasis or human papillomavirus; wearing tight-fitting underwear and pants, especially synthetic materials; sexual activity; and tampon use (Katz, 2012). However, with all these triggers, research evidence is conflicting and the search for scientific evidence is ongoing.

Assessment of a woman with possible vulvodynia includes a health history including a mental health history, specifically inquiring about anxiety or depression. A thorough pain assessment is essential. Questions about provoking and palliative factors, the quality of pain, radiation of the pain, strength of the pain, and the timing of pain occurrence are included. A history may elicit complaints about burning, stinging, or irritation in the vulvar area, and reports of how the woman thinks her symptoms affect her physical activities and ability for sexual intimacy.

A thorough pelvic examination is recommended to rule out other causes of pain such as infection or trauma. The vulva should be inspected for erythema, ulcerations, and hyperpigmentation (Katz, 2012). A cotton swab is used to identify areas of pain on pressure to confirm presence of allodynia. A systematic assessment (e.g., using positions of the face of a clock) is suggested, and pain should be rated as mild, moderate, or severe. A speculum (a pediatric size is recommended) is used to examine the vagina for redness, erosions, and dryness. A swab of vaginal secretions is obtained and can be tested for yeast, increased white blood cells, and pH. Cultures for *Candida* and bacteria can be obtained. A bimanual examination may be performed (Katz).

Management strategies are individualized to the woman. Often a series of therapies or a combination of therapies is implemented to find the best treatment. There is little evidence to support one therapy over another. Oral medications include gabapentin and tricyclic antidepressants (Katz, 2012; Ventolini, 2011). Topical therapies include the use of lidocaine 5% ointment that can be applied nightly or prophylactically (i.e., before sexual intercourse) (Katz).

Other therapeutic measures that are reportedly helpful for symptoms include pelvic floor exercises, biofeedback, vaginal

dilator training, hypnosis, and cognitive-behavioral therapy (Katz, 2012; Ventolini, 2011).

Hygienic measures include wearing white cotton underwear, using 100% cotton menstrual pads, using soaps and detergents for sensitive skin, avoiding wearing tight clothing over the vulvar area, avoiding lubricants that contain propylene glycol, and using natural oils such as olive oil for lubricants (Ventolini, 2011).

Surgery is usually not recommended until other measures have proven to be ineffective. The surgical procedure is a vestibulectomy, a difficult procedure that removes the vestibule and hymen and has a high rate of complications (Katz, 2012). Success rates are reported to be between 65% and 90% (Ventolini, 2011). Laser ablation of the vulvar epithelium may also be an option, and response rates are reported to be similar to that of vestibulectomy (Ventolini).

Client information about vulvodynia including how to locate support groups is available on various websites including:

- International Society for the Study of Vulvovaginal Disease: www.issvd.org
- National Vulvodynia Association: www.nva.org
- Vulvar Pain Society: www.vulvarpainsociety.org

MALIGNANT NEOPLASMS

Malignant neoplasms of the reproductive system include cancers of the endometrium, the cervix, the ovary, the vulva, the vagina, and the uterine tubes. In 2014 an estimated 94,990 women in the United States were diagnosed with a gynecologic cancer; an estimated 228,790 women died from having endometrial cancer (ACS, 2014a). Overweight and obesity are associated with increased risk for developing many cancers, including cancers of the endometrium, ovary, and cervix. Evidence also suggests that being overweight increases the risk for cancer recurrence and decreases the likelihood of survival for these cancers (ACS).

Cancer of the Endometrium

Incidence and Etiology

Endometrial cancer is the most common malignancy of the reproductive system (ACS, 2014a). It is most commonly seen in perimenopausal and postmenopausal women between ages 50 and 65. Certain risk factors have been associated with the development of endometrial cancer, including obesity (especially upper body fat localization), nulliparity, infertility, late onset of menopause, diabetes mellitus, hypertension, PCOS, and family history of ovarian or breast disease (ACS; Creasman & Miller 2012). There appears to be an increased risk for endometrial cancer in families with hereditary nonpolyposis colorectal cancer (HNPCC). Hormone imbalance, however, seems to be the most significant risk factor. Numerous studies have correlated the use of exogenous estrogens (unopposed stimulation, i.e., absence of progesterone) in postmenopausal women with an increased incidence of uterine cancer. Tamoxifen taken by women for breast cancer also has been related to a slight increase in endometrial cancer (Creasman & Miller). Pregnancy and use of low-dose oral contraceptive pills appear to offer some protection (ACS). The incidence of endometrial cancer among Caucasian women is higher than that among African-American and Hispanic women; however, the mortality rates are higher in African-American women (ACS).

Endometrial cancer is slow growing and for that reason has a good prognosis if diagnosed at a localized stage. Most endometrial cancers are adenocarcinomas that develop from endometrial hyperplasia. The tumor usually develops in the fundus of the uterus and can spread directly to the myometrium and cervix, as well as to other reproductive organs. Metastasis (spread of cancer from its original site) is through the lymphatic system in the pelvis and through the blood to the liver, the lungs, and the brain.

CARE MANAGEMENT

Clinical Manifestations and Diagnoses

Assessment includes a history of physical symptoms. The cardinal sign of endometrial cancer is abnormal uterine bleeding (e.g., postmenopausal bleeding and premenopausal recurrent metrorrhagia). Thirty percent of postmenopausal bleeding is caused by carcinoma. Late signs include a mucosanguineous vaginal discharge, low back pain, or low pelvic pain. A pelvic examination may reveal the presence of a uterine enlargement or mass.

! NURSING ALERT

Women can be informed that they can identify their own risk for developing endometrial as well as ovarian, cervical, and breast cancers by filling out a confidential cancer risk assessment survey that is available at the American Cancer Society (ACS) website—www.cancer.org.

Histologic examination is used for diagnosis. A Pap test of cellular material obtained by aspiration of the endocervix identifies only one third to one half of cases. Endometrial biopsy or fractional curettage yields the most accurate results. Fractional curettage involves scraping the endocervix and endometrium for histologic evaluation to determine the grade of neoplasm and its stage (extent). Perforation of the uterus is a possible complication of this procedure. Endometrial biopsy is more commonly performed and identifies about 90% of cases (Creasman & Miller, 2012). It is usually done on an outpatient basis under local anesthesia. A suction-type curette is used to remove tissue for sampling. It is recommended that women at risk for HNPCC have an annual biopsy or transvaginal ultrasound beginning at age 35 (ACS, 2014a). Tests to determine the spread of cancer include liver function tests, renal function tests, chest x-ray, intravenous pyelography (IVP), barium enema, computed tomography (CT), magnetic resonance imaging (MRI), bone scans, and biopsy of suspicious tissues. The International Federation of Gynecology and Obstetrics (FIGO) classification system is used to describe the stages of endometrial carcinoma (Table 11-1).

Medical and Surgical Management

Collaborative efforts from various health disciplines are needed to work with the woman with endometrial cancer. All must have an understanding of the treatments that may be used.

For stage I adenocarcinoma of the endometrium limited to the uterus, total abdominal hysterectomy (TAH) and bilateral salpingo-oophorectomy (BSO) is the usual treatment

TABLE 11-1 2009 FIGO Classification of Endometrial Carcinoma

STAGE	DESCRIPTION
I (Includes grades 1, 2, or 3)	Tumor limited to corpus uteri
IA	No or less than half myometrial invasion
IB	Invasion equal to or more than half of the myometrium
II	Cervical stromal invasion, not extending beyond the uterus
III (Includes grades 1, 2, or 3)	Local and regional spread of tumor
IIIA	Tumor invades the serosa of the corpus uteri and/or adnexas
IIIB	Vaginal and/or parametrial involvement
IIIC	Metastases to pelvic and/or paraaortic lymph nodes
	IIIC1 Positive pelvic nodes
	IIIC2 Positive paraaortic lymph nodes with or without positive pelvic lymph nodes
IV (Includes grades 1, 2, or 3)	Tumor invasion of bladder and/or bowel mucosa and/or distant metastasis
IVA	Tumor invasion of bladder and/or bowel mucosa
IVB	Distant metastases, including intraabdominal metastasis and/or inguinal lymph nodes

From Creasman, W.T., & Miller, D.S. (2012). Adenocarcinoma of the uterine corpus. In P.J. DiSaia, W.T. Creasman, R.S. Mannel, & D.S. Mutch (Eds.), *Clinical gynecologic oncology* (8th ed.). Philadelphia: Saunders.

(Creasman & Miller, 2012). Radiation use in stage I continues to be studied; it can reduce the risk of recurrence, but evidence does not demonstrate improved survival rates or reduced metastasis to distant sites. It can be used when the woman is a poor surgical risk (Soliman & Lu, 2012). A **radical hysterectomy** (abdominal hysterectomy with wide excision of parametrial tissue laterally and uterosacral ligaments posteriorly), BSO, and pelvic node dissection usually are performed for stage II endometrial cancer. If nodes are positive or if there is extensive uterine disease or metastasis outside the uterus, external pelvic radiation (see “External Therapy” later in chapter) is usually done postoperatively. Internal radiation therapy or brachytherapy (placement of an applicator loaded with a radiation source into the uterine cavity) (see “Internal Therapy” later in chapter) also may be used before surgery or combined with external radiation. Treatment of advanced stages is individualized but usually includes a TAH-BSO plus chemotherapy or radiation, or both (Soliman & Lu).

Chemotherapy is used to treat advanced and recurrent disease, although no effective treatment regimen has been established (Soliman & Lu, 2012).

Progestational therapy—use of medroxyprogesterone (Depo-Provera) and megestrol (Megace)—may be effective for recurrent cancers, especially those that are estrogen receptor positive. These drugs usually do not cause acute side effects. Tamoxifen and raloxifene (see Medication Guide Guides: Tamoxifen and Raloxifene Hydrochloride: in Chapter 10) are antiestrogens that have shown some effectiveness against recurrent endometrial cancer (Creasman & Miller, 2012; Soliman & Lu, 2012).

Nursing Interventions

Nursing care is individualized to the woman and her specific situation and diagnosis. Interventions for the woman having surgery are directed by assessing her perception of the anticipated surgery, her knowledge of what to expect after surgery, and any

preoperative special procedures, such as cleansing enemas or douches. In today's practice of short hospital stays even for radical surgery, many of these preoperative procedures are performed at home before admission, so assessment of understanding becomes a critical nursing action (see Cultural Considerations). Nursing care for the woman having a TAH-BSO is similar to the care for a woman having a hysterectomy for leiomyoma described earlier. The following section focuses on care of the woman having a radical hysterectomy (see Nursing Care Plan).

CULTURAL CONSIDERATIONS

Meaning of Cancer

A woman's culture influences the meaning she attaches to cancer screening and diagnosis of cancer. Some women may be reluctant to be screened because of language barriers, lack of knowledge about the risks of gynecologic cancers, or belief that they are not at risk. Some women do not believe that care providers are sensitive to their values of modesty. A woman's response to a cancer diagnosis also must be appropriate to her cultural context for it to be acceptable to her. For example, body image issues (e.g., loss of uterus), the meaning of death, and pain responses (e.g., stoic or expressive) are influenced by cultural beliefs and values. In making assessments about these issues, the nurse takes into account the influence of culture before developing a plan of care.

Guimond, M.E., & Salman, K. (2013). Modesty matters: Cultural sensitivity and cervical cancer prevention in Muslim women in the United States. *Nursing for Women's Health, 17*(3), 210-217.

Preoperative Care. The nurse working with the woman preparing for a radical hysterectomy and pelvic node dissection should explain any preoperative procedures (see Box 11-2). Additional teaching is needed for the woman having a radical hysterectomy regarding possible postsurgical events (e.g., a suprapubic drain often remains in place for several days to a week).

Postoperative Care. Assessment of vital signs usually follows a postanesthesia protocol, gradually decreasing in frequency to two to four times a day. Intravenous fluids are maintained at a rate rapid enough to maintain hydration and electrolyte balance and are usually discontinued when the woman is taking oral fluids well and has no elevated temperature. A regular diet is resumed as tolerated. Intake and output are monitored. The Foley catheter is usually removed the morning after surgery and the first few voidings are measured.

The woman should turn and take deep breaths with assistance as needed. Breath sounds are assessed, and any deviations from normal are reported immediately. The most significant single cause of morbidity and prolonged hospitalization after major procedures is respiratory complications. Anesthesia and surgery alter breathing patterns and ability to cough. Atelectasis, pneumonia, and pulmonary embolus may occur.

To promote venous return and prevent deep vein thrombosis, the woman may wear antiembolic stockings or wear pneumatic pressure devices (i.e., boots) while she is in bed. Leg exercises and early ambulation are beneficial. Most women are encouraged to get out of bed the evening of or the day after surgery. Assistance in getting up and walking may be needed.

 **NURSING CARE PLAN**
Hysterectomy for Endometrial Cancer

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Anxiety related to lack of understanding of diagnosis, treatment, and prognosis of endometrial cancer as evidenced by woman's questions and concerns</i>	Woman will identify source of anxiety and verbalize understanding of diagnosis, effects of hysterectomy, and prognosis.	<p>Assess woman's level of understanding of procedure and its effects.</p> <p>Provide information about cancer of the endometrium, individualizing information to the woman's situation.</p> <p>Provide preoperative and postoperative teaching.</p>	<p>To correct any misunderstanding, provide clarification, and identify starting point for further information</p> <p>To provide clarification concerning treatment regimen</p> <p>To give anticipatory guidance and rationales for upcoming events</p>
<i>Fear related to diagnosis of endometrial cancer as evidenced by woman's questions and concerns</i>	Woman will be able to verbalize that fears have diminished after the procedure.	<p>Through therapeutic communication, encourage verbalization of fears.</p> <p>Encourage woman to identify support system.</p>	<p>To provide clarification and validation of feelings</p> <p>To have resources readily available as needed</p>
<i>Acute Pain related to surgical procedure as evidenced by woman's verbal and nonverbal behaviors</i>	Woman will verbalize decrease in intensity and number of painful episodes after interventions.	<p>Assess the location and intensity of pain by using a pain scale.</p> <p>Administer prescribed analgesics.</p> <p>Use nonpharmacologic techniques such as distraction, relaxation, position changes, and heat.</p> <p>Monitor effectiveness of interventions.</p>	<p>To use appropriate treatment</p> <p>To decrease perception of pain</p> <p>To decrease perception of pain</p> <p>To modify interventions if needed</p>
<i>Risk for Infection related to surgical incision and impaired skin integrity</i>	Woman will experience no infection after the procedure.	<p>Assess for clinical manifestations of infection: fever, drainage, redness, swelling at the incision site.</p> <p>Encourage a diet high in protein, vitamin C, and calories.</p> <p>Teach woman to maintain aseptic technique when performing dressing changes, such as good handwashing.</p>	<p>To provide prompt treatment</p> <p>To promote wound healing</p> <p>To decrease chance of introducing microorganisms at the incision site</p>
<i>Disturbed Body Image related to loss of uterus as evidenced by woman's statements of fears or concerns</i>	Woman will maintain a positive body image.	<p>Encourage expression of feelings through therapeutic communication.</p> <p>Encourage woman to share feelings with significant other.</p> <p>Assist woman to identify support systems.</p>	<p>To provide clarification of and validity of feelings</p> <p>To obtain emotional support</p> <p>To be available in case she needs to ventilate feelings</p>
<i>Sexual Dysfunction related to perceived loss of femininity</i>	Woman will resume sexual relationship with partner.	<p>Encourage verbalization of feelings related to sexuality.</p> <p>Provide opportunity for role-playing.</p> <p>Encourage communication with partner.</p> <p>Refer to sexual counselor.</p>	<p>To provide clarification</p> <p>To alleviate fears about interactions with partner</p> <p>To address concerns about resumption of sexual relations</p> <p>To provide in-depth intervention as needed</p>

Hemorrhage is always a possible complication after surgery. The wound drainage tube is emptied as needed or every 4 hours, and the amount and character of drainage are recorded. Drainage from any tube is assessed for bleeding. Vaginal drainage, if any, should be serosanguineous. Hematuria is noted and recorded. The primary health care provider is kept apprised of any deviations from normal expectations.

Paralytic ileus may occur after surgery in which the intestines have been manipulated. Use of a nasogastric tube, limiting oral fluids, and early ambulation all support the return of

gastrointestinal function. An enema or suppository may bring relief of flatus and stimulate the return of bowel function. Oral laxatives should not be given until lower bowel function has returned.

Narcotic analgesics and NSAIDs are used for postoperative pain. Nursing measures such as massages, repositioning, and emotional support are all helpful adjuncts to pharmacologic control of discomfort.

Because the in-hospital convalescent period is generally short, close observation by the nurse and attention to detail

BOX 11-4 Nutritional Management for Common Problems Related to Gynecologic Cancer or Treatment**Altered Taste**

- Rinse mouth with baking soda solution
- 1 teaspoon salt, 1 teaspoon baking soda to 1 quart (liter) water
- Use extra seasoning, spices
- Use sauces and marinades for meats
- Eat fish or chicken instead of red meat
- Eat tart foods to stimulate taste buds
- Try sugar-free mints, gum, hard sour candy

Anorexia

- Eat with family, friends
- Eat favorite foods any time
- Try new foods, recipes
- Use smaller servings
- Eat high-calorie, high-protein snacks
- Drink nutritional supplements
- Exercise before meals to stimulate appetite

Nausea and Vomiting

- Drink clear liquids
- Avoid carbonated fluids
- Avoid sweet, rich, fatty foods
- Eat cool foods rather than hot or warm foods
- Eat six to eight small meals a day
- Consume a high-calorie, high-protein diet
- Eat toast, bland foods
- Avoid lying down at least 1 hour after eating
- Take antiemetics before meals

Stomatitis

- Eat small meals
- Eat soft, bland foods
- Avoid rough-textured foods (e.g., chips, crackers)

- Drink 8 to 10 cups of fluids a day
- Avoid citrus fruits, spicy foods
- Avoid alcohol
- Avoid very hot or very cold foods
- Drink nutritional supplements, milkshakes
- Drink through a straw if mouth is sore
- Rinse mouth frequently with baking soda solution or prescribed mouthwash
- Eat liquid or pureed foods as needed

Constipation

- Increase fiber (bran, fresh fruits, and vegetables)
- Drink 8 to 10 cups of fluids a day (2 to 2.4 L/day)
- Eat natural laxative foods (prunes, apples)
- Avoid cheese products
- Drink warm drinks with breakfast

Diarrhea

- Limit milk to 2 cups a day (500 ml)
- Avoid high-fiber, spicy, fatty foods
- Eat foods high in potassium
- Increase fluid intake (3 L/day) (12.5 cups); avoid caffeine and carbonated fluids
- Add nutmeg to food to decrease gastric motility
- Eat a high-protein, high-carbohydrate diet
- Eat small meals and snacks

Postoperative Recovery

- Eat food high in iron
- Eat high-protein foods
- Eat foods high in vitamins C, B complex, and K
- Drink 6 to 8 glasses of fluids a day (1.5 to 2 L/day)

Data from American Cancer Society. (2013). *Managing eating problems caused by surgery, radiation, and chemotherapy*. Available at www.cancer.org.

are critical. Nursing actions appropriate to this period include monitoring for urinary retention after the catheter is removed, monitoring the woman's appetite and diet, monitoring bowel function, and encouraging progressive ambulation and self-care.

Discharge Planning and Teaching. Discharge planning and teaching are done throughout the preoperative and postoperative phases and culminate during the convalescent phase. Discharge teaching topics for the woman with a radical hysterectomy are similar to those that can be found in the Teaching for Self-Management box: Care After Myomectomy or Hysterectomy.

Care for the woman who has had external or internal radiation therapy is the same as that described for the woman with cervical cancer (see later discussion).

Nursing care for the woman undergoing chemotherapy depends on the type of drug given. If alopecia is likely, the nurse can suggest wigs, scarves, or other kinds of head coverings. If the therapy affects the appetite or causes gastrointestinal side effects, suggestions such as those in Box 11-4 may be useful.

After discharge the woman may require continued nursing care or monitoring of her physical status or advice for managing the treatment effects of the cancer. The family is likely to provide much of the woman's care. Nurses must identify

what families see as their greatest need so that interventions are planned that best use the family's resources.

Psychologic care for the woman with endometrial cancer is essential. A woman needs to be able to discuss her concerns about having cancer and the potential for recurrence. She may have fears of death, permanent disfigurement, and change in functioning; altered feelings of self as a woman; and concerns regarding her femininity, sexuality, and loss of reproductive capacity. She may have questions arising from things she has heard about posthysterectomy changes, radiation therapy, or chemotherapy. Significant others should be encouraged to express their questions and concerns as well. The client and her significant others may benefit from a referral to a community cancer support group (see the ACS website, www.cancer.org).

Cancer of the Ovary

Incidence and Etiology

Ovarian cancer is the second most frequently occurring reproductive cancer and causes more deaths than any other female genital tract cancer (ACS, 2014a). Because the symptoms of this type of cancer are vague and definitive screening tests do not exist, ovarian cancer is often diagnosed in an advanced stage. The 5-year survival rate for cancer diagnosed at a localized stage is about 92%; however, only about 15% of all ovarian cancers

are found at this stage. For advanced stages, the rate is about 27% (ACS). Malignant neoplasia of the ovaries occurs at all ages, including in infants and children. However, cancer of the ovary is seen primarily in women older than age 50, with the greatest number of cases found in women ages 60 to 64 years (Eisenhauer, Salani, & Copeland, 2012).

Major histologic cell types occur in different age groups, with malignant germ cell tumors most common in women between 20 and 40 years of age and epithelial cancers occurring in the perimenopausal age groups. The spread of ovarian cancer is by direct extension to adjacent organs, but distal spread can occur through the lymph system to the liver and the lungs.

The cause of ovarian cancer is unknown; however, a number of risk factors have been identified. These factors include nulliparity, infertility, previous breast cancer, family history of ovarian or breast cancer, and history of HNPCC. Inherited BRCA1 and BRCA2 mutations increase the risk, but 90% of women do not have inherited ovarian cancer (Coleman, Ramirez, & Gershenson, 2012; Eisenhauer, 2012). Women of North American or northern European descent have the highest incidence of ovarian cancers. Pregnancy and use of oral contraceptives seem to have some protective benefits against ovarian cancer, whereas use of postmenopausal estrogen may increase the risk. Research has shown that preventive removal of the ovaries and uterine tubes can decrease the risk (ACS, 2014a). Genital exposure to talc, a diet high in fat, lactose intolerance, and use of fertility drugs have been suggested as risk factors, but research findings are inconclusive (Coleman et al.; Eisenhauer et al.).

Clinical Manifestations and Diagnosis

Ovarian cancer was once called a silent disease because early warning symptoms that would send a woman to her health care provider are absent (e.g., no bleeding or other discharge and no pain). However research has shown that some women experience symptoms that are associated with early ovarian cancer. These include abdominal bloating, noticeable increase in abdominal girth, pelvic or abdominal pain, difficulty eating or feeling full quickly, and urinary urgency or frequency (ACS, 2014a; Eisenhauer et al., 2012). The increase in abdominal girth (caused by ovarian enlargement or ascites) is usually attributed to an increase in weight or a shift in weight that is seen commonly in women entering their middle years. An ovary enlarged 5 cm or more than normal that is found during routine examination requires careful diagnostic workup. Pelvic pain, anemia, and general weakness and malnutrition are signs of late-stage disease.

Early diagnosis of ovarian cancer is uncommon. Attempts at early detection have not proven to be reliable. Taking a family history is important because it may reveal cancer of the uterus or breast. Transvaginal ultrasound, CA-125 antigen (a tumor-associated antigen) testing, and frequent pelvic examinations have all been used without a great deal of success. Research continues on the use of proteomics (study of proteins in blood) to identify ovarian cancer in its earlier stages (Eisenhauer et al., 2012).

Transvaginal ultrasound and CA-125 screening currently are not recommended for routine screening in the general

population but are recommended for women who are at high risk (e.g., BRCA1 mutation carriers) (ACS, 2014a). Routine pelvic examination continues to be the only practical screening method for detecting early disease, even though few cancers are detected in women without symptoms. Any ovarian enlargement should be considered highly suggestive and needs further evaluation by laparoscopy or laparotomy. Responsibility for diagnosis rests with the pathologist. The size of the tumor is not indicative of the severity of disease. Clinical staging is done surgically and gives direction to treatment and prognosis (Eisenhauer et al., 2012).

Medical and Surgical Management

Treatment is dictated by the stage of the disease at the time of initial diagnosis. Surgical removal of as much of the tumor as possible is the first step in therapy for all stages. This may involve just the removal of one ovary and tube (if the cancer is limited to one ovary and childbearing is desired) or the radical excision of the uterus, ovaries, tubes, and omentum. Cytoreductive surgery (the debulking of the poorly vascularized larger tumors) also is done. The smaller the volume of tumor remaining, the better the response to adjuvant therapy. Because about three quarters of women are in stage II, III, or IV disease at the time of diagnosis, surgical cure is not possible; therefore, after tumor reduction surgery is performed, women with epithelial cell carcinoma will receive chemotherapy.

A platinum-based combination of antineoplastic drugs such as carboplatin and paclitaxel is recommended for most women with advanced disease (Eisenhauer et al., 2012).

Second-look surgery is used to determine the response of the disease to chemotherapy and whether treatment should be continued; however, this procedure usually is not done unless it is part of a research protocol (Eisenhauer et al., 2012).

Radiation has been used to treat early-stage disease, and some women have had long-term survival after debulking surgery followed by radiation therapy. It has also been used as a palliative measure in advanced disease (Coleman et al., 2012).

Nursing Interventions

Awareness of the symptoms of and risk factors for ovarian cancer are low in the general population. Therefore, nurses need to be involved in raising the awareness of these risks and symptoms with the public and with women who are seeking care in health care settings such as clinics and physician offices.

The woman diagnosed with ovarian cancer has concerns similar to those described for the woman with endometrial and cervical cancer. Nursing interventions for the woman having surgery, chemotherapy, or external radiation therapy for ovarian cancer are described in other sections of this chapter.

Women with advanced ovarian cancer have a significant rate of recurrence. Follow-up for 5 years must be intensive. When a cure or remission cannot be achieved, palliative measures are initiated that alleviate symptoms of the progressing disease and provide comfort and maximal function. As the disease progresses, nutritional support, including enteral feedings and parenteral hyperalimentation, may be needed because of the effects on the gastrointestinal tract of both the disease and the

treatments. The goal of nursing care is assisting the woman to maintain quality of life and to remain at home with her family as much as possible.

Because the period between a focus on cure and a focus on palliation is often prolonged, the woman with ovarian cancer is apt to experience most of the grief stages described by Kübler-Ross and to need support and encouragement through each stage. After diagnosis the woman often experiences denial and then anger. As treatment begins, she may “bargain” for a cure. If treatment is successful and death is forestalled by remission or cure, the process of adjustment to dying ceases, and the woman again focuses on life and its challenges but may continue to have uncertainty about her diagnosis. When treatment fails to secure a cure or remission ends, the woman must turn again to the task of adjustment (see Legal Tip).

LEGAL TIP: Advance Directives

Nurses who work with clients in hospitals with federal funding must know that because of the Patient Self-Determination Act, all clients must be asked if they have knowledge of advance directives and be provided with the information if desired. This is important to nurses working in gynecology-oncology settings, where decisions about living wills and “no codes” may be issues.

Family and friends also have diverse feelings. When grieving is prolonged, as it often is when the woman has cancer, the stress can be enormous and can interfere with other interpersonal relationships. If the woman is hospitalized, the environment may further intrude on relationships, limiting privacy and access to the woman and hindering opportunities for caring gestures. The nurse can assist the woman and her family to share their feelings with each other and help them develop a support network. Referral to a cancer support group may be useful (e.g., National Ovarian Cancer Coalition, www.ovarian.org; Ovarian Cancer National Alliance, www.ovariancancer.org).

Cancer of the Cervix

Incidence and Etiology

Cervical cancer is the third most common reproductive cancer. The accessible location of the cervix to both cell and tissue study and direct examination have led to a refinement of diagnostic techniques, contributing to improved diagnosis and management of these disorders. The incidence of invasive cancer has decreased since the 1980s, reducing mortality rates (ACS, 2014a).

Cancer of the cervix begins as neoplastic changes in the cervical epithelium. Terms that have been used to describe these epithelial changes or preinvasive lesions include **dysplasia** and **cervical intraepithelial neoplasia (CIN)**, the term currently used. CIN 1 refers to abnormal cellular proliferation in the lower one third of the epithelium; this change tends to be self-limiting and generally regresses to normal. CIN 2 involves the lower two thirds of the epithelium and may progress to carcinoma in situ. CIN 3 involves the full thickness of the epithelium and often progresses to carcinoma in situ. **Carcinoma in situ (CIS)** is diagnosed when the full thickness of epithelium is replaced with abnormal cells (Creasman, 2012) (Fig. 11-11).

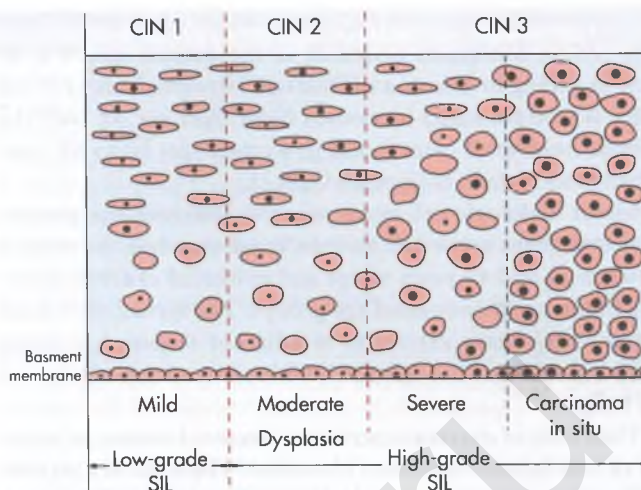

FIG 11-11 Diagram of cervical epithelium showing progressive changes and various terminology. *CIN*, Cervical intraepithelial neoplasia; *SIL*, squamous intraepithelial lesion.

FIG 11-12 Location of squamocolumnar junction according to age. The location where the endocervical glands meet the squamous epithelium becomes progressively higher with age. A, Puberty. B, Reproductive years. C, Postmenopausal.

Terms used to describe neoplastic changes in abnormal cervical cytology reports are low-grade and high-grade **squamous intraepithelial lesions (SILs)**; however, CIN continues to be a common term used in clinical practice.

Preinvasive lesions are limited to the cervix and usually originate in the squamocolumnar junction or **transformation zone** (Fig. 11-12). Intensive study of the cervix and the cellular changes that take place has shown that most cervical tumors have a gradual onset rather than an explosive one. Preinvasive conditions may exist for years before the development of invasive disease. These preinvasive conditions are highly treatable in many cases.

Invasive carcinoma is the diagnosis when abnormal cells penetrate the basement membrane and invade the stroma. There are two types of invasive carcinomas of the cervix: microinvasive and invasive. Microinvasive carcinoma is defined as one or more lesions that penetrate no more than 3 mm into the stroma below the basement membrane with no areas of lymphatic or vascular invasion (Creasman, 2012). Invasive carcinoma describes invasion that goes beyond these parameters. The staging of invasive carcinoma extends from CIS to distant metastasis or disease outside the true pelvis.

Approximately 90% of cervical malignancies are squamous cell carcinomas; 10% are adenocarcinomas. Squamous cell carcinomas can spread by direct extension to the vaginal mucosa, the pelvic wall, the bowels, and the bladder. Metastasis usually occurs in the pelvis, but it can occur in the lungs and the brain through the lymphatic system.

The average age range for the occurrence of cervical cancer is 40 to 50 years; however, preinvasive conditions may exist for 10 to 15 years before the development of an invasive carcinoma. About 70% to 80% of cervical cancers are caused by human papillomavirus (HPV) (Creasman, 2012). A strong link has been established between HPV types 16 and 18 and cervical neoplasia (see Chapter 7 for a discussion of HPV including preventive vaccines). Risk factors for persistent HPV infections include early age at first coitus (younger than 20 years), multiple sexual partners (more than two), a sexual partner with a history of multiple sexual partners, high parity, and belonging to a lower socioeconomic group. Potential factors include long-term use of OCs, cigarette smoking, and intrauterine exposure to diethylstilbestrol (DES) (ACS, 2014a; Creasman; Tewari & Monk, 2012). Low levels of beta-carotene, vitamin C, and folate are being investigated as potential risk factors (Tewari & Monk).

The incidence of cervical cancer in the United States is highest in Hispanic women and lowest in Native-American women, whereas the highest mortality occurs in African-American women (ACS, 2014a). Factors that may influence cervical screening behaviors for these groups include lack of a health promotion or disease prevention perspective, lack of knowledge about Pap tests and availability of services, financial barriers, and failure of health care providers to recommend screening (ACS). There also is a high rate of CIN in human immunodeficiency virus–positive women, suggesting that altered immune status is a risk factor (Creasman, 2012).

COMMUNITY ACTIVITY

- Visit the website www.cdc.gov/cancer/cervical/what_cdc_is_doing/amigas.htm.
- What is AMIGAS? What is a *promotora*? Why is this program important for the health of Hispanic women? How does this program promote cervical cancer screening among Hispanic women? What are the components of this educational model?
- Find out if there is an AMIGAS program in your community. If so, what is its effect?

Clinical Manifestations and Diagnosis

Preinvasive cancer of the cervix is often asymptomatic. Abnormal bleeding, especially postcoital bleeding, is the classic symptom of invasive cancer. Other late symptoms include rectal bleeding, hematuria, back pain, leg pain, and anemia. Diagnosis includes taking a history that includes menstrual and sexual activity information, particularly sexually transmitted infections and abnormal bleeding episodes (Creasman, 2012). A pelvic examination usually is normal except in late-stage cancer.

The most widely used method to detect preinvasive cancer is the Pap test, which can detect 90% of early cervical changes. According to the ACS, the American Society for Colposcopy and Cervical Pathology, and the American Society for Clinical Pathology, cervical cancer screening should begin at age 21. For women ages 21 to 29, screening should be done every 3 years with conventional or liquid-based Pap tests. For women ages 30 to 65, screening should be done every 5 years with both the HPV test and the Pap test (preferred method), or every 3 years with the Pap test alone (acceptable). Women who are 65 years or older who

BOX 11-5 2001 Bethesda System for Reporting Cervical Cytology Results

Results/Interpretations

Negative for Intraepithelial Malignancy

- Organisms (e.g., evidence of infections)
- Other nonneoplastic findings (e.g., inflammation, radiation changes, atrophy)
- Glandular cells status posthysterectomy
- Atrophy

Epithelial Cell Abnormalities

- Squamous cells
 - Atypical squamous cell (ASC)
 - Of undetermined significance (ASC-US)
 - Cannot exclude high-grade squamous intraepithelial lesion (HSIL) (ASC-H)
 - Low-grade squamous intraepithelial lesion (LSIL)
 - Human papillomavirus (HPV), cervical intraepithelial neoplasia (CIN) 1
 - HSIL
 - CIN 2, CIN 3
 - Squamous cell carcinoma

Glandular Cell

- Atypical cells including endocervical, endometrial, and glandular or not otherwise specified
- Atypical cells including endocervical or glandular, suggestive of neoplasia (endocervical or not otherwise specified)
- Endocervical adenocarcinoma in situ
- Adenocarcinoma (endocervical, endometrial, extrauterine, or not otherwise specified)

Data from Creasman, W. (2012). Preinvasive disease of the cervix. In P.J. DiSaia, W.T. Creasman, R.S. Mannel, & D.S. Mutch (Eds.), *Clinical gynecologic oncology* (8th ed.). Philadelphia: Saunders.

have had 3 or more consecutive negative Pap tests or more than 2 consecutive negative HPV and Pap tests within the past 10 years, with the most recent test occurring within 5 years, and women who have had a total hysterectomy can stop cervical cancer screening (ACS, 2014a; Moyer and U.S. Preventive Services Task Force, 2012; Saslow, Soloman, Lawson, et al., 2012). Women in high risk categories should have more frequent Pap tests.

Pap test results have been recorded by using several different classification systems. The reporting system most often used today is the Bethesda system, which reports on gynecologic cytology as well as histology of cervical lesions (Box 11-5). Changes secondary to inflammation, treatment (e.g., radiation), and contraceptive devices can be reported, as well as changes caused by infections. Epithelial cell abnormalities are described in three categories: atypias, or atypical squamous cells (ASC); low-grade squamous intraepithelial lesions (LSILs); and high-grade squamous intraepithelial lesions (HSILs).

Several options for follow-up of a finding of ASC of undetermined significance (ASC-US) are suggested. These include immediate colposcopy, repeating cytology at 6 months and 12 months, or HPV testing and referral for colposcopy if the test is positive. Colposcopy is recommended for evaluation of LSIL except in adolescents; teens can be followed with cytology tests at 6 and 12 months. Follow-up for a report of HSIL includes colposcopy or loop electrosurgical excision (Creasman, 2012).

Colposcopy is the examination of the cervix with a stereoscopic binocular microscope that magnifies the view of the cervix. Usually a solution of 3% acetic acid is applied to the cervix for better visualization of the epithelium and to identify areas for biopsy. Colposcopy is not an invasive procedure and is usually well tolerated. However, a woman who is scheduled for colposcopy because of an abnormal Pap test may be anxious and may need explanations or written information about what to expect during the procedure.

Biopsy is the removal of cervical tissue for study; several techniques can be used. An endocervical curettage is an effective diagnostic tool in about 90% of cases. It can be performed as an outpatient procedure with little or no anesthesia. It may be uncomfortable, and interventions to help the woman relax and cope with the pain may be needed.

Conization and loop electrosurgical excision procedure (LEEP) (see later discussion) can be done as outpatient procedures, although neither is usually performed unless the biopsy is positive or the results of the colposcopy are unsatisfactory. **Conization** involves removal of a cone of tissue from the exocervix and endocervix (Fig. 11-13). It can be a cold knife procedure, a laser excision, or an electrosurgical excision (Fig. 11-14) (see later discussion). There are two advantages to a cone biopsy. It can be used (1) to establish the diagnosis and (2) to effect a cure. If CIS is diagnosed, and if the woman wishes to retain her childbearing capacity, conization removes the abnormal tissue; further treatment (e.g., hysterectomy) is unnecessary. The woman is monitored with Pap tests and colposcopy when indicated.

If invasive cancer is diagnosed, other diagnostic tests can assess the extent of spread (see earlier discussion under endometrial cancer). Once the extent of the cancer is known, treatment begins.

CARE MANAGEMENT

For the woman diagnosed with invasive carcinoma of the cervix, pretherapy assessment includes physical, psychologic, and educational components, regardless of whether surgery or radiation is the method of treatment. Physical assessment includes a review of current medications because medications for other medical problems may have to be continued. Skin is assessed to identify potential pressure points; respiratory and gastrointestinal status and state of nutrition are important factors to assess. Urinalysis and complete blood count also are commonly performed. An electrocardiogram and a chest x-ray examination

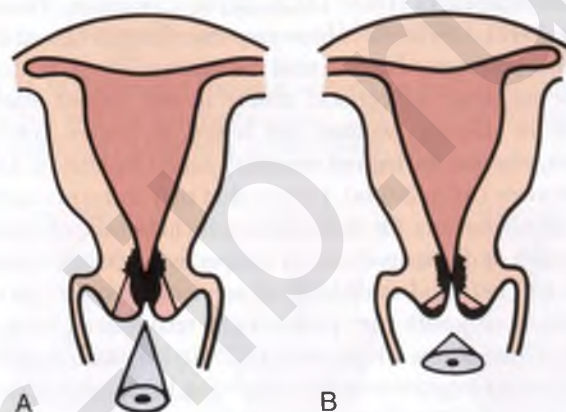

FIG 11-13 A, Cone biopsy for endocervical disease. Limits of lesion were not seen colposcopically. B, Cone biopsy for cervical intraepithelial neoplasia of the exocervix. Limits of lesion were identified colposcopically. (From Creasman, W. [2007]. Preinvasive disease of the cervix. In P.J. DiSaia, W.T. Creasman, R.S. Mannel, & D.S. Mutch [Eds.], *Clinical gynecologic oncology* [8th ed.]. Philadelphia: Saunders.)

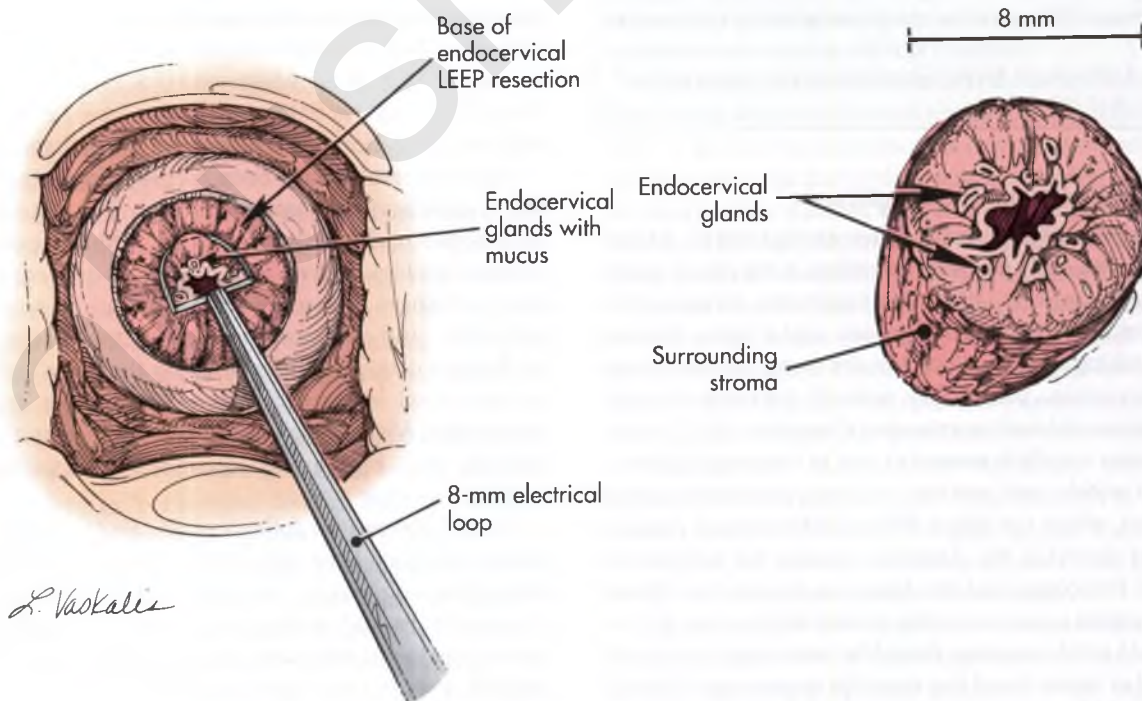

FIG 11-14 Electrosurgical excision. The electric loop vaporizes quickly and removes cone of tissue. LEEP, Loop electrosurgical excision procedure. (From Nichols, D., & Clark-Pearson, D. [2000]. *Gynecologic, obstetric, and related surgery* [2nd ed.]. St. Louis: Mosby.)

may be done if use of a general anesthetic is anticipated for surgery or placement of internal applicators.

Psychologic assessment is important because frequently these women are emotionally distressed about the diagnosis and anticipated treatment (i.e., fear of being radioactive and fear of surgery and pain) and fear that family or significant others will become distant.

Educational assessment involves identifying the woman's current knowledge base regarding the diagnosis and proposed therapeutic regimen.

Nursing diagnoses for the woman having surgery for cervical cancer are similar to those identified for the woman having a hysterectomy for endometrial cancer (see Nursing Care Plan: Hysterectomy for Endometrial Cancer). Nursing diagnoses for a woman having external or internal radiation therapy are listed in Box 11-6.

Medical and Surgical Management

Once a diagnosis has been identified, a course of treatment is planned. For preinvasive lesions, several techniques are used. As stated, because many preinvasive conditions are detected in younger women who may wish to continue childbearing, treatment is geared toward eradicating abnormal cells while attempting to preserve the structure of the cervix. The techniques available for preinvasive lesions are cryotherapy, laser therapy, and LEEP, all of which have comparable success rates in treating CIN (Creasman, 2012) (Box 11-7). Five-year survival rates are more than 91% when the cancer is localized (ACS, 2014a).

Treatment for invasive cancer includes surgery, radiation therapy, and chemotherapy. Once the cancer is staged, treatment is begun. Microinvasive cancer is usually treated with conization, but a hysterectomy is often done if childbearing is not desired. The choice of treatment for early-stage invasive cancer is hysterectomy or chemoradiation therapy (Tewari & Monk, 2012). A radical hysterectomy (see previous discussion) is performed if the cancer has extended beyond the cervix but

not to the pelvic wall. Locally advanced stages of cervical cancer usually are treated with radiation therapy, both external and internal, and chemotherapy. Late stages are usually treated with radiation and chemotherapy.

Radiation Therapy. Radiation may be delivered by internal radium applications to the cervix or external radiation therapy that includes lymphatics of the pelvic side wall. In preparation for radiation therapy the woman must maintain good nutritional status and a high-protein, high-vitamin, and high-calorie diet. Anemia, if present, should be corrected before initiating radiotherapy.

External radiation therapy and internal radiation therapy are given in various combinations for the best results and are tailored to each woman and her particular lesion. For example, external radiation may be given first to treat regional pelvic nodes and to shrink the tumor. External radiation is usually an outpatient procedure given 5 days a week for 4 to 6 weeks. Internal radiation therapy consists of one or two intracavitary treatments at least 2 weeks apart (Tewari & Monk, 2012).

External radiation is provided by megavoltage machines such as cobalt, and supervoltage machines such as linear accelerators and betatron, all of which have the distinct advantage

BOX 11-6 Nursing Diagnoses for the Woman Having Radiation Therapy

Deficient Knowledge related to:

- Treatment procedures

Fear/Anxiety related to:

- Diagnosis
- Anticipated pain
- Concerns about radioactivity
- The response of the significant other or family

Disturbed Sensory Perception related to:

- Internal radiation therapy
- Restricted contact with visitors and nursing staff

Risk for Impaired Skin Integrity related to:

- External radiation exposure
- Immobility and bed rest (internal radiation therapy)

Risk for Injury related to:

- Dislodgment of internal radiation source

Acute Pain related to:

- Internal applicators

Sexual Dysfunction related to:

- Treatment or concerns of significant other

BOX 11-7 Surgical Alternatives for Preinvasive Cancer of the Cervix

Cryosurgery

- A technique to freeze abnormal cells is used, and when sloughing occurs, normal tissue is regenerated.
- Side effects occurring after treatment are usually few and not serious. A profuse watery discharge can persist for 2 to 4 weeks.
- Endocervical cells are thought to regenerate, leaving a normal cervical canal in most instances.
- Surveillance with frequent Pap tests and colposcopic examination must continue indefinitely after this type of conservative therapy.

Laser Ablation

- A laser mounted on a colposcope that allows precise direction of a beam of light (heat) is used to remove diseased tissue.
- For treatment of the cervix (relatively insensitive tissue), little or no anesthesia may be needed, although a burning or cramping sensation may be noticed.
- The cervix treated with CO₂ laser will show epithelial regrowth beginning by 2 days afterward. The site is usually healed in 4 to 6 weeks. The original architecture of the cervix is preserved, and the squamocolumnar junction remains visible; however, there can be more damage to normal tissues than with other treatments.
- Women usually have less vaginal discharge than with cryosurgery, but can have more discomfort after the procedure (Noller, 2012).

LEEP (Loop Electrosurgical Excision Procedure)

- A standard treatment for cervical intraepithelial neoplasia in the United States that uses a wire loop electrode that can excise and cauterize with minimal tissue damage (see Fig. 11-14)
- Healing is rapid, and there is only a mild discharge afterward.
- Possible complications include bleeding, cervical stenosis, infertility, and loss of cervical mucus.

FIG 11-15 Intracavitary implant. Applicator in place in uterus is loaded with radium source.

of providing a more homogeneous dose to the pelvis. Before treatment begins, a localization procedure is done to determine the best way to deliver the treatments. Markings or small tattoos may be placed on the body to make sure the woman is positioned correctly to receive treatment (Workman, 2013).

For internal radiation therapy the woman may be treated in the hospital or in a special outpatient unit. If treatment is done in the hospital, she is taken to the operating room, and while she is under general or spinal anesthesia, a specially designed applicator is placed into her vagina and cervix. X-rays are taken to make sure the applicator is correctly placed. The woman is returned to her room, where the radioactive source is placed into the applicator (Fig. 11-15). The source remains in place from 12 hours to 3 days. If treatment is in the outpatient setting, the applicator is inserted into the uterus in a treatment room; use of high-dose implants shortens the treatment time and is being used more frequently than low-dose implants because no hospital stay is required (Tewari & Monk, 2012; Workman, 2013).

In advanced carcinoma of the cervix, conventional intracavitary applicators are not applicable. Interstitial therapy uses a template to guide the transperineal insertion of a group of 18-gauge hollow steel needles into the lesion (Fig. 11-16). After the needles are placed, the iridium wires are inserted when the woman is returned to her room.

Nursing Interventions. Nursing actions for external and internal radiation differ, so they are discussed separately.

External Therapy. Before external radiation therapy the woman's anxiety may be so high that information given by the radiologist may not be processed. The nurse should reinforce or fill in gaps, especially related to the following: the equipment, which is similar to that used for x-ray examination except larger; the hyperbaric oxygen chamber, which may be used to increase cellular oxygen and thus make tumor cells more radiosensitive; the radiotherapist, who will be behind a shield, but still close by and in communication with her; the position she will be put in and asked to maintain for some minutes; and the therapy, which is painless.

During the course of therapy, the woman is counseled regarding maintaining general good health. To maintain good skin care the woman is taught to assess her skin often; avoid

FIG 11-16 Interstitial-intracavitary implant.

soaps, ointments, cosmetics, and deodorants if the axilla is being irradiated because these may contain metals that alter the dose she receives and could lead to skin breakdown; wear loose clothing over the area and cotton underwear (or no underwear); use an air mattress or cover the mattress with foam pads or sheepskin; avoid exposing the irradiated areas to temperature extremes (e.g., hot tubs); and especially avoid removing the markings made by the radiologist. If her skin becomes red or itchy she can treat it with remedies recommended by the radiologist (e.g., aloe vera lotion, Aquaphor, or warm sitz baths). To treat skin that is broken or desquamating, the woman is shown how to use remedies prescribed by the radiologist (e.g., irrigation with warm water, application of antibiotic or lanolin ointment, exposure to air, and application of a loose dressing). The use of adhesive (or any) tape directly on the target area of skin should be avoided (Workman, 2013).

To maintain good nutrition the woman is reminded to keep a daily record of weight; use high-protein supplements; eat small, attractive, appetizing meals that are more bland than spicy; and keep the environment light, airy, clean, and quiet (especially before and after meals). A dietitian consult may be needed to help the woman and her family plan to meet her nutritional needs. If she is ill enough to be hospitalized, she may need total parenteral nutrition or tube feedings. Nausea interferes with adequate intake; therefore, the woman may take antiemetics, as necessary. High daily fluid intake (2 to 3 L) should be suggested if not contraindicated. To increase her comfort, minimize infection, and promote adequate food intake, she is encouraged to perform frequent oral hygiene. Box 11-4 provides other suggestions for nutritional problems associated with radiation treatment.

The nurse explains, as necessary, the need for routine blood studies to monitor the white blood cell count (to determine degree of immunosuppression). The woman and her family will need information about neutropenia, thrombocytopenia, and anemia and precautions to be taken. Because she is more vulnerable to infection, she is reminded of general measures to

avoid infection (e.g., practice good hygiene, avoid people with infection, avoid large crowds, keep environment clean).

After the radiation treatment is completed, the woman needs information for self-care (see Teaching for Self-Management). She should also be informed that side effects of the treatment, especially fatigue and altered taste sensations, can continue for weeks after the therapy is completed.

TEACHING FOR SELF-MANAGEMENT

Care After External Radiation Therapy

- Avoid infection and report symptoms of infection to the health care provider immediately.
- Maintain good nutrition and fluid intake.
- Anticipate possible effects of radiation for 10 to 14 days after the last treatment.
- Expect signs of healing to occur in about 3 weeks.
- Maintain good skin and mouth care to support a sense of well-being and prevent infection.
- Report the following symptoms to your health care provider:
 - Continued gastrointestinal symptoms (nausea, vomiting, anorexia, diarrhea)
 - Increasing skin irritation at the site of therapy (redness, swelling, pain, pruritus)
- Take medications as prescribed, and avoid any medications not prescribed or approved by the health care provider.

Internal Therapy. Internal radiation therapy may require hospitalization or may be done in a special outpatient unit. Radiation safety officers determine the precautions to be observed in each situation. This discussion focuses on treatment in the hospital setting, but similar precautions are used in the outpatient setting. Printed instruction sheets are usually available, stating precautions to be followed for each type of radiation substance used. A precaution sign is placed on the door of the woman's room.

SAFETY ALERT

Personnel who come into direct contact with anyone receiving radiation therapy should wear a film badge or other device to monitor the amount of exposure received.

Nurses must protect themselves from overexposure to radiation. Precautions include the following (Workman, 2013):

- Careful isolation techniques: wearing gloves while handling bodily fluids and observing good handwashing technique. These behaviors reflect knowledge that alpha and beta rays cannot pass through skin but may be in body fluids and excrement.
- Careful planning of nursing activity to limit time (to 30 minutes or less per 8 hours) spent in proximity to the woman to avoid exposure to gamma rays, which can penetrate several inches of lead.

Exposure to radiation is controlled in three ways: distance, time, and shielding (with lead). For the woman with sealed radiotherapy, a movable lead screen can be placed between the area in which the therapeutic applicator is located and the

personnel. The lead screen also is used to protect visitors from radiation. Increasing the distance from the source also decreases exposure (Workman, 2013).

Familiarity with applicators is a must for all nurses working with people receiving radiotherapy so that if a “strange object” is found in the linen or on the floor, it is not touched. Today most hospital protocols include having a lead container and forceps in the room for use if a radioactive implant is dislodged.

The woman is prepared for insertion with the following care, which is accompanied by an explanation for each activity. To reduce the need for attention to bowel elimination for a few days, the gastrointestinal tract is usually prepared by using low-residue diet, enemas, and sometimes bowel sedation. The vaginal vault is usually prepared with an antiseptic douche, such as povidone-iodine.

An indwelling urinary catheter is inserted, as ordered, to prevent bladder distention that could dislodge the applicator. Food and fluids are withheld for a specified time before the procedure in anticipation of using general anesthesia. Preoperative medications may be ordered for the morning of the procedure. Deep-breathing exercises, range-of-motion (ROM) exercises, and positioning are all demonstrated before the procedure to minimize the effects of immobilization afterward. An intravenous (IV) solution will probably be started before the procedure, and IV therapy may be continued if nausea prevents good intake of oral fluids. The woman is assured that pain will be managed.

Explanations about restricted visitation of personnel and visitors also are given in the preinsertion phase. Women are often encouraged to bring books, magazines, electronic readers, laptop computers, iPods, or other devices or materials to the hospital to combat the boredom that isolation imposes on them. In addition, many units are equipped with televisions and CD and DVD players.

The applicator is inserted into the woman's vaginal vault during surgery, and after the usual postanesthesia recovery care, the woman is returned to her room, where the applicators are loaded with the radioactive substance.

A lead shield is placed next to the bed in line with the woman's pelvic area to protect the caregivers and visitors. Vital signs are monitored every 4 hours. Active ROM and deep-breathing exercises are encouraged every 2 hours; the woman is positioned on her back and may not be permitted to turn from side to side, although log-rolling may be done occasionally to relieve back pressure. The head of the bed may or may not be elevated slightly.

The woman's diet is changed from clear liquid to low residue, as ordered. Many individuals have difficulty eating while lying flat or even if the bed is elevated slightly. The nurse arranges the food so that it is easy to reach. Finger foods or liquids are generally more manageable. Parenteral or oral fluids are given, up to 3 L daily.

The urinary catheter remains in the bladder while the implant is in place. However, no perineal or catheter care is given. Intake and output are measured. The woman is given a partial bath, washing only above her waist. Massage is restricted to her shoulders and neck. Linen is changed only as absolutely necessary. Any linen or equipment used is retained in the room until therapy is complete to prevent loss of an applicator or

seed. If vaginal or rectal bleeding or hematuria occurs, the physician is notified immediately.

Emotional support is provided by planning to be with the woman for short periods, encouraging her to verbalize concerns and needs, and encouraging family members, clergy, or others to visit for short periods daily or to communicate by telephone. Pregnant women and children are not permitted to visit.

Many women undergoing internal radiation treatment are given medication to prevent complications and to promote comfort during the procedure. Such medications might include antibiotics to prevent bladder infections, heparin injections to prevent thrombophlebitis, sedatives for relaxation, antiemetics for nausea, and narcotics for pain. The woman is considered radioactive during the time the internal sources are in place (Workman, 2013).

After the radium is removed the Foley catheter is removed, and the woman is assisted in getting out of bed the first time. She is usually discharged the same day. Discharge teaching can be found in the Teaching for Self-Management box: Care After Internal Radiation Therapy. The woman and her family are reassured that she is not radioactive after the treatment.

TEACHING FOR SELF-MANAGEMENT

Care After Internal Radiation Therapy

- Eat three balanced meals a day, and increase fluid to 3 L daily.
- Rest when tired, and resume normal activities as comfort permits.
- Maintain good hygiene (e.g., daily showers and daily douches until discharge stops).
- Use a vaginal dilator if needed for vaginal stenosis. Sexual intercourse may be resumed in 7 to 10 days or as recommended by your physician.
- Understand that sterility and cessation of menstruation usually occur with this procedure if you are premenopausal.
- Report any of the following to your health care provider: bleeding (vaginal, rectal, or in the urine), foul-smelling vaginal discharge, fever, abdominal distention, or pain.
- Take any prescribed medications as directed.
- Call your health care provider or clinic if there are concerns or problems.
- Keep scheduled follow-up visits to determine emotional as well as physical recovery.

Posttreatment complications range from those arising from immobilization, such as thrombophlebitis, pulmonary embolism, and pneumonia, to those arising from the treatment itself, such as hemorrhage, skin reactions (rashes or inflammation), diarrhea, cramping, dysuria, and vaginal stenosis. The woman is assessed for any of these complications before discharge.

The woman may experience altered patterns of sexuality related to treatment side effects. A decrease in vaginal secretions and sensation may occur, as well as vaginal stenosis. These can contribute to decreased sexual desire, because pain and discomfort during intercourse can affect the desire to resume sexual activities. The nurse can initiate a discussion with the woman and her partner, offer information about the effects of radiation on the ability to have sexual intercourse, and offer suggestions for specific problems, such as using a water-based lubricant for vaginal dryness and using a vaginal dilator as directed by her

health care provider. If necessary, the couple can be referred to other resources.

Complications of Radiation Therapy. Morbidity as a direct result from properly conducted therapy is usually minimal. Some of the morbidity seen may be caused by the uncontrolled tumor and not by the therapy. Acute treatment complications occurring during or shortly after therapy include irritation of the rectum, the small bowel, and the bladder; reactions in the skinfolds; and mild bone marrow suppression. Dysuria and frequency may occur. Late complications, although not common, include genital fistulas and necrosis (Yashar, 2012).

Recurrent and Advanced Cancer of the Cervix

Approximately one third of women with invasive cervical cancer have recurrent or persistent disease after therapy. The 1-year survival rate is between 10% and 15% (Terwari & Monk, 2012). Irradiation of metastatic areas is commonly successful in providing local control and symptomatic relief.

Pelvic Exenteration. The woman who has recurrence only within the pelvis may be considered for **pelvic exenteration** if a cure is thought to be possible. A total exenteration involves removal of the perineum, the pelvic floor, the levator muscles, and all reproductive organs. Additionally, pelvic lymph nodes, rectum, sigmoid colon, urinary bladder, and distal ureters are removed, and a colostomy and ileal conduit are constructed (Tewari & Monk, 2012) (Fig. 11-17, A). In select cases the procedure can be modified to either an anterior or a posterior exenteration. In anterior pelvic exenteration all of the previously mentioned pelvic viscera are removed except the rectosigmoid, which is preserved. Urine is rerouted through an ileal conduit (see Fig. 11-17, B). In the posterior pelvic exenteration procedure, all pelvic viscera with the exception of the bladder are removed. The feces are rerouted through a colostomy (see Fig. 11-17, C). A neovagina (new vagina) may be constructed.

Women are carefully selected for this procedure; 5-year survival rates range from 20% to 62% (Tewari & Monk, 2012). Many of the complications that follow this surgery are those that follow any form of major surgery, for example, pulmonary embolism, pulmonary edema, myocardial infarction, and cerebrovascular accident. These complications are seen immediately after surgery. Infection originating in the pelvic cavity usually occurs later, if it occurs.

Nursing Interventions. Nursing care of the woman having a pelvic exenteration depends on what is removed. General preoperative considerations include assessments similar to those for a woman having a radical hysterectomy. Additionally, a thorough sexual assessment is needed because of the dramatic changes involved. The woman needs information about the construction of a neovagina if that is an option. She will need to be assessed for stoma site selection and information about management of colostomy or ileal conduit if appropriate. Extensive preoperative bowel preparation is needed before surgery. Pain management is discussed, as is what to expect postoperatively (e.g., nasogastric tubes, arterial catheters). Significant others should be included in preoperative discussions when possible because their postoperative support is essential.

Postoperative care usually begins in an intensive care unit until the woman's condition is stable. She is monitored for shock, hemorrhage, pulmonary embolus and other pulmonary

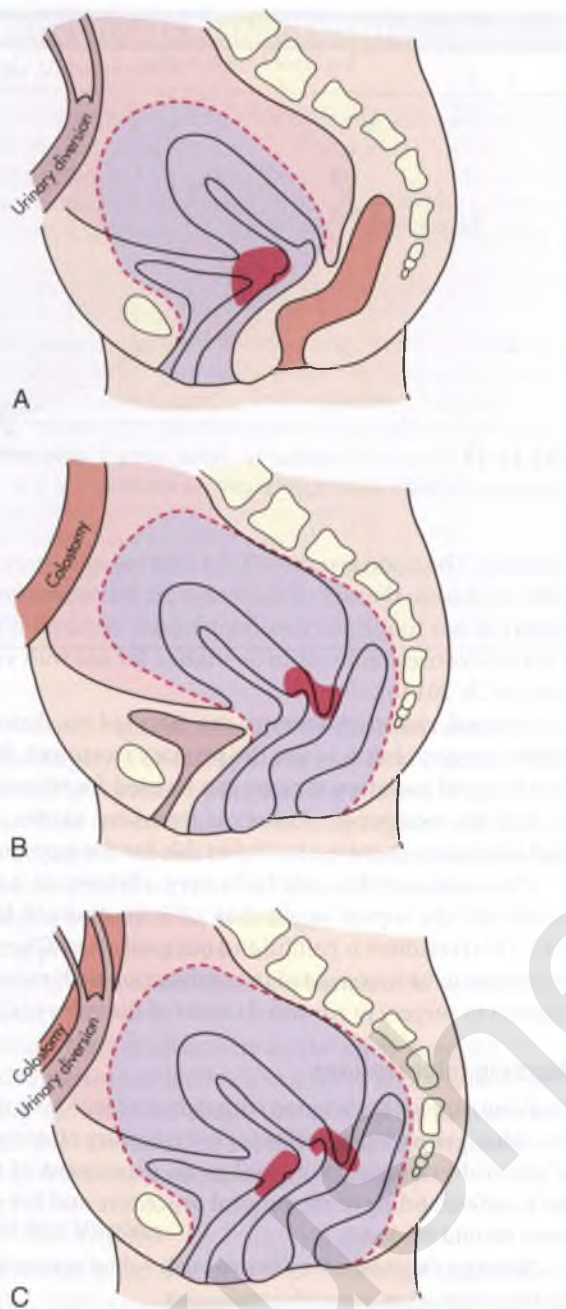

FIG 11-17 Pelvic exenteration procedures. **A**, Anterior exenteration. **B**, Posterior exenteration. **C**, Total exenteration.

complications, fluid and electrolyte imbalance, and urinary complications (Tewari & Monk, 2012). Nursing care continues after the woman is stabilized and moved back to her room. Wound care consists of irrigation with half-strength normal saline, followed by drying of the area with either a hair dryer on cool setting or a heat lamp placed at least 12 inches from the perineal area. The woman is taught how to care for her colostomy or ileal conduit when she is able to begin self-care. Assessment for psychologic reactions is important. The woman will probably experience a grief reaction over her mutilated body. She may become depressed during the long convalescence.

The woman may be discharged to a long-term care facility or to her home. She will need assistance in her physical care for at least 6 months. Teaching needed for home care includes

colostomy or ureterostomy care; dietary needs for healing; perineal care, including use of perineal pads to protect clothing from discharge; ROM exercises and physical activities permitted by her health care provider; and signs of complication, especially infection and bowel obstruction.

Because she will have sexual disruption and possibly be unable to have vaginal intercourse (if the vagina is not reconstructed), counseling about sexual activity is needed. Usually even with a vaginal reconstruction, vaginal intercourse is not advised until healing has taken place, usually in 12 to 18 months. Women with neovaginas may complain of decreased vaginal sensations or chronic discharge or that the vagina is too short or too long. Women with colostomies or ureterostomies may worry about leakage or odors during sexual activities or may be concerned about their change in appearance. They may need counseling about alternative activities for sexual expression for themselves and their partners. The woman and her partner may need referral for further sexual counseling.

Chemotherapy. Chemotherapy may be used in advanced cancer of the cervix to reduce tumor size before surgery or as adjuvant therapy for poor-prognosis tumors. In general, no long-term benefits are derived with chemotherapy, although chemotherapy concurrent with radiation therapy can improve survival (Tewari & Monk, 2012). Cisplatin is the most effective; other chemotherapeutic agents used in combination with cisplatin include carboplatin, cyclophosphamide, ifosfamide, methotrexate, mitomycin C, bleomycin, paclitaxel, topotecan, and hydroxyurea (Chu & Rubin, 2012).

Cancer of the Vulva

Incidence and Etiology

Vulvar carcinoma accounts for about 4% of all female genital malignancies and is the fourth most commonly occurring gynecologic cancer. It appears most frequently in women in their middle 60s to 70s (Schilder & Stehman, 2012). Vulvar cancers in older women do not appear to be caused by HPV infection. The incidence of vulvar cancer, specifically vulvar intraepithelial neoplasia (VIN), is increasing in younger women. Almost 20% of vulvar cancers occur in women younger than 50 years of age, and most women are in their 20s. HPV infection is thought to be responsible for most of these cancers (ACS, 2014b). Women who have a history of genital warts (condylomata acuminata) and who smoke have an increased risk of developing VIN (ACS).

By far the majority (90%) of vulvar carcinoma is squamous cell; other vulvar neoplasms are attributed to Paget disease, adenocarcinoma of Bartholin glands, fibrosarcoma and melanoma, and basal cell carcinoma. VIN is the first neoplastic change, progressing over time to CIS and then to invasive cancer. Metastasis is by direct extension and lymphatic spread (Schilder & Stehman, 2012).

Prognosis depends on the size of the lesion and the tumor grade at the time of diagnosis; 50% of women have symptoms for 2 to 16 months before seeking treatment. Fortunately vulvar cancer grows slowly, extends slowly, and metastasizes fairly late. Even with a pattern of delayed diagnosis, survival rates are approximately 90% if nodes are negative. Survival rates drop to 40% to 50%, however, if lymph node metastasis has occurred (Schilder & Stehman, 2012).

Clinical Manifestations and Diagnosis

Itching is the most common symptom of VIN; a lump or lesion is more common with invasive cancer (Schilder & Stehman, 2012). The most common site for vulvar lesions is on the labia majora. The vulvar lesion is usually asymptomatic until it is 1 to 2 cm in diameter. When it is symptomatic, women may complain of vulvar pruritus, burning, or pain. Necrosis and infection of the lesion result in ulceration with bleeding or watery discharge.

VINs are usually multifocal in young women. Unifocal lesions are associated with invasive cancer and are more common in older women. Initially, growth is superficial but later extends into the urethra, the vagina, and the anus. In approximately 50% of late cases, superficial inguinal and femoral lymph nodes become involved (Schilder & Stehman, 2012).

Simple biopsy with histologic evaluation reveals the diagnosis. The areas of pathologic involvement are identified by staining the vulva with toluidine blue (1%), allowing an absorption time of 3 to 5 minutes, and then washing with acetic acid (2% to 3%); abnormal tissue retains the dye. Biopsy is necessary to rule out such conditions as sexually transmitted infections (e.g., chancroid, granuloma inguinale, syphilis), basal cell carcinoma, and CIS. In situ malignancies are initially small, red, white, or pigmented friable papules. In Paget disease the lesions are red, moist, and elevated. Melanomas appear as bluish black, pigmented, or papillary lesions. Melanomas metastasize through the bloodstream and lymphatics (Schilder & Stehman, 2012).

Medical and Surgical Management

Treatment varies, depending on the extent of the disease. Laser surgery, cryosurgery, or electrocautery may be used to treat VIN. A disadvantage to these treatments is that healing is slow, and the treated area is painful. A local wide excision may be performed for localized lesions. Recurrence can occur after these treatments, so follow-up is important (Frumovitz & Bodurka, 2012).

Several types of **vulvectomy** procedures are used for CIS and invasive cancer. A *skinning vulvectomy* involves removal of the superficial vulvar skin; it is rarely performed.

A *simple vulvectomy* involves removal of all of the vulva (external genital organs including the mons pubis, labia majora and minora, and possibly the clitoris). The clitoris usually can be saved if cancer is not present.

For invasive disease, a *partial* or *complete radical vulvectomy* is performed. A partial vulvectomy is the removal of part of the vulva and deep tissues; a complete vulvectomy includes the removal of the whole vulva, deep tissues, and the clitoris (Fig. 11-18). These procedures are not used often.

Skin grafts may be done if a large area of skin is removed during the vulvectomy; however, most surgeries can be closed without grafts. If grafts are needed, a surgeon who performs reconstruction surgery may be consulted (ACS, 2014b).

The inguinal nodes may be removed through an inguinal (groin) node dissection. Usually only lymph nodes on the same side as the cancer are removed; however, nodes on both sides may be removed if the cancer is in the middle (see Fig. 11-18). Swelling of the leg often is a problem after this surgery.

A *sentinel node biopsy* may be done instead of the inguinal node dissection. This procedure involves injecting blue dye or radioactive material into the tumor site. A scan is performed to identify the sentinel (first) node to pick up the dye or radioactive

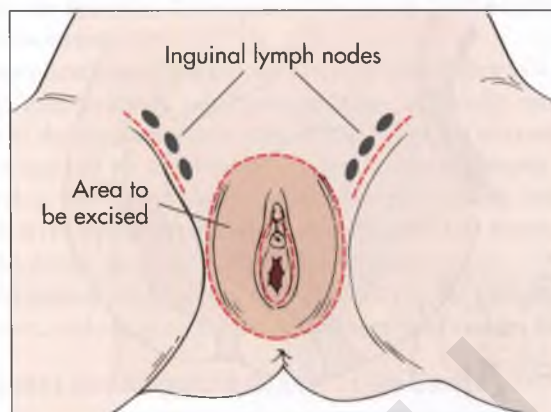

FIG 11-18 Radical vulvectomy. Note dotted lines denoting vulvectomy incision and inguinal groin incisions.

material. The node is removed for microscopic study. If cancer cells are found, the rest of the lymph nodes are removed, but if cancer is not found, further lymph node removal is not done. This procedure continues to be studied for use with vulvar cancers (ACS, 2014b).

External radiation therapy can be used to shrink tumors before surgery, but it is not the primary treatment. Postoperative external radiation therapy can be used for women who are at risk for recurrence. Radiation treatment causes dermatitis and ulceration that are uncomfortable for the woman.

Chemotherapy has not been very effective as a treatment except for the topical application of 5-fluorouracil for VIN or CIS. This treatment is painful and not used often. Chemotherapy continues to be investigated in combination with radiation as an adjunct to surgery in advanced cancer of the vulva (ACS, 2014b).

Nursing Interventions

Nursing care for the woman with vulvar cancer is similar to that for other gynecologic malignancies. A history of symptoms and a physical examination as well as an assessment of the woman's understanding of the surgical procedure and her emotional state should be done.

Nursing diagnoses for women with vulvar cancer are similar to those for other gynecologic cancers.

Interventions for the woman treated with laser therapy include applying topical steroids to the area, administering sitz baths and drying the area with a hair dryer, applying local anesthetics, or giving oral pain medication as needed. Women need to be informed that pain may get worse 3 to 4 days after the treatment.

Because there can be recurrences, information about vulvar self-examination and the need for follow-up with a health care provider is reinforced. Information about community support groups may be helpful, although a study by Likes, Russell, & Tillmanns (2008) found that women reported increased anxiety after having contact with Internet support groups.

A woman undergoing radical vulvectomy requires some special nursing actions in addition to routine postoperative care (see Teaching for Self-Management). She will need instructions about wound care and infection prevention as well as about possible complications, such as a change in her urine stream (may go to one side) related to tissue removal around the urethral opening, and lymphedema (Schilder & Stehman, 2012).

TEACHING FOR SELF-MANAGEMENT**Care After Vulvectomy**

- Avoid sexual activity for 4 to 6 weeks or as your health care provider directs.
- Rest frequently.
- Avoid crossing your legs, sitting, or standing for long periods.
- Avoid tight, constricting clothing, and wear cotton underwear.
- Keep wound area clean and dry. Rinse area with warm water and pat dry after voiding.
- Continue wound care as prescribed (e.g., irrigate with solution of warm water; pack with gauze; dry using hair dryer on coolest setting). Report to your health care provider any swelling, redness, unusual tenderness, drainage, or foul odor of incision site.
- Report any temperature greater than 39° C (102.2° F).
- Eat a well-balanced diet to promote healing.
- Take all medications as prescribed.
- Elevate your legs periodically to prevent pelvic congestion.
- Call your health care provider or clinic if there are concerns or problems.

The woman is at high risk for sexual dysfunction related to the effects of the surgery. For example, she may have concerns that her partner will be repulsed by the scarring and loss of the vulva. She also may have concerns about reaching orgasm and vaginal numbness or painful vaginal penetration. Nursing actions that focus on minimizing these risks include the following:

- Encouraging verbalization of feelings
- Providing privacy for discussion
- Encouraging open communication between the woman and her partner
- Discussing when sexual activity can be safely resumed
- Discussing alternative methods to achieve sexual satisfaction
- Providing information about use of vaginal dilators and water-soluble lubricants for painful vaginal intercourse
- Providing resources for counseling if necessary

Cancer of the Vagina

Vaginal carcinomas account for 1% to 3% of gynecologic malignancies, with more than 50% of cases occurring between the ages of 70 and 90 years (Slomovitz & Coleman, 2012). Most lesions are squamous cell carcinomas and are secondary rather than primary carcinomas of the vagina. Vaginal intraepithelial neoplasia (VAIN) is uncommon. Clear-cell adenocarcinoma is even rarer. It is found primarily in young women (ages 15 to 30 years) and is related to intrauterine exposure to DES (Badurka & Frumovitz, 2012).

The etiology is unknown, but vaginal cancer may be caused by chronic vaginal irritation, vaginal trauma, and genital viruses (e.g., HPV). Women with VAIN often have had cancer or currently have cancer of another part of the genital tract (Slomovitz & Coleman, 2012). Vaginal lesions, usually seen in the upper third of the vagina, often extend into the bladder and the rectum in late stages. Metastasis can occur early because of the rich lymphatic drainage in the vaginal area.

Some women with vaginal cancer are asymptomatic. Diagnosis often comes after an abnormal Pap test. Symptoms associated with vaginal cancer include bleeding after coitus

or examination, dyspareunia, and watery discharge. Bladder involvement results in urinary frequency or urgency; rectal extension causes painful defecation. A pelvic examination may reveal a single lesion, although multiple lesions are common (Slomovitz & Coleman, 2012).

Colposcopy examination and biopsy of Schiller-stained areas disclose the diagnosis. Therapy for vaginal cancer is directed by the extent of the lesion and the age and condition of the woman. Local excision is the preferred therapy for localized lesions. Topical application of 5-fluorouracil cream has been used with varying results. Laser surgery can be used to treat VAIN. Radical hysterectomy and removal of the upper vagina with dissection of the pelvic nodes or internal and external radiation are options for invasive cancer. Radiation therapy is the usual treatment of choice (Slomovitz & Coleman, 2012). If a vaginectomy is performed, sexual function will be lost without reconstructive surgery. Chemotherapy has not been effective in treating vaginal cancer, although studies are ongoing on the effectiveness of chemotherapy in combination with radiation. In early-stage cancer, 5-year survival rates are greater than 80%, with stage II survival rates in the 50% range (Slomovitz & Coleman, 2012).

Nursing care for the woman with vaginal cancer is similar to that for other gynecologic cancers. Women who are sexually active should be encouraged to continue sexual intercourse or to use a vaginal dilator to maintain vaginal patency (Slomovitz & Coleman, 2012). Sexual counseling or referral may be needed.

Cancer of the Uterine Tubes

Primary carcinoma of the uterine (fallopian) tube (usually the distal one third) is one of the rarest cancers of the female genital tract (less than 1%), with a peak incidence between ages 50 and 60 years (Bidus, Maxwell, & Rose, 2012). The cause is unknown. Most women are asymptomatic in the early stages of tubal cancer. Vaginal bleeding is the most common symptom of tubal cancer, but clear vaginal discharge and lower abdominal pain also occur frequently. An enlarging unilateral pelvic mass or ascites may occur and is often misdiagnosed as ovarian carcinoma or endometrial carcinoma. Differential diagnosis of tubal cancer is usually made postoperatively. Because uterine tube cancer is so rare, there is no established management. Current therapy guidelines parallel those established for ovarian carcinoma; therefore, tumor-reducing surgery such as a TAH with BSO, omentectomy (removal of connective tissue covering the organs), and lymph node sampling are performed (Bidus et al.). Postoperative therapy consists of chemotherapy with cisplatin or other platinum-based drugs combined with paclitaxel, sometimes followed by second-look surgery to determine whether further treatment is needed. Radiation therapy is sometimes used if the disease is limited to the tube, ovary, and uterus, although reports of its effectiveness vary. The overall 5-year survival rate for all stages is 69%; the 5-year survival rates for stages I and II are approximately 80% (Bidus et al.).

Nursing care for the woman with uterine tube cancer is similar to that of the woman with ovarian cancer.

Cancer and Pregnancy

Cancer occurs with relative infrequency during the reproductive years. Approximately 1 of every 1000 pregnant women

will have cancer (Salani, Eisenhauer, & Copeland, 2012). These malignancies may be responsible for up to one third of maternal deaths. Although all forms of neoplasms have been documented in conjunction with pregnancy, the most frequently occurring types are breast cancer, cervical cancer, melanomas, ovarian cancer, leukemia and lymphomas, and thyroid cancers. Other cancers, including other gynecologic cancers, rarely are diagnosed in pregnancy (Salani et al.). When pregnancy and cancer coincide, therapeutic issues are complex, and intense reactions occur in the woman, her family, and the health care team. Women are confronted with issues such as continuing or terminating the pregnancy. The selection and timing of therapies such as chemotherapy, radiation, and surgery are affected by the pregnancy. Add to this the conflicting feelings the woman has (i.e., the joy of pregnancy versus the fear and anxiety associated with cancer), and the task of providing comprehensive care for her and her family presents a formidable challenge to the health care team. A brief discussion of the most frequent types of cancers that occur during pregnancy and the current therapies associated with them follows.

Cancer of the Breast

Approximately 1% to 2% of women are pregnant or lactating at the time of diagnosis of cancer of the breast (Tewari, 2012). Breast cancer complicates about 1 in 3000 pregnancies. The survival rate for women who are diagnosed with breast cancer while pregnant may be as low as 15% to 20% because the disease is generally in the advanced stages when first diagnosed (Salani et al., 2012). Diagnosis is often delayed because breast engorgement may obscure the mass from palpation, and increased density of the tissue makes mammographic visualization more difficult. In addition, increased vascularity and lymphatic drainage in the breast of a pregnant woman may increase the speed of metastasis. Treatment is the same as for a nonpregnant woman, although surgery is usually the treatment of choice for breast cancer in pregnancy (Tewari). If an invasive tumor is found, it must be determined whether the tissue is positive or negative for estrogen receptors (ERs). ER-negative tumors spread more rapidly than ER-positive tumors and are more common in pregnancy (Salani et al.).

Maternal-fetal management involves consideration of the gestational age of the fetus, the extent of disease, the tumor growth potential, and the proposed treatment. Termination of the pregnancy in early stages of the disease appears to have no effect on survival. There is little evidence to suggest that pregnancy affects the malignant process. Therapeutic abortion may become an issue in the presence of advanced disease and may be deemed necessary to achieve effective palliation. In the first trimester, lumpectomy or partial mastectomy is the most commonly used surgical procedure, but radical mastectomy is tolerated well in these women. For advanced disease in the second or third trimester, alkylating agents, 5-fluorouracil, doxorubicin, and cyclophosphamide are relatively safe for the fetus. Radiation therapy is avoided if at all possible until after the birth, because even with careful shielding, the fetus may still receive sufficient radiation to produce detrimental effects (Salani et al., 2012; Tewari, 2012).

There is no agreement about whether a postpartum woman with breast cancer should breastfeed, although many surgeons

recommend formula feeding. There are theoretic concerns that if one of the oncogenes for breast cancer is a virus, as many have postulated, the remaining breast may be contaminated, and the virus may be passed to the newborn, possibly acting as a latent inducer of breast carcinoma. Another reason is that lactation increases vascularity in the remaining breast, which may contain a neoplasm as well (Tewari, 2012).

Breastfeeding after lumpectomy is possible, but the site of the incision may interrupt the milk ducts or prevent the nipple from extending during feeding. Breastfeeding is contraindicated if the woman is receiving chemotherapy. Women receiving radiation have diminished ability to lactate in the irradiated breast (Salani et al., 2012; Tewari, 2012).

Pregnancy incidence after mastectomy is influenced by many factors, including prior treatment and duration of survival. In general, women with good prognoses (e.g., no positive nodes) are likely to be counseled to wait at least 2 years before attempting pregnancy (Tewari, 2012).

Cancer of the Cervix

The incidence of cervical cancer concurrent with pregnancy is reported to be about 1 in 2200 pregnancies, making it the most common reproductive tract cancer associated with pregnancy (Salani et al., 2012). The outcome for a woman with cervical cancer is roughly the same as that for a nonpregnant woman (Tewari, 2012).

Cervical abnormalities are diagnosed during pregnancy with an abnormal Pap test. If the report suggests that the pregnant woman has a squamous intraepithelial lesion, a colposcopy, possibly with directed biopsy, is done. If invasive disease is not found, treatment is delayed until after the woman gives birth. Colposcopy is often repeated every 6 to 8 weeks until the birth and again postpartum (Salani et al., 2012). Conization is not advised during pregnancy unless necessary to rule out invasive cancer because it is associated with bleeding, miscarriage, and preterm birth (Tewari, 2012).

The therapy of invasive carcinoma of the cervix during pregnancy is affected by many factors. The stage of the disease and the trimester in which the cancer is diagnosed are important. Equally important are the beliefs and desires of the woman and her family in terms of initiating therapy that can interrupt the pregnancy, as opposed to postponing the therapy until fetal viability is achieved. If the woman chooses not to continue the pregnancy, external radiation to the pelvis is done. Miscarriage usually occurs, and then internal radiation is done. If miscarriage does not occur, a modified radical hysterectomy may be performed. If the woman desires to continue the pregnancy, treatment of early-stage invasive cervical cancer can be delayed until 34 to 36 weeks, without harmful effects on the woman. Cesarean birth is usually performed after the mother has received antenatal steroids and fetal lung maturity is documented; radiation therapy is then initiated (Salani et al., 2012; Tewari, 2012).

Leukemia

The average age for pregnant women with acute leukemia is 28 years; incidence during pregnancy is about 1 in 75,000 (Tewari, 2012). Pregnancy seems to have no specific effect on the course of the disease, but vigorous therapy is detrimental to early gestation. Preterm labor and postpartum hemorrhage are associated

with acute leukemia (Tewari). Acute myelocytic leukemia (60% of cases) has a more fulminant course and requires immediate therapy; in the presence of chronic myelocytic leukemia, therapy can be delayed somewhat. Some pregnant women with the chronic form of the disease who had chemotherapy and radiation therapy directed at the spleen have given birth to apparently healthy infants. The decision to terminate the pregnancy rests with the woman and her family; however, prompt, aggressive therapy is always advisable if remission is to be achieved. Decisions may be influenced by the aggressiveness of the disease.

Hodgkin Disease

Hodgkin disease is a malignant lymphoma that affects many younger people and complicates about one in 6000 pregnancies. Younger women (less than 40 years) have a better prognosis (Tewari, 2012).

Pregnancy appears to have no effect on the disease and vice versa, other than those effects resulting from therapy (Salani et al., 2012). Radiation therapy of the nodes and multiagent chemotherapy result in about a 90% cure rate. Unless gestation is well into the third trimester, delay in initiating therapy should be minimal, which brings up the dilemma of therapeutic abortion. Radiation therapy to diseased areas above the diaphragm can be initiated during the third trimester with proper shielding of the fetus (Salani et al.). Chemotherapy is strongly contraindicated during the first trimester, but certain agents (antitumor antibiotics and antimicrotubule agents) appear safe to use in the second and third trimesters. Termination of the pregnancy during the course of the disease is not definitely indicated (Tewari, 2012).

Melanoma

Malignant melanoma may be one of the rare cancers that can be affected by pregnancy. This is suggested by some reports in which pregnancy has been shown to induce or exacerbate a melanoma. These suggestions are based on changes that occur naturally during pregnancy and include hyperpigmentation, an increase in melanocyte-stimulating hormone (MSH), and increased estrogen production. ERs have been identified in about half of all melanomas. Although pregnancy has been implicated in the more rapid metastases to regional lymph nodes, stage for stage there does not seem to be a significant difference in the survival of pregnant and nonpregnant women (Salani et al., 2012; Tewari, 2012). As a result, most authorities recommend that women who have histories of malignant melanoma delay pregnancy for 2 to 3 years after surgical excision, because this is the period of highest risk for recurrence (Salani et al.; Tewari).

Diagnosis is established by biopsy. Therapy consists of radical local excision. For most other malignancies, the placenta is resistant to invasion by maternal cancer. Although melanoma accounts for few cases of malignant disease during pregnancy, it is the most common cancer to metastasize to the placenta (Tewari, 2012).

Thyroid Cancer

The incidence of thyroid cancer in pregnancy is not established. Normally the thyroid gland enlarges during pregnancy, and an asymptomatic nodular mass is a common finding. Diagnosis

is usually by cytologic testing of fine-needle aspirate. Thyroid suppression is the preferred treatment during pregnancy for a benign lesion. For a papillary or follicular malignancy found in the first or second trimester, the woman is advised to have a thyroidectomy in the second trimester followed by thyroid suppression (Tewari, 2012). If a tumor is found in the third trimester, surgery can be delayed until after the birth. With other thyroid malignancies, treatment is individualized based on the wishes of the woman and her family (Tewari).

MEDICATION ALERT

Radioactive iodine is contraindicated in pregnancy and lactation.

Colon Cancer

The incidence of colon cancer in pregnancy is approximately 1 in 13,000 (Terwari, 2012). The signs and symptoms such as constipation, hemorrhoids, and backache are often attributed to pregnancy, resulting in diagnosis at a more advanced stage. Colonoscopy and biopsy are usually not done in pregnancy because these procedures can cause placental abruption and fetal injury from maternal hypoxia or hypotension.

Management of the cancer is based on the weeks of gestation and tumor stage. In a woman who is less than 20 weeks of gestation, surgery may be performed to remove the tumor. If she is at more than 20 weeks, surgery may be delayed until after the birth. Chemotherapy and radiation are usually not used in pregnancy for colon cancer but may be used after the birth (Salani et al., 2012; Terwari, 2012).

Cancer Therapy and Pregnancy

Decisions about the type and timing of therapy for cancer in the pregnant woman evoke moral and philosophic dilemmas, as well as complex medical judgments and intense emotional responses.

Ethical Considerations. When a pregnant woman has cancer and her survival is contingent on treatment that will harm the fetus, the health care team must work with the woman and her significant others to make decisions about how to proceed with her care. If a one-client model of ethical decision making is used, the risk-benefit analysis is applied to the maternal-fetal unit. The pregnant woman decides what is best for her and the fetus. The woman may accept or refuse treatment. If a two-client model is used for decision making, more weight is given to fetal well-being, but the pregnant woman cannot be forced to accept harm to herself for the sake of the fetus. Thus she could elect to accept treatment.

The fetus is at risk with either chemotherapy or radiation therapy. The effect of cancer therapy on the fetus can include death, miscarriage, teratogenesis, alteration in growth and development, alterations in function, and genetic mutation. The long-term effects on the fetus are unknown. These theoretic dangers must be weighed against the potential detrimental effects to the mother if treatment is withheld (Gilbert, 2011).

Timing of Therapy. Timing of therapy is an important issue to discuss. Because most cancer therapy (except surgery) is geared toward having a differential and noxious effect on rapidly growing tissue, the fetus is most at risk during the first

trimester, when organogenesis and rapid tissue growth occur. Surgery offers the least potential risk to the fetus; however, the risk of miscarriage and preterm labor may be increased. Surgery is usually scheduled in the second trimester and has been discussed in the previous sections on gynecologic cancers in nonpregnant women.

Chemotherapy is avoided in the first trimester if at all possible. Although use of most chemotherapeutic agents has had isolated reports of fetal abnormalities, data on the agents used after the first trimester have recorded surprisingly few fetal abnormalities. The placenta may act as a barrier against the chemotherapeutic agents; therefore, although risk still exists, the judicious use of chemotherapy after the first trimester can result in live births with few congenital abnormalities. Acute drug toxicities may occur if treatment has occurred just before birth. Breastfeeding by women who are taking chemotherapeutic drugs is not recommended because most of these drugs may be excreted in breast milk (Salani et al., 2012; Terwari, 2012).

Radiation therapy presents its own set of issues. During embryonic development, tissues are extremely radiosensitive. If cells are genetically altered or killed during this time, the child either fails to survive or has specific organ damage. From a radiologic stance, there are three significant periods in embryonic development (Tewari, 2012):

1. Preimplantation: If irradiation does not destroy the fertilized egg, it probably does not affect it significantly.
2. Critical period of organogenesis: During this period, especially between days 18 and 38, the organism is most vulnerable; microcephaly, anencephaly, eye damage, growth restriction, spina bifida, and foot damage may occur.
3. After day 40: Large doses may still cause observable malformation and damage to the central nervous system.

Radiation therapy should be delayed until the postpartum period if possible (Salani et al., 2012).

Pregnancy After Cancer Treatment. If cancer therapy has not included the removal of the uterus, ovaries, or uterine (fallopian) tubes, there is a possibility that the woman may still be able to become pregnant. Although her menstrual cycle may have resumed, pregnancy may be difficult to achieve. Therapy that has affected the pituitary or thyroid gland may make conception difficult. Radiation appears to have the most deleterious effects on the endocrine system. The use of chemotherapy may result in temporary or permanent sterility, depending on the drug, the dose, and the length of time since the therapy was completed. Rates of ovarian failure are increased with pelvic irradiation (Tewari, 2012).

Of growing concern is the increase in the number of childhood and adolescent cancer survivors. Long-term effects of therapy on fertility, including incidence of congenital anomalies, are not well known. Counseling issues to be discussed with the pregnant woman after cancer treatment include the risk of recurrence and the likely sites of recurrence, how the prior cancer treatment can affect fertility or reproductive outcome, and if a future pregnancy will adversely affect a tumor that is estrogen-receptor positive (Salani et al., 2012).

For recovery from the disease and treatment to be complete, a delay of at least 2 years from the end of therapy to conception often is advised (Tewari, 2012). Before conception, a woman who has had cancer should have a complete physical examination to rule out complications that may place her or a fetus in

jeopardy. Cardiac, pulmonary, hematologic, neurologic, renal, or gonadal function can be impaired. The woman and the potential father (if partnered) may be referred for reproductive and genetic counseling as well.

Gestational Trophoblastic Neoplasia

Gestational trophoblastic disease (GTD) encompasses a spectrum of disorders arising from the placental trophoblast. It includes hydatidiform mole (see Chapter 28), invasive mole, and choriocarcinoma. *Gestational trophoblastic neoplasia (GTN)* refers to persistent trophoblastic tissue that is presumed to be malignant (Ko & Soper, 2012).

Table 11-2 describes the clinical classifications of GTN. For several reasons, GTN is recognized as the most curable gynecologic malignancy. There is a sensitive marker produced by the tumor (hCG); the tumor is extremely sensitive to various chemotherapeutic agents; high risk factors in the disease process can be identified, allowing individualized therapy; and the aggressive use of multiple treatment methods is possible.

Malignant disease follows normal pregnancy in about 25% of cases and hydatidiform mole in about 50% of cases. Miscarriage or ectopic pregnancy or another gestational event precedes about 25% of cases (Ko & Soper, 2012). Metastasis occurs most often in the lungs, vagina, liver, and brain.

Continued bleeding after evacuation of a hydatidiform mole is usually the most suggestive symptom of GTN. Other clinical signs include abdominal pain and uterine and ovarian enlargement. Signs of metastasis include pulmonary symptoms (e.g., dyspnea, cough). The diagnosis is usually confirmed by increasing or plateauing hCG levels after evacuation of a molar pregnancy. Once diagnosis is confirmed, other clinical studies (e.g., CT scan of lungs and brain, chest x-ray, pelvic ultrasound, and liver scan) can determine the extent of the disease (Ko & Soper, 2012).

For women who wish to preserve their fertility and who have low risk nonmetastatic or low risk metastatic GTN, single-agent chemotherapy is chosen. Methotrexate has been the treatment of choice for years. High-dose methotrexate followed by folinic

TABLE 11-2 Clinical Classification for Women with Malignant GTN

CLASSIFICATION	CRITERIA
Nonmetastatic disease	No evidence of disease outside uterus
Metastatic disease	Any disease outside uterus
Good prognosis metastatic disease	Short duration (<4 months) Low pretreatment hCG titer <40,000 milli-International Units/ml No prior term pregnancy No metastasis to brain or liver No prior chemotherapy
Poor prognosis metastatic disease	Any one risk factor: Long duration (>4 months) High pretreatment hCG titer >40,000 milli-International Units/ml Brain or liver metastasis Prior term pregnancy Prior chemotherapy

GTN, Gestational trophoblastic neoplasia; hCG, human chorionic gonadotropin. From Ko, E.M., & Soper, J.T. (2012). Gestational trophoblastic disease. In P.J. DiSaia, W.T. Creasman, R.S. Mannel, & D.S. Mutch (Eds.), *Clinical gynecologic oncology* (8th ed.). Philadelphia: Saunders.

acid rescue within 24 hours also has shown excellent results and causes fewer toxic effects (Ko & Soper, 2012). Dactinomycin has been used with equally good results and is used for women with liver or renal disease, both of which are contraindications for methotrexate. Hysterectomy with adjuvant chemotherapy is often the choice of treatment for nonmetastatic tumors in women who have completed their childbearing (Ko & Soper).

Women who have metastasis are classified as having either a good or poor prognosis, depending on the absence or presence of brain or liver metastasis, unsuccessful prior chemotherapy, symptoms lasting longer than 4 months, and serum β -hCG levels greater than 40,000 milli-International Units/ml. Treatment progresses from single-agent chemotherapy in the good-prognosis metastatic GTN to multiple-agent chemotherapy and multiple methods of treatment for the poor-prognosis group. Cure rates for the good-prognosis group are almost as

positive as for those with nonmetastatic disease, both approaching 100% (Ko & Soper, 2012).

Therapy is continued until negative hCG levels are obtained. After successful chemotherapy follow-up by serum hCG levels varies. One schedule is to obtain levels every 2 weeks for 3 months, every month for up to a year after completing therapy, and every 6 to 12 months up to 3 to 5 years (Ko & Soper, 2012; McGee & Covens, 2012). Physical examinations are done at least yearly as are chest x-rays if indicated. Contraception is needed until the woman has been in remission for 6 months to 1 year. Oral contraceptives are preferred, but barrier methods are acceptable if oral contraceptives are contraindicated (Ko & Soper; McGee & Covens). During a subsequent pregnancy, pelvic ultrasonography is recommended because the woman is at higher risk (1% to 2%) to develop another molar pregnancy. Serum hCG levels should be obtained 6 weeks after the birth (McGee & Covens).

KEY POINTS

- Gynecologic disorders diminish the quality of life for affected women and their families.
- Structural disorders of the uterus and vagina related to pelvic relaxation and urinary incontinence can be a delayed result of childbearing, but they can be seen in young or childless women.
- Bladder training and pelvic muscle exercises can significantly decrease or relieve mild to moderate urinary incontinence.
- The development of neoplasms, whether benign or malignant, can have a significant physical and emotional effect on a woman and her family.
- Abnormal uterine bleeding is the most common symptom of leiomyomas or fibroid tumors.
- Various alternatives to hysterectomy exist for structural and benign disorders of the uterus; women need to be informed about the risks and benefits to make an informed decision about treatment.
- Endometrial cancer is the most common reproductive system malignancy.
- Hysterectomy is the usual treatment for early-stage endometrial cancer.
- Human papillomavirus infection is the primary cause of cervical cancer and is linked to vulvar cancer in women younger than 50 years.
- The squamocolumnar junction is an important landmark identified with neoplastic changes of the cervix.
- Preinvasive cancer of the cervix may be treated with techniques such as electrosurgical excision, cryotherapy, and laser therapy to save the structure of the cervix, particularly in women who desire to retain childbearing ability.
- External and internal radiation therapy in combination is as successful as surgery in treating early stages of cancer of the cervix.
- A Pap test can detect approximately 90% of early cervical dysplasias.
- Cancer of the ovary causes more deaths than any other female genital tract cancer.
- Nurses can control their exposure to radiation by increasing the distance from the radiation source, by limiting the time of exposure, and by using lead shielding.
- Cancer is relatively infrequent during pregnancy, occurring about once in every 1000 pregnancies.
- Radiation or chemotherapy treatment of a pregnant woman who has cancer places the fetus at risk for death, miscarriage, teratogenesis, and alterations in growth and development.
- Gestational trophoblastic neoplasms are highly curable but require close monitoring of hCG levels after treatment.

Conception and Fetal Development

Shannon E. Perry

© <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Summarize the process of fertilization.
- Describe the development, structure, and functions of the placenta.
- Describe the composition and functions of amniotic fluid.
- Identify three organs or tissues arising from each of the three primary germ layers.
- Summarize the significant changes in growth and development of the embryo and fetus.
- Analyze the potential effects of teratogens during vulnerable periods of embryonic and fetal development.
- Relate selected congenital defects to stage of fetal development.

This chapter presents an overview of the process of fertilization and the development of the normal embryo and fetus.

CONCEPTION

Conception, defined as the union of a single egg and sperm, marks the beginning of a pregnancy. Conception occurs not as an isolated event but as part of a sequential process, which includes gamete (egg and sperm) formation, ovulation (release of the egg), fertilization (union of the gametes), and implantation in the uterus. An explanation of cell division by mitosis and meiosis precedes discussion of gametogenesis.

Cell Division

Cells are reproduced by two different methods: mitosis and meiosis. In **mitosis**, body cells replicate to yield two cells with the same genetic makeup as the parent cell. First the cell makes a copy of its deoxyribonucleic acid (DNA), and then it divides. Each daughter cell receives one copy of the genetic material. Mitotic division facilitates growth and development or cell replacement.

Meiosis, the process by which germ cells divide and decrease their chromosomal number by half, produces gametes (eggs and sperm). Each homologous pair of chromosomes contains one chromosome received from the mother and one from the father; thus meiosis results in cells that contain one of each of the 23 pairs of chromosomes. Because these germ cells contain 23 single chromosomes, half of the genetic material of a normal somatic cell, they are called *haploid*. This halving of the genetic material is accomplished by replicating the DNA once and then dividing twice. When the female gamete (egg or ovum) and the male gamete (spermatozoon) unite to form the zygote, the diploid number of human chromosomes (46, or 23 pairs) is restored.

The process of DNA replication and cell division in meiosis allows different *alleles* (genes on corresponding loci that code for variations of the same trait) for genes to be distributed at random by each parent and then rearranged on the paired chromosomes. The chromosomes then separate and proceed to different gametes. Many combinations of genes are possible on each chromosome because parents have genotypes derived from four different grandparents. This random mixing of alleles accounts for the variation of traits seen in the offspring of the same two parents.

Gametogenesis

Oogenesis, the process of egg (ovum) formation, begins during fetal life in the female. All the cells that may undergo meiosis in a woman's lifetime are contained in her ovaries at birth. The majority of the estimated 2 million primary oocytes (the cells that undergo the first meiotic division) degenerate spontaneously. Only 400 to 500 ova will mature during the approximately 35 years of a woman's reproductive life. The primary oocytes begin the first meiotic division (i.e., they replicate their DNA) during fetal life but they remain suspended at this stage until puberty (Fig. 12-1, A). Then, usually monthly, one primary oocyte matures and completes the first meiotic division, yielding two unequal cells: the secondary oocyte and a small polar body. Both contain 22 autosomes and one X sex chromosome.

At ovulation the second meiotic division begins. However, the ovum does not complete the second meiotic division unless fertilization occurs. At fertilization, when the sperm is united with the mature ovum, a second polar body and the **zygote** (the united egg and sperm) are produced (see Fig. 12-1, C). The three polar bodies degenerate.

When a male reaches puberty, his testes begin the process of **spermatogenesis**. The cells that undergo meiosis in the male are called *spermatocytes*. The primary spermatocyte, which

FIG 12-1 Gametogenesis. **A**, Oogenesis. Gametogenesis in the female produces one mature ovum and three polar bodies. Note the relative difference in overall size between the ovum and sperm. **B**, Spermatogenesis. Gametogenesis of the male produces four mature gametes, the sperm.

undergoes the first meiotic division, contains the diploid number of chromosomes. The cell has already copied its DNA before division, so four alleles for each gene are present. The cell is still considered diploid because the copies are bound together (i.e., one allele plus its copy on each chromosome).

During the first meiotic division two haploid secondary spermatocytes are formed. Each secondary spermatocyte contains 22 autosomes and one sex chromosome; one contains the X chromosome (plus its copy), and the other, the Y chromosome (plus its copy). During the second meiotic division the male produces two gametes with an X chromosome and two gametes with a Y chromosome, all of which will develop into viable sperm (see Fig. 12-1, B). When homologous chromosomes fail to separate during gametogenesis (nondisjunction), some gametes have 24 chromosomes and others have 22. If a gamete with 24 chromosomes unites with a normal gamete with 23 chromosomes, the resulting zygote has 47 chromosomes. This produces a trisomy as occurs in Down syndrome. When a gamete with 22 chromosomes unites with a normal gamete with 23 chromosomes, a zygote with 45 chromosomes results, producing a monosomy. Abnormal gametogenesis can occur in both sex chromosomes and in autosomes (Moore, Persaud, & Torchia, 2013). (See also Chapter 3.)

Ovum

Meiosis occurs in the female in the ovarian follicles and produces an egg, or ovum. Each month one ovum matures with a host of surrounding supportive cells. At ovulation the ovum is released from the ruptured ovarian follicle. High estrogen levels increase the motility of the uterine tubes so their cilia are able to capture the ovum and propel it through the tube toward the uterine cavity. An ovum cannot move by itself.

Two protective layers surround the ovum (Fig. 12-2). The inner layer is a thick, acellular layer, the *zona pellucida*. The outer layer, the *corona radiata*, is composed of elongated cells.

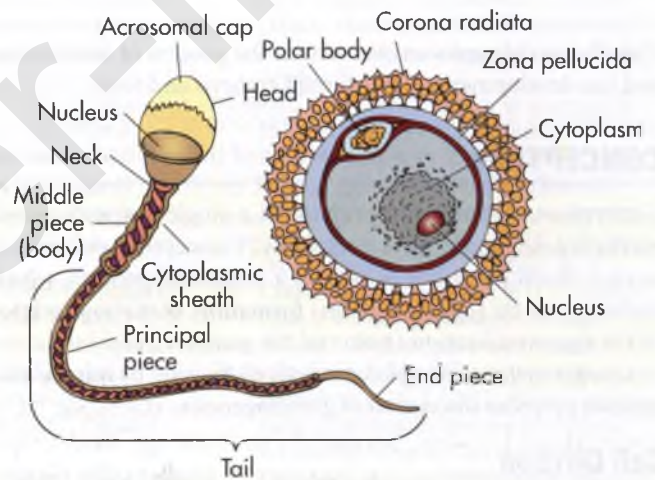

FIG 12-2 Sperm and ovum.

Ova are considered fertile for about 24 hours after ovulation. If not fertilized by a sperm, the ovum degenerates and is resorbed.

Sperm

Ejaculation during sexual intercourse normally propels about a teaspoon of semen containing as many as 200 to 500 million sperm, into the vagina. The sperm swim propelled by the flagellar movement of their tails. Some sperm can reach the site of fertilization within 5 minutes, but average transit time is 4 to 6 hours. Sperm remain viable within the woman's reproductive system for an average of 2 to 3 days. Most sperm are lost in the vagina, within the cervical mucus, or in the endometrium, or they enter the uterine tube that contains no ovum.

As the sperm travel through the female reproductive tract, enzymes are produced to aid in their capacitation. *Capacitation* is a physiologic change that removes the protective coating

FIG 12-3 Fertilization. A, Ovum fertilized by X-bearing sperm to form female zygote. B, Ovum fertilized by Y-bearing sperm to form male zygote.

from the heads of the sperm. Small perforations then form in the acrosome (a cap on the sperm) and allow enzymes (e.g., hyaluronidase) to escape (see Fig. 12-2). These enzymes are necessary for the sperm to penetrate the protective layers of the ovum before fertilization.

Fertilization

Fertilization takes place in the ampulla (outer third) of the uterine tube. When a sperm successfully penetrates the membrane surrounding the ovum, both sperm and ovum are enclosed within the membrane, and the membrane becomes impenetrable to other sperm; this process is termed the *zona reaction*. The second meiotic division of the secondary oocyte is then completed, and the nucleus of the ovum becomes the female pronucleus. The head of the sperm enlarges to become the male pronucleus, and the tail degenerates. The nuclei fuse, and the chromosomes combine, restoring the diploid number (46) (Fig. 12-3). Conception, the formation of the zygote (the first cell of the new individual), has been achieved.

Mitotic cellular replication, called *cleavage*, begins as the zygote travels the length of the uterine tube into the uterus. This transit takes 3 to 4 days. Because the fertilized egg divides rapidly with no increase in size, successively smaller cells, blastomeres, are formed with each division. A 16-cell **morula**, a solid ball of cells, is produced within 3 days and is still surrounded by the protective zona pellucida (Fig. 12-4, A). Further development occurs as the morula floats freely within the uterus. Fluid passes through the zona pellucida into the intercellular spaces between the blastomeres, separating them into two parts, the **trophoblast** (which gives rise to the placenta) and the **embryoblast** (which gives rise to the embryo). A cavity forms within the cell mass as the spaces come together, forming a structure called the *blastocyst cavity*. When the cavity becomes recognizable, the whole structure of the developing embryo is known as the **blastocyst**. Stem cells are derived from the inner cell mass of the blastocyst. The outer layer of cells surrounding the blastocyst cavity is the trophoblast. The trophoblast differentiates into villous and extravillous trophoblast (Fig. 12-5).

Implantation

The zona pellucida degenerates, the trophoblast cells displace endometrial cells at the implantation site, and the blastocyst embeds in the endometrium, usually in the anterior or posterior

FIG 12-4 First weeks of human development. B, Blastocyst embedded in endometrium. Germ layers forming. (A from Carlson, B. [2004]. *Human embryology and developmental biology* (3rd ed.). Philadelphia: Mosby; B adapted from Langley, L. [1980]. *Dynamic anatomy and physiology* [5th ed.]. New York: McGraw-Hill.)

fundal region. Between 6 and 10 days after conception, the trophoblast secretes enzymes that enable it to burrow into the endometrium until the entire blastocyst is covered. This is known as **implantation**. Endometrial blood vessels erode, and some women have slight implantation bleeding (slight spotting or bleeding at the time of the first missed menstrual period). **Chorionic villi**, finger-like projections, develop out of the trophoblast and extend into the blood-filled spaces of the endometrium. These villi are vascular processes that obtain oxygen and nutrients from the maternal bloodstream and dispose of carbon dioxide and waste products into the maternal blood.

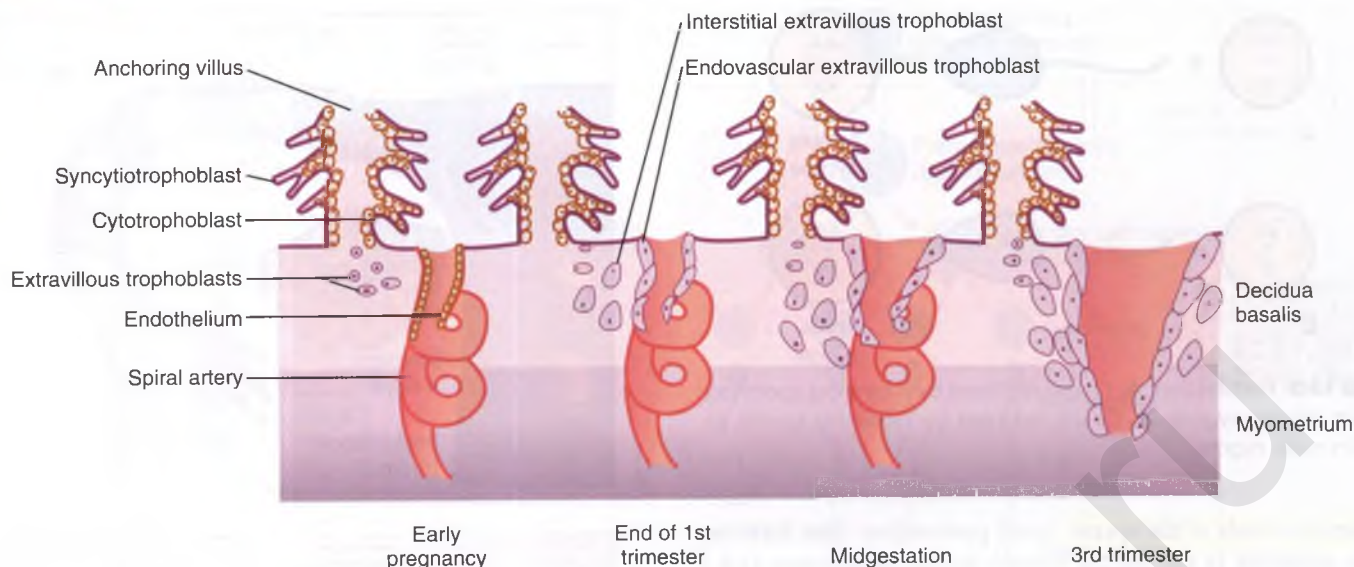

FIG 12-5 Extravillous trophoblasts are found outside the villus and can be subdivided into endovascular and interstitial categories. Endovascular trophoblasts invade and transform spiral arteries during pregnancy to create low-resistance blood flow that is characteristic of the placenta. Interstitial trophoblasts invade the decidua and surround spiral arteries. (From Cunningham, F., Leveno, K., Bloom, S., et al. [2014]. *Williams obstetrics* [24th ed.]. New York: McGraw-Hill.)

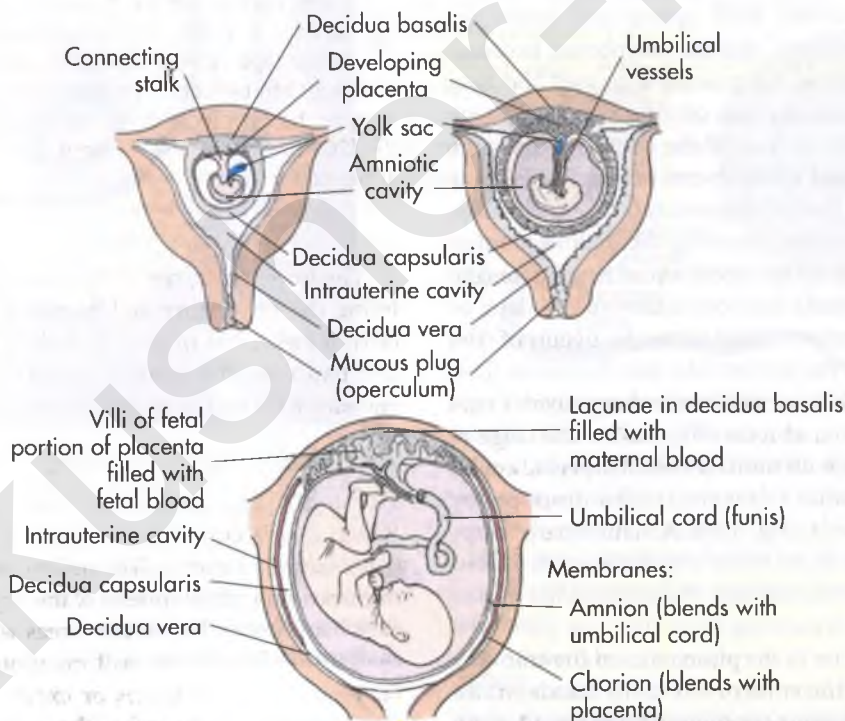

FIG 12-6 Development of the fetal membranes. Note gradual obliteration of intrauterine cavity as decidua capsularis and decidua vera meet. Also note thinning of uterine wall. Chorionic and amniotic membranes are in apposition to each other but may be peeled apart.

After implantation the endometrium is termed the *decidua*. The portion directly under the blastocyst, where the chorionic villi tap into the maternal blood vessels, is the **decidua basalis**. The portion covering the blastocyst is the *decidua capsularis*, and the portion lining the rest of the uterus is the *decidua vera* (Fig. 12-6).

EMBRYO AND FETUS

Pregnancy lasts approximately 10 lunar months, 9 calendar months, 40 weeks, or 280 days. Length of pregnancy is computed from the first day of the last menstrual period (LMP) until the day of birth. However, conception occurs approximately

FIG 12-7 Sensitive or critical periods in human development. During the first 2 weeks of development the embryo usually is not susceptible to teratogens. After that time a teratogen damages all or most of the cells, resulting in death of the embryo, or damages only a few cells, allowing the conceptus to recover and the embryo to develop without birth defects. The dark color denotes highly sensitive periods; the light color indicates stages that are less sensitive to teratogens. (From Moore, K.L., Persaud, T.V.N., & Torchia, M.G. [2013]. *Before we are born: Essentials of embryology and birth defects* [8th ed.]. Philadelphia: Saunders.)

2 weeks after the first day of the LMP; thus the postconception age of the fetus is 2 weeks less, for a total of 266 days, or 38 weeks. Postconception age is used in the discussion of fetal development.

Intrauterine development is divided into three stages: ovum or preembryonic, embryo, and fetus (Fig. 12-7). The stage of the ovum lasts from conception until day 14. This period covers cellular replication, blastocyst formation, initial development of the embryonic membranes, and establishment of the primary germ layers.

Primary Germ Layers

During the third week after conception, the embryonic disk differentiates into three primary germ layers: the ectoderm, the mesoderm, and the endoderm (or entoderm) (see Fig. 12-4, B). All tissues and organs of the embryo develop from these three layers.

The upper layer of the embryonic disk, the **ectoderm**, gives rise to the epidermis, the glands (anterior pituitary, cutaneous, and mammary), the nails and hair, the central and peripheral nervous systems, the lens of the eye, the tooth enamel, and the floor of the amniotic cavity.

The middle layer, the **mesoderm**, develops into the bones and teeth, the muscles (skeletal, smooth, and cardiac), the dermis and connective tissue, the cardiovascular system and spleen, and the urogenital system.

The lower layer, the **endoderm**, gives rise to the epithelium lining the respiratory and digestive tracts, and the glandular cells of associated organs, including the oropharynx, the liver and pancreas, the urethra, the bladder, and the vagina. The endoderm forms the roof of the yolk sac.

Development of the Embryo

The stage of the **embryo** lasts from day 15 until approximately 8 weeks after conception, when the embryo measures 3 cm from crown to rump. This embryonic stage is the most critical time in the development of the organ systems and the main external features. Developing areas with rapid cell division are the most vulnerable to malformation caused by environmental **teratogens** (substances or exposure that causes abnormal development). At the end of the eighth week, all organ systems and external structures are present, and the embryo is unmistakably human (see Fig. 12-7 and Visible Embryo, www.visembryo.com/baby, for a pictorial view of normal and abnormal development).

Membranes

At the time of implantation, two fetal membranes that will surround the developing embryo begin to form. The **chorion** develops from the trophoblast and contains the chorionic villi on its surface. The villi burrow into the decidua basalis and increase in size and complexity as the vascular processes develop into

the placenta. The chorion becomes the covering of the fetal side of the placenta. It contains the major umbilical blood vessels as they branch out over the surface of the placenta. As the embryo grows the decidua capsularis stretches. The chorionic villi on this side atrophy and degenerate, leaving a smooth chorionic membrane.

The inner cell membrane, the **amnion**, develops from the interior cells of the blastocyst. The cavity that develops between this inner cell mass and the outer layer of cells (trophoblast) is the amniotic cavity (see Fig. 12-4, B). As it grows larger, the amnion forms on the side opposite the developing blastocyst (see Figs. 12-4 and 12-6). The developing embryo draws the amnion around itself, forming a fluid-filled sac. The amnion becomes the covering of the umbilical cord and covers the chorion on the fetal surface of the placenta. As the embryo grows larger, the amnion enlarges to accommodate the embryo/fetus and the surrounding amniotic fluid. The amnion eventually comes into contact with the chorion surrounding the fetus.

Amniotic Fluid

The amniotic cavity initially derives its fluid by diffusion from the maternal blood. Fluid secreted by the respiratory and gastrointestinal tracts of the fetus also enters the amniotic cavity (Moore, Persaud, & Torchia, 2013). The amount of fluid increases weekly; 700 to 1000 ml of transparent liquid is normally present at term. The amniotic fluid volume changes constantly. The fetus swallows fluid, and fluid flows into and out of the fetal lungs. Beginning in week 11, the fetus urinates into the fluid, increasing its volume.

Amniotic fluid serves many functions. It helps maintain a constant body temperature. It serves as a source of oral fluid and a repository for waste and assists in maintenance of fluid and electrolyte homeostasis. It allows freedom of movement for musculoskeletal development. It cushions the fetus from trauma by blunting and dispersing outside forces. It acts as a barrier to infection and allows fetal lung development (Moore et al., 2013). The fluid keeps the embryo from tangling with the membranes, facilitating symmetric growth. If the embryo does become tangled with the membranes, amputations of extremities or other deformities can occur from constricting amniotic bands.

The volume of amniotic fluid is an important factor in assessing fetal well-being throughout pregnancy. Having less than 300 ml of amniotic fluid (**oligohydramnios**) is associated with fetal renal abnormalities. Having more than 2 L of amniotic fluid (**hydramnios** [**polyhydramnios**]) is associated with gastrointestinal and other malformations.

Amniotic fluid contains albumin, urea, uric acid, creatinine, lecithin, sphingomyelin, bilirubin, fructose, fat, leukocytes, proteins, epithelial cells, enzymes, and lanugo hair. Study of fetal cells in amniotic fluid through amniocentesis yields much information about the fetus. Genetic studies (karyotyping) provide knowledge about the sex and the number and structure of chromosomes (see Chapter 3). Other studies, such as the *lecithin/sphingomyelin* (L/S) ratio, determine the health or maturity of the fetus (see Chapters 26 and 35).

Yolk Sac

When the amniotic cavity and amnion are forming, another blastocyst cavity forms on the other side of the developing

embryonic disk (see Fig. 12-4, B). This cavity becomes surrounded by a membrane, forming the *yolk sac*. The yolk sac aids in transferring maternal nutrients and oxygen, which have diffused through the chorion, to the embryo. Blood vessels form to aid transport. Blood cells and plasma are manufactured in the yolk sac during the second and third weeks while uteroplacental circulation is being established and is forming primitive blood cells until hematopoietic activity begins. At the end of the third week the primitive heart begins to beat and circulate the blood through the embryo, the connecting stalk, the chorion, and the yolk sac.

The folding in of the embryo during the fourth week results in incorporation of part of the yolk sac into the embryo's body as the primitive digestive system. Primordial germ cells arise in the yolk sac and move into the embryo. The shrinking remains of the yolk sac degenerate (see Fig. 12-6). By the fifth or sixth week the remnant has separated from the embryo.

Umbilical Cord

By day 14 after conception, the embryonic disk, the amniotic sac, and the yolk sac are attached to the chorionic villi by the connecting stalk. During the third week the blood vessels develop to supply the embryo with maternal nutrients and oxygen. During the fifth week the embryo has curved inward on itself from both ends, bringing the connecting stalk to the ventral side of the embryo. The connecting stalk becomes compressed from both sides by the amnion and forms the narrower umbilical cord (see Fig. 12-6). Two arteries carry blood from the embryo to the chorionic villi, and one vein returns blood to the embryo. Approximately 1% of umbilical cords contain only two vessels: one artery and one vein (Blackburn, 2012). This occurrence is sometimes associated with congenital malformations.

The cord rapidly increases in length. At term the cord is 2 cm in diameter and ranges from 30 to 90 cm long (with an average of 55 cm). It spirals on itself and loops around the embryo/fetus. A true knot is rare, but false knots occur as folds or kinks in the cord and can jeopardize circulation to the fetus. Connective tissue called *Wharton's jelly* prevents compression of the blood vessels and ensures continued nourishment of the embryo or fetus. Compression can occur if the cord lies between the fetal head and the maternal pelvis or is twisted around the fetal body. When the cord is wrapped around the fetal neck, it is called a **nuchal cord**.

Because the placenta develops from the chorionic villi, the umbilical cord is usually located centrally. A peripheral location is less common and is termed *battledore placenta*. The blood vessels are arrayed out from the center to all parts of the placenta.

Placenta

Structure

The placenta begins to form at implantation. During the third week after conception the trophoblast cells of the chorionic villi continue to invade the decidua basalis. As the uterine capillaries are tapped, the endometrial spiral arteries fill with maternal blood. The chorionic villi grow into the spaces with two layers of cells: the outer syncytium and the inner cytotrophoblast. A third layer develops into anchoring septa, dividing the projecting decidua into separate areas called cotyledons. In each of the 15 to 20 cotyledons, the chorionic villi branch out, and a

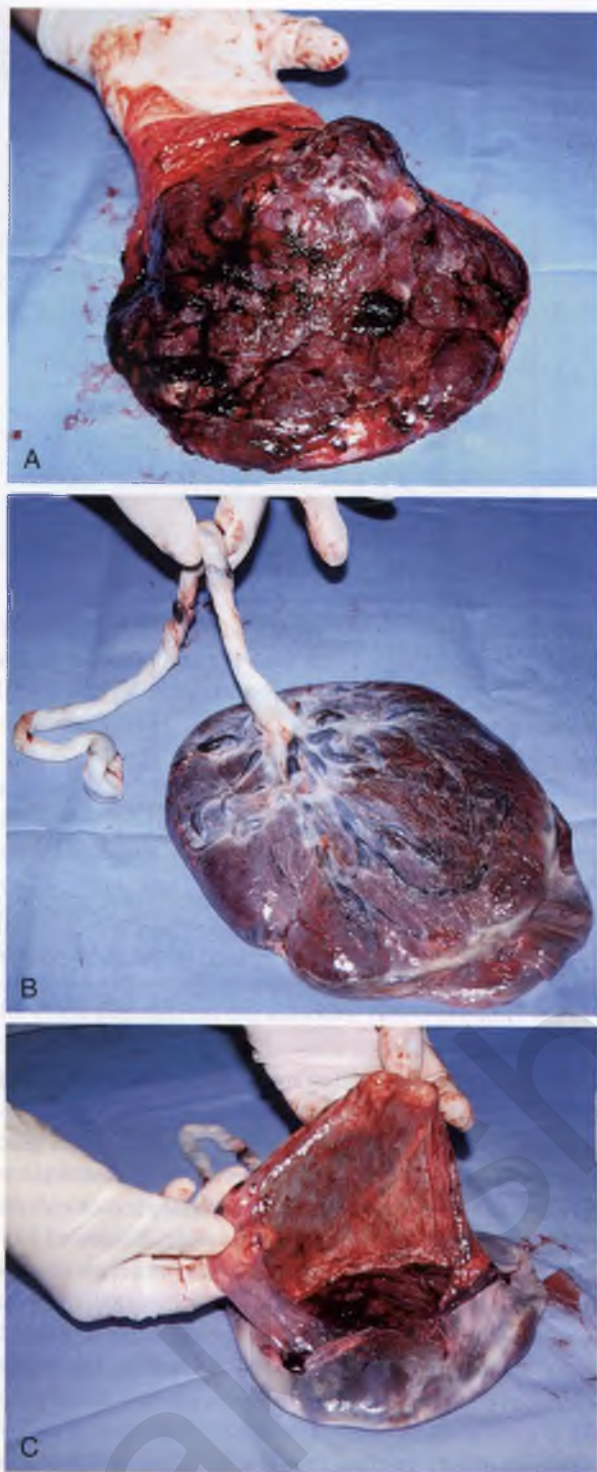

FIG 12-8 Term placenta. A, Maternal (or uterine) surface, showing cotyledons and grooves. B, Fetal (or amniotic) surface, showing blood vessels running under amnion and converging to form umbilical vessels at attachment of umbilical cord. C, Amnion and smooth chorion are arranged to show that they are (1) fused and (2) continuous with margins of placenta. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

complex system of fetal blood vessels forms. Each cotyledon is a functional unit. The whole structure is the **placenta** (Fig. 12-8).

The maternal-placental-embryonic circulation is in place by day 17, when the embryonic heart starts beating. By the end of the third week, embryonic blood is circulating between

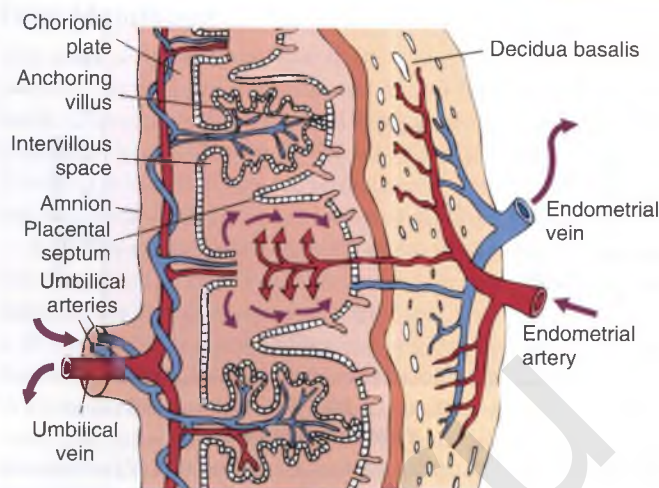

FIG 12-9 Schematic drawing of the placenta illustrating how it supplies oxygen and nutrition to the embryo and removes its waste products. Deoxygenated blood leaves the fetus through the umbilical arteries and enters the placenta, where it is oxygenated. Oxygenated blood leaves the placenta through the umbilical vein, which enters the fetus via the umbilical cord.

the embryo and the chorionic villi. In the intervillous spaces, maternal blood supplies oxygen and nutrients to the embryonic capillaries in the villi (Fig. 12-9). Waste products and carbon dioxide diffuse into the maternal blood.

The placenta functions as a means of metabolic exchange. Exchange is minimal at this time because the two cell layers of the villous membrane are too thick. Permeability increases as the cytotrophoblast thins and disappears; by the fifth month, only the single layer of syncytium is left between the maternal blood and the fetal capillaries. The syncytium is the functional layer of the placenta. By the eighth week, genetic testing can be done on a sample of chorionic villi by aspiration biopsy; however, limb defects have been associated with chorionic villus sampling done before 10 weeks. The structure of the placenta is complete by the twelfth week. The placenta continues to grow wider until 20 weeks, when it covers about half of the uterine surface. It then continues to grow thicker. The branching villi continue to develop within the body of the placenta, increasing the functional surface area.

Functions

Endocrine gland function. One of the early functions of the placenta is as an endocrine gland that produces four hormones necessary to maintain the pregnancy and support the embryo and fetus. The hormones are produced in the syncytium.

The protein hormone **human chorionic gonadotropin (hCG)** can be detected in the maternal serum by 8 to 10 days after conception, shortly after implantation. This hormone is the basis for pregnancy tests. The hCG preserves the function of the ovarian corpus luteum, ensuring the continued supply of estrogen and progesterone needed to maintain the pregnancy. Miscarriage occurs if the corpus luteum stops functioning before the placenta is producing sufficient estrogen and progesterone. The hCG reaches its maximum level at 50 to 70 days and then begins to decrease.

The other protein hormone produced by the placenta is **human chorionic somatomammotropin (hCS)**, formerly known

FIG 12-10 Distinct profile for the concentrations of human chorionic gonadotropin (hCG) and human chorionic somatomammotropin (hCS) in serum of women through normal pregnancy. IU, International Units. (Adapted from Cunningham, F., Leveno, K., Bloom, S., et al. [2014]. *Williams obstetrics* [24th ed.]. New York: McGraw-Hill.)

as human placental lactogen (hPL). This substance is similar to a growth hormone and stimulates the maternal metabolism to supply nutrients needed for fetal growth. hCS increases the resistance to insulin, facilitates glucose transport across the placental membrane, and stimulates breast development to prepare for lactation (Fig. 12-10).

The placenta eventually produces more of the steroid hormone *progesterone* than the corpus luteum does during the first few months of pregnancy. Progesterone maintains the endometrium, decreases the contractility of the uterus, and stimulates maternal metabolism and development of breast alveoli.

By 7 weeks after fertilization the placenta is producing most of the maternal estrogens, which are steroid hormones. The major estrogen secreted by the placenta is estriol, whereas the ovaries produce mostly estradiol. Estriol levels may be measured to determine placental functioning. Estrogen stimulates uterine growth and uteroplacental blood flow. It causes a proliferation of the breast glandular tissue and stimulates myometrial contractility. Placental estrogen production increases greatly toward the end of pregnancy. One theory for the cause of the onset of labor is the decline in the ratio of circulating levels of progesterone to the increased levels of estrogen (Fig. 12-11).

Metabolic functions. The metabolic functions of the placenta are respiration, nutrition, excretion, and storage. Oxygen diffuses from the maternal blood across the placental membrane into the fetal blood, and carbon dioxide diffuses in the opposite direction. In this way the placenta functions as lungs for the fetus.

Carbohydrates, proteins, calcium, and iron are stored in the placenta for ready access to meet fetal needs. Water, inorganic salts, carbohydrates, proteins, fats, and vitamins pass from the maternal blood supply across the placental membrane into the fetal blood, supplying nutrition. Water and most electrolytes with a molecular weight less than 500 readily diffuse through the membrane. Hydrostatic and osmotic pressures aid in the flow of water and some solutions. Facilitated and active transport assist in the transfer of glucose, amino acids, calcium, iron, and substances with higher molecular weights. Amino acids

FIG 12-11 Plasma level of progesterone, estradiol, estrone, and estriol in women during the course of gestation. (From Cunningham, F., Leveno, K., Bloom, S., et al. [2014]. *Williams obstetrics* [24th ed.]. New York: McGraw-Hill.)

and calcium are transported against the concentration gradient between the maternal blood and fetal blood.

The fetal concentration of glucose is lower than the glucose level in the maternal blood because of its rapid metabolism by the fetus. This fetal requirement demands larger concentrations of glucose than simple diffusion can provide. Therefore, maternal glucose moves into the fetal circulation by active transport.

Pinocytosis is a mechanism used for transferring large molecules, such as albumin and gamma globulins, across the placental membrane. This mechanism conveys the maternal immunoglobulins that provide early passive immunity to the fetus.

Metabolic waste products of the fetus cross the placental membrane from the fetal blood into the maternal blood. The maternal kidneys then excrete them. Many viruses can cross the placental membrane and infect the fetus. Some bacteria and protozoa first infect the placenta and then the fetus. Drugs also can cross the placental membrane and may harm the fetus. Caffeine, alcohol, nicotine, carbon monoxide, and other toxic substances in cigarette smoke, as well as prescription and recreational drugs (such as cocaine and marijuana) readily cross the placenta (Box 12-1).

Although no direct link exists between the fetal blood in the vessels of the chorionic villi and the maternal blood in the intervillous spaces, only one cell layer separates the maternal and fetal blood. Breaks occasionally occur in the placental

membrane. Fetal erythrocytes then leak into the maternal circulation, and the mother may develop antibodies to the fetal red blood cells (isoimmunized). This is often the way an Rh-negative mother becomes sensitized to the erythrocytes of her Rh-positive fetus. (See discussions of isoimmunization in Chapters 21 and 36.)

Although the placenta and the fetus are analogous to living tissue transplants, they are not destroyed by the host mother (Mor & Abrahams, 2013). Either the placental hormones suppress the immunologic response or the tissue evokes no response.

Adequate circulation necessary for placental function. Placental function depends on the maternal blood pressure supplying circulation. Maternal arterial blood, under pressure in the small uterine spiral arteries, spurts into the intervillous spaces (see Fig. 12-9). As long as rich arterial blood continues to be supplied, pressure is exerted on the blood already in the intervillous spaces, pushing it toward drainage by the low-pressure uterine veins. At term gestation, 10% of the maternal cardiac output goes to the uterus.

If there is interference with the circulation to the placenta, the placenta cannot supply the embryo or fetus. Vasoconstriction, such as that caused by hypertension and cocaine use, diminishes uterine blood flow. Decreased maternal blood pressure or cardiac output also diminishes uterine blood flow.

When a woman lies on her back with the pressure of the uterus compressing the vena cava, blood return to the right atrium is diminished (see discussion of supine hypotension in Chapter 19 and Fig. 19-5). Excessive maternal exercise that diverts blood to the muscles away from the uterus compromises placental circulation. Optimal circulation is achieved when the woman is lying at rest on her side. Decreased uterine circulation can lead to intrauterine growth restriction of the fetus and to infants who are small for gestational age.

Braxton Hicks contractions, painless contractions that occur intermittently after the first trimester, appear to enhance the movement of blood through the intervillous spaces, aiding placental circulation. Prolonged contractions or too-short intervals between contractions during labor, however, reduce blood flow to the placenta.

Fetal Maturation

The stage of the **fetus** lasts from 9 weeks (when the fetus becomes recognizable as a human being) until the pregnancy ends. Changes during the fetal period are not so dramatic, because refinement of structure and function is taking place. The fetus is less vulnerable to teratogens, except for those affecting functioning of the central nervous system.

Viability refers to the capability of the fetus to survive outside the uterus and is usually defined by fetal weight and pregnancy duration for statistical and legal purposes. A standard definition is 20 weeks gestation and birthweight of 350 g, 400 g, or 500 g, but this varies by state. Nurses must be aware of the laws in their states. With modern technology and advancements in maternal and neonatal care, infants who are 22 to 25 weeks of gestation are on the threshold of viability (Cunningham, Leveno, Bloom, et al., 2014). The limitations on survival outside the uterus when an infant is born at this early stage are based on central nervous system function and the oxygenation capability of the lungs.

Fetal Circulatory System

The cardiovascular system is the first organ system to function in the developing human. Blood vessel and blood cell formation begins in the third week and supplies the embryo with oxygen and nutrients from the mother. By the end of the third week the tubular heart begins to beat, and the primitive cardiovascular system links the embryo, connecting stalk, chorion, and yolk sac. During the fourth and fifth weeks the heart develops into a four-chambered organ. By the end of the embryonic stage the heart is developmentally complete.

The fetal lungs do not function for respiratory gas exchange, so a special circulatory pathway, the **ductus arteriosus**, bypasses the lungs. Oxygen-rich blood from the placenta flows rapidly through the umbilical vein into the fetal abdomen (Fig. 12-12). When the umbilical vein reaches the liver, it divides into two branches; one branch circulates some oxygenated blood through the liver. Most of the blood passes through the **ductus venosus** into the inferior vena cava. There it mixes with the deoxygenated blood from the fetal legs and abdomen on its way to the right atrium. Most of this blood passes straight through the right atrium and through the **foramen ovale**, an opening into the left atrium. There it mixes with the deoxygenated blood returning from the fetal lungs through the pulmonary veins.

The blood flows into the left ventricle and is squeezed out into the aorta, where the arteries supplying the heart, head, neck, and arms receive most of the oxygen-rich blood. This pattern of supplying the highest levels of oxygen and nutrients to the head, neck, and arms enhances the **cephalocaudal** (head-to-rump) development of the embryo/fetus. Deoxygenated blood returning from the head and arms enters the right atrium through the superior vena cava. This blood is directed downward into the right ventricle, where it is squeezed into the pulmonary artery. A small amount of blood circulates through the resistant lung tissue, but the majority follows the path with less resistance through the ductus arteriosus into the aorta, distal to the point of exit of the arteries supplying the head and arms with oxygenated blood. The oxygen-poor blood flows through the abdominal aorta into the internal iliac arteries, where the umbilical arteries direct most of it back through the umbilical cord to the placenta. There the blood gives up its wastes and carbon dioxide

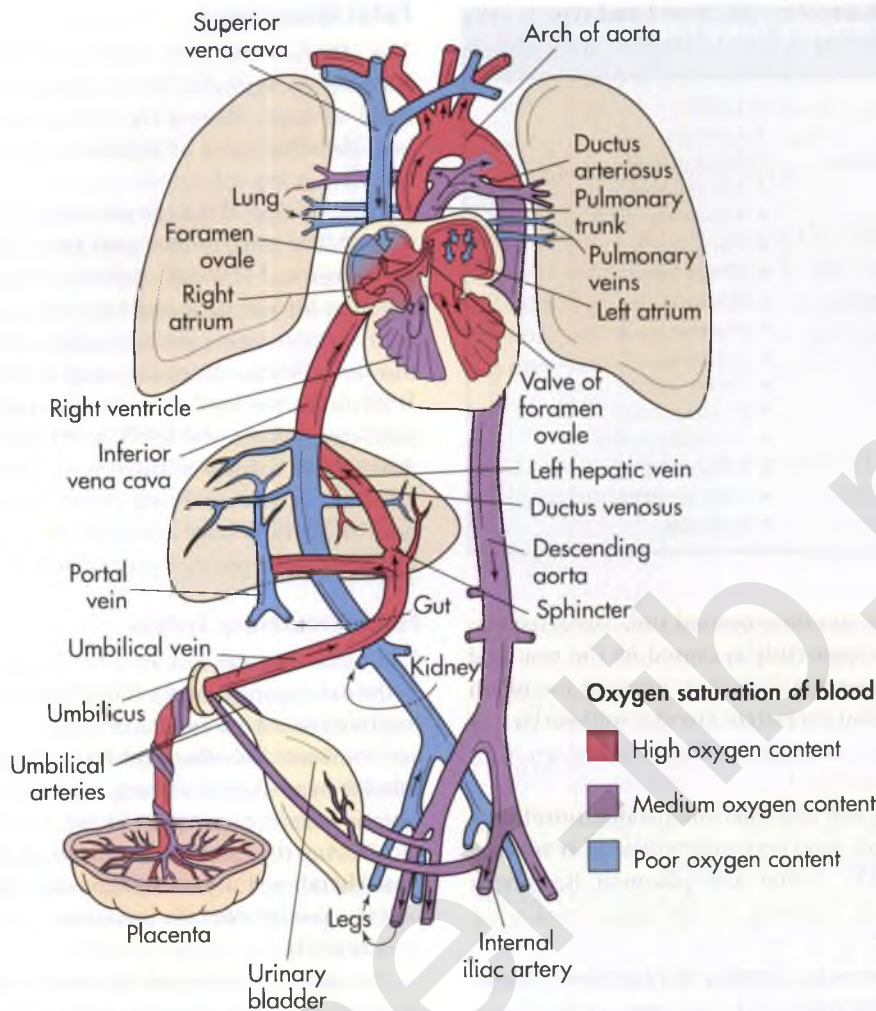

FIG 12-12 Schematic illustration of the fetal circulation. The colors indicate the oxygen saturation of the blood, and the arrows show the course of the blood from the placenta to the heart. The organs are not drawn to scale. Observe that three shunts permit most of the blood to bypass the liver and lungs: (1) ductus venosus, (2) foramen ovale, and (3) ductus arteriosus. A small amount of highly oxygenated blood from the inferior vena cava remains in the right atrium and mixes with poorly oxygenated blood from the superior vena cava. This medium oxygenated blood then passes into the right ventricle. The poorly oxygenated blood returns to the placenta for oxygen and nutrients through the umbilical arteries. (From Moore, K.L., Persaud, T.V.N., & Torchia, M.G. [2013]. *Before we are born: Essentials of embryology and birth defects* [8th ed.]. Philadelphia: Saunders).

in exchange for nutrients and oxygen. The blood remaining in the iliac arteries flows through the fetal abdomen and legs, ultimately returning through the inferior vena cava to the heart.

The following three special characteristics enable the fetus to obtain sufficient oxygen from the maternal blood:

- Fetal hemoglobin has a high affinity for oxygen and carries 20% to 30% more oxygen than maternal hemoglobin.
- The hemoglobin concentration of the fetus is about 50% greater than that of the mother.
- The fetal heart rate is 110 to 160 beats/minute, making the cardiac output per unit of body weight higher than that of an adult.

Hematopoietic System

Hematopoiesis, the formation of blood, occurs in the yolk sac (see Fig. 12-4, B) beginning in the third week. Hematopoietic stem cells seed the fetal liver during the fifth week, and hematopoiesis begins there during the sixth week. This accounts for the

relatively large size of the liver between the seventh and ninth weeks. Stem cells seed the fetal bone marrow, spleen, thymus, and lymph nodes between weeks 8 and 11 (for more information about stem cells see <http://stemcells.nih.gov>).

The antigenic factors that determine blood type are present in the erythrocytes soon after the sixth week. For this reason the Rh-negative woman is at risk for isoimmunization in any pregnancy that lasts longer than 6 weeks after fertilization.

Respiratory System

The respiratory system begins development during embryonic life and continues through fetal stages and into childhood. The development of the respiratory tract begins in week 4 and continues through week 17 with formation of the larynx, trachea, bronchi, and lung buds. Between 16 and 24 weeks the bronchi and terminal bronchioles enlarge, and vascular structures and primitive alveoli are formed. Between 24 weeks and term more

alveoli form. Specialized alveolar cells, type I and type II cells, secrete pulmonary surfactants to line the interior of the alveoli. After 32 weeks sufficient surfactant is present in developed alveoli to provide infants with a good chance of survival.

Pulmonary Surfactants. The detection of the presence of pulmonary surfactants, surface-active phospholipids, in amniotic fluid has been used to determine the degree of fetal lung maturity, or the ability of the lungs to function after birth. Lecithin (L) is the most critical alveolar surfactant required for postnatal lung expansion. It is detectable at approximately 21 weeks and increases in amount after week 24. Another pulmonary phospholipid, sphingomyelin (S), remains constant in amount. Thus the measure of lecithin in relation to sphingomyelin, or the **L/S ratio**, is used to determine fetal lung maturity. When the L/S ratio reaches 2:1, the infant's lungs are considered to be mature. This occurs approximately in the middle of the third trimester (Mercer, 2013).

Certain maternal conditions that cause decreased maternal placental blood flow, such as maternal hypertension, placental dysfunction, infection, or corticosteroid use, can accelerate fetal lung maturity. This apparently is caused by the resulting fetal hypoxia, which stresses the fetus and increases the blood levels of corticosteroids that accelerate alveolar and surfactant development.

Conditions such as gestational diabetes and chronic glomerulonephritis can inhibit fetal lung maturity. Using intrabronchial synthetic surfactant to treat respiratory distress syndrome in the newborn has greatly improved the chances of preterm infant survival.

Fetal respiratory movements have been seen on ultrasound examination as early as week 11. These fetal respiratory movements can aid in development of the chest wall muscles and regulate lung fluid volume. The fetal lungs produce fluid that expands the air spaces in the lungs. The fluid drains into the amniotic fluid or is swallowed by the fetus.

Shortly before birth, secretion of lung fluid decreases. The normal birth process squeezes out approximately one third of the fluid. Infants born by cesarean may have respiratory difficulty at birth, which is partially attributed to not having the benefit of this squeezing process (Ramachandrapa & Jain, 2008). The fluid remaining in the lungs at birth is usually reabsorbed into the infant's bloodstream within 2 hours of birth.

Gastrointestinal System

During the fourth week the shape of the embryo changes from being almost straight to a C shape, as both ends fold in toward the ventral surface. A portion of the yolk sac is incorporated into the body from head to tail as the primitive gut (digestive system).

The foregut produces the pharynx, part of the lower respiratory tract, the esophagus, the stomach, the first half of the duodenum, the liver, the pancreas, and the gallbladder. These structures evolve during the fifth and sixth weeks. The malformations that can occur in these areas are esophageal atresia, hypertrophic pyloric stenosis, duodenal stenosis or atresia, and biliary atresia (see Chapter 36).

The midgut becomes the distal half of the duodenum, the jejunum and the ileum, the cecum and the appendix, and the proximal half of the colon. The midgut loop projects into the umbilical cord between weeks 5 and 10. A malformation

(omphalocele) results if the midgut fails to return to the abdominal cavity, causing the intestines to protrude from the umbilicus (see Fig. 36-8, A). Meckel diverticulum is the most common malformation of the midgut. It occurs when a remnant of the yolk stalk that failed to degenerate attaches to the ileum, leaving a blind sac.

The hindgut develops into the distal half of the colon, the rectum and parts of the anal canal, the urinary bladder, and the urethra. Anorectal malformations are the most common abnormalities of the digestive system.

The fetus swallows amniotic fluid beginning in the fifth month. Gastric emptying and intestinal peristalsis occur. Fetal nutrition and elimination needs are taken care of by the placenta. As the fetus nears term, fetal waste products accumulate in the intestines as dark green to black, tarry meconium. Normally this substance is passed through the rectum within 24 hours of birth. Sometimes with a breech presentation or fetal hypoxia, meconium is passed in utero into the amniotic fluid. The failure to pass meconium after birth can indicate atresia somewhere in the digestive tract, an imperforate anus (see Fig. 36-9), or meconium ileus, in which a firm meconium plug blocks passage (seen in infants with cystic fibrosis).

The metabolic rate of the fetus is relatively low, but the fetus has great growth and development needs. Beginning in week 9 the fetus synthesizes glycogen for storage in the liver. Between 26 and 30 weeks the fetus begins to lay down stores of brown fat in preparation for extrauterine cold stress. Thermoregulation in the neonate requires increased metabolism and adequate oxygenation.

The gastrointestinal system is mature by 36 weeks. Digestive enzymes (except pancreatic amylase and lipase) are present in sufficient quantity to facilitate digestion. The neonate cannot digest starches or fats efficiently. Little saliva is produced.

Hepatic System

The liver and biliary tract develop from the foregut during the fourth week of gestation. The embryonic liver is prominent, occupying most of the abdominal cavity. Bile, a constituent of meconium, begins to form in the twelfth week.

Glycogen is stored in the fetal liver beginning at week 9 or 10. At term, glycogen stores are twice those of the adult. Glycogen is the major source of energy for the fetus and neonate stressed by intrauterine hypoxia, extrauterine loss of the maternal glucose supply, the work of breathing, or cold.

Iron also is stored in the fetal liver. If the maternal intake is sufficient, the fetus can store enough iron to last for 5 months after birth.

During fetal life the liver does not have to conjugate bilirubin for excretion because the unconjugated bilirubin is cleared by the placenta. Therefore, the glucuronyl transferase enzyme needed for conjugation is present in the fetal liver in amounts less than those required after birth. This predisposes the neonate, especially the preterm infant, to hyperbilirubinemia.

Coagulation factors II, VII, IX, and X cannot be synthesized in the fetal liver because of the lack of vitamin K synthesis in the sterile fetal gut. This coagulation deficiency persists after birth for several days and is the rationale for the prophylactic administration of vitamin K to the newborn.

Renal System

The kidneys form during the fifth week and begin to function approximately 4 weeks later. Urine is excreted into the amniotic fluid and forms a major part of the amniotic fluid volume. Oligohydramnios is indicative of renal dysfunction. Because the placenta acts as the organ of excretion and maintains fetal water and electrolyte balance, the fetus does not need functioning kidneys while in utero. At birth, however, the kidneys are required immediately for excretory and acid-base regulatory functions.

A fetal renal malformation can be diagnosed in utero. Corrective or palliative fetal surgery may treat the malformation successfully, or plans can be made for treatment immediately after birth.

At term the fetus has fully developed kidneys. However, the glomerular filtration rate (GFR) is low, and the kidneys lack the ability to concentrate urine. This makes the newborn more susceptible to both overhydration and dehydration.

Most newborns void within 24 hours of birth. With the loss of the swallowed amniotic fluid and the metabolism of nutrients provided by the placenta, the amount voided for the first days of life is scanty until fluid intake increases.

Neurologic System

The nervous system originates from the ectoderm during the third week after fertilization. The open neural tube forms during the fourth week. It initially closes at what will be the junction of the brain and spinal cord, leaving both ends open. The embryo folds in on itself lengthwise at this time, forming a head fold in the neural tube at this junction. The cranial end of the neural tube closes, and then the caudal end closes. During week 5, different growth rates cause more flexures in the neural tube, delineating three brain areas: the forebrain, the midbrain, and the hindbrain.

The forebrain develops into the eyes (cranial nerve II) and the cerebral hemispheres. The development of all areas of the cerebral cortex continues throughout fetal life and into childhood. The olfactory system (cranial nerve I) and the thalamus also develop from the forebrain. Cranial nerves III and IV (oculomotor and trochlear) form from the midbrain. The hindbrain forms the medulla, the pons, the cerebellum, and the remainder of the cranial nerves. Brain waves can be recorded on an electroencephalogram by week 8.

The spinal cord develops from the long end of the neural tube. Another ectodermal structure, the neural crest, develops into the peripheral nervous system. By the eighth week nerve fibers traverse throughout the body. At term the fetal brain is approximately one fourth the size of an adult brain. Neurologic development continues. Stressors on the fetus and neonate (e.g., chronic poor nutrition or hypoxia, drugs, environmental toxins, trauma, disease) cause damage to the central nervous system long after the vulnerable embryonic time for malformations in other organ systems. Neurologic insult can result in cerebral palsy, neuromuscular impairment, intellectual disability, and learning disabilities.

Sensory Awareness. Purposeful movements of the fetus have been demonstrated in response to a firm touch transmitted through the mother's abdomen. Because the fetus can feel pressure and pain, anesthesia is required for invasive procedures.

Fetuses respond to sound by 24 weeks. Different types of music evoke different movements. The fetus can be soothed by the sound of the mother's voice. Acoustic stimulation can be used to evoke a fetal heart rate response. The fetus becomes accustomed (i.e., habituates) to noises heard repeatedly. Hearing is fully developed at birth.

The fetus is able to distinguish taste. By the fifth month, when the fetus is swallowing amniotic fluid, a sweetener added to the fluid causes the fetus to swallow faster. The fetus also reacts to temperature changes. A cold solution placed into the amniotic fluid can cause fetal hiccups.

The fetus can see. Eyes have both rods and cones in the retina by the seventh month. A bright light shone on the mother's abdomen in late pregnancy causes abrupt fetal movements. During sleep time, rapid eye movements have been observed similar to those occurring in children and adults while dreaming.

Endocrine System

The thyroid gland develops along with structures in the head and neck during the third and fourth weeks. The secretion of thyroxine begins during the eighth week. Maternal thyroxine does not readily cross the placenta; therefore, the fetus who does not produce thyroid hormones will be born with congenital hypothyroidism. If untreated, hypothyroidism can result in severe intellectual disability. Hypothyroidism is included in routine newborn screening after birth.

The adrenal cortex is formed during the sixth week and produces hormones by the eighth or ninth week. As term approaches, the fetus produces more cortisol. This is believed to aid in initiation of labor by decreasing the maternal progesterone and stimulating production of prostaglandins.

The pancreas forms from the foregut during the fifth through eighth weeks. The islets of Langerhans develop during the twelfth week. Insulin is produced by week 20. In fetuses of mothers with uncontrolled diabetes, maternal hyperglycemia produces fetal hyperglycemia, stimulating hyperinsulinemia and islet cell hyperplasia. This results in a macrosomic (large) fetus. The hyperinsulinemia also blocks lung maturation, placing the neonate at risk for respiratory distress (see Chapter 34) and hypoglycemia when the maternal glucose source is lost at birth (see Chapters 23 and 29). Control of the maternal glucose level before and during pregnancy minimizes problems for the fetus and infant.

Reproductive System

Sex differentiation begins in the embryo during the seventh week. Female and male external genitalia are indistinguishable until after the ninth week. Distinguishing characteristics of female and male genitalia appear around the ninth week and are fully differentiated by the twelfth week. When a Y chromosome is present, testes are formed. By the end of the embryonic period, testosterone is being secreted and causes formation of the male genitalia. By week 28 the testes begin descending into the scrotum. After birth low levels of testosterone continue to be secreted until the pubertal surge.

The female, with two X chromosomes, forms ovaries and female external genitalia. By the sixteenth week oogenesis has been established. At birth the ovaries contain the female's lifetime supply of ova. Most female hormone production

is delayed until puberty. However, the fetal endometrium responds to maternal hormones, and withdrawal bleeding or vaginal discharge (*pseudomenstruation*) can occur at birth when these hormones are lost. The high level of maternal estrogen also stimulates mammary engorgement and secretion of fluid (“witch’s milk”) in newborn infants of both sexes.

CLINICAL REASONING CASE STUDY

Ultrasound Examination During Pregnancy

Veronica is 16 weeks pregnant. She has taken a folic acid supplement since 3 months before she became pregnant. On ultrasound a neural tube defect, myelomeningocele, was detected. Veronica is extremely upset and states that she took folic acid from before the time she was pregnant until now. She asks how this defect could have happened and what she should do about it. What information should the nurse provide Veronica?

1. Evidence—Is there sufficient evidence to draw conclusions about what information the nurse should provide Veronica?
2. Assumptions—What assumptions can be made about the following factors related to neural tube defects:
 - a. Veronica’s knowledge of folic acid and the cause of myelomeningocele
 - b. Veronica’s concern for her fetus
 - c. Veronica’s knowledge of myelomeningocele and its treatment
 - d. Veronica’s need for genetic counseling
3. What implications and priorities for nursing care can be made at this time?
4. Does the evidence objectively support your conclusion?

Musculoskeletal System

Bones and muscles develop from the mesoderm by the fourth week of embryonic development. At that time the cardiac muscle is already beating. The mesoderm next to the neural tube forms the vertebral column and ribs. The parts of the vertebral column grow toward each other to enclose the developing spinal cord. Ossification, or bone formation, begins. If there is a defect in the bony fusion, various forms of spina bifida can occur. A large defect affecting several vertebrae may allow the membranes and spinal cord to pouch out from the back, producing neurologic deficits and skeletal deformity.

The flat bones of the skull develop during the embryonic period, and ossification continues throughout childhood. At birth connective tissue sutures exist where the bones of the skull meet.

The areas where more than two bones meet (called *fontanels*) are especially prominent. The sutures and fontanels allow the bones of the skull to mold, or move during birth, enabling the head to pass through the birth canal (see Fig. 23-9).

The bones of the shoulders, arms, hips, and legs appear in the sixth week as a continuous skeleton with no joints. Differentiation occurs, producing separate bones and joints. Ossification continues through childhood to allow growth. Beginning in the seventh week, muscles contract spontaneously. By week 11 or 12 the fetus makes respiratory movements, moves all extremities, and changes position in utero. The fetus can suck his or her thumb and swim in the amniotic fluid pool, turn somersaults, and occasionally tie a knot in the umbilical cord. Arm and leg

movements are visible on ultrasound examination, although the mother does not perceive them until sometime between 16 and 20 weeks.

Integumentary System

The epidermis begins as a single layer of cells derived from the ectoderm at 4 weeks. By the seventh week there are two layers of cells. The cells of the superficial layer are sloughed and become mixed with the sebaceous gland secretions to form the white, cheesy *vernix caseosa*, the material that protects the fetus’s skin. The vernix is thick at 24 weeks but becomes scant by term.

The basal layer of the epidermis is the germinal layer, which replaces lost cells. Until 17 weeks the skin is thin and wrinkled, with blood vessels visible underneath. The skin thickens and all layers are present at term. After 32 weeks, as subcutaneous fat is deposited under the dermis, the skin becomes less wrinkled and red.

By 16 weeks the epidermal ridges are present on the palms of the hands, the fingers, the bottom of the feet, and the toes. Handprints and footprints are unique to each infant.

Hairs form from hair bulbs in the epidermis that project into the dermis. Cells in the hair bulb keratinize to form the hair shaft. As the cells at the base of the hair shaft proliferate, the hair grows to the surface of the epithelium. Very fine hairs, called *lanugo*, appear first at 12 weeks on the eyebrows and upper lip. By 20 weeks they cover the entire body. At this time the eyelashes, eyebrows, and scalp hair are beginning to grow. By 28 weeks the scalp hair is longer than the lanugo, which thins and may disappear by term gestation.

Fingernails and toenails develop from thickened epidermis at the tips of the digits beginning during the tenth week. They grow slowly. Fingernails usually reach the fingertips by 32 weeks, and toenails reach toe tips by 36 weeks.

Immunologic System

During the third trimester albumin and globulin are present in the fetus. The only immunoglobulin that crosses the placenta, immunoglobulin G (IgG), provides passive acquired immunity to specific bacterial toxins. The fetus produces IgM by the end of the first trimester. These are produced in response to blood group antigens, gram-negative enteric organisms, and some viruses. IgA is not produced by the fetus; however, colostrum, the precursor to breast milk, contains large amounts of IgA and can provide passive immunity to the neonate who is breastfed.

The normal-term neonate can fight infection but not so effectively as an older child. The preterm infant is at much greater risk for infection.

Table 12-1 summarizes embryonic and fetal development.

Multifetal Pregnancy

Twins

The incidence of twinning is 1 in 43 births. There has been a steady rise in multiple births since 1973 (Benirschke, 2013). This is partly attributed to the availability of assisted reproductive technologies and the increasing age at which women give birth as well as use of ovulation-enhancing drugs (Benirschke).

Dizygotic Twins. When two mature ova are produced in one ovarian cycle, both have the potential to be fertilized by separate sperm. This results in two zygotes, or *dizygotic twins*

(Fig. 12-13). There are always two amnions, two chorions, and two placentas, that may be fused (Fig. 12-14). These dizygotic, or fraternal, twins can be the same sex or different sexes and are genetically no more alike than siblings born at different times. Dizygotic twinning occurs in families, more often among African-American women than among Caucasian women and least often among Asian women. Dizygotic twinning increases in frequency with maternal age up to 35 years, with parity, and with the use of fertility drugs.

Monozygotic Twins. Identical, or **monozygotic, twins** develop from one fertilized ovum, which then divides (Fig.

12-15). They are the same sex and have the same genotype. If division occurs soon after fertilization, two embryos, two amnions, two chorions, and two placentas that can be fused will develop. Most often, division occurs between 4 and 8 days after fertilization, and there are two embryos, two amnions, one chorion, and one placenta. Rarely, division occurs after the eighth day after fertilization. In this case there are two embryos within a common amnion and a common chorion with one placenta. This often causes circulatory problems because the umbilical cords may tangle together, and one or both fetuses may die. Monozygotic twinning occurs approximately 3.5 to

TABLE 12-1 Milestones in Human Development Before Birth Since Last Menstrual Period

4 WEEKS	8 WEEKS	12 WEEKS
<p>External Appearance Body flexed, C-shaped; arm and leg buds present; head at right angles to body</p> 	<p>Body fairly well formed; nose flat, eyes far apart; digits well formed; head elevating; tail almost disappeared; eyes, ears, nose, and mouth recognizable</p> 	<p>Nails appearing; resembles a human; head erect but disproportionately large; skin pink, delicate</p> 
<p>Crown-to-Rump Measurement; Weight 0.4-0.5 cm; 0.4 g</p>	<p>2.5-3 cm; 2 g</p>	<p>6-9 cm; 19 g</p>
<p>Gastrointestinal System Stomach at midline and fusiform; conspicuous liver; esophagus short; intestine a short tube</p>	<p>Intestinal villi developing; small intestines coil within umbilical cord; palatal folds present; liver very large</p>	<p>Bile secreted; palatal fusion complete; intestines have withdrawn from cord and assume characteristic positions</p>
<p>Musculoskeletal System All somites present</p>	<p>First indication of ossification—occiput, mandible, and humerus; fetus capable of some movement; definitive muscles of trunk, limbs, and head well represented</p>	<p>Some bones well outlined, ossification spreading; upper cervical to lower sacral arches and bodies ossify; smooth muscle layers indicated in hollow viscera</p>
<p>Circulatory System Heart develops, double chambers visible, begins to beat; aortic arch and major veins completed</p>	<p>Main blood vessels assume final plan; enucleated red cells predominate in blood</p>	<p>Blood forming in marrow</p>
<p>Respiratory System Primary lung buds appear</p>	<p>Pleural and pericardial cavities forming; branching bronchioles; nostrils closed by epithelial plugs</p>	<p>Lungs acquire definite shape; vocal cords appear</p>
<p>Renal System Rudimentary ureteral buds appear</p>	<p>Earliest secretory tubules differentiating; bladder-urethra separates from rectum</p>	<p>Kidney able to secrete urine; bladder expands as a sac</p>
<p>Nervous System Well-marked midbrain flexure; no hindbrain or cervical flexures; neural groove closed</p>	<p>Cerebral cortex begins to acquire typical cells; differentiation of cerebral cortex, meninges, ventricular foramina, cerebrospinal fluid circulation; spinal cord extends entire length of spine</p>	<p>Brain structural configuration almost complete; cord shows cervical and lumbar enlargements; fourth ventricle foramina are developed; sucking present</p>
<p>Sensory Organs Eye and ear appearing as optic vessel and otocyst</p>	<p>Primordial choroid plexuses develop; ventricles large relative to cortex; development progressing; eyes converging rapidly; internal ear developing; eyelids fuse</p>	<p>Earliest taste buds indicated; characteristic organization of eye attained</p>
<p>Genital System Genital ridge appears (fifth week)</p>	<p>Testes and ovaries distinguishable; external genitalia sexless but begin to differentiate</p>	<p>Sex recognizable; internal and external sex organs specific</p>

TABLE 12-1 Milestones in Human Development Before Birth Since Last Menstrual Period—cont'd

16 WEEKS	20 WEEKS	24 WEEKS
<p>External Appearance Head still dominant; face looks human; eyes, ears, and nose approach typical appearance on gross examination; arm/leg ratio proportionate; scalp hair appears</p> 	<p>Vernix caseosa appears; lanugo appears; legs lengthen considerably; sebaceous glands appear</p> 	<p>Body lean but fairly well proportioned; skin red and wrinkled; vernix caseosa present; sweat glands forming</p> 
<p>Crown-to-Rump Measurement; Weight 11.5-13.5 cm; 100 g</p>	<p>16-18.5 cm; 300 g</p>	<p>23 cm; 600 g</p>
<p>Gastrointestinal System Meconium in bowel; some enzyme secretion; anus open</p>	<p>Enamel and dentine depositing; ascending colon recognizable</p>	
<p>Musculoskeletal System Most bones distinctly indicated throughout body; joint cavities appear; muscular movements can be detected</p>	<p>Sternum ossifies; fetal movements strong enough for mother to feel</p>	
<p>Circulatory System Heart muscle well developed; blood formation active in spleen</p>		<p>Blood formation increases in bone marrow and decreases in liver</p>
<p>Respiratory System Elastic fibers appear in lungs; terminal and respiratory bronchioles appear</p>	<p>Nostrils reopen; primitive respiratory-like movements begin</p>	<p>Alveolar ducts and sacs present; lecithin begins to appear in amniotic fluid (weeks 26 to 27)</p>
<p>Renal System Kidney in position; attains typical shape and plan</p>		
<p>Nervous System Cerebral lobes delineated; cerebellum assumes some prominence</p>	<p>Brain grossly formed; cord myelination begins; spinal cord ends at level of first sacral vertebra (S1)</p>	<p>Cerebral cortex layered typically; neuronal proliferation in cerebral cortex ends</p>
<p>Sensory Organs General sense organs differentiated</p>	<p>Nose and ears ossify</p>	<p>Can hear</p>
<p>Genital System Testes in position for descent into scrotum; vagina open</p>		<p>Testes at inguinal ring in descent to scrotum</p>

Continued

TABLE 12-1 Milestones in Human Development Before Birth Since Last Menstrual Period—cont'd

28 WEEKS	30-31 WEEKS	36-40 WEEKS
<p>External Appearance Lean body, less wrinkled and red; nails appear</p>	<p>Subcutaneous fat beginning to collect; more rounded appearance; skin pink and smooth; has assumed birth position</p>	<p>36 weeks: Skin pink, body rounded; general lanugo disappearing; body usually plump</p>
		
		<p>40 weeks: Skin smooth and pink; scant vernix caseosa; moderate to profuse hair; lanugo on shoulders and upper body only; nasal and alar cartilage apparent</p>
<p>Crown-to-Rump Measurement; Weight 27 cm; 1100 g</p>	<p>31 cm; 1800-2100 g</p>	<p>36 weeks: 35 cm; 2200-2900 g; 40 weeks: 40 cm; 3200+ g</p>
<p>Musculoskeletal System Astragalus (talus, ankle bone) ossifies; weak, fleeting movements, minimum tone</p>	<p>Middle fourth phalanges ossify; permanent teeth primordia seen; can turn head to side</p>	<p>36 weeks: Distal femoral ossification centers present; sustained, definite movements; fair tone; can turn and elevate head 40 weeks: Active, sustained movement; good tone; may lift head</p>
<p>Respiratory System Lecithin forming on alveolar surfaces</p>	<p>L/S ratio = 1.2:1</p>	<p>36 weeks: L/S ratio >2:1 40 weeks: Pulmonary branching only two thirds complete</p>
<p>Renal System</p>		<p>36 weeks: Formation of new nephrons ceases</p>
<p>Nervous System Appearance of cerebral fissures, convolutions rapidly appearing; indefinite sleep-wake cycle; cry weak or absent; weak suck reflex</p>		<p>36 weeks: End of spinal cord at level of third lumbar vertebra (L3); definite sleep-wake cycle 40 weeks: Myelination of brain begins; patterned sleep-wake cycle with alert periods; strong suck reflex</p>
<p>Sensory Organs Eyelids reopen; retinal layers completed, light-receptive; pupils capable of reacting to light</p>	<p>Sense of taste present; aware of sounds outside mother's body</p>	
<p>Genital System</p>	<p>Testes descending to scrotum</p>	<p>40 weeks: Testes in scrotum; labia majora well developed</p>

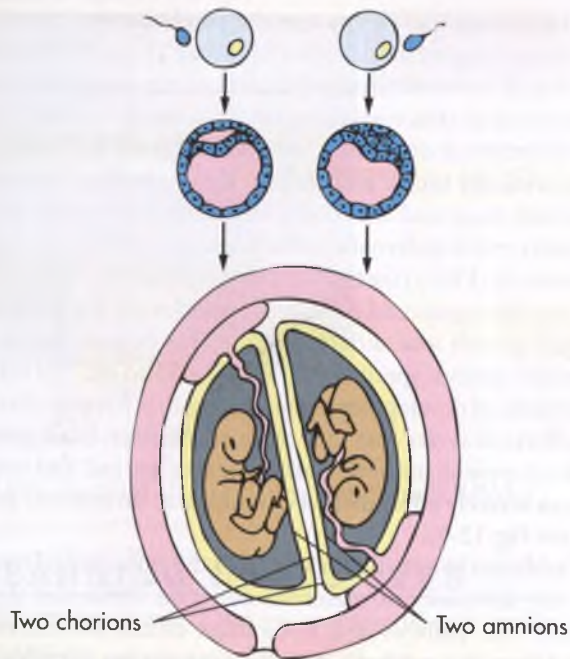

FIG 12-13 Formation of dizygotic twins, with fertilization of two ova, two implantations, two placentas, two chorions, and two amnions.

FIG 12-14 Diamniotic dichorionic (separate) twin placenta. (From Benirschke, K. [2013]. Multiple gestation. The biology of twinning. In R. Creasy, R. Resnik, J. Iams, et al. (Eds.), *Creasy and Resnik's maternal-fetal medicine: Principles and practice* (7th ed.). Philadelphia: Saunders.)

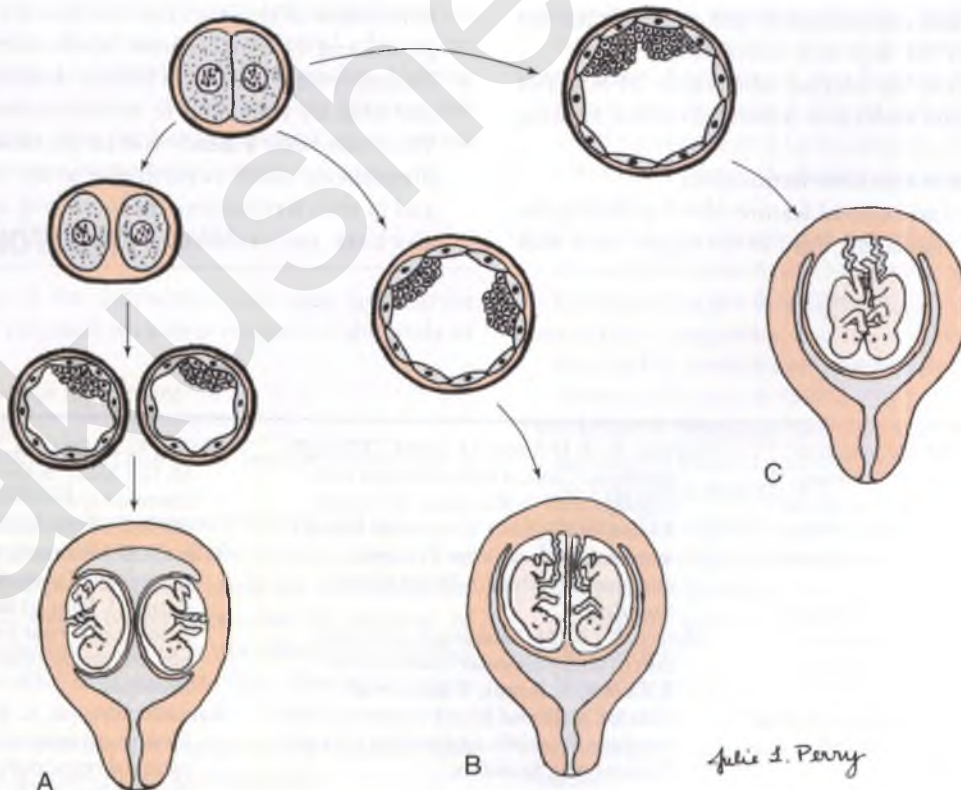

FIG 12-15 Formation of monozygotic twins. **A**, One fertilization: blastomeres separate, resulting in two implantations, two placentas, and two sets of membranes. **B**, One blastomere with two inner cell masses, one fused placenta, one chorion, and separate amnions. **C**, One blastomere with incomplete separation of cell mass, resulting in conjoined twins.

4 per 1000 births (Benirschke, 2013). There is no association with race, heredity, maternal age, or parity. Fertility drugs increase the incidence of monozygotic twinning.

Conjoined, or “Siamese,” twins are a type of monozygotic twins in which cleavage is incomplete and occurs late (13 to 15 days postconception) (see Fig. 12-15). The estimated frequency is 1.5 in 100,000 births (Malone & D’Alton, 2013). Prenatal diagnosis is possible with three-dimensional ultrasonography. Cesarean birth minimizes trauma to mother and fetuses.

Other Multifetal Pregnancies

The occurrence of **multifetal pregnancies** with three or more fetuses has increased with the use of fertility drugs and in vitro fertilization. Triplets occur in approximately 1 of 1341 pregnancies (Benirschke, 2013). They can occur from the division of one zygote into two, with one of the two dividing again, producing identical triplets. Triplets also can be produced from two zygotes, one dividing into a set of identical twins, and the second zygote developing as a single fraternal sibling, or from three zygotes. Quadruplets, quintuplets, sextuplets, and so on, likewise have similar possible derivations.

NONGENETIC FACTORS INFLUENCING DEVELOPMENT

Congenital disorders may be inherited, may be caused by environmental factors, or may be a result of inadequate maternal

nutrition. **Congenital** means that the condition was present at birth. Some congenital malformations may be caused by teratogens, that is, environmental substances or exposures that result in functional or structural disability. In contrast to other forms of developmental disabilities, disabilities caused by teratogens are theoretically totally preventable. Known human teratogens are certain drugs and chemicals, infections, exposure to radiation, and certain maternal conditions such as diabetes and phenylketonuria (PKU) (see Box 12-1). A teratogen has the greatest effect on the organs and parts of an embryo during its periods of rapid growth and differentiation. This occurs during the embryonic period, specifically from days 15 to 60. During the first 2 weeks of development, teratogens either have no effect or have effects so severe that they cause miscarriage. Brain growth and development continue during the fetal period, and teratogens can severely affect mental development throughout gestation (see Fig. 12-7).

In addition to genetic makeup and the influence of teratogens, the adequacy of maternal nutrition influences development. The embryo and fetus must obtain the nutrients needed from the mother’s diet; they cannot tap the maternal reserves. Malnutrition during pregnancy produces low-birth-weight newborns who are susceptible to infection. Malnutrition also affects brain development during the latter half of gestation and can result in intellectual disabilities in the child. Inadequate folic acid is associated with neural tube defects.

KEY POINTS

- Human gestation lasts approximately 280 days after the last menstrual period or 266 days after conception.
- Fertilization occurs in the uterine tube within 24 hours of ovulation. The zygote undergoes mitotic divisions, creating a 16-cell morula.
- Implantation begins 6 days after fertilization.
- The organ systems and external features develop during the embryonic period, that is, the third to the eighth week after fertilization.
- Refinement of structure and function occurs during the fetal period, and the fetus becomes capable of extrauterine survival.
- During critical periods in human development, the embryo and fetus are vulnerable to environmental teratogens.
- There has been a steady rise in the incidence of multifetal pregnancies, which is partly due to the use of fertility drugs and in vitro fertilization, the increasing age at which women give birth, and ovulation-enhancing drugs.

Anatomy and Physiology of Pregnancy

Kathryn R. Alden

 <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Determine gravidity and parity using the two- and five-digit systems.
- Describe the various types of pregnancy tests, including the timing of tests and interpretation of results.
- Explain the expected maternal anatomic and physiologic adaptations to pregnancy.
- Differentiate among presumptive, probable, and positive signs of pregnancy.
- Identify maternal hormones produced during pregnancy, their target organs, and their major effects on pregnancy.

The goal of maternity care is a healthy pregnancy with a physically safe and emotionally satisfying outcome for mother, infant, and family. Consistent health supervision and surveillance are of utmost importance. However, many maternal adaptations are unfamiliar to pregnant women and their families. Helping the pregnant woman recognize the relationship between her physical status and the plan for her care assists her in making decisions and encourages her to participate in her own care.

GRAVIDITY AND PARITY

An understanding of the following terms used to describe pregnancy and the pregnant woman is essential to the study of maternity care:

Gravida: A woman who is pregnant

Gravidity: Pregnancy

Nulligravida: A woman who has never been pregnant and is not currently pregnant

Primigravida: A woman who is pregnant for the first time

Multigravida: A woman who has had two or more pregnancies

Parity: The number of pregnancies in which the fetus or fetuses have reached 20 weeks of gestation, not the number of fetuses (e.g., twins) born. Parity is not affected by whether the fetus is born alive or is stillborn (i.e., showing no signs of life at birth).

Nullipara: A woman who has not completed a pregnancy with a fetus or fetuses beyond 20 weeks of gestation

Primipara: A woman who has completed one pregnancy with a fetus or fetuses who have reached 20 weeks of gestation

Multipara: A woman who has completed two or more pregnancies to 20 weeks of gestation or more

Preterm: A pregnancy that has reached 20 weeks of gestation but ends before completion of 37 weeks of gestation

Late preterm: A pregnancy that has reached between 34 weeks 0 days and 36 weeks 6 days of gestation

Early term: A pregnancy that has reached between 37 weeks 0 days and 38 weeks 6 days of gestation (American College of Obstetricians and Gynecologists [ACOG] Committee on Obstetric Practice & Society for Maternal-Fetal Medicine [SMFM], 2013)

Full term: A pregnancy that has reached between 39 weeks 0 days and 40 weeks 6 days of gestation (ACOG Committee on Obstetric Practice & SMFM, 2013)

Late term: A pregnancy that has reached between 41 weeks 0 days and 41 weeks 6 days of gestation (ACOG Committee on Obstetric Practice & SMFM, 2013)

Post term: A pregnancy that has reached between 42 weeks 0 days and beyond of gestation (ACOG Committee on Obstetric Practice & SMFM, 2013)

Viability: The capacity to live outside the uterus; there are no clear limits of gestational age or weight. Infants born at 22 to 25 weeks of gestation are considered to be on the threshold of viability and are especially vulnerable to brain injury if they survive.

Gravidity and parity information is obtained during history-taking interviews. Obtaining and documenting this information accurately is important in planning care for a pregnant woman.

Information may be recorded in client records in a variety of ways because no one standardized system exists. It is important that the nurse understand the documentation system used by the health care facility.

TABLE 13-1 Obstetric History Using Five-Digit and Two-Digit System

CONDITION	FIVE-DIGIT SYSTEM					TWO-DIGIT SYSTEM
	G	T	P	A	L	G/P
	GRAVIDITY	TERM BIRTH	PRETERM BIRTHS	ABORTIONS AND MISCARRIAGES	LIVING CHILDREN	GRAVIDITY/PARITY
Olivia is pregnant for the first time.	1	0	0	0	0	1/0
She carries the pregnancy to term, and the neonate survives.	1	1	0	0	1	1/1
She is pregnant again.	2	1	0	0	1	2/1
Her second pregnancy ends in miscarriage at 10 weeks.	2	1	0	1	1	2/1
During her third pregnancy, she gives birth at 36 weeks to twins.	3	1	1	1	3	3/2

Two commonly used systems of summarizing the obstetric history are discussed here. Gravidity and parity can be described with only two digits: the first digit indicates the number of pregnancies the woman has had, including the present one, and parity the number of pregnancies that have reached 20 weeks of gestation. For example, the abbreviation gravida 1, para 0 (1/0) means that a woman is pregnant for the first time (primigravida) and has not carried a pregnancy to 20 weeks (nullipara). If a woman had twins at 36 weeks with her first pregnancy, she would be gravida 1, para 1.

Another system consisting of five digits is commonly used. This system provides more information about the woman's obstetric history, although it may not provide accurate information about parity because it provides information about births and not pregnancies reaching 20 weeks of gestation. The first digit represents gravidity, the second digit represents the total number of term births, the third indicates the number of preterm births, the fourth identifies the number of abortions (miscarriage [spontaneous abortion] or elective termination of pregnancy before 20 weeks), and the fifth is the number of children currently living. The acronym GTPAL (gravidity, term, preterm, abortions, living children) can be helpful in remembering this system of notation. For example, if a woman pregnant only once gives birth at week 35 and the infant survives, the abbreviation that represents this information is "1-0-1-0-1." During her next pregnancy the abbreviation is "2-0-1-0-1." Additional examples are in Table 13-1.

While the GTPAL notation for obstetric history is commonly used, the current recommendation is that term pregnancy (beyond 37 weeks) is classified as early term, full term, late term, or post term. Use of this uniform classification by clinicians, researchers, and public health officials will facilitate the provision of quality health care, clinical research, and data reporting (ACOG Committee on Obstetric Practice & SMFM, 2013).

PREGNANCY TESTS

Early detection of pregnancy allows for early initiation of prenatal care. Human chorionic gonadotropin (hCG) is the earliest biologic marker for pregnancy. Pregnancy tests are based on the recognition of hCG or a beta (β) subunit of hCG. Production of β -hCG begins as early as the day of implantation and can be detected in maternal serum or urine as soon as 7 to 8 days

before the expected menses. hCG levels usually double approximately every 2 days for the first 4 weeks of pregnancy. The level of hCG rises until it peaks at 60 to 70 days and then declines to lowest levels at about 100 to 130 days as the placenta becomes the primary source of estrogen and progesterone. Plasma levels of hCG remain at this lower level for the remainder of the pregnancy. Higher than normal levels of hCG are associated with abnormal gestation (e.g., fetus with Down syndrome, gestational trophoblastic disease) or multiple gestation. Abnormally slow increase in hCG or lower levels can indicate impending miscarriage or ectopic pregnancy (Liu, 2014).

Serum and urine pregnancy tests are performed in clinics, offices, women's health centers, and laboratory settings. Urine tests can also be done at home. Both serum and urine tests can provide accurate results.

Quantitative serum testing—the β -hCG test—has a high level of accuracy because it measures the exact amount of hCG in the blood and can detect even small amounts. hCG levels greater than 25 International Units/L are diagnostic for pregnancy. For serum testing, a 7- to 10-ml sample of venous blood is collected (Pagana & Pagana, 2013).

Sandwich-type immunoassay testing is the most popular method of testing for pregnancy and is the basis for most home pregnancy tests. It uses a specific monoclonal antibody (anti-hCG) with enzymes that bond with hCG in urine. Many different pregnancy tests are available (Fig. 13-1). With these one-step tests the woman usually applies urine to a strip or absorbent-tipped applicator and reads the results. The test kits come with directions for collection of the specimen, the testing procedure, and reading of results.

The accuracy of the results is related to following the instructions correctly. However, instructions for some home pregnancy tests do not comply with the recommended guidelines for use of plain language, and many instructions are written at a seventh-grade reading level or above, which limits understanding by some users. A positive test result is indicated by a simple color change reaction or a digital reading. Most manufacturers of the kits provide a toll-free telephone number to call if users have concerns or questions about test procedures or results. A common error in performing home pregnancy tests is doing the test too early in pregnancy before a significant rise in hCG level; this can cause a false-negative result (Pagana & Pagana, 2013) (see Clinical Reasoning Case Study).

FIG 13-1 Many pregnancy test products are available over the counter. (Courtesy Dee Lowdermilk, Chapel Hill, NC.)

COMMUNITY ACTIVITY

- Review web-based information about home pregnancy tests. Explore websites such as www.babycenter.com and www.parents.com. Assess the accuracy of information.
- Visit a pharmacy in your neighborhood. How many different types of home pregnancy test kits are available in the pharmacy? Read the labels on three different types of home pregnancy test kits. Do the kits include material for more than one test? Are the directions printed in more than one language? After reading the directions, do you have questions about how to perform the test or how to interpret the results? If so, what does that say about the likelihood that the tests will be used correctly?

CLINICAL REASONING CASE STUDY

Pregnancy Testing

When her menstrual period was 10 days late, Regine purchased a home pregnancy test on her way home from work and performed the test that evening. The result was negative. Regine and her partner have been trying to get pregnant so that the baby will be born when she is on summer break from her teaching job at the elementary school. She is disappointed that the test was negative and she calls the clinic to ask the nurse if she should come in for a blood test to see if she is pregnant.

1. Evidence—Is there sufficient evidence to draw conclusions about the advice the nurse should provide to Regine?
2. Assumptions—What assumptions can be made about the following issues?
 - a. Proper use of home pregnancy tests
 - b. Factors that can affect results of home pregnancy tests
 - c. Human chorionic gonadotropin (hCG) levels in pregnancy
3. What are the implications and priorities for providing information to Regine?
4. Does the evidence objectively support your conclusion?

Interpreting the results of pregnancy tests requires some judgment. The type of pregnancy test and its degree of sensitivity (the ability to detect low levels of a substance) and specificity (the ability to discern the absence of a substance) must be considered in conjunction with the woman's history. This includes the date of her last normal menstrual period, her usual cycle

length, and results of previous pregnancy tests. It is important to know about any medications or other substances she is taking. Medications such as anticonvulsants and tranquilizers can cause false-positive results, whereas diuretics and promethazine can cause false-negative results (Pagana & Pagana, 2013). Improper collection of the specimen, hormone-producing tumors, and laboratory errors can also cause inaccurate results.

Women who use a home pregnancy test should be advised about the variations in accuracy and to use caution when interpreting results. Whenever there is any question, further evaluation or retesting may be appropriate (see Teaching for Self-Management).

TEACHING FOR SELF-MANAGEMENT

Home Pregnancy Testing

1. Follow the manufacturer's instructions carefully. Do not omit steps.
2. Review the manufacturer's list of foods, medications, and other substances that can affect the test results.
3. Use a first-voided morning urine specimen.
4. If the test done at the time of your missed period is negative, repeat the test in 1 week if you still have not had a period.
5. If you have questions about the test, contact the manufacturer.
6. Contact your health care provider for follow-up if the test result is positive or if the test result is negative and you still have not had a period.

ADAPTATIONS TO PREGNANCY

Maternal physiologic adaptations are attributed to the hormones of pregnancy and to mechanical pressures arising from the enlarging uterus and other tissues. These adaptations protect the woman's normal physiologic functioning, meet the metabolic demands that pregnancy imposes on her body, and provide a nurturing environment for fetal development and growth. Although pregnancy is a normal phenomenon, problems can occur.

Signs of Pregnancy

Some physiologic adaptations are recognized as the signs and symptoms of pregnancy. Three commonly used categories of these signs and symptoms are:

- **Presumptive**—those changes felt by the woman (e.g., amenorrhea, fatigue, breast changes)
- **Probable**—those changes observed by an examiner (e.g., Hegar sign, ballottement, pregnancy tests)
- **Positive**—those signs attributed only to the presence of the fetus (e.g., hearing fetal heart tones, visualizing the fetus, palpating fetal movements)

Table 13-2 summarizes these signs of pregnancy in relation to when they might occur and gives other possible causes for their occurrence.

Reproductive System and Breasts

Uterus

Changes in Size, Shape, and Position. High levels of estrogen and progesterone stimulate phenomenal uterine growth in the first trimester. Early uterine enlargement results from increased vascularity and dilation of blood vessels, hyperplasia (production of new muscle fibers and fibroelastic tissue) and

TABLE 13-2 Signs of Pregnancy

TIME OF OCCURRENCE (GESTATIONAL AGE)	SIGN	OTHER POSSIBLE CAUSE
Presumptive		
3-4 wk	Breast changes	Premenstrual changes, oral contraceptives
4 wk	Amenorrhea	Stress, vigorous exercise, early menopause, endocrine problems, malnutrition
4-14 wk	Nausea, vomiting	Gastrointestinal virus, food poisoning
6-12 wk	Urinary frequency	Infection, pelvic tumors
12 wk	Fatigue	Stress, illness
16-20 wk	Quickening	Gas, peristalsis
Probable		
5 wk	Goodell sign	Pelvic congestion
6-8 wk	Chadwick sign	Pelvic congestion
6-12 wk	Hegar sign	Pelvic congestion
4-12 wk	Positive pregnancy test (serum)	Hydatidiform mole, choriocarcinoma
6-12 wk	Positive pregnancy test (urine)	False-positive result may be caused by pelvic infection, tumors
16 wk	Braxton Hicks contractions	Myomas, other tumors
16-28 wk	Ballottement	Tumors, cervical polyps
Positive		
5-6 wk	Visualization of fetus by real-time ultrasound examination	No other causes
6 wk	Fetal heart tones detected by ultrasound	No other causes
16 wk	Visualization of fetus by radiographic study	No other causes
8-17 wk	Fetal heart tones detected by Doppler ultrasound stethoscope	No other causes
17-19 wk	Fetal heart tones detected by fetal stethoscope	No other causes
19-22 wk	Fetal movements palpated by examiner	No other causes
Late pregnancy	Fetal movements visible to examiner	No other causes

hypertrophy (enlargement of preexisting muscle fibers and fibroelastic tissue), and development of the decidua. By 7 weeks of gestation, the uterus is the size of a large hen's egg; by 10 weeks, it is the size of an orange (twice its nonpregnant size); and by 12 weeks, it is the size of a grapefruit. After the third month, uterine enlargement is primarily the result of mechanical pressure of the growing fetus.

As the uterus enlarges it also changes in shape and position. At conception the uterus is shaped like an upside-down pear. During the second trimester, as the muscular walls strengthen and become more elastic, the uterus becomes spherical or globular. Later, as the fetus lengthens, the uterus becomes larger and more ovoid and rises out of the pelvis into the abdominal cavity.

The pregnancy may "show" after the fourteenth week, although this depends to some degree on the woman's height and weight. Abdominal enlargement may be less apparent in the nullipara with good abdominal muscle tone (Fig. 13-2). Posture also influences the type and degree of abdominal enlargement that occurs. In normal pregnancies the uterus enlarges at a predictable rate.

As the uterus grows it can be palpated above the symphysis pubis sometime between the twelfth and fourteenth weeks of pregnancy (Fig. 13-3). The uterus rises gradually to the level of the umbilicus at 22 to 24 weeks of gestation and nearly reaches the xiphoid process at term. Between weeks 38 and 40, fundal height decreases as the fetus begins to descend into the pelvis (**lightening**) in preparation for birth (see Fig. 13-3, *dashed line*). Generally lightening occurs in the nullipara about 2 weeks before the onset of labor and in the multipara at the start of labor.

FIG 13-2 Comparison of abdomen, vulva, and cervix in A, nullipara, and B, multipara, at the same stage of pregnancy.

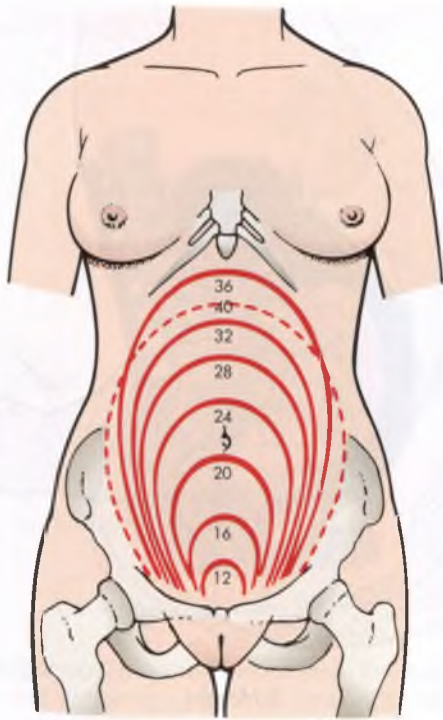

FIG 13-3 Height of fundus by weeks of normal gestation with a single fetus. *Dashed line*, Height after lightening. (From Seidel, H.M., Ball, J.W., Dains, J.E., et al. [2011]. *Mosby's guide to physical examination* [7th ed.]. St. Louis: Mosby.)

Uterine enlargement is determined by measuring fundal height (see Fig. 14-8). This measurement is commonly used to estimate the weeks of gestation. However, variations in the position of the fundus or the fetus, variations in the amount of amniotic fluid present, the presence of more than one fetus, maternal obesity, and differences in examiner technique can reduce the accuracy of this estimation.

Generally the uterus rotates to the right as it enlarges and rises in the abdomen, probably because of the presence of the rectosigmoid colon on the left side. However, the extensive hypertrophy (enlargement) of the round ligaments keeps the uterus in the midline. Eventually the growing uterus touches the anterior abdominal wall and displaces the intestines to either side of the abdomen (Fig. 13-4). When a pregnant woman is standing, most of her uterus rests against the anterior abdominal wall and contributes to altering her center of gravity.

At approximately 6 weeks of gestation, softening and compressibility of the lower uterine segment (uterine isthmus) occurs (**Hegar sign**) (Fig. 13-5). This results in exaggerated uterine anteversion during the first 3 months of pregnancy. In this position the uterine fundus presses on the urinary bladder, causing the woman to have urinary frequency.

Changes in Contractility. Soon after the fourth month of pregnancy, uterine contractions can be felt through the abdominal wall. These are referred to as **Braxton Hicks contractions**. Braxton Hicks contractions are irregular and painless contractions that occur intermittently throughout pregnancy. Although Braxton Hicks contractions are not painful, some women complain that they are annoying. After the twenty-eighth week, these contractions become more definite, but they usually cease with walking or exercise. Braxton Hicks

contractions can be mistaken for true labor; however, they do not increase in intensity or duration or cause cervical dilation. Conversely, premature labor contractions can be mistaken for Braxton Hicks contractions, which can lead to a delay in seeking treatment.

Uteroplacental Blood Flow. Placental perfusion depends on the maternal blood flow to the uterus. Blood flow increases rapidly as the uterus increases in size. Although uterine blood flow increases 10-fold, the fetoplacental unit grows even more rapidly (Norwitz, Mahendroo, & Lye, 2014). Consequently, more oxygen is extracted from the uterine blood during the latter part of pregnancy. In a normal-term pregnancy, one sixth of the total maternal blood volume is within the uterine vascular system. The rate of blood flow through the uterus averages 450 to 650 ml/minute at term, and oxygen consumption of the gravid uterus increases to meet fetal needs. Three factors known to decrease uterine blood flow are low maternal arterial pressure, contractions of the uterus, and maternal supine position. Estrogen stimulation can increase uterine blood flow. Doppler ultrasound examination may be used to measure uterine blood flow velocity, especially in pregnancies at risk because of conditions associated with decreased placental perfusion (e.g., hypertension, intrauterine growth restriction, diabetes mellitus, multiple gestation) (Blackburn, 2013).

By using an ultrasound device or a fetal stethoscope to auscultate fetal heart tones, the examiner may also hear the **uterine souffle** or bruit, a rushing or blowing sound of maternal blood flowing through uterine arteries to the placenta that is synchronous with the maternal pulse. The **funic souffle**, which is synchronous with the fetal heart rate and is caused by fetal blood coursing through the umbilical cord, may also be heard, as well as the fetus's actual heartbeat (see Fig. 14-7).

Cervical Changes. In a normal, unscarred cervix, softening of the cervical tip can be observed about the beginning of the sixth week. This probable sign of pregnancy, **Goodell sign**, is brought about by increased vascularity, slight hypertrophy, and hyperplasia (increase in number of cells). The muscle and its collagen-rich connective tissue become loose, edematous, highly elastic, and increased in volume. The glands near the external os proliferate beneath the stratified squamous epithelium, giving the cervix the velvety appearance characteristic of pregnancy. **Friability** (tissue is easily damaged) is increased and can result in slight bleeding after vaginal examination or after coitus with deep penetration.

Pregnancy can also cause the squamocolumnar junction, the site for obtaining cells for cervical cancer screening, to be located away from the cervix. Because of these changes, evaluation of abnormal Papanicolaou (Pap) tests during pregnancy can be complicated. However, careful assessment of all pregnant women is important because approximately 3% of all invasive cervical cancers occur during pregnancy (Salani, Eisenhauer, & Copeland, 2012).

The cervix of the nullipara is rounded. Lacerations of the cervix can occur during the birth process. After birth, with or without lacerations, the cervix becomes more oval in the horizontal plane and the external os appears as a transverse slit (see Fig. 13-2).

Changes Related to the Presence of the Fetus. Passive movement of the unengaged fetus is called **ballottement**

FIG 13-4 Displacement of internal abdominal structures and diaphragm by the enlarging uterus at 4, 6, and 9 months of gestation.

and can be identified by the examiner generally between the sixteenth and eighteenth weeks. Ballottement is a technique of palpating a floating structure by bouncing it gently and feeling it rebound. To palpate the fetus, the examiner places a finger within the vagina and taps gently upward on the cervix, causing the fetus to rise. The fetus then sinks, and a gentle tap is felt on the finger (Fig. 13-6).

Quickening is the first recognition of fetal movements, or “feeling life.” It can be detected by the multiparous woman as early as 14 to 16 weeks. The nulliparous woman may not notice these sensations until the eighteenth week or later. Quickening

is commonly described as a flutter and is difficult to distinguish from peristalsis. Fetal movements gradually increase in intensity and frequency as pregnancy progresses. The week in which quickening occurs provides a tentative clue in dating the duration of gestation.

Vagina and Vulva

Pregnancy hormones prepare the vagina for stretching during labor and birth by causing the vaginal mucosa to thicken, the connective tissue to loosen, the smooth muscle to hypertrophy, and the vaginal vault to lengthen. Increased vascularity results

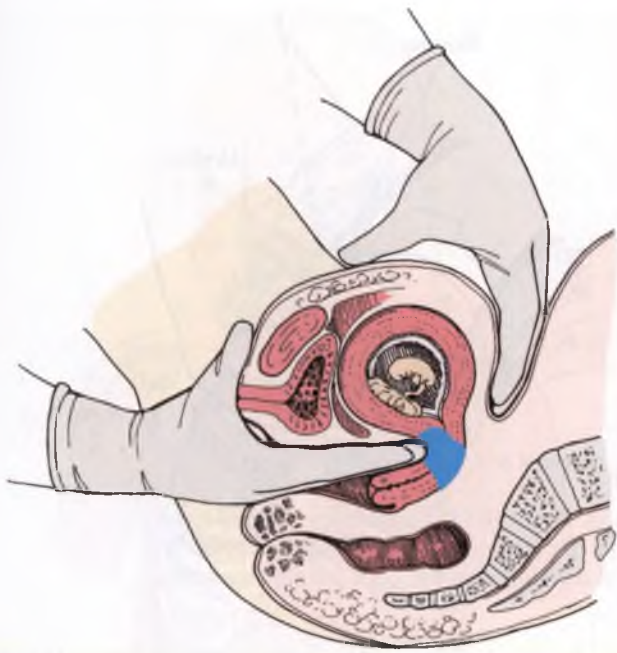

FIG 13-5 Hegar sign. Bimanual examination for assessing compressibility and softening of isthmus (lower uterine segment) while the cervix is still firm.

FIG 13-6 Internal ballottement (18 weeks).

in a violet-blue vaginal mucosa and cervix. This is known as the **Chadwick sign** and can be evident as early as the sixth week but is easily noted by the eighth week of pregnancy (Blackburn, 2013).

Leukorrhea is a white or slightly gray mucoid discharge with a faint musty odor. This copious mucoid fluid occurs in response to cervical stimulation by estrogen and progesterone. The fluid is whitish because of the presence of many exfoliated vaginal epithelial cells caused by the hyperplasia of normal pregnancy. This normal vaginal discharge is never pruritic or blood stained. The mucus fills the endocervical canal, resulting in the formation of the mucus plug (**operculum**) (Fig. 13-7). The operculum acts as a barrier against bacterial invasion during pregnancy.

During pregnancy the pH of vaginal secretions is more acidic, ranging from about 3.5 to about 6.0 (nonpregnant, 4.0 to 5.0), because of increased production of lactic acid. Although this acidic environment provides more protection from some organisms, the pregnant woman is more vulnerable to other infections, especially yeast infections because the glycogen-rich environment of the vagina is more susceptible to *Candida albicans*.

The increased vascularity of the vagina and other pelvic viscera results in a marked increase in sensitivity. The increased sensitivity can lead to a high degree of sexual interest and

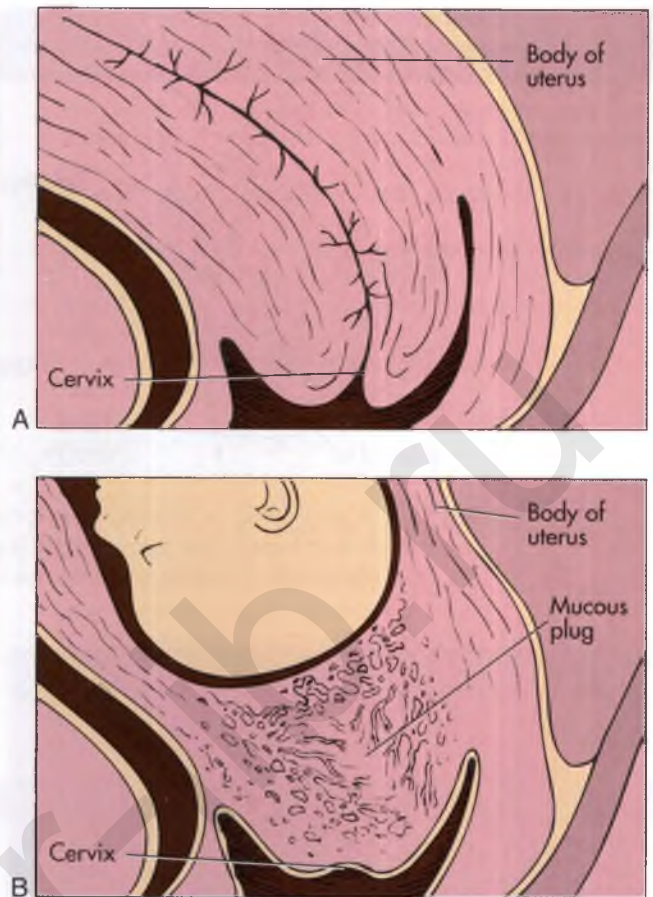

FIG 13-7 A, Cervix in nonpregnant woman. B, Cervix during pregnancy.

arousal, especially during the second trimester of pregnancy. The increased congestion, plus the relaxed walls of the blood vessels and the heavy uterus, can result in edema and varicosities of the vulva. The edema and varicosities usually resolve during the postpartum period.

External structures of the perineum are enlarged during pregnancy because of an increase in vasculature, hypertrophy of the perineal body, and deposition of fat (Fig. 13-8). The labia majora of nulliparous women approximate (come together) and obscure the vaginal introitus; those of the parous woman separate and gape after childbirth and perineal or vaginal injury. See Figure 13-2 for a comparison of the nullipara and the multipara in relation to the pregnant abdomen, vulva, and cervix.

Breasts

Fullness, heightened sensitivity, tingling, and heaviness of the breasts begin in the early weeks of gestation in response to increased levels of estrogen and progesterone. Breast sensitivity varies from mild tingling to sharp pain. Nipples and areolae become more pigmented; secondary pinkish areolae develop, extending beyond the primary areolae; and nipples become more erectile. Hypertrophy of the sebaceous (oil) glands embedded in the primary areolae, called **Montgomery tubercles**, may be seen around the nipples. Within the tubercles are sebaceous and sweat glands that secrete lubricating and anti-infective substances to help protect the nipples and areolae during breastfeeding.

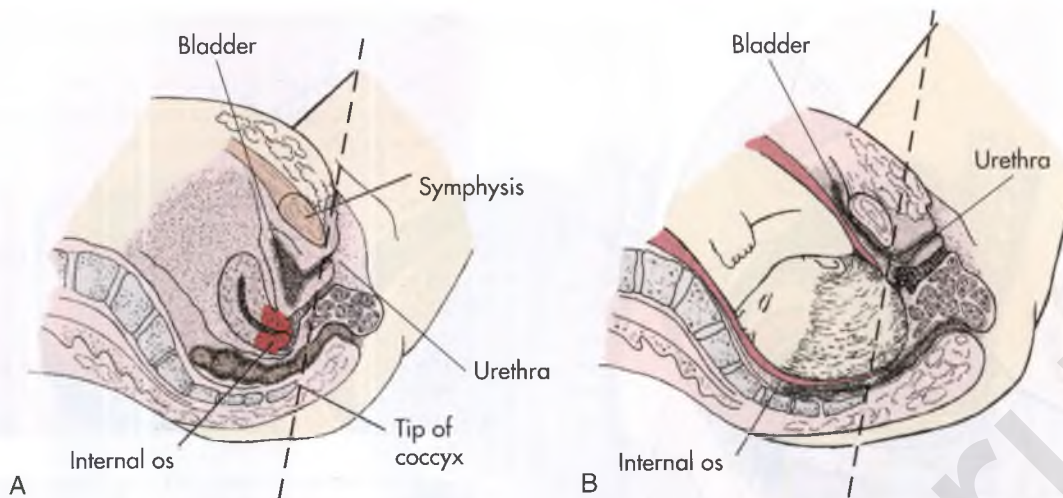

FIG 13-8 A, Pelvic floor in nonpregnant woman. B, Pelvic floor at end of pregnancy. Note marked hypertrophy and hyperplasia below dotted line joining tip of coccyx and inferior margin of symphysis. Note elongation of bladder and urethra as a result of compression. Fat deposits are increased.

FIG 13-9 Enlarged breasts in pregnancy with venous network and darkened areolae and nipples. (From Seidel, H.M., Ball, J.W., Dains, J.E., et al. [2011]. *Mosby's guide to physical examination* [7th ed.]. St. Louis: Mosby.)

The richer blood supply causes the vessels beneath the skin to dilate. Once barely noticeable, the blood vessels become visible, often appearing in an intertwining bluish network beneath the surface of the skin. Venous congestion in the breasts is more obvious in primigravidas. **Striae gravidarum**, or stretch marks, can appear at the outer aspects of the breasts.

During the second and third trimesters, growth of the mammary glands accounts for the progressive breast enlargement (Fig. 13-9). The high levels of luteal and placental hormones in pregnancy promote proliferation of the lactiferous ducts and lobule-alveolar tissue so that palpation of the breasts reveals a generalized coarse nodularity. Glandular tissue displaces connective tissue, resulting in the tissue becoming softer and looser.

Although development of the mammary glands is functionally complete by midpregnancy, lactation is inhibited until the progesterone level decreases after birth. A thin, clear, viscous secretory material (precolostrum) can be found in the acinar cells by the third month of gestation. **Colostrum**, the yellow to yellowish-orange premilk fluid secreted during the second

trimester may be expressed from the nipples as early as 16 weeks of gestation (Lawrence & Lawrence, 2011). See Chapter 25 for a discussion of lactation.

General Body Systems

Cardiovascular System

Maternal adjustments to pregnancy involve extensive anatomic and physiologic changes in the cardiovascular system. Cardiovascular adaptations protect the woman's normal physiologic functioning, meet the metabolic demands pregnancy imposes on her body, and provide for fetal developmental and growth needs.

Slight cardiac hypertrophy (enlargement) is probably secondary to increased blood volume and cardiac output that occur in pregnancy. The heart returns to its normal size after birth. As the diaphragm is displaced upward by the enlarging uterus, the heart is elevated upward and rotated forward to the left (Fig. 13-10). The apical impulse, or point of maximal intensity (PMI), is shifted upward and laterally about 1 to 1.5 cm. The degree of shift depends on the duration of pregnancy and the size and position of the uterus.

The changes in heart size and position and the increases in blood volume and cardiac output contribute to auscultatory changes common in pregnancy. There is more audible splitting of S_1 and S_2 , and S_3 can be readily heard after 20 weeks of gestation. More than 95% of women develop systolic murmurs; they are most audible over the left sternal border. These changes are transient and disappear in most women shortly after they give birth.

Maternal heart rate begins to increase at about 5 weeks of gestation, reaching a peak of 10 to 15 beats/minute over the pre-pregnancy baseline by 32 weeks and persisting until term. In the late third trimester, this increased heart rate helps to maintain cardiac output (Monga & Mastrobattista, 2014).

The pregnant woman may experience palpitations and the cardiac rhythm can be disturbed. She can experience sinus dysrhythmia, premature atrial contractions, and premature ventricular systole. In the healthy woman with no underlying heart disease, no therapy is needed. Women with preexisting heart disease need close medical and obstetric supervision during pregnancy (see Chapter 30).

FIG 13-10 Changes in position of heart and in pregnancy. *Broken line*, Nonpregnant state; *solid line*, change that occurs in pregnancy.

Blood Pressure. Arterial blood pressure (brachial artery) varies with age, activity level, presence of health problems, circadian rhythm, use of alcohol, smoking, and pain. Additional factors to consider during pregnancy include maternal position and type of blood pressure apparatus. Maternal anxiety can elevate readings. If an elevated reading is found, the woman is given time to rest and the reading is repeated.

Maternal position affects readings. Brachial blood pressure is highest when the woman is sitting; lowest when she is lying in the lateral recumbent position; and intermediate when she is supine, except for some women who experience hypotensive syndrome (see later discussion). Therefore, at each prenatal visit the reading should be obtained in the same arm and with the woman in a seated position with her back and arm supported and her upper arm at the level of the right atrium. The position and arm used should be recorded along with the reading.

The proper-size cuff is essential for accurate readings. A cuff that is too small yields a falsely high reading; a cuff that is too large yields a falsely low reading (Box 13-1).

Caution should be used when comparing auscultatory and oscillatory blood pressure readings because discrepancies can occur. Automated monitors can give inaccurate readings in women with hypertensive conditions.

During pregnancy maternal blood pressure remains the same or decreases slightly. This is due to reduced systemic vascular resistance caused primarily by the vasodilatory effects of progesterone, prostaglandins, and relaxin. The uteroplacental vascular system holds a large percentage of the maternal blood volume, which also contributes to decreased systemic vascular resistance (Monga & Mastrobattista, 2014). Systemic vascular

BOX 13-1 Procedure for Blood Pressure Measurement

1. Use correct cuff size; cuff should cover approximately 80% of the upper arm or be 1.5 times the length of the upper arm.
2. Measure blood pressure (BP) after the woman sits for 5 minutes.
3. Instruct the woman to refrain from tobacco or caffeine use 30 minutes before BP measurement.
4. Measure BP with the woman sitting or semi-reclining with her feet flat, not dangling.
5. The arm should be supported on a desk at the level of the heart.
6. Measurements with an automated device should be checked with a manual device.
7. Diastolic pressure should be recorded at Korotkoff phase V (disappearance of sound).
8. If the BP is elevated, have the woman rest for 5 to 10 minutes and then retake it.
9. BP may vary by more than 10 mm Hg from one arm to the other; record the higher reading.
10. Take the average of two readings at least 1 minute apart.

Data from Peters, R. (2008). High blood pressure in pregnancy. *Nursing for Women's Health*, 12(5), 412-421.

BOX 13-2 Calculation of Mean Arterial Pressure

- Blood pressure: 106/70
- Formula:

$$\begin{aligned} & \text{Systolic} + 2 (\text{diastolic}) / 3 \\ & 106 + 2 (70) / 3 \\ & 106 + 140 / 3 \\ & 246 / 3 = 82 \text{ mm Hg} \end{aligned}$$

resistance is lowest at 16 to 34 weeks and increases gradually, approximating nonpregnant values by term. During the first trimester, systolic blood pressure usually remains the same as the prepregnancy level but can decrease slightly as pregnancy advances. Diastolic blood pressure begins to decrease in the first trimester, continues to drop until 24 to 32 weeks, and gradually increases, returning to prepregnancy levels by term (Blackburn, 2013).

Calculating the *mean arterial pressure* (MAP) (mean of the blood pressure in the arterial circulation) can increase the diagnostic value of the findings. MAP is useful in predicting gestational hypertensive disorders in the second and third trimesters (Gaillard, Bakker, Willemsen, et al., 2011). Normal MAP readings in the nonpregnant woman are 86 ± 7.5 mm Hg. MAP readings during pregnancy range from 84 to 87 ± 7 (Galan & Goetzl, 2012). Box 13-2 illustrates one way to calculate MAP.

Some degree of compression of the vena cava occurs in any woman who lies on her back during the second half of pregnancy. Cardiac output is reduced by as much as 25% to 30% when a pregnant woman is turned from left lateral recumbent to supine position. Some women experience a fall of more than 30 mm Hg in their systolic pressure. After 4 to 5 minutes, a reflex bradycardia is noted, cardiac output is reduced by half, and the woman feels faint. This condition is called

supine hypotensive syndrome or *vena caval syndrome* (Monga & Mastrobattista, 2014) (see Fig. 19-5).

Compression of the iliac veins and inferior vena cava by the uterus causes increased venous pressure and reduced blood flow in the legs, except when the woman is in the lateral position. These alterations contribute to the dependent edema, varicose veins in the legs and vulva, and hemorrhoids that develop in the latter part of term pregnancy.

Blood Volume and Composition. Total blood volume (TBV), consisting of plasma and red blood cell volume, increases significantly during pregnancy by approximately 30% to 45%. During the first half of pregnancy TBV increases rapidly, peaks around 28 to 34 weeks, and then stabilizes or decreases slightly by term (Blackburn, 2013). In a singleton pregnancy, plasma volume increases by approximately 1200 to 1500 ml, or 45% above prepregnancy levels by 32 weeks of gestation, decreasing slightly by term. By term, there is an increase in red blood cell mass of 250 to 450 ml, or approximately 20% to 30% over prepregnancy values (Monga & Mastrobattista, 2014). The percentage of increase depends on the amount of iron available (Blackburn). Increased blood volume is a protective mechanism. It is essential for meeting the blood volume needs of the hypertrophied vascular system of the

enlarged uterus, for adequately hydrating fetal and maternal tissues when the woman assumes an erect or supine position, and for providing a fluid reserve to compensate for blood loss during birth and postpartum. Blood volume increases are greater with multiple gestation. Peripheral vasodilation allows for a normal blood pressure despite the increased blood volume in pregnancy.

Because the plasma increase is greater than the increase in red blood cell (RBC) production, there is a decrease in normal hemoglobin values (12 to 16 g/dl blood) and hematocrit values (37% to 47%). This state of hemodilution is referred to as *physiologic anemia*. The decrease is more noticeable during the second trimester, when rapid expansion of blood volume occurs faster than RBC production. If the hemoglobin value drops to 11 g/dl or less during the first or third trimester or less than 10.5 g/dl during the second trimester or if the hematocrit decreases to 32% or less, the woman is considered anemic (Hark & Catalano, 2012).

The total white blood cell count increases during the second trimester and peaks during the third trimester. This increase is primarily in the granulocytes; the lymphocyte count stays about the same throughout pregnancy. See Table 13-3 for laboratory values during pregnancy.

TABLE 13-3 Laboratory Values for Pregnant and Nonpregnant Women

VALUES	NONPREGNANT	PREGNANT
Hematologic		
Complete Blood Count		
Hemoglobin, g/dl	12-16*	>11*
Hematocrit, packed cell volume, %	37-47	>33*
RBC volume, per ml	1400	1650
Plasma volume, per ml	2400	40%-45% increase
RBC count, million/mm ³	4.2-5.4	5-6.25; 20%-30% increase
White blood cells, total per mm ³	5000-10,000	5000-15,000
Neutrophils, %	55-70	60-85
Lymphocytes, %	20-40	15-40
Erythrocyte sedimentation rate, mm/hr	20	Elevated in second and third trimesters
Mean corpuscular hemoglobin concentration (MCHC) (g/dl packed RBCs) g/dl packed RBCs	32-36	No change
Mean corpuscular hemoglobin (MCH) (pg), pg	27-31	No change
Mean corpuscular volume (MCV), per mm ³	80-95	No change
Blood Coagulation and Fibrinolytic Activity†		
Factor VII	65-140	Increases in pregnancy, returns to normal in early puerperium
Factor VIII	55-145	Increases during pregnancy and immediately after birth
Factor IX	60-140	Same as factor VII
Factor X	45-155	Same as factor VII
Factor XI	65-135	Decreases in pregnancy
Factor XII	50-150	Same as factor VII
Prothrombin time (PT), sec	11-12.5	Decreases slightly in pregnancy
Partial thromboplastin time (PTT), sec	60-70	Decreases slightly in pregnancy and decreases during second and third stages of labor (indicates clotting at placental site)
Bleeding time, min	1-9 (Ivy method)	No appreciable change
Coagulation time, min	6-10 (Lee-White method)	No appreciable change
Platelets, per mm ³	150,000-400,000	No significant change until 3-5 days after birth and then increases rapidly (may predispose woman to thrombosis) and gradually returns to normal
Fibrinolytic activity		Decreases in pregnancy and then abruptly returns to normal (protection against thromboembolism)
Fibrinogen, mg/dl	200-400	Levels increase late in pregnancy
Mineral/Vitamin Concentrations		
Vitamin B ₁₂ , folic acid, ascorbic acid	Normal	Moderate decrease

TABLE 13-3 Laboratory Values for Pregnant and Nonpregnant Women—cont'd

VALUES	NONPREGNANT	PREGNANT
Blood Glucose		
Fasting, mg/dl	70-105	60-90 before breakfast; 60-105 before lunch, supper, bedtime snack
2-hr postprandial, mg/dl	<140	<120
Acid-Base Values in Arterial Blood		
P _O ₂ , mm Hg	80-100	104-108 (increased)
P _{CO} ₂ , mm Hg	35-45	27-32 (decreased)
Sodium bicarbonate (HCO ₃), mEq/L	21-28	18-31 (decreased)
Blood pH	7.35-7.45	7.40-7.45 (slightly increased, more alkaline)
Hepatic		
Bilirubin, total, mg/dl	≤1	Unchanged
Serum cholesterol, mg/dl	120-200	Increases from 16-32 wk of pregnancy; remains at this level until after birth
Serum alkaline phosphatase, units/L	30-120	Increases from wk 12 of pregnancy to 6 wk after birth
Serum albumin, g/dl	3.5-5	Increases 25% by term
Renal		
Bladder capacity, ml	1300	1500
Renal plasma flow, ml/min	490-700	Increases by 25%-30%
Glomerular filtration rate, ml/min	88-128	Increases by 30%-50%
Nonprotein nitrogen, mg/dl	25-40	Decreases
Blood urea nitrogen, mg/dl	10-20	Decreases
Serum creatinine, mg/dl	0.5-1.1	Decreases
Serum uric acid, mg/dl	2.7-7.3	Decreases but returns to prepregnancy level by end of pregnancy
Urine glucose	Negative	Present in 20% of pregnant women
Intravenous pyelogram	Normal	Slight to moderate hydronephrosis and hydronephrosis; right kidney larger than left kidney

pg, picogram; ABC, Red blood cell.

*At sea level. Permanent residents of higher levels (e.g., Denver) require higher levels of hemoglobin.

†Pregnancy represents a hypercoagulable state.

Data from Blackburn, S. (2013). *Maternal, fetal, & neonatal physiology: A clinical perspective* (4th ed.). St. Louis: Saunders; Gordon, M.C. (2012). Maternal physiology. In S.G. Gabbe, J.R. Niebyl, J.L. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (6th ed.). Philadelphia: Saunders; Landon, M.B., Catalano, P.J., & Gabbe, S.G. (2012). Diabetes mellitus complicating pregnancy. In S.G. Gabbe, J.R. Niebyl, J.L. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (6th ed.). Philadelphia: Saunders; Pagana, K.D., & Pagana, T.J. (2013). *Mosby's diagnostic and laboratory test reference* (11th ed.). St. Louis: Mosby; Samuels, P. (2012). Hematology complications of pregnancy. In S.G. Gabbe, J.R. Niebyl, J.L. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (6th ed.). Philadelphia: Saunders.

Cardiac Output. Cardiac output increases 30% to 50% over the nonpregnant rate by week 32 of pregnancy; it declines to about a 20% increase at 40 weeks of gestation. This elevated cardiac output is largely a result of increased stroke volume and heart rate and occurs in response to increased tissue demands for oxygen (Monga & Mastrobattista, 2014). Cardiac output increases with any exertion such as labor and birth. Table 13-4 summarizes cardiovascular changes in pregnancy.

Circulation and Coagulation Times. Pregnancy is considered a hypercoagulable state in which women are at a five- to sixfold increased risk for thromboembolic disease (Gordon, 2012). The circulation time decreases slightly by week 32 and returns to near normal by term. There is a greater tendency for blood to coagulate (clot) during pregnancy because of increases in various clotting factors (i.e., factors VII, VIII, IX, X, and fibrinogen) and decreases in factors that inhibit coagulation (e.g., protein S). This tendency, combined with the fact that fibrinolytic activity (the splitting up or dissolving of a clot) is depressed during pregnancy and the postpartum period, provides a protective function to decrease the chance of bleeding but also makes the woman more vulnerable to thrombosis, especially after cesarean birth.

TABLE 13-4 Cardiovascular Changes in Pregnancy

PARAMETER	CHANGE
Heart rate	Increases 10 to 15 beats/min
Blood pressure	
Systolic	Slight or no decrease from prepregnancy levels
Diastolic	Slight decrease to midpregnancy (24-32 wk) and gradual return to prepregnancy levels by end of pregnancy
Blood volume	Increases by 1200 to 1500 ml or 40% to 45% above prepregnancy level
Cardiac output	Increases 30% to 50%

Data from Gordon, M.C. (2012). Maternal physiology. In S.G. Gabbe, J.R. Niebyl, J.L. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (6th ed.). Philadelphia: Saunders

Respiratory System

Structural and ventilatory adaptations occur during pregnancy to provide for maternal and fetal needs. Maternal oxygen requirements increase in response to the acceleration in metabolic rate and the need to add to the tissue mass in the uterus and breasts. In addition, the fetus requires oxygen and a way to eliminate carbon dioxide.

TABLE 13-5 Respiratory Changes in Pregnancy

PARAMETER	CHANGE
Respiratory rate	Unchanged or slightly increased
Tidal volume	Increased 33%
Vital capacity	Unchanged
Inspiratory capacity	Increased 6%
Expiratory reserve volume	Decreased 20%
Total lung capacity	Unchanged to slightly decreased
Minute ventilation	Increased 30% to 50%
Oxygen consumption	Increased 20% to 40%

Data from Monga, M., & Mastrobattista, J.M. (2014). Maternal cardiovascular, respiratory, and renal adaptation to pregnancy. In R.K. Creasy, R. Resnik, J.D. Iams, et al. (Eds.), *Creasy & Resnik's maternal-fetal medicine: Principles and practice* (7th ed.). Philadelphia: Saunders.

Elevated levels of estrogen cause the ligaments of the rib cage to relax, permitting increased chest expansion. The transverse diameter of the thoracic cage increases by about 2 cm and the circumference by 6 cm. The costal angle increases, and the lower rib cage appears to flare out. The chest may not return to its prepregnant state after birth (Seidel, Ball, Dains, et al., 2011).

The diaphragm is displaced by as much as 4 cm during pregnancy. With advancing pregnancy, chest breathing replaces abdominal breathing and it becomes less possible for the diaphragm to descend with inspiration. Thoracic breathing is accomplished primarily by the diaphragm rather than by the costal muscles (Blackburn, 2013).

The upper respiratory tract becomes more vascular in response to elevated levels of estrogen. As the capillaries become engorged, edema and hyperemia develop within the nose, pharynx, larynx, trachea, and bronchi. This congestion within the tissues of the respiratory tract gives rise to several conditions commonly seen during pregnancy, including nasal and sinus stuffiness, epistaxis (nosebleed), changes in the voice, and marked inflammatory response to even a mild upper respiratory infection (Gordon, 2012).

Increased vascularity of the upper respiratory tract also can cause the tympanic membranes and eustachian tubes to swell, giving rise to symptoms of impaired hearing, earaches, or a sense of fullness in the ears.

Pulmonary Function. Respiratory changes in pregnancy are related to the elevation of the diaphragm and changes in the chest wall. Changes in the respiratory center result in a lowered threshold for carbon dioxide. The actions of progesterone and estrogen are presumed to be responsible for the increased sensitivity of the respiratory center to carbon dioxide. See Table 13-5 for respiratory changes in pregnancy. Although pulmonary function is not impaired by pregnancy, diseases of the respiratory tract can be more serious during this time. One important factor responsible for this can be the increase in oxygen requirements.

Basal Metabolic Rate. The basal metabolic rate (BMR) increases during pregnancy. The elevation in BMR reflects increased oxygen demands of the uterine-placental-fetal unit and greater oxygen consumption because of increased maternal cardiac work. This increase varies considerably, depending on the prepregnancy nutritional status of the woman and fetal growth. By the third trimester the BMR is increased by

10% to 20% over the nonpregnant state. The BMR returns to nonpregnant levels by 5 to 6 days after birth. Peripheral vasodilation and acceleration of sweat gland activity help dissipate the excess heat resulting from the increased BMR during pregnancy. Pregnant women can experience heat intolerance. Lassitude and fatigability after only slight exertion are experienced by many women in early pregnancy. These feelings, along with a greater need for sleep, can persist and be caused in part by the increased metabolic activity.

Acid-Base Balance. By about the tenth week of pregnancy, there is a decrease of about 5 mm Hg in the partial pressure of carbon dioxide (P_{CO_2}). Progesterone may be responsible for increasing the sensitivity of the respiratory center receptors so that tidal volume increases and P_{CO_2} decreases, the base excess (HCO_3^- , or bicarbonate) decreases, and pH increases slightly. These alterations in acid-base balance indicate that pregnancy is a state of respiratory alkalosis (Gordon, 2012) (see Table 13-3). These changes also facilitate the transport of CO_2 from the fetus and O_2 release from the mother to the fetus.

Renal System

The kidneys are responsible for maintaining electrolyte and acid-base balance, regulating extracellular fluid volume, excreting waste products, and conserving essential nutrients.

Anatomic Changes. Changes in renal structure result from hormonal activity (estrogen and progesterone), pressure from an enlarging uterus, and an increase in blood volume. As early as the tenth week of pregnancy, the renal pelves and the ureters dilate. Dilation of the ureters is more pronounced above the pelvic brim, in part because they are compressed between the uterus and the pelvic brim. In most women the ureters below the pelvic brim are normal size. The smooth-muscle walls of the ureters undergo hyperplasia and hypertrophy and muscle tone relaxation. The ureters elongate, become tortuous, and form single or double curves. In the latter part of pregnancy the renal pelvis and ureter dilate more on the right side than on the left because the heavy uterus is displaced to the right by the sigmoid colon (Monga & Mastrobattista, 2014).

Because of these changes, a larger volume of urine is held in the pelves and ureters and urine flow rate is slowed. Urinary stasis or stagnation has several consequences:

- A lag occurs between the time urine is formed and when it reaches the bladder. Therefore, clearance test results may reflect substances contained in glomerular filtrate several hours before.
- Stagnated urine is an excellent medium for the growth of microorganisms. In addition, the urine of pregnant women contains more nutrients, including glucose, that increase the pH (making the urine more alkaline). This makes pregnant women more susceptible to urinary tract infection (Cheung & Lafayette, 2013).

Bladder irritability, nocturia, and urinary frequency and urgency (without dysuria) are commonly reported in early pregnancy. These bladder symptoms may return near term, especially after lightening occurs.

Urinary frequency results initially from increased bladder sensitivity and later from compression of the bladder (see Fig. 13-8). In the second trimester the bladder is pulled up out of the true pelvis into the abdomen. The urethra lengthens to

7.5 cm as the bladder is displaced upward. The pelvic congestion that occurs in pregnancy is reflected in hyperemia of the bladder and urethra. This increased vascularity causes the bladder mucosa to be easily traumatized. Bladder tone may decrease, which increases the bladder capacity to 1500 ml. At the same time, the bladder is compressed by the enlarging uterus, resulting in the urge to void even if the bladder contains only a small amount of urine.

Functional Changes. In normal pregnancy renal function is altered considerably. Renal plasma flow (RPF) rises significantly from early in pregnancy, peaking by the end of the first trimester. RPF remains elevated above nonpregnant levels throughout pregnancy, although it begins to decrease somewhat as term approaches (Colombo, 2012). By the end of the first trimester, glomerular filtration rate (GFR) has increased by 50% and remains elevated throughout pregnancy. These changes are caused by pregnancy hormones; an increase in blood volume; and the woman's posture, physical activity, and nutritional intake. The woman's kidneys must manage the increased metabolic and circulatory demands of the maternal body as well as the excretion of fetal waste products. The increase in GFR results in increased creatinine clearance and a reduction in serum creatinine, blood urea nitrogen (BUN), and uric acid levels (Gordon, 2012).

Renal function is most efficient when the woman lies in the lateral recumbent position and least efficient when the woman assumes a supine position. A side-lying position increases renal perfusion, which increases urine output and decreases edema. When the pregnant woman is lying supine, the heavy uterus compresses the vena cava and the aorta, and cardiac output decreases. As a result, blood flow to the brain and heart is continued at the expense of other organs, including the kidneys and uterus.

Fluid and Electrolyte Balance. Selective renal tubular reabsorption maintains sodium and water balance, regardless of changes in dietary intake and losses through sweat, vomitus, or diarrhea. About 950 mg of sodium is cumulatively retained during pregnancy to meet fetal needs, although maternal serum levels of sodium decrease by 3 to 4 mmol/L (Gordon, 2012). To prevent excessive sodium depletion, the maternal kidneys undergo a significant adaptation by increasing tubular reabsorption. Because of the need for increased maternal intravascular and extracellular fluid volume, additional sodium is needed to expand fluid volume and maintain an isotonic state.

MEDICATION ALERT

As efficient as the renal system is, it can be overstressed by excessive dietary sodium intake or restriction or by use of diuretics. Severe hypovolemia and reduced placental perfusion are two consequences of using diuretics during pregnancy.

The capacity of the kidneys to excrete water is more efficient during the early weeks than later in pregnancy. As a result, some women feel thirsty in early pregnancy because of the greater amount of water loss. The pooling of fluid in the legs in the latter part of pregnancy decreases renal blood flow and GFR. This pooling is sometimes referred to as *physiologic or dependent edema* and requires no treatment. The normal diuretic

response to the water load is triggered when the woman lies down, preferably on her side, and the pooled fluid reenters general circulation.

Normally the kidney reabsorbs almost all the glucose and other nutrients from the plasma filtrate. However, in pregnant women tubular reabsorption of glucose is impaired, causing glucosuria to occur at varying times and to varying degrees (Cheung & Lafayette, 2013). Nonpregnant women excrete less than 100 mg/day, whereas pregnant women with normal blood glucose levels excrete 1 to 10 g of glucose each day (Gordon, 2012). The mechanism by which this occurs is unclear, although it may be related to the increased GFR and tubular flow rate that exceeds the capacity for tubular reabsorption of glucose (Blackburn, 2013). Although glucosuria can be found in normal pregnancies (2+ levels can be seen with increased anxiety states), the possibility of diabetes mellitus and gestational diabetes must be considered.

During normal pregnancy there is an increase in urinary excretion of protein and albumin, most notable after 20 weeks of gestation (Cheung & Lafayette, 2013). This is due to increased GFR and impaired proximal tubular function. It is considered abnormal when proteinuria exceeds 300 mg/24 hours or albuminuria is greater than 30 mg/24 hours. The amount of protein excreted is not an indication of the severity of renal disease, nor does an increase in protein excretion in a pregnant woman with known renal disease necessarily indicate a progression in her disease. However, a pregnant woman with hypertension and proteinuria must be evaluated carefully because she may be at greater risk for adverse pregnancy outcomes (Gordon, 2012).

Integumentary System

Alterations in hormone balance and mechanical stretching are responsible for several changes in the integumentary system during pregnancy. Hyperpigmentation is stimulated by the anterior pituitary hormone *melanotropin*, which is increased during pregnancy. Darkening of the nipples, areolae, axillae, and vulva occurs at about the sixteenth week of gestation. **Melasma** (also called chloasma or mask of pregnancy) is a blotchy, brownish hyperpigmentation of the skin over the cheeks, nose, and forehead, especially in pregnant women with dark complexions. Melasma appears in 50% to 70% of pregnant women, beginning after the sixteenth week and increasing gradually until term. The sun intensifies this pigmentation in susceptible women. Melasma caused by normal pregnancy usually fades after birth but often recurs with oral contraceptive use or subsequent pregnancies (Kroumpouzou, 2012).

The **linea nigra** (Fig. 13-11) is a pigmented line extending from the symphysis pubis to the top of the fundus in the midline. This line is known as the linea alba before hormone-induced pigmentation. In primigravidas, the extension of the linea nigra, beginning in the third month, keeps pace with the rising height of the fundus; in multigravidas, the entire line often appears earlier than the third month. Not all pregnant women develop linea nigra, and some women notice hair growth along the line with or without the change in pigmentation.

Striae gravidarum (see Fig. 13-11) appear in 50% to 80% of pregnant women during the second half of pregnancy. Striae reflect separation within the underlying connective (collagen) tissue of the skin. These slightly depressed streaks tend to

FIG 13-11 Striae gravidarum and linea nigra in a dark-skinned person. (Courtesy Shannon Perry, Phoenix, AZ.)

occur over areas of maximum stretch (the abdomen, thighs, and breasts). The stretching sometimes causes a sensation that resembles itching. The tendency to develop striae may be familial (Rapini, 2014). After birth they usually fade, although they never disappear completely. No topical therapy has been shown to affect the course of striae, although pulsed laser therapy can reduce redness of early lesions (Rapini).

Angiomas are commonly referred to as vascular spiders. These tiny star-shaped or branched, slightly raised, and pulsating end-arterioles are usually found on the neck, thorax, face, and arms. They occur as a result of elevated levels of circulating estrogens. The spiders are bluish and do not blanch with pressure. Vascular spiders appear during the second to fifth months of pregnancy in about 65% of Caucasian women and 10% of African-American women. The spiders usually disappear after birth (Blackburn, 2013).

Pinkish red, diffusely mottled, or well-defined blotches are seen over the palmar surfaces of the hands in about 70% of Caucasian women and 30% of African-American women during pregnancy (Krompouzos, 2012). These color changes, called **palmar erythema**, are related primarily to increased estrogen levels.

Some dermatologic conditions have been identified as unique to pregnancy or as having an increased incidence during pregnancy. The most common dermatologic symptom during pregnancy is itching (pruritis). Mild pruritus, also known as **pruritus gravidarum**, usually occurs over the abdomen. Less than 2% of women have significant pruritus that requires further evaluation (Krompouzos, 2012). The problem usually resolves during the postpartum period.

The most common specific dermatosis is **pruritic urticarial papules and plaques of pregnancy (PUPPP)**, affecting 1 in 130 to 1 in 300 pregnancies. PUPPP is more common in multiple gestations. Although it can cause significant maternal discomfort, it does not cause adverse outcomes for the mother or fetus. Mild PUPPP is usually treated with oral antihistamines and topical antipruritic and corticosteroid creams. Oral steroids may be needed in more severe cases (Krompouzos, 2012) (see Chapter 30 and Fig. 30-1).

The effect of pregnancy on acne is variable. In some women the skin clears and looks radiant. Acne can worsen or occur for the first time during pregnancy or postpartum. Commonly used

topical treatments for acne (e.g., benzyl peroxide, topical antibiotics) are considered safe during pregnancy; topical retinoids should be avoided in the first trimester (Tyler & Zirwas, 2013).

MEDICATION ALERT

Women with severe acne taking isotretinoin (e.g., Accutane) should avoid pregnancy while receiving the treatment because it is teratogenic and is associated with fetal loss and major fetal malformations (Tyler & Zirwas, 2013).

Nail and hair growth may be accelerated. Some women notice thinning and softening of the nails. Hirsutism, the excessive growth of hair or growth of hair in unusual places, is commonly reported. An increase in fine hair growth can occur but tends to disappear after pregnancy. However, growth of coarse or bristly hair does not usually disappear after pregnancy. The rate of scalp hair loss slows during pregnancy; increased hair loss may be noted in the postpartum period (Rapini, 2014).

Increased blood supply to the skin leads to increased perspiration. Women feel hotter during pregnancy, possibly related to a progesterone-induced increase in body temperature and the increased BMR.

Musculoskeletal System

The gradually changing body and increasing weight of pregnancy usually cause noticeable changes in a woman's posture (Fig. 13-12). The great abdominal distention that causes the pelvis to tilt forward, decreased abdominal muscle tone, and increased weight bearing require a realignment of the spinal curvatures. The woman's center of gravity shifts forward. An increase in the normal lumbosacral curve (lordosis) develops, and a compensatory curvature in the cervicodorsal region (exaggerated anterior flexion of the head) develops to help her maintain balance. Aching, numbness, and weakness of the upper extremities can result. Large breasts and a stoop-shouldered stance further accentuate the lumbar and dorsal curves. The ligamentous and muscular structures of the middle and lower spine can be severely stressed. These and related changes often cause musculoskeletal discomfort such as back pain, especially in older women or those with a back disorder or a faulty sense of balance.

The hormones relaxin and progesterone cause loosening of ligaments of the pubic symphysis and sacroiliac joints to facilitate labor and birth. By 28 to 32 weeks of gestation, the symphysis widens from approximately 3 to 4 mm to 7.7 to 7.9 mm. Separation of the symphysis pubis and the instability of the sacroiliac joints can cause pain and difficulty in walking. A waddling gait is common. Obesity or multifetal pregnancy tends to increase the pelvic instability (Gordon, 2012).

SAFETY ALERT

Pregnant women are at increased risk of falling due to the shifting center of gravity, impaired balance, and joint laxity.

The muscles of the abdominal wall stretch and ultimately lose some tone. During the third trimester the rectus abdominis muscles can separate (**diastasis recti abdominis**) (Fig. 13-13),

FIG 13-12 Postural changes during pregnancy. A, Nonpregnant. B, Incorrect posture during pregnancy. C, Correct posture during pregnancy.

FIG 13-13 Possible change in rectus abdominis muscles during pregnancy. A, Normal position in nonpregnant woman. B, Diastasis recti abdominis in pregnant woman.

allowing abdominal contents to protrude at the midline. The umbilicus flattens or protrudes. After birth, the muscles gradually regain tone. However, separation of the muscles can persist.

Neurologic System

Little is known about specific alterations in function of the neurologic system during pregnancy aside from hypothalamic-pituitary neurohormonal changes. Specific physiologic alterations resulting from pregnancy can cause the following neurologic or neuromuscular symptoms:

- Compression of pelvic nerves or vascular stasis caused by enlargement of the uterus can result in sensory changes in the legs.
- Dorsolumbar lordosis can cause pain because of traction on nerves or compression of nerve roots.

- Edema involving the peripheral nerves can result in **carpal tunnel syndrome** during the last trimester. The syndrome is characterized by paresthesia (abnormal sensation such as burning or tingling) and pain in the hand, radiating to the elbow. The sensations are caused by edema that compresses the median nerve beneath the carpal ligament of the wrist. Smoking and alcohol consumption can impair the microcirculation and worsen the symptoms. The dominant hand is usually affected most, although many women report symptoms in both hands. Symptoms usually regress after pregnancy. In some cases, surgical treatment is necessary.
- Acroesthesia (numbness and tingling of the hands) is caused by the stoop-shouldered stance (see Fig. 13-11, B) assumed by some women during pregnancy. The condition is associated with traction on segments of the brachial plexus.
- Tension headache is common when anxiety or uncertainty complicates pregnancy. However, vision problems such as refractive errors, sinusitis, or migraine may also be responsible for headaches.
- Lightheadedness, faintness, and even syncope (fainting) are common during early pregnancy. Vasomotor instability, postural hypotension, or hypoglycemia may be responsible.
- Hypocalcemia can cause neuromuscular problems such as muscle cramps or tetany.

Gastrointestinal System

Appetite. During pregnancy a woman's appetite and food intake fluctuate. Early in pregnancy some women have nausea with or without vomiting ("morning sickness"), possibly in response to increasing levels of hCG and altered carbohydrate metabolism (Gordon, 2012). Nausea and vomiting of pregnancy (NVP) appears at about 4 to 6 weeks of gestation and usually subsides by the end of the third month (first trimester) of pregnancy (see Chapter 15). Severity varies from mild distaste

for certain foods to more severe vomiting. The condition can be triggered by the sight or odor of various foods. By the end of the second trimester the appetite increases in response to increasing metabolic needs. Rarely does NVP have harmful effects on the embryo, the fetus, or the woman. Whenever the vomiting is severe or persists beyond the first trimester or when it is accompanied by fever, pain, or weight loss, further evaluation is necessary and medical intervention is likely.

Women can have changes in their sense of taste, leading to cravings and changes in dietary intake. Some women have non-food cravings (pica) such as for ice, clay, and laundry starch. Pica should be considered as a potential factor in cases of iron deficiency or poor weight gain (Gordon, 2012). (See Chapter 15 for a discussion of nutrition in pregnancy.)

Mouth. The gums become hyperemic, spongy, and swollen during pregnancy. They tend to bleed easily because the increasing levels of estrogen cause selective increased vascularity and connective tissue proliferation (a nonspecific gingivitis). An **epulis** (gingival granuloma gravidarum) is a red, raised nodule on the gums that bleeds easily. This lesion may develop around the third month and often continues to enlarge as pregnancy progresses. It is usually managed by avoiding trauma to the gums (e.g., using a soft toothbrush). An epulis commonly regresses spontaneously after birth.

Some pregnant women complain of **ptyalism** (excessive salivation), which can be caused by the unconscious decrease in swallowing by the woman when nauseated or caused by stimulation of salivary glands by eating starch.

Esophagus, Stomach, and Intestines. Increased progesterone causes decreased tone and motility of smooth muscles, resulting in esophageal regurgitation (reflux), slower emptying time of the stomach, and reverse peristalsis. As a result, the woman can experience acid indigestion, or heartburn (**pyrosis**), beginning as early as the first trimester and intensifying through the third trimester.

The incidence of hiatal hernia is increased during pregnancy as a result of the upward displacement of the stomach by the enlarging uterus, which causes a widening of the hiatus of the diaphragm. Hiatal hernia occurs more often in multiparas and older or obese women.

In response to increased needs during pregnancy, iron is absorbed more readily in the small intestine. Even when the woman is deficient in iron, it continues to be absorbed in sufficient amounts for the fetus to have a normal hemoglobin level.

Smooth muscle relaxation and reduced peristalsis caused by increased progesterone and estrogen result in an increase in water absorption from the colon and can cause constipation (Gordon, 2012). Constipation can also result from food choices, lack of fluids, iron supplementation, decreased activity level, abdominal distention by the pregnant uterus, and displacement and compression of the intestines. If the pregnant woman has hemorrhoids and is constipated, the hemorrhoids can evert or bleed during straining at stool.

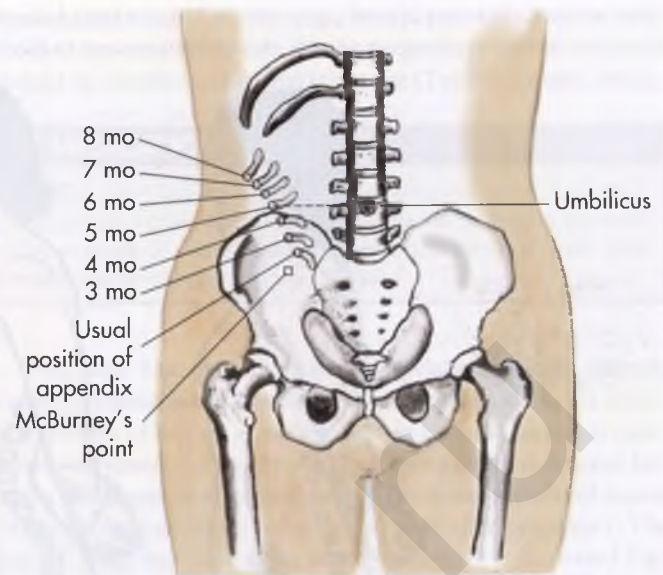

FIG 13-14 Change in position of appendix in pregnancy. Note McBurney's point.

Gallbladder and Liver. The gallbladder is often distended because of its decreased muscle tone during pregnancy. Increased emptying time and thickening of bile caused by prolonged retention are typical changes. These features, together with slight hypercholesterolemia from increased progesterone levels, can contribute to the development of gallstones during pregnancy (Blackburn, 2013).

Hepatic function is difficult to appraise during pregnancy. However, only minor changes in liver function develop. Occasionally intrahepatic cholestasis (retention and accumulation of bile in the liver caused by factors within the liver) occurs late in pregnancy in response to placental steroids. It can result in severe itching with or without jaundice (Rapini, 2014).

Abdominal Discomfort. Intraabdominal alterations that can cause discomfort include pelvic heaviness or pressure, round ligament tension, flatulence, distention and bowel cramping, and uterine contractions. In addition to displacement of intestines, pressure from the expanding uterus causes an increase in venous pressure in the pelvic organs. Although most abdominal discomfort is a consequence of normal maternal alterations, the health care provider must be constantly alert to the possibility of disorders such as bowel obstruction or an inflammatory process.

Appendicitis can be difficult to diagnose in pregnancy because the appendix is displaced upward and laterally, high and to the right, away from McBurney's point (Fig. 13-14).

Endocrine System

Profound endocrine changes are essential for pregnancy maintenance, normal fetal growth, and postpartum recovery. Hormones, their sources, and their effects on the pregnancy are presented in Table 13-6.

TABLE 13-6 Hormones and Effects of Changes During Pregnancy

HORMONE	SOURCE	EFFECTS OF CHANGES DURING PREGNANCY
Human chorionic gonadotropin (hCG)	Fertilized ovum and chorionic villi	Maintains corpus luteum production of estrogen and progesterone until placenta takes over the function
Progesterone	Corpus luteum until 14 wk of gestation, then the placenta	Suppresses secretion of FSH and LH by the anterior pituitary; maintains pregnancy by relaxing smooth muscles, decreasing uterine contractility; causes fat to deposit in subcutaneous tissues over the maternal abdomen, back, and upper thighs; decreases mother's ability to use insulin
Estrogen	Corpus luteum until 14 wk of gestation, then the placenta	Suppresses secretion of FSH and LH by the anterior pituitary; causes fat to deposit in subcutaneous tissues over the maternal abdomen, back, and upper thighs; promotes enlargement of genitals, uterus, and breasts; increases vascularity; relaxes pelvic ligaments and joints; interferes with folic acid metabolism; increases the level of total body proteins; promotes retention of sodium and water; decreases secretion of hydrochloric acid and pepsin; decreases mother's ability to use insulin
Serum prolactin	Anterior pituitary	Prepares breasts for lactation
Oxytocin	Posterior pituitary	Stimulates uterine contractions; stimulates milk ejection from breasts
Human chorionic somatomammotropin (previously called <i>human placental lactogen</i>)	Placenta	Acts as a growth hormone; contributes to breast development; decreases maternal metabolism of glucose; increases the amount of fatty acids for metabolic needs
Thyroxine-binding globulin, thyroxine, triiodothyronine	Thyroid	With adequate iodine intake, little or no enlargement of thyroid gland. Total T ₃ and T ₄ levels are slightly increased, peak by midpregnancy; by term are 10% to 15% lower than nonpregnant.
Parathyroid	Parathyroid	Controls calcium and magnesium metabolism
Insulin	Pancreas	Increases production of insulin to compensate for insulin antagonism caused by placental hormones; effect of insulin antagonists is to decrease tissue sensitivity to insulin or ability to use insulin
Cortisol	Adrenal glands	Stimulates production of insulin; increases peripheral resistance to insulin
Aldosterone	Adrenal glands	Stimulates reabsorption of excess sodium from the renal tubules

FSH, Follicle-stimulating hormone; LH, luteinizing hormone.

KEY POINTS

- The biochemical, physiologic, and anatomic adaptations that occur during pregnancy are profound and revert to the nonpregnant state after birth and lactation.
- Maternal adaptations are attributed to the hormones of pregnancy and to mechanical pressures arising from the enlarging uterus and other tissues.
- Adaptations to pregnancy protect the woman's normal physiologic functioning, meet the metabolic demands that pregnancy imposes, and provide for fetal developmental and growth needs.
- Accuracy of results of home pregnancy tests is dependent on following instructions correctly.
- Presumptive, probable, and positive signs of pregnancy aid in the diagnosis of pregnancy; only positive signs (identification of a fetal heart tone, verification of fetal movements, and visualization of the fetus) can establish the diagnosis of pregnancy.
- Physiologic anemia of pregnancy results from increase in plasma volume greater than the increase in red blood cells.
- During pregnancy maternal blood pressure remains the same or decreases slightly.
- Heart rate increases 10 to 15 beats/minute by 32 weeks of gestation and persists until term.
- Respiratory rate is unchanged during pregnancy, although tidal volume and minute ventilation increase by 30% to 50%.
- Pregnancy is a hypercoagulable state with increased risk for thrombotic disease.
- Dilation of renal pelvis and ureters during pregnancy increases the risk of urinary tract infection.
- Balance and coordination are affected by changes in joints and in the woman's center of gravity as pregnancy progresses.
- Decreased muscle tone during pregnancy contributes to heartburn, reflux, and constipation.
- Endocrine changes are essential to maintaining pregnancy and promoting fetal growth.

Nursing Care of the Family During Pregnancy

Denise G. Link

Ⓔ <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Describe strategies for confirming pregnancy and estimating the date of birth.
- Summarize the physical, psychosocial, and behavioral changes that usually occur as the expectant mother and other family members adapt to pregnancy.
- Evaluate the benefits of prenatal care and problems of accessibility for some women.
- Outline the patterns of health care used to assess maternal and fetal health status at initial and follow-up visits during pregnancy.
- Select the typical nursing assessments, diagnoses, interventions, and methods of evaluation in providing care for the pregnant woman.
- Plan education needed by pregnant women to understand and manage physical discomforts related to pregnancy and to recognize signs and symptoms of potential complications.
- Evaluate the effect of age, parity, and number of fetuses on the response of the family to the pregnancy and on the prenatal care provided.
- Analyze the effects of cultural beliefs and practices on care of women during pregnancy.
- Compare the options for health care providers and birth setting choices that are available.

The prenatal period is a time of physical and psychologic preparation for birth and parenthood. Becoming a parent is considered one of the maturational milestones of adult life. It is a time of intense learning for parents and those close to them. The prenatal period provides a unique opportunity for nurses and other members of the health care team to influence family health. During this period essentially healthy women seek regular care and guidance. The nurse's health promotion interventions can affect the well-being of the woman, her unborn child, and the rest of her family for many years.

Regular prenatal visits, ideally beginning soon after the first missed menstrual period, offer opportunities to safeguard the health of the expectant mother and her infant. Prenatal health care enables discovery, diagnosis, and treatment of preexisting maternal disorders and any disorders that develop during the pregnancy. Prenatal care is designed to monitor the growth and development of the fetus and to identify abnormalities that will interfere with the course of normal labor. Prenatal care also provides education and support for self-management and parenting.

Pregnancy spans 9 months, but health care providers do not use the familiar monthly calendar to determine fetal age or to discuss the pregnancy. Instead, they use lunar months, which last 28 days, or 4 weeks. Normal pregnancy lasts about 10 lunar months, which is the same as 40 weeks or 280 days. Health care

providers also refer to early, middle, and late pregnancy as **trimesters**. The first trimester lasts from weeks 1 through 13; the second, from weeks 14 through 26; and the third, from weeks 27 through 40. A pregnancy is considered to be at term if it advances to the completion of 37 weeks. The focus of this chapter is on meeting the health needs of the expectant family over the course of pregnancy, which is known as the *prenatal period*.

DIAGNOSIS OF PREGNANCY

Women suspect pregnancy when they miss a menstrual period. Many women come to the first prenatal visit after a positive home pregnancy test; however, the clinical diagnosis of pregnancy before the second missed period is difficult in some women. Physical variations, obesity, or tumors, for example, confound even the experienced examiner. Accuracy is important, however, because emotional, social, health, or legal consequences of an inaccurate diagnosis, either positive or negative, can be extremely serious.

Signs and Symptoms

The physical cues of pregnancy vary greatly; therefore, the diagnosis of pregnancy is uncertain for a time. Many of the indicators of pregnancy are clinically useful in the diagnosis of

pregnancy and are classified as presumptive, probable, or positive (see Table 13-2).

Presumptive indicators of pregnancy include subjective symptoms and objective signs. Subjective symptoms are reported by the woman and include amenorrhea, nausea and vomiting (**morning sickness**), breast tenderness, urinary frequency, and fatigue. *Quickening*, the mother's first perception of fetal movement, is noted between weeks 16 and 20. Objective signs that are validated by the examiner include elevation of basal body temperature (BBT), breast and abdominal enlargement, and changes in the uterus and vagina. Other visible changes occur in the skin, such as striae gravidarum, deeper pigmentation of the areola, melasma (mask of pregnancy), and linea nigra (pigmented line on the abdomen). The presumptive indicators of pregnancy can be caused by conditions other than gestation; therefore, these signs alone are not reliable for diagnosis of pregnancy.

Probable indicators of pregnancy are detected by an examiner and are related mainly to physical changes in the uterus. Objective signs include uterine enlargement, Braxton Hicks contractions, placental souffle (sound of blood passing through the placenta), ballottement (examiner is able to feel the fetus float during a vaginal examination), and a positive pregnancy test. When combined with presumptive signs and symptoms, they strongly suggest pregnancy, but they are not conclusive.

The *positive* indicators of pregnancy are directly attributed to the fetus and include the presence of a fetal heartbeat distinct from that of the mother, fetal movement felt by someone other than the mother, and visualization of the fetus with a technique such as ultrasound examination.

Estimating Date of Birth

After the diagnosis of pregnancy the woman's first question usually concerns when she will give birth. This date has traditionally been termed the *estimated date of confinement* (EDC), although *estimated date of delivery* (EDD) also has been used. To promote a more positive perception of both pregnancy and birth, however, the term **estimated date of birth** (EDB) is suggested. Accurate dating of pregnancy and calculation of the EDB have implications for timing of specific prenatal screening tests, assessing fetal growth, and making critical decisions for managing pregnancy complications.

Ultrasound has become a standard procedure for determining the gestational age of the fetus. The American Institute of Ultrasound in Medicine (AIUM), in collaboration with the American College of Radiology (ACR), the American College of Obstetricians and Gynecologists (ACOG), and the Society of Radiologists in Ultrasound (SRU), published guidelines for the safe and effective use of ultrasound in prenatal care (AIUM, 2013).

Naegele's rule is a common method for calculating the EDB. It is based on the woman's accurate recall of her last menstrual period (LMP). It assumes that the woman has a 28-day cycle and that fertilization occurred on the 14th day. According to Naegele's rule, after determining the first day of the LMP, subtract 3 calendar months and add 7 days (Box 14-1). Only about 5% of women give birth spontaneously on the EDB as determined by Naegele's rule. Most women give birth during the period extending from 7 days before to 7 days after the EDB.

BOX 14-1 Use of Naegele's Rule

December 10, 2015, is the first day of the last menstrual period (LMP).

	MONTH	DAY	YEAR
LMP	12	10	2015
	-3	+7	
Estimated day of birth:	9	17	2016
The estimated date of birth (EDB) is September 17, 2016.			

ADAPTATION TO PREGNANCY

Pregnancy affects all family members, and each family member must adapt to the pregnancy and interpret its meaning in light of his or her own needs. This process of family adaptation to pregnancy takes place within a cultural environment influenced by societal trends. Dramatic changes have occurred in Western society in recent years, and the nurse must be prepared to support not only traditional families in the childbearing experience but also single-parent families, reconstituted families, dual-career families, and alternative families.

Much of the research on family dynamics in pregnancy in the United States and Canada has been done with Caucasian middle-class nuclear families. Therefore, the findings may not apply to families who do not fit the traditional North American model. Adaptation of terms is appropriate to avoid embarrassment to the nurse and offense to the family. Additional research is needed on a variety of families to determine if study findings generated in traditional families are applicable to others.

Maternal Adaptation

Women of all ages use the months of pregnancy to adapt to the maternal role, a complex process of social and cognitive learning. Early in pregnancy nothing seems to be happening, and a woman may spend much time sleeping secondary to the increased fatigue of this stage. With the perception of fetal movement in the second trimester, the woman turns her attention inward to her pregnancy and to relationships with her mother and other women who have been or who are pregnant.

Pregnancy is a maturational milestone that can be stressful but also rewarding as the woman prepares for a new level of caring and responsibility. Her self-concept changes in readiness for parenthood as she prepares for her new role. She moves gradually from being self-contained and independent to being committed to a lifelong concern for another human being. This growth requires mastery of certain developmental tasks: accepting the pregnancy, identifying with the role of mother, reordering the relationships between herself and her mother and between herself and her partner, establishing a relationship with the unborn child, and preparing for the birth experience. The partner's emotional support is an important factor in successfully accomplishing these developmental tasks. Single women with limited support can have difficulty making this adaptation.

Accepting the Pregnancy

The first step in adapting to the maternal role is accepting the idea of pregnancy and assimilating the pregnant state into the

woman's way of life. Mercer (1995) described this process as *cognitive restructuring* and credited Reva Rubin (1975, 1984) as the nurse theorist who pioneered our understanding of maternal role attainment. The degree of acceptance is reflected in the woman's emotional responses. Many women are upset initially when they discover they are pregnant, especially if the pregnancy is unintended. Eventual acceptance of pregnancy parallels the growing acceptance of the reality of a child. However, nonacceptance of the pregnancy does not equate with rejection of the child, because a woman can dislike being pregnant but feel love for the child to be born.

Women who are happy and pleased about their pregnancy often view it as biologic fulfillment and part of their life plan. They have high self-esteem and tend to be confident about outcomes for themselves, their babies, and other family members. Despite a general feeling of well-being, many women are surprised to experience *emotional lability*, that is, rapid and unpredictable changes in mood. These swings in emotions and increased sensitivity to others are disconcerting to the expectant mother and those around her. Increased irritability and explosions of tears and anger can alternate with feelings of great joy and cheerfulness apparently with little or no provocation.

Profound hormonal changes that are part of the maternal response to pregnancy can be responsible for mood changes. Other reasons such as concerns about finances and changes in lifestyle contribute to this seemingly erratic behavior.

Most women have ambivalent feelings during pregnancy whether the pregnancy was intended or not. *Ambivalence—having conflicting feelings simultaneously—is considered a normal response for people preparing for a new role.* For example, during pregnancy some women feel great pleasure that they are fulfilling a lifelong dream, but they also feel great regret that life as they know it is ending.

Even women who are pleased to be pregnant can experience feelings of hostility toward the pregnancy or unborn child from time to time. Such incidents as a partner's chance remark about the attractiveness of a slim, nonpregnant woman or news of a colleague's promotion can give rise to ambivalent feelings. Body sensations, feelings of dependence, or the realization of the responsibilities of child care also can generate such feelings.

Intense feelings of ambivalence that persist through the third trimester can indicate an unresolved conflict with the motherhood role (Mercer, 1995). After the birth of a healthy child, memories of these ambivalent feelings usually are dismissed. If the child is born with a defect, however, a woman may look back at the times when she did not want the pregnancy and feel intense guilt. She may believe that her ambivalence caused the birth defect. She then will need assurance that her feelings were not responsible for the problem.

Identifying with the Mother Role

The process of identifying with the mother role begins early in each woman's life when she is being mothered as a child. Her social group's perception of what constitutes the feminine role can subsequently influence her choosing between motherhood or a career, being married or single, being independent rather than interdependent, or being able to manage multiple roles. Practice roles,

FIG 14-1 A pregnant woman and her mother enjoying a walk together. (Courtesy Michael S. Clement, MD, Mesa, AZ.)

such as playing with dolls, babysitting, and taking care of siblings can increase her understanding of what being a mother involves.

Many women have always wanted a baby, liked children, and looked forward to motherhood. Their high motivation to become a parent promotes acceptance of pregnancy and eventual prenatal and parental adaptation. Other women have not considered in any detail what motherhood means to them. During pregnancy these women must resolve conflicts such as not wanting the pregnancy and child-related or career-related decisions.

Reordering Personal Relationships

Close relationships of a pregnant woman undergo change during pregnancy as she prepares emotionally for the new role of mother. As family members learn their new roles, periods of tension and conflict can occur. An understanding of the typical patterns of adjustment can help the nurse reassure the pregnant woman and explore issues related to social support. Promoting effective communication patterns between the expectant mother and her own mother and between the expectant mother and her partner are common nursing interventions provided during the prenatal visits.

The woman's relationship with her mother is significant in adaptation to pregnancy and motherhood. Important components in the pregnant woman's relationship with her mother are the mother's availability (past and present), her reactions to the daughter's pregnancy, respect for her daughter's autonomy, and the willingness to reminisce (Mercer, 1995).

The mother's reaction to the daughter's pregnancy signifies her acceptance of the grandchild and of her daughter. If the mother is supportive, the daughter has an opportunity to discuss pregnancy and labor with a knowledgeable and accepting woman (Fig. 14-1). Reminiscing about the pregnant woman's early childhood and sharing the prospective grandmother's account of her childbirth experience help the daughter anticipate and prepare for labor and birth.

FIG 14-2 A prospective mother and father walk together. Women respond positively to their partner's interest and concern. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

Although the woman's relationship with her mother is significant in considering her adaptation to pregnancy, the most important person to the pregnant woman is usually the father of her child (Fig. 14-2). With same sex couples, the most important person is the partner. Women express two major needs within this relationship during pregnancy: feeling loved and valued and having the child accepted by the partner.

The marital or committed partner relationship is not static but evolves over time. The addition of a child changes forever the nature of the bond between partners. This can be a time when couples grow closer, and the pregnancy has a maturing effect on the partners' relationship as they assume new roles and discover new aspects of each other. Partners who trust and support each other are able to share mutual-dependency needs (Mercer, 1995).

Sexual expression during pregnancy is highly individual. The sexual relationship is affected by physical, emotional, and interactional factors, including misinformation about sex during pregnancy, sexual dysfunction, and physical changes in the woman. An individual may also inaccurately attribute anomalies, intellectual disability, and other injuries to the fetus and mother to sexual relations during pregnancy. Some couples fear that the birth process will dramatically change the woman's genitals. Some couples do not express their concerns to the health care provider because they are embarrassed or do not want to appear foolish.

As pregnancy progresses, changes in body shape, body image, and levels of discomfort influence both partners' desire for sexual expression. During the first trimester the woman's sexual desire usually decreases, especially if she has breast tenderness, nausea, or fatigue. As she progresses into the second trimester, however, her sense of well-being combined with the increased pelvic congestion that occurs at this time often increases her desire for sexual release. In the third trimester somatic complaints and physical bulkiness can increase her physical discomfort and again diminish her interest in sex.

Partners need to feel free to discuss their sexual responses during pregnancy with each other, their health care provider, and nurses involved in their care (see later discussion).

Establishing a Relationship with the Fetus

Emotional attachment—feelings of being tied by affection or love—begins during the prenatal period as women use fantasizing and daydreaming to prepare themselves for motherhood (Rubin, 1975, 1984). They think of themselves as mothers and imagine maternal qualities they would like to possess. Expectant parents desire to be warm, loving, and close to their child. They try to anticipate changes that the child will bring into their lives and wonder how they will react to noise, disorder, reduced freedom, and caregiving activities. The mother-child relationship progresses through pregnancy as a developmental process that unfolds in three phases.

In phase 1 the woman accepts the biologic fact of pregnancy. She needs to be able to state, "I am pregnant," and incorporate the idea of a child into her body and self-image. The woman's thoughts center on herself and the reality of her pregnancy. The child is viewed as part of herself, not a separate and unique person.

In phase 2 the woman accepts the growing fetus as distinct from herself. This is usually accomplished by the fifth month. She can now say, "I am going to have a baby." This differentiation of the child from the woman's self permits the beginning of the mother-child relationship that involves not only caring but also responsibility. Attachment of a mother to her child is enhanced by experiencing a planned or desired pregnancy, and it increases when ultrasound examination and quickening confirm the reality of the fetus. With acceptance of the reality of the child (hearing the heartbeat and feeling the fetus move) and an overall feeling of well-being, the woman enters a quiet period and becomes more introspective. A fantasy child becomes precious to her. As she seems to withdraw and concentrate her interest on the unborn child, her partner sometimes feels left out. If there are children in the family, they can become more demanding in their efforts to redirect the mother's attention to themselves.

During phase 3 of the attachment process, the woman prepares realistically for the birth and parenting of the child. She expresses the thought, "I am going to be a mother," and defines the nature and characteristics of the child. She may, for example, speculate about the child's sex (if unknown) and personality traits based on patterns of fetal activity.

Although the mother alone experiences the child within, both parents and siblings believe the unborn child responds in a very individualized, personal manner. Family members may interact a great deal with the unborn child by talking to the fetus and stroking the mother's abdomen, especially when the fetus shifts position (Fig. 14-3). The fetus may have a nickname used by family members.

Preparing for Birth

Many women actively prepare for birth by reading books and information on various websites, watching videos, attending parenting classes, and talking to other women. They seek the best caregiver possible for advice, monitoring, and caring. The multiparous woman has her own history of labor and birth that influences her approach to preparation for this birth experience.

FIG 14-3 A 4-year-old likes to examine his pregnant mother's abdomen. (Courtesy Kara George, Phoenix, AZ.)

Anxiety can arise from concern about a safe passage for herself and her child during the birth process (Mercer, 1995; Rubin, 1975, 1984). Some women do not express this concern overtly, but they give cues to the nurse by making plans for care of the new baby and other children in case “anything should happen.” Many women fear the pain of labor and birth because they do not understand anatomy and the birth process. Education by the nurse can alleviate many of these fears.

Toward the end of the third trimester, breathing is difficult, and fetal movements become vigorous enough to disturb the woman's sleep. Backaches, frequency and urgency of urination, constipation, and varicose veins can become troublesome. The bulkiness and awkwardness of her body interfere with the woman's ability to care for other children, perform routine work-related duties, and assume a comfortable position for sleep and rest. By this time most women become impatient for labor to begin, whether the birth is anticipated with joy, dread, or a mixture of both. A strong desire to see the end of pregnancy, to be over and done with it, makes women at this stage ready to move on to birth.

Paternal Adaptation

The father's beliefs and feelings about the ideal mother and father and his cultural expectations of appropriate behavior during pregnancy affect his response to his partner's need for him. One man may engage in nurturing behavior. Another may feel lonely and alienated as the woman becomes physically and emotionally engrossed in the unborn child. He may seek friends and relationships outside the home or become interested in a new hobby or involved with his work. Some men view pregnancy as proof of their masculinity and their dominant role. To others, pregnancy has no meaning in terms of responsibility to either mother or child. However, for most men, pregnancy is a time of preparation for the parental role with intense learning.

Accepting the Pregnancy

The ways fathers adjust to the parental role has been the subject of considerable research. In older societies the man enacted the ritual **couvade**; that is, he behaved in specific ways and respected

taboos associated with pregnancy and giving birth so his new status was recognized and endorsed. Some men experience pregnancy-like symptoms, such as nausea, weight gain, and other physical symptoms. This phenomenon is known as the **couvade syndrome**. Changing cultural and professional attitudes have encouraged fathers' participation in the birth experience.

The man's emotional response to becoming a father, his concerns, and his informational needs change during the course of pregnancy. Phases of the developmental pattern become apparent. May (1982) described three phases characterizing the developmental tasks experienced by the expectant father:

- The **announcement phase** lasts from a few hours to a few weeks. The developmental task is to accept the biologic fact of pregnancy. Men react to the confirmation of pregnancy with joy or dismay, depending on whether the pregnancy is desired, unplanned, or unwanted. Ambivalence in the early stages of pregnancy is common. If pregnancy is unplanned or unwanted, some men find the alterations in life plans and lifestyles difficult to accept. Some men engage in extramarital affairs for the first time during their partner's pregnancy. Others batter their wives for the first time or escalate the frequency of battering episodes (Forsyth, Skouteris, Wertheim, et al., 2011). Chapter 5 provides information about violence against women and offers guidance on assessment and interventions.
- The second phase, the **moratorium phase**, is the period when he adjusts to the reality of pregnancy. The developmental task is to accept the pregnancy. Men appear to put conscious thought of the pregnancy aside for a time. They become more introspective and engage in many discussions about their philosophy of life, religion, childbearing, and childrearing practices and their relationships with family members, particularly with their father. Depending on the man's readiness for the pregnancy, this phase can be relatively short or persist until the last trimester.
- The third phase, the **focusing phase**, begins in the last trimester and is characterized by the father's active involvement in both the pregnancy and his relationship with his child. The developmental task is to negotiate with his partner the role he is to play in labor and to prepare for parenthood. In this phase the man concentrates on his experience of the pregnancy and begins to think of himself as a father.

Identifying with the Father Role

Each man brings to pregnancy attitudes that affect the way in which he adjusts to the pregnancy and the parental role. His memories of the fathering he received from his own father, the experiences he has had with child care, and the perceptions of the male and father roles within his social group will guide his selection of the tasks and responsibilities he will assume. Some men are highly motivated to nurture and love a child. They are excited and pleased about the anticipated role of father. Others are more detached or even hostile to the idea of fatherhood.

Reordering Personal Relationships

The partner's main role in pregnancy is to nurture and respond to the pregnant woman's feelings of vulnerability. The partner also must deal with the reality of the pregnancy. The partner's

support indicates involvement in the pregnancy and preparation for attachment to the child.

Some aspects of a partner's behavior can indicate rivalry, and it can be especially evident during sexual activity. For example, some men protest that fetal movements prevent sexual gratification or feel that they are being watched by the fetus during sexual activity. However, feelings of rivalry are often unconscious and not verbalized, but expressed in subtle behaviors.

The woman's increased introspection can cause her partner to feel uneasy as she becomes preoccupied with thoughts of the child and of her motherhood, with her growing dependence on her health care provider, and with her reevaluation of the couple's relationship.

Establishing a Relationship with the Fetus

The father-child attachment can be as strong as the mother-child relationship, and fathers can be as competent as mothers in nurturing their infants. The father-child attachment also begins during pregnancy. A father may rub or kiss the maternal abdomen; try to listen, talk, or sing to the fetus; or play with the fetus as he notes movement. Calling the unborn child by name or nickname helps confirm the reality of pregnancy and promote attachment.

Men prepare for fatherhood in many of the same ways as women do for motherhood—by reading and fantasizing about the baby. Daydreaming about their role as father is common in the last weeks before the birth; however, men rarely describe their thoughts unless they are reassured that such daydreams are normal.

Nurses can help fathers identify concerns and prepare for the reality of a baby by asking questions such as:

- How do you expect the baby to look and act?
- How do you envision life as a father?
- How will you be involved in helping to care for the baby?
- How will having a baby affect your relationship with your partner?

Some fathers do not wish to answer such questions when they are asked but need time to think them through or discuss them with their partners.

As the birth date approaches, men have more questions about fetal and newborn behaviors. Some men are shocked or amazed at the smallness of clothes and furniture for the baby. If an expectant father can imagine only an older child and has difficulty visualizing or talking about an infant, this situation must be explored. The nurse can tell the father about the unborn child's ability to respond to light, sound, and touch and encourage him to feel and talk to the fetus. Discussions with new fathers, as in childbirth classes, may be welcomed.

Some men become involved by choosing the child's name and anticipating the child's sex, if it is not already known. Some couples select the name of the child as early as the first month of pregnancy. Family tradition, religious customs, and the continuation of the parent's name or names of relatives or friends are important in the selection process.

Preparing for Birth

The days and weeks immediately before the expected day of birth are characterized by anticipation and anxiety. Boredom and restlessness are common as the couple focuses on the birth

process; however, during the last 2 months of pregnancy, many expectant fathers experience a surge of creative energy at home and on the job. They become dissatisfied with their present living space. If possible, they tend to act on the need to alter the environment (remodeling, painting, etc.). This activity is their way of sharing in the childbearing experience. They are able to channel the anxiety and other feelings experienced during the final weeks before birth into productive activities. This behavior earns recognition and compliments from friends, relatives, and their partners.

Major concerns for the man are getting the woman to a health care facility in time for the birth and not appearing ignorant. Many men want to be able to recognize labor and determine when it is appropriate to leave for the hospital or call the obstetric care provider. They fantasize different situations and plan what they will do in response to them or rehearse taking various routes to the hospital, timing each route at different times of the day.

Some prospective fathers have questions about the labor suite's furniture and equipment, nursing staff, and location, as well as the availability of the obstetric and anesthesia care providers. Others want to know what is expected of them when their partners are in labor. The man also may have fears concerning safe passage of his child and partner and the possible death or complications of his partner and child. It is important he verbalize these fears; otherwise he cannot help his mate deal with her spoken or unspoken apprehension.

With the exception of childbirth preparation classes, a man has few opportunities to learn ways to be an involved and active partner in this rite of passage into parenthood. Mothers often sense the tensions and apprehensions of the unprepared, unsupportive father and it can increase their fears.

Adaptation to Parenthood for the Nonpregnant Partner

The same fears, questions, and concerns may affect birth partners who are not the biologic fathers or who are the nonpregnant partner in a same sex couple. Much attention is paid to the needs of the pregnant partner, but the nonpregnant partner's needs receive less attention. Nonpregnant partners, also referred to as co-mothers, can feel excluded by heterocentric maternity care service structures, but are likely to feel included by nursing staff (Cherguit, Burns, Pettle, & Tasker, 2012). Nonpregnant partners will be better prepared for the changes that come with pregnancy and parenting if they are included and considered in the process. In addition to dealing with their own feelings and the care of their partner, nonpregnant partners in a same sex couple are often not acknowledged or accepted as a parent-to-be from within their own families and in society in general. Partners need to be kept informed, supported, and included in all activities in which the mother desires their participation. Nurses can do much to promote pregnancy and birth as a family experience by providing information about resources for same sex parents such as community and on-line support groups.

Sibling Adaptation

Sharing the spotlight with a new brother or sister can be the first major crisis for a child. The older child often experiences

a sense of loss or feels jealous at being “replaced” by the new sibling. Some of the factors that influence the child’s response are age, the parents’ attitudes, the role of the father, the length of separation from the mother, the facility visitation policy, and the way the child has been prepared for the change.

A mother with other children must devote time and effort to reorganizing her relationships with them. She needs to prepare siblings for the baby’s birth (Fig. 14-4 and Box 14-2) and begin the process of role transition in the family by including the children in the pregnancy and being sympathetic to older children’s concerns about losing their places in the family hierarchy. No child willingly gives up a familiar position.

Siblings’ responses to pregnancy vary with their age and dependency needs. The 1-year-old infant seems largely unaware of the process, but the 2-year-old child notices the change in his

or her mother’s appearance and may comment that “Mommy’s fat.” Toddlers’ need for sameness in the environment makes children aware of any change. They can exhibit more clinging behavior and sometimes regress in toilet training or eating.

By age 3 or 4 years, children like to be told the story of their own beginning and accept a comparison of their own development with that of the present pregnancy. They like to listen to the fetal heartbeat and feel the baby moving in utero (see Fig. 14-3). Sometimes they worry about how the baby is being fed and clothed.

School-age children take a more clinical interest in their mother’s pregnancy. They may want to know in more detail, “How did the baby get in there?” and “How will it get out?” Children in this age-group notice pregnant women in stores, churches, and schools and sometimes seem shy if they need to approach a pregnant woman directly. On the whole, they look forward to the new baby, see themselves as “mothers” or “fathers,” and enjoy buying baby supplies and readying a place for the baby. Because they still think in concrete terms and base judgments on the here and now, they respond positively to their mother’s current good health.

Early and middle adolescents preoccupied with the establishment of their own sexual identity can have difficulty accepting the overwhelming evidence of the sexual activity of their parents. They reason that if they are too young for such activity, certainly their parents are too old. They seem to take on a critical parental role and may ask, “What will people think?” or “How can you let yourself get so fat?” or “How can you let yourself get pregnant?” Many pregnant women with teenage children will confess that the attitudes of their teenagers are the most difficult aspect of their current pregnancy.

Late adolescents do not appear to be unduly disturbed. They are busy making plans for their own lives and realize that they

FIG 14-4 A preschooler in a sibling class learns about childbirth and infant care using dolls and a bunny. (Courtesy Julie and Darren Nelson, Loveland, CO.)

BOX 14-2 Sibling Adaptation: Tips for Sibling Preparation

Prenatal

- Take your child on a prenatal visit. Let the child listen to the fetal heartbeat and feel the baby move.
- Involve the child in preparations for the baby, such as helping decorate the baby’s room.
- Move the child to a bed (if still sleeping in a crib) at least 2 months before the baby is due.
- Read books, show videos or DVDs, and/or take your child to sibling preparation classes, including a hospital tour.
- Answer your child’s questions about the coming birth, what babies are like, and any other questions.
- Take your child to the homes of friends who have babies so that the child has realistic expectations of what babies are like.

During the Hospital Stay

- Have someone bring the child to the hospital to visit you and the baby (unless you plan to have the child attend the birth).
- When the child arrives, make sure your arms are open to embrace the child.
- Do not force interactions between the child and the baby. Often the child will be more interested in seeing you and being reassured of your love.

- Help the child explore the infant by showing how and where to touch the baby.
- Give the child a gift (from you or from you, the father or your partner, and baby).

Going Home

- Leave the child at home with a relative or babysitter or have someone such as the grandmother available to focus on the child during hospital discharge and on the trip home.
- Have someone else carry the baby from the car so that you can hug the child first.

Adjustment After the Baby Is Home

- Arrange for a special time for the child to be alone with each parent.
- Do not exclude the child during infant feeding times. The child can sit with you and the baby and feed a doll or drink juice or milk or sit quietly with a game. You can read aloud to the child while you are feeding the infant.
- Prepare small gifts for the child so that when the baby gets gifts, the sibling will not feel left out. The child can also help open the baby gifts.
- Praise the child for acting age appropriately (so that being a baby does not seem better than being older).

FIG 14-5 A great-grandmother and grandmother admiring the new baby. (Courtesy Barbara Wilson, West Jordan, UT.)

soon will be gone from home. Parents usually report they are comforting and act more as other adults than as children.

Grandparent Adaptation

Most grandparents are delighted at the prospect of a new baby in the family. It reawakens the feelings of their own youth, the excitement of giving birth, and their delight in the behavior of the parents-to-be when they were infants. They set up a memory store of the child's first smiles, first words, and first steps that they can use later for "claiming" the newborn as a member of the family. These behaviors provide a link between the past and present for the parents and grandparents-to-be.

In addition, the grandparent is the historian who transmits the family history, a resource person who shares knowledge based on experience; a role model; and a support person. The grandparent's presence and support can strengthen family systems by widening the circle of support and nurturance (Fig. 14-5). Other sources of information cannot replace the unique contribution that grandparents make (www.grandparents.com; www.grandparenting.org).

For some expectant grandparents a first pregnancy in a child is undeniable evidence that they are growing older. Many think of a grandparent as old, white-haired, and becoming feeble of mind and body; however, some people face grandparenthood while still in their 30s or 40s. Some individuals react negatively to the news that they will be grandparents, indicating that they are not ready for the new role.

In some family units expectant grandparents are nonsupportive and can inadvertently decrease the self-esteem of the parents-to-be. Mothers may talk about their terrible pregnancies; fathers may discuss the endless cost of rearing children; and mothers-in-law may complain that their sons are neglecting them because their concern is now directed toward the pregnant daughters-in-law.

CARE MANAGEMENT

The goal of prenatal care is to promote the health and well-being of the pregnant woman, her fetus, the newborn, and the family (Gregory, Niebyl, & Johnson, 2012). It includes education about healthy lifestyle behaviors such as nutrition and physical

activity, self-care for the common pregnancy discomforts, and information about changes in the mother and growth of the developing fetus. Routine screening is offered during pregnancy to help identify existing risk factors and potential problems so that efforts to reduce risk of harm to mother or baby and management of identified conditions can be initiated at the earliest opportunity. Major emphasis is placed on preventive aspects of care, primarily to support the pregnant woman in self-management between visits with health care professionals and to help her to recognize and report changes that can signal problems early so that adverse effects for her or her unborn child can be prevented or minimized. If health behaviors must be modified in early pregnancy, nurses need to understand psychosocial factors that can influence the woman. In holistic care, nurses provide information and guidance about the physical changes and the psychosocial impact of pregnancy on the woman and members of her family. The goals of prenatal nursing care, therefore, are to foster a safe birth for the mother and infant and to promote satisfaction of the mother and family with the pregnancy and birth experience.

According to the National Center for Health Statistics (NCHS), more than 75% of women in the United States receive pregnancy care in the first trimester. Women who are least likely to begin early prenatal care are non-Hispanic African-American, non-Hispanic Native Hawaiian/Other Pacific Islander, and non-Hispanic American Indian/Alaska Native mothers (Martin, Hamilton, Sutton, et al., 2012). Although women of middle or high socioeconomic status routinely seek prenatal care, women's reasons for delaying prenatal care include cost, lack of insurance, child care, transportation barriers, or inability to take time off from work. Lack of culturally sensitive care providers, discrimination based on sexual orientation, and barriers to communication resulting from differences in language also interfere with access to care. Likewise, immigrant women who come from cultures in which prenatal care is not emphasized may not know to seek routine prenatal care. Birth outcomes in these populations are less positive, with higher rates of maternal and fetal or newborn complications. In particular, problems with low birth weight (LBW; less than 2500 g) and infant mortality are associated with lack of adequate prenatal care (Gregory et al., 2012).

The availability of advanced practice nurses (nurse practitioners and certified nurse-midwives [CNM]) as independent providers of care or in collaborative practice with physicians improves the availability and accessibility of prenatal care (American College of Nurse-Midwives [ACNM], 2012). A regular schedule of home visits by nurses aids in reducing barriers to care and contributes to improved maternal and infant outcomes (Agency for Healthcare Research and Quality [AHRQ], 2012). Under the Patient Protection and Affordable Care Act of 2010 (ACA), payment for innovative models for delivery of prenatal care, including home visits by unlicensed professionals, can reduce barriers to early prenatal care (Salinsky, 2013).

The traditional model for provision of prenatal care has been used for more than a century. The initial visit usually occurs in the first trimester, with monthly visits through week 28 of pregnancy. Thereafter, visits are scheduled every 2 weeks until week 36 and then every week until birth. Today the trend is toward individualizing the schedule of care. Women with low

BOX 14-3 Prenatal Visit Schedule

Traditional*

- First visit within the first trimester (12 weeks)
- Monthly visits weeks 16 through 28
- Every 2 weeks from weeks 29 to 36
- Weekly visits week 36 to birth

CenteringPregnancy†

- First visit within the first trimester (12 weeks)
- Every 4 weeks—weeks 16 to 28
- Every 2 weeks—weeks 29 to 40

Data from Centering Healthcare Institute. (2012). *CenteringPregnancy*. Available at www.centeringhealthcare.org/pages/centering-model/model-overview.php.

*Frequency of visits may be decreased in low risk women and increased in women with high risk pregnancies.

†Additional individual visits may be added as needed.

risk pregnancies may have fewer routine prenatal visits, whereas those at risk for complications may be seen more frequently than the traditional schedule (American Academy of Pediatrics [AAP] and American College of Obstetricians and Gynecologists [ACOG], 2012).

Group prenatal care is an alternative model to traditional care during pregnancy. In group prenatal care authority is shifted from the provider to the woman and other women who have similar due dates. The model creates an atmosphere that facilitates learning, encourages discussion, and develops mutual support. CenteringPregnancy (www.centeringhealthcare.org) is a well-known model of group prenatal care that involves three components: health care assessment, education, and peer support. Most care takes place in the group setting after the initial visit and continues for 10-hour sessions that begin at about 16 weeks. At each meeting, the first 30 to 40 minutes consist of assessments (by the woman herself and by the health care provider) and the remaining 60 to 75 minutes are spent in group discussion of specific issues such as discomforts of pregnancy and preparation for labor and birth (Box 14-3). Families and partners are encouraged to participate (Centering Healthcare Institute, 2012). Benefits associated with group prenatal care include improved birth outcomes such as lower rates of preterm birth, increased knowledge, improved satisfaction, and higher breastfeeding initiation rates (Herrman, Rogers, & Ehrenthal, 2012; Picklesimer, Billings, Hale, et al., 2012; Rotundo, 2011).

Prenatal care is ideally a multidisciplinary activity in which nurses work with certified nurse-midwives, nutritionists, physicians, social workers, and others. Collaboration among these individuals is necessary to provide holistic care. The case management model, which makes use of care maps and critical pathways, is one system that promotes comprehensive care with limited overlap in services. To emphasize the nursing role, care management for the initial visit and follow-up visits is organized around the central elements of the nursing process: assessment, nursing diagnoses, expected outcomes, plan of care and interventions, and evaluation.

In recent years the concept of preconception care has been recognized as an important contributor to good pregnancy outcomes (see Chapter 4). If women can be taught healthy lifestyle behaviors and then practice them before conception—specifically good nutrition, entering pregnancy with as healthy

a weight as possible, adequate intake of folic acid, avoidance of alcohol and tobacco use, and prevention of sexually transmitted infections (STIs) and other health hazards—a healthier pregnancy will result. Likewise, women who have health problems related to chronic diseases such as diabetes mellitus can be counseled regarding their special needs with the intent to minimize maternal and fetal complications.

Initial Visit

Once the presence of pregnancy has been confirmed and the woman's desire to continue the pregnancy has been validated, prenatal care is begun. The assessment process begins at the initial prenatal visit and is continued throughout the pregnancy. Assessment techniques include the interview, physical examination, and laboratory tests. Because the initial visit and follow-up visits are distinctly different in content and process, they are described separately.

Prenatal Interview

The therapeutic relationship between the nurse and the woman is established during the initial assessment interview. During this interview the nurse has the opportunity to gain the woman's trust.

The pregnant woman and family members who are present should be told that the first prenatal visit is longer and more detailed than future visits. The initial evaluation includes a comprehensive health history emphasizing the current pregnancy, previous pregnancies, the family, a psychosocial profile, a physical assessment, diagnostic testing, and an overall risk assessment. A prenatal history form (paper or electronic) is used to document information obtained.

One or more family members often accompany the pregnant woman. With the woman's permission, the nurse includes those accompanying the woman in the initial prenatal interview. Observations and information about the woman's family are then included in the database. For example, if the woman has small children with her, the nurse can ask about her plans for child care during the time of labor and birth. The nurse notes any special needs that are identified during this first interview (e.g., wheelchair access, assistance in getting on and off the examining table, difficulty speaking and/or understanding English, and cognitive deficits).

Reason for Seeking Care. Although pregnant women are scheduled for routine prenatal visits, they often come to the health care provider seeking information or reassurance about a particular concern. When the woman is asked a broad, open-ended question such as, "How have you been feeling?" she may reveal problems that could otherwise be overlooked. The woman's chief concerns should be recorded in her own words to alert other personnel to the priority of needs as identified by her. At the initial visit the desire for information about what is normal in the course of pregnancy is typical.

Current Pregnancy. The presumptive signs of pregnancy, such as nausea and vomiting, can be of great concern to the woman. A review of symptoms she is experiencing and how she is coping with them helps establish a database to develop a plan of care. Some early teaching may be provided at this time.

Childbearing and Female Reproductive System History. Data are gathered on the woman's age at menarche, menstrual

history, and contraceptive history; any infertility or reproductive system conditions; history of STIs; sexual history; and detailed history of all her pregnancies, including the present pregnancy, and their outcomes. The date of the last Papanicolaou (Pap) test and the result are noted. The date of her LMP is obtained to calculate the EDB.

Health History. The health history includes physical conditions or surgical procedures that can affect the pregnancy or that can be affected by the pregnancy. For example, a pregnant woman who has diabetes, hypertension, or epilepsy requires special care. A careful history of any allergies and the type of reaction, medication use, and immunizations must be included. Because most women are anxious during the initial interview, the nurse's attention to cues, such as a MedicAlert bracelet, can prompt the woman to recall allergies, chronic diseases, or medications being taken such as cortisone, insulin, or anticonvulsants.

The woman should also describe any previous surgical procedures. If a woman has undergone uterine surgery or extensive repair of the pelvic floor, a cesarean birth may be necessary; appendectomy rules out appendicitis as a cause of right lower quadrant pain in pregnancy; and spinal surgery may contraindicate the use of spinal or epidural anesthesia. The nurse notes any injury involving the pelvis as from a motor vehicle accident or childhood nutritional deficit.

Women who have chronic or handicapping conditions often forget to mention them during the initial assessment because they have become so adapted to them. Special shoes or a limp can indicate the existence of a pelvic structural defect, which is an important consideration in pregnant women. The nurse who observes these special characteristics and inquires about them with sensitivity can obtain individualized data that will provide the basis for a comprehensive nursing care plan (Signore, Spong, Krotoski, et al., 2011). Observations are vital components of the interview process because they prompt the nurse and woman to focus on the specific needs of the woman and her family.

Nutritional History. The woman's nutritional history is an important component of the prenatal history because her nutritional status has a direct effect on the growth and development of the fetus. A dietary assessment can reveal special dietary practices, food allergies, eating behaviors, the practice of *pica* (the consumption of nonfood substances), and other factors related to her nutritional status (see Box 15-7). Obese women should receive counseling about weight gain, physical activity, and healthy food choices. They should also be advised about the risk for maternal or fetal complications (ACOG Committee on Obstetric Practice, 2013a). Pregnant women are usually motivated to learn about healthy lifestyle behaviors and respond well to advice generated by this assessment. However, there is not enough rigorous research evidence to recommend any specific intervention for preventing excess weight gain during pregnancy (Muktabhant, Lumbiganon, Ngamjarus, & Dowswell, 2012). Women with a history of bariatric surgery are nutritionally at risk and should be followed closely throughout pregnancy to promote maternal and fetal well-being (Magdaleno, Pereira, Chaim, & Turato, 2012) (see Chapter 15).

History of Drug and Herbal Preparation Use. The prenatal history includes past and present use of drugs (legal over-the-counter [OTC] and prescription medications; vitamin

supplements such as A, C, D, and E; herbal preparations; caffeine; alcohol; nicotine) and street drugs (e.g., marijuana, cocaine, heroin). This is because many substances cross the placenta and can therefore pose a risk to the developing fetus. See Chapter 31 for discussion of substance abuse during pregnancy. Increasing numbers of individuals are using herbal preparations, and this includes pregnant women. Therefore, it is important for health care providers to question prenatal women regarding the use of herbal preparations and document their responses. Information about allergies to medications and the type of reaction should also be obtained and recorded in the health record.

The immunization record should be reviewed for vaccinations against diseases such as rubella (German measles), varicella (chickenpox), seasonal influenza, hepatitis B, and pertussis (whooping cough) that can pose a particular risk to pregnant women or their infants during pregnancy and immediately following birth. Recommendations for vaccinations during the perinatal period are discussed later in the chapter.

Family History. The family history provides information about the woman's immediate family, including parents, siblings, and children. These data help identify familial or genetic disorders or conditions that could affect the health status of the woman or her fetus.

Social, Experiential, and Occupational History. Situational factors such as the family's ethnic and cultural background and socioeconomic status are assessed while the history is obtained. The following information may be obtained in several encounters. The woman's perception of this pregnancy is explored by asking questions that focus on the following issues:

- Is this pregnancy planned or wanted?
- Is the woman pleased, displeased, accepting, or nonaccepting?
- Will any changes related to finances, career, or living accommodations occur as a result of the pregnancy?

The family support system is assessed by questioning the mother about these areas:

- What primary support is available to her?
- Are changes needed to promote adequate support?
- What are the existing relationships among the mother, father or partner, siblings, and expectant grandparents?
- What preparations are being made for her care and that of dependent family members during labor and for the care of the infant after birth?
- Is financial, educational, or other support needed from the community?
- What are the woman's ideas about childbearing, her expectations of the infant's behavior, and her outlook on life and the maternal role?

Other questions can provide perspective on the woman's perceptions about becoming a mother. Examples of issues to explore include:

- What does the woman think it will be like to have a baby in the home?
- How is her life going to change by having a baby?
- How prepared does she feel for becoming a mother?

During interviews throughout the pregnancy nurses should remain alert to the appearance of potential parenting problems, such as depression, lack of family support, and inadequate living conditions. Nurses assess the woman's attitude toward

health care, particularly during childbearing, her expectations of health care providers, and her view of the relationship between herself and the nurse.

Coping mechanisms and patterns of interacting are identified through observation and conversation with the mother. Early in the pregnancy the nurse should determine the woman's knowledge in various areas: pregnancy, maternal changes, fetal growth, self-care, and care of the newborn, including feeding. Asking about attitudes toward unmedicated or medicated labor and birth and about her knowledge of the availability of parenting skills classes is important. Before planning for nursing care, the nurse obtains information about the woman's decision-making abilities and living habits (i.e., exercise, sleep, diet, recreational interests, personal hygiene, clothing). Common concerns that can be sources of stress during childbearing include the baby's welfare, labor and birth process, behaviors of the newborn, the woman's relationship with her partner and her family, changes in body image, and physical symptoms.

The nurse explores attitudes concerning the range of acceptable sexual behavior during pregnancy by asking questions such as the following: What has your family (partner, friends) told you about sex during pregnancy? To gain insight into the woman's sexual self-concept, the nurse can ask questions such as the following: How do you feel about the changes in your appearance? How does your partner feel about your body now? How do you feel about wearing maternity clothes?

Women are questioned regarding their occupation—past and present—because this can adversely affect maternal and fetal health. For some women heavy lifting and exposure to chemicals and radiation are part of their daily work, and these activities can negatively affect the pregnancy. Standing for long periods at a retail checkout line or in front of a classroom is associated with orthostatic hypotension. For others long hours of sitting at a desk working on a computer can contribute to carpal tunnel syndrome or circulatory stasis in the legs.

History or Risk of Intimate Partner Violence. All women should be assessed for a history or risk of abuse in all forms—physical, sexual, or psychological—particularly because the likelihood of intimate partner violence (IPV) increases during pregnancy (see Chapter 5). This screening should be done at the first prenatal visit, at least once each trimester, and at the postpartum visit (ACOG Committee on Health Care for Underserved Women, 2012). It is essential that the screening is done in a safe, private setting with the woman alone. Nurses can ask the woman screening questions with routine assessments during pregnancy. Examples of questions that might be asked include:

- Are you with a spouse or partner who threatens or physically hurts you? If yes, who?
- Within the past year or in this pregnancy, has anyone hit, slapped, kicked, or otherwise hurt you? If yes, who? Are you currently with that person?
- Has anyone forced you to have sexual activities that made you uncomfortable? If yes, who? Are you currently with that person?

Although cues from the woman's appearance, behavior or how she responds to questions can suggest the possibility, no one profile of the abused woman exists. During pregnancy the target body parts can change during abusive episodes. Women may report physical blows directed to the head, breasts, abdomen, and genitalia; verbal abuse; and sexual assault. The nurse

should be prepared to offer support and community resources to women who are victims of intimate partner violence.

Abuse and pregnancy in teenagers constitute a particularly difficult situation. Adolescents can be trapped in the abusive relationship because of their inexperience, dependence on the abuser, and separation from family and friend support systems. Routine screening for abuse and sexual assault is recommended for pregnant adolescents (Centers for Disease Control and Prevention [CDC], 2013c). Because pregnancy in minor adolescent girls can be the result of sexual abuse, possibly from a relative, the nurse should know the state reporting laws and be prepared to contact protective services authorities if abuse or sexual assault is suspected (see Chapter 5 for further discussion).

Nurses should be aware that victims of human trafficking can be seen in prenatal settings because of unintended pregnancy. Similar to victims of IPV, these women are likely to exhibit signs of physical abuse or neglect such as scars, bruises, burns, unusual bald patches, or tattoos that can be a sign of branding. They are likely to be accompanied by someone who never leaves them alone and speaks for them. They may not speak English and may lack identification documents. If the woman is alone, she may have her cell phone on and in speaker mode so that the person on the other end can hear everything that is said during the visit. Nurses and other health care providers must be creative in getting the woman alone for questioning. Strategies might include sending the other person to the front desk to fill out paperwork, interviewing the woman in the restroom, or telling her she needs to go for testing and cannot take her cell phone. With the consent of suspected or confirmed victims of human trafficking, intervention plans can be developed. An excellent resource is the National Human Trafficking Resource Center (www.polarisproject.org/what-we-do/national-human-trafficking-hotline/the-nhtrc/overview) (1-888-373-7888) (Tracy & Konstantopoulos, 2012).

Review of Systems. During this portion of the interview the woman is asked to identify and describe preexisting or concurrent problems in any of the body systems, and her mental status is assessed. The nurse questions the woman about physical symptoms she has experienced, such as shortness of breath or pain. Pregnancy affects and is affected by all body systems; therefore, information on the current status of the body systems is important in planning care. For each sign or symptom described, the following additional data should be obtained: location, quality, quantity, chronology, aggravating or alleviating factors, and associated manifestations (signs or symptoms that occur with the primary symptom) (Seidel, Ball, Dains, et al., 2011).

Physical Examination

The initial physical examination provides the baseline for assessing subsequent changes. The nurse should determine the woman's needs for basic information regarding reproductive anatomy and provide this information, along with a demonstration of the equipment that may be used and an explanation of the procedure itself. The interaction requires an unhurried, sensitive, and gentle approach with a matter-of-fact attitude.

The physical examination begins with assessment of vital signs and height and weight (for calculation of body mass index [BMI]) (see Chapter 15). The bladder should be empty before pelvic examination; the woman may be asked to provide a urine specimen at this time if not already provided.

TABLE 14-1 Laboratory Tests in Prenatal Period

LABORATORY TEST	PURPOSE
Hemoglobin, hematocrit, WBC, differential	Detects anemia; detects infection
Hemoglobin electrophoresis	Identifies women with hemoglobinopathies (e.g., sickle cell anemia, thalassemia)
Blood type, Rh, and irregular antibody	Identifies women whose fetuses are at risk for developing erythroblastosis fetalis or hyperbilirubinemia in neonatal period
Rubella titer	Determines immunity to rubella
Tuberculin skin testing; chest film after 20 weeks of gestation in women with reactive tuberculin tests	Screens for exposure to tuberculosis
Urinalysis, including microscopic examination of urinary sediment; pH, specific gravity, color, glucose, albumin, protein, RBCs, WBCs, casts, acetone; hCG	Identifies women with glycosuria, renal disease, hypertensive disease of pregnancy; infection; occult hematuria; hCG for confirmation of pregnancy
Urine culture	Identifies women with asymptomatic bacteriuria
Renal function tests: BUN, creatinine, electrolytes, creatinine clearance, total protein excretion	Evaluates level of possible renal compromise in women with a history of diabetes, hypertension, or renal disease
Pap test	Screens for cervical intraepithelial neoplasia; if a liquid-based test is used, may also screen for HPV
Cervical cultures for <i>Neisseria gonorrhoeae</i> , <i>Chlamydia</i>	Screens for asymptomatic infection at first visit
Vaginal/anal culture	GBS test done at 35-37 weeks for infection
RPR, VDRL, or FTA-ABS	Identifies women with untreated syphilis, done at first visit
HIV antibody, hepatitis B surface antigen, toxoplasmosis	Screens for the specific infections
1-hour glucose tolerance	Screens for gestational diabetes; done at initial visit for women with risk factors; done at 24-28 weeks for pregnant women at risk whose initial screen was negative and for others who were not previously tested
3-hour glucose tolerance	Tests for gestational diabetes in women with elevated glucose level after 1-hour test; must have two elevated readings for diagnosis
Cardiac evaluation: ECG, chest x-ray, and echocardiogram	Evaluates cardiac function in women with a history of hypertension or cardiac disease

BUN, Blood urea nitrogen; ECG, electrocardiogram; FTA-ABS, fluorescent treponemal antibody absorption; GBS, group B streptococcus; hCG, human chorionic gonadotropin; HIV, human immunodeficiency virus; HPV, human papillomavirus; RBCs, red blood cells; RPR, rapid plasma reagin; WBCs, white blood cells; VDRL, Venereal Disease Research Laboratory.

Each examiner develops a routine for proceeding with the physical examination; most choose the head-to-toe progression. Heart and lung sounds are evaluated, and extremities are examined. Distribution, amount, and quality of body hair are of particular importance because the findings reflect nutritional status, endocrine function, and attention to hygiene. The thyroid gland is assessed carefully. The height of the fundus is noted if the first examination is done after the first trimester of pregnancy. During the examination the nurse must remain alert to the woman's cues that give direction to the remainder of the assessment and that indicate a potential threatening condition such as **supine hypotension**—low blood pressure (BP) that occurs while the woman is lying on her back, causing feelings of faintness (see Emergency Box). See Chapter 4 for a detailed description of the physical examination.

Whenever a pelvic examination is performed, the tone of the pelvic musculature and the woman's knowledge of Kegel exercises are assessed. Particular attention is paid to the size of the uterus because this is an indication of the duration of gestation. During the examination the nurse can coach the woman in breathing and relaxation techniques, as needed. One vaginal examination during early pregnancy is recommended; another is usually not performed until late in the third trimester unless indicated by the woman's health status.

Laboratory Tests

The laboratory data yielded by the analysis of the specimens obtained during the examination provide important information concerning the symptoms of pregnancy and the woman's health status.

Urine, cervical, and blood samples are requested during the initial visit for a variety of recommended screening and diagnostic tests for infectious diseases and metabolic conditions that

can affect the mother and/or developing fetus. (A list of the various tests is found in Table 14-1.) Women should receive information about the various tests and the purpose for each test and be provided an opportunity to opt-out of testing. All pregnant women should receive human immunodeficiency virus (HIV) risk-reduction counseling and be notified that they will be tested for antibody to HIV as part of the routine prenatal testing unless the test is declined (AAP & ACOG, 2012) (Box 14-4). If the woman refuses testing for HIV, this should be documented. The Centers for Disease Control and Prevention (CDC) also recommend testing during the first prenatal visit for syphilis, chlamydia, and hepatitis B. Screening for *Neisseria gonorrhoeae* is done for women who are at risk (CDC, 2013d). Screening for HIV, syphilis, chlamydia, and gonorrhea is repeated in the third trimester for women who are at high risk for contracting these infections. A purified protein derivative (PPD) tuberculin test may be administered to assess exposure to tuberculosis in women who are high risk. The urine is tested for protein, glucose, and leukocytes; urine culture may also be done. During the pelvic examination Papanicolaou test and culture for chlamydia and gonorrhea are done. In addition, pregnant women and fathers with certain ancestry or a family history of various genetically linked disorders may choose to undergo genetic testing (see Chapter 3). Antenatal testing for risk factors in pregnancy is discussed in Chapter 26.

Follow-up Visits

In traditional prenatal care, visits can occur more or less frequently, often depending on individual needs, complications, and risks of the pregnant woman. The pattern of interviewing the woman first and then assessing physical changes and performing laboratory tests continues.

BOX 14-4 Human Immunodeficiency Virus Screening

- Pregnant women are ethically obligated to seek reasonable care during pregnancy and to avoid causing harm to the fetus. Women's health nurses should be advocates for the fetus while accepting of the pregnant woman's decision regarding testing and/or treatment for HIV.
- Without treatment, the incidence of perinatal transmission from an HIV-positive mother to her fetus is approximately 25%. Triple drug antiviral or highly active antiretroviral therapy (HAART) during pregnancy decreases perinatal transmission to less than 1% (CDC, 2014).
- The Centers for Disease Control and Prevention (CDC, 2014) recommend testing for HIV infections for all pregnant women as early as possible in pregnancy and a second test in the third trimester for women in certain geographic areas and those who are at high risk for HIV infection.
- Testing has the potential to identify HIV-positive women who can then be treated. Health care providers have an obligation to ensure that pregnant women are well informed about HIV symptoms, testing, and methods of decreasing maternal-fetal transmission. The CDC and the American College of Obstetricians and Gynecologists (ACOG) recommend universal opt-out screening, which means that all pregnant women are offered HIV screening but have the opportunity to opt-out if desired (ACOG Committee on Obstetric Practice, 2011a; CDC, 2014). The Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN, 2008) supports this system of HIV screening that allows all pregnant women to be offered screening.

Sources: American College of Obstetricians and Gynecologists (ACOG) Committee on Obstetric Practice (2011). Committee opinion no. 418. Prenatal and perinatal human immunodeficiency virus testing—Expanded recommendations. *Obstetrics & Gynecology*, 104(5 Part 1), 1119-1124; AWHONN. (2008). *HIV screening procedures for pregnant women and newborns—Policy position statement*. Washington, DC: Author; Centers for Disease Control and Prevention. (2014). Reducing HIV transmission from mother-to-child: An opt-out approach to HIV screening. Available at www.cdc.gov/hiv/risk/gender/pregnantwomen/opt-out.html.

In prenatal care models that use a reduced-frequency screening schedule or in group prenatal care (e.g., CenteringPregnancy), the timing of follow-up visits varies, but assessments and care are similar (see Box 14-3).

Interview

Follow-up visits are briefer and less intensive than the initial prenatal visit. At each of these follow-up visits, the woman is asked to summarize relevant events that have occurred since the previous visit. She is asked about her general emotional and physiologic well-being, complaints, problems, and questions she may have. Family needs also are identified and explored (Fig. 14-6).

Emotional changes are common during pregnancy, and therefore asking whether the woman has experienced any mood swings, reactions to changes in her body image, bad dreams, or worries is reasonable. The nurse documents the reactions of the partner and other family members to the pregnancy and the woman's emotional changes.

During the third trimester it is important to assess current family situations and their effect on the woman as well as siblings' and grandparents' responses to the pregnancy and the coming child. This is a time to assess the woman and her family's knowledge of

FIG 14-6 A prenatal interview. (Courtesy Dee Lowdermill, Chapel Hill, NC.)

warning signs of emergencies, signs of preterm and term labor, the labor process and concerns about labor, and fetal development and methods to assess fetal well-being. The nurse should ask if the woman is planning to attend childbirth preparation classes and what she knows about management of discomfort during labor.

A review of the woman's physical systems is appropriate at each prenatal visit, and any suspicious signs or symptoms are assessed in depth. This review of systems includes identifying any discomforts reflecting adaptations to pregnancy. The nurse inquires about success with self-care measures as well as outcomes of prescribed therapy.

Physical Examination

Reevaluation is a constant aspect of a pregnant woman's care. Physiologic changes are documented as the pregnancy progresses and reviewed for possible deviations from normal progress.

At each visit physical parameters are measured. BP is measured using the same arm at every visit. The woman's weight is assessed, and the appropriateness of the gestational weight gain is evaluated in relationship to her BMI. Urine may be checked by dipstick, and the presence and degree of edema are noted. For examination of the abdomen, the woman lies on her back with her arms by her side and head supported by a pillow. A small wedge is placed under her right hip to tilt her slightly to the left. The bladder should be empty. Abdominal inspection is followed by measurement of the height of the fundus (see Fig. 14-8). While the woman lies on her back, the nurse should be alert for the occurrence of supine hypotension (see the Emergency box).

+ EMERGENCY

Supine Hypotension

Signs and Symptoms

- Pallor
- Dizziness, faintness, breathlessness
- Tachycardia
- Nausea
- Clammy (damp, cool) skin; sweating

Interventions

- Position woman on her side until her signs and symptoms subside and vital signs stabilize within normal limits.

The information provided through the interview and the physical examination reflects the status of maternal adaptations. When any of the findings are outside the expected range, an in-depth examination is performed. For example, careful interpretation of BP is important in the risk factor analysis of all pregnant women. Signs and symptoms other than hypertension also can be present that indicate potential complications (see Signs of Potential Complications).

SIGNS OF POTENTIAL COMPLICATIONS

First, Second, and Third Trimesters

SIGNS AND SYMPTOMS	POSSIBLE CAUSES
First Trimester	
Severe vomiting	Hyperemesis gravidarum
Chills, fever	Infection
Burning on urination	Infection
Diarrhea	Infection
Abdominal cramping; vaginal bleeding	Miscarriage, ectopic pregnancy
Second and Third Trimesters	
Persistent, severe vomiting	Hyperemesis gravidarum, hypertension, preeclampsia
Sudden discharge of fluid from vagina before 37 weeks	Preterm premature rupture of membranes (PPROM)
Vaginal bleeding, severe abdominal pain	Miscarriage, placenta previa, abruptio placentae
Chills, fever, burning on urination, diarrhea	Infection
Severe backache or flank pain	Kidney infection or stones; preterm labor
Change in fetal movements: absence of fetal movements after quickening, any unusual change in pattern or amount	Fetal jeopardy or intrauterine fetal death
Uterine contractions; pressure; cramping before 37 weeks	Preterm labor
Visual disturbances: blurring, double vision, or spots	Hypertensive conditions, preeclampsia
Swelling of face or fingers and over sacrum	Hypertensive conditions, preeclampsia
Headaches: severe, frequent, or continuous	Hypertensive conditions, preeclampsia
Muscular irritability or convulsions	Hypertensive conditions, preeclampsia
Epigastric or abdominal pain (perceived as heartburn or severe stomachache)	Hypertensive conditions, preeclampsia, abruptio placentae
Glycosuria, positive glucose tolerance test reaction	Gestational diabetes mellitus

Fetal Assessment

Gestational Age. In an uncomplicated pregnancy fetal gestational age is estimated after the duration of pregnancy and the EDB are determined. Fetal gestational age is determined from the menstrual history, contraceptive history, pregnancy test result, and the following findings obtained during the clinical evaluation:

- First uterine evaluation: date, size
- Fetal heart first heard: date, method (Doppler stethoscope, fetoscope)

- Date of quickening
- Current fundal height, estimated fetal weight (EFW)
- Current week of gestation by history of LMP and/or ultrasound examination
- Ultrasound examination: date, week of gestation, biparietal diameter (BPD)
- Reliability of dates

Quickening usually occurs between 16 and 20 weeks of gestation and is initially experienced as a fluttering sensation. The mother's report should be recorded. Multiparous women often perceive fetal movement earlier than primigravidas.

The use of ultrasound examination (also called a *sonogram*) in early pregnancy has become routine, and many health care providers have this equipment available in the office or clinic. This procedure may be used to establish the duration of pregnancy if the woman cannot give a precise date for her LMP or if the size of the uterus does not conform to the EDB as calculated by Naegele's rule. Ultrasound can detect a multiple gestation pregnancy and provide information about the well-being of the fetus or fetuses (see Chapter 26 for further discussion).

Fetal Heart Tones. The fetal heart tones (FHT) are checked on routine visits. Early in pregnancy the fetal heartbeat can be detected during ultrasound examination. Late in the first trimester the heartbeat can be heard with a Doppler device that transmits fetal heart tones through a speaker or attached ear pieces (Fig. 14-7, B). As the uterus grows and becomes an abdominal organ, the fetal heartbeat can also be auscultated with a fetoscope (see Fig. 14-7, A). Many practitioners use the Doppler device because it allows the mother and others who are present to easily hear the fetal heartbeat. Another tool for assessing fetal heart tones is the Pinard horn, which is a fetoscope commonly used by midwives and in much of Europe (see Fig. 14-7, C).

To detect the heartbeat before the fetal position can be palpated by Leopold maneuvers (see Chapter 19), the Doppler or fetoscope is moved around the abdomen until the heartbeat is heard. Each nurse develops a set pattern for searching the abdomen for the heartbeat—for example, starting first in the midline about 2 to 3 cm above the symphysis pubis, then moving to the left lower quadrant, and so on. The heartbeat is counted for 1 minute, and the quality and rhythm noted. A normal rate and rhythm are other good indicators of fetal health. Once the heartbeat is noted, its absence is cause for immediate investigation.

Health Status. The assessment of fetal health status often includes consideration of fetal movement. Absence of fetal movement is correlated with fetal death; women who report decreased fetal movement have an increased risk for adverse outcomes (AAP & ACOG, 2012). The mother is instructed to note the extent and timing of fetal movements and to report immediately if the pattern changes or if movement ceases. The woman may be instructed to count movements daily over a 1- or 2-hour period. Her perception of four or more movements in an hour is considered reassuring. There is no standard recommendation for the ideal number of movements or kicks or for the duration of daily fetal movement assessment. The most important consideration is the mother's perception that fetal movements have decreased relative to previous levels (AAP & ACOG).

Fetal health status is investigated intensively if any maternal or fetal complications arise (e.g., gestational hypertension, intrauterine growth restriction (IUGR), premature rupture of

FIG 14-7 Detecting fetal heartbeat. **A**, Father can listen to the fetal heart with a fetoscope (first detectable at 18 to 20 weeks with a fetoscope). **B**, Doppler ultrasound stethoscope (fetal heartbeat detectable at 12 weeks). **C**, Pinard fetoscope. Note: Hands should not touch fetoscope while listening. (A, Courtesy Shannon Perry, Phoenix, AZ. B, Courtesy Dee Lowdermilk, Chapel Hill, NC. C, Courtesy Julie Perry Nelson, Loveland, CO.)

membranes [PROM], irregular or absent FHR, or decreased or absent fetal movements after quickening). Careful, precise, and concise recording of the woman's responses and laboratory results contributes to the continuous supervision vital to promoting the well-being of the mother and fetus.

Fundal Height. During the second trimester the uterus becomes an abdominal organ. The fundal height (measurement of the height of the uterus above the symphysis pubis) is one indicator of fetal growth. The measurement also provides a gross estimate of the duration of pregnancy. From gestational weeks (GW) 18 to 30, the height of the fundus in centimeters is approximately the same as the number of weeks of gestation (± 2 GW), if the woman's bladder is empty at the time of measurement. As much as a 3-cm variation is possible if the bladder is full. For example, a woman of 28 weeks of gestation, with an empty bladder, would measure from 26 to 30 cm. The fundal height measurement can aid in identifying risk factors. A stable or decreased fundal height can indicate intrauterine growth restriction (IUGR); an excessive increase can indicate the presence of multifetal gestation (more than one fetus) or polyhydramnios.

A disposable paper metric tape measure is preferred for measuring fundal height; plastic retractable tape measures should be cleaned after use and prior to retraction. To increase the reliability of the measurement, the same person examines the pregnant woman at each of her prenatal visits, but often this is not possible. All clinicians who examine a particular pregnant

woman should be consistent in their measurement technique. Ideally a protocol should be established for the health care setting in which the measurement technique is explicitly set forth, and the woman's position on the examining table, the measuring device, and method of measurement used are specified. Conditions under which the measurements are taken also can be described in the woman's records, including whether the bladder was empty and whether the uterus was relaxed or contracted at the time of measurement.

Various positions for measuring fundal height have been described. The woman can be supine with her head elevated and/or knees flexed. Measurements obtained with the woman in the various positions differ, making it even more important to standardize the fundal height measurement technique.

Placement of the tape measure also can vary. The tape can be placed in the middle of the woman's abdomen and the measurement made from the upper border of the symphysis pubis to the upper border of the fundus, with the tape measure held in contact with the skin for the entire length of the uterus (Fig. 14-8, A). In another measurement technique, the upper curve of the fundus is not included in the measurement. Instead, one end of the tape measure is held at the upper border of the symphysis pubis with one hand, and the other hand is placed at the upper border of the fundus. The tape is placed between the middle and index fingers of the other hand, and the point where these fingers intercept the tape measure is taken as the measurement (see Fig. 14-8, B).

FIG 14-8 Measurement of fundal height from symphysis pubis that **A**, includes the upper curve of the fundus and **B**, does not include the upper curve of the fundus. Note position of hands and measuring tape. (Courtesy Chris Rozales, San Francisco, CA.)

Laboratory Tests

The number of routine laboratory tests done during follow-up visits in pregnancy is limited. A clean-catch urine specimen is obtained to test for glucose, protein, nitrites, and leukocytes at each visit. Urine specimens for culture and sensitivity are obtained, and cervical and vaginal smears and blood tests are repeated as necessary.

Sequential integrated screening (SIS) is an option for women who begin prenatal care before 14 weeks of gestation; it involves two blood tests and one ultrasound. This multiple marker screen can identify the following conditions: Down syndrome (trisomy 21), trisomy 18, neural tube defects (anencephaly and spina bifida), abdominal wall defects (gastroschisis and omphalocele), and Smith-Lemli-Opitz syndrome. The first blood test is performed between 10 and 13 weeks of gestation to measure two biochemical markers—pregnancy-associated placental protein (PAPP-A) and free beta-human chorionic gonadotropin (β -hCG). The second step for SIS is an ultrasound between 11 and 14 weeks of gestation to assess for nuchal translucency. The final step in SIS is performed between 15 and 20 weeks of pregnancy and measures the levels of four substances normally found in a pregnant woman's blood: alpha-fetoprotein (AFP), human chorionic gonadotropin (hCG), unconjugated estriol, and inhibin-A. This second group of four tests is also known as quad marker screening. Maternal serum marker levels that are higher or lower than normal are associated with increased risk

of chromosomal abnormalities (see Chapter 26). Women who begin their prenatal care between the fourteenth and twentieth weeks of pregnancy are too advanced in their pregnancy to be offered the first two steps in SIS, but can be offered the quad marker screening alone (Wapner, 2014). Noninvasive prenatal testing (NIPT) is a new genetic test used to identify fetuses at risk for trisomies 21, 18, and 13 and sex chromosome abnormalities. NIPT detects fetal deoxyribonucleic acid (DNA) circulating in the maternal blood (cell-free DNA) as a result of the breakdown of fetal cells. Positive NIPT results should be followed by a confirmatory test such as chorionic villus sampling or amniocentesis (National Coalition for Health Professional Education in Genetics, 2012).

The American College of Obstetricians and Gynecologists (2013) recommends glucose screening for all pregnant women. Assessment for risk factors can be done through review of the medical history, screening for clinical risk factors, or measurement of blood glucose levels. Risk factors that warrant early screening include obesity, history of gestational diabetes mellitus (GDM), or known impairment of glucose metabolism. If GDM is not diagnosed with early screening, blood glucose testing is repeated at 24 to 28 weeks. The standard screening test for GDM is a 1-hour, 50-g oral glucose tolerance test (GTT). If the glucose level is elevated, further testing is done using a 3-hour, 100-g GTT (see Chapter 29).

Group B streptococcus (GBS) testing is recommended between 35 and 37 weeks of gestation; cultures collected earlier will not accurately predict GBS status at time of birth. All pregnant women should have GBS testing, even those who are scheduled for a cesarean birth, because labor can begin or membranes can rupture prior to the routine administration of prophylactic antibiotics. Women with a history of GBS in a previous pregnancy should be retested with each pregnancy (ACOG Committee on Obstetric Practice, 2013d).

See Chapter 26 for other diagnostic tests available to assess the health status of the pregnant woman and fetus.

Nursing Interventions

After obtaining information through the assessment process, the data are analyzed to identify deviations from the norm and unique needs of the pregnant woman and her family. Care is optimized with a collaborative approach involving the physician or CNM, nurse, other relevant health care professionals, the woman, her partner, and her family.

The nurse-client relationship is critical in setting the tone for further interaction. The techniques of active listening with an attentive expression, using touch and eye contact (if culturally appropriate), have their place, as does recognizing the woman's feelings and her right to express these feelings. The interaction may occur in various formal or informal settings. A clinical setting, home visits, or telephone conversations all provide opportunities for contact and can be used effectively.

Education for Self-Management

The expectant mother needs information on many topics. The nurse who is observant, listens, and is familiar with typical concerns of expectant parents can anticipate the questions that will be asked and can encourage mothers and their partners to discuss what is on their minds. Printed literature can be given to

supplement the individualized teaching the nurse provides. To be most effective, educational materials should be appropriate for the pregnant woman's or couple's ethnicity, culture, and literacy level and the agency's resources. Women often avidly read books, pamphlets, and web information related to their own pregnancy experience. Nurses should be familiar with the educational materials that are distributed to expectant parents as well as popular web-based resources related to pregnancy. Nurses can direct pregnant women and their families to reliable websites that contain accurate information.

Because family members are common sources for health information, it is also important to include them in health education endeavors during pregnancy (U.S. Department of Health and Human Services Office of Disease Prevention and Promotion, 2013). This can enhance their ability to be supportive of the pregnant woman as she progresses through pregnancy.

Pregnant women who receive conflicting advice or instruction are likely to grow increasingly frustrated with members of the health care team and the care provided. Several topics that can cause concerns in pregnant women are discussed in the following sections.

Expected Maternal and Fetal Changes. Most expectant parents are curious about the growth and development of the fetus and the changes that occur in the mother's body during pregnancy. Mothers are often more tolerant of the discomforts related to the continuing pregnancy if they understand the underlying causes. Educational literature (printed, electronic, or web-based materials) that describes fetal and maternal changes can be used to explain changes as they occur. Couples can track the development of their growing fetus through websites such as www.babycenter.com/fetal-development or www.parents.com/pregnancy/stages/fetal-development.

Nutrition. Good nutrition is important for the maintenance of maternal health during pregnancy and the provision of adequate nutrients for embryonic and fetal development. Assessing a woman's nutritional status and weight gain and providing ongoing education about nutrition are part of the nurse's responsibilities in providing prenatal care. Education for pregnant women includes recommendations about daily intake of nutrients, calories, vitamins, and minerals. Based on the woman's BMI, the recommended weight gain during pregnancy is discussed. Additional information regarding nutrition during pregnancy may include foods high in iron, the importance of taking prenatal vitamins, and recommendations to avoid alcohol and to limit caffeine intake. Pregnant women are instructed about how to avoid food-borne illnesses such as listeriosis. At each visit the nurse assesses for practice of pica. In some settings a nutritionist counsels women individually or conducts classes for pregnant women about nutrition during pregnancy. Nurses can refer women to a nutritionist if a need is identified during the nursing assessment. (For detailed information concerning maternal and fetal nutritional needs and related nursing care, see Chapter 15.)

Personal Hygiene. During pregnancy the sebaceous (sweat) glands are highly active because of hormonal influences, and women often perspire freely. They can be informed that the increase is normal and that their previous patterns of perspiration will return after the postpartum period. Baths and warm showers can be therapeutic because they relax tense, tired

muscles; help counter insomnia; and make the pregnant woman feel fresh. Tub bathing is not restricted even in late pregnancy because little water enters the vagina unless under pressure. However, late in pregnancy, when the woman's center of gravity lowers, she is at risk for falling. Tub bathing is contraindicated after rupture of the membranes.

Prevention of Urinary Tract Infections. Because of physiologic changes that occur in the renal system during pregnancy (see Chapter 13), infections of the lower urinary tract (acute urethritis, acute cystitis) are common. *Escherichia coli* (*E. coli*) is the most common causative organism for urinary tract infection (UTI) in pregnant women (Duff, 2012). Although UTIs can be asymptomatic, typical symptoms include frequency, urgency, dysuria, dribbling, and hesitancy; gross hematuria can occur. Women should be instructed to inform their health care provider promptly if they experience these symptoms. Urinary tract infections pose a risk to the mother and fetus, and thus their prevention or early treatment is essential. Oral antibiotics are commonly prescribed.

The nurse can assess the woman's understanding and use of appropriate hand hygiene techniques before and after urinating and the importance of wiping the perineum from front to back. Soft, absorbent toilet tissue, preferably white and unscented, should be used; harsh, scented, or printed toilet paper can cause irritation. Bubble bath or other bath oils should be avoided because these can irritate the urethra. Women should wear all-cotton undergarments and cotton-lined pantyhose and avoid tight-fitting slacks or jeans for long periods; anything that allows a buildup of heat and moisture in the genital area can foster the growth of bacteria.

Some women do not consume enough fluid. The nurse should advise her to drink at least 2 L (eight glasses) of liquid a day, preferably water, to maintain an adequate fluid intake that ensures frequent urination. Pregnant women should not limit fluids in an effort to reduce the frequency of urination. Women need to know that if urine appears dark (concentrated), they must increase their fluid intake.

The nurse should review healthy urination practices with the woman. Women are told not to ignore the urge to urinate because holding urine lengthens the time bacteria are in the bladder and allows them to multiply. Women should plan ahead when they are faced with situations that can require them to delay urination (e.g., a long car ride). They always should urinate before going to bed at night. Bacteria can be introduced during intercourse; therefore, women are advised to urinate before and after intercourse, and then drink a large glass of water to promote additional urination. Consumption of cranberry juice has been offered as an intervention to prevent UTI. The effectiveness of cranberry juice in the prevention of UTIs is dependent on long-term adherence to daily consumption of about 10 ounces of juice (Jepson, Williams, & Craig, 2012). The value of recommending cranberry juice to prevent UTI must include consideration of cost, sugar content, and additional calories. Low-sugar or pure cranberry juices may be recommended. Some women take cranberry pills as an alternative to drinking juice.

Kegel Exercises. Kegel exercises (deliberate contraction and relaxation of the pubococcygeus muscle) strengthen the muscles around the reproductive organs and improve muscle tone. Many women are not aware of the muscles of the pelvic floor until it is pointed out that these are the muscles used

during urination and sexual intercourse that can be consciously controlled. The muscles of the pelvic floor encircle the vaginal outlet, and they need to be exercised because an exercised muscle can then stretch and contract readily at the time of birth. Practice of pelvic muscle exercises during pregnancy also results in fewer complaints of urinary incontinence in late pregnancy and postpartum (Kocaöz, Eroglu, & Sivaslioglu, 2013).

Several ways of performing Kegel exercises have been described. The method described in the Teaching for Self-Management box: Kegel Exercises in Chapter 4 demonstrates evidence-based nursing care. This method was developed by nurses involved in a research utilization project for continence in women. Teaching has been effective if the woman reports an increased ability to control urine flow and greater muscular control during sexual intercourse.

Preparation for Breastfeeding. During the first prenatal visit, the nurse asks if the woman is planning to breastfeed. A woman's decision about the method of infant feeding is usually made before pregnancy; thus it is essential to educate women of childbearing age about the benefits of breastfeeding. The woman and her partner are encouraged to decide which method of feeding is suitable for them; however, the benefits of breastfeeding should be emphasized. Once the couple has been given information about the advantages and disadvantages of breastfeeding and formula-feeding, they can make an informed choice. Most women who choose to breastfeed do so because they are aware of the numerous benefits (see Chapter 25). Lack of knowledge about the benefits of breastfeeding and perceived personal and social disadvantages to breastfeeding can influence a woman not to breastfeed. Modesty issues, lack of support by the partner and family, incompatibility with lifestyle, and lack of confidence are among the reasons cited by women who decide to formula-feed their infants (Lawrence & Lawrence, 2011; Nelson, 2012).

Assessment of breasts during the prenatal period can reveal potential concerns related to breastfeeding. Scars on the breast can indicate previous breast reduction surgery, which can affect milk production. The woman may have breast implants; this may affect successful breastfeeding. Asymmetry of the breasts or tubular-shaped breasts suggest a lack of glandular tissue and potential problems with adequate milk production. Examination of the breasts can reveal flat or inverted nipples, which can affect the baby's ability to successfully latch on to the breast. To determine if nipples are inverted, a woman can perform a test on her nipples to determine freedom of protrusion (Fig. 14-9). The woman places her thumb and forefinger on her areola and presses inward gently. A normal nipple will evert or stand erect while an inverted nipple will appear to withdraw (Lawrence & Lawrence, 2011).

Exercises to break the adhesions that cause the nipple to invert do not work and can cause uterine contractions. Some clinicians recommend the prenatal use of breast shells (Fig. 14-10) during the last trimester for women with flat or inverted nipples, although evidence to support their effectiveness is lacking. They can be uncomfortable and cause irritation to the nipple or areola. Breast stimulation is contraindicated in women at risk for preterm labor; therefore, the decision to suggest the use of breast shells to women with flat or inverted nipples must be made judiciously (Lawrence & Lawrence, 2011).

There is no special preparation of the nipples or breasts for breastfeeding. The woman is taught to cleanse the nipples with

warm water to keep the ducts from being blocked with dried colostrum. Soap, ointments, alcohol, and tinctures should not be applied because they remove protective oils that keep the nipples supple. Breast pads with plastic liners should be avoided (Lawrence & Lawrence, 2011).

FIG 14-9 Test for inverted nipples A, Normal nipple everts with gentle pressure. B, Inverted nipple inverts with gentle pressure. (Adapted from Lawrence, R.A., & Lawrence, R.M. [2011]. *Breastfeeding: A guide for the medical profession* [7th ed.]. St. Louis: Mosby.)

TEACHING FOR SELF-MANAGEMENT BOX

Exercise Tips for Pregnant Women

- *Consult your health care provider* when you know or suspect you are pregnant. Discuss your health and pregnancy history, your current exercise regimen, and the exercises you would like to continue throughout pregnancy.
- *Seek help* in determining an exercise routine that is well within your limit of tolerance, especially if you have not been exercising regularly.
- *Consider decreasing weight-bearing exercises* (jogging, running) and concentrating on non-weight-bearing activities such as swimming, cycling, or stretching. If you are a runner, starting in your seventh month, you may wish to walk instead.
- *Avoid risky activities* such as surfing, mountain climbing, skydiving, and racquetball because such activities, which require precise balance and coordination, can be dangerous. Avoid activities that require holding your breath and bearing down (Valsalva maneuver). Jerky, bouncy motions also should be avoided.
- *Exercise regularly every day* if possible, as long as you are healthy, to improve muscle tone and increase or maintain your stamina. Exercising sporadically can place undue strain on your muscles. Thirty minutes of moderate physical exercise is recommended. This activity can be broken up into shorter segments with rest in between. For example, exercise for 10 to 15 minutes, rest for 2 to 3 minutes, and then exercise for another 10 to 15 minutes.
- *Consider decreasing your exercise level* as your pregnancy progresses. The normal alterations of advancing pregnancy, such as decreased cardiac reserve and increased respiratory effort, can produce physiologic stress if you exercise strenuously for a long time.
- *Take your pulse every 10 to 15 minutes* while you are exercising. If it is more than 140 beats/min, slow down until it returns to a maximum of 90 beats/min. You should be able to converse easily while exercising. If you cannot, you need to slow down.
- *Avoid becoming overheated* for extended periods. It is best not to exercise for more than 35 minutes, especially in hot, humid weather. As your body temperature rises, the heat is transmitted to your fetus. Prolonged or repeated elevation of fetal temperature can result in birth defects, especially during the first 3 months of pregnancy. Your temperature should not exceed 38° C.
- *Do not use hot tubs and saunas.*
- *Perform warm-up and stretching exercises* to prepare your joints for more strenuous exercise and lessen the likelihood of strain or injury to your joints. After the fourth month of pregnancy you should not perform exercises flat on your back.
- *Include a cool-down period* of mild activity involving your legs after an exercise period to help bring your respiration, heart, and metabolic rates back to normal and prevent blood from pooling in the exercised muscles.
- *Rest for 10 minutes after exercising*, lying on your side. As the uterus grows it puts pressure on a major vein in your abdomen that carries blood to your heart. Lying on your side removes the pressure and promotes return circulation from your extremities and muscles to your heart, thereby increasing blood flow to your placenta and fetus. You should rise gradually from the floor to prevent dizziness or fainting (orthostatic hypotension).
- *Stay hydrated.* Drink two or three 8-ounce glasses of water after you exercise to replace the body fluids lost through perspiration. While exercising, drink water whenever you feel the need.
- *Increase your caloric intake* to replace the calories burned during exercise and provide the extra energy needs of pregnancy. Choose high-protein foods such as fish, milk, cheese, eggs, and meat.
- *Take your time.* This is not the time to be competitive or train for activities requiring speed or long endurance.
- *Wear a supportive bra.* Your increased breast weight can cause changes in posture and put pressure on the ulnar nerve.
- *Wear supportive shoes.* As your uterus grows your center of gravity shifts and you compensate for this by arching your back. These natural changes can make you feel off balance and more likely to fall.
- *Stop exercising immediately* if you experience shortness of breath, dizziness, numbness, tingling, pain of any kind, more than four uterine contractions per hour, decreased fetal activity, or vaginal bleeding, and consult your health care provider.
- *Recognize signs of danger*, including vaginal bleeding*; blurred vision*; nausea; dizziness; fainting*; breathlessness; heart palpitations; increased swelling in your hands, feet, and ankles; sharp pain in the abdomen and chest*; and sudden change in body temperature.
- *Avoid the following exercises* during pregnancy: downhill snow skiing because the center of gravity changes and there is a risk for falls; contact sports such as ice hockey, soccer, and basketball; and scuba diving because the pressure from the water could put the fetus at risk for decompression sickness.

Riding recumbent bicycle provides exercise while supplying back support. Big brother becomes involved. (Courtesy Julie Perry Nelson, Loveland, CO.)

*If you experience any of these signs, contact your physician or midwife immediately.

A bra that fits well and provides support promotes comfort as breasts increase in size during pregnancy. The woman who plans to breastfeed may want to purchase a nursing bra that will accommodate her increased breast size during the last few months of pregnancy and during lactation.

Dental Health. Dental care during pregnancy is especially important because nausea during pregnancy can lead to poor oral hygiene, allowing dental caries to develop. Fluoride toothpaste should be used daily. Inflammation and infection of the gingival and periodontal tissues can occur. Research links periodontal disease with preterm births and LBW and an increased risk for preeclampsia (Jared & Boggess, 2012).

Early in prenatal care, the nurse should ask the woman about her last dental visit. If it was more than 6 months earlier, she should schedule a dental examination soon (Oral Health Care During Pregnancy Expert Workgroup, 2012).

Because calcium and phosphorus in the teeth are fixed in enamel, the old adage “for every child a tooth” is not true. There is no scientific evidence to support the belief that filling teeth or even dental extraction involving the administration of local or nitrous oxide-oxygen anesthesia precipitates miscarriage or

preterm labor. Antibacterial therapy should be considered for prevention of sepsis, especially in pregnant women who have had rheumatic heart disease or nephritis.

Diagnosis and treatment of oral health problems, including necessary dental x-rays and the use of local anesthetics or nitrous oxide-oxygen anesthesia, are considered safe during pregnancy. Dental care and nonemergent procedures are best scheduled during the second trimester when the woman is past the stage of feeling nauseated and can sit comfortably in the chair. To avoid supine hypotension during dental procedures, the pregnant woman in her second or third trimester is positioned in the dental chair with a small pillow under her right hip (Oral Health Care During Pregnancy Expert Workgroup, 2012).

Physical Activity. Physical activity promotes a feeling of well-being in the pregnant woman. It improves circulation, promotes relaxation and rest, and counteracts boredom, as it does in the nonpregnant woman (Price, Amini, & Kappeler, 2012). Detailed exercise tips for pregnancy are presented in the Teaching for Self-Management box: Exercise Tips for Pregnant Women. Exercises that help relieve the low back pain that often arises during the second trimester because of the increased weight of the fetus are demonstrated in Figure 14-11 (see Clinical Reasoning Case Study).

Posture and Body Mechanics. Skeletal and musculature changes and hormonal changes in pregnancy can predispose the woman to backache and possible injury. As pregnancy progresses, the woman’s center of gravity changes, pelvic joints soften and relax, and stress is placed on abdominal musculature. Poor posture and body mechanics contribute to the discomfort and potential for injury. To minimize these problems, women can learn good body posture and body mechanics (Fig. 14-12). Strategies to prevent or relieve backache are presented in the Teaching for Self-Management box: Posture and Body Mechanics.

Rest and Relaxation. Nurses encourage women to plan regular rest periods, particularly as pregnancy advances. The side-lying position is recommended because it promotes uterine perfusion and fetoplacental oxygenation by eliminating pressure on the ascending vena cava and descending aorta, which can lead to supine hypotension (Fig. 14-13). The woman

CLINICAL REASONING CASE STUDY

Exercise in Pregnancy

Lourdes is 16 weeks pregnant with her second child. She wants to avoid gaining extra weight during this pregnancy and would like to continue her exercise habits: walking and Zumba classes. What guidance can you give to Lourdes?

1. Evidence—Is the evidence sufficient to make a recommendation for or against exercising during pregnancy?
2. Assumptions—Describe the underlying assumptions for each of the following issues:
 - a. Physiologic changes in pregnancy that affect balance, movement, respiration, and cardiac function
 - b. Maternal physiologic response during exercise
 - c. Benefits of exercise
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

FIG 14-11 Exercises. A, B, and C, Pelvic rocking relieves low backache (excellent for relief of menstrual cramps as well). D, Abdominal breathing aids relaxation and lifts abdominal wall off uterus.

TEACHING FOR SELF-MANAGEMENT

Posture and Body Mechanics

To Prevent or Relieve Backache

Do pelvic tilt:

- Pelvic tilt (rock) on hands and knees (see Fig. 14-11, A) and while sitting in straight-back chair
- Pelvic tilt (rock) in standing position against a wall, or lying on floor (see Fig. 14-11, B and C)
- Perform abdominal muscle contractions during pelvic tilt while standing, lying, or sitting to help strengthen rectus abdominis muscle (see Fig. 14-11, D).

Use good body mechanics.

- Use leg muscles to reach objects on or near floor. Bend at the knees, not from the back. Knees are bent to lower body to squatting position. Feet are kept 12 to 18 inches apart to provide a solid base to maintain balance (see Fig. 14-12, A).
- Lift with the legs. To lift a heavy object (e.g., young child) one foot is placed slightly in front of the other and kept flat as woman lowers herself onto one knee. She lifts the weight, holding it close to her body and never higher than her chest. To stand up or sit down she places one leg slightly behind the other as she raises or lowers herself (see Fig. 14-12, B).

To Restrict the Lumbar Curve

- For prolonged standing (e.g., ironing, employment), place one foot on low footstool or box; change positions often.
- Move car seat forward so that knees are bent and higher than hips. If needed, use a small pillow to support the low back area.
- Sit in chairs low enough to allow both feet to be placed on floor, preferably with knees higher than hips.

To Prevent Round Ligament Pain and Strain on Abdominal Muscles

- Implement suggestions given in Table 14-2.

FIG 14-12 Correct body mechanics. A, Squatting. B, Lifting. (Courtesy Julie Perry Nelson, Loveland, CO.)

should be shown how to rise slowly from a side-lying position to prevent placing strain on the back and to minimize the orthostatic hypotension caused by changes in position common in the later part of pregnancy. To stretch and rest back muscles at home or work, the nurse can show the woman the way to do the following exercises:

- Stand behind a chair. Support and balance self by using the back of the chair (Fig. 14-14). Squat for 30 seconds; stand for 15 seconds. Repeat 6 times, several times per day, as needed.
- While sitting in a chair, lower head to knees for 30 seconds. Raise head. Repeat 6 times, several times per day, as needed.

Conscious relaxation is the process of releasing tension from the mind and body through deliberate effort and practice. The techniques for conscious relaxation are numerous and varied. Box 14-5 gives some guidelines. The ability to relax consciously and intentionally is beneficial for the following reasons:

- To relieve the normal discomforts related to pregnancy
- To reduce stress and therefore diminish pain perception during the childbearing cycle
- To heighten self-awareness and trust in one's own ability to control responses and functions
- To help cope with stress in everyday life situations.

FIG 14-13 Side-lying position for rest and relaxation. (Courtesy Julie Perry Nelson, Loveland, CO.)

Employment. Employment of pregnant women usually has no adverse effects on pregnancy outcomes. Job discrimination that is based strictly on pregnancy is illegal. However, some job environments pose potential risk to the fetus (e.g., dry-cleaning plants, chemistry laboratories, parking garages). Excessive fatigue is usually the deciding factor in the termination of employment. Strategies to improve safety during pregnancy are described in the Teaching for Self-Management box: Safety During Pregnancy.

FIG 14-14 Squatting for muscle relaxation and strengthening and for keeping leg and hip joints flexible. (Courtesy Julie Perry Nelson, Loveland, CO.)

TEACHING FOR SELF-MANAGEMENT

Safety During Pregnancy

Changes in the body resulting from pregnancy include relaxation of the joints, alteration to the center of gravity, faintness, and discomforts. Problems with coordination and balance are common. Therefore, the woman should follow these guidelines:

- Use correct body mechanics.
- Use safety features on tools and vehicles (e.g., safety seat belts, shoulder harnesses, headrests, goggles, helmets) as specified.
- Avoid activities requiring coordination, balance, and concentration.
- Take rest periods; reschedule daily activities to meet rest and relaxation needs.

The developing fetus is vulnerable to environmental teratogens. Many potentially dangerous chemicals—cleaning agents, paints, sprays, herbicides, and pesticides—are present in the home, yard, and workplace. The soil and water supply may be unsafe. Therefore, the woman should follow these guidelines:

- Read all labels for ingredients and proper use of a product.
- Ensure adequate ventilation with clean air.
- Dispose of wastes appropriately.
- Wear gloves when handling chemicals.
- Change job assignments or workplace as necessary.
- Avoid travel to high-altitude regions above 12,000 feet.

Women with sedentary jobs need to walk around at intervals to counter the usual sluggish circulation in the legs. They also should neither sit nor stand in one position for long periods, and they should avoid crossing their legs at the knees, because all of these activities can increase the risk of varices and thrombophlebitis. Standing for long periods also increases the risk of preterm labor. The pregnant woman's chair should provide adequate back support. Use of a footstool can prevent pressure on veins, relieve strain on varicosities, minimize edema of the feet, and prevent backache.

Clothing. Some women continue to wear their usual clothes during pregnancy as long as they fit and feel comfortable. If maternity clothing is needed, outfits can be purchased new or found at thrift shops or garage sales in good condition. Comfortable, loose clothing is recommended. Tight bras and belts, stretch pants, garters, tight-top knee socks, panty girdles, and other

BOX 14-5 Conscious Relaxation Tips

Preparation—Loosen clothing, assume a comfortable sitting or side-lying position with all parts of your body well supported with pillows. The use of soothing music is optional.

Beginning—Allow yourself to feel warm and comfortable. Inhale and exhale slowly and imagine peaceful relaxation coming over each part of your body, starting with the neck and working down to the toes. People who learn conscious relaxation often speak of feeling relaxed even if some discomfort is present.

Maintenance—Use imagery (fantasy or daydream) to maintain the state of relaxation. Using *active imagery*, imagine yourself moving or doing some activity and experiencing its sensations. Using *passive imagery*, imagine yourself watching a scene such as a lovely sunset.

Awakening—Return to the wakeful state gradually. Slowly begin to take in stimuli from the surrounding environment.

Further retention and development of the skill—Practice regularly for some periods each day (e.g., at the same hour for 10 to 15 minutes each day to feel refreshed, revitalized, and invigorated).

FIG 14-15 Position for resting legs and reducing edema and varicosities. Encourage the woman with vulvar varicosities to include a pillow under her hips. (Courtesy Julie Perry Nelson, Loveland, CO.)

constrictive clothing should be avoided because tight clothing over the perineum increases the risk of vaginitis and miliaria (heat rash), and impaired circulation in the legs can cause varicosities.

Maternity bras are constructed to accommodate the increased breast weight, chest circumference, and size of breast tail tissue (under the arm). A well-fitting support bra can help prevent neckache and backache.

Maternal support hose give considerable comfort and promote greater venous emptying in women with large varicose veins. Ideally, support stockings should be put on before the woman gets out of bed in the morning. Figure 14-15 demonstrates a position for resting the legs and reducing swelling and varicosities.

Comfortable shoes that provide firm support and promote good posture and balance are advisable. Very high heels and platform shoes are not recommended because of the changes in the pregnant woman's center of gravity and softening of the pelvic joints in later pregnancy which can cause her to lose her balance. In addition, in the third trimester, the woman's pelvis

FIG 14-16 Relief of muscle spasm (leg cramps). **A**, Another person dorsiflexes foot with knee extended. **B**, Woman stands and leans forward, thereby dorsiflexing foot of the affected leg. (Courtesy Shannon Perry, Phoenix, AZ.)

tilts forward, and her lumbar curve increases. The resulting leg aches and cramps are aggravated by nonsupportive shoes. Exercises to relieve leg cramps are shown in Figure 14-16.

Travel. Travel is not contraindicated in low risk pregnant women; women with high risk pregnancies are advised to avoid long-distance travel after fetal viability has been reached to avert possible economic and psychologic consequences of giving birth to a preterm infant far from home. Travel to areas in which medical care is poor, water is untreated, or malaria is prevalent should be avoided. Women who contemplate foreign travel should be aware that many health insurance carriers do not cover a birth in a foreign setting or even hospitalization for preterm labor. In addition, some vaccinations for foreign travel are contraindicated during pregnancy (e.g., BCG vaccine for tuberculosis). Pregnant women who are accustomed to living and working abroad need to seek advice from their health care provider.

Pregnant women who travel for long distances should schedule periods of activity and rest. While sitting, the woman

FIG 14-17 Proper use of seatbelt and headrest. (Courtesy Brian and Mayannyn Sallee, Anchorage, AK.)

can practice deep breathing, foot circling, and alternately contracting and relaxing different muscle groups. She should avoid becoming fatigued. Although travel in itself is not a cause of adverse outcomes such as miscarriage or preterm labor, certain precautions are recommended while traveling in a car. For example, women riding in a car should wear automobile restraints and stop to walk every hour.

Motor vehicle accidents are a major cause of maternal morbidity and mortality, second only to violence (Schwartzberg, Mahoney, & Newton, 2013). Lack of seatbelt use during pregnancy is associated with a greater risk of fetal death (Luley, Fitzpatrick, Grotegut, et al., 2013). A combination lap belt and shoulder harness is the most effective automobile restraint, and both should be used whether the mother is a driver or passenger seated in the front or back seats. The lap belt should be worn low across the pelvic bones as snugly as is comfortable. The shoulder harness should be worn above the gravid uterus and below the neck to prevent chafing (Fig. 14-17). The pregnant woman should sit upright. The headrest should be used to prevent whiplash injury. Airbags if present should remain engaged, but the steering wheel should be tilted upward, away from the abdomen and the seat moved back away from the steering wheel as much as possible.

Airline travel in large commercial jets poses little risk to a healthy pregnant woman. She is advised to inquire about restrictions or recommendations from her carrier. Most health care providers allow air travel up to 36 weeks of gestation for domestic travel and 32 to 35 weeks for international destinations in women without health- or pregnancy-related complications. Metal detectors used at airport security checkpoints emit low levels of radiation and should not pose an increased risk of harm to the fetus (CDC, 2014). Exposure to cosmic radiation while in flight is below the dose that can cause harm at any stage of gestation (Health Physics Society, 2012). The 8% humidity at which the cabins of commercial airlines are maintained can result in some water loss; hydration (with water) should therefore be maintained. Sitting in the cramped seat of an airliner for prolonged periods can increase the risk of superficial and deep vein thrombosis therefore, the woman is encouraged to take a walk around the aircraft during each hour of travel and to wear graduated compression stockings to minimize this risk (CDC).

TABLE 14-2 Discomforts Related to Pregnancy

DISCOMFORT	PHYSIOLOGY	EDUCATION FOR SELF-MANAGEMENT
First Trimester		
Breast changes: pain, tingling, tenderness, enlargement	Hypertrophy of mammary glandular tissue and increased vascularization, pigmentation, and size and prominence of nipples and areolae caused by hormonal stimulation	Wear supportive maternity bras with pads to absorb discharge, may be worn at night; wash with warm water and keep dry; breast tenderness may interfere with sexual expression or foreplay but is temporary
Urgency and frequency of urination	Vascular engorgement and altered bladder function caused by hormones; bladder capacity reduced by enlarging uterus and fetal presenting part	Empty bladder regularly; perform Kegel exercises; limit fluid intake before bedtime; wear perineal pad; report pain or burning sensation to primary health care provider
Languor and malaise; fatigue (early pregnancy, most common)	Unexplained; may be caused by increasing levels of estrogen, progesterone, and hCG or by elevated basal body temperature; psychologic response to pregnancy and its required physical and psychologic adaptations	Rest as needed; eat well-balanced diet to prevent anemia
Nausea and vomiting, also known as morning sickness, occurs in 50%-75% of pregnant women; starts between first and second missed periods and lasts until about fourth missed period; can occur any time during day; fathers also may have symptoms	Cause unknown; may result from hormonal changes, possibly hCG; may be partly emotional, reflecting pride in, ambivalence about, or rejection of pregnant state	Avoid empty or overloaded stomach; maintain good posture—give stomach ample room; stop smoking; eat dry carbohydrate on awakening; remain in bed until feeling subsides, or alternate dry carbohydrate every other hour with fluids such as hot herbal decaffeinated tea, milk, or clear coffee until feeling subsides; eat five or six small meals per day; avoid fried, odorous, spicy, greasy, or gas-forming foods; wear acupuncture bands used to treat motion sickness; ginger or acupuncture may be helpful; vitamin B6 + doxylamine (Diclegis®) may be ordered if weight loss occurs; consult primary health care provider if intractable vomiting occurs
Ptyalism (excessive salivation) can occur starting 2 to 3 weeks after first missed period	Possibly caused by elevated estrogen levels; may be related to reluctance to swallow because of nausea	Use astringent mouthwash, chew gum, eat hard candy as comfort measures
Gingivitis and epulis (hyperemia, hypertrophy, bleeding, tenderness of the gums); condition disappears spontaneously 1 to 2 months after birth	Increased vascularity and proliferation of connective tissue from estrogen stimulation	Eat well-balanced diet with adequate protein and fresh fruits and vegetables; brush teeth gently with soft toothbrush and observe good dental hygiene; avoid infection; see dentist
Nasal stuffiness; epistaxis (nosebleed)	Hyperemia of mucous membranes related to increased estrogen levels	Use humidifier; avoid trauma; normal saline nose drops or spray may be used
Leukorrhea: often noted throughout pregnancy	Hormonally stimulated cervix becomes hypertrophic and hyperactive, producing abundant amount of mucus	Not preventable; do not douche; wear perineal pads; perform hygienic practices such as wiping front to back; report to primary health care provider if accompanied by pruritus, foul odor, or change in character or color
Psychosocial dynamics, mood swings, mixed feelings	Hormonal and metabolic adaptations; feelings about female role, sexuality, timing of pregnancy, and resultant changes in life and lifestyle	Participate in pregnancy support group; communicate concerns to partner, family, and health care provider; request referral for supportive services if needed (financial assistance)
Second Trimester		
Pigmentation deepens: darkening of areola and vulva; linea nigra; melasma (mask of pregnancy), acne, oily skin	Melanocyte-stimulating hormone (from anterior pituitary)	Not preventable; usually resolves during puerperium
Spider nevi (angiomas) appear over neck, thorax, face, and arms during second or third trimester	Focal networks of dilated arterioles (end arteries) from increased concentration of estrogens	Not preventable; they fade slowly during late puerperium; rarely disappear completely
Pruritus (noninflammatory)	Unknown cause; various types: nonpapular; closely aggregated pruritic papules Increased excretory function of skin and stretching of skin possible factors	Keep fingernails short and clean; contact primary health care provider for diagnosis of cause Not preventable; use comfort measures for symptoms; distraction; tepid baths with sodium bicarbonate or oatmeal added to water; lotions and oils; change of soaps or reduction in use of soap; loose clothing; oral or topical antihistamines or topical steroid cream if recommended by health care provider
Palpitations	Unknown; should not be accompanied by persistent cardiac irregularity	Not preventable; contact primary health care provider if accompanied by symptoms of cardiac decompensation
Supine hypotension (vena cava syndrome) and bradycardia	Caused by pressure of gravid uterus on ascending vena cava when woman is supine; reduces uteroplacental and renal perfusion	Side-lying position or semi-sitting posture, with knees slightly flexed (see Emergency box: Supine Hypotension)
Faintness and, rarely, syncope (orthostatic hypotension) may persist throughout pregnancy	Vasomotor lability or postural hypotension from hormones; in late pregnancy may be caused by venous stasis in lower extremities	Moderate exercise, deep breathing, vigorous leg movement; avoid sudden changes in position and warm crowded areas; move slowly and deliberately; keep environment cool; avoid hypoglycemia by eating five or six small meals per day; wear elastic hose; sit as necessary; if symptoms are serious, contact primary health care provider
Food cravings	Cause unknown; craving influenced by culture or geographic area	Not preventable; satisfy craving unless it interferes with well-balanced diet; report unusual cravings to primary health care provider

TABLE 14-2 Discomforts Related to Pregnancy—cont'd

DISCOMFORT	PHYSIOLOGY	EDUCATION FOR SELF-MANAGEMENT
Heartburn (pyrosis or acid indigestion): burning sensation, occasionally with burping and regurgitation of a little sour-tasting fluid	Progesterone slows gastrointestinal (GI) tract motility and digestion, reverses peristalsis, relaxes cardiac sphincter, and delays emptying time of stomach; stomach displaced upward and compressed by enlarging uterus	Limit or avoid gas-producing or fatty foods and large meals; maintain good posture; sip milk for temporary relief; drink hot herbal tea; primary health care provider may prescribe antacid between meals; contact primary health care provider for persistent symptoms
Constipation	GI tract motility slowed because of progesterone, resulting in increased resorption of water and drying of stool; intestines compressed by enlarging uterus; predisposition to constipation because of oral iron supplementation	Drink 2 L (8 to 10 glasses) of water per day; include roughage in diet; engage in moderate exercise; maintain regular schedule for bowel movements; use relaxation techniques and deep breathing; do not take stool softener, laxatives, mineral oil, other drugs, or enemas without first consulting primary health care provider
Flatulence with bloating and belching	Reduced GI motility because of progesterone, allowing time for bacterial action that produces gas; swallowing air	Chew foods slowly and thoroughly; avoid gas-producing foods, fatty foods, large meals; exercise; maintain regular bowel habits
Varicose veins (varicosities): can be associated with aching legs and tenderness; can be present in legs and vulva; hemorrhoids are varicosities in perianal area	Hereditary predisposition; relaxation of smooth muscle walls of veins because of hormones causing tortuous dilated veins in legs and pelvic vasocongestion; condition aggravated by enlarging uterus, gravity, and bearing down for bowel movements; thrombi from leg varices rare but can occur in hemorrhoids	Avoid lengthy standing or sitting, constrictive clothing, and constipation and bearing down with bowel movements; moderate exercise; rest with legs and hips elevated (see Fig. 14-15); wear support stockings; thrombosed hemorrhoid may be evacuated; relieve swelling and pain with warm sitz baths, local application of astringent compresses
Headaches (through week 26)	Emotional tension (more common than vascular migraine headache); eye strain (refractory errors); vascular engorgement and congestion of sinuses resulting from hormone stimulation	Conscious relaxation; contact primary health care provider for constant "splitting" headache to assess for preeclampsia; OTC analgesics may be used if recommended by health care provider (e.g., acetaminophen)
Carpal tunnel syndrome (involves thumb, second, and third fingers, lateral side of little finger)	Compression of median nerve resulting from changes in surrounding tissues; pain, numbness, tingling, burning; loss of skilled movements (typing); dropping of objects	Not preventable; elevate affected arms; splinting of affected hand may help; regressive after pregnancy; surgery is curative
Periodic numbness, tingling of fingers (acrodysesthesia)	Brachial plexus traction syndrome resulting from drooping of shoulders during pregnancy (occurs especially at night and early morning)	Maintain good posture; wear supportive maternity bra; condition will disappear after birth if lifting and carrying baby do not aggravate it
Round ligament pain (tenderness)	Stretching of ligament caused by enlarging uterus	Not preventable; rest, maintain good body mechanics to avoid overstretching ligament; relieve cramping by squatting or bringing knees to chest; sometimes heat helps
Joint pain, backache, and pelvic pressure; hypermobility of joints	Relaxation of symphyseal and sacroiliac joints because of hormones, resulting in unstable pelvis; exaggerated lumbar and cervicotoracic curves caused by change in center of gravity resulting from enlarging abdomen	Maintain good posture and body mechanics; avoid fatigue; wear low-heeled shoes; abdominal support may be useful; conscious relaxation; sleep on firm mattress; apply local heat or ice; get back rubs; do pelvic tilt exercises; rest; condition will disappear 6 to 8 weeks after the birth
Third Trimester		
Shortness of breath and dyspnea occur in 60% of pregnant women	Expansion of diaphragm limited by enlarging uterus; diaphragm is elevated about 4 cm; some relief after lightening	Good posture; sleep with extra pillows; avoid overloading stomach; stop smoking; contact health care provider if symptoms worsen to rule out anemia, emphysema, and asthma
Insomnia (later weeks of pregnancy)	Fetal movements, muscle cramping, urinary frequency, shortness of breath, or other discomforts	Reassurance; conscious relaxation; back massage or effleurage; support of body parts with pillows; warm milk or warm shower or bath before bedtime
Psychosocial responses: mood swings, mixed feelings, increased anxiety	Hormonal and metabolic adaptations; feelings about impending labor, birth, and parenthood	Reassurance and support from significant other and health care providers; improved communication with partner, family, and others
Urinary frequency and urgency return	Vascular engorgement and altered bladder function caused by hormones; bladder capacity reduced by enlarging uterus and fetal presenting part	Empty bladder regularly; Kegel exercises; limit fluid intake before bedtime; reassurance; wear perineal pad; contact health care provider for pain or burning sensation
Perineal discomfort and pressure	Pressure from enlarging uterus, especially when standing or walking; worse with multifetal gestation	Rest, conscious relaxation, and good posture; contact health care provider for assessment and treatment if pain is present
Braxton Hicks contractions	Intensification of uterine contractions in preparation for work of labor	Reassurance; rest; change of position; practice breathing techniques when contractions are bothersome; effleurage; differentiate from preterm labor
Leg cramps (gastrocnemius spasm), especially when reclining	Compression of nerves supplying lower extremities because of enlarging uterus; reduced level of diffusible serum calcium or elevation of serum phosphorus; aggravating factors: fatigue, poor peripheral circulation, pointing toes when stretching legs or when walking, drinking more than 1 L (1 qt) of milk per day	Check for Homans sign; if negative, use massage and heat over affected muscle; dorsiflex foot until spasm relaxes (see Fig. 14-16); stand on cold surface; oral supplementation with calcium carbonate or calcium lactate tablets; aluminum hydroxide gel, 30 ml, with each meal removes phosphorus by absorbing it (consult primary health care provider before taking these remedies)
Ankle edema (nonpitting) to lower extremities	Edema aggravated by prolonged standing, sitting, poor posture, lack of exercise, constrictive clothing, or hot weather	Ample fluid intake for natural diuretic effect; put on support stockings before arising; rest periodically with legs and hips elevated (see Fig. 14-15); exercise moderately; contact health care provider if generalized edema develops; diuretics are contraindicated

Medications and Herbal Preparations. Although much has been learned in recent years about fetal drug toxicity, the possible teratogenicity of many medications, both prescription and OTC, is still unknown. This is especially true for new medications and combinations of drugs. Moreover, certain subclinical errors or deficiencies in intermediate metabolism in the fetus may cause an otherwise harmless drug to be converted into a hazardous one. The greatest danger of drug-caused developmental defects in the fetus extends from the time of fertilization through the first trimester, a time when the woman may not realize she is pregnant. Self-treatment must be discouraged. The use of all drugs, including OTC medications, herbs, and vitamins, should be limited and a careful record kept of all therapeutic and nontherapeutic agents used.

The use of complementary and alternative medicine by pregnant women is widespread (Frawley, Adams, Sibbritt, et al., 2013). There is limited research evidence about the safety of herbal preparations, especially during pregnancy. Although the use of complementary and alternative therapies is consistent with the holistic, woman-centered approach to care, caution is warranted in their use because of the lack of evidence related to their safety and efficacy.

MEDICATION ALERT

Although complementary and alternative medicine (CAM) may benefit the woman during pregnancy, some practices should be avoided because they can increase the risk for complications. It is important to ask the woman about OTC products (including herbals and vitamins) she is using.

Immunizations. Immunization with live or attenuated live viruses is contraindicated during pregnancy because of potential teratogenicity; recommended vaccination with these agents should be part of postpartum care. Live-virus vaccines include those for measles (rubeola and rubella), varicella (chickenpox), and mumps, as well as the Sabin (oral) poliomyelitis vaccine (no longer used in the United States). Vaccines that can be administered during pregnancy include combined tetanus-diphtheria-acellular pertussis (Tdap), recombinant hepatitis B, and influenza (inactivated) vaccines (CDC, 2013a).

Reported cases of pertussis (whooping cough) have increased significantly in the United States and Canada in recent years. Pertussis can cause serious and life-threatening complications in mothers and infants. To provide maximal maternal antibody response and transfer passive immunity to the infant, Tdap should be administered between 27 and 36 weeks of pregnancy. Maternal antipertussis antibodies are short lived and antibody levels drop significantly during the first year after vaccination. As a result, it is unlikely that a Tdap vaccination in one pregnancy will transfer passive immunity from mother to infant in a subsequent pregnancy. Therefore, the recommendation is to administer Tdap to a pregnant woman during each pregnancy regardless of her prior vaccination history. If Tdap is not administered during pregnancy, it should be given immediately postpartum. Adolescents and adults (parents, grandparents, siblings, child care workers, and health care personnel) who will have close contact with an infant less than 12 months of age

should receive a single dose of Tdap if not vaccinated previously (CDC, 2013e).

All women who are pregnant during the influenza season (November through March) should be offered an influenza vaccination. The injectable inactivated influenza vaccine is safe throughout pregnancy. The intranasal influenza vaccine is contraindicated during pregnancy because it contains a live virus (AAP & ACOG, 2012; CDC, 2011).

Alcohol, Cigarette Smoke, Caffeine, and Drugs. A safe level of alcohol consumption during pregnancy has not been established. Complete abstinence is strongly advised in order to avoid any risk of pregnancy complications. Maternal alcoholism is associated with high rates of miscarriage and fetal alcohol spectrum disorders (FASDs); the risk for miscarriage in the first trimester is dose related (three or more drinks per day) (CDC, 2013b).

Cigarette smoking or continued exposure to secondhand smoke (even if the mother does not smoke) is associated with IUGR and an increase in perinatal and infant morbidity and mortality. Smoking is associated with an increased frequency of preterm labor, PROM, abruptio placentae, placenta previa, and fetal death, possibly resulting from decreased placental perfusion. Smoking cessation activities should be incorporated into routine prenatal care (ACOG Committee on Obstetric Practice, 2013c). All women who smoke should be strongly encouraged to quit or at least reduce the number of cigarettes they smoke.

Caffeine crosses the placenta easily and the fetus does not produce the enzymes that inactivate caffeine. Conflicting results have been obtained in studies investigating caffeine intake and the occurrence of spontaneous abortion, preterm birth, fetal death, congenital malformations, and fetal growth restriction (Sengpiel, Elind, Bacelis, et al., 2013). Because other effects are unknown, pregnant women are advised to limit their caffeine intake, particularly coffee, because it has high caffeine content per unit of measure (see Table 15-5). The ACOG Committee on Obstetric Practice (2013b) recommends 200 mg as the recommended maximum daily intake of caffeine during pregnancy.

Any drug or environmental agent that enters the pregnant woman's bloodstream has the potential to cross the placenta and harm the fetus. Marijuana, heroin, and cocaine are common examples. Although the problem of substance abuse in pregnancy is considered a major public health concern and comprehensive care of drug-addicted women improves maternal and neonatal outcomes, few facilities are available for treatment of these women (see Chapters 32 and 35).

Normal Discomforts. Pregnant women have physical symptoms that would be considered abnormal in the nonpregnant state. They have an increased need for explanations of the causes of the discomforts and for advice on ways to relieve them. The discomforts of the first trimester are fairly specific. Information about the physiology, prevention, and self-management of discomforts experienced during the three trimesters is given in Table 14-2. Box 14-6 lists alternative and complementary therapies that may be safely used during pregnancy. Nurses can do much to allay a first-time mother's anxiety about such symptoms by telling her about them in advance and using terminology that the woman (or couple) can understand. Understanding the rationale for treatment

BOX 14-6 Alternative Therapies Used in Pregnancy**Touch and Energetic Therapies**

Massage
 Acupressure
 Therapeutic touch
 Healing touch
 Mind-body healing
 Imagery
 Meditation, prayer, reflection
 Biofeedback
 Aromatherapy

Other modalities that may fall outside of nurse practice guidelines unless the nurse has completed additional training or certification:

Herbs
 Homeopathy
 Traditional Chinese medicine

promotes their participation in their care. Interventions should be individualized, with attention given to the woman's lifestyle and culture (see Nursing Care Plan).

Recognizing Potential Complications. One of the most important responsibilities of care providers is to alert the pregnant woman to signs and symptoms that indicate a potential complication of pregnancy. The woman needs to know how and to whom to report such warning signs. She and her family should receive a printed list of warning signs, written at the appropriate literacy level and in their language, that warrant a call to the health care provider (HCP) or clinic; phone numbers for the HCP or clinic should be listed.

The nurse answers questions as they arise during pregnancy. Pregnant women often have difficulty deciding when to report signs and symptoms. The mother is encouraged to refer to the printed list of potential complications and to listen to her body. If she senses that something is wrong, she should call her care provider. Several signs and symptoms must be discussed more

NURSING CARE PLAN**Discomforts of Pregnancy and Warning Signs**

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
First Trimester			
<i>Anxiety related to deficient knowledge about schedule of prenatal visits throughout pregnancy as evidenced by woman's questions and concerns</i>	Woman will verbalize correct appointment schedule for duration of pregnancy and feelings of being "in control."	Provide information regarding schedule of visits, tests, and other assessments and interventions that will be occurring throughout pregnancy. Allow woman time to describe level of anxiety. Provide information to woman regarding prenatal classes and labor area tours.	To empower woman to function in collaboration with caregiver and diminish anxiety To establish basis for care To decrease feelings of anxiety about unknown
<i>Imbalanced Nutrition: Less Than Body Requirements related to nausea and vomiting as evidenced by woman's report and weight loss</i>	Woman will gain 1 to 2.5 kg (2.2 to 5.5 lb) during first trimester.	Verify prepregnant weight. Obtain diet history. Advise woman to consume small, frequent meals and avoid having empty stomach. Suggest that woman eat a simple carbohydrate such as dry crackers before arising in morning. Advise woman to call health care provider if vomiting is persistent and severe.	To plan realistic diet according to individual woman's nutritional needs To identify current meal patterns and foods that may be implicated in nausea To avoid further nausea episodes To avoid empty stomach and decrease incidence of nausea and vomiting To identify possible incidence of hyperemesis gravidarum
<i>Fatigue related to hormonal changes in first trimester as evidenced by woman's complaints</i>	Woman will report decreased number of episodes of fatigue.	Advise woman to rest as needed. Advise woman to eat well-balanced diet. Discuss use of support systems to help with household responsibilities. Reinforce to woman the transitory nature of first-trimester fatigue. Explore with woman a variety of techniques to prioritize roles.	To avoid increasing feeling of fatigue To meet increased metabolic demands and avoid anemia To decrease workload at home and decrease fatigue To provide emotional support To decrease family expectations

Discomforts of Pregnancy and Warning Signs

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
Second Trimester			
<i>Constipation related to progesterone influence on gastrointestinal (GI) tract as evidenced by woman's report of altered patterns of elimination</i>	Woman will report return to normal bowel elimination pattern after implementation of interventions.	<p>Provide information to woman regarding pregnancy-related causes: progesterone slowing GI motility, growing uterus compressing intestines, and influence of iron supplementation.</p> <p>Assist woman to plan diet that will promote regular bowel movements, such as increasing amount of oral fluid intake to at least 8 to 10 glasses (2 L) of water a day, increasing the amount of fiber in daily diet, and maintaining moderate exercise program.</p> <p>Reinforce for woman that she should not take any laxatives, stool softeners, or enemas without first consulting the health care provider.</p>	<p>To provide basic information for self-management during pregnancy</p> <p>To promote self-management care</p> <p>To prevent any injuries to woman or fetus</p>
<i>Readiness for Enhanced Knowledge about course of first pregnancy as evidenced by woman's questions regarding possible complications of second and third trimesters</i>	Woman will correctly list signs of potential complications that can occur during second and third trimesters and exhibit no overt signs of stress.	<p>Provide information concerning potential complications or warning signs that can occur during second and third trimesters, including possible causes of signs and importance of calling health care provider immediately.</p> <p>Provide a written list of complications.</p>	<p>To ensure identification and treatment of problems in timely manner</p> <p>To have a reference list for emergencies</p>
Third Trimester			
<i>Fear related to inexperience regarding onset and processes of labor as evidenced by woman's questions and statement of concerns</i>	Woman will verbalize basic understanding of signs of labor onset and when to call health care provider, identify resources for childbirth education, and express increasing confidence in readiness to cope with labor.	<p>Provide information regarding signs of labor onset and when to call health care provider; give written information regarding local childbirth education classes.</p> <p>Promote ongoing effective communication with health care provider.</p> <p>Provide woman with decision-making opportunities.</p> <p>Provide opportunity for woman to verbalize fears regarding childbirth.</p>	<p>To empower and promote self-management</p> <p>To promote trust and decrease fear of unknown</p> <p>To promote effective coping</p> <p>To assist in decreasing fear through discussion</p>
<i>Disturbed Sleep Pattern related to discomforts or insomnia of third trimester as evidenced by woman's report of inadequate rest</i>	Woman will report improvement of quality and quantity of rest and sleep.	<p>Assess current sleep pattern, and review need for increased requirement during pregnancy.</p> <p>Suggest change of position to side-lying with pillows between legs or to semi-Fowler position.</p> <p>Reinforce possibility of use of various sleep aids such as relaxation techniques, reading, and decreased activity before bedtime.</p>	<p>To identify need for change in sleep patterns</p> <p>To increase support and decrease any problems with dyspnea or heartburn</p> <p>To decrease possibility of anxiety or physical discomforts before bedtime</p>
<i>Ineffective Sexuality Pattern related to changes in comfort level and fatigue</i>	Woman will verbalize feelings regarding changes in sexual desire, and woman and her partner will express satisfaction with sexual activities.	<p>Assess couple's usual sexuality patterns.</p> <p>Provide information regarding expected changes in sexuality patterns during pregnancy.</p> <p>Allow couple to express feelings in nonjudgmental atmosphere.</p> <p>Refer couple for counseling as appropriate.</p> <p>Suggest alternative sexual positions.</p>	<p>To determine how patterns have been altered by pregnancy</p> <p>To correct any misconceptions</p> <p>To promote trust</p> <p>To assist couple to cope with sexuality pattern changes</p> <p>To decrease pressure on enlarging abdomen of woman and increase sexual comfort and satisfaction of couple</p>

extensively. These include vaginal bleeding, alteration in fetal movements, symptoms of gestational hypertension, rupture of membranes, and preterm labor (see Signs of Potential Complications box: First, Second, and Third Trimesters).

Recognizing Preterm Labor. Teaching each expectant mother to recognize preterm labor is necessary for early diagnosis and treatment. Preterm labor is the occurrence of uterine contractions after the twentieth week but before the thirty-seventh week of pregnancy that, if untreated, cause the cervix to open earlier than normal and result in preterm birth. Warning signs and symptoms of preterm labor are discussed in Chapter 32.

Sexual Counseling

Sexual counseling of expectant couples includes countering misinformation, providing reassurance of normality, and suggesting alternative behaviors. The uniqueness of each couple is considered within a biopsychosocial framework (see Teaching for Self-Management box: Sexuality in Pregnancy). Nurses can initiate discussion about sexual adaptations during pregnancy, based on sound knowledge about the physical, social, and emotional responses to sex during pregnancy. Not all maternity nurses are comfortable dealing with the sexual concerns of their clients. Nurses should be aware of their personal strengths and limitations in dealing with sexual content and be prepared to make referrals if necessary.

TEACHING FOR SELF-MANAGEMENT

Sexuality in Pregnancy

- Be aware that maternal physiologic changes, such as breast enlargement and tenderness, nausea, fatigue, abdominal changes, perineal enlargement, leukorrhea, pelvic vasocongestion, and orgasmic responses can affect sexuality and sexual expression.
- Discuss concerns about sexuality during pregnancy with your partner.
- Keep in mind that cultural prescriptions (“do’s”) and proscriptions (“don’ts”) can affect your attitudes and responses.
- Although your libido can be depressed during the first trimester, it often increases during the second trimester.
- Discuss and explore with your partner:
 - Alternative behaviors (e.g., mutual masturbation, foot massage, cuddling)
 - Alternative positions (e.g., female superior, side-lying) for sexual intercourse
- Intercourse is safe as long as it is not uncomfortable. There is no correlation between intercourse and miscarriage, but observe the following precautions:
 - Abstain from intercourse if you experience uterine cramping or vaginal bleeding; report these symptoms to your physician or midwife as soon as possible.
 - Abstain from intercourse (or any activity that results in orgasm) if you have a history of premature dilation of the cervix, until otherwise advised by your health care provider.
- Continue to use risk-reducing sexual behaviors. Women at risk for acquiring or conveying sexually transmitted infections should use condoms during sexual intercourse throughout pregnancy.

Many women merely need permission to be sexually active during pregnancy. Many others, however, need to be given information about the physiologic changes that occur during pregnancy, have the myths that are associated with sex during

pregnancy dispelled, and participate in open discussions of positions for intercourse that decrease pressure on the gravid abdomen (Fig. 14-18). Such tasks are within the purview of the nurse and should be an integral component of the health care rendered.

Some couples need to be referred for sex therapy or family therapy. Couples with long-standing problems with sexual dysfunction that are intensified by pregnancy are candidates for sex therapy. Whenever a sexual problem is a symptom of a more serious relationship problem, family therapy can be beneficial.

Using the History. The couple’s sexual history provides a basis for counseling, but history taking also is an ongoing process. The couple’s receptivity to changes in attitudes, body image, partner relationships, and physical status are relevant topics throughout pregnancy. The history reveals the woman’s knowledge of female anatomy and physiology and her attitudes about sex during pregnancy, as well as her perceptions of the pregnancy, the health status of the couple, and the quality of their relationship.

Countering Misinformation. Many myths and much of the misinformation related to sex and pregnancy are masked by seemingly unrelated issues. For example, a discussion about the baby’s ability to hear and see in utero can be prompted by questions about the baby being an “unseen observer” of the couple’s sexual activities. The counselor must be extremely sensitive to the concerns behind such questions when counseling in this highly charged emotional area.

Safety and Comfort During Sexual Activity. For most women, there are no restrictions on sexual intercourse during pregnancy. However, pregnant women should be aware that they are likely to experience alternations in sexual desire and comfort during sexual activity. Uterine activity can increase with sexual intercourse; this can be related to breast stimulation, orgasm, or prostaglandins in male ejaculate. For the majority of women, this is not a problem. However, a history of more than one miscarriage, a threatened miscarriage in the first trimester, impending miscarriage in the second trimester, and PROM, bleeding, or abdominal pain during the third trimester may warrant caution regarding coitus and orgasm (Gregory et al., 2012).

Solitary and mutual masturbation and oral-genital intercourse may be used by couples as alternatives to penile-vaginal intercourse. Partners who enjoy cunnilingus (oral stimulation of the clitoris or vagina) can feel “turned off” by the normal increase in the amount and odor of vaginal discharge during pregnancy. Couples who practice cunnilingus should be cautioned against the blowing of air into the vagina, particularly during the last few weeks of pregnancy when the cervix can be slightly open. An air embolism can occur if air is forced between the uterine wall and the fetal membranes and enters the maternal vascular system through the placenta.

Showing the woman or couple pictures of possible variations of coital position often is helpful (Fig. 14-18). The female-superior, side-by-side, rear-entry, and side-lying are possible alternatives to the traditional male-superior position. The woman astride (superior position) allows her to control the angle and depth of penetration, as well as to protect her breasts and abdomen. During the third trimester, the side-by-side position or any position that places less pressure on the pregnant abdomen and requires less energy will likely be preferred.

FIG 14-18 Positions for sexual intercourse during pregnancy. A, Female superior. B, Side by side. C, Rear entry. D, Facing each other.

Some women, especially multiparas, have significant breast tenderness in the first trimester. The nurse can recommend a coital position that avoids direct pressure on the breasts and decreased breast fondling during sexual activity. The woman also should be reassured that this condition is normal and temporary.

During the first and third trimesters, some women complain of lower abdominal cramping and backache after orgasm. A back rub can often relieve some of the discomfort and provide a pleasant experience. A tonic uterine contraction, often lasting up to a minute, replaces the rhythmic contractions of orgasm during the third trimester. Changes in the FHR without fetal distress also have been reported.

Risk-reduction measures against the acquisition and transmission of STIs (e.g., syphilis, gonorrhea, chlamydia, herpes simplex virus [HSV], HIV) are advised during sexual activity at all times, including during pregnancy. Because these diseases can be transmitted to the woman and her fetus, using condoms is recommended throughout pregnancy if the woman is at risk for acquiring an STI (e.g., adolescents) (AAP & ACOG, 2012).

Psychosocial Support

Esteem, affection, trust, concern, consideration of cultural and religious responses, and listening are all components of

the emotional support given to the pregnant woman and her family. The woman's satisfaction with her relationships—partner and family—and their support, her feeling of competence, and her sense of being in control are important issues to be addressed in the third trimester. A discussion of fetal responses to stimuli, such as sound and light, as well as patterns of sleeping and waking, can be helpful. Other common concerns for the pregnant woman and her partner include fear of pain, loss of control, and possible birth of the infant before reaching the hospital; anxieties about parenthood; parental concerns about the safety of the mother and unborn child; siblings and their acceptance of the new baby; social and economic responsibilities; and issues arising from conflicts in cultural, religious, or personal value systems. In addition, the woman may have concerns about the father's or partner's commitment to the pregnancy and to the couple's relationship. Providing the prospective parents with an opportunity to discuss their concerns and validating the normality of their responses can meet their needs to varying degrees. Anticipatory guidance and health promotion strategies can help partners cope with their concerns. Nurses can facilitate and encourage open dialogue between the expectant mother and her partner.

VARIATIONS IN PRENATAL CARE

The course of prenatal care described thus far may seem to suggest that the experiences of childbearing women are similar and that nursing interventions are uniformly consistent across all populations. Although typical patterns of response to pregnancy are easily recognized and many aspects of prenatal care indeed are consistent, pregnant women and their families enter the health care system with unique concerns and needs. The nurse's ability to assess unique needs and to tailor interventions to the woman and her family is the hallmark of expertise in providing care. Variations that influence prenatal care include culture, maternal age, medical and obstetric history, and number of fetuses.

Cultural Influences

All health care professionals are responsible for providing safe, evidence-based care that helps people to attain and maintain their optimal state of health. Services that are offered in a way that respects people's cultural and linguistic preferences have been demonstrated to improve the quality of health care and to reduce health disparities. The U.S. Department of Health and Human Services Office of Minority Health (2013) has developed standards for the delivery of culturally and linguistically appropriate health care; the standards can be accessed at <http://minorityhealth.hhs.gov>.

Prenatal care as we know it is a phenomenon of Western health practices. In the U.S. model of health care, women are encouraged to seek prenatal care as early as possible in pregnancy by visiting a physician or certified nurse-midwife. This recommendation not only is unfamiliar but also seems strange to women of other cultures.

Many cultural variations are found in prenatal care. Even if the prenatal care described is familiar to a woman, some practices can conflict with the beliefs and practices of a subculture

group to which she belongs. Because of these and other factors, such as lack of money, lack of transportation, and language barriers, women from diverse cultures may not seek prenatal care until late in pregnancy or they may not participate in the prenatal care system at all. A concern for modesty can be a deterrent to seeking prenatal care. For some women, exposing body parts, especially to a male, is considered a serious violation of their modesty. For many women, an invasive procedure such as a vaginal examination is so threatening that they cannot discuss it, even with their own husbands. Many women prefer a female health care provider. Too often, health care providers assume women lose this modesty during pregnancy and labor, but actually most women value and appreciate efforts to maintain their modesty.

Because pregnancy is considered a normal process and the woman is in a state of health, many cultural groups regard care from a health care professional to be necessary only in times of illness. Therefore, the services of a clinician are considered inappropriate during pregnancy. Western medicine's view of problems in pregnancy can differ from that of members of other cultural groups.

Although pregnancy is considered normal by many, certain practices are expected of women of all cultures to promote a good outcome. **Cultural prescriptions** tell women what to do, and **cultural proscriptions** establish taboos. The purposes of these practices are to prevent maternal illness resulting from a pregnancy-induced imbalanced state and to protect the vulnerable fetus. Prescriptions and proscriptions regulate the woman's emotional response, clothing, activity, rest, sexual activity, and dietary practices. Exploring her beliefs, perceptions of the meaning of childbearing, and health care practices can help health care professionals foster the woman's self-actualization, promote attainment of the maternal role, and positively influence her relationship with her partner.

To provide culturally responsive care, nurses must be knowledgeable about practices and customs, although it is not possible to know all there is to know about every culture and subculture or the many lifestyles that exist. It is important to learn about the varied cultures in the setting where each nurse practices. When exploring cultural beliefs and practices related to childbearing, the nurse can support and nurture those beliefs that promote physical or emotional adaptation. However, if potentially harmful beliefs or activities are identified, the nurse should sensitively provide education and propose modifications (see Community Activity).

Emotional Response

Virtually all cultures emphasize the importance of maintaining a socially harmonious and agreeable environment for a pregnant woman. A lifestyle with minimal stress is important in promoting positive outcomes for the mother and baby. Harmony with other people must be fostered, and visits from extended family members may be required to demonstrate pleasant and noncontroversial relationships. If discord exists in a relationship, it is usually dealt with in culturally prescribed ways.

Some cultural proscriptions involve forms of magic. For example, some Mexicans believe pregnant women should not be allowed to witness an eclipse of the moon because it can cause a cleft palate in the infant. They also believe that exposure to an earthquake can precipitate preterm birth, miscarriage, or a breech presentation. In some cultures a pregnant woman must not ridicule someone with an affliction for fear her child might be born with the same handicap. A mother should not hate a person lest her child resemble that person. Dental work should not be done during pregnancy because it may cause a baby to have a cleft lip. A folk belief widely held in many cultures is that the pregnant woman should refrain from raising her arms above her head and from tying knots because such movements tie knots in the umbilical cord and can cause it to wrap around the baby's neck. Another belief is that placing a knife under the bed of a laboring woman will "cut" her pain.

Physical Activity and Rest

Norms that regulate the physical activity of mothers during pregnancy vary tremendously. Some cultural groups encourage women to be active, to walk, and to engage in normal, although not strenuous, activities to ensure that the baby is healthy and not too large. Conversely, some groups believe that any activity is dangerous, and family members willingly take over the work of the pregnant woman, believing that this inactivity protects the mother and child. The mother is encouraged simply to produce the succeeding generation. If health care professionals are unaware of this belief, they can misinterpret their behavior as laziness or nonadherence with the desired prenatal health care regimen. It is important for the nurse to find out how each pregnant woman views activity and rest.

Clothing

Although most cultural groups do not prescribe specific clothing to be worn during pregnancy, modesty is an expectation of many. Amulets, medals, and beads are worn by women from some cultures to promote health or protect the woman and fetus from danger. For example, some Mexican women of the U.S. Southwest and women of Central America wear a cord beneath the breasts and knotted over the umbilicus. This cord, called a *muñeco*, is thought to prevent morning sickness and ensure a safe birth (Fig. 14-19).

Sexual Activity

In most cultures sexual activity is not prohibited until the end of pregnancy. Some groups view sexual activity as necessary to keep the birth canal lubricated. Others may have definite

COMMUNITY ACTIVITY

Select an immigrant or other minority group in your community and identify childbearing-related beliefs and practices that are unique to that group. Are there stores in the area that sell items that meet that group's needs? Does the community center have activities or classes that are directed toward the group? Are perinatal education programs available that provide essential information while incorporating cultural patterns? Are classes available in languages other than English? What could you, as a nurse, contribute to the community that would help meet the needs of that group?

FIG 14-19 A young woman from Honduras wearing a red muñeco given to her by her mother to ensure a safe birth. (Courtesy Dee Lowdermilk, Chapel Hill, NC.)

proscriptions against sexual intercourse, requiring abstinence throughout the pregnancy because it is thought that sexual intercourse can harm the mother and fetus.

Diet

Nutritional information given by Western health care providers can be a source of conflict for some cultural groups. Such a conflict commonly is not known by health care providers unless they understand the dietary beliefs and practices of the people for whom they are caring. For example, some religious groups have strict regulations regarding preparation of food, and if meat cannot be prepared as prescribed, they omit meats from their diets. Many cultures permit pregnant women to eat only warm foods.

Age Differences

The age of the childbearing couple can have a significant influence on their physical and psychosocial adaptation to pregnancy. Normal developmental processes that occur in both very young and older mothers are interrupted by pregnancy and require a different type of adaptation to pregnancy than that of the woman of typical childbearing age. Although the individuality of each pregnant woman is recognized, special needs of

NURSING CARE PLAN

Adolescent Pregnancy

NURSING DIAGNOSIS	EXPECTED OUTCOME	INTERVENTIONS	RATIONALES
<i>Imbalanced Nutrition: Less Than Body Requirements related to intake insufficient to meet metabolic needs of fetus and adolescent client</i>	Adolescent will gain weight as prescribed by age, take prenatal vitamins/iron as prescribed, and maintain normal hematocrit and hemoglobin.	<ul style="list-style-type: none"> Assess current diet history/intake. Compare prepregnancy weight with current weight. Provide information concerning food prescriptions for appropriate weight gain, considering preferences for "fast food" and peer influences. Include adolescent's immediate family or support system during instruction. 	<ul style="list-style-type: none"> To determine prescriptions for additions or changes in present dietary pattern To determine if pattern of weight gain is consistent with appropriate fetal growth and development To correct any misconceptions and increase chances for compliance with diet To ensure that person preparing family meals receives information
<i>Risk for Injury, maternal or fetal, related to inadequate prenatal care and screening</i>	Adolescent will experience uncomplicated pregnancy and give birth to healthy fetus at term.	<ul style="list-style-type: none"> Provide information, using therapeutic communication and confidentiality. Discuss importance of ongoing prenatal care and possible risks to adolescent client and fetus. Discuss risks of alcohol, tobacco, and recreational drug use during pregnancy. Assess for evidence of sexually transmitted infection (STI), and provide information regarding sexual practices. Screen for preeclampsia on an ongoing basis. 	<ul style="list-style-type: none"> To establish relationship and build trust To reinforce that ongoing assessment is crucial to health and well-being of client and fetus, even if client feels well. The adolescent client is more at risk for certain complications that may be avoided or managed early if prenatal visits are maintained. To minimize risks to client and fetus because adolescent clients have higher abuse rate than rest of pregnant population To minimize risk to client and fetus because adolescent is more at risk for STIs To minimize risk because adolescent population is more at risk for preeclampsia

<i>Social Isolation related to body image changes of pregnant adolescent as evidenced by client statements and concerns</i>	Adolescent will identify support systems and report decreased feelings of social isolation.	<ul style="list-style-type: none"> Establish a therapeutic relationship. Discuss with client changes in relationships that have occurred as result of pregnancy. Provide referrals and resources appropriate for developmental stage of client. Provide information regarding parenting classes, breastfeeding classes, and childbirth preparation classes. 	<ul style="list-style-type: none"> To listen objectively and establish trust To determine extent of isolation from family, peers, and baby's father To give information for client support To give further information and group support, which lessens social isolation
<i>Interrupted Family Processes related to adolescent pregnancy</i>	Adolescent will reestablish relationship with her mother and baby's father.	<ul style="list-style-type: none"> Encourage communication with mother. Encourage communication with father of baby (if she desires continued contact). Refer to support group. 	<ul style="list-style-type: none"> To clarify roles and relationships related to birth of infant To ascertain level of support to be expected of baby's father To learn more effective problem-solving methods and reduce conflict within the family
<i>Disturbed Body Image related to situational crisis of pregnancy</i>	Adolescent will verbalize positive comments regarding her body image during pregnancy.	<ul style="list-style-type: none"> Assess pregnant adolescent's perception of self related to pregnancy. Give information regarding expected body changes occurring during pregnancy. Provide opportunity to discuss personal feelings and concerns. 	<ul style="list-style-type: none"> To provide basis for further interventions To provide a realistic view of these temporary changes To promote trust and support
<i>Risk for Impaired Parenting related to immaturity and lack of experience in new role of adolescent mother</i>	Parents will demonstrate parenting roles with confidence.	<ul style="list-style-type: none"> Provide information on growth and development. Initiate discussion of child care. Assess parenting abilities of adolescent mother and father. Provide information on parenting classes that are appropriate for parents' developmental stage. Assist parents to identify pertinent support systems. 	<ul style="list-style-type: none"> To enhance knowledge so that adolescent mother can have basis for caring for her infant To assist adolescent in problem solving for future needs To provide baseline for education To enhance knowledge, obtain support, and share common feelings and concerns To give assistance with parenting as needed

expectant mothers 15 years of age or younger or those 35 years of age or older are summarized.

Adolescents

Teenage pregnancy is a worldwide problem. The United States has one of the highest teen birth rates among industrialized nations. However, the rate of teen births has declined in the United States since the 1950s. From 2011 to 2012, the teen birth rate decreased 6% to the historic low of 29.4%. Hispanic adolescents have the highest birth rate, although the rate for African-American adolescents also is high (Martin, Hamilton, Osterman et al., 2013). Most of these young women are unmarried, and many are not ready for the emotional, psychosocial, and financial responsibilities of parenthood.

Numerous adolescent pregnancy-prevention programs have had varying degrees of success. Characteristics of

programs that make a difference are those that have sustained commitment to adolescents over a long time, involve the parents and other adults in the community, promote abstinence and personal responsibility, and assist adolescents to develop a clear strategy for reaching goals such as a college education or a career.

When adolescents become pregnant and decide to give birth, they are much less likely than older women to receive adequate prenatal care, often receiving no health care at all. These young women also are more likely to smoke and less likely to gain adequate weight during pregnancy. As a result, babies born to adolescents are at greatly increased risk of LBW, of serious and long-term disability, and of dying during the first year of life (Elfenbein & Felice, 2011).

Delayed entry into prenatal care can be the result of late recognition of pregnancy, denial of pregnancy, or confusion about the available services. Such a delay in care can leave an

FIG 14-20 Pregnant adolescents review fetal development. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA).

inadequate time before birth to attend to correctable problems. The very young pregnant adolescent is at higher risk for each of the variables associated with poor pregnancy outcomes (e.g., socioeconomic factors) and for those conditions associated with a first pregnancy, regardless of age (e.g., gestational hypertension).

The role of the nurse in reducing the risks and consequences of adolescent pregnancy is to encourage early and continued prenatal care; to provide early and ongoing education about pregnancy, birth, and parenting (Fig. 14-20); and to refer the adolescent, if necessary, for appropriate social support services, which can help decrease the effects of a negative socioeconomic environment (see Nursing Care Plan). Adolescents often see the nurse as trustworthy and someone who will maintain confidentiality, as well as provide them with accurate information. Therefore, effective communication is essential in providing care to the pregnant adolescent (U.S. Department of Health and Human Services Office of Adolescent Health, 2013) (see Nursing Care Plan).

Women Older Than 35 Years

Two groups of older parents have emerged in the population of women having a child late in their childbearing years. One group consists of multiparous women who intentionally or unintentionally become pregnant in the peri-menopausal period. The other group consists of primigravidas: women who have deliberately delayed childbearing until their late 30s or early 40s and those who previously were unable to conceive due to fertility problems and became pregnant through assisted reproductive technology.

In contemporary times, women living in high-income countries who become pregnant after the age of 35 are more likely to be healthy, well educated, and of higher socioeconomic status than in previous decades. As a result, there is a greater likelihood of vaginal birth to a term infant of normal weight (Carolan & Frankowska, 2011). There is evidence that women whose first birth occurs at an older age may have some psychologic advantages such as fewer symptoms of anxiety and depression,

and they may be more resilient (McMahon, Boivin, Gibson, et al., 2011).

However, in general, pregnancy for women older than age 35 is associated with increased risk of miscarriage, stillbirth, diabetes, hypertension, placenta previa, placental abruption, and cesarean birth (Carolan & Frankowska, 2011). These women are more likely than younger primiparas to have infants with chromosomal abnormalities, LBW infants, preterm birth, and multiple gestation (Johnson & Tough, 2012).

Multiparous Women. For some multiparous women over the age of 35, pregnancy is desired, such as with a new marriage or partner. For others, it may be unplanned. Some multiparous women have never used contraceptives because of personal choice or lack of knowledge concerning contraceptives. Others may have used contraceptives successfully during the childbearing years, but as menopause approaches they cease menstruating regularly or stop using contraceptives and consequently become pregnant.

Pregnancy can bring feelings of joy as women consider continuing the maternal role and expanding the family. For some older multiparas, pregnancy can evoke feelings of isolation. She may feel that pregnancy separates her from her peer group and that her age is a hindrance to close associations with young mothers.

Primiparous Women. First-time birth rates for U.S. women over age 35 have steadily increased across all ethnicities. From 2000 to 2012, there was a 24% rise in first births among women ages 35 to 39 and a 35% increase for women ages 40 to 44 (Mathews & Hamilton, 2014).

Seeing women in their late 30s or 40s during their first pregnancy is no longer unusual for health care providers. Reasons for delaying pregnancy include a desire to obtain advanced education, career priorities, and use of better contraceptive measures. Women who are infertile do not delay pregnancy deliberately but can become pregnant at a later age as a result of fertility studies and therapies.

Many primigravidas over the age of 35 deliberately choose parenthood. They often are successfully established in a career and a lifestyle with a partner that includes time for self-attention, the establishment of a home with accumulated possessions, and freedom to travel. When asked the reason they chose pregnancy later in life, many reply, “Because time is running out.”

The dilemma of choice includes the recognition that being a parent will have positive and negative consequences. Couples should discuss the joys, responsibilities, and challenges of childbearing and childrearing before committing themselves to this lifelong venture. Partners in this group seem to share the preparation for parenthood, planning for a family-centered birth, and desire to be loving and competent parents; however, the reality of child care can prove difficult for such parents.

First-time mothers older than 35 years select the “right time” for pregnancy; this time is influenced by their awareness of the increasing possibility of infertility or of genetic defects in infants of older women. Such women seek information about pregnancy from books, friends, and electronic resources. They actively try to prevent fetal disorders and are careful in searching for the best possible maternity care. They identify sources of

stress in their lives. They have concerns about having enough energy and stamina to meet the demands of parenting and their new roles and relationships.

If older women with a history of infertility become pregnant through assisted reproductive technology, they can suddenly have negative or ambivalent feelings about the pregnancy. They can experience a multifetal pregnancy that can create emotional and physical problems. Adjusting to parenting two or more infants requires adaptability and additional resources.

During pregnancy parents explore the possibilities and responsibilities of changing identities and new roles. They must prepare a safe and nurturing environment during pregnancy and after birth. They must integrate the child into an established family system and negotiate new roles (parent roles, sibling roles, grandparent roles) for family members.

Adverse perinatal outcomes are more common in older primiparas than in younger women, even when they receive good prenatal care. The occurrence of these complications is quite stressful for the new parents, and nursing interventions that provide information and psychosocial support are needed, as well as care for physical needs.

Multifetal Pregnancy

With the increased use of assistive reproductive technology and ovulation induction agents, the incidence of multifetal pregnancy has risen (AAP & ACOG, 2012). In the United States, the twin birth rate has stabilized at 33.1 per 1000 live births. The birth rate for triplets and higher order multiples is 124.4 per 1000 live births; this is a drop from 153.5 per 1000 live births in 2009 (Martin, Hamilton, Osterman, et al., 2013).

A multifetal pregnancy, or pregnancy with more than one fetus, places the mother and fetuses at increased risk for adverse outcomes. The maternal blood volume is increased, resulting in an increased strain on the maternal cardiovascular system. Anemia often develops because of a greater demand for iron by the fetuses. Marked uterine distention, increased pressure on the adjacent viscera and pelvic vasculature, and diastasis of the rectus abdominis muscles can occur (see Fig. 13-13). Women are at increased risk for gestational diabetes, hypertension, and preeclampsia (AAP & ACOG). Placenta previa develops more commonly in multifetal pregnancies because of the large size or placement of the placentas. Premature separation of the placenta can occur before the second and any subsequent fetuses are born (Gilbert, 2011).

Multifetal pregnancies often end prematurely. The risk of preterm labor and birth increases with the number of fetuses. Spontaneous rupture of membranes is common. Fetuses are likely to experience growth restriction or discordant growth. There can be local shunting of blood between placentas (twin-to-twin transfusion); this causes the recipient twin to be larger and the donor twin to be small, pallid, dehydrated, malnourished, and hypovolemic. However, the larger twin can develop congenital heart failure during the first 24 hours after birth. The risk of death of one or more fetuses increases significantly with higher order multiples (Newman & Unal, 2012).

If the presence of more than three fetuses is diagnosed, parents may receive counseling regarding selective reduction to reduce the incidence of premature birth and improve the opportunities for the remaining fetuses to grow to term

gestation (ACOG Committee on Ethics, 2013). This situation poses an ethical dilemma for many couples, especially those who have worked hard to overcome problems with infertility and have strong values regarding right to life. Nurses can initiate discussions with couples to help them identify resources (e.g., a minister, priest, rabbi, or mental health counselor) to aid in the decision-making process (see Chapter 37).

The likelihood of a multifetal pregnancy is increased if any one or a combination of the following factors is noted during a careful assessment:

- History of dizygotic twins in the female lineage
- Use of fertility drugs
- More rapid uterine growth for the number of weeks of gestation
- Polyhydramnios (excessive amt amniotic fluid in sac)
- Palpation of more than the expected number of small or large fetal parts
- Asynchronous fetal heartbeats or more than one fetal electrocardiographic tracing
- Ultrasound evidence of more than one fetus

The diagnosis of multifetal pregnancy comes as a shock to many expectant parents. They need additional support and education to help them cope with the changes they face.

The prenatal care for women with multifetal pregnancies includes changes in the pattern of care and modifications in other aspects. Prenatal visits are scheduled more frequently. Frequent ultrasound examinations, nonstress tests, and FHR monitoring will be performed. The mother needs information related to self-management of a multifetal pregnancy because guidelines differ in comparison with a singleton pregnancy. Specific instruction should be provided regarding nutrition so that she consumes a well-balanced diet with adequate caloric intake and gains weight appropriately. Other pertinent information includes maternal adaptations during pregnancy, management of discomforts, and the risk of preterm labor and birth, including warning signs and when to call the provider. The uterine distention associated with multifetal pregnancy can cause the backache commonly experienced by pregnant women to be even worse. Maternal support hose may be worn to control leg varicosities. If risk factors such as premature dilation of the cervix or bleeding are present, abstinence from orgasm and nipple stimulation during the last trimester is recommended to help avert preterm labor. Some practitioners recommend bed rest beginning at 20 weeks in women carrying multiple fetuses to prevent preterm labor. Other practitioners question the value of prolonged bed rest. If bed rest is recommended, the mother assumes a lateral position to promote increased placental perfusion. If birth is delayed until after the thirty-sixth week, the risk of morbidity and mortality decreases for the neonates.

Multiple newborns can place a strain on finances, space, workload, and the woman's and family's coping capabilities. Lifestyle changes can be necessary. Parents need assistance in making realistic plans for the care of the infants (e.g., whether to breastfeed and whether to raise them as "alike" or as separate people). Parents should be referred to national organizations such as Parents of Twins and Triplets (www.nashvilleparents.com/directories/parents-of-twins-and-triplets-organization-potato), Mothers of Twins and Triplets (www.nomotc.org), and the La Leche League (www.llli.org) for further support.

PERINATAL EDUCATION

The goal of perinatal education is to assist women and their family members to make informed, safe decisions about pregnancy, labor and birth, infant care, and early parenthood. It also is to assist them to comprehend the long-lasting potential that empowering birth experiences have in the lives of women and that early experiences have on the development of children and the family.

Classes for Expectant Parents

The perinatal education program is an expansion of the earlier childbirth education movement that originally offered a set of classes in the third trimester of pregnancy to prepare parents for birth. Today perinatal education programs consist of a menu of class series and activities from preconception through the early months of parenting.

Expectant parents and their families have different interests and information needs as the pregnancy progresses. Parents may select a variety of classes such as:

- Early pregnancy (“early bird”) classes provide fundamental information including (1) early fetal development, (2) physiologic and emotional changes of pregnancy, (3) human sexuality, and (4) the nutritional needs of the mother and fetus. The classes often address environmental and workplace hazards. Exercises, nutrition, warning signs, drugs, and self-medication also are topics of interest and concern.
- Midpregnancy classes emphasize the woman’s participation in self-management. Classes provide information on preparation for breastfeeding and formula feeding, infant care, basic hygiene, common discomforts and simple safe remedies, infant health, parenting, and planning for labor and birth.
- Late pregnancy classes emphasize different methods of coping with labor and birth, and these are often the basis for various prenatal classes. These include Lamaze, Bradley, and Dick-Read. These classes usually include a tour of the birthing facility. Because fear of pain in labor is a key issue for many women, childbirth preparation classes provide information on management of discomfort during labor and birth. Topics include nonpharmacologic methods to reduce discomfort such as relaxation and breathing techniques, imagery and visualization, and biofeedback. Pharmacologic interventions such as intravenous medications and epidural analgesia are also discussed. An emphasis on nonpharmacologic pain management strategies helps couples manage the labor and birth with dignity and increased comfort. Most instructors teach a flexible approach, which helps couples learn and master many techniques to use during labor (see Chapter 17 for further discussion).
- Perinatal education programs offer classes to meet specific learning needs. These include classes for adolescents, first-time mothers older than age 35, single women, adoptive parents, parents of multiples, or women with special needs such as those with visual or hearing impairments. In some agencies, classes are also offered in languages other than English. Refresher classes for parents with children not only review coping techniques for labor and birth but also help couples prepare for sibling reactions and adjustments to a new baby. Cesarean birth classes are available for couples who have this

FIG 14-21 Learning relaxation exercises in a family-centered childbirth education class. (Courtesy Marjorie Pyle, RNC, Life-circle, Costa Mesa, CA).

kind of birth scheduled because of breech presentation or other risk factors. Other classes focus on vaginal birth after cesarean (VBAC) because many women can successfully give birth vaginally after previous cesarean birth.

For the most part, the pregnant woman and her partner attend perinatal education classes, although sometimes a friend or parent is the designated support person (Fig. 14-21). There are also classes for grandparents and siblings to prepare them for their attendance at birth or the arrival of the baby. Siblings often see a film about birth and learn ways they can help welcome the baby. They also learn to cope with changes that include a reduction in parental time and attention. Grandparents learn about current child care practices and how to help their adult children adapt to parenting in a supportive way.

Perinatal classes include discussion of support systems that people can use during pregnancy, labor and birth, and in the postpartum period. Such support systems help parents function independently and effectively. During all the classes the open expression of feelings and concerns about any aspect of pregnancy, birth, and parenting is welcomed. Perinatal education is focused on health promotion and emphasizes how a healthy body is best able to adapt to the changes that accompany pregnancy. Without this context of health, routine care and testing for risks can contribute to a mindset of families that pregnancy is a state of illness as opposed to a healthy mind-body-spirit event.

Some of the decisions the childbearing family must consider are the decision to have a baby, followed by choices of a health care provider and type of care (a midwifery model [natural oriented] versus a medical [intervention oriented] model); the place for birth (hospital, birthing center, home); the type of infant feeding (breast or formula); and infant care. If a woman has had a cesarean birth, she may consider having a vaginal birth. Perinatal education can provide information to help childbearing families make informed decisions about these issues.

Previous pregnancy and childbirth experiences are important influences on current learning needs. The woman’s (and support person’s) age, cultural background, personal philosophy with regard to labor and birth, socioeconomic status, spiritual beliefs, and learning styles are assessed to develop the best plan to help the woman meet her needs.

PERINATAL CARE CHOICES

Often the first decision the woman makes is to select her primary health care provider for the pregnancy and birth. This decision usually affects where the birth will take place. The nurse can provide information about the different types of obstetric health care providers and the kind of care to expect from each one. Women are encouraged to ask potential care providers a series of pertinent questions (Box 14-7).

Physicians

According to the National Center for Health Statistics (NCHS), physicians (obstetricians, family medicine physicians, osteopathic physicians) attended 92% of hospital births and 5% of home births in the United States (MacDorman, Mathews, & Declercq, 2014). Family practice physicians and osteopathic physicians provide care for primarily low risk pregnant women and refer high risk women to obstetricians. Obstetricians see low risk and high risk pregnant women. Care often includes pharmacologic and medical management of problems as well as use of technologic procedures.

Midwives

Increasing numbers of pregnant women are choosing certified nurse-midwives (CNM) and certified midwives (CM) as their obstetric care providers. From 2005 to 2012, there was a 6% increase in CNM/CM attended births, accounting for 7.6% of all hospital births and 30.4% of out-of-hospital births. Out-of-hospital births attended by CNMs and CMs occurred in freestanding birth centers (2.55%) and homes (2.47%) (Martin, Hamilton, Osterman, et al., 2013).

The midwifery model of care emphasizes the natural ability of women to experience pregnancy, labor, and birth with minimal intervention. Compared with the medical model of care, midwifery care throughout pregnancy, labor, and birth is associated with benefits for mothers and babies. These include reduced use of epidurals and fewer episiotomies and instrument-assisted births. Midwifery care is associated with an increased likelihood of spontaneous vaginal birth (Sandall, Solntani, Gates, et al., 2013).

The services provided by midwives are dependent on their licensing and certification as well as the practice regulations in each state. Women who are interested in midwifery care should be knowledgeable about the various types of midwives, the care that is available, where they are allowed to practice and attend births, and reimbursement by insurance companies.

In the United States there are three types of credentialed professional midwives: certified nurse midwives (CNM), certified midwives (CM), and certified professional midwives (CPM). CMs and CPMs are known as direct-entry midwives. CNMs are legally approved to practice in all 50 states and the District of Columbia. Fewer states allow CMs and CPMs to practice.

Certified Nurse-Midwives

Certified nurse-midwives (CNM) are registered nurses with education in the two disciplines of nursing and midwifery. They are certified by the American College of Nurse-Midwives (ACNM). Nurse-midwifery programs are graduate level; since 2010, ACNM has mandated that entry into practice requires at least a master's degree. CNMs are trained to provide women's health

BOX 14-7 Questions to Ask When Seeking a Maternity Care Provider

The Coalition for Improving Maternity Services (CIMS, 2013), a group of more than 50 nursing and maternity care-oriented organizations, produced a document to assist women in selecting their perinatal care. After some explanation of choices, the nurse can encourage women to ask potential care providers the following questions:

- Who can be with me during labor and birth?
- What happens during a normal labor and birth in your setting?
- How do you allow for differences in culture and beliefs?
- May I walk and move around during labor? What position do you suggest for birth?
- How do you make sure everything goes smoothly when my nurse, doctor, nurse-midwife, or agency works with one another?
- What things do you normally do to a woman in labor?
- How do you help mothers stay as comfortable as they can be? Besides drugs, how do you help mothers relieve the pain of labor?
- What if my baby is born early or has special problems?
- Do you circumcise babies?
- How do you help mothers who want to breastfeed?

Modified from Coalition for Improving Maternity Services (CIMS). (2000). *Having a baby? 10 questions to ask*. Available at www.motherfriendly.org/Resources/Documents/Having_a_Baby-English.pdf.

care throughout the lifespan, not just during pregnancy and birth. Nurse-midwives practice collaboratively with physicians or independently with an arrangement for physician backup. They usually see low risk women. Care is often noninterventionist, and the woman and her family are encouraged to be active participants in the care. Certified nurse-midwives co-manage and/or refer pregnant women with complications to physicians.

Direct-Entry Midwives

Certified midwives (CM) are trained in midwifery schools, colleges, or universities. A nursing degree is not required, although a bachelor's degree and specific health and science courses are required prior to entering a CM training program. Certified midwives are credentialed by the ACNM based on a certification examination; a graduate degree is required for entry into practice.

Certified professional midwives (CPM) meet the standards of certification set by the North American Registry of Midwives (NARM) in collaboration with Midwives Alliance of North America (MANA). They are educated in midwifery programs in colleges, universities, or midwifery schools, or through self-study and apprenticeship.

Traditional or Lay Midwives

Independent or *lay midwives* are also known as traditional or community-based midwives. These midwives are not certified. They are usually trained through self-study and apprenticeship. It is up to the woman seeking care from a lay midwife to assess the level of experience and expertise of a lay midwife. Lay midwives can legally practice and are licensed in some states, although there are specific requirements and guidelines that must be followed. Care by lay midwives is usually not covered by third-party payers.

Doulas

A **doula** is trained to provide physical, emotional, and informational support to women and their partners during labor and birth. The doula does not become involved with clinical tasks. Today many couples, no matter which type of childbirth classes they take, also use a doula for labor support.

Continuous labor support provided by a doula has been shown to decrease the use of pain medication, increase satisfaction, and increase the likelihood of a spontaneous vaginal birth. There are no known risks associated with labor support by a doula (Hodnett, Gates, Hofmeyr, & Sakala, 2012).

A doula typically meets with the woman and her husband or partner before labor. At this meeting she ascertains the woman's expectations and desires for the birth experience. With this information as her guide during labor and birth, the doula focuses her efforts on assisting the woman to achieve her goals. Doulas work collaboratively with other health care providers and the husband or other supportive individuals, but their primary goal is to assist the woman. Doulas who are also trained medical interpreters can enhance the care of women with limited English proficiency (Maher, Crawford-Carr, & Neidigh, 2012).

Doulas can be found through community contacts, health care providers, or childbirth educators; a number of organizations offer information or referral services. It is important that the expectant mother is comfortable with the doula who will be attending her. (See Box 14-8 for a list of questions to ask when arranging for a doula.) Doula International (DONA) is an organization that certifies doulas (www.dona.org). Although the doula role originally developed as an assistant during labor, some women benefit from assistance during the postpartum period. There are small but growing numbers of postnatal doulas who provide assistance to the new mother as she develops competence with infant care, feeding, and other maternal tasks.

BOX 14-8 Questions to Ask When Choosing a Doula

To discover the specific training, experience, and services offered by anyone who provides labor support, potential clients, nursing supervisors, physicians, midwives, and others should ask the following questions of that person:

- What training have you had?
- Tell me about your experience with birth, both personally and as a doula.
- What is your philosophy about childbirth and supporting women and their partners through labor?
- May we meet to discuss our birth plans and the role you will play in supporting me through childbirth?
- May we call you with questions or concerns before and after the birth?
- When do you try to join women in labor? Do you come to our home or meet us at the hospital?
- Do you meet with us after the birth to review the labor and answer questions?
- Do you work with one or more backup doulas for times when you are not available? May we meet them?
- What is your fee?

Adapted from Doula International. (2012). *Position paper: The birth doula's contribution to modern maternity care*. Available at www.dona.org/pdfs/position_papers/BIRTH%20Paper-%204%20page.pdf.

Birth Plans

The **birth plan** is a natural evolution of a contemporary wellness-oriented lifestyle in which women assume a level of responsibility for their own health. The birth plan is a tool with which parents can explore their childbirth options and choose those that are most important to them. The plan must be viewed as tentative because the realities of what is feasible may change as the actual labor and birth unfold. It is understood to be a preference list based on a best-case scenario.

It is useful for the nurse in a prenatal practice setting to initiate a discussion of choices and birth planning during the first and second prenatal visits. Some maternity practices provide printed material describing available options and giving answers to commonly asked questions, and tours of the birth setting are offered by almost all birthing facilities. The nurse can provide couples with pertinent information and make them aware of the various options for care and the advantages and consequences of each so they can begin making informed decisions. Early plans can be modified as the couple learns more details in their childbirth classes. Topics for the expectant parents to consider when creating a birth plan are listed in Box 14-9.

The birth plan can serve as a means of open communication between the pregnant woman and her partner and between the couple and health care providers. An early introduction to the idea of a birth plan allows the couple time to think about events or situations that could make their childbearing experience more meaningful and those they would prefer to avoid (Anderson & Kilpatrick, 2012).

BOX 14-9 Creating a Birth Plan

Topics for birth plan discussion and decision making may include any or all of the following:

Partner's participation: Attend prenatal visits? Childbirth and parent education classes? Present during labor? During birth? During cesarean birth?

Birth setting: Hospital delivery room or birthing room (if available)? A birthing center? Home?

Labor management: Walk around during labor? Use a rocking chair? Use a shower? Use a Jacuzzi, if available? Intermittent versus continuous use of an electronic fetal monitor? Have music or dimmed lighting? Have older children or other people present? Is telemetry monitoring available? Consider stimulation of labor? Consider medication—what kind?

Birth: Positions—Side-lying? On hands and knees, kneeling, or squatting? Use a birthing bed or delivery table? Will you be photographing, videotaping, or recording any of the labor or birth? Who would you like to be present—partner, older siblings, other family members, or friends? What do you know about the use of forceps? Episiotomy? Will your partner want to cut the umbilical cord? Emergency considerations/contingencies (e.g., cesarean)?

Immediately after birth: Do you want to hold the baby skin-to-skin right away? Breastfeed immediately?

Postpartum care: What kind of care do you anticipate—labor, delivery, recovery, postpartum room; mother-baby couplet care? How long does your insurance company provide coverage for you to stay? Would you like to attend self-management classes, or do you prefer to get such information from media sources? On which subjects?

Traditionally, birth plans are created prenatally and implemented on admission to the labor and birth unit. However, when women without predesigned birth plans are admitted, nurses can use a template with simple questions about preferences for care to help them develop a simple birth plan (Anderson & Kilpatrick, 2012). This is in accordance with the Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) position statement on nursing support of laboring women, specifically creating individualized care plans for laboring women based on their needs, desires, and expectations (AWHONN, 2011).

Birth Setting Choices

With careful thought the concept of natural or family- or woman-centered maternity care can be implemented in any setting. The three primary options for birth settings are the hospital, free-standing birth center, and home. Women consider several factors in choosing a setting for birth, including the preference of their health care provider, characteristics of the birthing unit, and reimbursement by third party payors.

While the majority of births occurs in hospital settings, there has been an increase in out-of-hospital births from 0.87% in 2004 to 1.36% in 2012. Of those births, 66% were at home, 29% occurred in free-standing birth centers, and the remaining 5% took place in a physician's office, clinic, or other location (MacDorman, Mathews, & Declercq, 2014).

Hospital

The types of labor and birth services in hospital settings vary greatly, from the traditional labor and delivery rooms with separate postpartum and newborn units to in-hospital birthing centers where all or almost all care takes place in a single unit.

Labor, delivery, and recovery (LDR) and labor, delivery, recovery, and postpartum (LDRP) rooms offer families a comfortable, private space for labor and birth (Fig. 14-22). Women are admitted to LDR units, labor and give birth, and spend the first 1 to 2 hours postpartum there for immediate recovery and to have time with their families to bond with their newborns. After this period, the mothers and newborns move to a postpartum unit and nursery or mother-baby unit for the duration of their stay.

In LDRP units, the same nursing staff usually provides total care from admission through postpartum discharge. The woman and her family may stay in this unit for 6 to 48 hours after giving birth. The units are furnished to provide a homelike atmosphere, as LDR units are, but have accommodations for family members to stay overnight (see Fig. 14-22, A).

Both units have fetal monitors, emergency resuscitation equipment for mother and newborn, and heated cribs or warming units for the newborn. Often this equipment is out of sight in cabinets or closets when it is not being used (see Fig. 14-22, B).

Birth Centers

Free-standing birth centers are usually built in locations separate from the hospital but are often located nearby so that quick transfer of the woman or newborn can occur when needed. These birth centers offer families a safe and cost-effective alternative to hospital or home birth. The centers are usually staffed by CNMs or physicians who also have privileges at the local hospital. Only women at low risk for complications are included for care.

Birth centers typically have homelike accommodations, including a double bed for the couple and a crib for the newborn (Fig. 14-23, A). Emergency equipment and drugs are usually in cabinets, out of view but easily accessible. Private bathroom facilities are incorporated into each birth unit. There may be an early labor lounge or a living room and small kitchen (see Fig. 14-23, B). The family is admitted to the birth center for labor and birth and will remain there until discharge, which often takes place within 6 hours of the birth.

Services provided by the free-standing birth centers include those necessary for safe management of low risk pregnant women during the childbearing cycle. Attendance at birthing and parenting classes is required of all clients. Expectant families develop birth plans. They must understand that some situations require transfer to a hospital, and they must agree to abide by those guidelines.

Birth centers and hospitals with comprehensive birthing programs usually provide resources for parents such as a lending library that includes books and DVDs, reference files on related topics, and supplies and reference materials for child-birth educators. The centers may also have referral files for community resources that offer services relating to birth and early parenting, including support groups (e.g., for single parents, for

FIG 14-22 Labor, delivery, recovery, and postpartum (LDRP) units. (A, Courtesy Dee Lowdermilk, Chapel Hill, NC. B, Courtesy Mercy Hospital, St. Louis, MO.)

FIG 14-23 Birth center. **A**, Note double bed, baby crib, and birthing stool. **B**, Lounge and kitchen. (**A**, Courtesy Dee Lowdermilk, Chapel Hill, NC. **B**, Courtesy Michael S. Clement, MD, Mesa, AZ. Photo location: Bethany Birth Center, Phoenix, AZ.)

postbirth support, and for parents of twins), genetic counseling, women's issues, and consumer action.

Ambulance service and emergency procedures must be readily available. Fees vary with the services provided by birthing centers but typically are less than or equal to those charged by local hospitals. Some base fees on the ability of the family to pay (a reduced-fee sliding scale). Several third-party payers, as well as Medicaid and the Civilian Health and Medical Programs of the Uniformed Services (TRICARE/CHAMPVA, recognize and reimburse these centers.

Home Birth

Home birth has always been popular in certain countries, such as the Netherlands. In developing countries, hospitals or adequate lying-in facilities often are unavailable to most pregnant women, and home birth is a necessity. Although the number of home births in the United States has increased in recent years,

still less than 1% of all births takes place in the home (MacDorman et al., 2014).

Home birth remains a controversial topic in American health care. Organizations such as the ACOG and the American Medical Association (AMA) agree that the safest setting for birth is a hospital or birthing center that meets standards set forth by AAP and ACOG or a free-standing birth center that meets standards of the Accreditation Association for Ambulatory Health Care (ACOG Committee on Obstetric Practice, 2011; AMA, 2008). ACOG emphasizes the need to inform women considering planned home birth about risks and benefits; although they note that absolute risk may be low, they cite a two- to threefold increased risk for neonatal death with home birth compared with planned hospital birth (ACOG Committee on Obstetric Practice). Research findings based on cohort and observational studies do not support this stance. Large-scale studies have documented the safety of planned home birth for healthy, low risk women who are attended by CNMs and when there is a system in place for transfer to a hospital facility (Cheyney, Bovbjerg, Everson, et al., 2014; Cox, Schlegel, Payne, et al., 2013; McIntyre, 2012). The National Perinatal Association (2008) and the American College of Nurse-Midwives (ACNM, 2011) support planned home birth for carefully selected low risk women within a system that provides hospitalization as needed.

In response to the increase in home births, opponents are disseminating documentation about the risks of home births for mother and infant and actively discouraging families from choosing a home birth when there are safe and compassionate hospitals and birth centers available (Chervenak, McCullough, Brent, et al., 2013). National groups supporting home birth are the Home Oriented Maternity Experience (HOME) and the National Association of Parents for Safe Alternatives in Childbirth (NAPSAC). These groups work to foster more humane childbearing practices at all levels, integrating the alternatives for childbirth to meet the needs of the total population.

There are advantages of planned home birth. The family is in control of the experience. The birth may be more physiologically normal in familiar surroundings. The mother may be more relaxed than she would be in the hospital environment. Care providers who participate in home births tend to be more support oriented and less intervention oriented. The family can assist in and be a part of the happy event, and contact with the newborn is immediate and sustained. In addition, home birth may be less expensive than a hospital or birth center. Serious infection may be less likely, assuming strict aseptic principles are followed, because people generally are relatively immune to their own home bacteria.

KEY POINTS

- The prenatal period is a preparatory one both physically, in terms of fetal growth and parental adaptations, and psychologically, in terms of anticipation of parenthood.
- Pregnancy affects parent-child, sibling-child, and grandparent-child relationships.
- Discomforts and changes of pregnancy can cause anxiety for the woman and her family and require sensitive attention and a plan for teaching self-management measures.
- Education about safety during activity and exercise is essential given maternal anatomic and physiologic responses to pregnancy.
- Important components of the initial prenatal visit include detailed and carefully documented findings from the interview, a comprehensive physical examination, and selected laboratory tests.

KEY POINTS—cont'd

- Follow-up visits are shorter than the initial visit and are important for monitoring the health of the mother and fetus and providing anticipatory guidance as needed.
- Even in normal pregnancy the nurse must remain alert to hazards such as supine hypotension, signs and symptoms of potential complications, and signs of family maladaptations.
- Blood pressure is evaluated based on absolute values and length of gestation and interpreted in light of modifying factors.
- Each pregnant woman needs to know how to recognize and report signs of potential complications such as preterm labor.
- There is an increased incidence of physical, mental, and verbal abuse during pregnancy.
- Culture, age, parity, and multifetal pregnancy can have a significant effect on the course and outcome of the pregnancy.
- Nurses must ask pregnant women and their families about preferences, practices, and customs related to childbearing to provide culturally sensitive care.
- Childbirth education teaches tuning in to the body's inner wisdom and strategies that enhance women's ability to cope effectively with labor and birth.
- Perinatal education strives to promote healthier pregnancies and family lifestyles.
- Nurses can assist pregnant women and their families to make informed decisions about care providers, birth settings, and labor support.

Maternal and Fetal Nutrition

Mary Courtney Moore

<http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Discuss recommendations for maternal weight gain during pregnancy.
- Compare the recommended level of intake of energy sources, protein, and key vitamins and minerals during pregnancy and lactation.
- Give examples of the food sources that provide the nutrients required for optimal maternal nutrition during pregnancy and lactation.
- Examine the role of nutritional supplements during pregnancy.
- List nutritional risk factors during pregnancy.
- Analyze examples of eating patterns of women from two different ethnic or cultural backgrounds, and identify potential dietary concerns. Assess nutritional status during pregnancy.
- Discuss nutritional considerations for pregnant women who are obese and those who have had bariatric surgery.
- Describe food safety precautions for pregnant women.

Nutrition is one of the many factors that influence the outcome of pregnancy (Fig. 15-1). However, maternal nutritional status is an especially significant factor because it is potentially alterable and because good nutrition before and during pregnancy is an important preventive measure for a variety of problems. These problems include birth of low birth weight (LBW) (birth weight of 2500 g or less) and preterm infants. Evidence is growing that a mother's nutrition and lifestyle affect the long-term health of her children. Thus the importance of good nutrition must be emphasized to all women of childbearing potential. Key components of nutritional care during the preconception period and pregnancy include (Harnisch, Harnisch, & Harnisch, 2012):

- Nutrition assessment that includes appropriate weight for height, adequacy and quality of dietary intake and habits, and preexisting issues that can affect nutritional status and planning, such as maternal phenylketonuria (PKU) or smoking
- Diagnosis of nutrition-related problems or risk factors such as diabetes and obesity
- Interventions based on an individual's dietary goals and plan to promote appropriate weight gain, ingestion of a variety of foods, appropriate use of dietary supplements, and physical activity
- Evaluation as an integral part of the nursing care provided to women during the preconception period and pregnancy, with referral to a nutritionist or dietitian as necessary.

NUTRIENT NEEDS BEFORE CONCEPTION

The first trimester of pregnancy is crucial in terms of embryonic and fetal organ development. A healthful diet before

conception is the best way to ensure that adequate nutrients are available for the developing fetus. Folate or folic acid intake is of particular concern in the periconception period. Folate is the form in which this vitamin is found naturally in foods, and folic acid is the form used to fortify grain products and other foods and vitamin supplements. Neural tube defects (NTDs), or failures in closure of the neural tube, are more common in infants of women with poor folic acid intake. Proper closure of the neural tube is required for normal formation of the spinal cord, and the neural tube begins to close within the first month of gestation, often before the woman realizes that she is pregnant. Therefore, all adolescents and women who are capable of becoming pregnant should take 0.4 mg of folic acid every day, in addition to consuming dietary sources of folate (Box 15-1). During pregnancy the supplement is increased to 0.6 mg daily. A woman who has had a pregnancy involving a child with NTD should take a 4.0-mg folic acid supplement daily even if not planning another pregnancy. If she decides to become pregnant, she should consult with her health care provider before conception to determine whether a larger supplement is advisable (Centers for Disease Control and Prevention [CDC], 2012).

Maternal and fetal risks in pregnancy are increased when the mother is significantly underweight or overweight when pregnancy begins. Moreover, the child born to a woman who is obese during pregnancy is more likely to be obese and diabetic as an adult. Overweight and obese women who lose weight before pregnancy are likely to have healthier pregnancies (Box 15-2). Counseling in regard to healthy diet and lifestyle

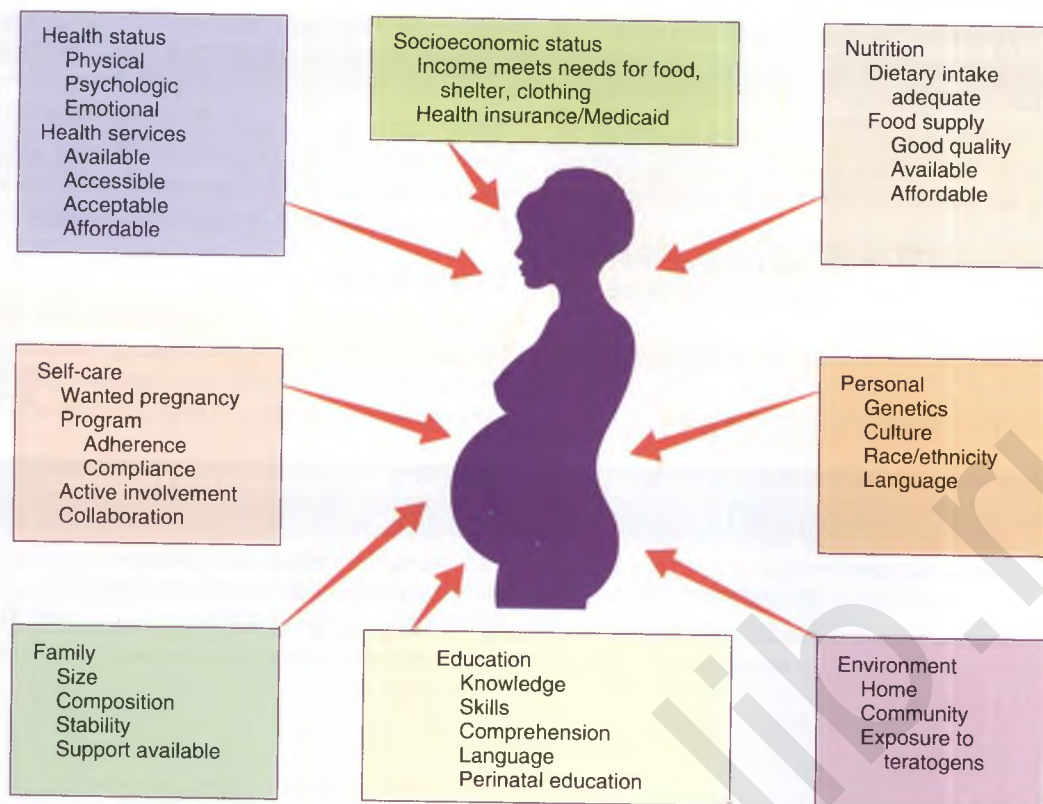

FIG 15-1 Factors that influence the outcome of pregnancy.

BOX 15-1 Food Sources of Folate*

Foods Providing 500 mcg or More per Serving

- Liver: chicken, turkey, goose (100 g [3.5 oz])

Foods Providing 200 mcg or More per Serving

- Liver: lamb, beef, veal (100 g [3.5 oz])
- Rice, enriched, cooked (1 cup)
- Breakfast cereals, ready-to-eat, fortified (1 cup)

Foods Providing 100 mcg or More per Serving

- Legumes, cooked (½ cup)
 - Peas: black-eyed, chickpea (garbanzo)
 - Beans: black, kidney, pinto, red, navy
 - Lentils
- Vegetables (½ cup)
 - Asparagus
 - Spinach, cooked
- Papaya (1 medium)
- Wheat germ (¼ cup)

Foods Providing 50 mcg or More per Serving

- Vegetables (½ cup)
 - Broccoli
 - Beans: lima beans, baked beans, or pork and beans
 - Greens: collards or mustard, cooked
 - Okra, cooked
 - Spinach, raw
- Fruits (½ cup)
 - Avocado
 - Orange or orange juice
- Pasta, cooked (1 cup)

Foods Providing 20 mcg or More per Serving

- Bread (1 slice)
- Egg (1 large)
- Corn (½ cup)

*See www.nutrition.gov/whats-food for additional food sources of folate.

BOX 15-2 Bariatric Obstetric Care

Obstetricians are seeing more morbidly obese pregnant women, including women who weigh over 250 kg (550 lb). Obesity creates many risks for pregnant women, including hypertension, thromboembolic complications, diabetes, and preterm birth. To manage their conditions and to meet their logistical needs, a new medical subspecialty—bariatric obstetrics—has arisen. Extra-wide blood pressure cuffs, scales that can accommodate up to 400 kg (880 pounds), and extra-wide surgical tables designed to hold the weight of these women are used. Special techniques for ultrasound examination and longer surgical instruments for cesarean birth are required.

practices, as well as behavioral modification techniques, should be available to women before they become pregnant (American College of Obstetricians and Gynecologists [ACOG] Committee on Obstetric Practice, 2013).

NUTRIENT NEEDS DURING PREGNANCY

Nutrient needs are determined, at least in part, by the stage of gestation. During the first trimester the synthesis of fetal tissues places relatively few demands on maternal nutrition. Therefore, during the first trimester, when the embryo or fetus is very small, the needs are only slightly increased over those

before pregnancy. In contrast, the last trimester is a period of noticeable fetal growth, when most of the fetal stores of energy sources and minerals are deposited. Thus as fetal growth progresses during the second and third trimesters, the pregnant woman's need for some nutrients increases greatly. Factors that contribute to the increase in nutrient needs include the following:

- Development and growth of the uterine-placental-fetal unit
- Increase in maternal blood volume and red blood cell production
- Maternal mammary development in preparation for lactation
- 20% increase in metabolic rate during pregnancy

Dietary Reference Intakes (DRIs) (www.iom.edu) have been established in the United States and Canada and are updated regularly. The DRIs include recommendations for daily nutritional intakes that meet the needs of almost all (97% to 98%) of the healthy members of the population. They are divided into age, sex, and life-stage categories (e.g., infancy, pregnancy, and lactation) and can be used as goals in planning individuals' diets (Table 15-1).

Energy Needs

Energy (kilocalories [kcal]) needs are met by carbohydrate, fat, and protein in the diet. No specific recommendations exist for the amount of carbohydrate and fat in the diet of pregnant women, but the intake of these nutrients should be adequate

TABLE 15-1 Recommendations for Daily Intakes of Selected Nutrients During Pregnancy and Lactation

NUTRIENT (UNITS)	RECOMMENDATION FOR NONPREGNANT WOMAN*	RECOMMENDATION FOR PREGNANCY*	RECOMMENDATION FOR LACTATION*	ROLE IN RELATION TO PREGNANCY AND LACTATION	FOOD SOURCES
Energy (kilocalories [kcal] or kilojoules [kJ] †)	Variable	First trimester, same as nonpregnant; second trimester, nonpregnant needs + 340 kcal (1424 kJ); third trimester, nonpregnant needs + 452 kcal (1892 kJ)	First 6 months, nonpregnant needs + 330 kcal (1382 kJ); second 6 months, nonpregnant needs + 400 kcal (1675 kJ)	Growth of fetal and maternal tissues; milk production	Carbohydrate, fat, and protein
Protein (g)	46	First trimester, same as nonpregnant; second and third trimesters, 71 g [‡]	Nonpregnant needs + 25 g	Synthesis of the products of conception; growth of maternal tissue and expansion of blood volume; secretion of milk protein during lactation	Meats, eggs, cheese, yogurt, legumes (dry beans and peas, peanuts), nuts, grains
Water (L) in food and beverages	2.7	3	3.8	Expansion of blood volume, excretion of wastes; milk secretion	Water and beverages made with water, milk, juices; all foods, especially frozen desserts, fruits, lettuce and other fresh vegetables
Fiber (g)	25	28	29	Promotes regular bowel elimination; reduces long-term risk for heart disease, diverticulosis, and diabetes	Whole grains, bran, vegetables, fruits, nuts and seeds
Minerals					
Calcium (mg)	1300/1000	1300/1000	1300/1000	Fetal skeleton and tooth formation; maintenance of maternal bone and tooth mineralization	Milk, cheese, yogurt, sardines or other fish eaten with bones left in, dark green leafy vegetables except spinach or Swiss chard, calcium-set tofu, baked beans, tortillas
Iron (mg)	15/18	27	10/9	Maternal hemoglobin formation, fetal liver iron storage	Liver, meats, whole grain or enriched breads and cereals, dark green leafy vegetables, legumes, dried fruits
Zinc (mg)	9/8	12/11	13/12	Component of numerous enzyme systems, possibly important in preventing congenital malformations	Liver, shellfish, meats, whole grains, milk
Iodine (mcg)	150	220	290	Increased maternal metabolic rate	Iodized salt, seafood, milk and milk products, commercial yeast breads, rolls, and donuts
Magnesium (mg)	360/310-320	400/350-360	360/310-320	Involved in energy and protein metabolism, tissue growth, muscle action	Nuts, legumes, cocoa, meats, whole grains

TABLE 15-1 Recommendations for Daily Intakes of Selected Nutrients During Pregnancy and Lactation—cont'd

NUTRIENT (UNITS)	RECOMMENDATION FOR NONPREGNANT WOMAN*	RECOMMENDATION FOR PREGNANCY*	RECOMMENDATION FOR LACTATION*	ROLE IN RELATION TO PREGNANCY AND LACTATION	FOOD SOURCES
Fat-Soluble Vitamins					
A (mcg)	700	750/770	1200/1300	Essential for cell development, tooth bud formation, bone growth	Dark green leafy vegetables, dark yellow vegetables and fruits, liver, fortified margarine and butter
D (IU)	600	600	600	Involved in absorption of calcium and phosphorus, improves mineralization	Fortified milk and breakfast cereals; salmon, tuna, and other oily fish; butter, liver
E (mg)	15	15	19	Antioxidant (protects cell membranes from damage), especially important for preventing breakdown of red blood cells (RBCs)	Vegetable oils, green leafy vegetables, whole grains, liver, nuts and seeds, cheese, fish
Water-Soluble Vitamins					
C (mg)	65/75	80/85	115/120	Tissue formation and integrity, especially connective tissue; enhancement of iron absorption	Citrus fruits, strawberries, melons, broccoli, tomatoes, peppers, raw dark green leafy vegetables
Folate (mg)	0.4	0.6	0.5	Prevention of neural tube defects, increased maternal RBC formation	Fortified ready-to-eat cereals and other grain products, green leafy vegetables, oranges, broccoli, asparagus, artichokes, liver
B ₆ or pyridoxine (mg)	1.2/1.3	1.9	2	Involved in protein metabolism	Meats, liver, dark green vegetables, whole grains
B ₁₂ (mcg)	2.4	2.6	2.8	Production of nucleic acids and proteins, especially important in formation of RBCs and neural functioning	Milk and milk products, eggs, meats, liver, fortified soy milk

*When two values appear, separated by a diagonal slash, the first is for females younger than 19 years and the second is for those 19 to 50 years of age

†The international metric unit of energy measurement is the joule (J). 1 kcal = 4.184 kJ.

‡Add an additional 25 g in twin pregnancies.

Data from Otten, J.J., Helwig, J.P., & Meyers, L.D. (Eds.) (2006). *Dietary reference intakes: The essential guide to nutrient requirements*. Washington, DC: National Academies Press.

to support the recommended weight gain. Longitudinal assessment of weight gain during pregnancy is the best way to determine whether the kcal intake is adequate; very underweight or active women may require more than the recommended increase in kcal to sustain the desired rate of weight gain. Although protein can provide energy, it is unique in its ability to provide amino acids for the synthesis of new tissues (see discussion later in this chapter).

The recommended energy (kcal) intake corresponds to the recommended pattern of gain (see Table 15-1). There is no increment for the first trimester; an additional 340 kcal per day and 462 kcal per day over the prepregnant intake is recommended during the second and third trimesters, respectively (Panel on Dietary Reference Intakes for Macronutrients, Institute of Medicine [IOM], 2005). These recommendations are most appropriate for singleton pregnancy and may need to be adjusted in multiple gestation. The amount of food providing the needed increase in energy is not large. The 340 additional

kcal needed during the second trimester can be provided by two additional servings from any one of the following groups: dairy (all low fat or fat free), fruits, vegetables, and grains. In the third trimester an additional half a serving will provide the needed kcal.

Weight Gain

The desirable weight gain during pregnancy varies among women. The primary factor to consider in making a weight gain recommendation is the appropriateness of the prepregnancy weight for the woman's height—that is, whether the woman's weight was normal before pregnancy or whether she was underweight or overweight. Whenever possible, the woman should achieve a weight in the normal range for her height before pregnancy. Maternal and fetal risks in pregnancy are increased when the mother is significantly underweight or overweight before pregnancy and when weight gain during pregnancy is either too low or too high. Severely underweight

women are more likely to have preterm labor and to give birth to LBW infants. Both normal-weight and underweight women with inadequate weight gain during pregnancy have an increased risk of giving birth to an infant with intrauterine growth restriction (IUGR). Greater than expected weight gain during pregnancy can occur for many reasons, including multiple gestation, edema, gestational hypertension, and overeating.

At the first health care visit the pregnant woman should be helped to establish a weight gain goal for pregnancy that is based on her prepregnancy weight (ACOG Committee on Obstetric Practice, 2013). Progress toward this goal should be monitored at each visit. A commonly used method of evaluating the

appropriateness of weight for height is the **body mass index (BMI)**, which is calculated by the following formula:

$$\text{BMI} = \frac{\text{Weight}}{\text{Height}^2}$$

in which the weight is in kilograms and height is in meters. Thus for a woman who weighed 51 kg before pregnancy and is 1.57 m tall:

$$\text{BMI} = \frac{51 \text{ kg}}{(1.57 \text{ m})^2}, \text{ or } 20.7$$

Prepregnant BMI can be classified into the following categories: less than 18.5, underweight or low; 18.5 to 24.9, normal; 25 to 29.9, overweight or high; and greater than 30, obese. The BMI can be calculated on this website: www.nhlbi.nih.gov/guidelines/obesity/BMI/bmicalc.htm.

The Institute of Medicine (IOM) (2009) issued guidelines for weight gain during pregnancy based on the prepregnancy BMI. For women with single fetuses, recommendations are that women with normal BMI should gain 11.3 to 15.9 kg (25 to 35 lb) during pregnancy (Fig. 15-2). Table 15-2 lists recommended weight gain for pregnancies with single fetuses and twin gestations for women who are normal weight, underweight, and overweight. Women's views of appropriate weight gain during pregnancy are likely to be affected by their racial or cultural backgrounds.

Pattern of Weight Gain. The optimal rate of weight gain depends on the stage of pregnancy. During the first and second trimesters, growth takes place primarily in maternal tissues; during the third trimester growth occurs primarily in fetal tissues. During the first trimester of singleton pregnancy, the average total weight gain is only 1 to 2 kg (2.2 to 4.4 lb). Thereafter, the recommended weight gain increases to approximately 0.5 kg (1.1 lb) per week for an underweight woman and 0.4 kg (0.9 lb) per week for a woman of normal weight. The recommended weekly weight gain for overweight women during the second and third trimesters is 0.3 kg (0.7 lb), and for obese women, 0.2 kg (0.4 lb) (Table 15-2).

The reasons for an inadequate weight gain (less than 1 kg [2.2lb] per month for normal-weight women or less than 0.5 kg [1.1 lb] per month for obese women during the last two trimesters) or

FIG 15-2 Chart for plotting prenatal weight gain for normal-weight women.

TABLE 15-2 Weight Gain During Pregnancy

PREPREGNANCY WEIGHT CATEGORY	BODY MASS INDEX	RECOMMENDED RANGE OF TOTAL WEIGHT	RECOMMENDED RATES OF WEIGHT GAIN IN THE SECOND AND THIRD TRIMESTERS (MEAN RANGE/WK)*
• Underweight	• Less than 18.5	• 12.7-18.1 kg (28-40 lb)	• 0.45-0.6 kg (1-1.3 lb)
• Normal weight	• 18.5-24.9	• 11.3-15.9 kg (25-35 lb)	• 0.36-0.45 kg (0.8-1 lb)
• Overweight	• 25-29.9	• 6.8-11.3 kg (15-25 lb)	• 0.23-0.32 kg (0.5-0.7 lb)
• Obese (includes all classes)	• 30 and greater	• 5-9.1 kg (11-20 lb)	• 0.18-0.27 kg (0.4-0.6 lb)

For twin gestations the recommended total weight gain is 21 to 28 kg (46 to 62 lb) for women who are underweight before conception; 17 to 25 kg (37 to 54 lb) for normal-weight women; 14 to 23 kg (31 to 50 lb) for overweight women; and 11 to 19 kg (25 to 42 lb) for obese women. The provisional recommendations for women with more than two fetuses suggest that women who were normal weight before pregnancy should gain 17 to 25 kg (37 to 54 lb), overweight women should gain 14 to 23 kg (31 to 50 lb), and obese women should gain 11 to 19 kg (25 to 42 lb). There is no recommendation for women who were underweight before pregnancy (Institute of Medicine, 2009).

*Based on weight gain of 0.5-2.2 kg (1.1 to 4.4 lb) during first trimester.

From Institute of Medicine. (2009). *Weight gain during pregnancy: Reexamining the guidelines*. Washington, DC: National Academies Press.

excessive weight gain (more than 3 kg [6.6 lb] per month) should be evaluated thoroughly. Possible reasons for deviations from the expected rate of weight gain, besides inadequate or excessive dietary intake, include measurement or recording errors or differences in weight of clothing or time of day. An exceptionally high gain is likely to be caused by an accumulation of fluids, and a gain of more than 3 kg (6.6 lb) in a month, especially after the twentieth week of gestation, often is associated with the development of preeclampsia.

Hazards of Restricting Adequate Weight Gain. An obsession with thinness and dieting pervades the North American culture. Figure-conscious women may find it difficult to make the transition from guarding against weight gain before pregnancy to valuing weight gain during pregnancy. In counseling these women the nurse emphasizes the positive effects of good nutrition as well as the adverse effects of maternal malnutrition (manifested by poor weight gain) on infant growth and development.

This counseling includes information on the components of weight gain during pregnancy (Table 15-3) and the amount of this weight that will be lost at birth. Because lactation can help reduce maternal energy stores gradually (Lawrence & Lawrence, 2011), this also provides an opportunity to promote breastfeeding.

Pregnancy is not a time for a weight reduction diet. Even overweight or obese pregnant women need to gain at least enough weight to equal the weight of the products of conception (fetus, placenta, and amniotic fluid). If they limit their energy intake to prevent weight gain, they can also excessively limit their intake of important nutrients. Moreover, dietary restriction results in catabolism of fat stores, which in turn augments the production of ketones. The long-term effects of mild ketonemia during pregnancy are not known, but ketonuria is associated with preterm labor. It should be stressed to obese women (and to all pregnant women) that the quality of the weight gain is important, with emphasis placed on consuming nutrient-dense foods and avoiding empty-calorie foods.

Excessive Weight Gain. In the United States, 60% of women who give birth are overweight or obese; only 30% follow the weight gain recommendations for pregnancy, with most women gaining excessive amounts (CDC, 2014). Obesity during pregnancy is associated with increased use of health care services and longer hospital stays. During pregnancy an emphasis on regular physical activity and a healthy dietary intake can help avert excessive weight gain (see Clinical Reasoning Case Study). Excessive weight gained during pregnancy can be difficult to

lose after pregnancy, thus contributing to chronic overweight or obesity—an etiologic factor in a host of chronic diseases, including hypertension, diabetes mellitus, and arteriosclerotic heart disease. The woman who gains 18 kg or more is especially at risk (Box 15-3). Food energy intake and particularly intake of fat is likely to be high among pregnant women, especially low-income women (see Evidence-Based Practice box).

CLINICAL REASONING CASE STUDY

Nutrition and the Pregnant Woman with Excessive Weight Gain

Claudia, a 29-year-old Hispanic woman, has been followed at the clinic since her twelfth week of pregnancy. At her first visit she was overweight (5'2" tall, 70.9 kg [156 lb]). She received counseling about healthy diet choices for pregnancy. At today's clinic appointment (24 weeks of gestation), you record that she has gained a total of 10 kg (22 lb) since her first visit. You are asked to develop with Claudia a nutrition and lifestyle plan that provides for optimal fetal growth while helping to curb excessive weight gain. You know that it is important to include consideration of personal preferences and cultural factors in your plan. With Claudia, identify barriers to implementing the plan.

- Evidence—Is there sufficient evidence to draw conclusions about an appropriate nutrition plan, considering personal preferences and cultural factors?
- Assumptions—Describe underlying assumptions about each of the following issues:
 - Dietary Reference Intakes for pregnancy and lactation
 - Indicators of nutritional risk in pregnancy
 - Daily food guide for pregnancy and lactation
 - Lifestyle factors contributing to overweight; physical activities that may be acceptable to the client, whose cultural background does not encourage physical activity among girls and women
 - Effects of weight gain during pregnancy on future health of the woman and her infant
- What implications and priorities for nursing care can be drawn at this time? What interventions and teaching are likely to be indicated?
- Does the evidence objectively support your conclusion?

TABLE 15-3 Tissues Contributing to Maternal Weight Gain at 40 Weeks of Gestation

TISSUE	KILOGRAMS	POUNDS
Fetus	3.2-3.9	7-8.5
Placenta	0.9-1.1	2-2.5
Amniotic fluid	0.9	2
Increase in uterine tissue	0.9	2
Breast tissue	0.5-1.8	1-4
Increased blood volume	1.8-2.3	4-5
Increased tissue fluid	1.4-2.3	3-5
Increased stores (fat)	1.8-2.7	4-6

BOX 15-3 Indicators of Nutritional Risk in Pregnancy

- Adolescence or less than 2 years post menarche
- Frequent pregnancies: three within 2 years
- Poor fetal outcome in a previous pregnancy
- Poverty/food insecurity
- Poor diet habits with resistance to change
- Use of tobacco, alcohol, or drugs
- Weight at conception under or over normal weight
- Problems with weight gain
 - Any weight loss
 - Weight gain of less than 1 kg (2.2 lb)/month after the first trimester
 - Weight gain of more than 3 kg (6.6 lb)/month after the first trimester
- Multifetal pregnancy
- Low hemoglobin and/or hematocrit values
- Diabetes
- Chronic illness, including an eating disorder, that affects intake, absorption, or metabolism of nutrients

EVIDENCE-BASED PRACTICE

Weight Management in Pregnancy**Ask the Question**

For obese and overweight pregnant women, are weight management interventions safe and beneficial to the mother and baby?

Search for the Evidence**Search Strategies**

- English language research-based publications on pregnancy, obesity, weight gain, diet, and exercise were included.
- Exclusions included trials in developing countries with food shortages.

Databases Used

- Cochrane Collaborative Database, National Guideline Clearinghouse (Agency for Healthcare Research and Quality [AHRQ]), CINAHL, PubMed, UpToDate, and the professional website for the Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN)

Critical Appraisal of the Evidence

- Obesity in pregnancy is associated with offspring with attention deficit hyperactivity disorder (ADHD) in childhood, eating disorders in adolescence, and psychotic disorders in adulthood (Van Lieshout, Taylor, & Boyle, 2011).
- Weight management interventions for obese pregnant women result in significantly decreased weight gain and significantly less preeclampsia and shoulder dystocia (Thangaratinam, Rogozinska, Jolly, et al., 2012).
- The most effective interventions are dietary, resulting in decreased risk for preeclampsia, gestational hypertension, and preterm birth, with no harm to the fetus (Thangaratinam et al.).
- In a systematic review, researchers found that goal setting is a useful technique for achieving optimal weight gain. Obese women may require further counseling (Brown, Sinclair, Liddle, et al., 2012).
- Regular activity improves maternal glycemic control and fetal outcomes. Caregivers should recommend physical activity to most pregnant women as safe and beneficial (Ferraro, Gaudet, & Adamo, 2012).

Apply the Evidence: Nursing Implications

- Preconception counseling should include prevention of obesity, ideally from childhood. Obese women are at risk for cardiac and pulmonary diseases, gestational hypertension and diabetes, and obstructive sleep apnea. Obesity in pregnancy can result in higher risk for congenital abnormalities, operative birth, and surgical complications (ACOG, 2013).
- Nurses are frequently the primary educators for pregnant women. Counseling obese pregnant women about nutrition and food choices and using collaborative goal setting for weight

gain can prevent pregnancy risks and avoid weight gain that may persist beyond pregnancy.

- Activity needs to be frequent, fun, and affordable. An excellent idea is encouraging the woman to walk with other women, which provides social support and increased safety. In addition, the nurse can advocate for low-cost indoor facilities in the community.

Quality and Safety Competencies: Evidence-Based Practice* Knowledge

- Explain the role of evidence in determining best clinical practice.
- Both nutrition counseling and motivation work best for weight management in pregnancy.

Skills

- Locate evidence reports related to clinical practice topics and guidelines.
- Dietary and activity interventions are safe and beneficial in pregnancy for obese women.

Attitudes

- Appreciate the importance of regularly reading relevant professional journals.
- Systematic reviews and professional guidelines highlight interventions that have evidence of success, such as motivational goal setting for weight management.

Pat Mahaffee Gingrich

*Adapted from Quality and Safety Education for Nurses (QSEN) at www.qsen.org.

When obesity is present (either preexisting obesity or obesity that develops during pregnancy), there is an increased likelihood of preeclampsia; gestational diabetes; macrosomia and cephalopelvic disproportion; operative vaginal birth; emergency cesarean birth; postpartum hemorrhage; wound, genital tract, or urinary tract infection; birth trauma; and late fetal death (American Academy of Pediatrics [AAP] & ACOG, 2012; Langford, Joshu, Chang, et al., 2011). Maternal obesity is also associated with increased risk of miscarriage, congenital anomalies, growth abnormalities, and stillbirth

(AAP & ACOG, 2012). In addition, the infant of a woman who is obese during pregnancy is more likely to be obese and to develop diabetes as an adult.

Protein

Adequate protein is needed for tissue growth during pregnancy that results from:

- The rapid growth of the fetus
- The enlargement of the uterus and its supporting structures, the mammary glands, and the placenta

- The increase in the maternal circulating blood volume and the subsequent demand for increased amounts of plasma protein to maintain colloidal osmotic pressure
- The formation of amniotic fluid

The recommendation for daily protein intake during pregnancy is approximately 71 g/day, which is an increase of 25 g/day over the nonpregnant level (Otten, Helwig, & Meyers, 2006). Milk, meat, eggs, yogurt, and cheese are complete protein foods with a high biologic value. Legumes (dried beans and peas), whole grains, and nuts are also valuable sources of protein. In addition, these protein-rich foods are a source of other nutrients such as calcium, iron, and B vitamins. Plant sources of protein often provide needed dietary fiber. The recommended daily food plan (Table 15-4) is a guide to the amounts of these foods that supply the quantities of protein needed.

Protein intake in many people in the United States is relatively high; thus, many women may not need to increase their intake at all during pregnancy. Three servings of milk, yogurt, or cheese (four for adolescents) and two servings (5 to 6 ounces [140 to 168 g]) of meat, poultry, or fish supplies most of the recommended protein for a pregnant woman. Additional protein is provided by vegetables and breads, cereals, rice, or pasta. Pregnant adolescents, women from impoverished backgrounds, and

women adhering to unusual diets such as a macrobiotic (highly restricted vegetarian) diet are those whose protein intake is most likely to be inadequate. High-protein supplements are not recommended during pregnancy because of potentially harmful effects on the fetus.

Omega-3 Fatty Acids

The long-chain polyunsaturated fatty acids (LC-PUFAs) docosahexaenoic acid (DHA) and arachidonic acid (AA) are considered essential to brain development and neurologic function. Supplementation of omega-3 (n-3) LC-PUFA during pregnancy has been associated with reduced risk of preterm birth and improved neurologic and visual development in the offspring. However, there is a lack of conclusive evidence on the specific beneficial effects of DHA supplementation (Gould, Smithers, & Makrides, 2013; Lo, Sienna, Mamak, et al., 2012). Many providers recommend at least 300 mg/day of DHA for pregnant women. Some prenatal vitamins contain DHA; fish oil supplements are another source of DHA. Women can get adequate amounts of DHA by eating 8 to 12 ounces of seafood per week. Because of the risk of fetal neurotoxicity of methylmercury, pregnant women are cautioned to select fish species known to have lower levels of methylmercury.

TABLE 15-4 Daily Food Guide for Pregnancy and Lactation

FOOD GROUP	DAILY AMOUNT OF FOOD RECOMMENDED FOR WOMEN*	SERVING SIZE
Grains	6- to 8-ounce equivalents At least half of grain servings should be whole grains. <i>Whole grains</i> are those that contain the entire grain kernel (bran, germ, endosperm) (e.g., whole wheat or whole cornmeal, oatmeal, quinoa, bulgur, and brown rice). <i>Refined grains</i> have been milled to remove the bran and germ (e.g., white flour, white bread, degermed cornmeal, white rice, and masa harina and corn or flour tortillas, unless they are labeled as whole grain).	1-ounce equivalent = 1 slice bread; $\frac{3}{4}$ to 1 cup ready-to-eat cereal, $\frac{1}{2}$ cup cooked rice, pasta, or cooked cereal; 1 small muffin; or 1 small (6") tortilla
Vegetables	$2\frac{1}{2}$ to 3 cups Dark green (e.g., kale, collards, spinach, broccoli) and red/orange (e.g., winter squash, pumpkin, and sweet potato) vegetables should be included often.	1 cup = 2 cups raw leafy greens; 1 cup of other vegetables, raw or cooked; or 1 cup of vegetable juice
Fruits	2 cups	1 cup = 1 cup raw, frozen, or canned fruit; 1 cup 100% juice; or $\frac{1}{2}$ cup dried fruit
Dairy	3 cups Most dairy choices should be fat free or low fat.	1 cup = 1 cup (8 ounces) milk or yogurt; $\frac{1}{2}$ ounces natural cheese; 2 ounces processed cheese (e.g., American); 2 cups cottage cheese; 1 cup frozen yogurt or $\frac{1}{2}$ cups ice cream (choose fat free or low fat most often); 1 cup calcium-fortified soy milk
Protein foods	$5\frac{1}{2}$ - to 6 $\frac{1}{2}$ -ounce equivalents Most meat and poultry choices should be lean or low fat. Fish, nuts, and seeds contain healthy oils, so choose these foods frequently.	1-ounce equivalent = 1 ounce (30 g) cooked meat, poultry, or fish; $\frac{1}{4}$ cup cooked dried beans or peas [†] ; 1 egg; 1 tablespoon (15 ml) peanut butter; $\frac{1}{2}$ ounce nuts or seeds
Oils	5-6 teaspoons (25-30 ml) Choose oils rather than solid fats. Solid fats are fats that are solid at room temperature, such as butter, shortening, stick margarine, and pork, chicken, or beef fat. Read the label: choose products with no <i>trans</i> fats, limit intake of saturated fats, and choose oils high in monounsaturated and polyunsaturated fats.	1 teaspoon = 1 teaspoon liquid oil (e.g., olive, canola, sunflower, safflower, peanut, soybean, cottonseed) or soft margarine (tub or squeeze bottle); 1 tablespoon mayonnaise-type or Italian salad dressing; $\frac{3}{4}$ tablespoon Thousand Island salad dressing; 8 large olives [‡] ; $\frac{1}{8}$ medium avocado [‡] ; $\frac{1}{3}$ ounce dry-roasted nuts or peanuts [‡]

*These are approximate amounts and should be individualized. Intake may have to be increased for women with a more active lifestyle or multiple gestation, those who are underweight before pregnancy, or those exhibiting poor gestational weight gain. Needs during lactation may be greater than these recommendations.

[†]Beans are also part of the vegetable group.

[‡]Avocados and olives are part of the vegetable group; nuts and seeds are part of the protein foods group. These foods are also high in oils.

SAFETY ALERT

High levels of mercury can harm the developing nervous system of the fetus or young child, and certain fish are especially high in mercury. Women who may become pregnant, women who are pregnant or nursing, and young children need to follow some precautions: (1) avoid eating shark, swordfish, king mackerel, and tilefish; (2) check local advisories about the safety of fish caught by family and friends in local bodies of water, but if no advisory is available, limit intake of these fish to 6 ounces and eat no other fish that week; and (3) eat as much as 12 ounces a week of a variety of commercially caught fish and shellfish low in mercury, such as shrimp, salmon, pollock, catfish, and canned light tuna (but limit intake of albacore or “white” tuna and tuna steaks, which contain more mercury, to 6 ounces per week) (U.S. Food and Drug Administration [FDA], 2013b).

Fluids

Water is the main substance of cells, blood, lymph, amniotic fluid, and other vital body fluids. It is essential during the exchange of nutrients and waste products across cell membranes. It also aids in maintaining body temperature. A good fluid intake promotes regular bowel function, which is sometimes a problem during pregnancy. The recommended daily intake is about 8 to 10 glasses (2.3 L) of fluid. Water, milk, and decaffeinated or herbal tea are good sources. Foods in the diet should supply an additional 700 ml or more of fluid. Dehydration can increase the risk of cramping, contractions, and preterm labor.

Minerals and Vitamins

In general, the nutrient needs of pregnant women, with perhaps the exception of folate and iron, can be met through dietary sources. Counseling about the need for a varied diet rich in vitamins and minerals should be a part of early prenatal care of every pregnant woman and should be reinforced throughout pregnancy (see Community Activity box). It has been suggested that taking a micronutrient supplement (including vitamins and trace minerals) before and during pregnancy reduces the risk for congenital defects, LBW, and preterm birth, as well as preeclampsia. There is no conclusive evidence to support this suggestion; further research is needed on maternal and fetal benefits of micronutrient supplementation. Supplements are especially advisable for women with known nutritional risk factors (Box 15-4). It is important that the pregnant woman understand that the use of a vitamin-mineral supplement does not lessen the need to consume a nutritious, well-balanced diet.

COMMUNITY ACTIVITY

Visit a prenatal clinic. Identify sources of nutrition education that are evident in the waiting room. Does the clinic employ a nutritionist or dietitian? Who provides nutrition counseling in the clinic? Do all clinic clients receive nutrition counseling, in either individual or group settings? What ethnic and language groups are served by the clinic? Are print materials available in multiple languages? Are interpreters available? Are there sources for free materials on nutrition that could be placed in the clinic? Identify strengths and weaknesses of nutrition education in that setting. Develop a feasible plan for improving nutrition education in the clinic.

Iron

Women are at increased risk for iron deficiency during pregnancy related to the associated increased iron requirements. Iron is needed to allow transfer of adequate iron to the fetus and to permit expansion of the maternal red blood cell (RBC) mass. Beginning in the latter part of the first trimester, the blood volume of the mother increases steadily, peaking at about 1500 ml more than that in the nonpregnant state. In twin gestations the increase is at least 500 ml greater than that in singleton pregnancies. Plasma volume increases more than RBC mass, with the difference between plasma and RBCs being greatest during the second trimester. The relative excess of plasma causes a modest decrease in the hemoglobin concentration and hematocrit, known as **physiologic anemia of pregnancy**. This is a normal adaptation during pregnancy.

Poor iron status, which can result in iron deficiency anemia, is relatively common among women in the childbearing years. Anemic women are poorly prepared to tolerate hemorrhage at the time of birth. In addition, women who have iron deficiency anemia during early pregnancy are at increased risk for preterm birth. Iron deficiency during the third trimester apparently does not carry the same risk. In the United States, anemia is most common among adolescents, African-American women, and women of lower socioeconomic status.

The recommended iron intake for pregnant women is 27 mg/day, compared with 18 mg/day in nonpregnant females (Otten et al., 2006). A supplement of 30 mg of ferrous iron daily starting by 12 weeks of gestation helps ensure an adequate iron intake. Prenatal vitamins typically contain 30 mg

BOX 15-4 Calcium Sources for Women Who Do Not Drink Milk

Each of the following provides approximately the same amount of calcium as 1 cup of milk:

Fish

- 3-oz can of sardines
- 4½ -oz can of salmon (if bones are eaten)

Beans and Legumes

- 3 cups cooked dried beans
- 2½ cups refried beans
- 2 cups baked beans with molasses
- 1 cup tofu (calcium added)

Greens

- 1 cup collards
- 1½ cups kale or turnip greens

Baked Products

- 3 pieces cornbread
- 4 slices French toast
- 2 (7-inch diameter) waffles

Fruits

- 11 dried figs
- 1½ cups orange juice with calcium added

Sauces

- 3 oz creamy pesto sauce
- 5 oz cheese sauce

of iron. Iron supplements can be poorly tolerated during the nausea prevalent in the first trimester, and starting the supplement after this point may improve tolerance. If maternal iron deficiency anemia is present (preferably diagnosed by measurement of serum ferritin, a storage form of iron), increased dosages (60 to 120 mg daily) may be required; iron supplements are often recommended for women who are pregnant with multiple fetuses (Hark & Catalano, 2012). Certain foods taken with an iron supplement can promote or inhibit absorption of iron from the supplement. See the Teaching for Self-Management box: Iron Supplementation later in the chapter. Even when a woman is taking an iron supplement, she should also include good food sources of iron in her daily diet (see Table 15-1).

Calcium

There is no increase in the DRI of calcium during pregnancy and lactation (see Table 15-1). The DRI (1000 mg daily for women 19 years and older and 1300 mg for those younger than 19 years [Ross, Taylor, Yaktine, & Del Valle, 2011]) appears to provide sufficient calcium for fetal bone and tooth development while maintaining maternal bone mass. Milk and yogurt are especially rich sources of calcium, providing approximately 300 mg per cup (240 ml). Nevertheless, many women do not consume these foods or do not consume adequate amounts to provide the recommended intakes of calcium. One problem that can interfere with milk consumption is **lactose intolerance**, the inability to digest milk sugar (lactose) caused by the lack of the lactase enzyme in the small intestine. It is relatively common in adults, particularly African-Americans, Asians, Native Americans, and Inuits (Alaska Natives). Milk consumption can cause abdominal cramping, bloating, and diarrhea in these populations, although many lactose-intolerant individuals can tolerate small amounts of milk without symptoms. Yogurt, sweet acidophilus milk, buttermilk, cheese, chocolate milk, and cocoa may be tolerated even when fresh fluid milk is not. Commercial lactase supplements (e.g., Lactaid®) are widely available to consume with milk, and many supermarkets stock lactase-treated milk, making it possible for lactose-intolerant people to drink milk. An alternative to cow's milk is calcium-fortified almond milk; natural almond milk does not contain adequate calcium. However, almond milk is lower in protein than cow's milk.

In some cultures it is uncommon for adults to drink milk. For example, Puerto Ricans and other Hispanic people may use milk only as an additive in coffee. Pregnant women from these cultures may need to consume nondairy sources of calcium (see Box 15-4). If calcium intake appears low and the woman does not change her dietary habits despite counseling, a daily supplement containing 600 mg of elemental calcium may be needed. Calcium supplements may also be recommended when a pregnant woman experiences leg cramps caused by an imbalance in the calcium-to-phosphorus ratio.

Other Minerals and Electrolytes

Magnesium. Diets of women in the childbearing years are likely to be low in magnesium, and as many as half of pregnant and lactating women may have inadequate intakes. Adolescents and low-income women are especially at risk. The recommended daily intake during pregnancy is 400 mg (Otten

et al., 2006). Dairy products, nuts, whole grains, and green leafy vegetables are good sources of magnesium.

Sodium. During pregnancy the need for sodium increases slightly, primarily because the body water is expanding (e.g., the expanding blood volume). Sodium is essential for maintaining body water balance. In the past, dietary sodium was routinely restricted in an effort to control the peripheral edema that commonly occurs during pregnancy. It is now recognized that moderate peripheral edema is normal, occurring as a response to the fluid-retaining effects of elevated levels of estrogen. Sodium is not routinely restricted in pregnancy, and restriction has not proved effective in reducing the rates of preeclampsia. Severe sodium restriction can make it difficult for pregnant women to achieve an adequate diet. Grain, milk, and meat products, which are good sources of nutrients needed during pregnancy, are significant sources of sodium. In addition, sodium restriction can stress the adrenal glands and the kidneys as they attempt to retain adequate sodium. In general, sodium restriction is necessary only if the woman has a medical condition such as renal or liver failure or hypertension that warrants it.

Excessive intake of sodium is discouraged during pregnancy because it can contribute to development of hypertension in salt-sensitive individuals. An adequate sodium intake for pregnant and lactating women, as well as for nonpregnant women in the childbearing years, is estimated to be 1.5 g/day, with a recommended upper limit of intake of 2.3 g/day (Otten et al., 2006). Table salt (sodium chloride) is the richest source of sodium, with approximately 2.3 g of sodium in 1 teaspoon (5 g) of salt. Most canned foods contain added salt unless the label states otherwise. Large amounts of sodium are also found in many processed foods, including smoked or cured meats, cold cuts, and corned beef; frozen entrees and meals; baked goods; mixes for casseroles or bread products; soups; and condiments. Products low in nutritive value and excessively high in sodium include pretzels, potato and other chips (except salt free), pickles, catsup, prepared mustard, steak and Worcestershire sauces, some soft drinks, and bouillon. A moderate sodium intake can usually be achieved by salting food lightly during cooking, adding no additional salt at the table, and avoiding low-nutrient, high-sodium foods.

Potassium. Diets including adequate intakes of potassium are associated with reduced risk for hypertension. Potassium has been identified as one of the nutrients most likely to be lacking in the diets of women of childbearing years. A diet including 8 to 10 servings of unprocessed fruits and vegetables daily, along with moderate amounts of low-fat meats and dairy products, reduces sodium intake while providing adequate amounts of potassium (Frisoli, Schmieder, Grodzicki, & Messerli, 2011).

Zinc. Zinc is a constituent of numerous enzymes involved in major metabolic pathways. Zinc deficiency is associated with malformations of the central nervous system in infants. When large amounts of iron and folic acid are consumed, the absorption of zinc is inhibited and the serum zinc levels are reduced as a result. Because iron and folic acid supplements are commonly prescribed during pregnancy, pregnant women should be encouraged to consume good sources of zinc daily (see Table 15-1). The recommended intake for pregnant women is 11 mg/day (Otten et al., 2006). Women with anemia who receive high-dose iron supplements also need supplements of zinc and copper.

Fat-Soluble Vitamins

The fat-soluble vitamins include vitamins A, D, E, and K. Fat-soluble vitamins are stored in the body tissues; in the event of prolonged overdoses, these vitamins can reach toxic levels. Because of the high potential for toxicity, pregnant women are advised to take fat-soluble vitamin supplements only as prescribed. Toxicity from dietary sources is very unlikely.

Adequate intake of vitamin A is needed so that sufficient amounts of the vitamin can be stored in the fetus. A well-chosen diet, including adequate amounts of deep yellow and dark green vegetables—leafy greens, broccoli, and carrots—and fruits such as cantaloupe and apricots, provides sufficient amounts of carotenes that can be converted in the body to vitamin A. Congenital malformations such as spina bifida and cleft palate have occurred in infants of mothers who took excessive amounts of preformed vitamin A (from supplements) during pregnancy; thus extra supplements, in addition to the commonly prescribed prenatal vitamins, are not recommended routinely for pregnant women (Hark & Catalano, 2012).

Vitamin D plays an important role in the absorption and metabolism of calcium. The main food sources of this vitamin are enriched or fortified foods such as milk and ready-to-eat cereals. Vitamin D is also produced in the skin by the action of ultraviolet light (in sunlight). A severe deficiency can lead to neonatal hypocalcemia and tetany, as well as to poor development of tooth enamel. Women with lactose intolerance, those on vegan diets, and others who do not include milk in their diet for any reason are at risk for vitamin D deficiency. Other risk factors are dark skin (African-American women are at high risk for deficiency), habitual use of clothing that covers most of the skin, and living in northern latitudes where sunlight exposure is limited, especially during the winter. Use of recommended amounts of sunscreen with a sun protection factor (SPF) rating of 15 or greater reduces skin vitamin D production by as much as 99%, thus bringing about a need for regular intake of fortified foods or a supplement. Health care providers may prescribe vitamin D supplements of 1000 to 2000 IU/day for women with low serum vitamin D levels (AAP & ACOG, 2012).

Vitamin E is needed to protect against the increased oxidative stress associated with pregnancy. Oxidative stress above that usually associated with pregnancy has been proposed as an explanation for the etiology of preeclampsia, although supplementation with vitamin E has not been shown to prevent preeclampsia (Conde-Agudelo, Romero, Kusanovic, & Hassan, 2011). Vegetable oils and nuts are especially good sources of vitamin E, and whole grains and green leafy vegetables are moderate sources.

Water-Soluble Vitamins

Body stores of water-soluble vitamins are much smaller than those of fat-soluble vitamins, and the water-soluble vitamins, in contrast to fat-soluble vitamins, are readily excreted in the urine. Therefore, good sources of these vitamins must be consumed frequently. Toxicity with overdose is less likely than it is when taking fat-soluble vitamins.

Folate and Folic Acid. Because of the increase in RBC production during pregnancy, as well as the nutritional requirements of the rapidly growing cells in the fetus and

placenta, pregnant women should consume about 50% more folic acid than nonpregnant women, or about 0.6 mg (600 mcg) daily. In the United States, all enriched grain products (which include most white breads, flour, and pasta) must contain folic acid at a level of 1.4 mg/kg of flour. All women of childbearing potential need careful counseling about including good sources of folate in their diets (see Box 15-1).

Vitamin C. Vitamin C, or ascorbic acid, plays an important role in tissue formation and enhances iron absorption (Hark & Catalano, 2012). The recommended intake of vitamin C during pregnancy is 85 mg/day. The vitamin C needs of most women are readily met by a diet that includes at least one or two daily servings of citrus fruit or juice or another good source of the vitamin (see Table 15-1), but women who smoke need more.

Vitamin B₆. Pyridoxine, or vitamin B₆, is essential for carbohydrate, protein, and fat metabolism and is involved in the synthesis of red blood cells, antibodies, and neurotransmitters. Although the recommended intake during pregnancy is 1.9 mg/day, there is evidence that larger doses (10 to 25 mg) are effective for some women in reducing nausea and vomiting (Hark & Catalano, 2012).

Vitamin B₁₂. Vitamin B₁₂ is involved in production of nucleic acids and proteins; it is especially important in formation of RBCs and in neural functioning. It is found naturally only in animal products (milk and dairy products, eggs, meats, liver, fish, and poultry). Commercial dried cereals, as well as some plant milks (almond, rice, or soy), and other vegan products are fortified with vitamin B₁₂. For women who do not include these sources of the vitamin in their diets, a daily or weekly supplement is essential. The recommended daily intake during pregnancy is 2.6 mcg/day (Otten et al., 2006).

Other Nutritional Issues During Pregnancy

Alcohol

Alcohol use is contraindicated throughout pregnancy. There is no safe amount or type of alcohol during pregnancy and there is no time during pregnancy when alcohol consumption is without risk. Because alcohol is a teratogen, it can cause birth defects, impaired cognitive and psychomotor development, and emotional and behavioral problems. Fetal alcohol syndrome can result from maternal alcohol consumption; this severe disorder involves growth restriction, central nervous system abnormalities, and facial dysmorphism (ACOG Committee on Health Care for Underserved Women, 2013) (see Chapter 31).

Women who have been consuming alcohol during pregnancy should be advised to stop immediately to prevent further risk to the fetus. On discovering they are pregnant, many women who have been consuming low levels of alcohol will be very concerned about potential effects on the fetus. Health care providers should inform them that having consumed low levels of alcohol during pregnancy is not an indication for terminating pregnancy (ACOG Committee on Health Care of Underserved Women, 2013).

Caffeine

The safety of caffeine use in pregnancy is not yet clear. Data suggest that excess caffeine intake can contribute to intrauterine growth restriction (IUGR) (Sengpiel, Elind, Bacelis, et al.,

TABLE 15-5 Caffeine* Content of Common Beverages and Foods

BEVERAGE OR FOOD	CAFFEINE (mg)
Coffee (8 oz [240 ml])	95

2013). In their review, Jahanfar and Jaafara (2013) found that there is insufficient evidence to determine whether caffeine has any effect on pregnancy outcome. Although the evidence about caffeine is far from conclusive, ACOG and the March of Dimes recommend a daily intake of no more than 200 mg of caffeine (ACOG Committee on Obstetric Practice, 2013; March of Dimes, 2012). Caffeine is found not only in coffee but also in tea, some soft drinks, and chocolate (Table 15-5).

Artificial Sweeteners

Aspartame (NutraSweet, Equal), acesulfame potassium (Sunett), and sucralose (Splenda)—artificial sweeteners commonly used in low- or no-calorie beverages and low-calorie food products—have not been found to have adverse effects on the normal mother or fetus and therefore are approved by the U.S. Food and Drug Administration (FDA) for use during pregnancy. Aspartame, which contains phenylalanine, should be avoided by pregnant women with PKU. Stevia (stevioside) is a sweetener sold as a dietary supplement; no acceptable daily intake has been established for stevia. Agave is another dietary supplement sweetener, but little is known about its safety or effects in pregnancy.

Pica and Food Cravings

Pica, which is the practice of consuming nonfood substances (e.g., clay, soil, and laundry starch) or excessive amounts of foodstuffs low in nutritional value (e.g., cornstarch, ice or freezer frost, baking powder, or baking soda), is often influenced by the woman's cultural background (Fig. 15-3). One

FIG 15-3 Nonfood substances consumed in pica: red clay from Georgia, Nzu from East Nigeria, baking powder, cornstarch, baking soda, laundry starch, and ice. Some individuals practice poly-pica, consuming more than one of these or other nonfood substances. (Courtesy Shannon Perry, Phoenix, AZ.)

problem with pica is that regular and heavy consumption of low-nutrient products can cause more nutritious foods to be displaced from the diet. As an example, cornstarch ingestion is popular among African-American women. It is a source of “empty” calories; half a cup (64 g) provides 240 kcal but almost no vitamins, minerals, or protein. Overuse of cornstarch can contribute to development of gestational diabetes. In addition, the pica items consumed can interfere with the absorption of nutrients, especially minerals. Women with pica have been found to have lower hemoglobin levels than those without pica.

Moreover, there is a risk that nonfood items are contaminated with heavy metals or other toxic substances. Among Mexican-American women, consumption of *tierra* includes both soil and pulverized Mexican pottery. Lead contamination of soils and soil-based products has caused high levels of lead in pregnant women and their newborns. Regular household use of Mexican pottery in cooking or serving food or ingestion of ground pottery must be included in interviews or questionnaires regarding nutrition intake of pregnant women. The possibility of pica must be considered when pregnant women are found to be anemic, and the nurse should provide counseling about the health risks associated with pica.

The practice of pica, as well as details of the types and amounts of products ingested, is likely to be discovered only by the sensitive interviewer who has developed a relationship of trust with the woman. It has been proposed that pica and food cravings (e.g., the urge to have ice cream, pickles, or pizza) during pregnancy are caused by an innate drive to consume nutrients missing from the diet. However, research has not supported this hypothesis.

Many women experience food cravings during pregnancy. In general, consuming foods to satisfy the cravings is not harmful. However, there is some concern that it can lead to dietary imbalances, especially if the cravings involve pica. The nurse can suggest choosing healthy alternatives for cravings, eating small amounts of the craved foods (buying single servings), eating regularly and including healthy snacks to avoid drops in blood glucose levels, and using distraction to curb the craving (take a walk or make a call to a friend).

Adolescent Pregnancy Needs

Many adolescent females have diets that provide less than the recommended intakes of key nutrients, including calcium and iron. Pregnant adolescents and their infants are at increased risk for complications during pregnancy and birth. Growth of the pelvis is delayed in comparison with growth in stature, and this helps explain why cephalopelvic disproportion and other mechanical problems associated with labor are common among young adolescents. Competition for nutrients between the growing adolescent and the fetus can also contribute to some of the poor outcomes apparent in teen pregnancies. Recommended weight gain goals do not differ from those of adult women. Pregnant adolescents are encouraged to choose a weight gain goal at the upper end of the range for their BMI. BMI is calculated as for adult women (IOM, 2009) rather than by using the adolescent BMI growth charts available from the Centers for Disease Control and Prevention (CDC).

Adolescent females who have given birth are more likely to be obese than those who have not (Chang, Choi, Richardson, & Davis, 2013); thus, the adolescent mother needs careful teaching regarding nutritional intake and physical activity to control body weight in the postpartum period.

Efforts to improve the nutritional health of pregnant adolescents focus on:

- Improving the nutrition knowledge, meal planning, and selection and food preparation skills of young women
- Promoting access to prenatal care
- Developing nutrition interventions and educational programs that are effective with adolescents
- Striving to understand the factors that create barriers to change in the adolescent population

Physical Activity During Pregnancy

Moderate exercise during pregnancy yields numerous benefits, including improving muscle tone, potentially shortening the course of labor, and promoting a sense of well-being. Almost all pregnant women, except the few with medical or obstetric problems that contraindicate physical activity, should engage in a minimum of 30 minutes of moderate physical exercise on most, if not all, days of the week (see Chapter 14). A liberal amount of fluid should be consumed before, during, and after exercise because dehydration can trigger preterm labor. Caloric intake may need to be adjusted according to physical activity.

CARE MANAGEMENT

During pregnancy, nutrition plays a key role in achieving an optimal outcome for the mother and her unborn baby. The motivation to learn about nutrition is usually greater during pregnancy because parents strive to “do what’s right for the baby.” Optimal nutrition cannot eliminate all problems that can arise during pregnancy, but it does establish a good foundation for supporting the needs of the mother and her developing fetus.

Assessment

Ideally a nutritional assessment is performed before conception so that any recommended changes in diet, lifestyle,

and weight can be undertaken before the woman becomes pregnant. At the initial prenatal visit, information on nutrition and diet is obtained from an interview and review of the woman’s health records, physical examination, and laboratory results.

Obstetric and Gynecologic Effects on Nutrition

Nutrition reserves can be depleted in the multiparous woman or one who has had frequent pregnancies (especially three pregnancies within 2 years). A history of preterm birth or the birth of an LBW or small for gestational age (SGA) infant can indicate inadequate dietary intake. Maternal diabetes mellitus can be associated with the birth of a large for gestational age (LGA) infant.

Contraceptive methods also can affect reproductive health. Increased menstrual blood loss often occurs during the first 3 to 6 months after placement of an intrauterine contraceptive device; consequently, the user can have low iron stores or even iron deficiency anemia. Oral contraceptive agents are associated with decreased menstrual losses and increased iron stores.

Health History

Chronic maternal illnesses such as diabetes mellitus, renal disease, liver disease, cystic fibrosis or other malabsorptive disorders, seizure disorders and the use of anticonvulsant agents, hypertension, and PKU can affect a woman’s nutritional status and dietary needs. In women with illnesses that have resulted in nutrition deficits or that require dietary treatment (e.g., diabetes mellitus, PKU), it is extremely important for nutritional care to be started and for the condition to be optimally controlled before conception. A registered dietitian can provide in-depth counseling for the woman who requires medical nutrition therapy during pregnancy and lactation.

Usual Maternal Diet

The nurse interviews the pregnant woman to determine her usual food and beverage intake, any dietary modifications, food allergies and intolerances, medications and nutrition supplements being taken, cultural practices related to nutrition such as pica, and the adequacy of her income and other resources to meet her nutrition needs. In addition, the nurse inquires about the presence and severity of nutrition-related discomforts of pregnancy such as nausea and vomiting, constipation, and pyrosis (heartburn). The nurse should be alert to any evidence of eating disorders such as anorexia nervosa, bulimia, or frequent and rigorous dieting before or during pregnancy. Box 15-5 provides a simple tool for obtaining diet history information. When potential problems are identified, further assessment is needed. The health care provider is notified and a nutritional consultation may be needed.

The effect of food allergies and intolerances on nutritional status varies. Lactose intolerance is of special concern in pregnant and lactating women because no other food group equals milk and milk products in terms of calcium content. If a woman has lactose intolerance, the interviewer should explore her intake of other calcium sources (see Box 15-4).

The assessment must include an evaluation of the woman’s financial status and her knowledge of sound dietary practices. The quality of the diet improves with increasing

BOX 15-5 Food Intake Questionnaire

Which of the following did you eat or drink yesterday? If the way you ate yesterday wasn't the way you usually eat, choose a recent day that was typical for you.

socioeconomic status and educational level. Poor women may not have access to adequate refrigeration and cooking facilities and may find it difficult to obtain adequate nutritious food.

Physical Examination

Anthropometric (body) measurements provide short- and long-term information on a woman's nutritional status and are thus essential to the assessment. At a minimum, the woman's height and weight are determined at her initial prenatal visit, and her weight is measured at each subsequent visit (see earlier discussion of BMI).

A careful physical examination can reveal objective signs of malnutrition (Table 15-6). It is important to note, however, that some of these signs are nonspecific and that the physiologic changes of pregnancy can complicate the interpretation of physical findings. For example, lower extremity edema often occurs when calorie and protein deficiencies are present but it can also be a normal finding in the third trimester of pregnancy. The interpretation of physical findings is made easier by a thorough health history and by laboratory testing when indicated.

Laboratory Testing
